Table 5 Pre- and postharvest contamination of cereals with their most commonly associated mycotoxins

Cereals	Preharvest	Post-harvest
Barley	DON, NIV, Zea, HT-2, T-2	OTA, Afla, Cit
Maize	DON, Fum, Zea,	Zea, Afla,
Oats	DON, NIV, HT-2, T-2	OTA, Cit
Rice	—	Afla, Sterig, OTA
Rye	Ergot	OTA
Sorghum	—	Afla
Wheat	DON, NIV, Zea, ergot	OTA, Afla, Cit

Note: Afla, aflatoxins; Cit, citrinin; DON, deoxynivalenol; Ergot, ergotamine; HT-2, HT-2 toxin; NIV, nivalenol; OTA, ochratoxin A; Sterig, sterigmatocystin; T-2, T-2 toxin; Zea, zearalenone.
Adapted from Petterrson, 2004.

Table 6 Some mycotoxigenic *Fusarium* species and the mycotoxins they produce[a]

Species	Mycotoxin
F. acuminatum	Acuminatum, aurofusarin, beauvericin, chlamydosporol, enniatins, fusarins, moniliformin, trichothecenes
F. armeniacum	Beauvericin, fusarins, trichothecenes
F. crookwellense	Aurofusarin, butenolide, culmorin, cyclonerodiol, fusaric acid, fusarins, trichothecenes, zearalenone
F. culmorum	Aurofusarin, butenolide, chlamydosporol, culmorin, cyclonerodiol, cyclonerotriol, fusarins, moniliformin, trichothecenes, zearalenone
F. equiseti	Beauvericin, equisetin, fusarochromanone, moniliformin, trichothecenes, zearalenone
F. graminearum	Aurofusarin, butenolide, chlamydosporol, culmorin, cyclonerodiol, fusarins, trichothecenes, zearalenone
F. proliferatum	Beauvericin, enniatins, fumonisins, fusaric acid, fusaproliferin, moniliformin
F. pseudograminearum	Trichothecenes, zearalenone
F. sporotrichioides	Aurofusarin, beauvericin, butenolide, culmorin, enniatins, fusarins, moniliformin, trichothecenes
F. verticillioides	Fumonisins, fusaric acid, fusarins, naphthoquinones

[a]Adapted from Desjardins, 2006.

and most recently Desjardins (2006). These books trace the evolution of *Fusarium* taxonomy and show quite graphically the number of metabolites that different *Fusarium* species can produce.

Historically, *Fusarium* classification relied on morphological characteristics of the fungus, but with recent advances, molecular techniques have been used to confirm previous classifications (Benyon *et al*., 2000; Desjardins, 2006). However, as emphasized by a number of authors, in particular Burgess and his colleagues (Burgess *et al*., 1994), it is critical when classifying fungi that a large number of isolates of the fungus in question are adequately assessed before making any definitive conclusions on the status of a species. The following examples give an indication of the classification difficulties that have occurred. *Fusarium moniliforme* was the species from which fumonisins were isolated and it has been reclassified as *Fusarium verticillioides*. This does create some confusion in the literature as neither fumonisins nor moniliformin, which were named after *F. moniliforme* (a species name which no longers exists), from which they were isolated, now relate to the fungus in question (Desjardins, 2006). *Fusarium graminearum*, which was described as two populations designated Group 1 and Group 2 (Burgess *et al*., 1994) has now been classified as *Fusarium pseudograminearum* and *Fusarium graminearum,* respectively (Desjardins, 2006). This has significant ramifications, as different crops are affected by these two species. *Fusarium* species may produce very different mycotoxin profiles, as shown in **Table 6**. Moreover, it can be seen from **Table 6** that many of the *Fusarium* produce a range of mycotoxins, many of which are structurally distinct (Cole *et al*., 2003) and give rise to different clinical signs and pathology in man and animals.

Table 1 shows the array of mycotoxins that can be produced by fungi and **Table 6** indicates that some fungi produce many different toxins. As noted above, it is considered globally that there are five major toxins that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

may cause significant food losses, and also impair human and animal health. In addition to these there are a number of other toxins, especially produced by *Fusarium* that could have significant and profound effects on man and animals. Interestingly, some of these toxins are produced by many species, whereas other toxins are produced by relatively few (Bryden *et al*., 2001; Desjardins, 2006; Jestoi, 2008). In most instances there have not been systematic surveys of these toxins because of the lack of routine analytical methods, so there is no appreciation of the extent of their occurrence in nature. Moreover, the possible interactions between toxins in disease aetiology and pathogenesis requires further study (CAST, 2003; Speijers and Speijers, 2004). In many instances intoxication is likely to result from the ingestion of low concentrations of a number or 'cocktail' of mycotoxins. The role that mycotoxins play for fungi in nature is a question that creates much speculation (Desjardins, 2006).

Many of the initial studies that examined the infection of agricultural commodities by *Aspergillus* species concentrated on stored commodities. However, it was eventually shown that aflatoxins could also be formed in plant products prior to harvest, especially in peanuts and corn (Payne, 1998). The *Aspergillus* sp. that produce aflatoxins are *A. flavus*, *A. parasiticus* and *A. nomii* (Dorner, 2008). The factors that contribute to *Aspergillus* invasion of peanuts are shown in **Figure 4**. In overview, as conditions of water and heat stress affect plants, especially late in the growing season, this gives the fungus a competitive advantage over other fungi, and, at the same time, places the plant, whether it be a peanut or a maize plant, under considerable stress. The initial isolation of aflatoxin was made from groundnuts. In this crop, plant varieties with a high incidence of pod splitting, drought conditions and soils with a low water-holding potential interact to increase fungal invasion and aflatoxin production before harvest (Diener *et al*., 1987; Dorner *et al*., 1989). Interestingly, very high kernel moistures may prevent aflatoxin formation, presumably by facilitating growth of other micro-organisms, or it may be a reflection of active host cells that can resist invasion. In some field situations, especially in peanuts, where *A. flavus* tends to be the dominant species, cyclopiazonic acid can also be formed. Cyclopiazonic acid, like ochratoxin, can be formed by both *Aspergillus* and *Penicillium* species and be a co-contaminant with aflatoxin (Bryden *et al*., 2004) in cereal grains. The contamination of grapes and wine with ochratoxin following field invasion of the crops with *Aspergillus* species, especially *A. carbonarius* is of growing concern internationally (Visconti *et al*., 2008). The rheological behaviour of starch is influenced by fungal growth in, and DON contamination of, the wheat from which it was derived (Lancova *et al*., 2008a).

Aflatoxin production in field maize (Payne, 1998; Munkvold, 2003) is facilitated by drought stress and other stress conditions that predispose the plant to attack by a number of pests, including toxin-producing fungi. Fungal attack is facilitated by a damaged seed. Insects cause the type of damage generally associated with fungal infection and probably serve as vectors of the initial fungal inoculum (Dowd, 1998). Developing kernels are most susceptible to infection during the late milk-dough stage. Damaged kernels are usually associated with mycotoxin contamination, but intact, undamaged kernels have been reported to contain aflatoxin, suggesting fungal invasion via the silk (Payne, 1998). These inter-relationships are shown graphically in **Figure 5**.

3.1.3 Storage Conditions

Stored grain is not static; it is in a dynamic state and may be contaminated both externally and internally by fungi and insects. These interrelationships are affected by climatic factors such as temperature and humidity, by geographical location, by the type of storage container and by the mode of grain handling and transport (Christensen, 1974; Chelkowski, 1991; Jayas *et al*., 1995). Moisture depends mostly on water content at harvest, the amount of drying, aerating and turning of the grain before or during storage as well as the respiration of insects and microorganisms. Provided grain is dry when placed in storage, moisture can only rise from leaks or condensation. Grain may go into storage at a uniform temperature but over a period the grain mass will cool at a different rate in the centre than at the periphery. As a result of temperature differentials moisture migrates through the storage bin, resulting in condensation and the provision of ideal conditions for mould growth or the development of 'hot spots' in localized areas (Wicklow, 1995). If grain of widely different moisture contents is blended to give a presumably safe average moisture content, there is a great danger of development of self-propagating 'hot spots'. Similarly, microbial and insect growth in stored grain also results in moisture condensation and the potential development of 'hot spots'. The minimum critical levels for the growth of fungi are 7–15% moisture (depending on commodity) and 80–85% RH. Temperatures at which toxin production can take place vary from 0 to 35 °C, depending on the fungal species concerned (Wicklow, 1995; Frisvad, 1995).

3.2 Mycotoxins

Mycotoxins vary greatly in their structure and chemical composition (Cole *et al*., 2003) which has significant ramifications for analysis, metabolism and toxicity.

3.2.1 Mycotoxin Analysis

Mycotoxin analysis is a highly developed field that continues to expand, and the interested reader is referred to the following reviews, which detail the latest developments in mycotoxin analysis (Gilbert and Anklam, 2002; Logrieco *et al*., 2005; Maragos, 2004; Krska *et al*., 2008). Sampling is the greatest source of error in quantifying mycotoxin contamination (Whitaker *et al*., 1995; Whitaker, 2004) because of the difficulty of obtaining food samples representative of that which may have caused a mycotoxicosis or for regulatory purposes from large grain consignments. These difficulties arise because of the existence of 'hot spots' of fungal proliferation and the resulting uneven distribution of toxin within a commodity and the low levels, ranging from microgram per gram to milligram per gram, at which mycotoxins occur (CAST, 1989). Other major difficulties for the analyst are the vast array of chemical compounds that constitute mycotoxins and the different food matrices in which they occur. This is further complicated by the occurrence of conjugated mycotoxins in foodstuffs. These so-called 'masked' mycotoxins can occur following plant metabolism (Gareis *et al*., 1990; Berthiller *et al*., 2007) and are not detected with conventional analytical procedures. For example, zearalenone-4-glucoside, a conjugate of zearalenone, and DON-3-glucoside, a conjugate of DON, can constitute up to 20% of the total content of the precursor mycotoxin in the foodstuffs (Berthiller *et al*., 2005; 2006; Lancova *et al*., 2008b). It is likely that these conjugates will be hydrolysed following ingestion, thus increasing exposure to the precursor toxin. There is also evidence that OTA and fumonisins are conjugated by plants (Berthiller *et al*., 2007) and fumonisins may also be conjugated during food processing (Humpf and Voss, 2004). Recently, Krska and his colleagues have developed chromatographic techniques that allow the simultaneous determination of mycotoxins and their conjugates (Berthiller *et al*., 2007; Krska *et al*., 2005; 2008).

The analytical procedures for mycotoxins can be summarized as follows (Cole, 1986a). After a sample has been obtained, it is ground and subsampled prior to analysis. Mycotoxins are usually extracted from food or agricultural products using organic solvents, and after extraction filtration it is often necessary to remove unwanted solids. Various clean-up techniques have been developed to remove substances that interfere with accurate quantification of the mycotoxins during analysis. A variety of solid-phase extraction columns or immunoaffinity columns are used extensively in the clean-up of samples for mycotoxin analysis. Aflatoxin, zearalenone, patulin and ochratoxin contain a chromaphore and can therefore be quantified using thin-layer chromatography (TLC) or high-performance liquid chromatography (HPLC). Mycotoxins that do not contain a distinctive chromaphore, for example, fumonisins and some of the trichothecenes, can be derivatized and analysed by HPLC or gas chromatography (GC). Alternatively, these compounds can be analysed directly by GC/mass spectrometry (GC/MS) or LC/MS.

Application of immunological methods to mycotoxin analysis is an exciting advance in mycotoxin detection (Pestka, 1994). Immunoassays appear to offer the best opportunity for the development of rapid, repeatable and sensitive assays. These techniques are based on the highly specific reaction between an antibody and an antigen and require the development of an antibody against the mycotoxin that is to be assayed. Mycotoxins are nonantigenic, but are able to illicit an antibody response after conjugation to a protein or polypeptide carrier. The availability of antibodies to a number of mycotoxins has allowed the development of radioimmunoassays (RIAs)

and enzyme-linked immunosorbent assays (ELISAs) for the detection of toxins in feedstuffs and residual mycotoxins or metabolites in body fluids (Krska *et al*., 2005). The ELISA technique offers advantages over RIA in that radioisotopes and appropriate monitoring equipment are not required. The ELISA is also more adaptable to field use. Commercial ELISA kits have become available for aflatoxins, zearalenone, DON, ochratoxins and fumonisins.

3.2.2 Mycotoxin Occurrence

Fungi are able to grow on all kinds of food, including cereals, fruit, vegetables, nuts and the products produced from these different commodities. Extensive surveys have been published on the occurrence of mycotoxins, including those by Scott (1978), van Egmond and Speijers (1994), Filtenborg *et al*. (1996), Meister and Springer (2004), Drusch and Aumann (2005), Binder *et al*. (2007), Roscoe *et al*. (2008) and Trucksess and Scott (2008). Some mycotoxins remain within the fungal mycelium or within spores, but most are excreted by the fungus into the food. In grains and solid foods like cheeses, bread and apples, the diffusion of the toxin from the fungus is usually only in the immediate area surrounding the fungus, leaving much of the product uncontaminated. For liquid foods, and fruits like peaches and tomatoes, diffusion of the mycotoxins is throughout the food product. However, most mycotoxins are very stable and once in a food product are resistant to further food processing. The corollary to this is that the use of mouldy material during food processing may result in the product being contaminated with the mycotoxin. This has been demonstrated with the transfer of DON from barley into beer (Lancova *et al*., 2008b) and ochratoxin from grapes into wine (Visconti *et al*., 2008).

As indicated above, there are five major classes of mycotoxins that are considered to be the most significant threat to food safety globally. The fungi that produce these toxins also produce other toxins (**Table 1**) and in field situations co-contamination is likely to occur. Binder *et al*. (2007) have completed a global survey of the major mycotoxins and found low-level contamination throughout the world, with significant regional differences, especially between tropical and temperate areas. Most food products, because of their chemical composition and the conditions under which they are produced and/or processed, have only a limited number of toxigenic fungi associated with them and it has been estimated that there is usually only 2–10 species that will contaminate any given food commodity (Filtenborg *et al*., 1996).

In many situations, mycotoxin-contaminated cereal grains are diverted to manufacture feed for livestock. This poses the question, is there likely to be significant contamination of animal products with mycotoxins or their metabolic products that will be subsequently consumed by the human population? The major area of concern is the transfer of mycotoxins into milk (Shreeve *et al*., 1979) especially aflatoxin (van Egmond, 1989; Fink-Gremmels, 2008). The hydroxylated metabolite of aflatoxin B_1, aflatoxin M_1, is excreted into milk from 1 to 6% of dietary intake (Petterrson, 2004; Fink-Gremmels, 2008). This large variation in the carry-over of aflatoxin M_1 into milk may reflect the studies undertaken, including feeding practices, breed and productivity of cows, toxin excretion rates and/or analytical procedures used. Nevertheless, it is recognized that milk can be an important vehicle for aflatoxin exposure, not only in dairy animals, but also in human breast milk (El Nezami *et al*., 1995).

OTA is rapidly metabolized in the rumen to ochratoxin α and phenylalanine, but low levels may escape rumen metabolism and low quantities have been detected in cow's milk. OTA has been found in tissues of pigs and poultry that had been fed OTA-contaminated feed. There are significant differences amongst studies and this is presumably due to differences in absorption and metabolism of the toxin; it has been shown that the half-life in pigs and chickens is 180–140 hours and approximately four hours, respectively (Petterrson, 2004). Residues of other mycotoxins, including zearalenone, trichothecenes and fumonisins are not considered to be of public-health importance, as only very low levels of the toxins have been found in the tissues of animals that had been fed very high levels of the toxins in experimental situations (Pestka, 1995; Petterrson, 2004). Cyclopiazonic acid, which can occur as a co-contaminant with aflatoxin, has been shown experimentally to accumulate in meat, milk and eggs of animals and poultry fed this toxin (Dorner *et al*., 1994). Pestka (1995) conducted an extensive review on the possibility of residues occurring in animal products and concluded that trace levels of mycotoxins and their metabolites may carry over into edible tissues of meat-producing animals, but the evidence suggests that the levels transmitted do not pose a public-health risk.

4 STRATEGIES FOR MYCOTOXIN MITIGATION

Conditions favouring the development of mycotoxins in food commodities before and after harvest have been discussed in preceding sections. There are many factors that affect mycotoxin formation and any control or management programme that seeks to reduce contamination by these compounds must take into account the complex interaction between these different factors. Overall, there are a number of approaches that can be taken to minimize mycotoxin contamination in the food chain, and these involve prevention of fungal growth and therefore mycotoxin formation, strategies to reduce or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat157
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

eliminate mycotoxins from contaminated commodities or diverting contaminated products to low-risk uses.

4.1 Genetic Modification of Fungi and Crops

Fungal geneticists have unravelled the pathways and the genes responsible for the synthesis and regulation of the production of the major mycotoxins, especially aflatoxin and the trichothecenes (Yu and Keller, 2005; Bhatnagar *et al*., 2008). In the future this may allow the development of approaches that will reduce or eliminate mycotoxin production by the fungus, including the production of inhibitors which could be incorporated into plants and thus reduce the synthesis of the toxin and/or increase the tolerance of the plant to the toxin (Holmes *et al*., 2008). There has been much interest in developing crop varieties that are resistant to toxigenic fungi, but studies in maize (Duvick, 2001; Munkvold, 2003) and peanuts have shown that it is difficult to achieve a high level of genetic resistance to toxigenic fungi. Moreover, in many field situations, the extremes of climate and changes in agronomic practices may render a crop variety vulnerable to fungal infection and effectively eliminate any advantages made in genetic progress.

There has been increasing interest in the application of transgenic resistance against toxigenic fungi and mycotoxins (Bhatnagar *et al*., 2008). There are three basic strategies that can be used; (i) reducing infection by the pathogen, (ii) inserting genes capable of degrading the toxin or (iii) reducing mycotoxin accumulation by interfering with the biosynthetic pathway. Theoretically, these techniques have great promise for the reduction of mycotoxin accumulation in crops, but are only in their infancy, and numerous technical, economic and social aspects will need to be overcome before there will be widespread acceptance of these approaches (Bhatnagar *et al*., 2008; Wu, 2008). Moreover, the difficulty with any of these transgenic approaches is that they are likely only to be effective against one toxin or perhaps a fungal genera and this then leaves the crop vulnerable to the accumulation of other toxins. In some respects, this is demonstrated by the success of the Bt maize hybrids, which have been developed as a means of transgenic insect protection. The transgenic Bt corn or maize contains a gene from the soil bacterium *Bacillus thuringiensis* which encodes for a protein that is toxic to common lepidopteran maize pests. These hybrids offer a new tool for mycotoxin management because insect damage is often a major aetiological factor in facilitating toxigenic fungal infection of crops (Wicklow, 1995; Dowd, 1998).

Bt maize is effective in reducing the incidence of fumonisin contamination, but less effective in reducing DON contamination. This reflects different disease patterns and pathogens as DON is associated with *Gibberella* ear rot, whereas fumonisin production is associated with *Fusarium* ear rot and the occurrence of *Gibberella* ear rot is not as strongly influenced by insect damage as is fumonisin accumulation. Aflatoxin contamination of maize has not been consistently reduced in Bt hybrids compared with non-Bt hybrids (Munkvold, 2003). Aflatoxin accumulation is influenced by insect injury to the plant, but this is probably overridden by drought and high temperatures, which explains the inconsistent results that have been found with aflatoxin accumulation and the use of Bt maize hybrids.

4.2 Agronomic and Biological Control Measures

There are a number of agronomic factors that need to be considered if fungal infection and mycotoxin production is to be prevented. Essentially these techniques involve reducing crop stress or changing the ecological niche of the fungus in such a manner that the spore load of the fungus is reduced and the probability of fungal infection of the crop correspondingly decreased. Good Agricultural Practice (GAP) would indicate that crop rotations, tillage and ploughing practices, soil fertilizer regimens and planting date all have a significant impact on the viability of a crop and whether it can withstand fungal attack (Munkvold, 2003; Jouany, 2007). Other agronomic aspects, including insect control, weed control and also tillage practices have a major impact on the spore load. Weeds are often natural reservoirs for many fungi, especially *Fusarium* (Burgess *et al*., 1975). Depending on crop rotations and the depth to which the remnants of the previous crop is ploughed into the ground, the debris is often a major source of subsequent fungal infection, as all of these fungi are soil organisms (Dill-Macky and Jones, 2000). The complexity of fungal infection in the field, especially with *Fusarium* sp., make it difficult to control these diseases with fungicides; application rate and application timing are important for optimum efficacy (Jennings, 2004). Suboptimal application rates of some fungicides can result in the stimulation of mycotoxin production (Magan, 2006).

An aspect of the ecology of the fungus that has been recently exploited by a number of groups is using the concept of 'competitive exclusion', in which a nontoxigenic fungus is used to displace the toxigenic fungus in the field. Studies have been conducted with peanuts, cotton and maize. In the studies with peanuts (Dorner and Horn, 2007; Dorner, 2008) it has been shown that using a nontoxigenic strain of *A. flavus* over a couple of growing seasons considerably reduced the incidence of aflatoxin contamination of field peanuts. It appears

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat157
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

that *A. flavus* strains are more effective than *A. parasiticus* in displacing toxigenic strains in the environment (Dorner and Horn, 2007). The other aspect of the application of nontoxigenic strains to field situations is that great care must be taken to ensure that the fungus does not produce other toxins; for example, in the work carried out with peanuts, only *A. flavus* strains that did not produce cyclopiazonic acid were used (Dorner, 2008). If this approach is applied to *Fusarium* it may be more difficult to find strains that are nontoxigenic, because as noted above (**Table 6**), many *Fusarium* species produce a number of different toxins.

4.3 Climate Modelling to Predict Mycotoxin Risk

Climate conditions during fruiting or seed setting and at harvest can play a significant role in toxin accumulation. If, for example, peanuts are harvested and left in wind rows without adequate drying, significant accumulation of aflatoxin can occur. With maize, the stage of the kernel at harvest can have significant ramifications for contamination by fumonisins and other *Fusarium* toxins, and infection by *Aspergillus* at this time can lead to greater build up of aflatoxins.

Examination of the climatic conditions under which crops are grown gives a good indication of the possible threat of fungal invasion and mycotoxin accumulation prior to harvest. With this understanding a number of groups have used climatic conditions to model or predict preharvest toxin production and accumulation (Schaafsma and Hooker, 2007). Models for aflatoxin contamination of peanuts (Wright *et al*., 2005; Dorner, 2008) and maize (Chauhan *et al*., 2008) have been developed. A model has also been developed to minimize DON production in wheat. The model developed in Australia and called AFLOMAN by Wright *et al*. (2005) allows farmers to evaluate the risk of aflatoxin contamination of their peanuts. They may decide to harvest earlier than normal to minimize aflatoxin contamination and therefore avoid the financial penalties that occur when this mycotoxin contaminates their crop. The Canadian model DONcast (Hooker *et al*., 2002) for the prediction of DON in wheat has been used successfully commercially and adapted for use in the United States, Uruguay and France (Schaafsma and Hooker, 2007; Miller, 2008). Greater difficulty has been experienced in developing models to predict aflatoxin, DON and fumonisin accumulation in maize, due to the more complex fungal, insect/crop interaction compared with wheat (Schaafsma and Hooker, 2007). Nevertheless, it is possible to develop models to predict mycotoxin risk in crops and use that information to change management practices on a season-by-season basis. At this time, this approach is only appropriate for developed countries with significant infrastructure that allows online monitoring of meteorological data. In the future, as remote sensing technology becomes more sophisticated and available, it should be possible to apply modelling technology in less developed economies.

4.4 Storage Management

Moisture and temperature are two factors that have a crucial effect on fungal proliferation and toxin elaboration during storage, as noted above. Moisture depends mostly on water content at harvest, and the amount of drying, aerating and turning of the grain before or during storage, as well as the respiration of insects and micro-organisms (Christensen, 1974). Rewetting may occur by leaks or flooding into storage units, but by far the most common cause is condensation, which can give rise to the development of 'hot spots'. Condensation often results from moisture migration in bulk stores under the influence of temperature differentials within the grain that are mediated by fluctuations in ambient temperature (CAST, 1989). These problems are minimized if storage time is kept to a minimum. As described above, with knowledge of the composition of the food commodity and storage conditions it should be possible to predict the likely fungal spoilage organisms and develop control programmes that target those fungi and prevent their growth and the production of mycotoxins in the food commodity (Filtenborg *et al*., 1996).

Prevention of mycotoxin formation in stored feeds is a major goal in controlling mycotoxicoses in livestock and poultry (Smith and Henderson, 1991). Good feed management practices (for example, systematic clean-up of feedlines and augers; feed grain storage at proper moisture content, that is, below 13%; inspection of grain regularly for temperature, insects and wet spots) will limit the possibility of fungal development in feedstuffs and complete feeds. The risk of feed contamination will be reduced in units with rapid turnover of feed because there will be less time for fungal growth and toxin production. Apart from methods that modify the fungal environment, many compounds are available that will inhibit mould growth in feedstuffs. Organic acids, especially propionic acid, form the basis of many commercial antifungal agents used in the stockfeed industry and give excellent protection (Hamilton, 1985). An alternative approach is the application of essential oils, such as cinnamon and clover-leaf oil, which have the capacity to control fungal growth (Magan, 2006).

4.5 Food Processing

Many studies have been completed that have followed the levels of mycotoxins in food commodities as they have been processed (Jackson and Bullerman, 1999;

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat157
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Humpf and Voss, 2004; Murphy *et al*., 2006). Mycotoxins may appear to be destroyed, but in many instances the mycotoxin is not destroyed, but accumulates in one fraction of the commodity during the process. As is shown in **Table 7**, the processing of peanuts through colour sorting, blanching and so on can virtually remove all the aflatoxin from the finished product (Dorner, 2008). In instances like this, all of the contaminated peanuts are removed and those remaining are essentially toxin free. The oil is subsequently removed from the contaminated nuts and the resulting meal is often diverted to animal feed, but only if below regulatory levels.

In instances where there is only surface colonization of the grain, removal of bran fractions will remove most of the toxin, and these fractions can then be diverted to animal feeds (Meister and Springer, 2004). In many situations, removing screenings from maize will remove the greatest portion of the grain that is contaminated with fumonisins. However, as this can be a substantial fraction of the total amount of grain, this can be uneconomical in many circumstances. Wet milling of maize results in starch almost free of zearalenone, fumonisins, DON and nivalenol (NIV). DON and NIV are recovered in steep water, whereas fumonisins and zearalenone are found mainly in the gluten fraction. In dry-milled food products, the distribution of mycotoxins among the fractions depends on the fungal penetration of the endosperm (Meister and Springer, 2004; Castells *et al*., 2005). Scudmore *et al*. (2008a; 2008b) have shown that the relationship between the concentration of *Fusarium* mycotoxins in cereal grains and finished products is toxin and process dependent.

The primary amine group in fumonisins is key to its chromotagraphic detection and can be derivatized with acids and/or react with reducing sugars (Humpf and Voss, 2004). The products formed in these processes are essentially nontoxic. Alkaline processing of maize contaminated with fumonisins releases the tricarballylic groups and hydrolysed fumonisins have reduced toxicity. It appears that the cooking, steeping and rinsing processes involved in the production of tortillas (Mexican Style) is effective in reducing the fumonisin content (Murphy *et al*., 2006), but baking *per se* has little effect on the fumonisin content in the final product (Humpf and Voss, 2004). The difficulty with many studies that have attempted to quantify the toxicity of products after processing is that the biological activity of fumonisin breakdown products is unknown. Moreover, these products may bind to the food matrix and become 'hidden', but may become reactivated following ingestion. Ammoniation has also been shown to reduce fumonisin concentrations in maize (Norred *et al*., 1991).

It has been shown that roasting peanuts resulted in greater reductions in chemically detectable aflatoxins than boiling (Dorner, 2008). There are other processes that involve alkali treatment and boiling of aflatoxin-containing commodities and these will reduce aflatoxin to very low levels (Murphy *et al*., 2006). Alkali processing, or nixtamalization, has been shown to significantly reduce aflatoxin levels in maize-based products. There are also reports that acidification of a product following nixtamalization can reconstitute the aflatoxin postprocess (Murphy *et al*., 2006). Perhaps this has implications for gastrointestinal kinetics of aflatoxin following these processes.

4.6 Detoxification

Approaches to detoxification of mycotoxin-contaminated grain and other food commodities have included physical, chemical and biological treatments (Cole, 1989; Trenholm *et al*., 1989; CAST, 2003; Kabak *et al*., 2006; Jouany, 2007). In cases of light to moderate mycotoxin contamination, physical methods for cleaning the kernel surface, and hence removing the more heavily contaminated particulate matter, have proven effective in reducing mycotoxin concentrations as noted above. A range of chemical treatments have been applied to contaminated products and have been found to vary in their effectiveness at reducing mycotoxin concentrations in contaminated grain or feed (Galvano *et al*., 2001). Ammoniation has been used widely to reduce aflatoxin levels and there have been some commercial plants developed for this process (Park and Price, 2001). However,

Table 7 Reduction of aflatoxins postharvest[a,b]

Process	Aflatoxin level ($\mu g\,kg^{-1}$)	Reduction (%)	Cumulative reduction (%)
Farmer's stock	217	—	—
Belt separator	140	35	35
Shelling plant	100	29	54
Colour sorting	30	70	86
Gravity table	25	16	88
Blanching/colour sorting	2.2	91	99.0
Re-colour sorting	1.6	27	99.3

[a]Results were obtained from processing of a 40 000 kg lot of contaminated peanuts.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

because of expense this process is not widely adopted. All processes that seek to decontaminate infected grain, especially where they involve rigorous chemical or heat treatments, must be cost effective and must not reduce the nutritional content of the grain or food if they are to be accepted generally.

A diverse variety of substances have been investigated as potential mycotoxin-binding agents (Galvano *et al*., 2001; Huwig *et al*., 2001), including lucerne, synthetic cation- or anion-exchange zeolites, bentonite, spent canola oil, bleaching clays and hydrated sodium calcium aluminosilicate (HSCAS). Several studies have examined the efficacy of HSCAS to reduce the toxicity of a variety of mycotoxins in several animal species. HSCAS is a high-affinity absorbent for aflatoxins, capable of forming a very stable complex with the toxin and hence reducing its bioavailability (Phillips, 1999). Other approaches have been used to bind mycotoxins (Jouany, 2007), in particular a yeast cell-wall-derived glucomanin prepared from *Saccharomyces cerevisiae* has been shown to efficiently adsorb aflatoxin, zearalenone and fumonisins (Dawson *et al*., 2001). A feed additive that is a new stabilized bacterial species can detoxify trichothecenes by removal of the epoxide group *in vivo* (Binder *et al*., 2001; Fuchs *et al*., 2002) and is a novel approach to mycotoxin decontamination (Molnar *et al*., 2004).

Many approaches have been used to reduce the toxicity of mycotoxin-contaminated commodities. However, most methods have been tested on a limited number of specific toxins. Since contaminated grain may contain a broad range of toxins of differing chemical characteristics, including heat stability, solubility and adsorbent affinity, a detoxification procedure that works well for individual toxins may not be effective for the diverse mycotoxin combinations that may occur naturally. Moreover, no single treatment has proved completely successful in degrading or removing toxins and retaining the nutritional and functional qualities of the treated commodity.

4.7 Integrated Mycotoxin Management

An integrated approach to mycotoxin control is the application of the Hazard Analysis and Critical Control Points (HACCP). This system is used extensively in the food industry to control bacterial contamination (Ropkins *et al*., 2003) and there has been much interest in its application to the control of mycotoxins throughout the food chain (Lopez-Garcia, 2001). Aldred and Magan (2004) have reviewed the application of this approach to mycotoxins and, as shown in the **Table 8**, there are seven principles that define a HACCP programme. The successful application of this approach should reduce mycotoxin contamination in all sectors of the food chain and have the added advantage of increasing production efficiency, which is an important consideration given the increasing need for food production globally. The development of a HACCP programme should evolve in conjunction with other complimentary approaches to agricultural production, namely GAP, Good Manufacturing Practice (GMP), Good Hygiene Practice (GHP) and Good Storage Practice (GSP) (Aldred and Magan, 2004).

Table 8 The HACCP principles

Principle 1: Identification of hazards; assessment of risk; description of control measures.
A hazard is something which can have a negative effect on health.
Risk is the probability of an adverse effect resulting from a hazard.
Principle 2: Identification of the critical control points (CCPs).
A critical control point is a step in a process where control is possible, and loss of control may lead to an unacceptable health hazard. A CCP may be a raw material, a location, a practise, a procedure or a process stage, but it must be specific.
Principle 3: Establishment of critical limits
Critical limits are the tolerances applied to CCPs which maintain a safe condition.
Principle 4: Establishment of procedures for monitoring of CCPs and
Principle 5: Establishment of corrective actions
Principle 6: Establishment of verification procedures
Principle 7: Documentation and record keeping

Adapted from Aldred and Magan, 2004.

A number of HACCP programmes (Aldred and Magan, 2004; Lopez-Garcia *et al*., 2008) have been developed for aflatoxin in maize, animal feeds, copra and coconut, groundnuts and pistachio nuts, and also for OTA in coffee. The success of these programmes will require the development of rapid diagnostic tools to monitor the occurrence of mycotoxigenic fungi using molecular technology (Niessen, 2008) and the application of molecular imprinted polymers and lateral flow devices for quantification of mycotoxins (Magan, 2006). The difficulty of applying this approach, especially in high-risk areas in developing countries, is that these processes may not be economically feasible or practical, and therefore the other approaches are required to minimize mycotoxin contamination.

4.8 Human Intervention

In the preceding sections, the emphasis has been on techniques that reduce exposure to mycotoxins, but complete elimination of mycotoxins from the food chain is extremely difficult, if not impossible. Therefore interventions that modify the metabolism and deposition of these toxins have been explored in animal models.

In the animal feed industry, for example, it has been shown that feed additives that adsorb or degrade mycotoxins are effective in significantly reducing risk. In the developing world, education programmes that describe the appropriate storage of food commodities is an important strategy to reduce mycotoxin contamination (Turner *et al*., 2005). Nevertheless, in many high-risk regions, it will be essential to include additional intervention strategies. In this regard HSCAS-marketed NovaSil is being evaluated in human clinical trials as a means of adsorbing or trapping aflatoxin and preventing its absorption from the gastrointestinal tract (Phillips *et al*., 2008), as discussed above.

Another interesting compound with anticarcinogenic properties is chlorophyllin, a water-soluble derivative of chlorophyll, which is able to sequest aflatoxin and also appears to induce enzymes that metabolize the toxin (Fahey *et al*., 2005). It has been shown to protect against aflatoxin carcinogenesis in trout (Dashwood *et al*., 1998) and rats (Simonich *et al*., 2007). It has been demonstrated in animal and human studies that oltipraz, a dithiolethione, is an effective agent in blocking aflatoxin DNA-adduct formation, which primarily reflects the induction of aflatoxin-detoxifying enzymes and increased conjugation of aflatoxin with glutathione (Kensler *et al*., 1999). However, the multiphase and long-term development of hepatocellular carcinoma may limit the effectiveness of chemotherapeutic agents, along with the cost and possible adverse effects of long-term drug intake (Kensler *et al*., 2004). It is the considered the view of the WHO that, because of the interaction of aflatoxin and the hepatitis B virus, the most cost-effective intervention to reduce the incidence of hepatocellular carcinoma is a vaccination against viral infection (Henry *et al*., 1999). Nevertheless, to break the cycle that begins with infection at birth, universal vaccination must be carried out for at least two generations (Kensler *et al*., 1999).

Groopman *et al*. (2008) have reviewed the interventions that can be applied to reduce aflatoxin-induced carcinogenesis, especially in developing countries. In addition to the possible interventions already noted, other possibilities include green tea polyphenols (Moyers and Kumar, 2004), which inhibit various chemically induced cancers in experimental animals, and sulforaphane (Talalay and Fahey, 2001). Glucosinolates, which are found in many plants (Cheeke, 1998), are a precursor of sulforaphane and therefore a potentially affordable chemopreventive agent. These examples and the lessons that have been learnt from aflatoxin will, in the future, no doubt be applied to other mycotoxins. A reoccurring point made by Groopman *et al*. (2008) is the importance of having suitable biomarkers, so that reliable data on mycotoxin exposure and dose can be determined. Biomarkers are also necessary to monitor the efficacy of intervention programmes.

5 REFLECTION

The link between human health and agriculture is often ignored by historians, but any consideration of population demographics demonstrates the importance of agricultural production and public health (Scholthof, 2003). In her fascinating book *Poisons of the Past: Mould, Epidemics and History,* Mary Matossian (1989) contends that mycotoxins have probably been responsible for more loss and suffering in animals and man than any other class of food toxin. In particular, she makes the following observation:

> *It may seem irregular to use plant health and climatic indicators of plant health as an index of human health, but the two are intimately related. If plants that people eat are toxic or diseased, people will either be diseased or simply not as healthy and fertile as they would be if they were properly nourished. The population in the area identified more or less, in the heart of western civilization, did not begin to thrive until the sixteenth century (and then only slowly until about 1750) and they grew at different rates in different regions. These regional differences in fact highlight the effects of plant health on human health because of the varied conditions of plant growth in different environments.*

She further explains that epidemics, outbursts of bizarre behaviour and low fertility and high death rates from the fourteenth to the eighteenth century may have been caused by food poisoning from mycotoxins, especially ergot alkaloids, in bread, the staple food in Europe and America during this period (Matossian, 1989).

Mycotoxins, which are natural environmental compounds, will continue to contaminate the food chain and remain a threat to global food security (Strange and Scott, 2005). In times of drought, flooding and other natural disasters, mycotoxins are likely to be more prevalent (Bryden, 2007). Food commodities that are subject to fungal attack, especially cereal grains, will continue to be important economically and nutritionally. There now are a number of strategies that include agronomic practices, plant breeding and transgenics, biotechnology, toxin binding/trapping food additives and education that are available to reduce the risk of mycotoxin exposure. Any realistic assessment of the present-day risk to human health posed by mycotoxins will show that the risk is very dependent on the country and the area in which the individual is living. The risk is greatest in developing countries (Wild, 2007), and acute mycotoxicoses still occur periodically in these populations.

However, it is the chronic effects of mycotoxins on human populations through modulation of the immune system and increased cancer risk that are of major concern to national and international regulatory agencies.

The ubiquitous nature of these natural contaminants in the food chain make it imperative that every effort be made to ensure that exposure is minimal, as a means to improve environmental, animal and human health.

1 INTRODUCTION

Toxicology is an essential part of safety evaluation for a wide variety of products, including pharmaceuticals, medical devices, cosmetics, industrial chemicals and materials, and a wide variety of different types of consumer products. Historically, the introduction of formal toxicology studies for use in the evaluation of product safety is a relatively recent event, but the concept of recognizing and making note of the potentially poisonous properties of manmade products or formulations has been occurring for millennia. So the concept of 'safety by design' that sometimes seems to be of modern origin, when espoused by modern-day toxicologists, chemists, engineers and even consumer groups, most likely had its conceptual origin somewhere in antiquity with the routine formulation of medicinal treatments and the design of potentially dangerous mechanical devices, along with the practical necessity of food tasters to ensure the safety of food products for the aristocracy.

Today, 'safety by design' means little without careful application of modern toxicology for many products. Some of these products require toxicological evaluation prior to entry into their respective markets, due to formal regulatory requirements (pharmaceuticals, pesticides, food additives, medical devices, etc.), whereas others (cosmetics, paints, textiles, foods, art materials, etc.) may not have formal guidance and specified requirements, but many of these products are often evaluated toxicologically in order to determine if some types of precautionary labelling are required, and to help assure product safety and quality for both the manufacturer and the consumer.

Product-safety data is used in many ways by a wide variety of industries. Chemical manufacturers, for example, need to know the toxicologic characteristics of their raw materials, as well as finished products in order to properly design manufacturing processes and select personal protective equipment (PPE) to protect their workers and to develop warning labels, as well as material safety data sheets (MSDS). Pharmaceutical companies need to have toxicologic data for the screening and selection of lead compounds for further development into pharmaceutical products, and the pharmaceutical products themselves require toxicologic evaluation to establish safe levels for administration to animal and human subjects in studies required for approval and registration of the pharmaceutical by regulatory bodies, such as the US Food Administration. Insurers and company risk managers also need to know about product safety in order to establish risk for marketed products. Products, such as pharmaceuticals, cosmetics, coatings, dyes, colourants, food additives and so on, may be evaluated for risk in a company's insurance portfolio, and toxicological data, combined with the potential for exposure, can be useful in obtaining rational estimates for a product's risk. Virtually any industry that one can think of requires some sort of use of toxicological data to establish product safety for the myriad of products that are manufactured or are in use all over the world every day.

2 THE DESIGN AND DEVELOPMENT OF SAFE PRODUCTS

Safe products don't 'just happen' as a result of the design and development of products that serve the purpose for which they are intended. Often, product design is so heavily focussed on function or aesthetics, such as appearance, fragrance, sound, feel and so on, that it is easy for product designers or innovators to put safety considerations aside, while the essential elements of design to meet market needs or intellectual property requirements are satisfied. Under these conditions, product safety obviously becomes more an afterthought of the design process or may be thought to be a necessary 'evil' or 'hurdle' that a newly developed product prototype must overcome. A typical product-development scheme of this nature is depicted in **Figure 1**. Industries, and the companies within them, that are in highly competitive markets often approach the 'normal' course of discovery and development of new products in such a manner that safety or toxicologic considerations are included 'along the way' in their product-development programmes. In companies of this nature, project-management schemes are typically focussed toward the earliest possible release into the market and they 'hope' that any required toxicological testing does not result in any 'snags' on the way to market. Such development programmes typically can be identified, not only by the position that the toxicology evaluation process occupies in their project management plans, but also often in the minimalism and frugality of their conception and implementation to do nothing more than 'satisfy' the most essential regulatory premarket requirements. Companies operating in this manner usually like to describe themselves as being 'market driven' and typically pride themselves on the number of new product launches achieved per year and the speed at which they are able to move products from concept to launch through their pipelines, using efficient and often aggressive, time and cost-efficient techniques. This aggressive road to market is considered necessary and simply 'good business' practice by companies competing for their market shares.

Naturally, most toxicologists are interested in doing their best to assist in the development of safe and effective or useful products that improve the quality of life. However, sometimes being able to do this to the best of their abilities and knowledge becomes a challenge, given the aggressive business practices in some of the companies they serve, and the never-ending need to put new products into their markets, to stay competitive and be responsive to customer needs.

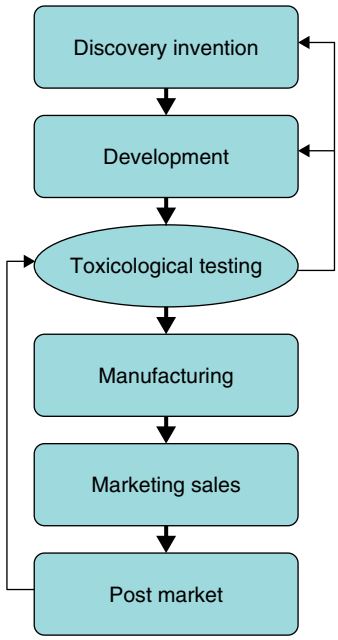

Figure 1 Typified product-development scheme for companies in highly competitive markets, showing the 'in-process' position of the toxicological evaluatory programme.

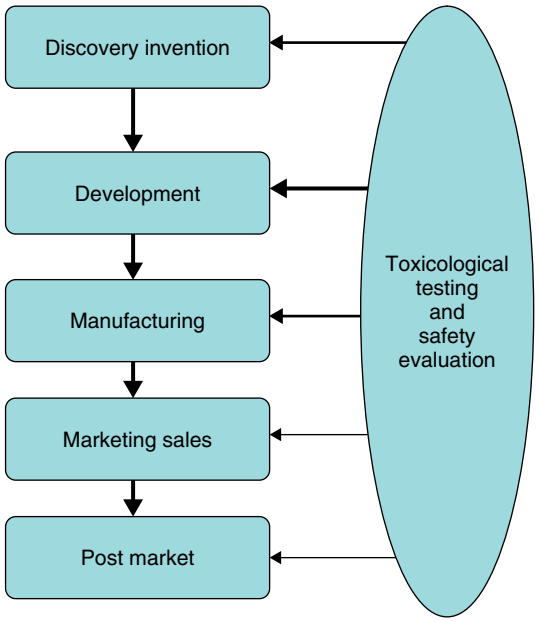

Figure 2 A product development scheme for companies operating with a high degree of product-safety awareness showing the 'continuous' nature of the toxicological evaluatory programme.

Under these conditions, product safety becomes less a toxicologically driven concern and more an issue of product liability (PL), regulatory compliance and market acceptance. Toxicologists working under these conditions often must continuously look for means and methods for improving the rate of 'throughput' and lowering the cost of their evaluatory programmes.

Thus, increasing throughput and lowering cost can become basic driving issues of product-safety programmes that may become a toxicological issue by way of creating a need for more short-term, lower-cost alternatives to currently accepted and established tests and evaluatory procedures.

Companies operating with a high degree of safety awareness or need, independently or within industries that demand a primary focus on product safety (e.g. pharmaceutical, medical device, pesticide, some truly 'green' companies, etc.), typically understand that toxicologic considerations need to be an integral part of their entire discovery, design and manufacturing processes. **Figure 2** shows how such a product development process might typically operate.

Not surprisingly, companies operating with a high safety need also need more short-term, lower-cost alternatives to currently accepted toxicologic procedures, not just because of a desire to improve throughput in their product lines and reduce the cost of testing, but also because there is a lot more for them to do early in the discovery process to select raw materials and develop prototypes with a high potential for proving themselves safe. The basic toxicologic issue for product safety in these development programmes becomes efficiency and accuracy of the tests and their results, such that toxicology evaluation in the early phases of discovery and development does not become a rate-limiting factor or 'bottleneck', where there are potentially many selections to be made based on safety data. Thus, no matter what drives the company with respect to the need for toxicologic evaluation, there is always a demand for improved testing procedures and evaluatory processes. Indeed, many of the 'emerging' methods and procedures presented in various chapters in this book have as their genesis some aspect of responding to this ongoing need. The purpose of the remainder of this chapter will be to define and describe how toxicologists arrive at concluding that a given product is 'safe' for its intended use, basic toxicologic requirements, recommendations and issues for product safety within different industries and basic product-safety testing and evaluation issues currently engaging the toxicologic community.

3 DEFINITIONS, CONCEPTS AND EXPRESSION OF PRODUCT SAFETY

'Safety' is defined as being the condition of being safe from undergoing or causing hurt, injury or loss (Merriam-Webster Online Dictionary, 2009). When used in context with the development and use of any of products of any sort, it is clear that a safe product would be an item 'produced' in some fashion (grown,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

hand-made, developed, manufactured, etc.) that somehow achieves or otherwise demonstrates itself capable of achieving the condition of being safe from undergoing or causing hurt, injury or loss of some significance.

Thus, a general perception would be that implementing product safety in any fashion somehow involves the prevention and/or protection of humans, animals, plants and the environment from the potentially harmful or damaging effects (including hurt, injury or loss) of a given product. Obviously, it is not surprising that the implementation of product safety for any product requires the collection of specific information, including the composition and physical nature of the product and its conditions of use, as well as its potential to cause physical and/or toxic damaging or harmful effects.

Since toxicology is the area of science primarily concerned with determining the adverse effects of substances and materials on biological systems, or more simply whether or not something is toxic to people, animals, plants or the environment, the public, as well as the scientific community at large looks to this discipline to produce data and arrive at sound, scientific findings and conclusions regarding the safety of the products that we discover, develop, manufacture and use. Because toxicologists, in the course of their comprehensive scientific investigations of product safety, also must learn something about the nature and potential for exposure to the substances and compositions of the materials and products that they investigate, they also begin to understand something of the nature and potential for these substances and their various combinations and forms to be hazardous to people, animals, plants and/or the environment. As in all areas of science, how much we know is dependent on the type, amount and quality of the toxicologic data we have available.

Thus, knowledge about the toxicity that a given product might produce, as well as the nature and magnitude of any exposures with respect to human, animal, plant or environmental systems, allows us to define and understand the hazard that the product could represent. This concept is generally expressed toxicologically with the following relationship:

$$\text{Hazard} = \text{Toxicity} \times \text{Exposure} \qquad (1)$$

where 'Hazard' refers to the extent to which a particular adverse effect or event might occur in an exposed population due to a specific type of toxicity (response) and exposure (dose) for a given substance or product.

Evaluation of the toxicity or toxicologic characterization of raw materials, product prototypes, formulations, finished goods and by-products from product degradation and disposal throughout a product's life cycle can all be issues that often must be addressed in product safety evaluations. Indeed, product 'life cycle' analyses to include such toxicologic assessments have become an integral part of current movement toward the development and use of 'green' or 'environmentally friendly' products.

How a toxicologist arrives at a sound science-based conclusion, judgement or finding on a product's 'safety' is not guesswork, as some might tend to believe. A conclusion of safety, or lack thereof, is rather the end stage of a process of investigation that requires the highest state-of-the-art skill and knowledge that toxicologists have toward collecting, analyzing and evaluating as much evidence as is possible regarding dose–response effects and the estimation of toxicologic risk for the product under investigation.

'Dose–response assessment' is the process that toxicologists typically use to quantitatively evaluate the toxicity of a given chemical agent or formulated product as a function of exposure (human, animal or plant) to that agent or product. The relationship between the dose of the agent or product administered or received into the human, animal or plant test system, and the incidence of adverse biologic effects in the exposed test population, forms the basis for the 'quantitative dose–response relationship'. From these relationships, toxicity values (e.g. reference doses and slope factors) are derived that can be used to estimate the incidence or potential for adverse effects (hazard) might occur in an exposed population.

'Hazard identification' is the process of determining whether exposure to a chemical agent or formulated product might cause an increase in the incidence of a particular adverse health effect (e.g. death, cancer, birth defects) and whether the adverse health effect is likely to occur in humans, animals or plants. This process examines the available scientific data for a given chemical or product and develops a data package called termed 'weight of evidence' to determine and characterize any links between the potential for adverse or negative effects, and exposure to the agent or product.

'Toxicologic risk' generally refers to the potential or likelihood that adverse health effects may be induced by exposure to a chemical toxicant, biological toxin or some types of physical agents (e.g. radiation).

'Risk Assessment' is a process that aims to understand, describe and, in some cases, quantify the likelihood that potentially adverse health effects may be induced by exposure to chemical, biological and/or physical agents.

'Risk', in toxicologic terms, refers to the probability or likelihood that a toxicologically significant exposure might occur for a given population. Often this is given as incidence of occurrence of a toxicologically significant event (e.g. death, organ damage, cancer) per some number of individuals in the population (e.g. per 1000 animals or people). Sometimes risk is expressed in terms of a reference or control population in the form of an 'excess likelihood' of an adverse event (e.g. cancer) occurring, relative to a 'baseline' or 'background' incidence of the same adverse event in a nonexposed reference population. For example, when estimating risk

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

for low levels of exposure to relatively low levels of carcinogens in drinking, the US Environmental Protection Agency (EPA) has used the available data and a theoretical 'model' of how chemicals cause cancer to estimate the carcinogenic potency of a given chemical. This potency is considered an 'upper-bound estimate' such that the true risk is not likely to be higher and may be lower. The estimated lifetime cancer risk for exposure to the chemical is the upper-bound estimate of the increase in one's probability of contracting cancer as a result of exposure for a lifetime. The 'unit cancer risk' is the EPA's estimate of risk per some unit of exposure such as one's increased risk from drinking 1 g of the chemical per litre of drinking water for a lifetime. The higher the unit risk, the greater is the estimated carcinogenic potency of the chemical (US EPA, 1997). Risk can usually be estimated in some manner for all types of exposures to chemicals, as well as toxicological effects if the exposure or dose can be determined in a reasonable manner and there is a quantifiable relationship between dose and the effect.

'Risk characterization' is the estimation of the incidence and severity of the adverse effects likely to occur in a human or animal population due to actual or predicted exposure to a substance. This process usually involves comparing the exposure (measured or estimated) with the hazard.

'Relative risk' (RR) is the risk of a toxic adverse event (or of toxic injury) relative to exposure. RR is a ratio of the probability of the event occurring in the exposed group vs. that of a nonexposed group.

$$\mathrm{RR} = \frac{P_{\text{exposed}}}{P_{\text{non-exposed}}} \tag{2}$$

For example, if the probability of developing lung cancer among smokers was 30% and among nonsmokers 1%, then the RR of cancer associated with smoking would be 30. Smokers would be 30 times as likely as nonsmokers to develop lung cancer.

Another term for the RR is the 'risk ratio' because it is the ratio of the risk in the exposed divided by the risk in the unexposed.

Taking everything above into consideration, it should be clear that 'safety' is a concept or an expression that attempts to describe the condition of being relatively low or free from toxicologically significant risk. In practice, safety is often expressed in toxicologic studies as an observed incidence of adverse outcomes (or lack thereof) as being no different (or sometimes even less) than a nonexposed control or reference group or population sample. This same concept is very often applied in preclinical studies, epidemiology studies, clinical trials and environmental field studies, wherever a suitable control or reference population can be identified and included in the study design. Thus, a finding of 'safety' based on this type of data is predicated on having a suitable control or reference group included in the study design and selection of appropriate endpoints for toxicologic investigation. Since these studies often involve animals or human subjects, they must be very carefully planned, and executed with the highest degree of scientific integrity and data quality possible in order to obtain results that are most likely to be reproducible.

Another means of expressing safety might be use of an 'odds ratio (OR)' approach. This can sometimes be of value in expressing and communicating toxicologic findings to the general public. The OR is a measure of effect size in a population group exposed to a toxicant relative to effect size in a nonexposed or control population group. It can also be used to compare effect size in one exposed population group to that of another exposed population group (e.g. differences between men and women, one product vs. another product, etc.). An OR is defined as the ratio of the odds of an event occurring in one group to the odds of it occurring in another group, or to a sample-based estimate of that ratio. These groups might be males and females, an experimental group and a control group, or any other dichotomous classification. If the incidence of a potentially adverse event (e.g. skin damage) in each of two product-formulation-exposed groups are 'Formulation A' and 'Formulation B' then the results matrix for a population sample of 1000 subjects to which both formulations were applied prior to a similar regimen of sunlight exposure might be expressed as follows:

	No skin damage	Skin damage
Formulation A	884	116
Formulation B	147	853

and the OR comparing Formulation A with Formulation B relative to 'skin damage' is:

$$\mathrm{OR} = \frac{884 \times 853}{147 \times 116} = \frac{754052}{17052} = 44.2 \tag{3}$$

This indicates that Formulation-A-exposed treatment areas were substantially more likely to be free of skin damage than Formulation-B areas.

An OR of one would indicate that the condition or event under study is equally likely in both groups, which could denote a condition of 'safety' between a product treatment group and an appropriate control or vehicle treatment group. An OR greater than one indicates that the condition or event is more likely in the first group and an OR less than one indicates that the condition or event is less likely in the first group. The OR must be greater than or equal to zero. As the odds of the first

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

group approaches zero, the OR approaches zero. As the odds of the second group approaches zero, the OR approaches positive infinity.

For example, suppose that in a sample of 100 men, 90 have developed headaches while taking a product over the past month, while in a sample of 100 women taking the same product only 20 developed headaches in the same period. The odds of a man developing a headache are 90 : 10 or 9 : 1, while the odds of a woman developing a headache are only 20 : 80 or $1 : 4 = 0.25 : 1$. The OR is thus 9/0.25 or 36, showing that men taking the product are much more likely to develop a headache than women.

The above example also shows how ORs are sometimes sensitive in stating relative positions: in this sample men are $90/20 = 4.5$ times more likely to develop a headache than women, but have 36 times the odds.

'Safety factors' are also a historical means of approximating safe levels of exposure to toxic materials or products. Using this approach, 'safety factors' are added to experimental toxicity data to account for uncertainties in data and evaluation processes. For example, if a toxicant dose is observed to be safe for a laboratory rodent at a particular 'no-effect' dose level, one might assume that one hundredth of that dose would be safe for a human, allowing a safety factor of 100 to allow for interspecies differences between two different mammals; if the toxicant exhibits reproductive or other adverse effects at a high dose level, then the safety factor applied to the rodent no-effect dose level might be 1000. On the other hand, if toxicant exposure data is available from two substantially dissimilar mammalian species (e.g. laboratory rodent and miniature pig) and no substantial adverse effects are observed at the highest dose levels in either species, application of a safety factor of 10 to the 'no-effect' level for the species most similar in body mass, anatomy and biochemistry to the human (i.e. the miniature pig) might be applied to estimate a reasonably safe exposure level. An increased protection factor may also be used for individuals believed to be more susceptible to toxic effects, such as in pregnancy or with certain diseases; or, a newly synthesized and previously unstudied chemical that is believed to be very similar in effect to another compound could be assigned an additional protection factor of 10 to account for possible differences in effects that are probably much smaller. Obviously, this approach is very approximate, but such protection factors are deliberately very conservative and the method has been found to be useful in a wide variety of applications.

The magnitude of the RR or safety for the use of a given product is determined by some function related to the size of the population that would be affected, and any additional events or circumstances that might differentially affect the probability of exposure or toxicologic effect for different segments of the population (age, gender, genetics, health status, environmental conditions, etc.).

In reality, differing perceptions and definitions of 'safety' for different types of products occur and this results in concepts of 'product safety' being viewed differently by various industries and often even between different product lines within an industry. In actuality, there is no such thing as a 'completely safe' product because, no matter how small, there is always some amount of risk associated with the use of any product. So, for this reason, many find the concept of 'safe for the intended use' to be the practical concept for product safety to which formal risk assessment practices may be applied in order to arrive at some level of 'acceptable risk', and a determination of product safety that can be supported with data and communicated for a given product to the community in which its perception of safety is operating.

A conclusion of 'safety' or lack thereof, from a toxicologic perspective, is therefore best arrived at following a careful evaluation of dose–response relationships involving potential toxicologic endpoints that are relevant to the product under review, followed by the application of some form of rational risk assessment directed toward the known or anticipated product-use conditions. This is not something that is easily mastered and there are many potential pitfalls and opportunities for making mistakes. Product-safety conclusions should always be performed with the cognizance that they will be scrutinized by other experienced toxicologists (and sometimes the public) that will likely have the advantage of time in the intended market and outcomes from actual use to draw from. Therefore, it is highly recommended and indeed imperative that any product-safety finding be carefully documented or 'qualified' with a succinct, but comprehensive disclosure of the information that was available and the procedures used to arrive at the conclusion.

Products found to be safe and placed in their respective markets should always be followed or 'tracked' in some fashion by the manufacturer, distributor or market-responsible party to ensure that any possible adverse effects experienced by product handlers or users are collected and periodically evaluated. Assisting companies with the development of effective and manageable product-safety tracking systems often can be an issue that is addressed most effectively and timely with expert toxicologic assistance, as a lack of proper vigilance in this regard for some products can result in substantial problems for the ongoing success of a marketed product such as PL litigation, loss of product acceptance and declining brand recognition.

4 STRATEGIES AND PROCEDURES FOR SAFETY ASSESSMENT

Modern strategies for the assessment of product safety using toxicological data vary with the type of product

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

being evaluated, as well as the elements of applying sound, evidence-based, risk assessment and toxicological principles to arrive at acceptable communications of product safety and risk. Product-safety evaluations are, therefore, typically done on a individualized product and intended-use basis, with data packages to support the assessment of risk and a finding of acceptance or rejection of 'safety for intended use' that is soundly supported by scientific evidence. When provided this type of data package and a clear, unbiased assessment, appropriately experienced toxicologists are able to evaluate the type, nature and quality of toxicological information presented and will arrive at reasonably similar conclusions.

Figure 3 shows a basic strategy for product-safety assessment leading to the filing of an investigational new drug (IND) application to the US Food and Drug Administration (FDA). A similar process is followed when preparing formal safety assessments based on toxicologic data for pesticide applications submitted to the US EPA and to other international regulatory bodies concerned with pharmaceutical or pesticide regulation and registration. This type of product-safety assessment is 'regulatory driven' because the entire process is always focussed on completion of a safety assessment that meets the criteria for acceptability, both in content and quality, for the planned regulatory submission. The information collected and studies performed in support of the safety assessment for a pharmaceutical product are directed specifically towards the clinical indications for the product, anticipated therapeutic dose level or dose range and the desired route of administration. Similarly, information required and studies performed in support of a pesticide application are focussed on the determination of any potential toxicity to humans, animals or the environment, as well as determination of no-observed-effect exposure levels that can be used to evaluate product safety.

Not all product-safety assessments are regulatory driven. Many are performed to identify any potential safety concerns and to establish that a product is safe for its intended use, or to determine the magnitude to which people need to be protected from exposure to the material due to the potential for harm. These types of assessments can also be of substantial value to insurers for accurately determining PL. Some insurance companies require this information as part of their PL determinations. **Figure 4** shows a strategy to conduct a product-safety assessment that is driven by primarily by practical needs and concerns only rather than specific regulatory requirements. Although the overall objective is similar to the regulatory-driven assessment, the process differs in that it lacks the strict regulatory guidance, data quality requirements and agency interactions necessary for regulatory safety evaluation and is, therefore, often less costly and also may include tests, such as *in vitro* alternatives and so on, that are not yet accepted for regulatory-driven evaluations. This type of safety evaluation is conducted largely because it is simply good business practice to have this type of information in a product portfolio to satisfy internal concerns regarding the safety of a company's products for employees (management, safety personnel, R&D, manufacturing, packaging, warehouse, etc.), as well as to be able to provide scientifically sound information to distributors, transportation workers, customers, insurers, for MSDS preparation and so on, when needed.

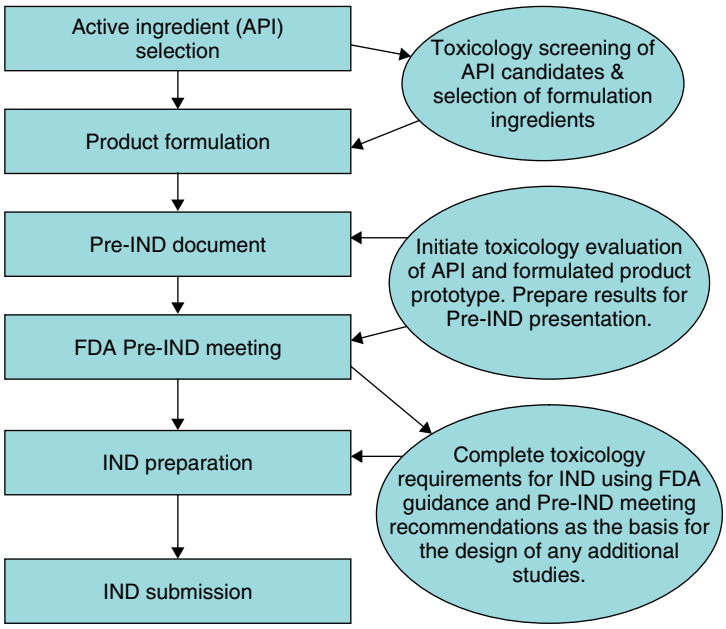

Figure 3 A basic strategy for product-safety assessment leading to the filing of an investigational new drug (IND) application to the US Food and Drug Administration (FDA).

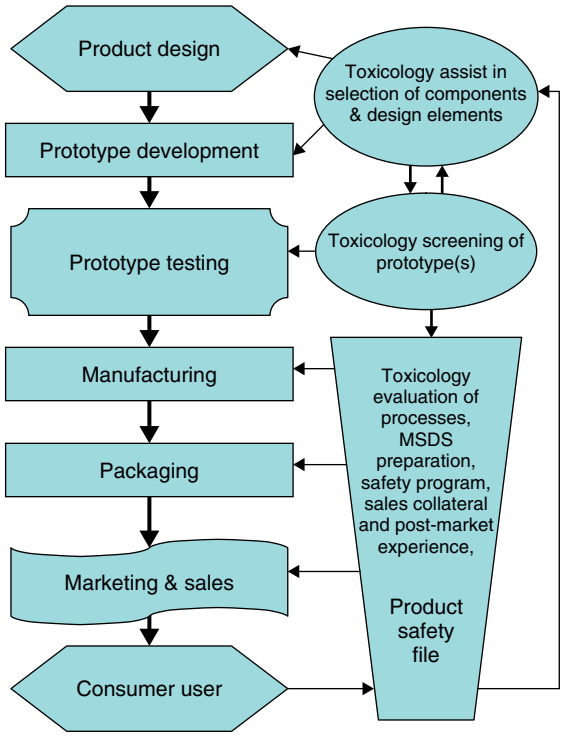

Figure 4 A strategy for toxicological involvement in product-safety assessment, monitoring and improvement that is not regulatory driven.

Whether formal and regulatory driven or business driven, the conduct of basic, unbiased, toxicological assessments of product safety with a high degree of consensus requires: (i) the involvement of a toxicologist with training, certification and experience to be competent to perform risk and product-safety assessments and (ii) the development and implementation of a sound product-safety programme that is focussed on quality and is supported at the highest levels of a company or organization that understands and expects integrity, quality and clarity in its product-safety assessments.

5 WHO SHOULD PERFORM PRODUCT-SAFETY EVALUATIONS?

As indicated above, training and certification of toxicologists to perform risk and product-safety assessments in a comprehensive and competent manner is an issue that gets the attention of experienced toxicologists, product developers and regulatory officials. Although chemistry, physiology, biochemistry, pathology and even pharmacology are disciplines integral to training in toxicology, a chemist is not necessarily a toxicologist, nor is a biochemist, pathologist, pharmacologist or pharmacist, unless they have had formal training in the subject adequate to the toxicologic issues they are attempting to address. Even though there are many academic programmes offering toxicology training, sometimes leading to a formal degree in toxicology, there are no commonly accepted requirements that a graduating toxicologist demonstrate competence in being able to complete a basic risk assessment and product-safety evaluation prior to successful graduation from these training programmes. This creates a situation where some training programmes are stronger than others with respect to this practical necessity of the commercial market for toxicologists. This has been a topic of discussion for some professional toxicology organizations such as the American College of Toxicology (*www.act.org*) and the Society of Toxicology (*www.toxicology.org*) that occasionally offer continuing education courses and workshops that attempt to address this need. Bodies that certify toxicologists by education, experience and examination, such as the American Board of Toxicology Inc. (*www.abtox.org*) make an effort to evaluate whether or not a practising toxicologist that is applying for certification demonstrate, by examination, that they have some degree of basic competence with toxicologic risk assessment and product-safety testing and evaluation. Thus, not all 'toxicologists' are created equal with respect to this practical and industr- important capability, which is why the internet, news media and forums not subject to peer review by competent and experienced toxicologists are so full of product-safety claims and concerns that have little or no basis in actual scientific fact. Therefore, at present, the best means of establishing that a toxicologist is competent to complete an acceptable risk assessment and product-safety evaluation appears to be a demonstrated history of doing so in a successful manner, combined with a degree in toxicology from an accredited institution of higher learning known for the quality of its toxicology training programme, and board certification from an internationally recognized certifying organization that requires demonstrating risk assessment and product-safety evaluation ability as one of the competencies that it evaluates as a requisite for certification.

Computational methods for evaluating toxicological information are commonly used today and are generally accepted as tools for making some types of predictions and as aids in experimental design (Lyons *et al*., 2008; Rabinowitz *et al*., 2008; Bruce *et al*., 2008; Clark *et al*., 2004; Blaauboer, 2003). However, computational methods are also used for toxicological risk assessment and it is generally understood by the toxicologists that use these methods that they have limitations with respect to the quantity and quality of useful data that are used to make risk predictions for given chemical substance or product formulation. These models have been found to be useful in the evaluation of environmental risk from complex mixtures, and may also

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be useful for making safety predictions for formulations of some complex products (e.g. nanoproducts) in the very near future (Liao *et al*., 2002; Ahlers *et al*., 2008) The development of these computational tools for use by experienced toxicologists who understand their limitations now appears to be entering a new phase in response to an increasing demand for rapid or 'instant' assessment of toxicologic risk for chemical substances by nontoxicologists for a variety of purposes, including queries regarding potentially safe levels of toxic substances in commerce or in the environment, as well as making predictions with respect to formulated products for public 'right-to-know' regulations and chemical registration (Worth *et al*., 2007; Grindon *et al*., 2008; Combes *et al*., 2008; Lilienblum *et al*., 2008). This use of computational toxicology and expert systems may prove useful in the protection of people, animals or the environment from potential harm, as well as aid nontoxicologists in the regulation of toxic substances and products that contain them. Chemists, engineers and lawmakers may find such systems valuable in making rapid, rudimentary determinations of potential risk for chemical substances that have been entered into computational databases due to the need for vigilance and concern. Some of these systems look up information in data tables and apply this information to conditions that are input by the user regarding the conditions of exposure, and others have as their basis for estimation the use of quantitative structure–activity relationships (QSARs) that attempt to relate chemicals or substances of interest on the basis of the chemical and/or molecular structural similarities or dissimilarities to known toxicants. While these systems may be useful for determining whether there is a potential concern sufficient to involve a toxicologist or not, such methodologies must be rigorously tested and validated before they are used to arrive at any risk assessment or product-safety evaluation that would be likely to be acceptable for establishing, with respect to current standards of practice, any sort of risk estimate adequate for product-safety evaluation. Nevertheless, it is conceivable that, in time, expert computational systems will emerge that can access more information more quickly than even the best toxicologist, and even compile and evaluate content substantially for use in performing preliminary risk assessments that, with appropriate involvement of an experienced toxicologist, could be used as the basis for product-safety evaluations in the future.

However, we are all aware that it is always the actual experience with the product in use over time that determines whether or not a product is truly safe for its intended use or not, so there is always a need for formal, ongoing vigilance practices with respect to continuous monitoring of the use history, with respect to ensuring the that the products we develop and use are safe.

6 APPLICATION OF TOXICOLOGY PRINCIPLES TO PRODUCT SAFETY

The foundation of a sound product-safety programme for products where toxicity is a potential concern always involves the collection of some sort of toxicologic data relevant to evaluation of the potential for adverse effects to occur under controlled experimental conditions that relate to anticipated use exposures and/or 'worst case' in-use (e.g. accidental) exposure. It is for this reason that the proper application of toxicology to product-safety evaluation requires a substantial knowledge of the applied and well-validated aspects of the discipline, including the proper selection and design of toxicologic evaluation programmes, as well as individual study design. This generally requires a reasonable understanding of any regulations and guidance that are applicable to the product type being evaluated. There are many sources of regulations and guidance internationally that provide the toxicologist with useful perspectives on toxicology programmes and study-design considerations, as well as quality, content and format requirements for the successful collection of toxicologic data and preparation of product-safety evaluations (US FDA, 1994; 1995; 1996; 1997; 2008; US EPA, 1998a; 1998b; 1998c; 1998d; OECD, 1981; 1992; 1995; 1998a; 1998b). There are also valuable published resources for the design of product-safety programmes, as well as the design of toxicologic studies to support product-safety evaluations (Gad, 1999; Derelanko and Hollinger, 2002; Ross, 2003). It is also important to acquire and have available computational capabilities sufficient to manage and analyze the data necessary to perform scientifically rational safety evaluations for the specific product types of interest, for the preparation of reports of product-safety findings and for archiving.

A current awareness of emerging techniques and new or changing regulations is also necessary to ensure that product-safety evaluations are conducted in accordance with toxicologic formats that meet or exceed the data content and quality required for the type of product being evaluated. There are many sources of regulations and guidance for the evaluation of different types of products. Some examples of different types of product categories and United States, European Union (EU) or other international agencies or bodies regulating and/or providing product-safety guidance for them, are shown in **Table 1**.

Navigating the data and study-design requirements to arrive at the completion of a toxicology testing portfolio that may be considered 'state of the art' for the evaluation of safety for a given product is not a trivial process. Without appropriate training and practical experience, it is not uncommon to have just enough knowledge to get started doing relatively straightforward, short-term toxicity studies, without adequate planning for repeat-dose studies, that are generally done using two

Table 1 Examples of various sources of product-safety regulatory requirements and/or guidelines for different types of products

Organization	Product responsibility	Purpose
US Food and Drug Administration (FDA)	Pharmaceuticals (human and animals), biologics, medical devices, food including food additives	Regulatory oversight for the United States. Provides guidance for safety evaluation by documentation or consultation. *http://www.fda.gov*
US Consumer Product Safety Commission (CPSC)	Consumer products of all types, except food, over the counter drugs, pesticides and so on	Regulatory oversight of consumer product safety. Guidance on product safety. *http://www.cpsc.gov*
US Environmental Protection Agency	Pesticides, environmental (air, water, soil) effects of all types of products mined, manufactured, waste and so on. Registration of chemicals under the Toxic Substances Control Act (TOSCA)	Regulatory oversight of pesticide products. Provides guidance for registration of pesticides and for environmental impact assessment. *http://www.epa.gov*
US Department of Transportation (DOT)	Packaging and labelling for transportation on US roadways, railways, waterways or airways.	Regulatory oversight of packaging and labelling of consumer products shipped in the USA *http://www.dot.gov*
Organization for Economic Cooperation and Development (OECD)	Serves member nations and convenes expert panels to develop recommendations and methods with member acceptance.	Produces standard toxicological testing methods for various endpoints and test materials.
European Chemicals Agency (ECHA)	European Union (EU) Agency responsible for administration of the REACH	Reference and repository of REACH information and records. Chemical regulation is by EU member states.
European Medicines Agency (EMEA)	European Union Agency responsible for administration of medicinal products (human and veterinary)	Scientific advice and assessments for medicinal products. Regulation is by EU member states.
European Food Safety Authority (EFSA)	European Union Agency responsible for risk assessment regarding food and feed safety.	EFSA produces scientific opinions and advice to provide a sound foundation for European policies and legislation. Regulation is by EU member states. *http://ww.efsa.eu.int*
European Environment Agency (EEA)	European Union Agency responsible for assessments and reports regarding environmental issues.	EEA Produces reports to support environmental policies and legislation. Regulation is by EU member states. *http://www.eea.europa.eu/*

different species. Experienced contract research organizations (CROs) sometimes make study-design errors that are even more likely when working with assumptions or incomplete or confused information from a sponsor that is pushing to get studies completed as quickly as possible. This practice often results in the sponsor jumping into costly and time-consuming studies that may not provide the data necessary for a reasonable determination of safety necessary to satisfy most regulatory bodies.

Effective and efficient product-safety evaluations begin at the product-design or product-formulation stage. By having the toxicologist evaluate the raw materials that are going to be used in formulating or manufacturing the product, as well as having input into the design and manufacturing process, product development can be adjusted in ways that are insignificant to the overall outcome, but can eliminate problems that might cause toxicologic problems when finished products are evaluated for safety. An example of this is the elimination of sources of latex or lanolin containing raw materials and elements of the manufacturing process that come into contact with the formulated product in the manufacture of dermatologic products. Other examples are the careful selection of preservatives, surfactants and other ingredients used in the manufacture of ophthalmic products and the prequalification of new cosmetic raw materials or new raw material sources for cosmetics using *in vitro* testing to help eliminate skin and ocular irritation.

Early-stage involvement by the toxicologist in the product development and manufacturing process can

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

also be of substantial value to the toxicologist in the design of a comprehensive product-safety plan for the new product. Having a complete understanding of the formulation essentials, as well as its manufacturing process allows the toxicologist to be more effective in making constructive and workable suggestions to help eliminate product-safety issues, should they arise. This knowledge is also valuable, should the toxicologist be called upon to provide expert testimony in cases involving frivolous claims of PL or negligence.

7 ESSENTIAL TOXICOLOGY CONSIDERATIONS FOR PRODUCT-SAFETY EVALUATIONS

Initiation of a successful product-safety evaluation requires some planning by the toxicologist. The process of developing a product-safety data portfolio that is adequate to cover potential hazards associated with the development, manufacture, sale and use of the product requires some forethought and design.

Beginning with a complete understanding of the product itself, as well as any exposures that may be toxicologically significant from development and throughout the product life cycle, a determination of the information needed to support safety assessments is made. Some of the informational needs can be obtained from interviews and literature information that is obtained and evaluated as a preliminary to determining what types of studies will be needed to complete the data required to prepare the evaluation. Some of these studies may be of a chemical or physical characterization nature and others will be toxicology studies. In some cases, environmental monitoring of the workplace and/or effluents and disposal sites may also be necessary.

Some basic informational considerations for effective product-safety evaluations that should be collected into a comprehensive product development file for each new product include the following.

7.1 Product Concept

A clear and concise product concept should be developed that answers essential questions for the toxicologist, such as how the product is going to be used, who will use the product and where the product will be used. Any constraints on the formulation or manufacturing process that are required for manufacturing or by the intended market should be provided (e.g. colour, no colour, fragrance, no fragrance, etc.). Any constraints on the safety-assessment process, such as the desire for the product to not be tested using animals, should also be included in the product concept.

7.2 Claims

A draft of the desired or anticipated use claims to include claims of efficacy and safety for pharmaceuticals, medical devices, cosmetics, food additives and so on, should be developed for the product with the toxicologist participating if possible. Pharmaceuticals and medical devices should also provide their desired therapeutic claims or indications, as well as list the type and nature of any active ingredients and their modes of action, if known.

7.3 Composition or Formulation

Formulated products should begin by listing any and all active ingredients, as well as all known formulation components and their amounts (preferably as percentage weight/weight values and Chemical Abstracts Service reference numbers (CAS number). If there are any known hazardous materials used in the manufacture or formulation of the product, MSDSs should be obtained and placed into the product information file. Similar considerations and information should be obtained for the composition of nonformulated products that also includes what is known about any components that might be released, off-gas or leach from the finished product.

7.4 Exposure

The type and nature of any human, animal, plant or environmental exposure to the product should be determined and listed in order of maximum likelihood of occurrence. If the product is a pharmaceutical, the anticipated product dose should be provided. If it is a cosmetic, the location and amount of intended application should be determined. Other manufactured products, including medical devices, should note the area of the body that is most likely to come into contact with the item and in what form the product might be when coming into contact with biological tissues (e.g. surface material, off-gassed chemicals or particulate emissions, liquid release or transfer, etc.). All potential routes of exposure should be considered and listed, if applicable, for each product.

7.5 Life cycle

Product life-cycle analysis is fast becoming a fixture in the development of products, especially products that wish to demonstrate themselves to minimally impact the environment, for example ‘green’ products. Sourcing and disposal of raw materials to avoid excess or waste entering the environment, as well as streamlining the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

manufacturing process to reduce waste, including the use of excess energy and methods for the final disposal of the used product, including any packaging, are all considerations that a toxicologist should be aware of and allowed to make contributions to.

7.6 Required Labelling and Warnings

Any regulatory requirements for labelling or product-safety warnings should be identified as well as the agencies, domestic and international, that will regulate the products. In most large companies this aspect of the product-development portfolio can be provided by the regulatory affairs section or departments. In some cases, this is the responsibility of the legal department. In smaller companies, this may be the responsibility of the toxicologist or some other department that has knowledge of product regulatory and labelling requirements.

7.7 Alternatives or Competing Products

Information regarding composition, claims, safe-use history and so on, should be collected and maintained on an ongoing basis in the product file. This is not for marketing purposes, but rather allows the toxicologist to consider the prior history of product use in the market and make any necessary or desirable changes or alterations in the emerging new product that improve product safety. This offers, not only a potential competitive claim, but it also takes advantage of 'lessons learned' to develop better products for everyone.

After collecting the initial information, the product-safety evaluation programme is designed and the required toxicology studies are identified and designed appropriately. Basic considerations for the design of product-safety studies are presented below.

8 STUDY DESIGNS FOR PRODUCT-SAFETY EVALUATION

Once the objectives and requirements of the product-safety evaluation are understood, the selection of appropriate toxicological studies and their design can commence. During this process, certain types of information are required, whether the toxicologist is going to conduct the studies in-house or work with a CRO. A practical means of initiating this sort of study planning is to prepare an outline of all the studies required for completion of the dataset needed for product-safety evaluation. Having this outline is helpful in determining what studies need to be completed sequentially and what studies can be performed within the same timeframe. The basic information necessary for the design of initial studies includes the following:

- Chemical composition of the test substance or material (test article)
- Physical characteristics of the test article
- Route, or routes, of administration or exposure to the test article
- Expected dose or exposure level, or range, to the test article
- Duration of administration or exposure to the test article
- How and where dose preparation is to be done
- Toxicological endpoints to be evaluated for safety
- The data quality requirements (GLP or non-GLP)
- Source for dose confirmation analysis
- Source for bioanalytical analysis
- Selection of an experienced study director, toxicologist and pathologist.

The route and duration of exposure combined with the overall objective of the product-safety evaluation studies is then used to establish what studies should be included in the product-safety data portfolio. The exposure duration is determined relative to the anticipated longest duration of exposure to the product that is expected in actual use. If the product exposure will be accidental then an acute or single-dose study at a very high dose level, using the anticipated exposure might be adequate. The exposure route should be that which will be used or encountered in actual administration or exposure to the product and may include other routes such as intravenous administration as necessary to maximize the systemic dose or to evaluate 'worst case' exposure conditions.

The order in which toxicological studies are performed to complete the portfolio is also important, and generally starts with short-duration or 'acute' studies and progresses to longer-duration or 'chronic' studies, as necessary. This is both practical and necessary because acute studies often provide information essential to the estimation of doses to be used in longer-term, repeat-dose studies, and they are also generally less expensive and allow the toxicologist and the company an opportunity to stop and re-evaluate further development of a product, should initial results indicate that is has undesirable toxicologic concerns. Studies typical of this initial phase of product-safety evaluation include the following:

- Mutagenicity: evaluates potential to cause genotoxic effects
- Skin corrosivity: evaluates the potential for direct contact to cause skin corrosion

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Primary dermal irritation: evaluates the potential for a single dose to cause skin irritation
- Primary ocular irritation: evaluates the potential for a single dose to cause eye irritation
- Dermal sensitization: evaluates the potential for delayed-contact hypersensitivity
- Phototoxicity: evaluates the potential for sunlight photoactivation to cause toxicity
- Photosensitization: evaluates the potential to cause photoactivated delayed-contact hypersensitivity.
- Lethality: determines the potential for a single dose to be lethal.

Not all of the studies above are required and the selection of the studies to be included depends on the route of exposure, prior information known about the test article and objectives of the safety-evaluation programme. For example, lethality studies may not be required if there is sufficient evidence that the test material has been tested previously or historically to the extent that there is essentially no need to conduct these studies. In some cases, structure–activity data may be used to estimate the potential for lethality sufficient to reduce or eliminate this requirement.

Acute studies with different routes may be necessary if more than one type of accidental exposure is possible and there is a need to evaluate different endpoints for each route. Typical routes used in acute study designs are oral, dermal, intravenous, subcutaneous, intraperitoneal, ocular and inhalation.

Following completion of acute studies, longer-duration studies can be designed and initiated as necessary. Longer-duration studies are needed for product-safety evaluation if exposure is expected to be repeated over the course of a period of time necessary to treat a disease condition, or if the product is only going be in contact with the body for some duration of time (i.e. treatment of a skin rash, short-duration pain, healing wounds, etc.). The common durations of these studies, as well as the general purposes for each duration is provided in **Table 2**. In these studies, doses are administered at intervals, or continuously, in such a manner that the route and frequency of exposure in actual use is simulated as closely as experimentally possible.

Special studies, such as reproductive outcome, multigenerational, teratological, behavioural and so on, may be required if the potentially exposed population has special considerations, such as being of reproductive age, or if the product has characteristics that indicate the need to evaluate special endpoints (behavioural toxicity, renal toxicity, neurotoxicity, immunotoxicity, etc.).

9 SCHEDULING AND PLACEMENT OF TOXICOLOGY STUDIES

Planning and networking are keys to successful scheduling, placement and completion of toxicology studies in a timely and cost-effective manner. Since a product-safety evaluation for a new product will likely require that at least a few studies be conducted with the product, some whose design requirements are dependent on the outcome of others, it is obvious that the order of completion can be important. The longest-duration studies do need to get started as soon as possible, but not before preliminary studies that yield essential information regarding critical design parameters are completed. For example, toxicokinetic information essential for determining the dose levels and dosing intervals may be necessary before designing longer-term

Table 2 Durations and general purposes of repeat dose or continuous exposure toxicology studies

Study objectives	2 wk	4 wk	13 wk	'Lifetime chronic'
Establish dose levels or exposures for longer studies	X	X	X	—
Evaluate organ toxicity	X	X	X	—
Identify highly toxic test articles doses or exposures	X	X	X	—

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

studies to ensure that high dose levels are at a tolerance level acceptable to support the study requirements. Studies that are independent of the outcome of others may be completed whenever it is desirable within the programme to do so, as long as they are completed and reported well before completion of the longest-duration study that will be required.

Often the scheduling and placement of toxicology studies is driven by budgetary constraints, as well as time-to-market concerns. While these factors should always be a consideration, quality in the performance of the study and preparation of the study report can outweigh concerns related to financial performance when it comes to studies that are critical for the establishment of product safety. Therefore it is essential that the toxicologist concerned with documentation of product safety carefully select sources with proven performance records in completion of studies on time, with the highest standards of data and report quality.

A toxicologist experienced in product-safety testing is valuable in all aspects of the safety-evaluation process. However, virtually anyone can begin contracting for product-safety studies with some testing facilities. This approach may work satisfactorily for tests with simple, straightforward designs that require little in the way of data interpretation, but it doesn't take much deviation from the expected state of affairs, with respect to test outcomes, to get the novice into trouble. Further testing, if done without experience, can simply create more problems of interpretation and indeed confound the product data set to the point that, as one attorney who attempted this once said, 'this product is beginning to smell', indicating that the safety-data package was in such poor shape that the product (which actually was quite safe) had safety portfolio issues that could be legally challenging under certain circumstances. Product-safety portfolios must be objective, coherent and as comprehensive as possible. They must be up to date with current regulatory requirements, as well as test methods, without creating conflicting findings due to poor study design or management. This is why corporate regulatory affairs professionals and toxicologists will often engage the services of an experienced consulting toxicologist to provide advice and assistance with product-safety programme design and the conduct of safety testing, particularly with products of extreme importance to the company. Here are some reasons why a consulting toxicologist can add significant value to a product-safety evaluation programme:

- Experience with all phases of the product-safety evaluation process, including insurance and litigation, in some cases, that is of value in designing and establishing appropriate testing strategies to ensure safe products for current and future markets.
- Contacts and experience working with many more CROs and the ability to select sources for testing, based on current knowledge that often allows rapid identification of the study locations based on appropriate experience, timing and pricing.
- Experience working with regulatory agencies and up-to-date knowledge of critical regulations.
- Broad product experience across several companies and markets.
- Experience in the preparation of study protocols with many different CROs.

10 THE PRODUCT-SAFETY FILE

All products placed into a marketplace where exposure to humans, animals or the environment is possible, should have some sort of product-safety file. Pharmaceutical and medical device product-safety files are typically quite comprehensive and contain much of the information mentioned above for the product-development file, plus all information collected from the published literature, as well as all study data and reports of product testing that relate in any fashion to the safety and efficacy of the product.

Product-safety files are often opened and maintained by the research and development department, initially, and then are turned over to the regulatory-affairs department upon completion of a new drug or medical device. In other industries, this file can be maintained by a safety, engineering or legal department, or the concern that has been designated to respond to any inquiries regarding product safety.

Having product-safety information readily available and properly summarized is necessary to answer any regulatory inquiries for highly regulated products such as pharmaceuticals, medical devices (which also require a comprehensive design history to be included) and pesticides. This is also extremely valuable in other industries for working most cost-effectively with insurers, responding to product-safety inquiries, concerns, claims or litigation. It should not come as any surprise what can happen to companies not having the ability to rapidly demonstrate an appropriate amount of concern for product safety with products in markets where there is a reasonable possibility of human, animal or environmental exposure.

A product-safety file should contain data sufficient to support a reasonable, up-to-date risk assessment for the intended use of the product, as well as a product-safety assessment if the product is to have significant contact with humans, animals or the environment at any stage of its life cycle, and data on the market history of the product, to include any and all complaints and their

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

responses that have any bearing whatsoever on product safety.

Product-safety files should be reviewed regularly (e.g. annually) for any update needs, including product-safety testing and should be maintained actively throughout the market life of the product and then archived for the life of the company.

11 INDUSTRY AND PRODUCT-SPECIFIC SAFETY-EVALUATION ISSUES

11.1 Bulk Chemicals and Raw Materials

The chemical industry includes a wide variety of concerns and is generally concerned with product safety, from raw-material mining through to finished goods production, use and disposal. Worldwide, this industry is regulated heavily in developed countries, with registration requirements under programmes such as the Toxic Substances Control Act (TOSCA), requirement for chemical registration in the US and the EUs new regulation concerning the registration, evaluation, authorization and restriction of chemicals (REACH). Product-safety evaluations that include toxicological testing requirements for registration, inclusion in MSDS documents, environmental-impact assessment and life-cycle analysis are all areas of potential toxicological issues that may arise. At present, the need to perform safety testing using a variety of new methodologies developed for use with REACH is an issue of note for chemical companies doing business in the EU (Combes *et al*., 2008; Ahlers *et al*., 2008). The European Chemicals Agency (ECHA), in Helsinki, Finland is responsible for administration of the REACH program. The ECHA began taking applications for REACH chemicals on 1 June 2008. REACH requires manufacturers and importers to generate data on the substances they manufacture or import, to use these data to assess the risks related to these substances and to develop and recommend appropriate risk-management measures. REACH registration provisions require the submission of a 'registration dossier' containing information in accordance with the guidance provisions of the regulation (e.g. Article 10). More information regarding the registration process and guidance on REACH requirements can be found at the ECHA web site (*http://echa.europa.eu/reachen.asp*). The REACH paradigm attempts to move away from extensive standard testing to a more intelligent, substance-tailored approach (see **Regulatory Toxicology**; **Risk Assessment of Chemicals**).

11.2 Nanomaterials

Nanotechnology is an emerging science involving manipulation of matter at the nanometre scale. Nanomaterials have characteristic morphological features smaller than a one tenth of a micrometre in at least one dimension Engineered nanomaterials, nanoparticles are 'nanoproducts' that represent emerging new segments of the chemical and manufactured products industries, that are gaining support and are increasing in usage internationally in a relatively quiet fashion, despite various concerns from some toxicologists and other scientists and engineers that their safety is relatively unknown and that use of these materials should be slowed or even stopped until safety assessments can be performed. The issue for these materials and products is that scientists, as well as regulatory agencies, are not decided on what sort of testing is of value and should be required despite the availability of proceedings from many meetings and conferences over the past several years that have considered this problem and made many recommendations. The problem seems to be that there is indifference to safety testing in some industries that are essentially self-regulated, whereas in highly regulated industries, nanoproducts have already been or are already being evaluated for safety on a case-by-case basis, which seems the most rational and prudent course to take, at least until there is sufficient data available to indicate otherwise.

It has been established in many toxicologic studies that nanomaterials behave differently to larger particles or chemical substances. Therefore, due to handling and dose-preparation issues alone, it is necessary to develop specialized approaches to testing and monitoring their effects on human and animal health and on the environment (Stern and McNeil, 2008).

Due to concerns over nanomaterial risks, there has been an increase in safety research with nanomaterials of various types. The toxicology community is currently working to identify areas of agreement and discordance with regard to: (i) the potential for nanomaterial exposure, (ii) the relative hazard nanomaterials pose to humans and the environment and (iii) the present deficits in our understanding of risk. Nevertheless, product-safety studies have been performed with nanomaterials, and nanoparticulate pharmaceutical forms have been approved and currently have a safe-use history in their respective markets. In designing product-safety evaluations involving nanomaterials or nanoparticles, special attention must be paid to study design and methodologies. The particle size, surface area, shape, surface charge, chemical composition and aggregation state are variables that can impact the outcomes of some toxicologic tests. These are practical complexities encountered with nanomaterial safety assessment atypical of other product forms. Recent data demonstrate the impact of surface characteristics on nanomaterial biocompatibility and point to the inadequacy of the current

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

size-dependent mechanistic paradigms, with nanoscale materials lacking unique or characteristic toxicity profiles (Stern and McNeil, 2008).

The lung, gastrointestinal tract and skin appear to act as significant barriers to the systemic exposure of many nanomaterials and the acute systemic toxicity of many nanomaterials appears to be low. In contrast, the potential pulmonary toxicity of certain nanomaterials (e.g. carbon nanotubes) appears to be of greater concern, and more comprehensive studies are needed to adequately support risk assessment. Many scientists, including some toxicologists, feel that nanomaterial safety data are limited substantially, to the point that until such time as exposures, hazards and the environmental life cycles of nanomaterials have been more clearly defined, cautious development and implementation of nanotechnology is the best course.

The Organization for Economic Cooperation and Development (OECD) Chemicals Committee has established the Working Party on Manufactured Nanomaterials to address this issue and to study the practices of OECD member countries with regards to nanomaterial safety. OECD is currently developing methods for the testing of nanomaterials for the purpose of safety evaluation and has initiated the evaluation of safety for a few of the more common nanomaterials.

Nanomaterials and nanotechnologies are expected to yield important health and healthcare advances, such as more targeted methods of delivering drugs, new cancer therapies and methods of early detection of diseases. Engineered or manufactured nanoparticles have increased surface-area-to-volume ratios and their greater specific surface area (surface area per unit weight) is thought to potentially lead to increased rates of absorption through the skin, lungs or digestive tract; however, the main problem with nanoparticles may actually be recognition by the immune system, which may cause some unwanted localized effects, whether substantially absorbed or not.

There is concern over the use of engineered nanomaterials in food products to enhance aesthetic characteristics, improve nutritional content or reduce caloric levels. In September 2008, the US FDA convened hearings to begin to address concerns regarding the regulation of nanotechnology products in food, drugs and cosmetics. This is an emerging area of toxicologic safety assessment that will, most likely, result in a number of new regulatory guidance documents that could have some impact on the way safety-assessment studies are designed and conducted with nanomaterials (see **Nanotoxicology-The Toxicology of Nanomaterials**).

11.3 Alternative Energy Products and Fuels

There is an increasing interest in the USA and EU in the development and use of alternative fuels for use primarily in transportation, heating and power stations. Safety evaluations of alternative fuels and their associated manufacturing, use and life-cycle properties are the responsibility of the US Department of Energy (DOE) in the USA. The DOE has been evaluating the safety of a flexible-fuel transportation system in the USA since 1991 that could easily switch between petroleum and another fuel, depending on price and availability. Safety evaluations for some fuels such as gasohol have been reported (US DOE, 1991).

11.4 Pesticides

Except for antimicrobial agents intended for use as disinfectants in medicine, the US EPA is responsible for the oversight of pesticide registration and use in the USA. This includes fungicides, insecticides and rodenticides, under the Federal Insecticide, Fungicide and Rodenticide Act, which was first passed in 1947 and then underwent a major revision in 1972. The EPA has different review processes for three categories of pesticides: antimicrobials, biopesticides and conventional pesticides. The three categories have a similar application process, but have different data requirements and review policies. Depending on the category of pesticide, the review process can take several years. The application of nanotechnology to the formulation of pesticides is one of the most significant emerging issues for the EPA, which recently issued a white paper stating its current position on how it intends to establish risk and conduct safety assessments for these emerging products (US EPA, 2007).

11.5 Toxic Toys

Safety evaluation of toys and other consumer products that might pose a significant toxicologic risk is the responsibility of the Consumer Product Safety Commission (CPSC) via the Federal Hazardous Substances Act (FHSA). The FHSA requires precautionary labelling on the immediate container of hazardous household products to help consumers safely store and use those products and to give them information about immediate first aid steps to take if an accident happens. The act also allows the CPSC to ban certain products that are so dangerous or the nature of the hazard is such that the labelling the act requires is not adequate to protect consumers. An example of how the CPSC acts occurred in late 2007, when China confirmed US findings that exports of toys were contaminated with a toxic chemical. US safety officials voluntarily recalled about 4.2 million of these Chinese-made toys. In late 2007, a highly popular toy was found to contain a butylene glycol adhesive solvent that, once metabolized, converts into the toxic 'date rape' drug γ-hydroxy butyrate (GHB).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The CPSC warned that children who swallow the beads can become comatose, develop respiratory depression or have seizures. This incident serves as an example of the product alerts that the CPSC issues each year. Obviously, it is the responsibility of the manufacturer and distributor to ensure product safety. A careful review of the raw materials and manufacturing process (including solvents used) by an experienced toxicologist might have eliminated the problem in favour of an alternate, less toxic, solvent system. Based on a significant number of recent product alerts in the US regarding potential toxicity from exposures to imported products from certain countries, it would seem prudent for importing companies to perform product-safety evaluations to include toxicity hazard assessment for these products prior to export, if possible.

11.6 Pharmaceuticals

Pharmaceutical products are of note as a basic toxicologic issue for product safety because they are subject to continuous scrutiny and monitoring for safety by the pharmaceutical companies, the FDA, international pharmaceutical regulatory agencies and clinicians using them. In some cases, a pharmaceutical with a tainted safety record may attract the attention of the legal profession. In any case, toxicologists engaged in the development of pharmaceutical products must realize this and be continuously vigilant with respect to any potential for a product-safety concern through all aspects of development, for the pharmaceuticals for which they are responsible. This vigilance extends beyond product launch and includes monitoring for any reports of adverse effects (especially for patterns of effects that may indicate toxicity beyond what was known at NDA (US FDA New Drug Application) submission). Toxicologists should review any manufacturing changes, including site changes that may introduce a component or contaminant that was not evaluated in studies submitted for registration and perform any required additional evaluation or testing as necessary to ensure that the product remains safe for its intended use (see **Toxicological Considerations for Pharmaceutical Products**).

11.7 Medical Devices

Some 'medical devices' consist entirely of a chemical formulation that is intended to produce its desired effect by purely physical means, with little or no substantial absorption and biochemical interaction with the patient. Toxicologists need to be aware of this because product safety is usually determined by evaluating the nature and extent of systemic and local exposure to the device or its constituent chemicals by methods that often require some degree of oversight and data review. 'Combination' medical devices are devices designed to deliver a drug substance in some controlled and/or special fashion. These so-called 'drug-device' combinations are typically evaluated for safety on the basis of: (i) the nature of the effects of the device itself on the systemic and/or local areas that it is in contact with or may affect by direct physical contact or physical emanation, such as electrical, heat, light, sound and so on, and; (ii) the amount and quality of the dose of drug released by the device to the patient. The design and interpretation of safety-assessment studies with such combination devices can be challenging and create issues beyond those encountered for drug substances or medical devices alone. An example of such a device is a 'microneedle' transdermal drug-delivery system. These systems are exciting new collaborations merging engineering with pharmaceutical technology. By painlessly punching arrays of microscopic holes in the stratum corneum, microneedles appear to have the potential to expand the range of drugs and vaccines that can be delivered transdermally (Bal *et al*., 2008; Coulman *et al*., 2008; Donnelly *et al*., 2009; Vandervoort and Ludwig, 2008). Microneedles alone can cause differential effects in the skin due to design factors such as needle length and construction. Safety evaluation for this type of device must necessarily focus on both the effects of the physical damage and the drug being delivered, such that all questions regarding potential risks from the use of this device are investigated appropriately in preclinical studies are addressed in the product-safety evaluation (see **Toxicological Considerations in Relation to the Regulatory Safety Evaluation of Medical Devices**).

11.8 Food Products

Toxicologists must be involved in the evaluation of product safety for food additives. Involvement in the safety review and submission of food-additive petitions to ensure the safety of food products is the responsibility of experienced toxicologists working for the food industry. US FDA regulations require the 'views of experts qualified by scientific training and experience to evaluate the safety of substances directly or indirectly added to food'. For example, the US FDA makes formal determinations of 'generally recognized as safe' (GRAS) food ingredients according to the following provisions of Section 170 of Title 21 of the US Code of Federal Regulations.

> *Sec. 170.30 Eligibility for classification as generally recognized as safe (GRAS).*
> *(a) General recognition of safety may be based only on the views of experts qualified by scientific training and experience to evaluate the safety of substances directly or indirectly added to food. The basis of such views may be either (1) scientific procedures or (2) in*

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the case of a substance used in food prior to January 1, 1958, through experience based on common use in food. General recognition of safety requires common knowledge about the substance throughout the scientific community knowledgeable about the safety of substances directly or indirectly added to food.
(b) General recognition of safety based upon scientific procedures shall require the same quantity and quality of scientific evidence as is required to obtain approval of a food additive regulation for the ingredient. General recognition of safety through scientific procedures shall ordinarily be based upon published studies which may be corroborated by unpublished studies and other data and information.
(c) (1) General recognition of safety through experience based on common use in food prior to January 1, 1958, may be determined without the quantity or quality of scientific procedures required for approval of a food additive regulation. General recognition of safety through experience based on common use in food prior to January 1, 1958, shall be based solely on food use of the substance prior to January 1, 1958, and shall ordinarily be based upon generally available data and information. An ingredient not in common use in food prior to January 1, 1958, may achieve general recognition of safety only through scientific procedures.
(2) A substance used in food prior to January 1, 1958, may be generally recognized as safe through experience based on its common use in food when that use occurred exclusively or primarily outside of the United States if the information about the experience establishes that the use of the substance is safe within the meaning of the act (see Sec. 170.3(i)). Common use in food prior to January 1, 1958, that occurred outside of the United States shall be documented by published or other information and shall be corroborated by information from a second, independent source that confirms the history and circumstances of use of the substance. The information used to document and to corroborate the history and circumstances of use of the substance must be generally available; that is, it must be widely available in the country in which the history of use has occurred and readily available to interested qualified experts in this country. Persons claiming GRAS status for a substance based on its common use in food outside of the United States should obtain FDA concurrence that the use of the substance is GRAS.

The introduction of nanotechnology-derived materials into foods is an emerging product-safety assessment issue for food toxicologists that presents challenges in dose preparation and the design of toxicology studies, as well as the selection of appropriate methods to evaluate the distribution and metabolism. This was the topic of a public meeting held in September 2008 by the US FDA, seeking information and input for consideration of the need to provide guidance to industry for use of nanomaterials in food products (US FDA, 2007).

The US EPA has also recently issued a position paper on nanotechnology products. (US EPA, 2007).

11.9 Dietary Supplements

Many people regularly take some type of dietary supplement, and there is some evidence that these vitamins and minerals and other products could offer significant health benefits. In the USA, the Dietary Supplement Health and Education Act (DSHEA) of 1994 amended the Federal Food, Drug and Cosmetic (FD&C) Act to establish a regulatory framework for these products. DSHEA is intended to balance between providing consumers access to safe dietary supplements they choose to improve their health, and giving the FDA, or the Agency, regulatory authority to take action against supplements and supplement ingredients that present safety problems, have false or misleading claims, or are otherwise adulterated or misbranded. DSHEA establishes special requirements for dietary supplements that differ in some respects from those covering 'conventional' foods. DSHEA defines the term 'dietary supplement' as a product that is intended for ingestion, is intended to supplement the diet, is labelled as a dietary supplement, is not represented as a conventional food or as a sole item of a meal or diet, and contains one or more 'dietary ingredients'. 'Dietary ingredients' are defined as vitamins, minerals, amino acids, herbs or other botanicals, dietary substances (such as enzymes) and concentrates, metabolites, constituents, extracts or combinations of the preceding types of ingredients. Dietary supplements may be found in many forms, such as tablets, capsules, powder, liquids or bars. The need to evaluate the safety of dietary supplement products is thus an issue for toxicologists because these items, while not being closely regulated by the FDA, nevertheless have a regulatory authority to act if product-safety concerns become an issue.

There is no requirement for manufacturers of most dietary supplements to provide evidence of product safety to the FDA prior to marketing. The FDA regulates the safety of dietary supplements primarily through a postmarket evaluation of whether the product is adulterated under one of the provisions of the FD&C Act. The burden of proving lack of safety rests with the Federal Government. There is a 75-day premarket notification requirement for dietary supplements that contain certain dietary ingredients that were not marketed in the United States before 15 October 1994, or 'new dietary ingredients'. The manufacturer or distributor of a supplement that contains one or more new dietary

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

ingredients must submit a premarket notification to the FDA, unless all new dietary ingredients in the product have been present without chemical alteration in the food supplement as articles used for food. In this notification, the manufacturer or distributor of the supplement must submit information, including citations to published scientific articles that form the basis for the firm's conclusion that the dietary supplement containing the new dietary ingredient will reasonably be expected to be safe. This information is best prepared and submitted with the conclusions of a trained and experienced toxicologist. The supplement will be deemed adulterated by the FDA, unless there is a history of use or other evidence of safety establishing that the new dietary ingredient will reasonably be expected to be safe when used as recommended or suggested in the labelling.

11.10 Cosmetics

Cosmetics, like dietary supplements, are not actively regulated by the FDA like pharmaceuticals or medical devices (except sunscreens, which are typically regulated by the FDA as over-the-counter (OTC) products). The FDA, however, may act to remove a cosmetic product from the market, if the agency has sufficient evidence to show that the product is unsafe. Therefore, it is incumbent on cosmetic companies to evaluate their products for safety prior to market and to monitor the consumer experience with the products in such a manner that any adverse effects are noted and potentially harmful products are reformulated or are removed from the market. Since cosmetics also don't require premarket approval, a basic toxicologic issue for product-safety evaluation with this class of products is what form, if any, should toxicology testing take? Cosmetic ingredients are reviewed for safety by the Cosmetic Ingredient Review (CIR) panel of expert toxicologists, and their reviews are regularly published in the International Journal of Toxicology on an annual basis. Since many cosmetic consumers and consumer groups don't feel that cosmetics should be tested using animals, the evaluation of cosmetics for safety has been at the forefront of attempting to identify alternative tests that are usually conducted using *in vitro* procedures. Historical data from studies performed with animals on cosmetic ingredients can be used in the safety assessment process, even though no animals are used in testing the formulated product. Toxicologists involved in safety assessments for cosmetic products are generally aware that the initial *in vivo* experience with the product will most likely be human exposure in an exposure study involving human subjects, or in premarket tests with small numbers of consumers and monitor for any indication of an adverse reaction to the new product (see **Dermal Toxicology of Cosmetics and Body-Care Products**).

12 CURRENT TOXICOLOGY ISSUES FOR PRODUCT-SAFETY EVALUATION

12.1 Changing Markets with Expanding International Participation

Products that require safety testing to protect workers, consumers and the environment are developed in an expanding international marketplace. Product-safety testing has been expanding internationally to include new operations in China and India, as well as the many established operations in the USA, EU and Japan. Similarly, product-safety evaluations are becoming necessary to meet the requirements of registration programmes that are growing worldwide. The acceptance and success of many products, as well as their sustainability in many markets (foods, drugs, cosmetics, nutritional supplements, toys, etc.) is becoming as dependent on product safety as it is performance.

12.2 New Materials and Methods of Manufacturing or Formulation

New materials for use in the fabrication and manufacturing of new products are increasing the need for evaluations of materials as well as product safety. Nanomaterials are currently the best example of new materials that have raised much concern over the need for re-evaluation of product-safety evaluations to ensure that they meet the needs for determining the safety of emerging products that contain nanomaterials. Much thought has been given to the need for the testing of new nanomaterials for safety, and as a result there have been many recommendations as to approaches that might be taken (NIST, 2008; NIOSH, 2006; European Commission, 2008). Regulatory agencies may eventually make some recommendations and provide guidance on the safety evaluation of products that contain nanomaterials, however, in actuality, the necessity for testing these materials is new and companies, as well as their insurers and consumers are required to perform product-safety evaluations as a matter of 'best practise' in a world that requires knowledge of product safety as a prerequisite to market acceptance and product sustainability.

12.3 Consumer 'Right-to-Know' Regulations

In some parts of the world, there is consumer interest in having product labelling regulations that include affixing product labelling informing consumers of ingredients

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

or components that have individually shown to have significant adverse effects (carcinogenicity, reproductive effects, teratogenicity, etc.). California Proposition 65 is one such regulation (State of California, 1986). Toxicologists involved in product-safety testing of products that will be marketed in these regions need to be aware of their requirements and perform product-safety evaluations that are capable of detecting any potential for adverse effects of concern.

12.4 New Methods for Safety Evaluation

There is increasing interest in the use of computational, QSAR and *in vitro* methods for use in product-safety evaluation, as the recent literature and adoption of some of these techniques for routine use bears out (Benfenati, 2007; Bruce *et al*., 2008). These methods have the attraction of being less costly and time consuming than traditional testing procedures, while reducing animal requirements. However, in order for a new method to be accepted by toxicologists as a complete replacement, these new 'alternative' methods have to be rigorously validated against those traditional methods they seek to replace. Whether or not an emerging new method is capable of complete replacement of a traditional method at times may not be the issue, if the new method can be used as a first tier test to screen out and reduce potentially unsafe materials or formulations from a larger number of alternatives that may then be tested using more costly traditional methods.

The Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) is comprised of representatives from 15 US Federal regulatory and research agencies that use, generate, or disseminate toxicological information. ICCVAM promotes the scientific validation and regulatory acceptance of toxicological test methods that more accurately assess the safety or hazards of chemicals and products and that reduce, refine (decrease or eliminate pain and distress) and/or replace animal use. The activities of ICCVAM are well worth monitoring for any developments in toxicologic testing alternatives of value for product-safety assessments (*http://iccvam.niehs.nih.gov/*).

In October 2007, ICCVAM forwarded recommendations on two *in vitro* test methods to identify ocular corrosives or severe irritants to Federal agencies for their consideration of regulatory acceptance as required by the ICCVAM Authorization Act of 2000 (42 USC. 285 l-3). These are the first alternative nonanimal test methods for ocular safety testing reviewed by ICCVAM and transmitted to agencies. ICCVAM recommended that the bovine corneal opacity and permeability (BCOP) test method and the isolated chicken eye (ICE) test method be used in a tiered testing strategy to determine ocular hazards, with specific limitations for certain chemical classes and/or physical properties. Substances that test positive in these assays can be classified as ocular corrosives or severe irritants without further testing in animals. The report also recommends that these *in vitro* test methods should be considered before using animals for ocular testing and used when determined appropriate. These recommendations, which have been accepted by Federal agencies, will result in a reduction of the number of animals used for safety testing to determine permanent or temporary damage to the eye. ICCVAM estimates that the use of these two alternative test methods will likely reduce the use of live animals for eye safety testing by 10% or more and that the use of these tests will eliminate eye safety testing in animals of most substances likely to cause the most severe pain and discomfort.

On 28 February 2008, ICCVAM forwarded recommendations on the use of *in vitro* test methods for estimating starting doses for acute oral systemic toxicity tests. ICCVAM recommended that the *in vitro* basal cytotoxicity test methods tested in the joint ICCVAM/ECVAM (European Centre for the Validation of Alternative Methods) validation study should be considered before using animals for acute oral toxicity testing, and that the methods should be used where determined appropriate. Two cytotoxicity test methods were recommended, the BALB/c 3T3 NRU method and the NHK NRU method. Details for the conduct and validation of each method can be found in a report issued by the National Institutes of Health (2006). ICCVAM recommends that data from the test methods should be used in a weight-of-evidence approach for determining starting doses for *in vivo* studies. Using these *in vitro* methods, where appropriate, is expected to reduce the number of animals required for each toxicity test. ICCVAM concluded that the *in vitro* test methods are not sufficiently accurate to replace animals for regulatory hazard classification purposes (see **Alternatives to In vivo Studies in Toxicology**).

12.4.1 Local Lymph Node Assay

The murine local lymph node assay (LLNA) is a method for assessing the potential of a test substance to induce allergic contact dermatitis. In January 2007, the US CPSC requested that the National Toxicology Program Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM) and ICCVAM assess the validation status of: (i) the LLNA as a stand-alone assay for potency determination for classification purposes; (ii) modified LLNA protocols; (iii) the LLNA limit test; (iv) the use of LLNA to test mixtures, aqueous solutions and metals and (v) the applicability domain for LLNA. In response to comments received, ICCVAM endorsed these activities as high priorities. NICEATM and ICCVAM prepared drafts for each topic, which were peer-reviewed in a public meeting in March 2008. The

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

peer-review panel's initial LLNA report is now available on the ICCVAM website (*http://iccvam.niehs.nih.gov/*) and another panel meeting to review additional uses of the LLNA is scheduled for April 28–29, 2009, to evaluate three nonradioactive modified versions and new applications for the murine LLNA. Updates and final reporting of this activity and all LLNA-related documentation may be found at the ICCVAM website by searching for the keyword 'LLNA'. The ICCVAM has been receptive to receiving alternative methods for consideration and further evaluation as warranted. Alternative methods for dermal corrosion testing, as well as proposed methods for endocrine disrupter and teratogenesis are currently under consideration.

In the EU, the REACH program has established as its goal for its Optimized Strategies for Risk Assessment of Industrial Chemicals through Integration of Non-Test and Test Information (OSIRIS) project to develop integrated testing strategies (ITS) fit for REACH that enable the programme to significantly increase the use of nontesting information for regulatory decision-making, and thus to minimize the need for animal testing (reducing costs and time) without sacrificing accuracy, validity and reliability of the results. In this programme, operational procedures are developed, tested and disseminated that guide a transparent and scientifically sound evaluation of chemical substances in a risk-driven, context-specific and substance-tailored manner.

OSIRIS periodically conducts workshops to provide overviews of the preliminary results of OSIRIS and its contributions to the REACH characterization and risk-assessment process. These workshops involve experts from industry, academia and government that present the available testing methods and explain how they can be used in REACH. These workshops also allow for an open scientific discussion on the pros and cons of the approaches taken by REACH.

Under the OSIRIS program, a decision-theory framework is envisaged, including alternative methods, such as chemical and biological read-across, *in vitro* results, *in vivo* information on analogues, qualitative and quantitative SAR, thresholds of toxicological concern and exposure-based waiving. OSIRIS also allows for cost-benefit analyses, and it recognizes the gap between risk and societal risk perception.

12.5 Computational Risk-Assessment Modelling

There has long been an interest in using computational tools and toxicology-oriented databases to predict potential safety issues for various materials and products (Holmes, 1976; Jaworska *et al*., 2005; Cronin *et al*., 2003; Patlewicz *et al*., 2008). Initially, the power and speed, as well as the data storage and archiving capabilities of computational systems created practical limitations; however, this is no longer a significant issue and there is more interest in these methods than ever. The purposes of these efforts has been varied, but most often includes a desire to reduce animal requirements, reduce the cost of toxicologic testing, screen raw materials more rapidly and to shorten the time required to complete product-safety risk assessments. A recent project, OSIRIS has as its goal to develop ITS fit for REACH that enable a significant increase in the use of nontesting information for regulatory decision-making, and thus to minimize the need for animal testing. To this end, operational procedures are developed, tested and disseminated that guide a transparent and scientifically sound evaluation of chemical substances in a risk-driven, context-specific and substance-tailored manner.

OSIRIS takes into account cost–benefit analyses, and it aims to close the gap between risk and societal risk perception. It is based on the new REACH paradigm to move away from extensive standard testing to a more intelligent, substance-tailored approach.

Europe's REACH regulations have become the subject of much debate among toxicologists, as well as industry officials. A general consensus has emerged that full implementation of REACH would require testing of around 30 000 existing substances, cost more than 2 billion Euros and could require the use of 10–22 million test animals, if no alternatives to animal testing were available. Simultaneously with the implementation of REACH, the EU desires to develop a policy of replacing, reducing, and refining (the 3 Rs) the use of animals in safety tests. QSARs, have emerged as a valuable means by which to determine and express mathematical relationships between the biological activity of a series of chemical compounds and their physicochemical properties. Until recently, QSARs were unlikely to be acceptable in a regulatory context for a number of reasons. QSARs were developed for a narrow range of closely related molecules, and were unlikely to be relevant for the wide diversity of chemicals falling under REACH. Also, QSARs were generally not developed for toxicological endpoints required under REACH. Furthermore, for all QSARs, validation is not a trivial problem. Despite considerable knowledge of computational methods, recent toxicology graduates may lack the experience with animal models to develop and validate QSARs. So the best approach requires a team of scientists to develop the models and then validation by comprehensive review from an independent team or multiple teams. This process takes time, despite the attractiveness of QSARs, and sometimes results in translational problems between *in vivo* experimental results and *in silico* QSAR assumptions or constraints. However, due to the substantial increases in computational power in recent years, coupled with the availability of good-quality toxicological datasets, the construction of comprehensive

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

QSARs is much more amenable and, with the use of extensive data mining and machine learning capabilities, the possibilities for developing QSARs that can operate using more heterogeneous data sets is improving.

The OECD has recently developed comprehensive guidance on what is considered acceptable for a QSAR to be used in a regulatory context with regard to validation requirements (OECD, 2008). To be useful for regulatory purposes, the OECD guidelines suggest that QSARs should have:

1. A defined endpoint; the QSAR must relate to a toxicological parameter used in REACH as an indicator of safety.
2. An unambiguous algorithm; the model must have been generated by a specific definable and repeatable mathematical process.
3. A defined domain of applicability; types of chemicals for which the model is valid must be stated.
4. Appropriate measures of goodness-of-fit, robustness and predictability; in addition to statistical tests for validation, it is now required that an external test set be applied and the resulting accuracy of prediction specified.
5. A mechanistic interpretation, if possible; an understanding of how the model works at the biological level is useful in establishing its validity.

Computer-Assisted Evaluation of Industrial Chemical Substances According to Regulations (CAESAR) is a current project to develop robust, validated QSARs specifically for REACH, and to provide the models free of charge on the internet. CAESAR emerged from an earlier EU project, DEMETRA (Development of Environmental Modules for Evaluation of Toxicity of Pesticide Residues in Agriculture), which developed QSARs for pesticides (Benfenati, 2007) for use by those involved in the pesticide industry or its regulation. This approach seemed ideal for REACH chemicals, and so CAESAR was born. An important lesson learned in DEMETRA and applied in CAESAR was that quality assurance at all stages of the QSAR process is vital. Built into the CAESAR project plan is a series of steps involving checking and cross checking of data by two or more partners with expertise in biochemistry, toxicology, computational chemistry and data mining. A further major step in the early part of the CAESAR project was the quality assurance of the structural data. In cross-checking the many thousands of structures, using desktop molecular modelling software, many errors were found in the published data files, as well as, occasionally, in proprietary 'chemical-finder' web sites. Datasets had to be 'cleaned' of all incorrect structures, ambiguous or mixed structures and those containing inorganic elements, cross-checked by at least two partners and then submitted to partners for descriptor calculation and mathematical modelling. A range of mathematical techniques are used, including linear regression, neural networks, self-organizing maps, genetic algorithms and machine learning.

The availability of CAESAR project output is anticipated in mid-2009. The project team anticipates that a set of models for developmental toxicity, mutagenicity, skin sensitization, bioaccumulation and carcinogenicity, valid for a wide range of chemical types, will be submitted to the European Chemicals Bureau for validation for use within REACH.

In addition to CAESAR and DEMETRA, a wide variety of publicly available and commercial computational tools have been developed, or are under development, that are suitable for the development and application of (Q)SARs. These tools include methods for a range of QSAR development-related tasks, including data management and data mining, descriptor generation, molecular similarity analysis, analogue searching and hazard assessment. All of these computational tools are built upon some experimental toxicity data with rules derived from the data (Matthews and Contrera, 1998; 2007; Kruhlak *et al*., 2007; Contrera *et al*., 2007; Jacobson-Kram and Contrera, 2007). Examples of QSAR rule-based systems include TOPKAT and MCASE. Knowledge-based systems include Derek, OncoLogic® and HazardExpert, whereas other systems, such as TIMES and ECOSAR, are hybrids.

Although QSAR is not likely to provide the complete product-safety assessment, it will undoubtedly be used as part of the 'body of evidence' for a wide range of chemicals, especially in the early years of REACH, when the completion of submissions may have to rely heavily on nonanimal data.

13 RECENT DEVELOPMENTS IN INTERNATIONAL CONSUMER PRODUCT-SAFETY LEGISLATION

Some recent developments in consumer product-safety reporting and legislation of interest to toxicologists include the following, by country or region.

13.1 United States

The Consumer Product Safety Improvement Act of 2008, HR 4040, became Public Law No 110–314 on 14 August 2008 (US Government, 2008). This act treats as a banned hazardous substance under the FHSA, any children's product (which is defined as a consumer product designed or intended primarily for children 12 years of age or younger) containing more than specified amounts of lead. If this is not technologically feasible, alternate limits are allowed which require periodic review and, when

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

technologically feasible, more stringent limits. The limits are inapplicable to any component that is not accessible to a child through use and abuse. Specific products or materials may be excluded if the products or materials will neither: (i) result in human lead absorption, taking into account reasonably foreseeable use and abuse by a child, nor (ii) have any other adverse impact on public health or safety. It prohibits considering paint, coatings or electroplating to be a barrier rendering substrate lead inaccessible to a child, or to prevent human absorption of lead. The act also provides for special regulations related to lead exposure for certain electronic devices such as batteries and products that contain them.

This act makes it unlawful to manufacture, sell, distribute or import a children's toy or childcare article containing specified concentrations of particular phthalates. It requires the CPSC to begin appointing a Chronic Hazard Advisory Panel to study the effects on children's health of all phthalates and phthalate alternatives, as used in children's toys and child care articles.

The act requires a manufacturer of a children's product, before importing any children's product that is subject to a safety rule, to have the product tested by an accredited third party for compliance with such rule and to certify that the product complies. It also requires the CPSC to: (i) publish accreditation requirements and a list of accredited entities; (ii) initiate a programme by which a manufacturer may label a product as complying with the certification requirements and (iii) establish protocols and standards relating to the testing of children's products.

Specific CPSC reforms are provided under this act, including enhanced enforcement authorities.

13.2 European Union

Directive 2001/95/EC, enacted by the European Parliament, is now in force, as of 15 January 2004 (European Parliament, 2001). This directive, also known as the General Product Safety Directive (GPSD), is designed as an EU-wide effort to improve consumer health and safety, and the availability of quality products. Originally created 3 December 2001, the directive sets safety requirements for consumer products ranging from sports equipment and household products, to medical-device equipment. The directive empowers member states to establish requirements, depending on the risk and hazard posed by individual products either being introduced within the EU or already in circulation.

This directive empowers member states to take any necessary action to remove any 'serious risk requiring rapid action'. These actions include, but are not limited to:

- An entire ban and recall where a 'serious risk requiring rapid action' is identified
- Information regarding such actions being available to the general public
- A ban on exporting the product from the EU to other countries.

Work is underway in the EU to establish a list of potentially dangerous products of EU-wide concern, as well as establishing within the member states means of monitoring and testing these products. The GPSD is a 'per-product' format directive, meaning that the requirements and actions required vary across products and are evaluated on a product-by-product basis.

On 13 March 2007 the Commission adopted a 'Consumer Policy Strategy' (European Commission, 2007). The strategy sets out the challenges, role, priorities and actions of EU consumer policy. The priorities of the strategy are to:

- Increase consumer confidence in the internal market—which contributes to the improvement of business competitiveness—by establishing a uniform regulatory environment that is equally enforced across the European market and which effectively protects consumers.
- Strengthen consumers' position in the marketplace by developing consumer-education tools, the active support of EU consumer organizations and their involvement in policy-making.
- Ensure that consumer concerns are taken into account in all EU policies.
- Complement member states' consumer policies.
- Collect consumer-related data to support the development of legislative proposals and other initiatives.

'RAPEX' is the recently introduced (EU) rapid alert system for dangerous consumer products (food, pharmaceutical and medical devices are covered by other reporting means), that facilitates the rapid exchange of information between member states and the Commission on measures taken to prevent or restrict the marketing or use of products posing a serious risk to the health and safety of consumers (European Commission, 2004). Measures ordered by national authorities and measures taken voluntarily by producers and distributors are reported by RAPEX:

- Every Friday, the Commission publishes a weekly overview of the dangerous products reported by the national authorities (the RAPEX notifications).
- When a product (e.g. a toy, a childcare article or a household appliance) is found to be dangerous, the competent national authority takes appropriate action to eliminate the risk. It can withdraw the product from the market; recall it from consumers or issue warnings. The National Contact Point then informs the European Commission (Directorate-General for Health and Consumer Protection) about the product,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat158
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the risks it poses to consumers and the measures taken by the authority to prevent risks and accidents.
- The European Commission disseminates the information that it receives to the National Contact Points of all other EU countries. It publishes weekly overviews of dangerous products and the measures taken to eliminate the risks on the internet.
- The National Contact Points in each EU country ensure that the authorities responsible check whether the newly notified dangerous product is present on the market. If so, the authorities take measures to eliminate the risk, either by requiring that the product be withdrawn from the market, by recalling it from consumers or by issuing warnings.

13.3 United Kingdom

The General Product Safety Regulations 2005 (GPSR) is a statutory enactment of the parliament of the United Kingdom that demands that, 'No producer shall (supply or) place a (consumer) product on the market unless the product is a safe product', and provides broad enforcement powers. The regulations implement EU directive 2001/95/EC.

Unless the product is a safe product, the GPSR regulations require that no producer shall:

- Place a product on the market
- Offer or agree to place a product on the market, or expose or possess a product for placing on the market
- Offer or agree to supply a product or expose or possess a product for supply
- Supply a product.

A producer must provide appropriate information to consumers. Either a producer or distributor must inform an enforcement authority if they become aware that they have supplied a dangerous product (regulation 9). The authority must inform the Secretary of State, as of 2008 the Secretary of State for Business, Enterprise and Regulatory Reform, who must inform the European Commission.

A distributor must exercise due care in helping to ensure safety by:

- Not selling dangerous products
- Providing information to purchasers
- Maintaining traceability
- Cooperating with enforcement authorities.

13.4 Japan

Japan's national legislature, the Diet, enacted the country's first law specific to products liability: the PL Law (Law No. 85, 1994) (PL Law) on 1 July 1994. The law, which introduced the concept of strict liability and expanded the definition of a liable manufacturer, went into effect one year later, on 1 July 1995.

Prior to the PL Law, no specific cause of action for strict PL existed in Japanese jurisprudence. Individual plaintiffs were forced to bring claims under Japan's Civil Code using a theory of contractual liability or negligence. These theories afforded little relief for injured parties—and left individual plaintiffs at a particular disadvantage. The number of PL lawsuits filed in Japan has increased since the PL Law went into effect. Many of these PL lawsuits are being brought by individuals or small groups for relatively small claims. Even more importantly, individual plaintiffs are now prevailing in their lawsuits and obtaining judgments against manufacturer defendants for claims that a few short years ago would have been unactionable.

14 THE ROLE OF TOXICOLOGY IN PRODUCT-SAFETY VIGILANCE

The maintenance of successful products in the market requires continual vigilance on many fronts, including performance, satisfaction, quality, cost and so on, but for many reasons, the importance and significance of product safety cannot and must not be overlooked. A long history of product safety can, in fact, be of great benefit to product longevity and marketing. However, if overlooked, consumer and regulatory concerns can rapidly result in significant losses to a product's market share, as well as affect a company's brand recognition. In fact, even a well-established product can rapidly and completely lose market share if a problem in manufacturing or distribution occurs due to a cause that is not rapidly identified and promptly addressed.

Toxicologic problems with products create substantial concern with consumers and can even become exaggerated if not rapidly addressed and resolved. Toxicologists can be of assistance in such circumstances, but not without appropriate data. Therefore, it is important that product-safety evaluation be an essential part of the development process for all products, most especially consumer products that enter a highly diverse international marketplace where there is a high likelihood of having unexpected things happen. So, the design of toxicological safety assessment programmes must learn to anticipate and 'expect the unexpected' to the greatest degree possible. The establishment of an effective post-market vigilance programme can do a lot to provide the information needed for continuous review and improvement of a product's safety file, including any additional testing, as indicated by market experience. Without such vigilance, the product is left in the hands of the consumer

to do with what they will and this may create unexpected liability issues for the producer and distributor, including some of a toxicologic nature.

Products that are currently being marketed should always be monitored for product safety and all substantive issues or complaints addressed effectively and promptly. An experienced toxicologist can be of substantial value in establishing and maintaining an effective product-safety programme for any product involving consumer contact or exposure. Even if the product is only used within a particular industry, where worker protection is in place to help document and ensure that such protections are adequate to protect against any potential hazards. If the product-safety file is lacking with respect to information on an important issue, effort should be expended to obtain this information in an expeditious manner to protect the consumer, as well as the producer and distributor.

ACKNOWLEDGEMENTS

The author wishes to acknowledge the assistance of Robin Guy, M.S., DABT in providing information with respect to US food and food additive product-safety requirements.

Cellular Tight Junctions as Mediators of Adverse Effects

Yula Sambuy

CONTENTS

1 INTRODUCTION

Epithelial and endothelial cells form diffusion barriers that generate and maintain the distinct composition of the different body compartments by selective exchange functions. Epithelial cells lining the surfaces of the body that are exposed to the external environment provide a selective barrier to allow the physiological exchange of beneficial molecules and the exclusion or removal of potentially toxic compounds. Endothelial cells lining the blood and lymphoid vessels express various degrees of selectivity in their barrier function, depending on the vascular district, and play important roles in the maintenance of tissue integrity, vascular permeability, leukocyte extravasation and angiogenesis. To perform these functions, epithelial and endothelial cells are equipped with highly specialized junctional complexes (tight and adherens junctions) that join cells to each other at the apical end of the lateral membrane (Schneeberger and Lynch, 2004). Tight junctions serve both as 'gates' that seal the paracellular space and as diffusion 'fences', to maintain the apical/basolateral polarity that is essential to perform asymmetrical exchanges. Tight junctions maintain epithelial cell polarity by preventing intermixing of plasma membrane proteins and restricting diffusion of lipids in the exoplasmic membrane leaflet (Cereijido *et al*., 2008). Epithelial cells, in their position at the border between the external and the internal environment, are exposed to all kinds of injuries, which are dealt with by frequent cellular replacing and by specific repair mechanisms. For these dynamic processes to occur, tight junctions need to be plastic structures, rapidly responding to extracellular stimuli to maintain the integrity of the epithelial cell monolayer. This occurs both in adult life (i.e. in the small intestinal mucosa, epithelial cells proliferate in the crypts, migrate towards the apex of the villi and are finally shed in the lumen), but is particularly important in tissue remodelling during embryogenesis (Cereijido *et al*., 2007).

In recent years, changes in the permeability of epithelial and endothelial barriers have increasingly been reported to represent early indicators of adverse effects from exposure to chemical or infective agents, but also

to be involved in the development of morbidity and in the progression of various diseases (Forster, 2008; Mullin *et al*., 2005; Prozialeck and Edwards, 2007). The aim of this chapter is to briefly review structure and regulation of epithelial tight and adherens junctions and to report some examples of the mechanisms involved in alterations of tight junction permeability during toxic exposure and in pathological states.

2 TIGHT AND ADHERENS JUNCTIONS

In early ultrastructural studies, epithelial junctional complexes were described as tripartite structures between adjoining cell membranes formed by tight junction (*zonula occludens),* intermediate junction (*zonula adhaerens)* and desmosome (*macula adhaerens),* in which the tight junctions were characterized by fusion of the adjacent cell membranes (Farquhar and Palade, 1963). Later on, employing freeze-fracture electron microscopy, a technique that allows visualization of the hydrophobic membrane surfaces, the tight junctions appeared as a circumferential network of anastomizing strands that are generally assumed to represent polymers of interacting transmembrane components. The barrier is formed where strands of adhesive transmembrane proteins contact across the paracellular space, and it behaves as if perforated by pores possessing size and charge selectivity, the exact molecular nature of which is still unknown despite the identification of several tight junction proteins (Van Itallie *et al*., 2008b). In the tight junctions, transmembrane proteins (occludin, claudins and JAMs (junctional adhesion molecules)) mediate cell–cell adhesion and form the paracellular diffusion barrier, and bind to a group of cytoplasmic plaque proteins that function as cytoskeletal linkers, scaffolds, and regulators of junction assembly and function (**Figure 1**). Most of the transmembrane proteins of the tight junction contain special sequences on their cytoplasmic tail, called PDZ-binding domains, that recruit and bind proteins containing PDZ (PSD95/DlgA/ZO-1 homology) motifs, including the peripheral proteins of the cytoplasmic plaque, the zonula occludens proteins (ZO-1, ZO-2, ZO-3) and other regulatory proteins (Schneeberger and Lynch, 2004). In addition to proteins exclusively associated with the tight junctions, a recently described class of proteins appear to shuffle between the membrane and the nucleus, the *N*uclear *A*dhesion *Co*mplexes (NACo) proteins, where they are involved in the regulation of transcription (Matter and Balda, 2007).

2.1 Adherens Junctions

Adherens junctions are structures that link membrane and cytoskeletal components at discrete contact regions situated just below the most apically located tight junctions (**Figure 1**). Adherens junctions consist of two basic adhesive units: the cadherin/catenin and nectin/afadin complexes. Classical cadherins, such as

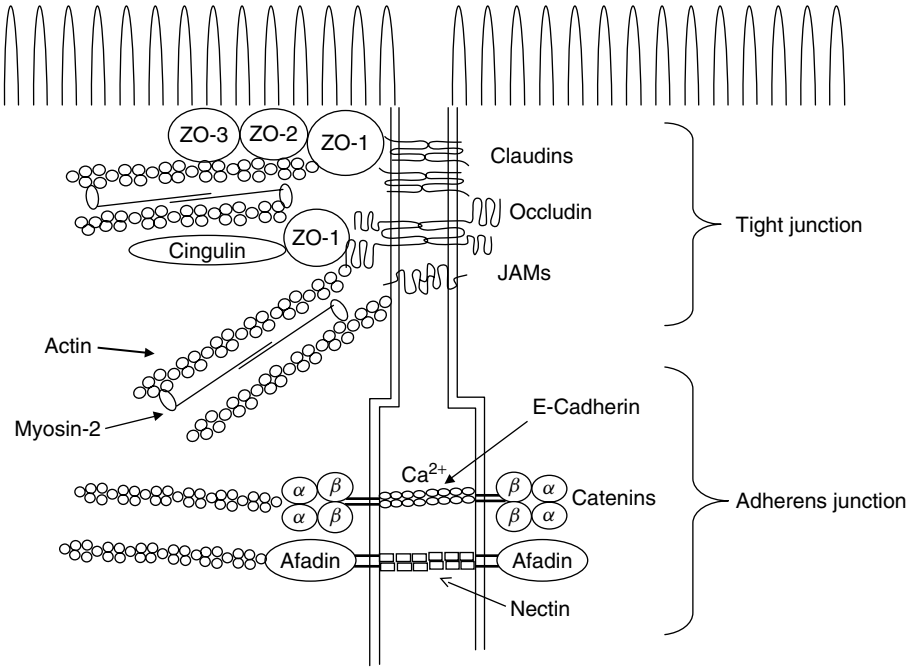

Figure 1 Tight and adherens junction composition. A schematic drawing of the composition of tight and adherens junctions in which only the major proteins and their interactions are shown. Several regulatory proteins participating in the control of junction assembly and function have been omitted for the sake of clarity.

E-cadherin, are single-pass transmembrane glycoproteins that promote adhesion between homotypic opposing cells by a Ca^{2+}-dependent mechanism, but also bind directly and indirectly to many cytoplasmic proteins, particularly members of the catenin family (i.e. p120-catenin, α-catenin and β-catenin), which locally regulate the organization of the actin cytoskeleton, cadherin stability and intracellular signalling pathways involved in the control of gene transcription. Nectin, a member of the IgG (immunoglobulin G) superfamily of Ca^{2+}-independent adhesion molecules, links through its C-terminal PDZ-binding domain to the actin-binding protein afadin, which also interacts with the Ras/Rap family of GTPases as well as with other actin-binding proteins such as ZO-1 and α-catenin (Niessen and Gottardi, 2008). Adherens junctions play important roles in stabilizing the epithelium by promoting tight junction formation and epithelial cell polarity. When junctions are formed *de novo* or following epithelial injury, adherens junctions assemble first, and this leads to formation of tight junctions (Schneeberger and Lynch, 2004).

In recent years the great molecular complexity of the organization and regulation of epithelial apical junctions (tight and adherens junctions) is fully emerging, and some excellent reviews provide ample details and updated references on the subject (Anderson and Van Itallie, 2008; Ebnet, 2008; Hartsock and Nelson, 2008; Miyoshi and Takai, 2008; Niessen and Gottardi, 2008). Although the adherens junctions will also be mentioned in the chapter, major attention will be placed on the involvement of tight junctions in toxic and pathological events.

2.2 Integral Membrane Proteins of the Tight Junction

2.2.1 Occludin

Occludin, the first transmembrane protein identified in tight junctions, is a tetraspan membrane protein with two extracellular loops, a short intracellular turn, and N- and C-terminal cytoplasmic domains. Its C-terminal tail binds actin and ZO-1, which in turn associates with actin and other proteins of the cytoplasmic plaque (Paris *et al*., 2008). Occludin appears also to interact, directly or indirectly, with claudins, and is recruited into the strands formed by co-transfection of claudins 1 and 2 into fibroblasts (Furuse *et al*., 1998a). When first discovered, occludin was believed to be responsible for tight junction barrier properties, although a single protein could hardly account for the wide range of permeabilities encountered in different epithelial and endothelial tight junctions. Transfection and transgenic mice experiments later showed that occludin expression was not essential to the formation of structurally and functionally mature tight junctions, although occludin-null mice showed postnatal growth retardation and complex phenotypes in various organs. The C-terminal tail of occludin has several residues that can be phosphorylated and dephosphorylated by various protein kinases and phosphatases, providing means of rapid regulation during tight junction assembly and disassembly (reviewed in Chiba *et al*., 2008).

2.2.2 Claudins

Claudins constitute a large family of proteins that share the tetraspan transmembrane topology with occludin, tricellulin and connexins (gap junction proteins), without considerable sequence homology (Krause *et al*., 2008). Claudin expression is fundamental for strand structure since their expression in nonepithelial fibroblasts was shown to be sufficient to recapitulate the strand morphology of tight junctions (Furuse *et al*., 1998b). Claudins can form homotypic or heterotypic interactions among different members of the family. The interactions of claudins of neighbouring cells occur between the two extracellular loops, but it is the first loop, which varies widely among claudins in the position and number of charged amino acids, that is believed to be responsible for the characteristics of the paracellular pores for cations or anions (Van Itallie and Anderson, 2006). Permeability of small uncharged solutes appears to be proportional to the pore number, but small electrolytes may be subject to further selectivity by the specific profile of claudins expressed, thus explaining the frequently reported dissociation between the permeability to small uncharged solutes and the electrical resistance (Van Itallie *et al*., 2008b).

The 24 claudins that have so far been identified are expressed in specific combinations, conferring tissue-specific barrier properties that can range from almost complete tightness of the paracellular route for solutes, as observed in the bladder, to the formation of paracellular pores for specific charged ions (cations or anions), as observed in different segments of the renal tubules (recently reviewed in Chiba *et al*., 2008; Krause *et al*., 2008). Claudin 16/paracellin 1, for example, is primarily expressed in the thick ascending loop of Henle, where it is specifically involved in Mg^{2+} resorption (Simon *et al*., 1999). At least seven claudins (claudins 2, 3, 4, 7, 8, 12 and 15) are abundantly expressed along the intestinal tract with remarkable variations in the level of expression both throughout the intestinal segments and along the crypt-to-villus axis (reviewed in Chiba *et al*., 2008). Although results of transfections or other experiments in single tissues or cell types have ascribed specific functions to single claudins, the distinct tightness properties of a given tissue seem to be largely dependent on the combination of the claudins that are expressed and on the manner

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat159
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in which they co-polymerize. Through a PDZ-binding motif at their C-terminus, most claudins directly bind to PDZ domain-containing peripheral membrane proteins of the cytoplasmic plaque (i.e. ZO proteins); this binding appears to be essential for the spatial organization of claudin-based membrane strands in epithelial cells, and to the transmission of signals to the regulatory proteins (Guillemot *et al*., 2008). The dynamic nature of tight junctions appears to be conferred, at least in part, by the fast turnover of claudins (with half-lives much shorter than other transmembrane proteins) and by their many phosphorylations, indicating the existence of short-term regulatory mechanisms. Phosphorylation by different protein kinases of various claudin isoforms can result in rapid changes in tight junction permeability, frequently accompanied by movement of the claudins away from the membrane and dissociation from other junction proteins (Gonzalez-Mariscal *et al*., 2008; Krause *et al*., 2008).

2.2.3 Tricellulin

Tricellulin has been identified as a four-pass transmembrane protein that is concentrated at the vertically oriented tight junction strands of tricellular contacts of epithelial cell sheets, and is required for the maintenance of the transepithelial barrier (Ikenouchi *et al*., 2005). It shows a 30% homology in the C-terminal tail with occludin, and recent data indicate that occludin is required for tricellulin correct localization to the tight junction (Ikenouchi *et al*., 2008). Down-regulation of tricellulin by RNA interference in cultured epithelial cells produced disorganization of both bicellular and tricellular tight junctions (Ikenouchi *et al*., 2005). Tricellulin is ubiquitously expressed in epithelial junctions throughout the body, and different splice variants in the tricellulin gene have been described in humans affected by autosomal recessive hearing impairment (Chishti *et al*., 2008; Riazuddin *et al*., 2006). The mechanisms for such a critical role of tricellulin in the inner ear have not yet been fully elucidated, and it has been suggested that at least one underlying cause of cellular dysfunction in the cochlea may be the inability to incorporate these mutant tricellulin proteins into the cytosolic scaffold formed by ZO proteins (Riazuddin *et al*., 2006).

2.2.4 Junctional Adhesion Molecules

Junctional adhesion molecules (JAMs) are glycosylated transmembrane proteins that belong to the immunoglobulin (Ig) superfamily, and consist of two extracellular Ig-like domains, a single transmembrane region and a C-terminal cytoplasmic domain with a PDZ-binding domain. Based on their PDZ-binding domain they can be distinguished and assigned to two groups, JAM-A, JAM-B, JAM-C, and JAM-4, CAR, CLMP and ESAM (Ebnet, 2008). They show homophilic and heterophilic interactions through their extracellular domains among distinct cell types (i.e. leukocytes, platelets and/or endothelial cells), and also bind to various regulatory proteins of the cytoplasmic plaque (Chiba *et al*., 2008). Except for JAM-A, there is only little information on the role of these proteins in the development or the function of tight junctions. All but CLMP interact with tight junction-associated scaffolding proteins of the cytoplasmic plaque like ZO-1, PAR-3 and MAGI-1. For JAM-A there is good evidence for its involvement in the regulation of epithelial and endothelial tight junctions and in the development of apical/basal cell polarity in epithelial cells by recruiting multiprotein signalling complexes crucial for apical domain formation (Ebnet, 2008). In addition, certain JAMs have been implicated in the regulation of leukocyte extravasation through endothelial cells (Cook-Mills and Deem, 2005).

2.2.5 Cytoplasmic Plaque Proteins

The cytoplasmic plaque is composed of a series of proteins (ZO-1, ZO-2, ZO-3) belonging to the membrane-associated guanylate kinase (MAGUK) superfamily, and of an array of other molecules, including cingulin; symplekin; the Ras target, leukaemia fusion-6 (AF-6); the multi-PDZ protein, MUPP-1 (multi-PDZ domain protein 1); the membrane-associated guanylate kinase inverted proteins (MAGIs); and proteins involved in the establishment of epithelial cell polarity (PAR-3, PAR-6, PALS-1 and PATJ). Many of the scaffolding proteins contain multiple PDZ domains and other protein–protein interaction domains, with which they bind to and regulate different types of signalling proteins, ranging from small and heterotrimeric GTP-binding proteins and guanine nucleotide exchange factors for Rho-family GTPases, to protein phosphatases and kinases (for reviews, see Aijaz *et al*., 2006; Ebnet, 2008; Guillemot *et al*., 2008; Schneeberger and Lynch, 2004). More than 30 proteins have been described to be associated with the cytoplasmic aspect of the tight junctions (Schneeberger and Lynch, 2004), playing a scaffolding role to couple the transmembrane proteins to the actin cytoskeleton and to other regulatory proteins in the cytoplasm, as well as a coordinating role for the complex signalling pathways involved in the regulation of epithelial junction assembly and permeability.

2.2.5.1 NACo Proteins (Nuclear Adhesion Complexes)

Recent evidence suggests that tight junctions also participate in signal transduction mechanisms that regulate epithelial cell proliferation, gene expression, differentiation and morphogenesis. One important class of tight junction-associated signal transduction mechanisms is based on dual localization of certain proteins both at junctions and in the nucleus (Matter and Balda, 2007).

At the level of the adherens junction the best and most intensively studied example is the β-catenin, an adherens

junction-associated NACo that binds to cadherins and plays crucial roles in the Wnt/Wingless signalling pathway, important in development and cancer. Once stimulated, β-catenin accumulates in the nucleus, owing to decreased ubiquitin–proteasome-mediated degradation, and binds to and activates the transcription factor LEF/TCF (lymphoid enhancer factor/T cell factor), leading to transcription of genes involved in proliferation and epithelial–mesenchymal transition (Cadigan, 2008).

In tight junctions, the Y-box transcription factor ZONAB (*ZO*-1-associated *N*ucleic *A*cid *B*inding protein), the canine homologue to human DbpA, was described in postproliferative confluent epithelial cells to be transcriptionally inactive and to reside exclusively in the cytoplasm, bound to ZO-1, and in proliferating cells to move away from the junction to the nucleus to initiate transcription (Balda and Matter, 2000). ZONAB has been shown to affect G1/S-phase transition by regulating the nuclear accumulation of the cell division kinase CDK4 (cyclin-dependent kinase 4) and the expression of genes involved in cell cycle regulation (Balda and Matter, 2003; Sourisseau *et al*., 2006). Interaction of the heat shock protein, Apg-2, with ZO-1 was found be stimulated by heat shock and to result in nuclear translocation and transcriptional activation of ZONAB, presumably by displacing it from its junctional adaptor (Tsapara *et al*., 2006). The ZO-1–ZONAB pathway is therefore emerging not only as a mediator of proliferation, but also in cellular responses to certain stresses. Although it is currently not known which types of stresses may affect the transcriptional activity of ZONAB, it is possible that conditions that interfere with junctional integrity (i.e. oxidative stress or energy depletion) also induce ZONAB activation, as recently shown for the ethanol metabolite phosphatidylethanol (see below).

3 ENDOTHELIAL JUNCTIONS

The endothelium forms a semipermeable barrier lining the vascular vessels that regulates fluid and solute exchange between the blood and the interstitial fluid. The junctional structures joining together endothelial cells are related to those found in epithelia, as they contain tight junctions and adherens junctions (**Figure 1**); however, their organization is more variable, and in most vascular beds their topology is less restricted than in epithelial cells. In pathological conditions, endothelial barrier dysfunction can lead to protein-rich tissue oedema, as observed in atherosclerosis and diabetes-associated vascular disease (reviewed in Bakker *et al*., 2008; Hadi *et al*., 2005).

Adherens junctions represent the majority of junctions comprising the endothelial barrier, in contrast to the epithelium where tight junctions predominate, and are composed of vascular endothelial (VE)-cadherin consisting of five cadherin-like repeats that associate homotypically with VE-cadherin on the adjacent cell in a Ca^{2+}-dependent manner. The juxtamembrane domain of VE-cadherin binds p120-catenin, whereas the C-terminal domain binds with β-catenin and α-catenin, which in turn link to the actin cytoskeleton. Although adhesion between cadherin and catenins is required for maintaining adherens junction integrity, p120 binding to cadherins is perhaps the most important determinant of their stability. The scaffold function of p120 serves to regulate the interactions between cadherins, kinases, phosphatases and Rho GTPases, which in turn control the phosphorylation state and stability of cadherin interaction with one another, as well as with catenins (reviewed in Vandenbroucke *et al*., 2008).

Endothelial tight junctions are much less well known than their epithelial counterparts. They contain occludin, ZO-1, ZO-2 and ZO-3 that associate to cortical actin through cingulin. Only claudin 5 is expressed in endothelial tight junctions. In the different segments of the vascular tree the tight junctions show considerable variability in strand complexity and composition with strong impact on vascular permeability and leukocyte extravasation (the process by which at inflammatory sites, mostly in postcapillary venules, leukocytes cross endothelial cells either through transcellular or paracellular routes) (Vestweber, 2007; Wallez and Huber, 2008). Large artery endothelial cells, which are exposed to high flow rates, display a well-developed system of tight junctions. Within the microvasculature, tight junctions are less complex in capillaries than in arterioles, and even less in venules. The blood–brain barrier (BBB) and the blood–retinal barrier are particularly rich in tight junctions whose barrier properties are believed to be determined by interactions with the perivascular astrocytes and the closely associated pericytes. Both cells produce factors, including angiopoietin-1, TGFβ (transforming growth factor β) and probably other uncharacterized molecules, that are required to induce the barrier phenotype (reviewed in Wallez and Huber, 2008).

Various evidence supports a different mode of tight junction regulation in epithelial and endothelial cells, and in the following paragraphs the focus will be primarily on epithelial tight junction regulation, because of the still limited information available on the endothelium (Liebner *et al*., 2006).

4 REGULATORY PATHWAYS INVOLVED IN CONTROL OF EPITHELIAL TIGHT JUNCTION PERMEABILITY

Several regulatory pathways are involved in the control of tight junction assembly and maintenance during embryogenesis, tissue remodelling, normal physiological

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat159
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

turnover and in response to toxic or pathological signals. This highly dynamic structure, whose degree of sealing is controlled by external stimuli, requires a complex crosstalk between distinct regulatory pathways relying on activation of signalling cascades for rapid modulation of protein phosphorylation and on the production of intracellular second messengers leading to mobilization of specific transcription factors. For an extensive review of the subject refer to Gonzalez-Mariscal *et al*. (2008). Briefly, the state of phosphorylation of tight junction proteins is regulated by an array of kinases and phosphatases. Among these are the phosphokinase C (PKC) family, 12 known Ser/Thr-specific isozymes that differ in their mechanism of action, subcellular distribution, substrate type and expression; the phosphokinase A (PKA), regulated by the rise in intracellular cAMP, and the phosphokinase G (PKG) whose activation by cGMP in brain endothelial cells exerts different effects depending on the state of the tissue. While Ser/Thr phosphorylation of several tight junction proteins promotes the barrier function of tight junctions, several protein phosphatases, PP1, PP2A and PP2B, exert opposite effects on the barrier function of tight junctions depending on the role of the kinase isoform they are inhibiting. The Rho family of small GTPases includes RhoA, Rac and Cdc-42, which regulate distinct actin structures in response to diverse signals, and are therefore involved in the maintenance of the stability of the scaffold between the junction proteins and the cytoskeleton, thus affecting junction permeability. Another important pathway involved in regulation of tight junction permeability by external stress or pro-inflammatory cytokines is the Myosin Light Chain Kinase (MLCK) pathway that Ser-phosphorylates the Myosin 2 Light Chain (MLC), leading to contraction of the perijunctional actomyosin ring and opening of the paracellular space. In certain systems a crosstalk between PKC and MLCK has been proposed where MLCK is itself phosphorylated by activated PKC. Finally, another important pathway in tight junction regulation is that of the mitogen-activated protein kinases (MAPKs). This signalling pathway has a membranous and a cytoplasmic phase, the first in close proximity to the growth factor receptors, involving the activation of small GTP binding proteins (i.e. Ras), that initiates a cascade of sequential activations of several cytoplasmic kinases, MAP3K, MAP2K and finally MAPK, all phosphorylated on Ser/Thr residues. MAPKs can then phosphorylate a large number of proteins that are located both in the cytoplasm and the nucleus, including transcription factors that regulate the expression of diverse genes. The different MAPKs expressed in mammalian tissues are the extracellular signal-regulated kinases (ERKs), also known as classical MAP kinases that have been found to interact with occludin, the c-Jun N-terminal kinases (JNKs) and p38 isoforms activated by stress stimuli and involved in cell differentiation and apoptosis, and ERK5, participating in cell proliferation and activated by both growth factors and stress stimuli.

In conclusion, given the potential for feedback and crosstalk linking all the regulatory pathways involved in the control of tight junction permeability, it is unlikely that simple linear pathways will adequately explain the complex relationship between external toxic or pathological stimuli, intracellular signalling and junction responses. It is therefore important to abandon the view that single kinases, phosphatases or GTPases will mediate a single cellular or tissue outcome (Braga and Yap, 2005).

5 EXPERIMENTAL MODELS AND ASSESSMENT OF TIGHT JUNCTION PERMEABILITY

In clinical practice, changes in intestinal permeability as indicators of several pathological conditions of the gut, including inflammatory bowel disease (IBD) and coeliac disease, are measured by the lactulose/mannitol test, and in the renal disease, kidney creatinine or inulin clearance are employed. However, an increasing number of pathological conditions are found to be associated with changes in permeability of the epithelial or the endothelial barrier, and simple clinical tests are not available for all areas. For the study of the molecular mechanisms involved in pathological changes to epithelial and endothelial barriers, both animal disease models and excised mucosal tissue mounted in Ussing chambers have been employed (Li *et al*., 2004). The use of knockout mice for genes coding for tight junction protein, and the positional cloning of gene mutations in several hereditary diseases involving tight junction proteins, are two different experimental approaches that have recently contributed to further understanding of tight junction function and regulation *in vivo* (Furuse, 2008).

But in many cases, detailed dissection of the molecular composition and regulation of tight junctions during assembly or disassembly, in response to a wide array of different physiological and pathological stimuli, has required the use of cell-culture models of well-differentiated epithelial and endothelial cells from various organs. These *in vitro* models also allow expression of exogenous or silencing of endogenous genes, as well as expression of chimaeric proteins, and all these techniques have been extensively utilized to dissect the roles of single components within the junctional complexes. Although cell culture models cannot account for immune-mediated or neural-controlled stimuli, they have been essential to single-out and unravel molecular mechanisms of tight junction regulation.

Among the most widely used models for the study of epithelial tight junctions are the Madin Darby canine kidney (MDCK) cell lines and the human intestinal Caco-2 cell lines. In MDCK cell lines, differences in transepithelial electrical resistance (TER), which distinguish the high-resistance MDCK Type I line from the low-resistance MDCK Type II line, have been attributed to changes in the expression of the pore-forming claudin 2 and in the basal activity of the regulatory kinases ERK 1/2 (Lipschutz *et al*., 2005), while strand structure and ZO-1 content were identical in the two lines. Caco-2 cells, originally obtained from a human colon adenocarcinoma, when grown on permeable filter supports, differentiate over a period of two to three weeks in a postmitotic monolayer of well-polarized cells coupled by functional tight junctions and expressing many characteristics of mature small intestinal enterocytes (Delie and Rubas, 1997). Both MDCK and Caco-2 cell lines have proved very useful for investigation of epithelial junction permeability, although care should be taken in the comparison of results from different laboratories since extensive cell- and culture-related variability has been reported with these culture models (Sambuy *et al*., 2005; Volpe, 2008). Other well-differentiated cell culture models useful to study tight junction regulation in different tissues are the renal porcine proximal tubules line LLC-PK1 (Gopalakrishnan *et al*., 2003), the human pancreatic cell line HPAF-II (Rajasekaran *et al*., 2004), as well as primary or established cell lines of the human airways epithelium (Bao and Knoell, 2006a; Verstraelen *et al*., 2008).

The BBB is a highly regulated barrier of brain capillaries that segregate the central nervous system (CNS) from systemic blood circulation and maintain a delicate homeostasis of the CNS environment. In the BBB, glial astrocytes surround endothelial cells, providing them with a biochemical support. Culture models of endothelial brain cells have a low TER and form tight junction networks of low complexity. However, when they are maintained in co-culture with astrocytes or in astrocyte-conditioned media the TER doubles, tight junctions more closely resemble those of brain endothelium *in vivo* and the cells express specific BBB markers. An established co-culture method of bovine brain capillary endothelial cells (BBCECs) with rat glial cells (Cecchelli *et al*., 1999) has recently been optimized by replacing the co-culture with a differentiation medium containing glial-conditioned medium and by shortening the time required to obtain well-differentiated endothelial cells resembling those of the BBB (Culot *et al*., 2008). Another cell culture model is the immortalized human brain microvascular endothelial cell line hCMEC/D3 that retains the morphological characteristics of primary brain endothelial cells and expresses specific brain endothelial markers and cell surface adhesion molecules (Weksler *et al*., 2005). It was recently shown that these cells, when cultured on hollow microporous fibres under physiological flow conditions, maintain *in vitro* the physiological properties of the BBB even in the absence of abluminal astrocytes, and respond to inflammatory stimuli with barrier failure and extravasation of leukocytes (Cucullo *et al*., 2008).

Properties of the epithelial paracellular barrier include electrical resistance and solute permeability, which can be independently assessed by measuring the TER, the transepithelial ionic diffusion potentials determined by short circuit currents (I_{sc}), or the diffusion of labelled charged or uncharged tracer molecules of various sizes (Rajasekaran *et al*., 2008). TER is the most sensitive measure of mucosal barrier function since it allows for fast and continuous assessment of changes in the paracellular conductance. In relatively leaky epithelia such as that of the small intestine, TER essentially reflects the paracellular resistance, and alterations of the apical membrane conductance by activation of ionic channels have little effect on total resistance. However, in tight epithelia (i.e. in the colon or in renal proximal tubules), activation of ionic membrane channels may lead to large changes in TER, and appropriate control of selective ionic permeability by I_{sc} measurement must be undertaken to distinguish between transcellular and paracellular contributions to TER (Madara, 1998). Measurements of transepithelial ionic diffusion potentials can also assess the ionic selectivity of the tight junction pathway, while measurements of diffusion of tracer molecules have the advantage of being size selective. This is particularly relevant in conditions of toxic or pathological changes where both transcellular permeability (largely controlled by ionic channel activity) and paracellular permeability (tight junctions) can contribute to different extents to the observed changes.

Paracellular solute permeability can be measured with molecules that are excluded by the cells and detected by colour (phenol red), fluorescence (Lucifer yellow or FITC-dextran) or radioactive label (^{3}H- or ^{14}C-labelled inulin or mannitol). The size of the tight junction pores can be evaluated employing paracellular tracers of different sizes as recently shown in different epithelial cell lines and in porcine ileum, with a series of noncharged polyethylene glycols (PEGs) detected by high-performance liquid chromatography (HPLC) after fluorescent derivatization (Van Itallie *et al*., 2008b). In experimental practice a widely shared opinion is that TER and noncharged tracer diffusion studies are complementary, but not mutually exclusive methods to measure paracellular permeability.

In addition, when using whole-tissue mounts in Ussing chambers (i.e. intestinal mucosal sheets) some investigators have employed methods of impedance analysis that allow one to differentiate the epithelial and the subepithelial portion of transmural resistance, resulting in a more accurate assessment of the electrical pathways contributing to the overall TER (Gitter *et al*., 1998).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Although these methods are not very commonly utilized, as they require more sophisticated instrumentation and mathematical modelling, it is important to recognize the possible contribution of the various constituents of TER in the evaluation of the physiological significance of recorded changes in tight junction permeability in the different experimental models.

Since tight junctions are highly dynamic structures that rapidly respond to various physiological and pathological stimuli, appropriate experimental approaches are necessary to correctly interpret the mechanisms involved. Until recently, for example, it was difficult to analyse the mechanisms by which actin depolymerization led to tight junction disruption, as studies of fixed tissues showed morphological changes only after loss of barrier function. The development of well-validated fluorescent fusion constructs of representative tight junction proteins have allowed continuous real-time assessment of tight junction structure and function in live epithelial monolayers, demonstrating that during exposure to drugs depolymerizing actin, occludin was removed from the junction by caveolae-mediated endocytosis at the precise time that barrier function was disrupted, while claudin 1 and ZO-1 delocalization occurred at a later stage (Turner, 2006).

6 AGENTS CAUSING INCREASED TIGHT JUNCTION PERMEABILITY

First studies reporting alterations to tight and adherens junction permeability were conducted on cultured epithelial cells treated with pharmacological agents causing either actin depolymerization (Madara, 1987) or calcium chelation (Cereijido *et al*., 2000). Several different stimuli leading to changes in tight junction permeability were found to be mediated by the actin cytoskeleton, suggesting a physical link between the cytoskeleton and the junction proteins. This physical link was later identified in the scaffolding role of cytoplasmic plaque proteins (i.e. ZO-1) linking the apical ring of filamentous actin to the adhesive transmembrane proteins of the tight and adherens junctions (reviewed in Miyoshi and Takai, 2005). Calcium mediates the adhesion between extracellular domains of E-cadherin in adherens junctions, and calcium depletion causes endocytosis of adherens junction (E-cadherin) and tight junction (claudins, occludin) proteins (Hartsock and Nelson, 2008) The rapid disassembly/reassembly of junctions in response to changes in extracellular calcium have been exploited in the 'calcium-switch' model that is frequently utilized to follow and characterize the molecular mechanisms involved in modulation of the apical junction (Cereijido *et al*., 2000). Since the early studies, this field has grown enormously both in the number of proteins and regulatory pathways identified and in the complexity of their interactions. Over the years, an increasing number of noxious stimuli have been reported to affect the structure and permeability of epithelial and endothelial tight junctions, and these early toxic effects have frequently been shown to precede further damage to the cells, leading to cell death by apoptosis or necrosis. Examples of chemical noxious stimuli to epithelia and endothelia that will be discussed here are ethanol, oxidative stress and metals (in particular cadmium, iron and zinc).

6.1 Ethanol

Ethanol is one of the numerous exogenous compounds thought to have harmful effects on the gastrointestinal mucosa, in particular due to the regular and repeated contact with ethanol of the gastrointestinal mucosa of chronic alcohol consumers. Chronic ethanol consumption is associated with an increased risk of developing cancers of the digestive tract, and in particular colorectal carcinomas, and strong proliferative response and mucosal hyperplasia in colon and rectum have been reported following alcohol abuse (Boffetta and Hashibe, 2006). In addition, high ethanol concentrations are known to produce significant mucosal damage, allowing the paracellular passage of luminal substances that may favour cytotoxicity and inflammation. Ethanol effects are not restricted to the gastrointestinal tract since alcohol consumption is also a major risk factor in other pathological conditions such as neurobehavioural diseases, inflammation disorders in different organs and enhanced susceptibility to bacterial infection, frequently involving changes in junction permeability of epithelial and endothelial cells, and accompanied by a strong inflammatory response.

Ethanol treatment of cultured intestinal epithelial cells was first shown to activate MLCK, leading to disorganization of the perijunctional actomyosin ring and increase in paracellular permeability (Ma *et al*., 1999). Regulation of tight junction permeability by MLCK phosphorylation of MLC and of tight junction proteins is a mechanism common to different stimuli, including oxidative stress and pro-inflammatory cytokines, that has been described in several epithelial and endothelial cells both *in vivo* and *in vitro* (Eutamene *et al*., 2005; Haorah *et al*., 2005b; Ma *et al*., 2005). The toxic effects of ethanol are generally attributed to the production of acetaldehyde by specific isoforms of alcohol dehydrogenase (ADH) in epithelial and endothelial cells and in the intestinal lumen by the action of enteric microbial fermentation. Acetaldehyde is a highly mutagenic and carcinogenic molecule, also reported to generate a number of reactive oxygen metabolites. At the level of the intestinal epithelium, acetaldehyde has been shown to disrupt tight junctions and

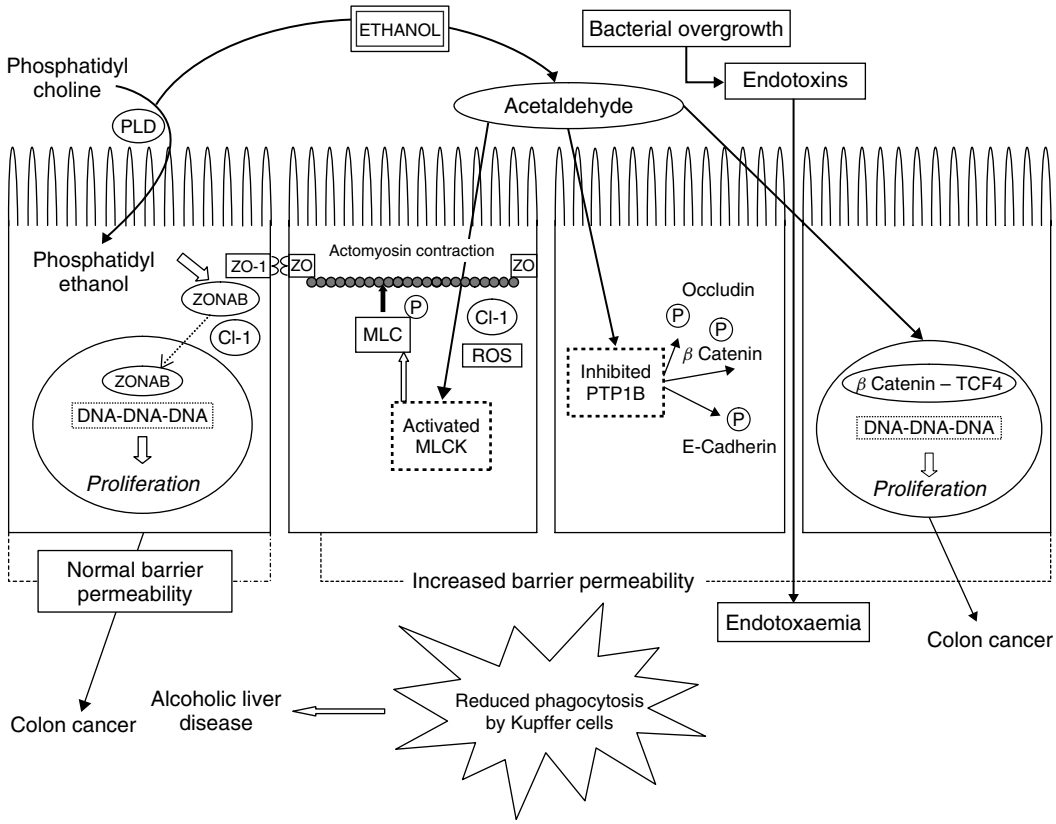

Figure 2 Multiple pathways of ethanol toxicity in the intestinal epithelium leading to diverse pathological effects. Formation of phosphatidylethanol from ethanol and phosphatidylcholine by the membrane enzyme phospholipase D (PLD) can cause dissociation of the transcription factor ZONAB from ZO-1 and its translocation to the nucleus, leading to the activation of genes involved in reinitiation of proliferation. These effects occur in the absence of changes in intestinal barrier function. Acetaldehyde, produced in intestinal cells by the enzyme alcohol dehydrogenase, can activate phosphorylation (P) of myosin light chain kinase (MLCK) either directly or through the formation of reactive oxygen species (ROS), which in turn phosphorylates myosin 2 light chain (MLC) and causes the contraction of the perijunctional actomyosin ring and increased epithelial barrier permeability, with claudin 1 (Cl-1) internalization. Acetaldehyde can also inhibit the protein tyrosine phosphatase 1B (PTP1B), blocking occludin, β-catenin and E-cadherin in their phosphorylated state. Phosphorylated occludin is internalized and contributes to barrier dysfunction. Phosphorylated β-catenin dissociates from E-cadherin and migrates to the nucleus where, with the transcription factor TCF4, it activates genes involved in proliferation. Chronic ethanol consumption can enhance intestinal bacterial overgrowth with increased production of endotoxins that can freely migrate across the permeabilized intestinal mucosa, leading to endotoxaemia. In the liver, acetaldehyde reduces endotoxin clearance by Kupffer cells and can contribute to alcoholic liver disease. Activation of proliferative events by different ethanol metabolites can contribute to the development of colon carcinogenesis.

increase paracellular permeability by different mechanisms (**Figure 2**). In the human intestinal Caco-2 cell line that lacks ADH activity, acetaldehyde treatment induced inhibition and dissociation of Protein Tyrosine Phosphatase 1 B (PTP1B) from the E-cadherin–β-catenin complex of the adherens junction, resulting in sustained tyrosine phosphorylation of β-catenin that led to its dissociation from E-cadherin and loss of homophilic interaction between extracellular domains of E-cadherin (Sheth *et al*., 2007). Inhibition of PTP1B was also shown to maintain occludin phosphorylation, causing its redistribution to the cytoplasm together with ZO-1 (Basuroy *et al*., 2005). The combined effects of acetaldehyde on the phosphorylated state of proteins of tight and adherens junctions resulted in increased epithelial barrier permeability. Such effects could be prevented by treatment with EGF or L-glutamine, a protection that was shown to be mediated by ERK activity (Basuroy *et al*., 2005; Seth *et al*., 2004).

However, acetaldehyde is not the only toxic mediator of ethanol effects (**Figure 2**). Recently, chronic low-dose ethanol exposure was shown both *in vivo* and *in vitro* to be associated with increased production of phosphatidylethanol in intestinal epithelial cells, resulting in changes in the localization of claudin 1 and ZO-1 and its associated transcription factor ZONAB, in the absence of changes to tight junction permeability (Pannequin *et al*., 2007). Detachment of

ZONAB from the tight junction protein ZO-1 and its migration to the nucleus resulted in transcriptional activation of genes involved in cell proliferation. Therefore, the disruption of ZONAB-mediated physiologic signals sent by the tight junction complexes to stop the proliferation of confluent epithelial cells might, in addition, facilitate the stimulatory role of other ethanol metabolites, such as acetaldehyde, on the proliferation of cells within intestinal crypts, thereby contributing to the well-established co-carcinogenic role of alcohol consumption in the colon (Pannequin *et al*., 2007).

Elevated intestinal permeability appears to be one of the major factors in the mechanism of alcohol-induced endotoxaemia, a crucial event in the pathogenesis of alcoholic liver disease (Nagata *et al*., 2007). Bacteria of the intestinal flora are the source of endotoxins (lipopolysaccharides (LPS), derived from the intestinal wall of Gram-negative bacteria) that normally penetrate the intestinal mucosa only in trace amounts. In chronic ethanol consumption, microbial proliferation is increased and the acetaldehyde-mediated opening of intestinal tight junctions can significantly enhance the passage of endotoxins into the circulation. Plasma endotoxin levels are higher in patients with alcoholic liver disease (ALD) than in normal subjects or in patients with nonalcoholic cirrhosis. In addition, alcohol metabolites appear to reduce the phagocytic activity of Kupffer cells, while endotoxins activate cytokine production, further contributing to the development of liver disease. The role of intestinal permeability and endotoxaemia in alcoholic liver disease has been reviewed by (Rao *et al*., 2004).

In cultured brain microvascular endothelial cells (BMVECs), an *in vitro* model of the BBB, ethanol activated MLCK, leading to phosphorylation of serine residues of claudin 5 and occludin that resulted in BBB impairment (Haorah *et al*., 2005a). In addition, ethanol exposure significantly increased the levels and activity of ADH, producing toxic acetaldehyde, and of the ethanol-metabolizing enzyme, cytochrome P450-2E1 (CYP2E1), that enhances reactive oxygen species (ROS) generation, implicating oxidative damage in ethanol-induced BBB damage (Haorah *et al*., 2005b). The *in vivo* effects of chronic ethanol drinking on the BBB were studied in rat brain endothelial cells and neurons challenged with the bacterial endotoxins LPS. Increase in endothelial tight junction permeability correlated with decreased mRNA expression and increased phosphorylation of junction proteins, associated with an increase in ERK, p38 MAPK, JNK, and activation of RelA-p50 and p50-p50 (inducers of pro-inflammatory signals). Thus, chronic alcohol drinking may cause higher predisposition to infection and inflammation-related diseases possibly by augmenting the effects of pathogens on the BBB (Singh *et al*., 2007).

6.2 Oxidative Stress

ROS and reactive nitrogen species (RNS, e.g. nitric oxide and its radical, $NO^{\bullet}$) are well known to play a dual role within the cell, both as deleterious toxic agents and as key second messengers in numerous signalling pathways involved in transcriptional regulation, differentiation, proliferation and programmed cell death (apoptosis). The complexity of the involvement of free radicals and antioxidants in normal physiological functions and human disease have recently been extensively reviewed (see Valko *et al*., 2007 and **Nitric Oxide Pathways in Toxic Responses**; **Reactive Oxygen Species in the Induction of Toxicity**). In addition, ROS and RNS have frequently been implicated in changes to the permeability of epithelial (Basuroy *et al*., 2006; Han *et al*., 2004; Hashimoto *et al*., 2008; Holgate, 2007; Oshima *et al*., 2007) and endothelial (Usatyuk *et al*., 2006; Vandenbroucke *et al*., 2008) tight junctions. Pathways frequently involved in ROS-mediated alteration of tight junction permeability in different epithelia are those involving the MAPKs. Generation of ROS by direct means (i.e. metals or other redox-active substances), or via cytokines and growth factors binding to specific receptors, can transmit signals by activating MAPKs signalling pathways (reviewed in Gonzalez-Mariscal *et al*., 2008; Valko *et al*., 2007). MAPKs (ERKs, JNKs and p38 isoforms) have been involved in tight junction protein phosphorylation in both epithelia and endothelia exposed to oxidative stress, resulting in delocalization of the proteins from the junctions and increased permeability, although their exact role in barrier function appears to vary, possibly due to cell type or stimulant specificity (Gonzalez-Mariscal *et al*., 2008). In human intestinal Caco-2 cells, EGF treatment prevented the oxidative-stress-induced Tyr phosphorylation and Thr dephosphorylation and redistribution of occludin and ZO-1 from the junctions, and disruption of the actin cytoskeletal architecture by a MAPK-dependent mechanism involving direct ERK interaction with occludin (Basuroy *et al*., 2006). In a different study performed on the Caco-2 cell line, hydrogen peroxide treatment increased tight junction permeability by a delocalization of claudin 4 from the membrane, accompanied by phosphorylation of p38 MAPK. This effect could be reversed by a specific inhibitor of p38 MAPK and by exogenous expression of the protein phosphatase Wip1, a member of the serine/threonine-specific protein phosphatase type 2C (PP2C) family, that selectively dephosphorylates and inactivates p38 MAPK, but not JNK or ERK (Oshima *et al*., 2007). Recently, two secretory proteins, p40 and p75, isolated from the probiotic strain *Lactobacillus rhamnosus GG* have been reported to significantly diminish the disruption of barrier function induced by hydrogen peroxide treatment of Caco-2 cells, attenuating the delocalization of tight junction (occludin and ZO-1) and adherens junction (β-catenin

and E-cadherin) proteins from the membrane. The probiotic proteins induced the membrane translocation of two PKC isoforms (β1 and ε) and activated ERK1/2, thus blocking both PKC- and MAPK-dependent alterations to the tight junctions (Seth *et al*., 2008).

The vascular endothelium, which regulates the passage of macromolecules and circulating cells from blood to tissues, is a major target of oxidative stress, playing a critical role in the pathophysiology of several vascular diseases and disorders. Specifically, oxidative stress increases VE permeability and promotes leukocyte adhesion, which is coupled with alterations in endothelial signal transduction and redox-regulated transcription factors (Lum and Roebuck, 2001). In bovine lung microvasculature endothelial cells (BLMVECs), treatment with 4-hydroxy-2-nonenal (4-HNE), one of the major aldehydes formed during inflammation and oxidative stress, led to protein Tyr phosphorylation and actin cytoskeletal rearrangements, and activation of ERK 1/2, p38 MAPK and JNK, resulting in increased junction permeability (Usatyuk *et al*., 2006) Using two different models of the BBB, it was shown that ROS led to endothelial barrier dysfunction by cytoskeletal rearrangement, redistribution and disappearance of occludin and claudin 5, mediated by RhoA activation of phosphatidyl inositol 3 (PI3) kinase and its downstream target, PKB (Schreibelt *et al*., 2007). Overall, oxidative stress is certainly involved in the regulation of tight junction permeability, although often it is not easy to determine whether it is a primary signal or secondary to inflammatory mediators.

6.3 Metals

The study of the toxicity of metals on epithelial and endothelial barriers is relevant not only for the toxic metals (i.e. cadmium, lead and mercury) but also for those metals (i.e. iron, zinc and copper) that are essential micronutrients and play important roles in cell physiology but, at high doses, can exert toxic effects (see **Toxicology and Biological Monitoring of Metals**). A correct supply of essential metal micronutrients from the diet is therefore of primary importance, especially in certain population groups, such as children, pregnant women and the elderly, in which suboptimal metals micronutrient status can have adverse health effects. In some cases, however, supplementation not warranted by a verified deficiency can cause excess metals accumulation with possible noxious effects. This is an important point in the light of the increasing use of nonprescribed micronutrient supplements whose allegedly health-promoting effects are widely advertised. Some examples of the effects of metals on the maintenance of epithelial and endothelial barrier function will be discussed.

Iron uptake in mammals is exclusively regulated at the level of the intestinal mucosa as there is no pathway for iron excretion. Iron is an essential micronutrient but, when present in excess, it can generate oxidative stress and can be toxic (Puntarulo, 2005). In cultured human intestinal Caco-2 cells, Fe(II) treatment was reported to exert a two-phase effect: a rapid increase in tight junction permeability, associated with claudin 4 delocalization and F-actin disorganization was followed, after iron removal, by a late-phase onset of apoptosis and necrosis that was ascribed to the generation of oxidative stress (Ferruzza *et al*., 2002; 2003). *In vivo* iron overload is well known to induce toxic effects in various organs (Puntarulo, 2005), but also iron supplementation could cause damage to the intestinal mucosa, as shown by the increased intestinal permeability found in African schoolchildren who had received iron supplements (Nchito *et al*., 2006).

Zinc is an essential micronutrient that plays fundamental housekeeping roles in physiology, cellular metabolism and gene expression. Depletion of intracellular zinc in airways epithelial cells was shown to increase cytokine-induced cell barrier dysfunction (Bao and Knoell, 2006a) and to enhance apoptosis (Bao and Knoell, 2006b). In intestinal epithelial cells, zinc deficiency was found to interfere with tight and adherens junction formation by delocalization of ZO-1, occludin and β-catenin, and changes to junction protein phosphorylation, and to promote chemokines secretion and transepithelial neutrophil migration (Finamore *et al*., 2008). A specific protective effect of zinc administration on cadmium toxicity to the kidney was observed *in vivo* in rats chronically intoxicated with repeated cadmium injections. Among the toxic effects of cadmium on ionic handling, apoptosis and necrosis in several renal areas, a specific effect on tight junction organization was observed, with disorganization of claudins 2 and 3 in proximal and distal epithelium and of claudin 5 in the endothelium, while co-treatment of zinc and cadmium completely reversed these effects and reduced apoptosis (Jacquillet *et al*., 2006). The protective role of zinc against several toxic or stress stimuli has been reported in various organs (Stefanidou *et al*., 2006), although a direct role for zinc on intercellular junctions has not been described.

Human exposure to the toxic metals cadmium, lead and arsenic can result in damage to a variety of organ systems, although the mechanisms of this toxicity have yet to be fully elucidated. Recently, the results from studies on the toxicity of these metals in the kidney and the vascular epithelium have been reviewed (Prozialeck and Edwards, 2007; Prozialeck *et al*., 2008). An interesting conclusion of both reviews was that, in most cases, a primary target of metal toxicity were the molecules responsible for cell–cell adhesion in epithelia and endothelia of the various organs, and changes in adhesion properties among cells often

occurred well before cellular death. Although some evidence exists for adverse effects of lead and mercury on brain barriers function, the mechanisms involved at the level of the endothelial junctions are still largely unknown. In a previous review of the toxic effects of metals on the blood brain barriers, the need for studies on the susceptibility of brain endothelial tight junctions to metal toxicants was emphasized (Zheng *et al*., 2003).

7 BARRIER FUNCTION AND DISEASE

The effect of disease processes on barrier functions of epithelia and endothelia almost invariably results in an increase in leakiness, often reflecting changes to the permeability of tight junctions. Pathogenetic or toxic mechanisms associated with alterations in tight junction permeability in different tissues and organs include inflammation, immune-mediated or direct response to pathogens and their toxins, response to oxidative stress, and specific response to toxic substances directly or indirectly altering tight junction structure. These mechanisms are involved to a different extent in a highly heterogeneous group of diseases that are still difficult to classify but that share early impairment of epithelial or endothelial tight junction permeability.

7.1 Genetic Diseases

A special case is represented by diseases caused by single mutations in genes coding for proteins of the tight junction or other genetic defects. Examples of these have recently emerged along with better molecular characterization of junction components. A human renal disease known as familial hypomagnesaemia, characterized by renal wasting of Mg^{2+} and Ca^{2+}, is caused by a dysfunction of claudin 16, paracellin, that concentrates at the tight junction of the thick ascending limb of Henle and functions as a paracellular pore for Mg^{2+} (Simon *et al*., 1999). Another example is congenital deafness due to mutations of the gene encoding claudin 14, which normally acts as a cation-restrictive pore in the tight junctions of reticular lamina in the organ of Corti of the inner ear. In the presence of mutated claudin 14, the tight junctions are unable to maintain the proper ionic composition of the fluid surrounding the basolateral surface of outer hair cells due to incorrect recruitment of the mutated protein to the tight junction (Wattenhofer *et al*., 2005). For further details on diseases caused by genetic defects the reader is referred to some recent reviews (Cereijido *et al*., 2007; Chiba *et al*., 2008; Forster, 2008; Lai-Cheong *et al*., 2007).

7.2 Cancers

Cancers are typically multifactorial diseases, but a common trait of all tumoural cells is their ability to spread metastatically, a property directly related to their loss or down-regulation of cell–cell adhesion that, for epithelial cell-derived tumours, is initiated by loss of tight junction barrier function. This break-down of tissue organization allows entry of single cells into the blood vessels and also facilitates nutrient uptake from luminal fluids (Mullin *et al*., 2000). Several alterations of tight junction structure (i.e. reduced number of strands and structural disorganization) as well as changes in the expression of tight and adherens junction proteins have been described in different epithelial tumours (reviewed in Forster, 2008; Gloushankova, 2008; Mullin *et al*., 2000). Unlike other junction molecules, expression of claudins is often increased in various tumours. For example, claudins 3, 4 and 7 are frequently up-regulated in a variety of cancers such as those originating from the ovary, fallopian tubes, breast, uterus, prostate, thyroid, pancreas, stomach, colon and bladder (reviewed in Chiba *et al*., 2008; Morin, 2007). Although the exact roles of over-expressed claudins in cancer are unclear, expression of some claudins in epithelial cells promotes cell invasion, motility and/or survival, suggesting potential functions of these proteins in tumorigenesis and metastasis. (Hewitt *et al*., 2006). In addition, the recent characterization of the role of ZO-1-associated ZONAB transcription factor in the control of genes involved in cellular proliferation suggests a possible novel connection between the loss of tight junction barrier and the pathogenesis of some epithelial cancers (Balda and Matter, 2003; Sourisseau *et al*., 2006).

In summary, tight junctions are typically disorganized, down-regulated or simply absent from epithelial neoplasia, and these changes occur very early in the progression of the tumour. However, when dealing with specific tight junction proteins there is no general rule on whether they are down-regulated or up-regulated in the disease. But given the importance of homotypic and heterotypic interactions between tight junction components, alterations in the proportion of specific molecules can disrupt the balance on which the junction is maintained, often resulting in altered junction permeability.

7.3 Pathological Micro-organisms

One of the challenging tasks of the gastrointestinal tract is to mount an aggressive response against enteric microbes while maintaining tolerance to commensal bacteria and to food antigens. Similarly, other epithelial and endothelial barriers delimiting the internal from the external environments need to tightly control 'what to let in and what to leave out'. On the other hand, pathogens have evolved

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat159
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

ways to get across these obstacles and often utilize apical junctional complexes as sites of entry into the body, even exploiting the same mechanisms of physiological junction regulation to overcome epithelial and endothelial barriers (Vogelmann *et al*., 2004). In most cases, bacterial pathogen effects on epithelial and endothelial barriers result in inflammatory reactions that can lead to barrier dysfunction. In this section, the discussion will be restricted to some examples of pathogens that affect barrier permeability by directly interacting with structural proteins of the junction or the cytoskeleton, or by targeting regulatory elements from inside or outside the cells (**Figure 3**).

Clostridium perfringens is a common cause of food-borne and antibiotic-associated diarrhoea. *C. perfringens* enteroxin (CPE) cytotoxicity is a multistep process that initiates with the binding of CPE to an extracellular loop on claudins 3 and 4, followed by formation of SDS-resistant complexes that contain claudins and occludin (McClane, 2001; Smedley *et al*., 2007). These large complexes are thought to represent the cytotoxic pores, which create a hole in the plasma membrane, allowing Ca^{2+} influx and ultimately leading to cell death. Toxin-induced cytolytic pore formation requires residues in the NH_2-terminal half, whereas residues near the COOH-terminus are required for binding to claudins. Although the isolated claudin-binding domain, whose structure has recently been elucidated (Van Itallie *et al*., 2008a), is not cytotoxic to cultured epithelial cells, its binding increased paracellular permeability accompanied by disappearance of claudin 4, indicating a direct effect on tight junctions (Kondoh *et al*., 2005). However, the increased tight junction permeability and removal of claudins from the junctions does not appear to be linked to CPE toxicity, thus the involvement of tight junction components in the toxicity of CPE may be restricted to its role as membrane receptor for the toxin.

Bacteroides fragilis, which accounts for only 0.5% of the human colonic flora, is the most commonly isolated anaerobic pathogen, due, in part, to its potent virulence factors. Some strains produce a toxin, a zinc-metalloproteinase called fragilysin or *B. fragilis* toxin (BFT), implicated as a cause of diarrhoeal disease in farm animals and humans. The pathogenic mechanisms of *B. fragilis* in the intestine have recently been reviewed (Holton, 2008). Briefly, fragilysin binding to a still-unknown receptor on intestinal epithelial cells requires its own protease action and leads, directly or indirectly, to the hydrolysis of the extracellular domain of E-cadherin, disrupting intercellular adhesion

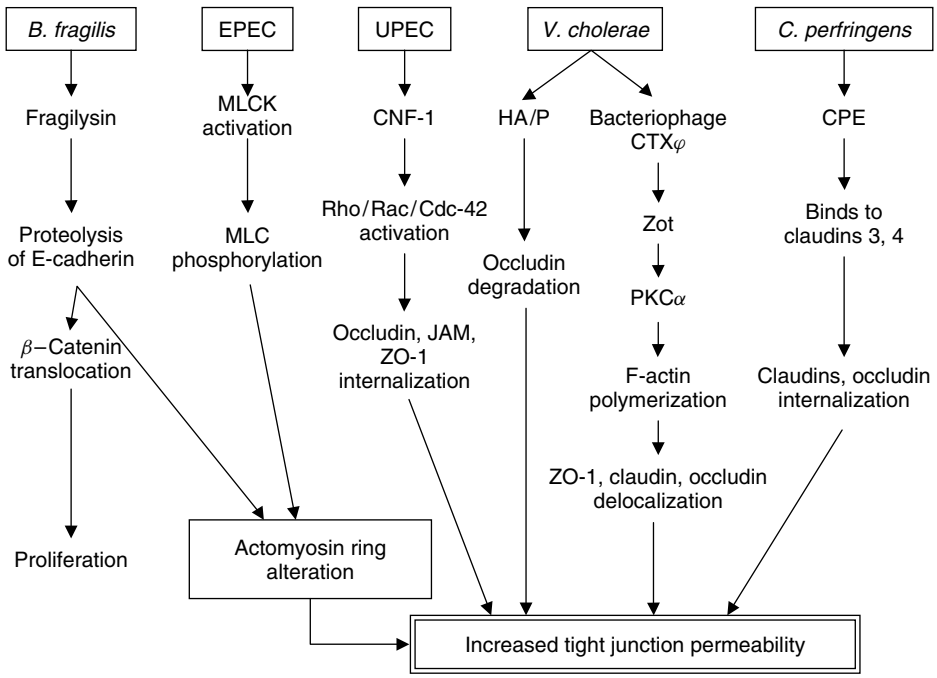

Figure 3 Epithelial tight junctions can be altered by various pathogens and their toxins. The disruption of tight junction barrier function induced by several pathogens can result from direct modification of tight junction proteins (claudins, occludin, ZO-1, JAM) or by alterations of the perijunctional actomyosin ring through activation of myosin light chain kinase (MLCK) phosphorylation of myosin 2 light chain (MLC). In addition, the proteolysis by the bacterial toxin fragilysin of the adherens junction protein E-cadherin, leading to actomyosin disruption and to proliferation, is also indicated. The regulatory pathways involved, when known, are indicated. Refer to the text for details. EPEC—enteropathogenic *E. coli*; UPEC—uropathogenic *E. coli*; PKCα—phosphokinase C member α; CPE—*C. perfringens* enterotoxin; ZOT—zonula occludens toxin.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat159

and thus increasing the permeability of the epithelium. The cleavage of E-cadherin releases β-catenin into the cytoplasm, and is accompanied by morphological changes and redistribution of F-actin. β-Catenin translocates to the nucleus, stimulates *MYC* transcription and ultimately cell proliferation. In addition, when exposed to fragilysin, colonocytes secrete cytokines (i.e. interleukin IL-8, epithelial neutrophil-activating peptide-78, and growth-regulated oncogene-α) under the control of the transcription factor NFκB and the MAPK pathways, and this leads to the induction of an inflammatory response.

Pathogenic *Escherichia coli* strains producing cytotoxic necrotizing factor 1 (CNF-1), such as the Uropathogenic *E. coli* (UPEC), have been associated with human disease including enteritis, urinary tract infections and prostatitis. The effect of CNF-1 targets the Rho family of GTPases to disrupt epithelial tight junctions. CNF-1 applied to polarized cells activates Rho/Rac-1 and Cdc-42 and blocks GTPase activity (i.e. preventing the hydrolysis of GTP to GDP), locking the Rho proteins in their GTP-bound activated state, and resulting in permanent activation of the proteins. This results in massive internalization of tight junction proteins (occludin, JAM and ZO-1) while adherens junctions remain grossly intact (Fasano and Nataro, 2004; Hopkins *et al*., 2003; Vogelmann *et al*., 2004). It has recently been shown that both pathogenic *E. coli* producing CNF-1 and CNF-2 and *Yersinia pseudotuberculosis*, producing CNF(Y), activate, by deamidation, the same Rho GTPases, although they bind to different surface receptors for internalization in host cells (Blumenthal *et al*., 2007). Others, such as the enteropathogenic *E. coli* (EPEC) have evolved two different strategies: they tightly adhere to the cell surface and modify the actin cytoskeleton beneath the attachment site, and through the secretion apparatus inject into the host cell effector molecules altering electrolyte secretion, tight junction permeability and inflammatory response. An increase in Ca^{2+} influx is associated to activation of the MLCK cascade, leading to perijunctional actomyosin ring contraction and loosening of tight junctions.

The discovery of zonula occludens toxin (Zot), an enterotoxin expressed by *Vibrio cholerae* that reversibly opens tight junctions, has greatly contributed to the understanding of some mechanisms of regulation of the intestinal paracellular pathway. Zot is a single polypeptide chain encoded by the cholera toxin bacteriophage (CTXϕ) present in the toxigenic strain of *V. cholerae*. Zot action is mediated through a cascade of events that lead to PKCα-dependent polymerization of actin microfilaments strategically localized to regulate the paracellular pathway. Zot, which is a homologue of the human intestinal zonulin, binds to the zonulin surface receptor, whose distribution along the intestine (expressed in the jejunum and distal ileum but not in the colon) coincides with the regional effect of Zot on intestinal permeability and with its preferential effect on the differentiated cells of the villi. Following binding to the zonulin receptor, Zot induces actin polymerization, followed by ZO-1–occludin and ZO-1–claudin detachment and by a down-regulation of occludin gene expression occurring only when cells are chronically exposed to the toxin (Fasano, 2008; Fasano and Nataro, 2004). *V. cholerae* also produces a haemagglutinin protease (HA/P) toxin that represents a typical example of direct effects of a bacterial protease on tight junction proteins. Epithelial cell monolayers exposed to HA/P showed decreased TER, disruption of ZO-1 and of the actin cytoskeleton, in a dose-dependent manner, as well as occludin degradation, indicating a specific effect on intestinal permeability (Wu *et al*., 2000).

7.4 Inflammatory Conditions

A central role of epithelial and endothelial barriers in the modulation and progression of several disease states has emerged for conditions ranging from IBD (Weber and Turner, 2007) to airway inflammation in asthma (Holgate, 2007) and cystic fibrosis (Coyne *et al*., 2002), coeliac disease (Fasano, 2008; Schulzke *et al*., 1998), and neuroinflammatory conditions such as multiple sclerosis, meningitis and encephalitis (Forster, 2008; Persidsky *et al*., 2006). In all these conditions, diverse and not always defined stimuli such as bacterial toxins, toxic chemicals, food allergens, and so on, can initiate an inflammatory response, leading to the secretion of pro-inflammatory cytokines that alter tight junction permeability and recruit neutrophils, macrophages and other inflammatory mediators, further contributing to tissue damage (see **Xenobiotic-Induced Inflammation: Pathogenesis and Mediators**; **Food Allergy and Intolerance**). In mucosal tissues, the inflammatory response is central to effective host defence against invading pathogens, yet must be tightly regulated to prevent abnormal responses to innocuous environmental antigens and commensal organisms which result in allergy or chronic inflammatory diseases (Kelsall, 2008).

A wide array of cytokines including tumour necrosis factor alpha (TNF-α), interferon-gamma (IFN-γ) and several interleukins, have been reported to perturb epithelial and endothelial barrier function by influencing the structure and function of the tight junction (reviewed in Capaldo and Nusrat, 2008). Although it is often difficult to determine whether the initial alteration of tight junction permeability precedes or is a consequence of early inflammatory response, tight junction dysfunction and inflammation are almost invariably associated. A vicious cycle is therefore created in which barrier dysfunction allows further leakage of contents from the extracellular milieu, thereby triggering an immune response that in turn promotes leakiness and further damage to the cells.

Impairment of the intestinal barrier was originally described *in vivo* in patients with small intestinal Crohn's disease (Hollander, 1988), but was later observed in patients or experimental models of a variety of inflammatory, immune-mediated and infectious intestinal diseases (Clayburgh *et al*., 2004). For Crohn's disease, intestinal barrier dysfunction may not only be a consequence of the inflammatory conditions but may also contribute to the activation of the disease. This early pathogenetic role of barrier dysfunction in the disease was suggested by the increased intestinal permeability in first-degree relatives of Crohn's disease patients in the absence of clinical symptoms (Weber and Turner, 2007) and by the higher risk of relapse in patients with clinically inactive disease presenting altered intestinal permeability (D'Inca *et al*., 1999; Wyatt *et al*., 1993). Recent studies have shown that in several forms of IBD (e.g. Crohn's disease, collagenous colitis, ulcerative colitis) the composition and organization of intestinal epithelial tight junctions is severely affected. A common finding in all these conditions was an elevated expression of claudin 2, the cation-pore forming claudin, a reduced number of strands and meshwork depth, and increased strand discontinuities in the tight junctions. The severity of these changes was correlated with the degree of inflammation of the tissue (Mankertz and Schulzke, 2007). High levels of the TNF-α are consistently observed in IBD, and anti-TNF-α antibodies have been shown to counteract the progression of inflammation. TNF-α has been shown to directly impair tight junction function in a number of epithelial and endothelial cell lines (Capaldo and Nusrat, 2008). However, conflicting responses to TNF-α have been reported in several systems, which may reflect cell-type-specific responses as well as experimental differences. Treatment of epithelial cells in culture with physiological concentrations of TNF-α caused increased tight junction permeability which was found to be mediated by the activation of the transcription factor NFκB, increased MLCK expression and phosphorylation, leading to contraction of the actomyosin ring (Turner, 2006; Ye *et al*., 2006). In intestinal cells, TNF-α was also reported to activate MLCK by transcriptional stimulation under the control of NFκB (Graham *et al*., 2006). The *in vitro* results on the effects of TNF-α on intestinal epithelial barrier function were also confirmed in a mouse *in vivo* model of acute immune-mediated diarrhoeal disease where epithelial barrier impairment, defined as both increased paracellular protein flux and tight junction disruption, was mediated by MLCK-dependent MLC phosphorylation. Such barrier dysfunction was required for diarrhoea to occur after T cell activation, but could be prevented by MLCK inhibition (Clayburgh *et al*., 2005). Under inflammatory conditions, target cells are simultaneously exposed to a variety of cytokines, and *in vitro* epithelial and endothelial cell models exposed simultaneously to IFN-γ and TNF-α showed increased paracellular permeability with several changes to the actomyosin ring, and localization of tight junction protein (reviewed in Capaldo and Nusrat, 2008). An interesting finding was that in intestinal monolayers the two cytokines acted synergistically towards transcriptional up-regulation of MLCK (Wang *et al*., 2005), and that IFN-γ priming of the cells activated the cell surface TNF-α receptor (Wang *et al*., 2006). Other pro-inflammatory cytokines that have been shown to alter tight junction permeability are the interleukins. IL-1β in Caco-2 cells activated MLCK by an NFκB-dependent pathway (Al-Sadi *et al*., 2008). Many other interleukins (i.e. IL-4, IL-6 and IL-13) were shown to act as modulators of tight junction components, controlling occludin, claudin and ZO-1 protein levels, leading to the formation of tight junctions with altered permeability characteristics. Conversely, IL-2 and IL-10 could antagonize the action of pro-inflammatory cytokines on tight junction permeability, although the mechanisms involved are poorly understood (Capaldo and Nusrat, 2008). The aberrant expression of claudins 2, 5 and 8 that was observed in Crohn's disease patients in inflamed intestinal segments was different to the claudins expression in noninflamed segments or in periods of remission of the same patients, suggesting that cytokines can induce tight junction remodelling and changes in claudin expression (Zeissig *et al*., 2007).

In endothelial cells, MLC phosphorylation and RhoA activation are early events after TNF-α treatment, and correlated with increased permeability (McKenzie and Ridley, 2007; Wadgaonkar *et al*., 2005). In addition, long-term effects of TNF-α treatment on endothelial cells were shown to involve occludin down-regulation and delocalization of claudin 5 and JAM-1 (McKenzie and Ridley, 2007). Disruption of the endothelial BBB has been described as a crucial step of neuroinflammatory conditions including brain tumours, cerebral ischaemia, meningitis, encephalitis and multiple sclerosis. Under normal conditions, the brain microvasculature endothelial cells form a tight barrier and limit extravasation of cells of the immune system (monocytes, lymphocytes and other leukocytes). In multiple sclerosis, an autoimmune condition characterized by myelin sheath destruction by reactive T lymphocytes, increased leukocyte extravasation was associated with endothelial tight junction disorganization (Forster, 2008). Reactive T cells interact with brain macrophages and microglial cells serving as antigen-presenting cells (Grigoriadis *et al*., 2006). Activated macrophages synthesize and produce cytokines (IFN-γ, TNF-α), matrix metalloproteinases (MMPs) and NO (Raivich and Banati, 2004). Cytokine-dependent opening of tight junctions in the BBB was shown to occur by degradation and decreased synthesis of junctional proteins, especially occludin and ZO-1 (Forster, 2008). Serum from multiple sclerosis patients induced down-regulation of occludin and VE-cadherin in cultured endothelial

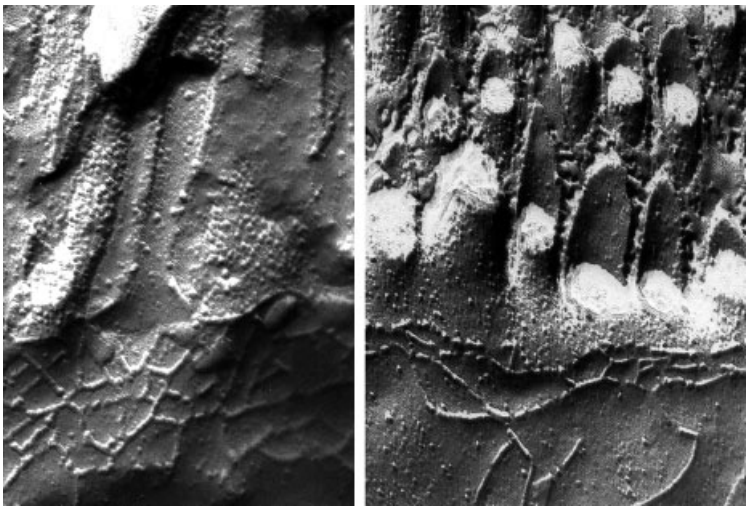

Figure 4 Freeze fracture replicas from human surface duodenal epithelium of normal (A) and of acute coeliac disease patient (B). The freeze fracture electron micrographs show the bottom part of the apical brush border and the intramembranous particle strands of the tight junctions. The mean strand count was reduced from about 5.3 in control tissue to 3.0 in the inflamed tissue from the coeliac patient (B), who also presented villus atrophy and diarrhoea. (Kindly provided by Prof. J.-D Schulzke, Dept. of Gastroenterology, Charité Berlin, Berlin, Germany.)

cells, and these effects appeared to precede massive infiltration of T lymphocytes that attack myelin sheath, forming demyelinating plaques (Minagar and Alexander, 2003).

7.5 Autoimmune Disease: Coeliac Disease

Coeliac disease is an immune-mediated enteropathy triggered by gliadin, a component of the grain protein, gluten. Gliadin consumption by affected patients leads to increased intestinal permeability, a postulated early event in the pathogenesis of coeliac disease. Mucosa of coeliac patients is characterized by a decrease in tight junction strand number in all regions of the jejunal surface–crypt axis (Schulzke *et al.*, 1998) (**Figure 4**), an indication of reduced tight junction complexity often associated with chronic inflammatory reactions, including IBD (Mankertz and Schulzke, 2007). The gliadin stimulus has been shown to activate the zonulin pathway. It has recently been shown that gliadin binds to the CXC chemokine receptor 3 (CXCR-3), and leads to MyD88-dependent zonulin release and increased intestinal permeability in cultured intestinal cells and human biopsy specimens, thus enabling paracellular translocation of gliadin and its subsequent interaction with macrophages in the submucosa. Zonulin is the mammalian homologue of Zot, that when secreted by the intestinal cells binds to its own receptor and initiates a cascade of reactions involving activation of phospholipase C, release of inositol 1,4,5-tris phosphate and diacylglycerol, activation of PKCα, phosphorylation of target proteins leading to F-actin polymerization and tight junction proteins delocalization and increased barrier permeability (Fasano, 2008). In addition, mucosal expression of CXCR-3 was found to be elevated in active coeliac disease but returned to baseline levels following implementation of a gluten-free diet (Lammers *et al.*, 2008).

8 CONCLUSIONS

Tight junctions are highly dynamic structures, undergoing rapid reorganization in response to many physiological stimuli. In the presence of toxic/pathological events the response is just as rapid and is often contrasted by the body/tissue/cellular stress responses, repair mechanisms or immune-mediated reactions. However, if the tissue is unable to rapidly restore barrier function or if the immune response is excessively or continuously activated, disruption of tight junctions can lead to uncontrolled passage of potentially harmful molecules that can then reach internal organs and elicit further toxic events. The complexity and diversity of the mechanisms involved in tight junction dysfunction in response to different toxic stimuli is often difficult to interpret. However, one simple unifying concept is that several different stimuli in epithelial and endothelial cells from different organs, through either distinct or interacting regulatory pathways, almost invariably lead to the same end point, an increase in tight junction permeability, opening the way to several local and systemic adverse

effects. Thus, in endothelia and epithelia the initial toxic effect of several substances appears to be targeted to the molecules governing cell–cell interactions, well before the onset of additional cytotoxic mechanisms leading to cell death by apoptosis or necrosis.

The importance of investigating these changes by appropriate experimental approaches is particularly relevant, as the complexity of the pathways involved and the rapidity of tight junction modulation may lead to an overestimation of final end points, while missing the initial events causing alteration of barrier properties. In addition, the use of *in vitro* cell culture models has proved very useful to dissect molecular responses to different toxic stimuli, although *in vivo* or *ex vivo* studies are required to recreate the complex interactions between epithelia and other cell types to gain insight into the development of actual disease symptoms. Results need therefore to be interpreted within the perspective of the experimental model utilized, especially in this highly dynamic and critical cell function that can be influenced by very diverse stimuli from the internal and the external environments.

Chemokines as Mediators of Toxicant-Induced Inflammation and Fibrosis

François Huaux, Sandra Lo Re and Dominique Lison

CONTENTS

1 INTRODUCTION

1.1 The Chemokine Network

Chemokines represent a large superfamily of 8–15 kDa structurally related proteins and are usually secreted upon cell stimulation. Defined by a tetra-cysteine motif, these small proteins are subdivided into four distinct families according to the configurations of the cysteine residues at their amino terminus. There are two large subfamilies: CCL1 through CCL28 and CXCL1 through CXCL16 (CXCL—cysteine X cysteine chemokine ligand), as well as two small subfamilies: XCL1 through XCL2 and CX_3CL1 (**Table 1**) (Coelho *et al*., 2005; Schuh *et al*., 2003; Panina-Bordignon and D'Ambrosio, 2003). With nanomolar affinities, all chemokines bind to seven transmembrane spanning Type V G-protein couple receptors, which are also distributed in two large subfamilies: CCR1 through CCR10 and CXCR1 through CXCR6 (CXCR—cysteine X cysteine chemokine receptor), as well as two small subfamilies: XCR1 through XCL2 and CX_3R1 (**Table 1**) (Coelho *et al*., 2005; Schuh *et al*., 2003; Panina-Bordignon and D'Ambrosio, 2003). To date, almost 50 chemokines have been identified, which exert their effects through over 20 distinct receptors. A certain degree of promiscuity exists among chemokines, with the possibility for multiple ligands to be associated with a single receptor and vice versa. Indeed, most chemokine receptors can bind multiple ligands, for example, CCR3 can bind CCL5, CCL7, CCL8, CCL11, CCL13, CCL24 and CCL26. Many chemokines are capable of binding to more than one receptor; for example, CCL5 binds to CCR1, CCR3 and CCR5. A few chemokines and chemokine receptors demonstrate exclusive binding, such as the specific CCL25/CCR9 and CXCL12/CXCR4 pairs. Recent reports show that chemokines can also act as antagonists for chemokine receptors. For example, CXCL10 is a natural antagonist of CCR3 (Coelho *et al*., 2005; Palmqvist *et al*., 2007).

Chemokines can be further separated into constitutive and inducible, depending on their mode of expression. Constitutive chemokines are expressed primarily in secondary lymphoid organs, where they play a role in leukocyte homing. Inducible chemokines are involved mainly in the recruitment of cells to inflammatory sites and comprise most of the chemokine family members. These inflammatory chemokines are generally induced to high levels of expression by inflammatory stimuli such as lipopolysaccharide (LPS), interleukin (IL)-1 or tumour necrosis factor (TNF)-α (Coelho *et al*., 2005; Schuh *et al*., 2003).

1.2 Chemokines Orchestrate Leukocyte Recruitment

Chemokines play pivotal roles in coordinating tissue leukocyte navigation. Indeed, along with adhesion

Table 1 Chemokines and their receptors

Subfamilies	Other names	Chemokine receptors
CC chemokines		
CCL1	TCA-3, I-309	CCR8
CCL2	MCP-1, MCAF, murine JE	CCR2, CCR10
CCL3	MIP-1α, LD78α	CCR1, CCR5
CCL4	MIP-1β, Act-2, HC21	CCR5, CCR8
CCL5	RANTES	CCR1, CCR3, CCR5
CCL6	C10, murine MPR-1	CCR1
CCL7	MCP-3	CCR1, CCR2, CCR3, CCR10
CCL8	MCP-2	CCR1, CCR2, CCR3, CCR5
CCL9/10	MIP-1γ, MPR-2, murine CCF-8	CCR1
CCL11	Eotaxin-1	CCR3, CCR2 antagonist
CCL12	Murine MCP-5	CCR5
CCL13	MCP-4, CKβ10	CCR1, CCR2, CCR3
CCL14	HCC-1	CCR1, CCR5
CCL15	HCC-2, MIP-1δ, MIP-5, LKN-1	CCR1, CCR3
CCL16	HCC-4	CCR1
CCL17	TARC	CCR4, CCR8
CCL18	MIP-4, DC-CK1, PARC, AMAC-1	Not known, CCR3 antagonist
CCL19	MIP-3β, ELC, Exodus-3	CCR7
CCL20	MIP-3α, LARC, Exodus-1	CCR6
CCL21	6Ckine, SLC, TCA-4, Exodus-2, CKβ9	CCR7
CCL22	MDC, STCP-1, ABCD-1	CCR4
CCL23	MIPIF-1, CKβ8	CCR1
CCL24	Eotaxin-2, MPIF-2, CKβ6	CCR3
CCL25	TECK	CCR9
CCL26	Eotaxin-3	CCR3, CCR10, CCR1,2,5 antagonist
CCL27	CTACK, ILC, murine Eskine	CCR10
CCL28	MEC	CCR10
CXC chemokines		
CXCL1	GROα, MGSAα, murine KC	CXCR2, CXCR1 (low affinity)
CXCL2	GROβ, MGSAβ, MIP-2α	CXCR2, CXCR1 (low affinity)
CXCL3	GROγ, MGSAγ, MIP-2β	CXCR2, CXCR1 (low affinity)
CXCL4	PF4	CXCR3
CXCL5	ENA-78	CXCR2, CXCR1 (low affinity)
CXCL6	GCP-2	CXCR1, CXCR2
CXCL7	NAP-2, CTA-III	CXCR2, CXCR1 (low affinity)
CXCL8	IL-8, NAP-1, MDNCF, murine MIP-2	CXCR1, CXCR2
CXCL9	MIG	CXCR3
CXCL10	IP-10, CRG-2	CXCR3
CXCL11	ITAC, β-R1, H174, IP-9	CXCR3
CXCL12	SDF-1, PBSF	CXCR4
CXCL13	BLC, BCA-1	CXCR5
CXCL14	BRAK, bolekine	Not known
CXCL15	Murine lungkine	Not known
CXCL16	—	CXCR6
C chemokines		
XCL1	Lymphotactin, SCM-1α, ATAC	XCR1
XCL2	SCM-1β	XCR1
CX_3C chemokines		
CX_3CL1	Fractalkine, neurotaxin, ABCD-3	CX_3CR1

molecules, such as integrins and selectins, chemokines and their receptors act primarily as part of a complex molecular network that facilitates the selective movement of leukocytes into and out of injured tissue. The principal targets of chemokines are bone marrow-derived cells, as motility is an essential part of their function. Chemokine downstream signalling triggers integrin activation, which enables firm adhesion of leukocytes to endothelial cells. Focal actin polymerization of the leading edge of the cell leads to forward extension. At the rear end of the cell, focal activation of myosin II and contraction of myosin–actin complexes retracts the cell, allowing migration in the direction of the chemotactic gradient (Friedl and Weigelin, 2008; Thelen and Stein, 2008; Palmqvist *et al*., 2007).

Recent evidence allowed a better understanding of how xenobiotics can lead to immune diseases and the specific recruitment of monocytes, granulocytes and lymphocytes inside the injured tissue (**Figure 1**). After recognition by the receptors of the immune innate system, resident cells produce large quantities of colony-stimulating factors (CSFs) which induce the differentiation and the mobilization of myeloid cells that populate the bone marrow. These growth factors are a family of glycoproteins playing a major role in the proliferation, differentiation and survival of primitive haematopoietic stem and progenitor cells. These factors are well identified during inflammation and mainly include M (monocyte)-CSF, G (granulocyte)-CSF and GM (granulocyte/monocyte)-CSF (**Figure 1A**). They have been demonstrated to be effective in the emergence of differentiated monocytes, granulocytes and granulocytes/monocytes, respectively (Hamilton, 2008). Leukocyte extravasation usually occurs through a multistep process, involving first the selectins, then chemoattractant receptor signalling, followed by firm adhesion to vessel walls through the actions of integrins. Thereafter, leukocytes migrate along chemotactic gradients, by means of chemoattractant receptor signalling and the actions of adhesion molecules, particularly integrins (Mackay, 2008). Classical genetic approaches, such as knockout and transgenic experiments have elegantly identified unique immunological functions for these factors and demonstrated that chemokines dictated the specific influx of particular immune cells. For instance, it is well known that monocytes/macrophages mainly migrate through CCL2 gradient after highly expressing CCR2. In the same way, CXL1, 2, 3 and 8/CXCR1 and 2 are required for neutrophil accumulation, while the CCL11/CCR3 pair is essential for eosinophil recruitment. Recently, it has been shown that other circulating cells such as fibrocytes also require the CXCL12 chemokine and the CXCR4 receptor for their efficient migration into the inflamed tissue (**Figure 1A**) (Coelho *et al*., 2005; Schuh *et al*., 2003; Kunkel, 1999). CCR4 or the CCR4 ligands CCL17 or 22 and CXCR5 are determinant factors for the entry and the positioning of T and B lymphocytes in secondary lymphoid organs (**Figure 1B**) (Acosta-Rodriguez *et al*., 2007; Bromley *et al*., 2008). Migration of dendritic cells (DCs) from tissues to lymph nodes through a gradient of CCL19 and 21 is dependent on CCR7 (**Figure 1B**) (Randolph *et al*., 2005; Sigmundsdottir and Butcher, 2008). These general chemotactic mechanisms are probably also essential for lymphocyte recruitment during toxicant-induced inflammation. Indeed, it has been observed that DCs present in the tissue may be activated after toxic agent exposure and migrate to lymphoid tissue to present and activate lymphocyte responses (Ryan *et al*., 2007). However, it is still unknown whether this lymphocyte mobilization induced by nonprotein xenobiotics is similar to that triggered by specific antigens (**Figure 1B**). The main chemokines and receptors implicated in the recruitment of the principal leukocyte populations are summarized in **Table 2**.

1.3 Resident Cells as a Major Source of Chemokines

Recent evidence demonstrates that tissue-resident cells, including fibroblasts, epithelial cells and sentinel macrophages are capable of both chemokine release and receptor expression, strongly suggesting that these cells play an early and key role in controlling local inflammatory events (Filer *et al*., 2008; Palmqvist *et al*., 2007; Coelho *et al*., 2005). Indeed, all these cells can be significant sources of chemokine production during various inflammatory responses. For example, fibroblasts produce different patterns of chemokines in response to different inflammatory alarm stimuli. Human peritoneal, synovial or corneal fibroblasts are able to release CXCL8 and CCL2 as well as increased levels of the corresponding messenger RNAs (mRNAs), when stimulated or not with LPS or pro-inflammatory cytokines such as IL-1β and TNF-α (Filer *et al*., 2008; Witowski *et al*., 2001). As with fibroblasts, epithelial cells and macrophages from various tissues have been shown to respond to immune signals by secreting an array of chemokines and expressing various chemokine receptors known to participate in immune responses (Schuh *et al*., 2003; Panina-Bordignon and D'Ambrosio, 2003; Kunkel, 1999).

Based on the fact that a very large variety of exogenous (pathogen residues) and endogenous (inflammatory mediators, cellular components) molecules strongly induced chemokine expression, it has been postulated that inflammatory toxicants can also directly activate the production of chemokines by these resident cells. Interestingly, very different types of xenobiotics such as toxic inorganic particles (e.g. silica), antibiotics (e.g. bleomycin) and industrial solvents (e.g. carbon tetrachloride (CCl_4)) can all induce the release of numerous chemokines by macrophages, epithelial

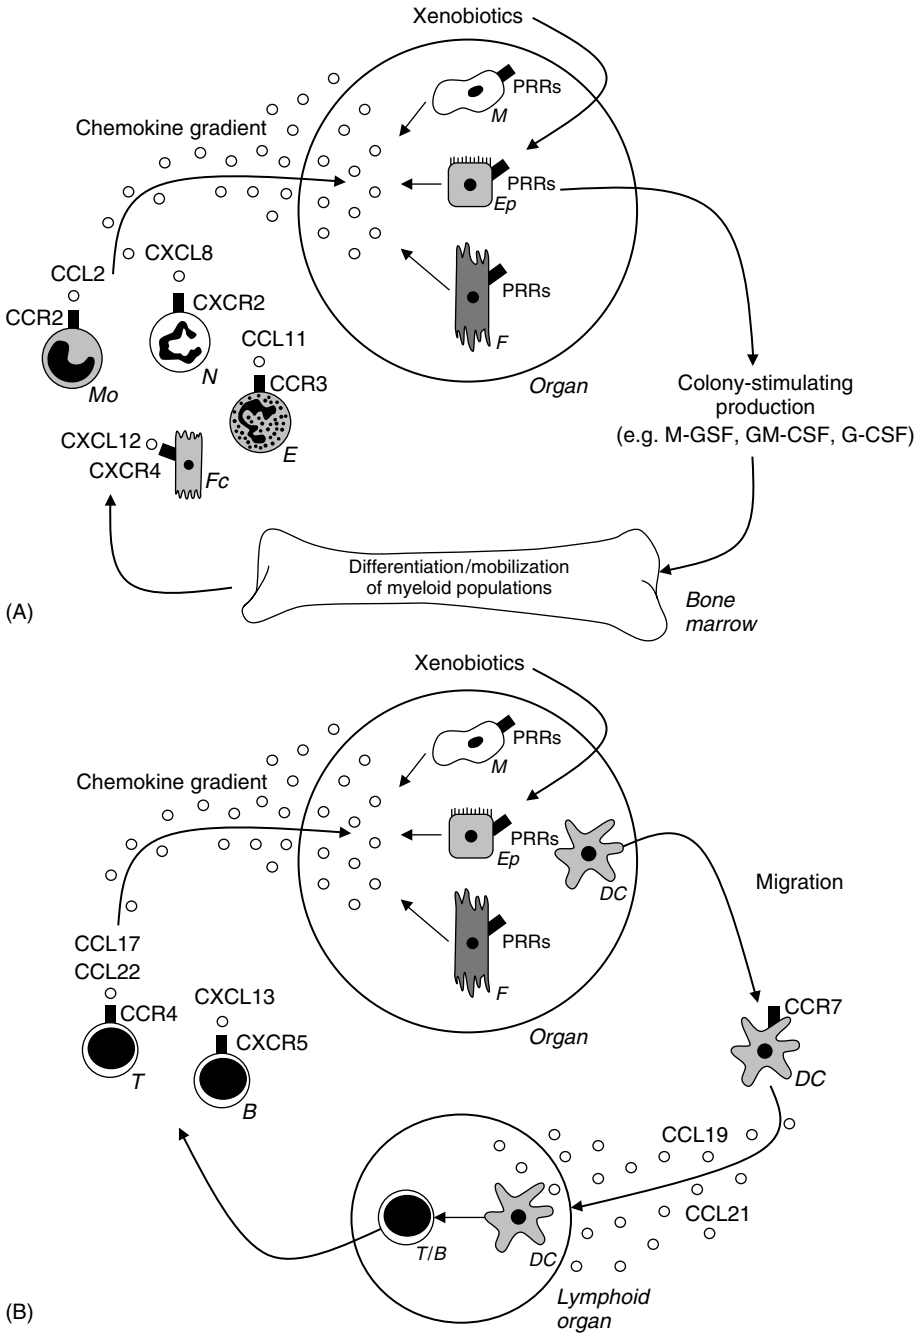

Figure 1 The role of chemokines in leukocyte infiltration in an inflamed organ after toxicant exposure. (A) After recognition of the xenobiotic by pattern recognition receptors (PRRs) of the innate immune system, tissue-resident cells such as macrophages (*M*), epithelial cells (*Ep*) and fibroblasts (*F*) release colony-stimulating factors such as granulocyte/monocyte colony-stimulating factor GM-CSF, granulocyte colony-stimulating factor G-CSF and monocyte colony-stimulating factor M-CSF. These factors communicate with the myeloid progenitors located in the bone marrow to differentiate and mobilize monocytes (*Mo*), neutrophils (*N*), eosinophils (*E*) and fibrocytes (*Fc*), and expand leukocytes that express CCR2, CXCR2, CCR3 and CXCR4 into the circulation. Chemokine receptor-expressing cells can thus traffic through the circulation and extravasate into the injured tissue in response to the specific ligands of these receptors (i.e. CCL2, CXCL8, CCL11 and CXCL12, respectively) also produced by the activated resident cells. (B) T cell (*T*) and B cell (*B*) expansion is orchestrated by xenobiotic-activated dendritic cells (*DC*) in the lymphoid organs. By expressing CCR7, these presenting cells migrate from the injured tissue to lymphoid organs through a gradient of CCL21 and CCL19 chemokines. After activation, T and B cell homing is then directed by a gradient of chemokines (i.e. CXCL17, CCL22 and CXCL13) and by the expression of CCR4 and CXCR5.

Table 2 Main chemokine receptors and chemokines for the recruitment of leukocytes

Immune cells	Chemokine receptors	Chemokines
Monocytes/macrophages	CCR1, CCR2, CCR5, CCR8	CCL2–10
Dendritic cells	CCR7	CCL19 and 21
Neutrophils	CXCR1–2	CXCL1–3 and 8
Eosinophils	CCR3–5	CCL11 and 5
T lymphocytes	CCR4	CCL17 and 22
B lymphocytes	CXCR5	CXCL13
Fibrocytes	CXCR4	CXCL12

cells or fibroblasts. Indeed, it is well detailed that lung epithelial cells exposed to silica overproduce chemokines related to neutrophil tissue accumulation such as CXCL chemokines (Driscoll *et al*., 1993; 1996; 2001). This effect appears related to the capacity of the toxic particles to promote free-radical release and pro-inflammatory TNF-α production (Barrett *et al*., 1998; 1999; Desaki *et al*., 2000; Schins *et al*., 2000; Driscoll *et al*., 2001), and requires activation of p38 and extracellular signal-regulated kinase (ERK) signalling pathways as well as epidermal growth factor (EGF) receptor activation (Øvrevik *et al*., 2006; 2004). Silica-exposed pulmonary macrophages also release significant amounts of CXCL chemokines by similar activation pathways (Barrett *et al*., 1998; 1999; Kanj *et al*., 2006). These *in vitro* effects are not limited to noxious particles, since bleomycin or CCl_4 also induced the expression of CXCL8 or CXCL10 by endothelial cells and hepatocytes (Fichtner *et al*., 2004; Holden *et al*., 2000; Koniaris *et al*., 2001). The contribution of resident cells to the local cytokine/chemokine environment is thus an important consideration when assessing the deleterious activity of toxicants. However, it is important to keep in mind that all recruited leukocytes have the potential to actively participate in chemokine production as demonstrated for recruited and activated macrophages, neutrophils, eosinophils and lymphocytes trafficking through inflamed tissues (Schuh *et al*., 2003; Coelho *et al*., 2005).

1.4 Chemokines and Toxicant-Induced Diseases

Several lines of evidence support the view that the pathogenesis of some toxicant-induced inflammation and fibrosis involves uncontrolled immune processes. The fundamental concept usually put forward to explain the pathogenesis of these diseases is relatively simple and can be presented as follows: resident cells sense xenobiotics by innate immunity receptors and produce chemokines and CSFs which orchestrate specific influxes of inflammatory cells invading the toxicant-injured organ. The chronic recruitment of leukocytes exacerbates initial injuries and damages and destructs organ architecture as these cells are activated to release toxic mediators. By overproducing growth factors, chronically recruited leukocytes also pilot the exaggerated accumulation of mesenchymal cells and their connective tissue, leading to an unsolved fibrotic reaction (Huaux, 2007; Rimal *et al*., 2005; Fujimura, 2000). It is very intriguing that tissue inflammation and fibrosis appear after exposure to very diverse agents (chemical or not, inorganic or organic) and in different organs, suggesting that similar pathogenic pathways leading to these severe disorders exist and potentially involve a comparable network of mediators. This is particularly true for the chemokine network, since it is becoming evident that the pathophysiological responses to toxicants include a critical and general role of a set of chemokines implicated in differentiation, activation and mobilization of the inflammatory cells and the fibroblasts. This is particularly well illustrated by the macrophage-related chemokine CCL2 and its major receptor CCR2, which are both essentials for the development of lung or liver inflammatory and fibrotic reactions induced by silica, bleomycin or CCl_4.

In the following sections, we focus on the role of chemokines in regulating tissue inflammation and fibrosis after exposure to harmful agents by reviewing data from animal models of lung and liver toxicity.

2 CHEMOKINES REGULATE TOXICANT-INDUCED INFLAMMATION

Understanding how toxicants trigger immune cellular responses and chemokine production is crucial in order to elucidate what characteristics determine their harmful effects. New lines of evidence suggest that pattern recognition receptors (PRRs) recognizing viral and bacterial pathogens also sense and recognize xenobiotics. Indeed, recent studies have shown that scavenger receptors, essential for micro-organism recognition by the innate immunity, such as MARCO

(macrophage receptor with collagenous structure), are responsible for the uptake of silica particles, free radical production and cytokine up-regulation, as well as cell death signalling in macrophages (Hamilton *et al*., 2006; Brown *et al*., 2006). The aryl hydrocarbon receptor (AHR), a ligand-dependent transcription factor best known for mediating the toxicity of dioxins, is essential for the establishment of T helper-17 (Th17) lymphocyte responses and the release of pro-inflammatory cytokines such as IL-22, strongly inducing the production of CXC chemokines and colony-stimulating factors necessary for granulocyte differentiation and recruitment (Veldhoen *et al*., 2008). In addition this receptor plays a central role in CCL1 and CXCL8 production in macrophage cultures after exposure to specific AHR ligands (Podechard *et al*., 2008; N'Diaye *et al*., 2006). After activation, the amplification cascade of chemokine expression is dependent on the inflammatory mediators released during the establishment of inflammation itself. Indeed, chemokine induction is also clearly mediated by the pro-inflammatory mediators produced at the site of inflammation such as the pro-inflammatory cytokines TNF-α and IL-1β. Importantly, endogenous molecules released during tissue and cell injury, such as fibrinogen, elastase and defensins, for example, are also capable of inducing chemokine production through PRRs such as Toll-Like-Receptors (Devaney *et al*., 2003; Smiley *et al*., 2001).

Because toxicants directly induce the release of chemokines by resident cells *in vitro,* toxicologists tested the relevance of these observations *in vivo.* First, all the toxic compounds reviewed here are able when administered in mice or rats to induce a marked expression of several chemokines. In the lung, bleomycin or silica markedly increase the expression by macrophages and epithelial cells of chemokines, orchestrating the recruitment of macrophages (CCL1 and CCL2), neutrophils (CXCL1 and CXCL2) or eosinophils (CCL11) (Smith *et al*., 1994; 1996; Smith, 1996; Driscoll *et al*., 1993; Keane *et al*., 1999; Huaux *et al*., 2005). Remarkably, these CXC and CC chemokines were also increased in the liver of animals treated with CCl_4 (Czaja *et al*., 1994; Kanno *et al*., 2005). The abrogation of these chemokines or their receptors by neutralizing antibodies or by using genetically deficient mice has generally led to a significant reduction of the leukocyte accumulation during the inflammatory stage. Driscoll and coworkers were the first to show that antibodies against CXCL2 reduced neutrophil infiltration in the lung of silica-exposed rats (Driscoll *et al*., 1996). On the same line, inhibition of CCR1, CCR2, CCL2 or CCL3 signalling in mice demonstrated that these elements are required for monocyte/macrophage recruitment in lung or liver after bleomycin or CCl_4 treatment, respectively (Smith *et al*., 1996; Smith, 1996; Baran *et al*., 2007; Zamara *et al*., 2007; Campbell *et al*., 2005). With a similar approach, the authors demonstrated the requirement of CCL11/CCR3 for effective eosinophil recruitment induced by the toxic antibiotic bleomycin (Huaux *et al*., 2005). However, additional studies concluded that the inhibition of one chemokine is not systematically associated with limitation of one particular type of leukocyte. Indeed, inhibition of CCL2 and CCL3 as well as CCR3 resulted in macrophage, eosinophil but also neutrophil depletion after injection of bleomycin in mice (Kimura *et al*., 2007; Ferreira *et al*., 2006; Ishida *et al*., 2007). Furthermore, reducing CXCL1, CXCL2 or CXCL3 activity with blocking antibodies or receptor antagonists was ineffective in limiting the lung accumulation of neutrophils induced by bleomycin (Russo *et al*., 2009; Keane *et al*., 1999). Additionally, overexpression of CXCL1 in the liver was associated with acute hepatotoxicity without a concomitant infiltration of neutrophils (Stefanovic *et al*., 2005). These findings illustrate the fact that the chemokine network is complex and very imbricate.

One of the interesting aspects regarding chemokines is the ability of pro-inflammatory cytokines to regulate the expression of chemokines. It has long been appreciated by *in vitro* approaches that early response cytokines such as TNF-α and IL-1β are potent inducing agents for the expression of a variety of chemokines. In an effort to better understand by which mechanisms chemokines are constantly overexpressed after toxicant exposure, researchers tested whether these *in vitro* findings were applicable *in vivo.* The pro-inflammatory cytokine TNF-α and the activation of nuclear factor kappa B (NFκB) appeared to be essential mediators of chemokine overexpression (i.e. CXCL2–3, CCL2–3) in silica-treated mice but also after bleomycin or CCl_4 treatments in animals (Hubbard *et al*., 2002; Pryhuber *et al*., 2003; Driscoll, 2000; Smith *et al*., 1996; Smith, 1996; Baran *et al*., 2007; Simeonova *et al*., 2001; Campbell *et al*., 2005; Czaja *et al*., 1994).

For decades, many human and animal studies have confirmed the involvement of various chemokine receptors or ligands in inflammatory disease models, from asthma to rheumatoid arthritis, sepsis and transplantation, which makes chemoattractant receptors promising targets of anti-inflammatory drugs (Mackay, 2008). Interestingly, some authors tried to also control and regulate xenobiotic-induced chemokine expression and inflammation through an anti-inflammatory strategy. First, it has been shown that the anti-inflammatory cytokine IL-10, well known to regulate exaggerated immune responses, is able to limit CXC chemokine expression after silica treatment, for instance (Driscoll *et al*., 1998). Also, other inhibitors have been proposed and studied with success in the liver after CCl_4 treatment, such as the CCL1 and CCL2 antagonist, SKL-2841, or cluster differentiation (CD)44 agonists (Kimura *et al*., 2007; 2008).

3 CHEMOKINES ARE IMPLICATED IN XENOBIOTIC-INDUCED FIBROSIS

The inflammation induced by toxicants is often followed by a reparative phase in which polypeptide growth factors stimulate the recruitment and the proliferation of mesenchymal cells as well as regulate neovascularization and re-epithelialization of injured tissues. Tissue repair is accomplished by extracellular matrix deposition (mainly collagens I and III, fibronectin and proteoglycans) and tissue remodelling. During this phase, abnormal or uncontrolled reparative mechanisms may result in the development of fibrosis. Macrophages but also epithelial cells and recruited inflammatory cells are able, when appropriately activated, to release a number of potent polypeptide growth factors for mesenchymal cells, such as the fibrogenic cytokines TNF-α, IL-1 and transforming growth factor-β (TGF-β), and the growth factors such as platelet-derived growth factor (PDGF) and insulin-like growth factor (IGF) and fibronectin (Huaux, 2007; Rimal *et al*., 2005; Gulumian *et al*., 2006).

In vivo, it was first hypothesized that the participation of chemokines in fibrosis should be linked to their leukocyte chemotactic activity. Indeed, activated leukocytes are known to be potent sources of mediators modulating the biology of fibroblasts (Huaux, 2007). This postulate was supported by numerous studies documenting the reduced fibrotic process that went paired with reduced leukocyte infiltration. For instance, neutralizing antibodies directed against CCL2 or CCL3 not only reduced bleomycin-induced pulmonary mononuclear phagocyte accumulation but also fibrosis, clearly supporting the notion that leukocyte influx is linked to fibrosis (Smith *et al*., 1994; 1996; Smith, 1996). These conclusions were confirmed by neutralizing the main receptors of these two CC chemokines, that is, CCR1 and CCR2 (Tokuda *et al*., 2000; Baran *et al*., 2007). Again, similar mechanisms and mediators appear crucial in toxicant-induced liver fibrosis because CCL2 is intimately linked to the amplitude of fibrosis, and a treatment abrogating CCL2 blocked liver fibrosis as in the lung (Tsuruta *et al*., 2004; Kanno *et al*., 2005). Importantly, the authors of these studies argued that the limitation of fibrosis was associated with a reduced number of macrophages during the establishment of the disease. They also observed that activation and functions of these cells were also related to the chemokines/receptors. For instance, absence of CCR2 impaired the production of matrix metalloproteinase (MMP) by purified macrophages after bleomycin treatment (Okuma *et al*., 2004). Besides macrophage-related chemokines, those implicated in the influx of eosinophils and neutrophils seem to be important for fibrosis as well. For instance, CCR3 deficiency protected against bleomycin inducing lung fibrosis. Additionally, injection of the CCR3 ligand, CCL11, enhanced eosinophil and neutrophil recruitment and bleomycin-induced fibrosis (Huaux *et al*., 2005).

The beneficial antifibrotic activity provided by CXC or CC chemokine and receptor blockade was, however, not systematically accompanied with a similar reduction of leukocyte infiltration in several pioneer studies. This strongly suggested new profibrotic functions of chemokines with a minimum participation of inflammatory cells. For instance, CXCL2 depletion with antibody treatment reduced bleomycin-induced lung fibrosis without a change in the presence of pulmonary neutrophils (Keane *et al*., 1999). Similarly, lung fibrotic pathology was improved by treatment with the CXCR2 receptor antagonist DF2162 without interfering with neutrophil accumulation in the pulmonary parenchyma in bleomycin-treated mice (Russo *et al*., 2009). Again, observations made in the lung appear similar in the liver. Indeed, induced overexpression of CXCL1 in the liver of CCl_4-treated mice increased synthesis of Type I collagen without accumulation of neutrophils (Stefanovic *et al*., 2005). Finally, by studying the role of CCR4 in lung fibrosis after bleomycin treatment, Trujillo and coauthors demonstrated that this chemokine receptor plays a central role in fibrosis by regulating macrophage differentiation and activation instead of modulating lymphocyte recruitment (Trujillo *et al*., 2008).

Fibroblasts highly express chemokine receptors (Filer *et al*., 2008) and can therefore be directly activated by chemokines produced by the injured tissue after toxicant exposure, and may potentially contribute to uncontrolled fibroproliferative repair. Several studies, thus, explored the potential direct profibrotic functions of diverse chemokines expressed during the pathological inflammatory and fibrotic process induced by silica, bleomycin or CCl_4. Interestingly, addition of recombinant CXCL1 or CCL2 to lung, hepatic or skin fibroblasts in culture increased secretion and processing of Type I collagen (Gharaee-Kermani *et al*., 1996; Yamamoto and Nishioka, 2003; Stefanovic *et al*., 2005). In addition, Gharaee-Kermani and colleagues reported that CCR2 signalling regulates *in vitro* fibroblast responsiveness to TGF-β and fibrogenic cytokine expression (Gharaee-Kermani *et al*., 1996; 2003).

Not all chemokines possess profibrotic functions. Indeed, the CXCL10 and CXCL11 ligands of the CXCR3 receptor attenuate bleomycin-induced pulmonary fibrosis via inhibition of vascular remodelling (Burdick *et al*., 2005). In the same model of lung fibrosis, limitation of the tissue fibroproliferation by the activation of CXCR3 was mediated, in part, by the innate production of interferon (IFN)-γ, a well known antifibrotic cytokine (Jiang *et al*., 2004). Finally, other authors also observed that CXCL10 directly attenuated lung fibrosis by limiting migration and recruitment of fibroblasts in bleomycin-treated mice (Tager *et al*., 2004). The beneficial activity of CXCR3 ligands may represent a novel

therapeutic strategy for pulmonary disease, which could have applicability to a wide range of fibrotic illnesses.

Altogether, these experimental approaches using knockout and transgenic experiments have clearly highlighted that chemokines possess very diverse and multiple functions during the establishment of inflammation and fibrosis and are certainly not only simple chemotactic factors.

4 MULTIPLE ROLES OF CHEMOKINES

It is now recognized that chemokines play important roles in several activities including maintenance of homeostasis, angiogenesis/angiostasis, cellular differentiation and activation, tumour growth and metastasis, lymphocyte homing and development of lymphoid tissue, and influencing the overall Type 1/Type 2 balance of immune response (Strieter *et al*., 2007; Coelho *et al*., 2005). In this context, a variety of investigations provided evidence that specific chemokines are important factors for angiogenesis and fibrocyte tissue accumulation after toxicant exposure.

Indeed, it has been reported that samples from lungs of bleomycin-treated mice have a marked angiogenic activity; that is, almost entirely attributable to overexpression of the angiogenic CXC chemokines CXCL2 and CXCL3 and the relative down-regulation of the angiostatic CXC chemokines CXCL10 and CXCL11. Moreover, when endogenous CXCL2 and CXCL3 were depleted or when exogenous CXCL10 or CXCL11 was administered to the animals during exposure to bleomycin, a marked attenuation of pulmonary fibrosis was observed that was entirely attributable to a reduction in angiogenesis in the lung (Keane *et al*., 1997; Strieter *et al*., 2007). Taken together, these findings support the notion that CXC chemokines are important angiogenic and angiostatic factors balancing the development of vascular remodelling, and are critical to promote fibrosis after exposure to bleomycin. Interestingly, neutralization of CXCL10 with antibodies stimulated hepatocyte proliferation and facilitated remodelling of hepatic cords in CCl_4-induced acute liver injury (Yoneyama *et al*., 2007). The exact function of CXCL10 in chronic responses to CCl_4 is not determined, but it can be supposed that this chemokine may facilitate uncontrolled liver remodelling and fibroproliferative repair as observed in the lung. It is still unknown whether chemokines regulating angiogenesis are also important in the development of fibrosis after silica administration.

Previously, circulating fibrocytes have been shown to express several chemokine receptors, and to respond chemotactically to the cognate ligands, thus suggesting their possible roles in recruitment of bone marrow progenitor cells (Lama and Phan, 2006; Gharaee-Kermani *et al*., 2007). Fibrocytes express CD34 and CD45, two leukocyte markers, and appear to have the capacity to differentiate to tissue fibroblasts and myofibroblasts. Induction of CCL21 and CXCL12 in bleomycin-injured lung tissue, and their respective cognate receptors, CCR7 and CXCR4 in fibroblasts from injured lungs, suggests recruitment of these extrapulmonary progenitor cells via these chemokines (Hashimoto *et al*., 2004; Phillips *et al*., 2004). This is supported by evidence that CXCR12 neutralizing antibodies (Phillips *et al*., 2004) or CXCR4 antagonists (Xu *et al*., 2007) reduce recruitment of fibrocytes and bleomycin-induced pulmonary fibrosis. The CCL3/CCR5 pair is apparently also important for fibrocyte infiltration during the experimental lung fibrosis (Ishida *et al*., 2007). In this study, recruited fibrocytes represented the main producers of the profibrotic cytokine TGF-β besides macrophages. Thus, bone marrow progenitor cells can be mobilized and recruited to tissues in response to chemokine signals released from the injured tissue (Gharaee-Kermani *et al*., 2007; Lama and Phan, 2006). It is uncertain whether fibrocytes may also play a pivotal role after silica or CCl_4 injection as observed with bleomycin. However, liver injury and fibrosis in mice is associated with the marked accumulation of collagen-producing fibrocytes, suggesting that these cells participate in the pathogenesis of the fibrotic disease in the liver, potentially through the regulation of chemokines (Kisseleva *et al*., 2006). The fact that the CXCR4/CXCL12 interaction plays a role in stem cell homing towards the CCl_4-damaged liver strongly supports the notion that fibrocytes are important during experimental liver fibrosis (Jung *et al*., 2006).

5 CONCLUSIONS

Chemokines represent a remarkable superfamily of immune mediators strongly implicated in the development of diseases. Although chemokines initially attracted attention as chemoattractants for immune cells, they are now known to play essential roles in cellular differentiation and activation. This view is also shared by toxicologists exploring the role of chemokines in the establishment of tissue inflammation and fibrosis induced by certain toxic agents. The exact cascade of events implicated in chemokine functions in these disorders is now better identified and can be summarized as follows: probably initiated by the activation of receptors of the innate immunity, toxicants induce tissue injury and expression of chemokines which initiate accumulation of numerous leukocytes into the tissue. The early pro-inflammatory cytokines produced conjointly amplify and maintain chemokine production. The persistence of this chemokine overexpression loop sustains chronic inflammation and plays pivotal roles in the development of abnormal fibroproliferative repair by

Oncology Biomarkers

Michael A. Tainsky

CONTENTS

1 INTRODUCTION

1.1 Overview

Tumour biomarkers are molecules often produced by the tumour itself or the host system in response to the tumour, and provide the biological material to determine the risk of getting cancer, to detect cancer, to classify cancer, or to provide insight into prognosis and therefore a therapeutic advantage. Tumour biomarkers include cancer-specific mutations or changes in gene expression or promoter methylation, which can result in alterations in protein expression. Because cancer cells shed DNA and RNA in the circulation, a phenomenon rarely seen in healthy individuals, tumour-specific genetic changes such as promoter methylation, gene mutations or circulating small RNAs are detectable in nucleic acids prepared from plasma or other body fluids. Biomarker proteins, either overly abundant or variant proteins, can be detectable in the circulation as the free, shed proteins or as novel autoantibodies to such proteins; the latter indicating that the host immune system can be exploited as biosensor of the disease. In addition, tumour-specific biochemical changes result in post-translational modification of proteins via glycosylation or phosphorylation, providing a variety of biomarker molecules. Cancer-related biochemical changes often effect measurable metabolic variations within a cell or organism, which may be powerful biomarkers.

Cancer biomarkers are discovered and utilized with a specific purpose in mind, such as the (i) early detection

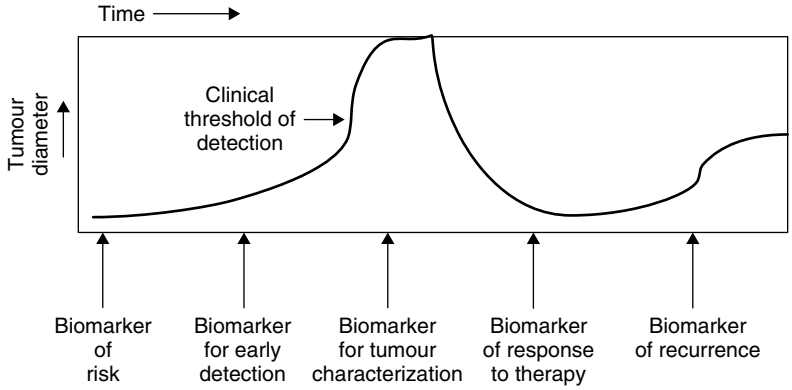

Figure 1 Different biomarkers for different stages of cancer progression. Biomarkers are employed for risk assessment, early detection, determining the mechanism of cancer development, response to therapy and cancer recurrence.

of cancer, (ii) diagnosis, (iii) prognosis, (iv) response to anticancer therapies, or (v) detection of cancer recurrence (**Figure 1**). Cancer cells provide the biomarker material that can lead to their own detection, which then provides the opportunity for their noninvasive detection in body fluids and tissues so as to reveal the presence of tumours or the level of tumour burden. Biomarkers for cancer diagnosis, prognosis and response to therapy became possible through elegant studies of specific carcinogenic mechanisms (McGuire, 1973; Heisterkamp *et al*., 1985; Slamon *et al*., 1987), leading to the development of clinical tests capable of predicting the optimal or targeted therapeutic approach for a given cancer. Alternatively, well-powered biomarker discovery projects have also led to clinical tests for therapeutic decisions for some cancers (Paik *et al*., 2004; 2006; Wolf *et al*., 2008; Lyman *et al*., 2007; van 't Veer *et al*., 2000; van de Vijver *et al*., 2002; Sotiriou *et al*., 2006).

There is an emerging expectation that panels of biomarker analytes rather than single markers will be required, to have sufficient sensitivity and specificity for the diagnosis or prognosis of cancer. This realization became apparent from the failure of single biomarkers to be adapted for clinical practice. The need for panels of biomarkers, specific for each cancer, is based on the experience from decades of molecular oncology research that has demonstrated molecular complexity of human carcinogenesis even within single cancer sites.

Biomarkers hold tremendous promise not only for diagnostic devices and to improve the effectiveness of clinical interventions, but also to stratify oncology patients to the most appropriate treatment. However, early detection must provide a patient with better survival, which ultimately can translate to more efficient delivery of healthcare. For example, early detection technologies applied to population-based screening for cancer of the cervix, colon and breast have resulted in reductions in disease-associated mortalities from cancers that are deadly if allowed to progress to an advanced stage. These screening approaches are technology driven but have proven that early detection will reduce the morbidity and mortality from cancer.

Biomarkers often can provide prognostic information of disease enabling intervention with the appropriate therapeutic agent and early decisions or corrections of cancer treatment. There has been a burst of novel technologies that are being used to discover and validate tumour biomarkers individually and where necessary in panels or combinations of biomarkers. Although biomarkers have the potential to provide personalized diagnostic, prognostic and therapeutic information for the individual patient, the devices to implement them clinically must ensure that healthcare providers have clear algorithms for step-by-step implementation for their patients.

2 BIOCHEMICAL ANALYTES AS ONCOLOGY BIOMARKERS

There are numerous analytical biochemistry approaches to identify and validate biomarkers. In the context of this chapter we will focus on three general areas of analytes, nucleic acids, and proteins and metabolites.

2.1 Nucleic Acid Biomarkers

2.1.1 RNA Expression Profiling

The identification of gene expression profiles for stage- or prognosis-specific classification of cancer patients is the future of biomarker-driven patient management. Gene expression profiles can be more effective than more standard methods of patient stratification such as histopathology biomarkers. To validate such biomarkers clinically using fresh or archived clinical samples, the RNA preparations must have minimal degradation or alternatively use gene measurement technologies that are not overly sensitive to some reduction in the RNA size.

Gene expression profiling coupled with well-designed bioinformatics methods has greatly facilitated the identification of genes and pathways that regulate cellular changes critical to cancer development and molecular targets of personalized medicines. The microarray screening procedures are quite reproducible but require biological replicates or multiple samples from a particular class of sample to eventually be able to use the biomarkers for class prediction on an independent validation set. In addition, the microarray technologies tend to underestimate the true changes in gene expression, so that additional validation using reverse transcription polymerase chain reaction (RT-PCR) or northern blot analysis is necessary to have confidence in the results. In principle, the particular changes in gene expression between classes of samples may be less informative than the pathways they impact. There are numerous software approaches to pathways analysis for a given gene expression dataset. Those that weight the impact of the particular genes provide additional guidance on the identification of shorter lists of biomarkers (Okuda *et al*., 2008; Segota *et al*., 2008; Draghici *et al*., 2007; Khatri *et al*., 2007).

2.1.2 DNA Sequencing

DNA sequencing is commonly used in research to identify genetic changes in candidate genes. The use of DNA sequences as diagnostic markers is entering into clinical practice for the detection of DNA sequence variants, disease-specific single nucleotide polymorphisms or small insertions or deletions in genes. Somatic changes in DNA sequences are present in tumour tissue but not present in the normal tissue from the same person. The selection of somatic DNA sequence changes is thought to be a critical part of the carcinogenic process resulting in alterations in important growth regulatory genes. Oncogenic DNA sequence variants are useful diagnostic biomarkers and have provided specific molecular targets for cancer therapies, as the altered proteins resulting from these mutations are pharmacologic targets. Large-scale sequencing of numerous candidate genes is providing new biomarkers for studies of diagnosis and prognosis of lung, germ-cell, colorectal and breast cancers (Davies *et al*., 2005; Bignell *et al*., 2006; Ding *et al*., 2008; Leary *et al*., 2008; Marguerat *et al*., 2008). Somatic DNA sequence analysis has expanded recently from such candidate gene studies to genome-wide high-performance DNA sequencing, leading to whole genome analysis of DNA sequence variations in tumours (Ley *et al*., 2008).

2.1.3 Epigenomics

There are several normal cellular processes that are regulated in part by epigenetic modification through DNA methylation, including developmental imprinting, X chromosome inactivation and tissue-specific gene expression. Aberrant chromatin-remodelling mechanisms, such as DNA methylation and histone acetylation, are epigenetic modifications that have been observed in tumour tissues leading to the inhibition of tumour suppressor gene expression. Understanding these mechanisms may provide biomarkers of response for cancer chemotherapy. Drugs targeting such epigenetic changes have not yet been developed into gene-specific therapies. DNA methylation, histone deacetylase inhibitors and poly-adenosine diphosphate (ADP)-ribosylation inhibitors are in clinical trials and may provide novel tools to enhance classical chemotherapies or other targeted therapies, potentially activating tumour suppressors or other key checkpoint genes.

Aberrant promoter methylation has been found in growth suppressive genes in human tumorigenesis (Baylin *et al*., 2000; Baylin and Herman, 2000; Esteller *et al*., 2001; Feinberg *et al*., 2002). CpG (cytidine-phosphate-guanine) dinucleotides are typically methylated. In contrast, CpG islands, which are CpG-rich stretches of DNA ranging from 200 to 2000 bp in length in the regulatory regions of genes, are generally unmethylated. The transfer of a methyl group from *S*-adenosyl-L-methionine to the cytosines in CpG sites is catalysed by DNA-methyltransferases (DNMTs) (Lopatina *et al*., 2002). There are three well-characterized DNMTs: DNMT1, DNMT3A and DNMT3B. DNMT1, the most abundant DNMT, is mainly responsible for maintenance methylation, while DNMT3a and DNMT3b are responsible for *de novo* methylation (Lopatina *et al*., 2002).

In human cancers, the silencing of tumour suppressor genes through aberrant DNA methylation of a CpG island(s) in the promoters in these genes is a common epigenetic change (Baylin and Herman, 2000). There is an assortment of pathways from which genes have been shown to be hypermethylated in cancer cells, including DNA repair, cell cycle control, invasion and metastasis. The tumour suppressor genes *BRCA1* (hereditary breast cancer gene 1), $p16^{INK4a}$, $p15^{INK4b}$, $p14^{ARF}$, $p73$ and *APC* (adenopolyposis coli, colon-cancer-predisposing gene) are among those that are silenced by hypermethylation, although the frequency of aberrant methylation is somewhat tumour type specific (Esteller *et al*., 2001). Aberrant hypermethylation of DNA can be reversed with chemical agents that inhibit DNMTs, which in effect 'demethylate' DNA. A commonly used inhibitor of DNMT is 5-aza-deoxycytidine (5-aza-dC), a cytosine analogue. 5-aza-dC and related drugs work by substituting for cytosine during replication. DNMTs recognize and covalently bind 5-aza-dC in DNA. The covalently bound DNMT1 is unable to catalyse the transfer of methyl groups to the cytosine analogue because the substituted nitrogen base cannot be methylated. Consequently DNMT1 is depleted following several rounds of replication. This in turn results in DNA hypomethylation

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and the expression of genes that were silenced by methylation (Haaf, 1995; Kanai *et al*., 2001; Takebayashi *et al*., 2001). Higher throughput methods are being developed to identify larger panels of methylation biomarkers for disease detection and tumour progression (Adorján *et al*., 2002; Bibikova *et al*., 2006; Ordway *et al*., 2006). From such studies, panels of biomarkers for individual cancers are being developed for early detection and response to chemotherapy (Belinsky *et al*., 2005; Weaver *et al*., 2006; San-Miguel *et al*., 2005; Gonzalez-Paz *et al*., 2007; Hoque *et al*., 2006; Jiao *et al*., 2007; Hsu *et al*., 2007; Chim *et al*., 2007; Tsou *et al*., 2007; Lofton-Day *et al*., 2008; Ibáñez de Cáceres and Cairns, 2007; Grützmann *et al*., 2008; Rimel *et al*., 2009; Altimari *et al*., 2008; Frattini *et al*., 2008). There are going to be difficulties in developing standards for implementation in a clinical setting (Barker *et al*., 2006), particularly as a major direction of this field is the early detection of cancer using methylation of circulating tumour DNA in plasma (Esteller *et al*., 1999; Rouprêt *et al*., 2008; Jin *et al*., 2007; Hampton, 2007; Hoque *et al*., 2006).

2.1.4 MicroRNA

Another form of epigenetic modification of gene expression and post-translational alteration of protein expression is through microRNA (miRNA or miR)-related mechanisms. miRNAs are synthesized by RNA polymerase II as long transcripts that are processed to pre-miRNAs. Some miRNAs are transcribed by RNA polymerase III (Borchert *et al*., 2006). Two RNase III-related enzymes, Drosha and Dicer, process the maturation of the miRNAs (Lee *et al*., 2003). In the cytoplasm, Dicer processes the pre-miRNA into a 22-nucleotide double-stranded miRNA, and then one strand of the RNA is degraded. The other strand, as part of the RNA-induced silencing complex (RISC), targets the 3′ untranslated region of specific messenger RNAs (mRNAs), destabilizing the target mRNA(s) or repressing their translation (Lai, 2002). Screening for miRNA expression levels is routinely performed using array technologies to obtain a miRNome profile and validation/confirmation performed using northern blot, RNase protection assay or primer extension assay. Quantitative RT-PCR, *in situ* hybridization (Wienholds *et al*., 2005) and serial analysis of gene expression (SAGE) have also been applied to these small RNAs (Cummins *et al*., 2006).

Although the existence of miRNAs in humans has only been recognized for less than a decade, the flurry of activity has identified roles for them in normal development and numerous diseases including cancer, leading to a Nobel Prize in 2006. Currently more than 500 human miRNAs have been identified and they often are found in chromosomal clusters. There is substantial evidence for differential expression of miRNAs in a variety of cancers. miR-15a and miR-16-1 are found within a cluster in chromosome 13q14, which is frequently a deleted region in B cell chronic lymphocytic leukaemia (Calin *et al*., 2002; 2004). The miRNome may provide a better classifier of cancer type than the mRNA expression profile and therefore the miRNome appears to be a useful technology for the diagnosis and prognosis of cancer (Calin *et al*., 2004). miRNAs have been found to be repressed by epigenetic mechanisms in cancers (Lehmann *et al*., 2008; Lujambio *et al*., 2008) and, consistent with that observation, more miRNAs are down-regulated than up-regulated in cancer as compared to their normal tissues (Calin *et al*., 2004; Porkka *et al*., 2007). Because of their small size, miRNAs have tremendous potential as biomarkers because they are easily quantified in normal and cancer tissues as well as body fluids (Gilad *et al*., 2008; Chen *et al*., 2008; Mitchell *et al*., 2008; Lawrie *et al*., 2008). However, this field is in its infancy and no miRNA biomarkers are in clinical use.

2.2 Protein Biomarkers

Protein biomarkers hold a strong opportunity to be converted into clinical diagnostic tests. Protein biomarkers are often identified in basic science studies of cancer cells as overexpressed proteins. Given the proven ability of most manufacturers of clinical laboratory tests to adapt a protein-based immunoassay on to a standard clinical platform, the rapid translation of protein discoveries to a test should be quite efficient. The difficulty can be at the level of developing antibody pairs for sandwich immunoassays when multiple protein analytes must be assayed in a body fluid such as serum, plasma or urine. If these panels of tumour biomarker proteins form a unit that is used together to classify test subjects for early detection or recurrence and if each member of the panel is required for sufficient accuracy, failing to develop an antibody pair for any single member of the panel will nullify the utility of the clinical test (Zolg, 2006). Cancer-specific alterations in a protein may occur at the level of protein abundance or post-translational protein modification such as glycosylation or phosphorylation. If the protein being developed as a biomarker is present in a body fluid but only the post-translational modification is cancer specific, then antibodies to these specific changes represent a difficult challenge for the development of the antibody pairs. In addition, the issue of matrix complexity is formidable. The concentration range of plasma proteins comprises about nine orders of magnitude (Anderson and Anderson, 2002). Given that the abundant plasma proteins may be functionally related to the disease processes, depleting abundant plasma proteins may cause the unintentional but direct removal of some important protein analytes, or indirectly may remove key biomarker proteins that were associated with the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat161
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

abundant protein, thus unintentionally removing them from the serum or plasma.

There are a number of direct approaches to identify cancer-specific changes in proteins including abundance or post-translational modifications. Proteomic changes in cancer can be discovered by a combination of two-dimensional gel electrophoresis for separation of the proteins, with a variety of potential methods for their visualization, such as direct radioactive labelling, covalent attachment of fluorescent tags, and silver staining. Mass spectrometric analysis can then be used for the sequence identification of each protein spot (Chen *et al*., 2002; Roessler *et al*., 2006). This technology is reliable but lacking in the ability to characterize low-abundance elements of the cancer proteome. Generally about 2000–4000 proteins can be resolved and identified from a complex matrix such as serum or tissue. Because of redundancy of multiple isoforms of proteins, the actual identification of abundant proteins by two-dimensional gel electrophoresis with mass spectroscopic identification results in as much as 10-fold fewer actual protein determinations. The complexity can be diminished using enrichment procedures such as immunoaffinity chromatography for the removal of the most abundant proteins (Brand *et al*., 2006) or using less-complex matrices such as urine or lavage fluids. These latter body fluids offer a better source of tumour-specific proteins if the organ being tested for cancer is bathed in these fluids. However, given the low sensitivity of the detection methods, many have migrated to mass spectroscopy-based protein biomarker discovery for undirected high-throughput searches.

2.2.1 Proteomic Mass Spectroscopy

Proteomic mass-spectroscopy-based platforms have provided the ability to identify large numbers of novel proteins with the potential to be biomarkers. These studies are being performed in various biological matrices such as cultures of normal and tumour cells or human clinical samples (serum, plasma and urine). Proteomic biomarker discovery strategies involve the identification of markers using multidimensional protein purification technology followed by mass spectroscopy. Next the biomarkers must be prioritized based on criteria such as cancer relevance and the likelihood for clinical assay development. Lastly, validation of prioritized markers using multiple sample sources is critical, as some proteomic mass-spectroscopy studies have been biased by study design issues, such that day-to-day laboratory variation or the samples' origins can be more easily classified than the essential biological variation, such as cancer versus healthy. Proteomic mass-spectroscopy-based methods hold promise for the discovery of novel biomarkers that might provide new clinical tests, but to date their contribution to the diagnostic armamentarium has been disappointing (Zolg and Langen, 2004). The importance of experimental study design to overall process of biomarker discovery and validation has been underestimated and led to overestimation of accuracy for a set of small protein fragments in an ovarian cancer study using surface-enhanced laser desorption/ionization (SELDI) technology (Petricoin *et al*., 2002; Diamandis, 2004; Baggerly *et al*., 2005; Ransohoff, 2005). Effective studies using SELDI will require thorough attention to study design and independent validation in order to develop successful protein or peptide biomarkers for noninvasive testing.

Novel proteomic biomarker discovery technologies are being developed using quantitative isotopic labelling, improved mass-spectroscopy algorithms, and addressing the problems of sample preparation. Abundant proteins are being depleted and multidimensional prefractionation is being used to identify low-abundance protein biomarkers. Isotopic labelling with deuterated or ^{13}C isotopes of acrylamide to cysteine residues is being exploited for relative quantitation of proteins by matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) or liquid chromatography with tandem mass spectrometry (LC-MS/MS) high-resolution mass spectrometry (Martosella *et al*., 2005; Faca *et al*., 2006). These and similar mass-spectrometry-based technologies generate enormous datasets from complex patient discovery studies that challenge current data analysis procedures (Andreev *et al*., 2006; Rauch *et al*., 2006).

2.2.2 Antibody Microarrays

Multianalyte protein detection in complex matrices is also being approached using immunoassays on antibody microarrays that are highly parallel enzyme-linked immunosorbent assays (ELISAs). There are a few approaches for this type of biomarker discovery tool (Haab, 2005; Sanchez-Carbayo, 2006). One strategy is to utilize previously validated antibody pairs from sandwich ELISA tests and then multiplex the spotted capture antibodies on a surface and label the detection antibodies for the parallelized assay. As with other ELISA tests, assay interference must necessarily be addressed (Gonzalez *et al*., 2008). Another strategy is to choose candidate overexpressed proteins from other studies and develop pairs of antibodies suitable for antibody microarrays (Kopf and Zharhary, 2007; Kingsmore, 2006). The protein analytes can be measured in serum, plasma or urine for noninvasive biomarker assays or in liquefied extracts of tumour tissue for evaluation of prognostic biomarkers or potential therapeutic targets (Sanchez-Carbayo *et al*., 2006).

2.2.3 Cancer Autoantibodies

Antibodies in the serum of cancer patients are induced by the humoral immune response to overexpressed or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

mutant proteins. Cancer autoantibodies have been found to HER2 (human epidermal growth factor receptor 2, also called HER2/neu) protein (Disis *et al*., 1997) and p53 (Crawford *et al*., 1984), but because these antibodies have been detected in 5–10% of cancer patients (Disis *et al*., 2000; Mack *et al*., 2000), their sensitivity for diagnosing cancer is low. In fact, the sensitivity for p53 autoantibodies is also low even if the patient has p53 missense mutation. Autoantibodies to mucin 1 (MUC1) have been found in the sera of women with benign breast disease, as well as breast cancer at early and advanced stage (von Mensdorff-Pouilly *et al*., 1996). MUC1 autoantibodies also are found in patients with other cancers, also indicating a lack of their specificity (Gourevitch *et al*., 1995). A series of lung cancer two-dimensional gels and western blotting revealed autoantibodies to those proteins from patients' sera, (Chen *et al*., 2002).

Direct screening for autoantigens can be performed in order to discover the autoantibodies, using the serologic identification of antigens by recombinant expression (SEREX) technology. This method has resulted in the discovery of numerous antigens for breast cancer, including annexin XI-A, RPA32 (replication protein A: 32 kDa subunit), NY-ESO-1 and many other proteins (Scanlan *et al*., 2001; Sahin *et al*., 1995; Jäger *et al*., 2001; Tomkiel *et al*., 2002; Minenkova *et al*., 2003). SEREX technology is based on screening tumour-derived cDNA (complementary DNA) libraries made from a particular patient with serum obtained from the same patient. As a result, the identified tumour associated antigens (TAAs) in most cases do not show high reactivity with allogeneic patients' sera. SEREX cloning tends to identify antigens that were overexpressed in the tumour and are thus highly abundant in tumour-derived cDNA libraries. Thus less abundant mRNAs that may be coding for tumour-relevant antigens are generally missed. As a prokaryotic system is used in this immunoscreening, this approach misses autoantibodies against tumour-specific post-translational modifications such as glycosylation, which is frequently part of the epitope recognized in TAAs. The cDNA clones derived from these studies were not only found expressed in tumours, but also in normal testis tissues, so they have been called cancer testis (CT) antigens. Several modifications have been introduced to improve SEREX technology. The first variation involves established tumour cell lines instead of fresh tumour specimen as a source of cDNA, thus avoiding contaminating tumour specimens with normal cell RNAs, so that they won't be included in cDNA preparation. Also this avoids cDNA cloning of immunoglobulin sequences expressed by tumour-infiltrating B cells, giving rise to false-positives in the library screening (Chen *et al*., 1998). Second, the screening of sera from cancer patients on allogeneic cDNA libraries, including testicular cDNA libraries, may result in identification of TAAs and CT antigens that will show higher reactivity with serum IgGs (immunoglobulin Gs) obtained from many different cancers. A third modification involves a combination of representational difference analysis (RDA) and SEREX. RDA is a PCR-based subtractive hybridization method which can effectively isolate differentially expressed genes from a given cDNA population (tester) compared with another (driver) (Lisitsyn *et al*., 1993). This combined technology of RDA and SEREX has been applied for the identification of additional CT antigens in melanoma (Güre *et al*., 2000). However, these antigens have not yet provided sufficient sensitivity across a large enough cross-section of cancer patients to provide clinically useful early detection markers.

SERPA (serological proteome analysis), a combination of serology and proteomics technology, is considered to be a 'top-down' or intact protein analysis approach that involves separation of proteins on two-dimensional gel electrophoresis (2-DE), followed by western blotting, and finally identification by mass spectrometry. Klade *et al*. have combined 2-DE and serological analysis to develop the SERPA technology for the discovery of tumour biomarkers that have mounted humoral immune responses in cancer patients (Klade *et al*., 2001). Using this technology, Hanash *et al*. have reported humoral immune response to calreticulin in pancreatic cancer (Hong *et al*., 2004). In SERPA, three 2-DE gels are run with equal amounts of cell lysates that are made from fresh tumour specimens or cancer cell lines. Two gels are blotted onto nitrocellulose membranes and are processed with serum IgGs obtained from cancer patients and healthy individuals. The third gel (the preparative gel) is stained with Coomassie blue. After comparing the immunoreactive spots from the blot of the cancer patient with that of the control individual, spots that appear brighter or unique to the patient are excised from the Coomassie blue-stained gel. Next, peptide mass fingerprinting analysis is performed using MALDI-TOF MS. The advantage of this technology is that it is a less labour-intensive procedure than SEREX. Although sodium dodecyl sulfate (SDS)/urea is used for protein denaturation, post-translational modifications are still intact. Therefore SERPA provides more immunoreactively antigenic epitopes for serological testing than SEREX. Despite the success, this technology has its shortcomings. Two-dimensional gel electrophoresis is only effective in identifying highly abundant proteins in patients compared to controls. Also, 2-DE is unable to separate different proteins that can co-migrate on gels due to certain post-translational modifications. With the use of high-performance liquid chromatography (HPLC) to resolve tumour cell lysates into several thousand individual protein fractions in combination with multiplex Luminex xMAP technology for serological screening, SERPA can be modified to identify newer tumour diagnostic biomarkers in cancer patients.

Higher-throughput tumour antigen cloning can be accomplished using phage display technology coupled with serological identification of tumour antigens and

profiling humoral immune responses in cancer patients on protein microarrays (Draghici *et al*., 2005; Chatterjee *et al*., 2006; Lin *et al*., 2007). A differential biopanning strategy was employed to immunoselect T7 phage tumour-derived cDNA libraries first with control serum IgGs (pooled from different age-matched normal healthy individuals) for the removal of common, nontumour antigens that bind to IgGs in normal sera. Next, the T7 phage remaining from the cDNA libraries are incubated with serum IgGs from cancer patients to enrich for phage clones bearing tumour antigens. These phage clones are then robotically printed on protein microarrays for immunoassays to identify circulating serum antibodies in those cancer patients mounting a humoral response against cancer antigens. These antigen arrays are then further processed with Cy3-labelled T7 monoclonal antibody that recognizes phage capsid protein, and Cy5-labelled secondary goat antihuman IgG that recognizes IgG from either patient or healthy control bound to the antigens on the arrays. After quantification of the fluorescent signals, statistical analysis is applied to the dataset of dye ratios and then further validated with an independent set of patients and controls (Chatterjee *et al*., 2006; Lin *et al*., 2007) using immunoassays on the antigen microarrays to validate the biomarkers as a diagnostic predictor of cancer. This approach has been adopted by others in the field of antigen biomarkers (Wang *et al*., 2005; Zhong *et al*., 2006). The strength of this approach is the development of large panels of biomarkers from the antigen space within the human serum proteome that are less sensitive to interpatient variations in the population. This methodology is capable of accurate detection of antibodies in the sera of test subjects. Like SEREX, a limitation is that the phage display technology cannot identify cancer-specific post-translational modifications such as glycosylation. Therefore, the serum antibody repertoire that this technology identifies is limited to amino acid epitopes of TAAs.

2.3 Metabolites and Metabolomics

Metabolomics is the global analysis of the small molecule metabolites produced by normal or abnormal cellular processes. In general, metabolomics is focussed on chemical profiles using a variety of analytical technologies. The separation technologies involve gas chromatography, HPLC and capillary electrophoresis, with detection and identification employing mass spectroscopy and nuclear magnetic resonance (NMR) spectroscopy. The human metabolome, however, cannot be defined by any single analytical method (Dunn and Ellis, 2005). There appear to be greater than 2000 metabolites that are accessible using current technologies, which results in a smaller range of potential molecular targets than genomics, transcriptomics or proteomics (Wishart *et al*., 2007). Metabolic patterns and biomarker classifiers for tumour staging and stratification have been developed for breast cancer (Bathen *et al*., 2007), prostate cancer (Cheng *et al*., 2005; Berger *et al*., 2007) and renal cell carcinoma (Sullentrop *et al*., 2002). Although in its infancy and not yet applied to clinical practice, the field of metabolomics should provide a readily accessible and easily measured set of analytes for the classification of cancers for early detection and prognostication. Given the well-known changes in the glycolytic pathways, apoptosis and phosphometabolic changes that occur upon carcinogenic progression, the changes in adenine nucleotide metabolic profiles provides a rich source for biomarker discovery (Mazurek and Eigenbrodt, 2003; Mazurek *et al*., 2002). The integration of metabolomics with other 'omics'-related technologies may provide more specific classifiers of alterations related to cancer stage, grade, response to therapy, and prognosis (Chung and Griffiths, 2007; Erb *et al*., 2008; Kim *et al*., 2008; Tomlins *et al*., 2006; Bathen *et al*., 2007).

3 BIOMARKERS FOR RISK PREDICTION

Cancer is a disease of somatic cell genetic damage resulting from the failure to recognize and repair mutations in DNA. Many germline mutations that predispose individuals and their relatives to cancer occur in genes that function in maintaining the integrity of the genome. The genes often code for proteins that are involved in DNA damage recognition or repair and also in genes involved in cell cycle checkpoint control. Those individuals born with one mutant allele of such genes are more prone to additional DNA damage and genomic instability and therefore accumulate these events leading to carcinogenic conversion of cells. Frequently the remaining wild-type allele of the cancer-predisposing gene is lost in the tumour cells. Evaluating the likelihood of developing cancer through these genomic biomarkers of risk is usually performed by DNA sequencing of candidate genes. Examples of such genes are shown in **Table 1**.

Genetic risk factors occur as mutations in DNA-repair and cell-cycle-control genes, leading to somatic genetic mutations and cancer. However, less than 10% of cancers can be traced to such Mendelian inheritance. Studies of genes responsible for this enhanced risk of developing certain cancers have led to a series of genetic biomarkers as germline mutations in cancer-causing genes (**Table 1**). The majority of inherited cancer syndromes result in particular types of cancers. These cancers are the indirect result of inherited germline mutations, due to the failure to repair somatic mutations in precursor cells leading to cancer development. The patterns of certain

Table 1 Germline mutations in hereditary cancer syndromes: cancer-causing genes as biomarkers of risk

Syndrome	Germline mutation gene name (chromosomal locus)	Cancer phenotypes
Familial breast and ovarian cancer syndromes	*BRCA1* (17q21)	Breast cancer; ovarian cancer; colon cancer; prostate cancer
	BRCA2 (13q12.3)	Breast cancer; ovarian cancer; melanoma skin cancer; pancreatic cancer
Familial colon cancer syndromes:		
Familial adenomatous polyposis	*APC* (5q21–q22)	Intestinal polyps, osteomas, fibromas and sebaceous cysts; adenocarcinoma of the colon and rectum
Hereditary nonpolyposis colon cancer	*MLH1* (3p21.3) *MLH3* (14q24.3) *MSH2* (2p22–p21) *MSH6* (2p16) *PMS2* (7p22)	Intestinal polyps; adenocarcinoma of the colon and rectum; endometrial, ovarian, brain, skin and stomach cancers
Peutz-Jeghers syndrome	*STK11 (*19p13.3)	Intestinal hamartomatous polyps; mucocutaneous melanocytic macules; intestinal polyps; intestinal cancer
Neurofibromatosis Type I	*NF1* (17q11.2)	Malignant peripheral nerve sheath tumour; pheochromocytoma; meningioma; glioma; acoustic neuroma; optic neuroma; mental retardation; hypertension; hypoglycaemia
Li-Fraumeni syndrome	*p53* (17p13.1) *CHK2* (22q12.1)	Adrenal cortical carcinoma, brain tumours; breast adenocarcinoma; osteogenic sarcoma; leukaemia; lymphoma; rhabdomyosarcoma; sarcoma
Multiple endocrine neoplasia I	*Menin* (11q13)	Tumours of pancreatic islet cell, parathyroid, anterior pituitary and posterior pituitary; gastrinomas; insulinomas
Multiple endocrine neoplasia II	*RET* (10q11.2) *CDKN1B* (12p13.1)	Thyroid carcinomas, pheochromocytomas
von Lippel-Hindau disease	*VHL* (3p26–p25)	Retinal and central nervous system haemangioblastomas; pheochromocytomas; cysts of the pancreas and kidneys; renal cysts progressing to carcinomas
Familial retinoblastoma	*Rb1* (13q14.1–q14.2)	Retinoblastoma; osteogenic sarcoma; breast adenocarcinoma; bladder cancer

cancers within families with inherited predisposition to cancer will trigger genetics professionals to determine the appropriate genes for clinical testing. The clarity of these observations and determining the gene that should be tested is often complicated by the incomplete penetrance of these genetic factors, meaning that not all individuals who carry a germline mutation in a cancer-predisposing gene will develop cancer.

Genetic testing is generally performed on peripheral blood lymphocyte DNA because large amounts of DNA can be obtained relatively noninvasively. The mutations when identified are in one of the two alleles of that gene, and often the wild-type allele undergoes loss of heterozygosity in the tumour tissue, indicating a total loss of function in the tumours. Those individuals who test positive for a germline mutation in a cancer-predisposing gene are in need of enhanced medical surveillance and screening using biomarkers for the early detection of cancer.

The identification of genetic alterations that increase the risk for developing cancer is useful for predisposition testing with mutational screening and counselling as part of the established subspecialty of cancer genetics. Despite the promise of this predisposition genetic testing for inherited cancer risk, this information could lead to unforeseen negative consequences unless genetic analysis data are used properly. Not all healthcare professionals are knowledgeable in the interpretation of genetic testing

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat161
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

results for cancer susceptibility. The complexities include interpreting family history data and choosing the correct gene to be sequenced.

In addition to well-executed molecular technologies for DNA testing, an accurate and detailed family history is the essential risk assessment tool in the evaluation of a hereditary cancer syndrome. Family history data include details of all cancers on both maternal and paternal sides within the family pedigree. Cancer-free relatives are included, because the frequency of both normal and affected relatives within a pedigree is a key factor in the evaluation of inheritance patterns. Family history data should be confirmed with medical and/or death records.

4 BIOMARKERS FOR EARLY DETECTION SCREENING

In order to detect cancer at its earliest stages when it is most curable, there is a need for biomarkers to detect individuals harbouring occult cancers. The expectation is that early detection tests will be pursued with particular targeted subsets of patients in mind who need more intensive diagnostic imaging after a positive test. One approach for accomplishing this objective is to detect molecular fingerprints of an organ in the process of developing a cancer and then to use the biomarkers to define a suitable treatment prior to a significant tumour burden. Effective biomarker identification depends on multiple levels of study design, each of which must be optimized to ensure the utility of a biomarker or panel of biomarkers specific to this clinical application, early detection. The success of biomarkers for the early detection of cancer is measured by the fact that they should not only detect disease early but also reduce the mortality from that cancer.

The choice of cellular tissue or body fluid for the early detection of cancer is clearly dictated by the breadth of the assay sought. A biomarker that can detect one cancer and rule out others will necessarily require a systemic body fluid such as plasma, serum or urine. Alternatively, if a biomarker is to have high sensitivity for a single cancer such breast cancer, then breast nipple aspirate fluid or ductal lavage fluid may provide a very specific matrix in which one would be less likely to find false positive results from other tissues. Likewise a test for a bladder cancer biomarker may reach a higher specificity if measured in urine rather than blood. Whether testing these matrices for early detection, diagnosis or prognosis of cancer, a variety of types of analytes and technologies are available, such as proteins, nucleic acids or metabolites.

4.1 Technological Issues

Noninvasive diagnostic approaches to detect early stage cancers may provide the clinician with evidence of cancer, but the criteria for a useful test depend on sensitivity and/or specificity of the test and how the results will affect the pathway of clinical intervention. The consequence of a positive result from an *in vitro* diagnostic cancer test may involve relatively invasive procedures to establish a true cancer diagnosis. Therefore the *in vitro* diagnostic test must be both specific, that is, rarely produce false positive results due to unrelated conditions, and relatively sensitive, that is, rarely produce false negative results, and only then such screening tests will offer life-saving potential for early detection and possibly a mechanism for personalized therapeutics using disease-related targets.

Various scenarios of diagnostic tests for the early detection of cancer have emerged using genomic, proteomic and metabolomic technologies. Because screening tests might involve panels of analytes, these technologies have opened a 'Pandora's Box' of questions on the steps in development of multianalyte clinical tests. Developing the reagents into a format that is amenable to a clinical laboratory is a rather daunting barrier to such a test. Even the development of a generic approach to measure dozens of analytes will require solutions to some unique optimization challenges, not the least of which is the informatics leading to a clinical decision. To ensure tests work properly during research and development, during production and in customer laboratories, kits require controls and calibrators for each analyte. A major barrier in multianalyte diagnostics will be the large number of controls and standards required for such a test. For nucleic acids-based tests these controls are more easily prepared; controls are particularly difficult for protein-based diagnostics. Controls for this approach may consist of cancer cell extracts, cancer patients' sera or other body fluids or alternatively panels of human recombinant proteins for each biomarker. Because patient material containing these biomarkers could be in short supply, the alternative approach of using recombinant proteins for each biomarker is preferable. However, preparing each of the recombinant proteins as controls, although feasible, is clearly a substantial technical challenge in that recombinant proteins will be missing critical cancer-specific post-translational modifications such as glycosylation or phosphorylation. A set of individual standards for multianalyte assays may not be possible, whether they are serum autoantibodies, circulating proteins or plasma genomic DNA or RNA targets. The danger is that the absence of true molecular standard calibrators may result in a test difficult to implement in clinical laboratories.

The true utility of a diagnostic test requires that the appearance of a positive test result must precede the development of late-stage or incurable cancer. However,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat161
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

there is no established method to define early detection. What constitutes early detection may vary among the different types of cancer. Diagnostics for any particular cancer may require either high specificity or high sensitivity, depending on the clinical pathway beyond the test. The prevalence of early stage disease and the costs of false positive and false negative results must be weighed against the benefits of early diagnosis. In balancing specificity vs. sensitivity, the intended goal of the diagnostic application must be part of the study design from discovery to implementation. An ideal screening test would have very high sensitivity, identifying nearly all individuals with disease. To accomplish this, the test may falsely identify many individuals who do not have cancer, resulting in lower specificity for the panel of biomarkers, leading to unnecessary, invasive, medical testing. Thus it is important that *in vitro* screening tests have both high sensitivity and high specificity. If test sensitivity is valued over test specificity, significant misclassification in the case of low-prevalence cancers may result in unnecessary and expensive medical follow-up. Conversely, valuing specificity over sensitivity may fail to detect cases of cancer. In light of all of these factors, a 'one-size-fits-all' approach to diagnostic standards for a multianalyte early detection screening test for cancer may be impossible. The balancing of specificity and sensitivity will depend on the nature of the clinical follow-up for each cancer. A high specificity imaging test following a high sensitivity biomarker screening test may be the best compromise solution.

4.2 Classical Screening Tests for Cancer

Carcinoembryonic antigen (CEA), first described in 1965 (Gold and Freedman, 1965), was among the first identified tumour biomarkers. CEA is a biomarker that is elevated in a variety of cancers including colorectal, breast, lung or pancreatic cancer. CEA in breast cancer detection has low diagnostic sensitivity and specificity (Hou *et al*., 1999; Clinton *et al*., 2003), with frequent false positives in normal individuals. High levels of CEA occur in many other cancers as well (Munjal *et al*., 1984). CEA is a better biomarker of ductal carcinomas than lobular carcinomas of the breast (Kuhajda *et al*., 1983). Because CEA can be found in the serum of patients with ductal carcinoma in situ, CEA may provide a biomarker indicative of an early stage of the cancer (De Potter *et al*., 1988) Mucins such as MUC1, or cancer antigen (CA) 15.3 and CA 27.29, MUC16 (CA 125) (Gion *et al*., 1999; Klee and Schreiber, 2004) and CA 549 (Dnistrian *et al*., 1991) have low sensitivity for presymptomatic diagnosis of breast cancer (Zamagni *et al*., 1992). With the advent of mass-spectroscopic protein identification in complex matrices such as serum and plasma, new biomarker proteins have emerged, including heat shock protein 27 (HSP27) and the transcriptional regulator 14-3-3 sigma, and the derivatives of the complement component C3a (Rui *et al*., 2003; Li *et al*., 2002; 2005). None of these biomarkers have become useful tools for breast cancer early detection.

A variety of ovarian tumour markers have been studied, and the most extensively investigated of these is CA125. This antigen was first recognized in 1981, using a murine monoclonal antibody developed in response to immunological challenge with an ovarian cancer cell line (Bast *et al*., 1981). CA125 levels were found to be increased in 50% of Stage I and 90% of Stage II ovarian cancers (Zurawski *et al*., 1988). Although sensitivity for Stage I disease using a simple cut-off of 30 U ml^{-1} was limited, it was apparent that CA125 was capable of detecting ovarian cancer preclinically. The use of a combination of markers to increase sensitivity and specificity has been extensively investigated and the marker that appears to exhibit the most complementarity to CA125 is OVX1, a monoclonal antibody developed using sequential immunization with three different ovarian cancer cell lines (Xu *et al*., 1991). OVX1 has been found to be elevated in 70% of patients with clinically evident ovarian cancer. In addition, 59% of patients with normal CA125 levels had increased OVX1, suggesting complementarity between the two markers. Although these results indicate improvement in sensitivity, preliminary data from different laboratories suggest that OVX1 may be unstable unless serum is rapidly separated, which could complicate its use in population screening if samples are sent by post. Another serum marker which exhibits complementarity to CA125 is macrophage colony stimulating factor (M-CSF). Among 25 patients with clinically evident tumours and a negative CA125, 56% had an elevated M-CSF serum level (Xu *et al*., 1991). A variety of other tumour markers have also been studied in ovarian cancer. Many of these have been shown to be of insufficient sensitivity or specificity regarding epithelial tumours. Among them, CEA has been reported to be elevated in 30–65% of epithelial tumours, mainly in patients with advanced stage disease (Schwartz *et al*., 1987). Cancer antigen 19-9 (CA19-9) is another carbohydrate antigen that can be found elevated in only 17–25% of patients with epithelial malignancies (Schwartz *et al*., 1987). Lipid-associated sialic acid (LSA) can be detected in serum of about 60% of patients with advanced stage disease (Patsner *et al*., 1988). The interleukins, IL-6 and IL-10, have been shown to be present in high levels in the ascites and serum of women with advanced stage epithelial cancer (Berek *et al*., 1991; Gotlieb *et al*., 1992). Measurement of serum levels of tumour-associated antigen CA125 (Bast *et al*., 1983), in conjunction with ultrasound screening as a second-line test, confers high specificity (Einhorn *et al*., 1992) but detects only approximately one half of early stage cases (Jacobs and Bast, 1989). Use of

multiple serum markers may provide a more sensitive test. Complementarity has been demonstrated between CA125 and two novel markers. M-CSF (Kacinski and Bloodgood, 1989) and OVX1 (Xu *et al*., 1991) identify a percentage of patients with persistent ovarian cancer who had normal CA125 levels prior to second-look surgical staging procedures. Other new markers, such as tetranectin (TN) or cancer-associated serum antigen (CASA), have not provided additional discriminative value (Hogdall *et al*., 2000). Serum levels of epidermal growth factor (EGF) and its receptor are significantly different between ovarian cancer patients and healthy women and this may provide a potential diagnostic and/or prognostic marker useful for the management of recurrence and late-stage cancer (Baron *et al*., 1999). Homeobox protein B7 (HOXB7) was recently found to be a tumour antigen whose up-regulated expression could play a role in promoting growth of ovarian carcinomas (Naora *et al*., 2001). Urban *et al*. have characterized the behaviour of five serum tumour markers in a large cohort of healthy women (Urban *et al*., 2000). Serial measurements of CA125, HER2/neu, urinary gonadotrophin peptide, lipid-associated sialic acid and Dianon marker 70/K during six years of follow-up of 1257 healthy women at high risk of ovarian cancer showed that the individual-specific tumour markers behaved independently with substantial heterogeneity among high-risk but cancer-free women. None of these research findings has yet translated into a reliable early detection clinical test.

5 MOLECULAR DIAGNOSTICS FOR CANCER

Large-scale gene expression profiling holds tremendous promise for developing molecular portraits of subtypes of human tumours with different clinical outcomes that could not be subclassified upon initial clinical presentation. One of the possible problems in performing such studies is the number of samples as compared to the number of genes tested, the so-called 'curse of dimensionality'. Without an independent validation set, studies with many more genes than samples may result in over-fitting of the data, thus leading to a gene panel that is only accurate on the discovery sample cohort or at the one site of sample collection. Another issue is that there may be small numbers of genes whose expression discriminates cancer subtypes but they may not be drivers of the carcinogenic process and therefore may provide little survival information. Another not surprising issue is that independent studies can identify different panels of genes with similar discriminatory specificity and power. This is likely to be due to the technical differences such as the type of microarray used or the algorithm that identified the genetic classifier, and because there is redundant information among the individual attributes of gene expression profiles. These points are illustrated below.

One of the earliest applications of gene expression profiling to finding biomarkers for clinical oncology was a project on diffuse large-B-cell lymphoma. The International Prognostic Index (IPI), was established as a predictor of outcome in diffuse large-B-cell lymphoma based on clinical characteristics of age, tumour stage, serum lactate dehydrogenase levels, performance status and number of extranodal disease sites (Vose, 1998). However, the outcome in patients with diffuse large-B-cell lymphoma who have identical IPI values varies considerably. Gene expression profiling was pursued to develop risk-adjusted classifiers for possible therapeutic outcomes for diffuse large-B-cell lymphoma suitable for clinical practice. One group identified a panel of genes characteristic of normal germinal-centre B cells, whose expression when elevated indicated a significantly longer survival among patients with diffuse large-B-cell lymphoma than patients whose tumours had low levels of expression of these same genes (Alizadeh *et al*., 2000). Another group identified a panel of 13 genes that was independent of the IPI. Only 3 of these 13 genes were present in the data analysed by Alizadeh *et al*. (2000), and of those 3, 2 were associated with survival (Shipp *et al*., 2002). Another group used supervised analysis of gene-array data from 160 patients with diffuse large-B-cell lymphoma and developed a 17-gene predictive model which when applied to a set of similar lymphomas from 80 other patients could predict survival (Rosenwald *et al*., 2002). However, there was no overlap with either of the other two classifiers or survival. Another report identified 36 genes that predicted survival in diffuse large-B-cell lymphoma previously discovered from either individual studies or from large published microarray datasets. Using RT-PCR they ranked the genes for their predictive power for longer overall survival. Using a weak z value of ± 1.5 (p-value = 0.13), they found that 6 genes (*LMO2, BCL6, FN1, CCND2, SCYA3* and *BCL2)* in a univariate analysis provided a predictor of survival. This 6-gene model was as accurate as the 17-gene model of Rosenwald *et al*. and was independent of the IPI values in predicting outcome (Lossos *et al*., 2004). However, as yet there is no test in clinical practice derived from these studies.

6 BIOMARKERS FOR PROGRESSION AND SELECTION OF CANCER TREATMENT

In the area of cancer prognosis, the challenge is to weigh the impact of a number of variables, including systemic versus tissue biomarkers that can be used to predict

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat161
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

outcome in patients with early-stage cancer. The expectation is that there is a subset of individuals who may not benefit from chemotherapy treatments and might be treated surgically with watchful waiting as a follow-up to surgery. Classical prognostic testing based on tumour tissue analyses was inexpensive and easy to perform. Some biological assays such as proliferative index, gene amplification and overexpression of oncogenes or their proteins are being employed in certain cancers as predictors of outcome. These tests have entered clinical practice, but far more complex test data are now appearing, often employing panels of genes whose expression levels are incorporated with the use of algorithms into the test reports. Not only can such tests predict outcome (Paik *et al*., 2004; 2006; Wolf *et al*., 2008; van 't Veer *et al*., 2000; van de Vijver *et al*., 2002; Sotiriou *et al*., 2006), but also can identify the tissue of origin in metastatic cancers of unknown primary (Ma *et al*., 2006; Dumur *et al*., 2008). A clinical practitioner will have to identify the appropriate test, or tests, that can predict when a therapeutic approach can improve the patient's outcome, or determine whether more classical diagnostic information alone is more clinically useful. A major goal of prognostic testing in cancer is to predict which patients will develop a recurrence of cancer and need treatment, and which will not require treatment. The prognostic value of a test is usually expressed in terms of relative risk (RR), which is the ratio of the risk of cancer recurrence in patients who have a positive test to the risk in those who test negative.

6.1 Biomarkers of Prognosis

With the advent of whole genome expression profiling, the opportunity to identify features of the transcriptome that indicated a good or poor survival became feasible. Likewise, proteomic profiling of primary tumour tissues could also provide a rich source of protein biomarkers that may distinguish differences in survival, but the impact of proteomic biomarkers is yet to be realized. Two gene-expression-based tests have been developed to determine the risk of recurrence in breast cancer patients with Stage I or II node-negative breast cancer. The first test, Oncotype DX™, is an RT-PCR-based assay performed on RNA extracted from paraffin-embedded tumour tissue. This test determines the expression levels of 21 genes, 16 of which are cancer-related genes and 5 are control reference genes. The Oncotype DX™ test specifically was developed to predict the risk of breast cancer recurrence in women with oestrogen receptor (ER)-positive, node-negative breast cancer, using the readily-available paraffin-embedded tumour tissue. The results are used to calculate a recurrence score that predicts the likelihood of cancer recurrence in patients treated with tamoxifen. Women with a low recurrence score need only treatment with tamoxifen, and those women with an intermediate- and high-risk score require additional treatment such as adjuvant chemotherapy.

The second multianalyte test for breast cancer recurrence is called MammaPrint®. Biomarkers of breast cancer subtypes were identified using patterns of gene expression measured by microarrays (Sørlie *et al*., 2001; Sorlie *et al*., 2003). Using hierarchical clustering of gene expression, large gene sets were able to identify five subtypes of breast cancer including basal-like, HER2-overexpressing subtype, two types of luminal cells, and a normal breast tissue-like subgroup. The basal-cell-type was often seen in carriers of BRCA1 mutations (Sorlie *et al*., 2003). These molecular classifiers were able to show that patients with the basal and HER2 subtypes had a good response to therapy. The genes associated with a complete response to chemotherapy in the basal subtype were different from those that defined the HER2-overexpressing subtype (Rouzier *et al*., 2005). This work has led to the 70-gene panel in the MammaPrint® technology. MammaPrint® involves an oligonucleotide microarray assay to analyse the expression of a panel of 70 genes, and is performed on fresh-frozen tumour tissue. MammaPrint® was developed to address early-stage breast cancers so as to evaluate them as having a high or low risk of future metastases. Those women categorized as having a high risk of metastasis are treated with more aggressive chemotherapy, while those categorized as low risk are spared unnecessary chemotherapy. The key to the successful development of these two tests was the establishment of a clear target population who would be candidates for each test, and focussing on establishing the parameters of the algorithms for each test on that population. Other prognostic tests for breast cancer are being developed using immunohistochemistry (IHC) or gene expression, but only MammaPrint® is currently approved by the US Food and Drug Administration (FDA).

6.2 Metastatic Cancer from Unknown Primary Tumours

About 10–15% of cancer patients present with metastases without an apparent site of origin at presentation with the cancer. In one-third of these patients no primary tumour can be identified histologically, and they are designated as having a cancer of unknown primary origin. This situation leaves tremendous ambiguity and often a failure to apply appropriate systemic combination chemotherapy. Clinical evaluation of metastatic lesions of unknown origin is unsuccessful in up to 60% of patients. In response to this clinical need, tissue-of-origin classification of uncertain

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat161
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

primary cancers was developed using microarray-based gene expression profiling of a 1668-gene probe set to evaluate the similarity of tumour specimens to 15 known tissue profiles (Dumur *et al*., 2008). A molecular similarity profile of each test-tumour specimen's expression pattern is compared to 15 patterns from unique tissue types including bladder, breast, colorectal, gastric, germ cell, hepatocellular, kidney, non-small-cell lung, non-Hodgkin's lymphoma, melanoma, ovarian, pancreatic, prostate, soft tissue sarcoma, and thyroid. For each test specimen, an algorithm reduces dimensionality of the expression data into 15 separate 'Similarity Scores', one for each tissue type. This test, referred to as Pathwork^{DX}, is approved by the FDA for the application of tissue-of-origin testing of metastases from unknown primary cancers.

6.3 Circulating Tumour Cells

The presence of circulating tumour cells (CTCs) in the blood of cancer patients was recognized in the 1950s, but only recently has technology become available to exploit them as biomarkers for the detection or prognosis of cancer (Roberts *et al*., 1957). The detection of CTCs has been commercially developed in a device and can predict which women with metastatic breast cancer will have a better progression-free period and overall survival (Cristofanilli *et al*., 2005). This technology has also been applied to the prognosis of prostate, colorectal and gastrointestinal cancers (de Bono *et al*., 2008; Cohen *et al*., 2008; Hiraiwa *et al*., 2008). Molecular events driving cancer development, and likewise therapeutic targets such as EGF-receptor mutations, are detectable in CTCs (Maheswaran *et al*., 2008a), and CTCs provide a novel and very specific diagnostic tool for the future.

6.4 Biomarkers for Treatment Selection

Targeted anticancer therapies have resulted from years of research focussed on understanding the changes in molecular mechanisms and biomarker differences between cancer cells and normal cells. Classical chemotherapies have killed rapidly dividing cells, a feature of cancer cells. Because certain normal cells proliferate rapidly, chemotherapies result in significant side effects. By targeting therapy to a molecular mechanism known to differ between normal and cancer cells, targeted therapies have been developed that attack the cancer cells without affecting the normal cells, thus reducing side effects. Targeted therapies by definition provide molecular biomarkers of efficacy, that is, the mechanisms being targeted. Targeted therapies focus on the functions of the cancer cell predefined as dysregulated, thereby providing biomarkers for the choice of the appropriate targeted therapy. These molecules get into the cell and disrupt the particular molecular function of the cells that caused them to be neoplastic.

Once individuals are detected with early disease and potentially gene profiling can indicate the dysregulation of particular pathways, there is a need to identify subsets of patients for specific targeted cancer therapy based on their molecular profiling. Because, even within a single cancer histologic type, there are a variety of responses to therapy; identifying one or more critical biomolecules that drive the cancer phenotype in a patient will provide a personalized targeted therapeutic approach. These molecular targets for cancer therapy are the products of years of research. Given the rate of identification of candidate genes, the appearance of cancer-specific mutations and potential therapeutic targets will rapidly expand due to emergence of next-generation DNA sequencing capabilities as applied to tumour tissues (Scott *et al*., 2005; Cox *et al*., 2005; Davies *et al*., 2005; Stephens *et al*., 2005; Edkins *et al*., 2006; Ikediobi *et al*., 2006; Greenman *et al*., 2007; Campbell *et al*., 2008). The selection of target-positive patient populations provides efficiencies in more rapid assessment of drug performance. Also smaller patient populations can provide rapid objective evaluation of treatment outcomes.

6.4.1 EGF-Receptor Family

Biomarkers for targeted or personalized cancer treatment using small molecule therapies and antibody-based therapies by necessity requires years of research and development. For example, overexpression of the HER2 growth factor receptor protein, often resulting from gene amplification, occurs in approximately 25% of breast cancer patients. HER2-overexpressing breast cancers are more aggressive, often associated with shortened disease-free and poor overall survival (Slamon *et al*., 1987; 1989; Gusterson *et al*., 1992; Andrulis *et al*., 1998). The therapeutic monoclonal antibody trastuzumab (Herceptin®) was directed against an epitope on the extracellular domain of the HER2 growth factor receptor protein. This agent has clinical efficacy against HER2-overexpressing breast cancers used as a single agent or when used in combination with chemotherapy (Cobleigh *et al*., 1999; Slamon *et al*., 2001; Vogel *et al*., 2002; Seidman *et al*., 2002). An early obstacle to adoption of HER2 as a diagnostic target and ultimately as a molecular target of therapy was the development of reliable tests for its gene amplification and protein overexpression (Slamon and Clark, 1988; Press *et al*., 2002). Clear HER2 biomarker guidelines are now available for using targeted therapies

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat161
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in breast cancer (Wolff *et al*., 2007). Trastuzumab, the commercial name for this monoclonal antibody targeting HER2, is now the first-line treatment of patients with HER2-positive metastatic breast cancer. HER2 can also be targeted using small-molecule inhibitors of its tyrosine kinase activity. A critical issue is now the optimal selection of patients for each type of therapy: monoclonal antibody versus small-molecule inhibitor. The monoclonal antibodies do not cross the blood–brain barrier efficiently, and although the small-molecule inhibitors are able to cross the blood–brain barrier, they have a shorter half-life in the blood (Imai and Takaoka, 2006). Lapatinib (commercial name Tyverb®) is a dual specificity tyrosine kinase inhibitor of both EGF receptor and HER2, that inhibits the autokinase activity of these proteins by binding to the adenosine triphosphate (ATP)-binding sites (Nelson and Dolder, 2006). Lapatinib in combination with capecitabine in women with HER2-positive metastatic breast cancer has significant efficacy in metastatic breast cancers that progressed after failure on trastuzumab-based therapy plus an anthracycline and a taxane (Geyer *et al*., 2006). Unfortunately there is no clear set of serum biomarkers of response to trastuzumab plus chemotherapy to indicate when to change to the small-molecule inhibitor plus capecitabine.

There are a series of approved therapies targeting the epidermal growth factor receptor (EGFR) protein. Rather than simple overexpression of the wild-type growth factor receptor, the biomarker of efficacy for these agents is EGFR kinase domain mutation at amino acid 858, changing a leucine to an arginine (L858R), or less frequently one of multiple possible in-frame deletions in exon 19 (Bean *et al*., 2008; Godin-Heymann *et al*., 2008; Molina-Vila *et al*., 2008; Maheswaran *et al*., 2008b; Yamamoto *et al*., 2009). Tumours with these mutational biomarkers of efficacy are sensitive initially, but acquire resistance to gefitinib and erlotinib second-site mutations in EGFR. Somatic mutations in the tyrosine kinase domain of the *EGFR* gene are associated with sensitivity of lung adenocarcinomas to the EGFR tyrosine kinase inhibitors, gefitinib and erlotinib. Acquired drug resistance is frequently (50%) associated with acquisition of a new biomarker of resistance with a secondary somatic missense mutation substituting a methionine for threonine at amino acid position 790 (T790M).

6.4.2 bcr-abl Oncogene

The *BCR-ABL* oncogene is the result of a translocation of DNA sequences from human chromosomes 9 and 22, often called the Philadelphia Chromosome (Nowell and Hungerford, 1964; Nowell, 2007), which forms a new fusion transcript producing a fusion protein from *BCR* (break point cluster) and *ABL* (Abelson leukaemia viral oncogene homolog protein kinase) genetic sequences (Heisterkamp *et al*., 1985). This translocation and the BCR-ABL tyrosine kinase are present in 95% of patients with chronic myelogenous leukaemia (CML), and have been implicated as the cause of this disease. A chemical compound (Druker *et al*., 1996), designed to inhibit the ABL protein tyrosine kinase, was evaluated for its effects on cells containing the BCR-ABL fusion protein. Cellular proliferation and tumour formation by BCR-ABL-expressing cells were specifically inhibited by this compound. This compound (STI 571 or CGP 57148B (O'Dwyer and Druker, 2001), commercially known as Gleevec or Imatinib mesylate) was developed into a highly selective treatment of BCR-ABL-positive CMLs (Beran *et al*., 1998; Dan *et al*., 1998; Druker *et al*., 2001; Gora-Tybor *et al*., 1998; le Coutre *et al*., 1999; Sausville, 1999). Mutation in the kinase domain of the *BCR-ABL* gene alters drug binding, renders CML patients Gleevec-resistant and as such is a biomarker of resistance (O'Hare *et al*., 2007a). In other patients, increased BCR-ABL expression is an excellent biomarker of Gleevec resistance (Mahon *et al*., 2000). Gleevec is also relatively nontoxic and effective in gastrointestinal stromal tumours with activation of the c-Kit receptor (cell surface receptor that binds to stem cell factor), indicating that this receptor is a biomarker of efficacy for this drug (DeMatteo, 2002; Heinrich *et al*., 2000; Joensuu *et al*., 2002; Patel, 2002; Tuveson *et al*., 2001).

Additional oncogene biomarkers resulting from chromosomal fusions of tyrosine kinases, such as ABL and PDGFRA/B (platelet-derived growth factor receptor, alpha polypeptide/beta polypeptide), are associated with leukaemias resembling CML, and have potential for targeted therapeutics and personalized medicine. Gleevec has remarkably improved the outcome of BCR-ABL-containing CML, but because there are some CML patients with a poor response to Gleevec, biomarkers of response beyond detection of the *BCR-ABL* fusion transcript are necessary. Thus cytogenetic and molecular testing for BCR-ABL and other biomarkers during treatment provides important prognostic information (O'Hare *et al*., 2007b; Ross and Hughes, 2008; Wu *et al*., 2008).

6.4.3 Oestrogen and Progesterone Receptors

The expression of oestrogen and progesterone receptors has long been known as an excellent prognostic biomarker for breast cancer (McGuire, 1973). Numerous biochemical studies preceded its implementation as a biomarker and therapeutic target (Furr and Jordan, 1984; Jordan, 1984; Tate and Jordan, 1984; Tormey and Jordan, 1984). As a biomarker, oestrogen receptor positivity in breast cancers indicated that the cancer may respond to chemotherapy and chemoprevention with selective oestrogen receptor antagonists tamoxifen and raloxifene

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat161
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Cummings *et al*., 1999; Fisher *et al*., 1989; 1998; Vogel *et al*., 2006), or respond in a postsurgical therapeutic setting. In women with advanced metastatic cancer, inhibitors of the enzyme aromatase, which is required for oestrogen biosynthesis, can increase the time to progression as compared to tamoxifen (Carpenter, 2008; Seo *et al*., 2008; Paridaens *et al*., 2008). In addition, most clinical trials revealed a survival advantage for treatment with aromatase inhibitors in early stage oestrogen receptor-positive breast cancer (Koeberle and Thuerlimann, 2007).

In summary, the use of biomarkers brings the era of personalized medicine for choice of cancer therapy to a new reality. It acknowledges the limitations of one-size-fits-all chemotherapy, and provides a rational basis for individualized cancer care.

7 SURROGATE BIOMARKERS OF TREATMENT OUTCOME AND RELAPSE

One area of biomarker use is the surveillance of cancer after treatment. The translocations associated with leukaemias and lymphomas are particularly useful molecular markers to determine the presence of minimal residual disease, and quantitative PCR assays of DNA can be used to determine whether the tumour burden is increasing. However, for most solid tumours there are few blood-based biomarkers of relapse. Some of the clinically utilized biomarkers are listed below, including prostate specific antigen (PSA), CA125, CEA, nuclear matrix protein 22 (NMP22) and CA19-9. For additional biomarkers of relapse see Nass and Moses (2007).

7.1 PSA

PSA is naturally secreted from normal prostate cells, but higher levels of PSA in serum have a correlation with the existence of prostate cancer. PSA is probably the only serum biomarker used in a primary-care setting. PSA was originally approved for the recurrence of prostate cancer but was used off-label so frequently that sufficient data arose to indicate its use presymptomatically. Other conditions can cause increased levels of PSA. Benign prostatitis, infections of the prostate gland, exercise that results in irritation of the surrounding tissues, and digital prostate examination by a doctor can result in a rise in PSA. The rate of PSA elevation and the fraction of free PSA generally determine the clinical pathway. PSA elevation above normal will often result in additional diagnostic testing to identify prostate cancer at an early stage. The clinical follow-up is usually digital rectal examination of the prostate, prostate biopsies and imaging. Even with such comprehensive clinical follow-up the majority of treated cases would probably result is no clinical cancer (Thompson and Ankerst, 2007). The high rates of over-diagnosis are evident from the fact that the lifetime chance of prostate cancer diagnosis is 18% but the likelihood of death from prostate cancer is only 3%. This low specificity is causing a considerable amount of unnecessary treatment, and better biomarkers for the presymptomatic detection of prostate cancer need to be found. Chromosomal translocations also involving ETS (avian erythroblastosis oncogene homolog)-family transcription factors have been observed in prostate cancer and should provide improvements in the diagnostic specificity for that disease using PSA (Tomlins *et al*., 2005; Rouzier *et al*., 2008).

7.2 Cancer Antigen 125 (CA125)

CA125, also known as MUC16, is a protein that binds a monoclonal antibody used for its testing. CA125 is a useful indicator of ovarian cancer recurrence, but as a biomarker for presymptomatic detection of ovarian cancer it has low sensitivity and low specificity. CA125 levels were found to be elevated in 50% of Stage I and 90% of Stage II ovarian cancers (Zurawski *et al*., 1988). However, multiple benign diseases, both gynaecological and nongynaecological conditions, can elevate serum levels of CA125 (Jacobs and Bast, 1989; Tuxen *et al*., 1995), and therefore the false-positive rate of CA125 is high. CA125 levels are elevated in people who have pancreatitis, kidney or liver disease, indicating its limited utility as a cancer diagnostic tool. CA125 is a good biomarker of recurrence of a previously treated ovarian cancer.

7.3 Carcinoembryonic Antigen (CEA)

CEA is synthesized during the development of the foetal gut, and is turned on in adult intestinal carcinomas and other cancers. CEA is a biomarker that is elevated in numerous cancers such as colorectal, breast, lung or pancreatic cancer. Although sometimes used as a screening test, there are several sources of false-positive tests, such as smoking. CEA testing after surgery for colon cancer is an effective way of determining the reduction of tumour burden and the recurrence of cancer after postoperative chemotherapy. However, there is no survival advantage of metastatic disease colon cancer between patients who went to a second-look surgery based on elevated CEA levels versus other criteria (Goldstein and Mitchell, 2005).

DOI: 10.1002/9780470744307.gat161
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

7.4 NMP22

NMP22 is a specific nuclear matrix protein involved in DNA synthesis, RNA transcription, the regulation of gene expression, and mitosis. Bladder cancer results in elevation of intracellular NMP22 up to 25-fold, and the protein is shed into the urine. A urine test for NMP22 was approved in a number of formats, first for bladder cancer recurrence and later for presymptomatic testing for bladder cancer. The commercial test was reported to be 68% sensitive and 65% specific (Friedrich *et al*., 2002). Combining NMP22 with a telomerase enzyme assay, called TRAP (telomere repeat amplification protocol), resulted in 100% sensitivity and 96% specificity (Saad *et al*., 2002). However, no combination of biomarkers demonstrated sufficient sensitivity to detection of low stage and grade bladder tumours or carcinoma *in situ* to replace standard urethrocystoscopy (Van der Poel and Debruyne, 2001).

7.5 CA19-9

CA19-9 is a tumour biomarker that, like CEA or CA125, is not sufficiently specific for the presymptomatic detection of gastrointestinal cancers. Non-neoplastic conditions such as gallstones, cirrhosis, pancreatitis and cholecystitis induce elevated levels of CA 19-9. Although CA19-9 was discovered in colorectal cancer patients, CA19-9 has also been detected in the serum of patients with pancreatic, stomach and bile duct cancer (Steinberg *et al*., 1986). Researchers have discovered that, in those who have pancreatic cancer, high levels of CA19-9 are associated with advanced pancreatic cancer. CA19-9 is a useful biomarker to evaluate whether a patient is responding to cancer treatment for bile duct and pancreatic cancers. CA19-9 is also an indicator of recurrence of pancreatic cancer (Safi *et al*., 1998).

7.6 Chromosomal Translocations

Chromosomal translocations, particularly in leukaemias and lymphomas, can be used to determine the presence of residual disease. This approach was first applied to the early relapse or the detection of minimal residual disease in patients having chromosomal translocation for follicular lymphomas, t(14;18)(q32;q21) (Lee *et al*., 1987), allowing the detection of cells with the t(14;18) translocated DNA sequences at 1 cell in 100 000. PCR was also applied to acute T cell leukaemia/lymphoma using the t(10;14)(q24;q11) chromosomal translocation as the biomarker target (Kagan *et al*., 1990). The Philadelphia chromosome is a specific biomarker of CML and has been used to target therapy using the therapeutic tyrosine kinase inhibitor Gleevec. The presence of the translocation protein BCR-ABL-kinase is detected by PCR to monitor response to therapy and the presence of residual disease (Kim *et al*., 2004; Paschka *et al*.,

Table 2 Chromosomal translocations in leukaemias and lymphomas

Genes in translocation	Chromosomal target	Disease	References
IgH–BCL2	t(14;18)(q32;q21)	FL	Yunis *et al*. (1987); Lee *et al*. (1987)
MLL–AF4	t(4;11)(q21;q23)	ALL	Kersey *et al*. (1998); Uckun *et al*. (1998)

2003; Merx *et al*., 2002; Press *et al*., 2006). Likewise for follicular lymphoma, a common type of non-Hodgkin Lymphoma, PCR using the characteristic 14:18 translocation is used for diagnosis and the presence of residual disease (Bakhshi *et al*., 1985; Lee *et al*., 1987; Crescenzi *et al*., 1988). Interestingly, patients with evidence of minimal residual disease can remain in remission, which indicates that additional biomarkers are necessary to improve the predictive values of these assays. For follicular lymphoma, further molecular markers such as *ras* oncogene mutations and *p53* mutations may provide additional prognostic value (Hirt *et al*., 2008; Cikota *et al*., 2007).

A summary of leukaemia/lymphoma translocations commonly employed clinically as biomarkers of disease, response to therapy and relapse are shown in **Table 2** (Gabert *et al*., 2003).

Sarcomas are highly variable in cell-type of origin, growth properties and response to chemotherapy. Sarcomas often arise with specific chromosomal translocations that can be used to differentiate various subtypes. For a review of chromosomal biomarkers in sarcomas see Ludwig (2008), Nambiar *et al*. (2008), Riggi and Stamenkovic (2007) and Cooper (1996).

ACKNOWLEDGEMENT

The author is indebted to Ms. J'nice Stork for assistance in the preparation of this chapter.

Ethical Issues in Toxic Chemical Hazard Evaluation, Risk Assessment and Precautionary Communications

Claude Viau

CONTENTS

1 INTRODUCTION

Some key questions that require attention for the ethics of risk assessments are: Who needs to be protected? Against what? How? In this chapter, attention is focussed on man-made chemicals that may bring both benefits to the end users and to the companies that fabricate them, and harm to the same or other end users, the environment and possibly the same companies that manufacture the chemicals. In examining any risk situation, it is important to identify who stands to win and who stands to lose. Who will have a conflict of interest? Who will have a conflict of loyalty? Who will have a conflict of responsibility? Ethics in this context can be viewed as a question of striving for consistency between our knowing and our doing. One way of escaping from achieving consistency might be that we see the task as too demanding so that we take shortcuts to 'get a number out'. Another escape is we may consider that the context in which we perform the risk-assessment task will not allow us to do all we may deem necessary, so we 'adapt' our knowledge to the expected outcome. Discussion of the ethical issues will be elaborated from this background.

Many professional organizations have adopted codes of ethics to guide the proper behaviour of their members. The latter are considered accountable to their fellow members of the same organization, but mostly to the publics, who are potentially concerned and affected by their decisions or recommendations. As an illustration, the International Commission on Occupational Health (ICOH) clearly spells our some of the duties and moral obligations of its members, for example:

The risk assessment of occupational hazards must lead to the establishment of an occupational safety

and health policy and of a programme of prevention adapted to the needs of undertakings and workplaces.
Source: (International Commission on Occupational Health, 2002).

A detailed analysis of this document would likely reveal that it embeds aspects of three theories of ethics: utilitarianism and consequentialism, deontological ethics and contractualism (Oughton, 2003). Consequentialism examines the moral value of an action based exclusively on its net consequences. By contrast, deontological ethics considers that consequences are not as central as respect for human autonomy and dignity in assessing the moral value of an action. Finally, contractualism insists on what is agreed upon by contracting parties under idealized conditions, insisting on the fair distribution of harms and benefits. The important aspect of any such analysis for the purpose of this chapter is to realize that in spite of all debates about the differences in these doctrines and their relative merits, there is large consensus on some key questions that the risk analyst ought to consider. Examples are: who is affected, how are risks and benefits distributed, and what possible courses of action are available to face the risk situation under study (Oughton, 2003)? In this chapter, I will emphasize areas of ethical questioning around risk assessment rather that attempting to circumscribe the epistemological contours of ethics as related to risk assessment. In agreement with Brownson *et al*. (2006), I will take the moral position that health scientists, to which category risk assessors belong, are obligated to contribute to the improvement of health in their area of expertise.

One of the immediate challenges in writing on the ethics of risk assessment is to define risk. Hatfield and Hipel (2002) outlined the controversy surrounding the very definition of this word in scientific journals devoted to this topic. For the purposes of this chapter, I will adopt the definition laid out by the International Organization for Standardization (ISO Technical Management Board Working Group on Risk Management Terminology, 2002): risk = the combination of the probability of an event and its consequences. I will consider that the 'event' has exposure to pollutants or drugs as at least one of its components and that 'consequences' are negative impacts on human health. This is not to say that ecological considerations are not in order, but simply that some focus is needed to discuss the topic of ethics in a short chapter. Finally, I will not explicitly consider Sandman's definition of risk (risk = hazard + outrage) (Sandman, 1993) although I fully acknowledge the importance of public representations of risks (Caux *et al*., 2007), and hope the reader will appreciate that due consideration is given in this chapter to a large range of factors that influence the outcome of a risk assessment.

2 SOME FUNDAMENTALS OF ETHICS

Most texts written on ethics mention the work of Beauchamp and Childress (2001). Although I have chosen to approach this chapter from an emergent rather than a theoretical perspective, this pillar of biomedical ethics deserves some consideration. The authoritative book by Beauchamp and Childress emphasizes four basic principles: autonomy, beneficence, nonmalfeasance and justice. Confronted with ethical dilemmas, physicians can analyse medical decisions through these lenses, which has the merit of allowing them to go beyond purely intuitive concepts of 'good' and 'bad' decisions. Transposing these concepts to public-health risk-assessment requires adaptation.

The autonomy of any individual can be respected insofar as that person has sufficient health literacy to appropriately weigh the advantages and disadvantages of the options proposed and assuming that the information is made available in a form that permits understanding by a lay person. A public-health context implies that the autonomy of a whole community must be considered (Chepesiuk, 2007), which certainly complicates the assessment of the health literacy and the development of a consultation process that ensures the best representation of the community's interests. Similarly, both beneficence and nonmalfeasance should be examined from a societal rather than an individual perspective (Vineis and Soskolne, 1993). Finally, the principle of justice should be understood as distributive or environmental justice, where the distribution of benefits and risks must be scrutinized from within-community and between-community perspectives (Roberts, 2000; Bauer, 2008).

3 ETHICAL BEHAVIOURS

In the early 1990s, Greenberg and Martell (1992) conducted a study among the members of the Society for Risk Analysis. About 25% of the membership of the society was surveyed and the response rate was near 30%. The questions were centred on observations made by members of the society of behaviours deemed unethical by self or other risk analysts. Among respondents, 51% reported having observed the 'deliberate overstatement of positive and understatement of negative results', 34% the 'deliberate failure to acknowledge data limits' and 33% the 'design of research to favour a specific result'. The authors discuss the bad policy decisions that can result from the use of unethical science. How well this study represents the frequency of professional misconduct among such professionals can be debated, but it highlights the relationship between available information, its interpretation, and the resulting public-health decisions that result from this process. The critical position of the risk assessor at the interface of the scientific

information and the risk-management decision-process is discussed below. For further examination of ethical issues for toxicology professionals, see **Ethical, Legal, Social and Professional Issues in Toxicology**.

4 RISK ASSESSMENT AND THE RISK-MANAGEMENT PROCESS

Every risk analyst knows the so-called 'red book' published by the US National Academies Press in 1983 entitled *Risk Assessment in the Federal Government: Managing the Process*. This publication was a cornerstone of modern risk assessment and management (Committee on the Institutional Means for Assessment of Risks to Public Health NRC, 1983). It was followed more than a decade later by the publication of the US Government framework on risk management (The Presidential/Congressional Commission on Risk Assessment and Risk Management, 1997). The latter document schematically represents risk assessment as part of the encompassing iterative process of risk management, as illustrated in **Figure 1** where 'Risk' stands for risk assessment. Whereas the first document places risk assessment at the interface between information gathering and risk-management decisions, the second clearly shows how risk assessment is intertwined with how the risk question is defined, the selection of risk-management options and consideration for affected and involved parties, designated as stakeholders in the document and in **Figure 1**.

Although numerous other frameworks and schematic representations have been developed by various government and standards-making organizations (ISO Technical Management Board Working Group on Risk Management Terminology, 2002; Joint Standards Australia/Standards New Zealand Task Group on Environmental Risk Management, 2006), there would probably be a large consensus that this representation is typical of current approaches to risk managements in modern societies.

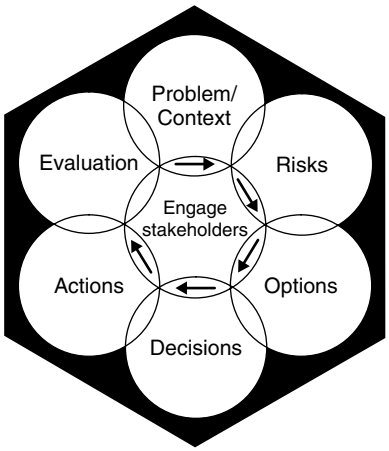

Figure 1 The Presidential/Congressional Commission on Risk Assessment and Risk Management schematic representation of their framework on risk management. 'Risk' means risk assessment in this diagram. (Reproduced from The Presidential/Congressional Commission on Risk Assessment and Risk Management, 2007.)

Many of the ethical questions related to hazard evaluation and risk assessment originate from the articulation between these various elements of the risk-management process. Some may argue that the best way to ensure an objective assessment of the risks is to isolate the scientific assessment from possible influences by other parts of the process. However, even scientific objectivity must be contextualized as Wing (2003) indicated:

> *Strong objectivity demands that scientists critically evaluate how the knowledge they create is shaped at every point by historical social forces. Strong objectivity is therefore not a static feature of scientific knowledge that, once attained, becomes a property of that knowledge.*

Furthermore, if the risk question is ill defined, no risk assessor can provide an appropriate answer to the actual situation that demands attention. A possible consequence here is to use science credentials and the general trust the public grants scientists (Eiser *et al*., 2008) to support a poorly defined risk question, whether intentionally or not.

5 THE RISK-ASSESSMENT INTERFACE

Figure 2 is a simplified illustration of the central role of risk assessment in the risk-management process. I will use this representation to discuss some of the potential ethical pitfalls that may affect risk assessment.

5.1 Sources of Information

In toxicological risk assessment, sources of information are numerous and originate from varied disciplines. The

Figure 2 The central role of risk assessment in the risk management process.

obvious ones are animal toxicity data and epidemiological studies. The recent years have seen the emergence of genomics, proteomics and metabolomics as additional sources of information to the risk analyst. A recent report by the US National Research Council (Committee on Toxicity Testing and Assessment of Environmental Agents—National Research Council, 2007) proposes to redefine the way in which toxicity testing is conducted.

In this framework, the goals of toxicity testing are to identify critical pathways that, when perturbed, can lead to adverse health outcomes and to evaluate the host susceptibility to understand the effects of perturbations on the human population.Viewing toxic responses in that manner shifts the focus away from the apical end points emphasized in the traditional toxicity-testing paradigm, towards biologic perturbations that can be identified more efficiently without the need for whole-animal testing and towards characterizing host vulnerability to provide the context for assessing the implications of test results.

The potential consequences on the way risk assessments might be conducted in the future are not trivial. A single risk assessor rarely possesses expertise in all relevant areas of risk assessment, and the emphasis on mechanisms of action as core elements of toxicity testing will require an unprecedented breadth of scientific knowledge. Weighing the various elements of the scientific evidence currently is and will remain challenging. And as science is the main backing of numerous risk decisions, there is a moral obligation not to overlook any of the relevant scientific information that contributes to the risk assessment. Two typical scenarios can be envisaged.

In the first case, a risk assessor or risk-assessment team does an extensive review of the original literature on a specific risk question. For years now, there has been increasing incentive towards using a weight-of-evidence approach in medicine and related fields. Weed (2005) characterized the use of this concept in the context of risk assessment from a survey of the scientific literature between 1994 and 2004. He concluded that the use of the expression 'weight of evidence' is unclear and diversely employed by authors. He found that the expression was used in a purely metaphoric sense in roughly 50% of the cases. Without a clear definition and usage of this expression, it can falsely further undeserved scientific credibility to a risk estimate that may actually rest on foggy scientific evidence. In the words of Weed:

> *This metaphorical category of 'weight of evidence' also highlights an important problem in the current practice of risk assessment: lack of transparency; that is, a tendency to underreport, even omit, the details of the interpretative methodology used.*

In the second case, risk assessments may be conducted or may already have been performed by an independent committee composed of experts from various disciplines who deliver a consensus assessment to a decision-making organization, and may make this information available for future assessments of comparable situations. This process has the potential to produce a balanced judgement about risks. However, Irvine *et al*. (2004) warn that problems that are examined in a multidisciplinary setting are unlikely to admit a single solution. The authors therefore call for what they term dialogic ethics organized around an extended notion of collegiality. Generally, consensus opinions are considered preferable to a single-expert assessment because they increase the confidence of the recipient of the recommendation that multiple dimensions were considered and that biases are better circumscribed and controlled. However, consensus reports may also lead to a false sense of 'unanimity' among experts for the very reason that the recipient may not distinguish consensus from unanimity. This is what Hansson (2004) termed the 'consensus fallacy'. Recognizing that oftentimes expert committees strive for compromises whenever possible, a consensus opinion may well mask minority opinions that might inform decision-makers about important, perhaps otherwise inopportunely hidden, aspects of the risk assessment.

Figure 3 shows the classical 'continuum', or stepwise relationship, between exposure to a pollutant and the development of a disease (Committee on Biological Markers of the National Research Council, 1987). There exist two broad categories of factors that can modulate the progression of the biological events along the illustrated continuum. The lower portion of the figure shows that individual biological susceptibility factors may play such a role. It is worth insisting here on a truism: without exposure, the genetic-susceptibility factors cannot render an individual more or less susceptible to a pollutant-related disease. In other words, search for susceptibility factors must not be performed at the expense of a search for means to reduce exposures to pollutants (Vineis, 1997; Viau, 2005; Vineis *et al*., 2005).

In addition to objective scientific evidence, other aspects of the risks need to be cautiously considered. Those concerned by the risk assessment need to be involved in the risk-assessment process (Chapman, 2007; Hermansson and Hansson, 2007). **Figure 3** shows how the social environment may have a profound influence on the relationship between exposure to environmental hazards and disease. For example, it has been shown that a lower socioeconomic status augments the deleterious effects of exposure to fine particulates (Wheeler and Ben-Shlomo, 2005; Forastiere *et al*., 2007). This effect may be attributed namely to geographical distribution of both traffic emissions and of disease burden. More generally, lower socioeconomic status may be associated with insufficient health literacy to efficiently use available information on the relationship between health and pollution (Chepesiuk, 2007), with higher exposures, with poorer defence mechanism (e.g. unbalanced nutrition),

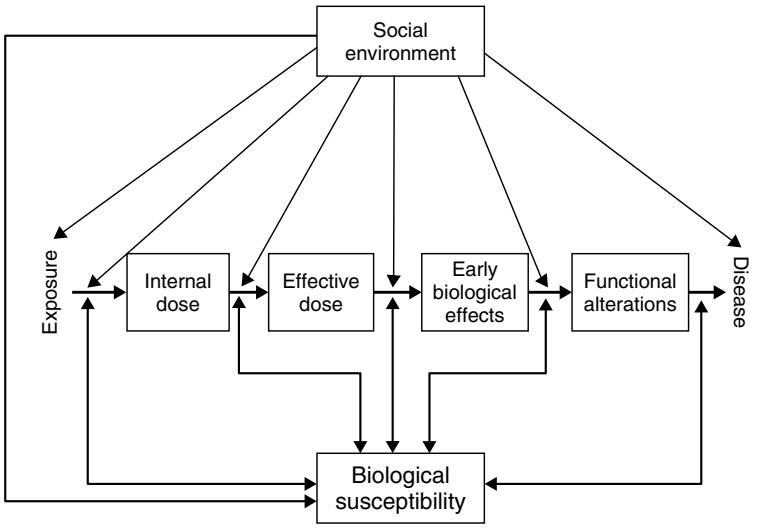

Figure 3 Modulating effect of the social environment on the classical relationship between exposure to an environmental hazard and disease.

with pre-existing health impairments and with limited access to health care. One might argue that these factors are intrinsically taken into account in the interindividual susceptibility factor used to elaborate reference doses or concentrations from no observed adverse-effect levels (NOAELs), obtained in animals or in humans. However, if a study of the social environment is not included in a risk assessment, are we assessing risks comprehensively enough to properly guide adequate public-health decisions and ensure environmental justice? Surely, the risk assessor must be involved in the examination of the influence of the social environment on environmental health issues to comprehend how such factors may modulate the continuum between exposure to pollutants and disease.

As Roberts (2000) stated:

> *If the central premise of the environmental justice movement is that minority and economically disadvantaged populations bear disproportionate health risks from pollution, then risk assessment should play a major role in identifying and rectifying inequitable situations.*

It is also appropriate to emphasize that in addition to its modulating effect, the social environment can itself be a cause of diseases, for example, through psychological stress that may affect the cardiac or central nervous system functions. It ensues that chemical factors may add up to or act synergistically with these social determinants in altering the health and wellbeing of members of a community. Contemplating toxicants as factors modulating the health effects of the social environment offers the risk analyst a different perspective altogether.

Another aspect that requires ethical thinking is scientific uncertainty. This topic will be further discussed in two other sections of this chapter dealing with risk management and the precautionary principle. From the standpoint of available information upon which to base a risk assessment, uncertainty needs to be recognized and fully discussed (Brody *et al*., 2007) although uncertainty may be seen by the public as an indication of either honesty or incompetence (Johnson, 2003). Judgements on risks are only exceptionally dichotomous ('safe' vs. 'dangerous'). Furthermore, as expert as they might be, judgements cannot be reduced to the abstract simplicity of an absolute risk estimate, as Horton (1998) asserted. Additionally, risk assessment along the safe–dangerous continuum should most of the time be considered as a range rather than a point estimate, reflecting the uncertainty of the estimate (Committee on Risk Assessment of Hazardous Air Pollutants, 1994). The complexity and uncertainty of assessing the risks associated with exposure to mixtures of chemicals should suffice to exemplify the uncertainty that surround many risk estimates (Cassee *et al*., 1998). Determining and revealing the boundaries of scientific (un)certainty should be an intrinsic part of risk assessment.

5.2 Context and Risk-Management Decisions

As already pointed out, defining the risk question shapes the way in which the risk assessment *per se* is performed (Hatfield and Hipel, 2002). It follows that for the risk assessment to be a true professional act, rather than a purely technical operation, risk assessors must ascertain that they fully understand the contours of the risk questions and that they can input into the process to help define these questions, based on their *a priori*

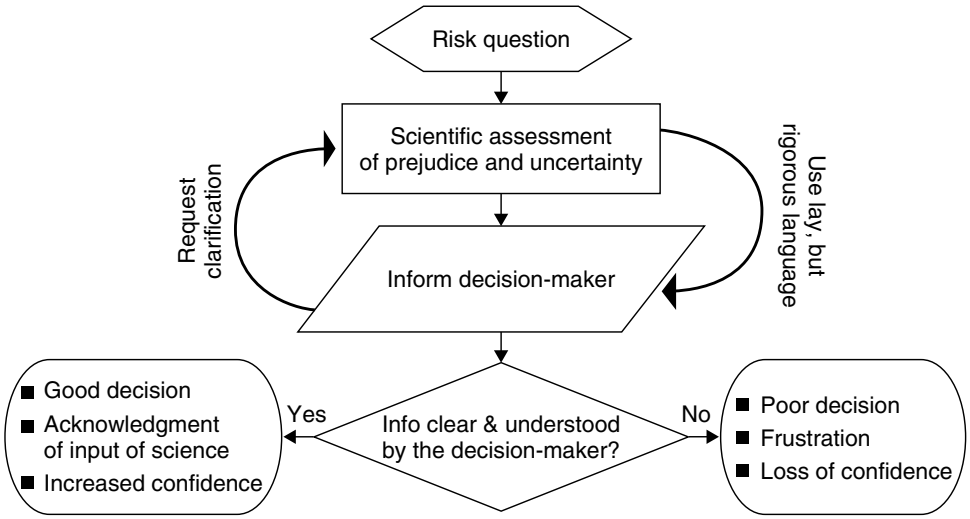

Figure 4 Communication of scientific risk assessment to decision-makers: an interactive process.

scientific knowledge. This actually contributes making the overall risk management process an iterative and interactive one. Science should not be used to bring credibility to pure ideology. Undocumented biases in the formulation of the risk question inevitably lead to biases in the risk assessment. Additionally, faced with complex questions, scientists tend to isolate elements of this complex system so as to better study, understand and explain the available information. By doing so, they may actually translate the complex system under study into scientifically manageable elements that, however, only remotely connect with reality. Put in plain language, scientists may end up looking only for the risks they are familiar with. It would appear adequate to acknowledge concerns about risk that are not addressed and to say why; additionally or alternately, risk assessors should indicate which concerns were considered, which were not, and how they both influenced their judgement.

It is interesting to observe how well-intentioned risk assessors can make radically different assessments based on the exact same scientific sources of information. Risk assessment is a value-laden process in which objectives, mandates, values and perspectives of the risk analysts influence the results of a risk assessment. Hatfield and Hipel (2002) have nicely illustrated this with the alachlor registration controversy in Canada in the 1980s. In this work, they showed how extrascientific factors led three groups to three different and contentious results, largely owing to the problem formulation and differences in the conceptualization of the system within which they were performing the risk assessment. The authors argue that discussion on the premise of the risk question and of its context can probably contribute to resolving some of these discrepancies. At least, an open discussion of the system parameters would have the merit of exposing the reasons for these discrepancies and, hence, of reducing suspicion of hidden agendas and ill-intention that may otherwise be expressed by the spectators of the scientific debate.

Once a scientifically sound and morally defensible risk assessment has been performed, there remains a key task to be accomplished: that of communicating the results to those concerned with the issue, including the decision-makers. All too often, this is seen as a one-way process: the risk assessor produces a report that is transmitted to those concerned and considers that step as the termination of his/her duties. **Figure 4** shows how inappropriately communicated or poorly understood scientific information can lead to poor decisions and nourish distrust and anger between parties. A typical comment from the decision-maker would be, 'I wish the scientists would provide me with useful and clear evidence upon which I can base a decision rather than an incomprehensible jargon cocktail'. Reciprocally, scientists might think, 'However clever and well-documented my recommendation might be, decision-makers always go with their own preconceived decisions that make no room for scientific evidence'. Two key points should be made here. Typically, scientists are not trained as science popularizers. They like to use scientific jargon that resonates in their knowledge sphere, but not in the nonspecialists' minds. Learning to communicate effectively is a challenge that involves making compromises between providing sufficient details to nuance one's expert opinion and 'getting to the point'. However, this is not an insurmountable endeavour and should be encouraged by the desire to make science serve its useful purpose. Conversely, the recipient of an expert opinion, especially if this person is a decision-maker, has the obligation to ensure that his/her opinion is based on the actual scientific assessment, not his/her biased interpretation of it.

6 THE PRECAUTIONARY PRINCIPLE

6.1 Pandora's Box

The precautionary principle became popular as principle 15 of the Rio Declaration (United Nations Environment Programme, 1992):

> *In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation.*

Numerous articles and editorials have been written in support of or against the precautionary principle. Some argue that this is nothing more than a policy tool to cover ignorance and favour protectionism (Tuomisto, 2004). Some consider it is an invalid principle for rational decision-making and untenable as a moral principle (Harris and Holm, 2002). Others believe it is an excellent example of a public-health decision-making approach that blends evidentiary and ethical considerations (Weed, 2004). Wandall (2004) compared the aims of pure science and risk assessment. She argues that it is crucial for the creation of new knowledge in pure science to try and avoid accepting hypotheses that may later turn out to be false. From that perspective, it is better to reject uncertain statements, even if they are proved true later. In risk assessment, she adds, it is vital to avoid concluding that a substance is harmless, when in fact it is not. This is a foundation of the precautionary principle. Weiss (2001) also insists on putting human-health protection at the forefront:

> *In essence, customary practice assumes that toxic agents and hazardous practices are entitled to more rights than the public and are innocent until proven guilty.*

Finally, Latour (2000) considers that the principal merit of the precautionary principle is to bring the scientific debate within the social arena rather than confining it to the experts' realm. The debate certainly has not come to a resolution yet and it would be both futile and presumptuous to hope to bring it to closure in this chapter. Suffice it to say that the precautionary principle does exist and is used by various organizations to support the decision-making process about risks. It has sufficient teeth that it has held in check the largest economic power on this planet around a number of issues (Whiteside, 2006). Furthermore, many people would probably agree that some form of guidance is required when important risk-management decisions must be taken in the face of large uncertainties, whether we call it the precautionary principle or not. It therefore probably deserves some attention.

6.2 The Muddled Boundaries of the Precautionary Principle

Just as the expression 'weight of evidence' was said to be largely diverted from its methodological sense in numerous scientific articles (Weed, 2005), many organizations and decision-makers pretend to base decisions on the precautionary principle in a purely metaphoric, and inappropriate, sense. Oftentimes, they actually mean 'based on a rigorous, and prudent, assessment of the risks, we have determined that . . . ' or, conversely, 'we have no scientific reason to take action here, but in consideration of public outrage, we have decided to . . . ' These misnomers largely contribute to the undermining of the precautionary principle as evolutionary thinking about risk management.

Principle 15 of the Rio Declaration and its numerous adaptations focus on two dimensions: the severity and irreversibility of a threat, and the uncertainty in the scientific assessment of the situation. Applied to toxic substances, severity and irreversibility refer to the harm that exposure to the substances might cause to people. Uncertainty concerns either the causal relationship between exposure and health outcomes, or the estimates of potential doses to which people might be exposed.

Figure 5 identifies various types of risk decisions based on appraisal of the severity and the uncertainty of a situation. The responsibility of assessing these parameters rests, at least in part, with the risk assessors. This is clear, at least as far as the scientific uncertainty is concerned, whereas severity is largely a value-based judgement that should involve those concerned by the risk situation. Admittedly, there can be no universal scale for severity. Amputation of a limb in a single industrial

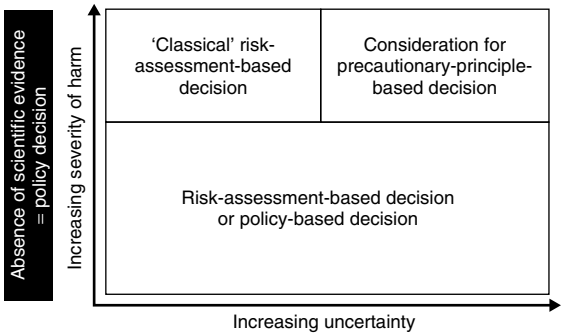

Figure 5 Labelling of various types of risk decisions based on the severity of a prejudice and the uncertainty of the assessment.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat162

worker would probably rank very high on the severity scale for this enterprise, whereas it would likely to be ranked much lower by an organization concerned with starvation or the propagation of deadly infections in a refugee camp of thousands of people. Although there can visibly be no universal rules for the application of the precautionary principle, an organization can still strive towards its consistent application. Building a consensus severity scale for potential outcomes within its mandate, establishing an uncertainty scale based on the weight of evidence, and mapping the various issues on a severity vs. uncertainty graph, such as the one shown in **Figure 5**, might constitute a first step towards consistency.

Two additional comments appear worthy at this point. First, there is nothing fundamentally wrong with taking a policy decision (lower portion of the graph) that is not based on scientific evidence, insofar as this is clearly spelled out and not erroneously labelled 'precautionary'. An example would be responsibly responding to public outrage that is not justified based on expert assessment of the scientific evidence. Second, there might be situations where all scientific evidence converges to indicate a given situation is not problematic (labelled 'Absence of scientific evidence' in **Figure 5**). Pretending a decision is based on the precautionary principle because 'absence of proof is not proof of absence' is nonsense. Sound application of the precautionary principle requires that there be 'some' credible indication of a severe threat based, for example, on structural similarity with other known toxic chemicals or partial epidemiological evidence. Otherwise, any decision based on the 'absence of proof is not proof of absence' principle is a policy, not a precautionary, decision.

7 RISK ASSESSMENT AND DIALOGUE ON ETHICAL ISSUES

I have attempted to identify areas in a toxicological risk-assessment process, including consideration of the precautionary principle, where a dialogue on ethical issues might be appropriate. One could term these potential 'ethical pitfalls'. This is illustrated in the flow diagram of **Figure 6**. I make no claim that this ought to be the only way risk assessments should be performed to be labelled 'ethical' or that the elements identified are comprehensive. The flow diagram illustrates a broad risk-management process and includes consideration of the precautionary principle, but focusses on areas that should directly involve the risk assessors. These are labelled E1–E6 and will be briefly examined below based on what has beendiscussed in this chapter. The abbreviation 'cMAD' stands for contextualized maximum allowable dose and can be interpreted loosely either in a standard setting sense of establishing a new reference dose or in determining whether an actual exposure situation is deemed acceptable, compared to a preset reference dose.

7.1 Scientific Certainty (E1)

Uncertainties arise when information is very scarce or when there are discrepancies among the findings of various pieces of independent and methodologically sound scientific investigations. However, scientific 'certainty' is a rather loose terminology in that it usually results from a professional judgement carrying some degree of subjectivity as to determining how certain is 'certain'. Hence, the judgement about certainty is not necessarily shared by other experts. In the context of toxicological risk assessment, it is possible that for a given substance, different reports will establish different levels of health effects, or establish different doses at which health effects may start to appear. There could also be dichotomous findings, where one group proposes an adverse health effect, while the other may propose that no adverse effects exist for the same exposure. Assessing (un)certainty based on a weight-of-evidence approach, supported by strong methodological bases and comparing one assessment to previous assessments to ensure consistency, should contribute to making this a reasonable process.

7.2 Severity of Harm (E2)

There might be a general consensus that life-threatening illnesses (e.g. cancer) or seriously debilitating and irreversible health effects (e.g. reproductive effects) are 'serious' health effects. However, the same effects that are mild or less than severe for a healthy individual may be perceived or experienced as very serious and even life-threatening by a sensitive individual (e.g. with a pre-existing health condition). Furthermore, from a public-health perspective, the number of potentially affected people also needs to be taken into account, as well as the distribution of the potential impact among various populations (Harrison, 2008). Once again, appreciation of the severity of harm will heavily depend on the organization's mission, but consistency can probably be achieved by mapping the potential consequences of the various risk situations encountered. Public involvement is essential here to avoid the biased judgement of one or more experts based on their own values.

7.3 Risk Acceptability (E3)

Substances with presumed no-threshold effects are treated differently from the ones where a threshold is deemed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

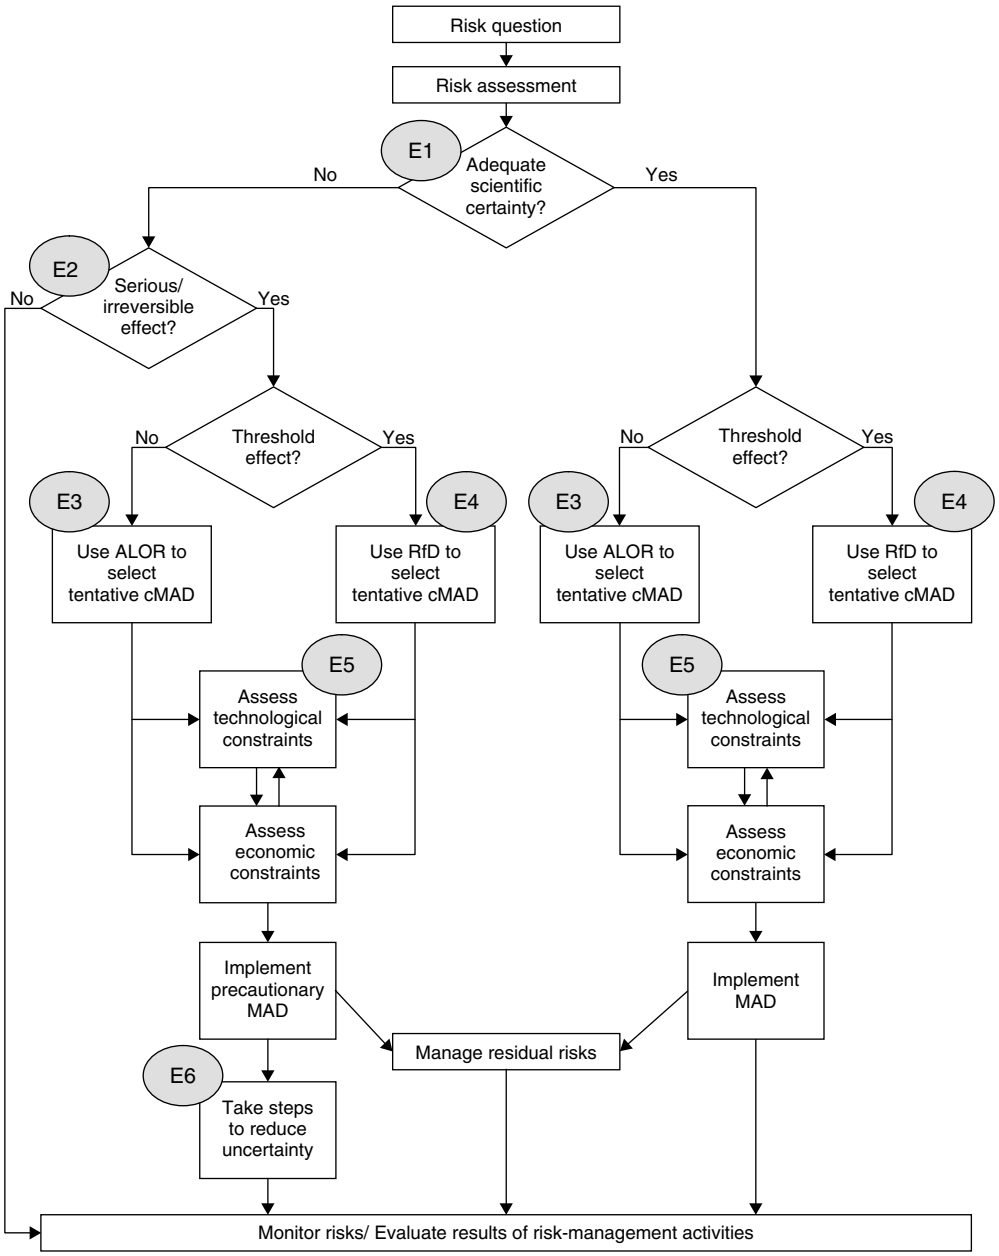

Figure 6 A risk-assessment flow diagram identifying potential ethical traps in the process. ALOR = acceptable level of risk; cMAD = contextualized maximum allowable dose; RfD = reference dose; E1–E6 = potential ethical pitfalls—see text for description.

to exist. For the nonthreshold chemicals, it is customary to estimate a 'residual' risk associated with exposure to one or more doses of chemicals. Since only a dose of zero corresponds to a null risk, a level of 'acceptable' risk needs to be defined for operational purposes. From a scientific perspective, risk acceptability should be a function of the severity of the potential hazard and of the probability that the risk materializes. Both these dimensions are profoundly conditioned by the perception of the risks by the public (Slovic *et al*., 2004). Some of the questions that need to be brought forward are: 'Acceptable to whom and with what consequences?' 'Who decides what is acceptable and on what basis?' One example will illustrate the complexity of these questions. It is 'generally accepted' that workers can be exposed in an occupational context to doses of chemicals that correspond to a potential risk of developing up to one cancer per thousand individuals. However, in the general population, the acceptable risk level is usually in the range of one per hundred thousand or one in a million. Justifications for the higher 'acceptable' risk levels in workers include the fact that they are healthier and stronger and they get benefits as salary from their job. Is this fair to people who are expected by society to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat162
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

contribute to its wellbeing (Ball, 2002)? Risks are more likely to be generally accepted for various reasons than they are truly acceptable.

7.4 Reference Doses (E4)

For threshold pollutants, reference doses (or concentrations) are typically established from the NOAELs obtained in an animal or epidemiological study. To account for interspecies and interindividual differences in susceptibility to develop toxicity from exposure to the studied pollutant, the NOAEL is divided by a series of so-called safety factors. Although in most cases this empirical and partially mechanistic approach has proved useful in protecting populations from the toxicity of pollutants, some expressed concerns about the general applicability of the factors (Hattis *et al*., 1999), in particular as they relate to the exposure of children (Landrigan *et al*., 2004). This brings back the initial questions asked at the beginning of this chapter: 'Who needs to be protected and against what?' The risk assessors would be well-advised to use NOAELs and safety factors as guidance, not absolute truth (Wennig, 2000).

7.5 Technological Constraints (E5)

Assessing the technological constraints or technological feasibility of lowering exposure to pollutants is not a risk-assessor's task *per se*. However, it is important to note that the engineers or other technical professionals examining the technical aspects of lowering exposures also have their own set of values that will influence their assessment and advice about what is feasible. It might therefore be appropriate, if not essential, that the risk-assessment issues be known to them before they conclude on the best 'possible technical solution'. The importance of this interaction between the risk assessors and the engineers may be even greater for the determination of 'ALARA' option, where the acronym stands for 'as low as reasonably achievable'. Alternative labels for such options have been 'as low as technically feasible' or 'as low as reasonably practicable'. All these expressions bear a heavy weight of value judgements. Comparable reasoning would also apply to economic assessment.

7.6 Uncertainty Reduction (E6)

A decision based on the precautionary principle must usually be considered temporary, awaiting further scientific evidence. It also obligates the decision-making body to take active steps in the reduction of uncertainty (World Trade Organization, 2008). Risk assessors of course have a role in identifying the knowledge gap to be filled and in determining when scientific information will be deemed sufficient to allow a more definitive risk-management decision. The reassessment of uncertainty must be performed in consistency with the initial assessment and with those made in other, comparable, cases.

8 CONCLUSION

Ethics is not static, but rather complex and adapting to the moving social context and values. It is therefore a paradoxical undertaking to try and 'conclude' this chapter on ethical issues in risk assessment and precautionary communications. It rather appears more appropriate to transform this conclusion into a series of invitations to risk assessors. An invitation to make their scientific knowledge contribute to the wellbeing of others. An invitation to openly acknowledge the limits of and the uncertainties in the scientific knowledge, as well as the contribution of social factors to chemical risks. An invitation to admit that most expert judgements are value-laden. An invitation to accept that those the risk-management process strives to protect need to have their say about the process. An invitation to strive for efficient translation of their knowledge to others, in order to contribute to wisdom in decision-making about risks. An invitation to make their knowing consistent with their doing.

ACKNOWLEDGEMENTS

I wish to thank Drs. David J. Roy, Suzanne M. Bisaillon and Subramanian Karthikeyan for helping me shape my vision of the ethical issues in risk assessment and risk management.

Food Allergy and Intolerance

Martinus Løvik

CONTENTS

1 INTRODUCTION TO FOOD ALLERGY: TERMS AND CONCEPTS

Allergy is a word meaning 'altered reactivity' and was first used by the Austrian physician Clements von Pirquet in 1906. Allergy as the word is used now represents an inappropriate, symptom-causing immune reaction against a substance foreign to the body. Allergy is a two-step process. First, upon exposure to the foreign substance, the allergic immune response develops (the 'learning phase', called *sensitization*), to establish a state of increased reactivity to the particular substance in the sensitized individual. Thereafter, upon prolonged or renewed exposure to the substance, the *allergic reaction* may develop ('triggering' or 'provocation' phase). The allergic reaction is a particular type of *inflammatory reaction* triggered by allergen-specific immune mechanisms. *Specificity* is very high—a change of one amino acid in the binding site (epitope) on the target molecule can

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

be enough to completely abolish reactivity of an antibody. Another typical feature of immunity, including allergy, is *memory*—the heightened state of reactivity is very long-lasting, often life-long. Another important feature is that sensitization (the allergic state of immunity) is not always accompanied by clinical reactivity, and the word allergy should be reserved for the state with *clinical reactivity*. Sensitized individuals without clinical reactivity will be 'false positives' in common allergy tests.

Even among immunologists, the word allergy is used with somewhat different meanings. Traditionally, the word was used for hypersensitivity reactions (abnormally strong reactions) mediated by immunoglobulin E (IgE) antibodies (Type I reactions, according to the traditional Coombs and Gell classification) and by specific cell-mediated immune reactions (Type IV reactions). The IgE-mediated reactions are associated with allergic diseases like allergic rhinoconjunctivitis (e.g. hay fever), allergic asthma, allergic urticaria and food allergy, whereas the cell-mediated allergic reactions mainly are seen in the form of allergic contact dermatitis to low-molecular-weight substances, both man-made (chemicals) and natural (e.g. poison ivy). However, a few years ago, a new nomenclature was proposed, according to which all specific immune reactions causing hypersensitivity to substances foreign to the body should be called allergic, regardless of immune mechanism (Johansson *et al*., 2004). This way, allergy would mirror *autoimmunity*, the main difference being that allergy is directed against foreign (environmental) substances, whereas autoimmunity is directed against our body's own molecules. However, some experts feel that naming most immunopathology caused by exaggerated immune reactions against foreign substances allergy, brings confusion rather than more clarity to the field. Therefore, in the scientific literature, the term allergy is used by some authors in the old specific meaning, and by others in the newly proposed wider meaning.

Food allergy is allergy to foods and their components. Usually we talk about food allergy only after oral intake. However, one should be aware that allergy is systemic and is, in principle, expressed anywhere in the body where immune system cells or immunoglobulins are present. Food allergens can, if airborne, trigger airway diseases like asthma and rhinoconjunctivitis. This is sometimes a problem in the workplace, for example crab processing plants, where, in this setting, crab, which is a fairly common food allergen, will trigger airway disease. Similarly, fish allergics may get asthmatic attacks in fishmarkets because of fish proteins in the air. Further, skin contact with foods may trigger allergic skin reactions (e.g. contact urticaria) and on rare occasions even anaphylactic reactions (Lucas and Atkinson, 2008). Birch-pollen-allergic individuals may get signs of intestinal inflammation during the pollen season (Magnusson *et al*., 2003), and there is a close link between food allergy and atopic dermatitis (Hauk, 2008). Food allergy, skin allergy and airway allergy are therefore just different expressions of systemic allergy, with the organ of expression ('shock organ') largely determined by the route of exposure.

Only some 10–25% of people reporting they are food allergic have a diagnosable, IgE-mediated allergy (Altman and Chiaramonte, 1996). The remainder may have an intolerance that often is difficult to diagnose. Food intolerance is, with a few exceptions, a diagnosis made by exclusion of other possible causes for the symptoms. Often, the symptoms seem to be caused by psychological mechanisms (Lind *et al*., 2005). However, in some cases, symptoms seem to be caused by IgE-producing cells located in the intestinal mucosa, with negative allergy tests in skin and blood (Lin *et al*., 2002). Also, in particular in children, there seems to be food allergy caused by non-IgE, probably cellular, mechanisms (Jyonouchi, 2008). These reactions come much later after exposure than IgE-mediated reactions (days instead of minutes). Their mechanisms remain unclear, and some doubt the existence of these late food allergic reactions as an entity because they are so ill-defined, whereas many paediatricians consider them an important clinical problem.

The clinically severe, acute forms of food allergy are exclusively caused by IgE-mediated mechanisms. Therefore, both diagnostic work and governmental regulatory efforts with regard to food allergy are focussed on IgE-mediated allergy. This chapter on food allergy will largely deal with IgE-mediated allergy, and, in addition, gluten intolerance (which is difficult to classify, but most often is considered an autoimmune condition elicited by an external factor (gluten)), and two non-immune-mediated hypersensitivities (intolerances), namely lactose and fructose intolerance.

The target molecules of allergic reactions are called *allergens*. An allergen is by strict definition an antigen that is able to elicit an allergic reaction (Johansson *et al*., 2004). Allergens are nearly always protein molecules, but IgE responses against carbohydrate groups occur. Carbohydrate epitopes as targets for IgE-mediated reactions are, however, considered to infrequently be of clinical importance, but may cause 'false' test positivity. Low-molecular-weight molecules (chemicals and metals) may sometimes also be involved in IgE mediated allergy, and then require binding to a protein ('haptenization') for the low-molecular weight substance ('hapten') to become able to induce allergy (become 'complete allergens'). For food allergens, the nomenclature may seem a bit confusing, because both the food (e.g. eggs) and the molecules that are the targets of the allergic immune reaction (e.g. the egg protein lysozyme) are called allergens. However, in the regulatory context, it always is the food that is the regulated allergen (e.g. 'fish and products thereof').

2 MECHANISMS AND SYMPTOMS OF FOOD ALLERGY

Adverse reactions to food can be grouped into those that, because of toxic, microbiological or pharmacological mechanisms, occur in all individuals who eat a sufficient quantity of the food, and those that occur only in some particularly sensitive individuals (**Figure 1**). The latter, apart from individuals in whom psychological mechanisms cause aversion and intolerance, suffer from food hypersensitivity. Food hypersensitivity consists of nonimmunological (nonallergic) hypersensitivity (intolerances because of metabolic conditions, for example enzyme deficiencies, or often conditions with unknown mechanisms) and food allergy. Food allergy consists of IgE-mediated food allergy, and non-IgE-mediated food allergy (Jyonouchi, 2008; Lin *et al.*, 2002). The most important and probably most common form of food allergy is IgE-mediated, and is linked to other IgE-mediated allergic diseases of the airways and the skin. Respiratory allergy, skin allergy and food allergy are closely related with regard to their development (environmental factors as well as genetic background), they share cellular and molecular mechanisms and they tend to occur together. IgE-mediated allergy has two phases, the sensitization phase and the provocation phase.

2.1 Sensitization

The sensitization phase represents an immune response, which results in the production of specific antibodies of the IgE class to the foreign protein (the allergen). The allergen is taken up by dendritic cells and presented in the context of Class II major histocompatibility complex molecules (MHC II) to T helper (Th) lymphocytes (**Figure 2A**). Two major classes of Th lymphocytes are recognized, Th1 and Th2 lymphocytes, which are important in determining the type of immune response that develops after antigen (allergen) stimulation. Additional classes are regulatory T lymphocytes (T_{reg}) (Akbari *et al.*, 2003; Bettelli *et al.*, 2008; Piccirillo, 2008; Stock *et al.*, 2006) and inflammation-promoting Th17 cells (Bettelli *et al.*, 2008; Chen and O'Shea, 2008; Steinman, 2007). The selection of a Th2-dominated response in favour of a Th1-dominated immune response is to a large extent decided by the antigen-presenting cells and the stimuli they get from the introduced foreign material and their microenvironment. Dendritic cells direct the Th cells by expressing costimulatory membrane molecules and secreting signal molecules (cytokines and chemokines) (Belkaid and Oldenhove, 2008) (**Figure 2A**).

Th2 lymphocytes direct B lymphocytes to produce antibodies of the IgE class, and thus promote an allergic immune response. The IgE antibodies will be distributed throughout the body in the blood and extravascular tissue fluid and will bind with their tail (Fc) part to high-affinity IgE receptors (FcεRI) on mast cells and basophil granulocytes, with their antigen-binding sites free. In particular, these cells will be located at the mucosal surfaces of the body (airways and gastrointestinal tract). The individual is now sensitized (**Figure 2A**, **2B**). If again exposed to the same allergen (provocation phase), the allergen will bind to IgE molecules sitting on the surface membrane of mast cells and thereby crossbind these molecules, leading to activation of the mast cell with release of their cytoplasmic granules with an array of potent mediators (histamine, leukotrienes, prostaglandins and others) causing the allergic inflammation (**Figure 2B**). Symptoms may be local or systemic, and can arise from different organs (**Figure 3**). Further, 6–12 hours after the early

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

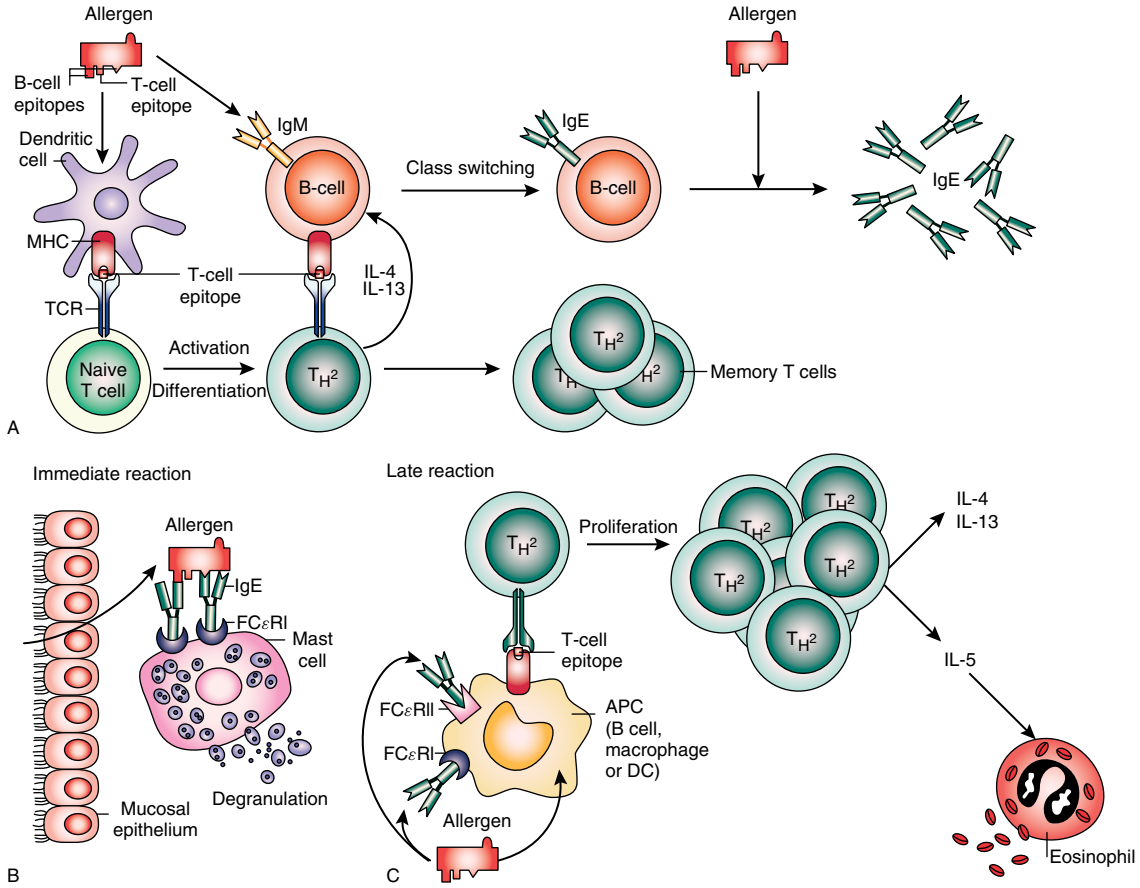

Figure 2 How allergens induce, maintain and trigger allergy. Upper panel (A) illustrates how an allergen at a mucosal surface is taken up by 'professional' antigen-presenting dendritic cells. After processing (digestion) of the protein allergen by the dendritic cell, a small allergen fragment, a T-cell epitope, is presented by dendritic cell MHC (major histocompatibility antigen) molecules on the surface of the dendritic cells, and is bound to the TCR (T cell receptor) of so-called naïve T cells (T cells not previously stimulated by an allergen). The T cells are activated and differentiate into so-called effector Th2 (in the figure T_H2)(T helper type 2) cells. These cells can differentiate into long-lived memory T cells that have specificity for the same T-cell epitope and rapidly will be activated into effector cells if they encounter the allergen again. Th2 effector cells interact with another class of lymphocytes, B cells. Naïve B cells carry IgM (immunoglobulin M) molecules on their plasma membrane, and the IgM molecules may mediate allergen uptake by the B cell if the allergen molecule displays a small part, a B-cell epitope, that matches the somewhat broad specificity of the IgM molecule. Similar to dendritic cells, B cells will then present T-cell epitopes of the allergen on their cell membrane MHC molecules. Upon recognition by Th2 cells with specificity for this epitope, the T cells will produce IL-4 (interleukin 4) and IL-13 (interleukin 13) signal molecules that stimulate the B cell to class switching. After immunoglobulin class switching, B cells will produce IgE (immunoglobulin E) molecules instead of IgM molecules, but with the same allergen specificity as before. Upon continued or later contact with the same allergen, the B cell will differentiate further and secrete large amounts of IgE molecules, all with the same allergen specificity. Lower left panel (B) shows how allergen, after penetration of the mucosal epithelial membrane, can cross-bind IgE molecules bound to the mast-cell membrane by FcεRI (IgE tail part (Fc) receptor one, the high-affinity Fcε receptor) molecules. The cross-binding of IgE molecules will activate the mast cell and cause the immediate release of cytoplasmic granules containing histamine and other mediator substances (degranulation), and an allergic inflammatory reaction will develop within minutes. This immediate reaction represents the first of two waves of allergic reaction upon exposure of an allergic individual to allergen. Lower right panel (C) illustrates the second wave of an IgE-mediated allergic reaction, the late reaction that develops 6–12 hours after allergen exposure. Allergen is taken up by an APC (antigen-presenting cell) either directly or by means of IgE molecules bound to cell membrane IgE high-affinity receptors (FcεRI) and IgE low-affinity receptors (FcεRII). The APC may be a B cell, a macrophage or a DC (dendritic cell). Allergen T-cell epitopes are then presented on MHC molecules to Th2 cells, which are stimulated to proliferate and produce interleukin 4, interleukin 13, and interleukin 5. Interleukin 5 attracts and activates eosinophil granulocytes, which are important contributors to the late reaction. (Reproduced, with permission, from Valenta, 2002.)

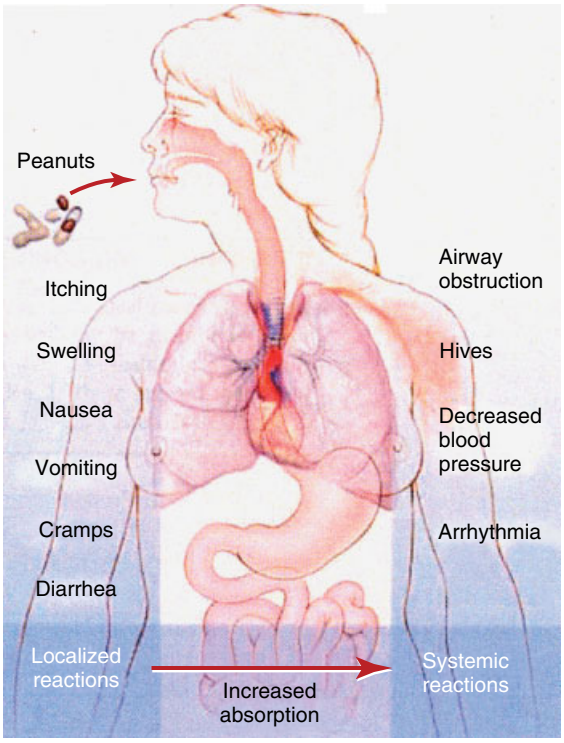

Figure 3 The development of clinical symptoms and signs after ingestion of allergen (here exemplified by peanut) by an individual with the particular allergy. Any combination of symptoms may occur, but systemic symptoms signal a more severe reaction that may develop into anaphylactic shock and cardiac arrest. (Reproduced, with permission, from Long, 2002.)

mast-cell response a second wave of inflammation will develop, with Th cells and eosinophil granulocytes as central actors (**Figure 2C**).

However, a Th2-dominated immune response is not sufficient to develop allergy. Various types of T_{reg} cells and other immunoregulatory cells are important players in the immune response. These cells may promote the production of the Th2-dependent antibody class immunoglobulin G4 (IgG4) instead of IgE, resulting in a 'nonallergic Th2-response', or they may, by other mechanisms, prevent the triggering of the allergic inflammation (Akbari *et al.*, 2003).

The assumed natural route of exposure for food allergic sensitization is the oral route. However, sensitization for IgE-mediated allergy may occur via the skin for certain chemicals and also for protein allergens, and the skin route appears in experimental systems to be strongly Th2- and thereby allergy-driving (Birmingham *et al.*, 2007; Strid *et al.*, 2004). The skin route may be of some relevance for food allergy, and some cases of peanut sensitization have been suggested to have been caused by the use of peanut oil for skin care (Lack, 2008), and cosmetics containing herbal products have also been suspected of inducing allergy. Crossreactivity between food-plant allergens and pollens does, in pollen-sensitized individuals, commonly result in the so-called oral allergy syndrome, or pollen food-allergy syndrome. This condition is caused by primary sensitization and clinical allergy to pollen, for example, birch pollen in Northern Europe. Ingesting foods which contain evolutionally conserved plant pan-allergens (see Section 5) will then cause an allergic reaction. Most often, this reaction is mild and limited to the oral cavity (oral allergy syndrome), but sometimes it may be stronger and even severe and systemic. Commonly, these crossreacting pollen allergens are heat sensitive and are destroyed by cooking, for example, birch-pollen-allergic individuals may react to raw carrots or apples, but not to boiled carrots or heat-treated apples. However, some of the allergens are heat-resistant, like the lipid transfer protein (LTP) (see Section 5). This allergen is involved in peach allergy, common in Southern Europe, and its development is possibly enhanced by inhalation of LTP-containing fuzz from the outside of the peach skin (Asero *et al.*, 2008a). As a result, hazelnut allergy in Northern Europe commonly is caused by crossreaction with heat-sensitive birch-pollen allergen, and the clinical reactions tend to be mild, while hazelnut allergy in Southern Europe is caused by crossreactivity between heat-resistant LTP proteins in peach and nuts, which tend to cause more severe clinical reactions.

What causes the development of food allergy is poorly understood. Clearly, there is a breakdown of normal immune regulation. Genetic predisposition is one important factor. Timing of antigen exposure in relation to development and maturation of the immune system is thought to be important. This also includes 'priming' via mother before birth, but it is uncertain whether and when prenatal exposure will result in tolerance and no allergy, and whether and when allergy development may be promoted instead. With regard to introduction of foods to the baby after birth, it has, for many years, been the dogma that early introduction of foods would promote allergy development, and the advice has been to introduce foods late, particularly so for commonly allergenic foods. A shift of the paradigm now occurs to be going on, because of recent evidence that early introduction of foods may be better in relation to allergy and may promote development of tolerance (Lack, 2008). However, to what extent this will affect advice given regarding the introduction of foods to babies, is not clear at present. The dose of food and the role of other food components and possible immune-stimulating factors ('adjuvants') in food is uncertain. Certain environmental factors, for example, cholera toxin and pertussis toxin, may promote a Th2 immune response at mucosal surfaces (Berin and Shreffler, 2008), while other factors, for example certain bacterial DNA motifs (CpG motifs) may prevent the development of a Th2 response and even turn an established Th2 response into a Th1-like response.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

In summary, the sensitization phase of allergy represents the immunization phase, making the individual ready to respond with an acute allergic reaction upon a new encounter with the relevant allergen. There is little specific knowledge about the conditions for food-allergy sensitization, and sometimes babies and small children experience a food-allergic reaction the first time (known) they ingest a particular food.

2.2 The Provocation Phase

Once a specific IgE has been produced and bound to the high-affinity receptors on mast cells, renewed encounter with the allergen may cause crossbinding of the specific IgE and mast-cell activation with granule exocytosis and mediator release (e.g. histamine, leukotrienes, cytokine and chemokines) (**Figure 2B**). The resulting allergic inflammatory reaction may be local or systemic, and may range from trival to life-threatening. There is no symptom specific for food allergy or for any particular food allergen. The IgE-mediated reactions usually cause symptoms that may start almost instantly, perhaps more often after a few minutes and usually within the first hour. Symptoms may be intestinal (nausea, vomiting, cramps, diarrhoea), cutaneous (urticaria, diffuse redness), from the upper airways and oral mucosa (itching, swelling, obstruction), from the lower airways (asthma symptoms) and the heart and vascular system (arrhythmia, decreased blood pressure) (**Figure 3**). A strong feeling of impending catastrophe is said to sometimes precede serious reactions. The degree of systemic involvement may vary, and any combination of symptoms is seen. Pre-existing asthma is a risk factor for severe food-allergic reactions, and some experts hold the notion that deaths are more often caused by respiratory failure than by cardiovascular collapse. Treatment is first of all intramuscular epinephrin (adrenalin), supplemented by antihistamines and corticosteroids and general emergency treatment. Severity of the reaction is dependent on personal factors including degree of sensitization, possible aggravating factors, food-matrix factors, and dose and potency of the allergen. It should be noted that the early, often almost immediate, reaction caused by preformed mediators released from mast-cell granules may be followed 6–12 hours later by a second wave of reaction, caused, at least in part, by the release of newly synthesized mediators (**Figure 2C**). The two waves of reaction may be separated by an almost symptom-free interval, and observation of sufficient length of patients with strong food-allergic reactions is therefore necessary.

2.3 Aggravating Factors

Food allergic reactions appear to be triggered more easily and become more severe if the person has ingested alcohol, or uses certain medications (e.g. nonsteroidal anti-inflammatory drugs (NSAIDs) and β-blockers). There are reports of patients with suspected food allergy, but a negative food challenge test to the food, who will, however, experience a reaction, if the food intake is combined with a bottle of beer and also exercise. Exercise is well documented to precipitate and aggravate food-allergic reactions, which in this case can come several hours after the food intake. Several food allergens have been reported to cause food-dependent exercise-induced anaphylaxis (FDEIA). Probably the most common allergen involved is wheat, with the ω-(5)-gliadins (part of the gluten molecule) representing the major group of proteins involved (Tatham and Shewry, 2008).

3 THE DIAGNOSIS OF FOOD ALLERGY

The diagnosis of food allergy rests on three pillars. These are: (i) the case history, (ii) tests for specific IgE in serum or skin reactivity to the food allergen in question (prick test) and (iii) food challenge to determine clinical reactivity to the food, preferentially in the form of a double-blind placebo-controlled food challenge (DBPCFC). Serum-specific IgG antibodies to the food have no diagnostic value in relation to allergy, and the intracutaneous test, which is used also by some medical institutions, tends to give a high number of false positives.

3.1 The Case History

Repeated symptoms upon intake of a food is an indication that food allergy to that food may be present, in particular if no other foods are eaten simultaneously (e.g. peanuts out of a bag), or if a few other foods eaten simultaneously vary from episode to episode, or are known to rarely cause food-allergy-like symptoms. However, often the culprit turns out to be different from the food suspected, for example, a patient thinks that they react to spice in hamburgers, but in reality react to the sesame seeds on the hamburger buns. Often the patient thinks she reacts to the most conspicuous or unusual component of the food, while the true cause is a common component. Also, it is important that often the causative component may not be visible ('hidden allergen') and may not be known to be present, for example, anchovies used to give more taste to liver paste may cause an allergic reaction in a fish-allergic individual, or casein used to give form and texture to salmon fillets may trigger an allergic reaction in a milk-allergic individual. Thus, pitfalls with regard to the case history are many. Symptoms may differ: perhaps most frequent are symptoms in the oral

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cavity (feeling of numbness, itching, pain, swelling of lips, tongue, and pharynx) and skin symptoms (redness, urticaria, angiooedema), but also gastrointestinal symptoms (vomiting, loose stools, belly pain) or respiratory symptoms (asthma-like) are not uncommon. Severe reactions may start with a perception of imminent catastrophe, and quickly lead to unconsciousness. Typical for an IgE-mediated allergic reaction is the quick onset of symptoms after food contact with the lips and food intake; often it is a matter of seconds, and a majority of reactions occur within 30 minutes. Thus, 'time to reaction' is an important element of the history. However, sometimes reactions may come somewhat later. In particular, in food-allergic reactions triggered by physical activity (exercise-induced food allergic reactions (FDEIA)), reactions may come a few hours after food intake (four hours is a limit reported by some, but reactions up to 24 hours after food intake have been claimed). If there appears to be inconsistencies and a varying relationship between intake of a food and suspected allergic reactions, one should consider whether varying the presence of cofactors may play a role (alcohol intake, physical exercise, mental stress, certain medications like NSAIDs, β-blockers, etc.). The presence of other IgE-mediated allergies (food, skin, respiratory) in the patient, siblings or parents is another important element in the history. Whereas, the case history sometimes may be very convincing and in practice allows an almost certain diagnosis of food allergy, in most cases additional evidence is needed.

3.2 Allergy Tests

Allergy tests fall into two main groups: serum-specific IgE and skin tests. *Serum-specific IgE determination* consists, as the name indicates, of the measurement of specific IgE antibodies to the (purified) allergen(s) in question. Several commercial systems are available, and these are generally well standardized and validated, and a very wide range of test allergens are available. Advantages are the high level of standardization, comparability with other labs and over time, and that the procedure is noninvasive (apart from the drawing of blood), in contrast to the skin test that entails exposure to the allergen, with a theoretical risk of boosting the allergy and a real risk of precipitating a clinical reaction (fortunately, it happens rarely). A disadvantage with specific IgE measurement is the relatively high cost, and that it may take time to get the answer if the blood specimen has to be sent away for analysis. *Skin tests* will, in practise, mean the so-called *skin-prick test* (*SPT*), in which a drop of fluid containing the allergen is placed on the skin (usually on the inner side of the forearm), whereupon the skin is pricked through this drop with a needle or special lancet so that a small amount of allergen penetrates into the skin. The reaction is read as area of swelling after 15 minutes. There are detailed international guidelines for the conduction of a SPT. Advantages are that the test is cheap and requires no special instruments. A variant (unstandardized) can be performed with the real food in question, by first pricking the lancet into the food (e.g. a fruit, piece of fish, etc.) and then pricking into the skin ('prick-to-prick test'). Disadvantages of the SPT include the exposure of the patient to the allergen, as discussed above, including the risk of precipitating an anaphylactic reaction, a certain subjective element in the evaluation of the test outcome, and influence by variable skin properties and conditions.

For both the determination of specific IgE, as well as the SPT, a critical point is the quality of the test allergens. This is often problematic and constitutes one major problem with allergy testing. Because some allergens are rather labile and easily destroyed by, for example, enzymatic activity or oxidation, and because they vary in their water and lipid solubility, components may be lost during preparation. Thus, there is much room for improvement of test allergen quality, and some discrepancies between different tests and between tests and clinical manifestation can be explained by test allergen differences. The ongoing introduction of recombinant allergen preparations is expected to bring great improvements, with regard to both specificity and reproducibility of allergy testing; however, natural allergens will also be needed, but may perhaps be used more for screening purposes.

It must be emphasized that both specific IgE and the SPT measure sensitization, not clinical allergy, and a 'positive' allergy test does not mean that clinical allergy is present. Sensitization is necessary, but not sufficient, for clinical allergy. Notably, depending on the test allergens and the tested population, as few as one fifth or one tenth of test positives may have clinical allergy, and, in general, the allergy tests discussed will grossly overestimate the number of food allergic individuals. Their negative predictive value is excellent, but their positive predictive value is poor. Whereas few individuals who test negative to an allergen will have an allergy to that food, a majority of those testing positive will have no allergic symptoms. However, a few individuals will test negative, but will, in spite of this, have the allergy. An explanation for these cases may be IgE-producing cells lodged in the mucosa, but little IgE reaching the blood (Lin *et al*., 2002).

3.3 Food Challenge

Food challenge is an obvious and important way to test for clinical food allergy. Optimally, this should be performed by a double-blind placebo-controlled protocol (DBPCFC). It is essential that the test food is properly disguised, for example in pancakes for children,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

that the allergens are not destroyed and that the placebo substance is not an allergen itself or otherwise has the capacity to trigger symptoms. The test food/allergen is given stepwise, beginning with a very low dose and giving a new higher dose after 15 or 30 minutes if no symptoms occurred after the previous dose. Ideally, one should start so low that there is no reaction to the first dose, as this may give an indication of the patient's individual threshold dose and contribute to the determination of a population threshold dose (see Section 8). The tolerated dose is usually given as the sum of the individual doses given without symptoms occurring. Symptoms are reported as subjective symptoms, and more reliably as objective symptoms. The dose interval from subjective symptoms occurring till objective symptoms appear is variable—sometimes 20- or 10-fold, sometimes less. There are several international and national guidelines for the DBPCFC. Variants of the challenge test are single-blinded challenges and open challenges; because of simplicity the latter are often used for screening, followed by DBPCFC for allergens found positive. The simplest challenge can be performed in the home. It consists of elimination and reintroduction of foods and food components, but the possibility of bias is large when one or both of the patient and the test administrator know if a suspected allergen is given. DBPCFC is often called the gold standard of food allergy testing. Still, both false positive and false negative results may occur, and, in addition, there are sometimes reactions to placebo. Furthermore, DBPCFC is not an allergy test in a strict sense, but a test for reactivity to the food. It should therefore always be performed in combination with allergy tests (specific IgE or SPT). The advantage with the DBPCFC is first of all its reliability with regard to demonstrating clinical reactivity to the food, with a relative absence of bias caused by expectations of the doctor and psychological factors of the patient. Disadvantages include its demand for high expertise and skill, it is time-consuming and expensive, and patients often fear reactions and discomfort they sometimes claim to experience for a long time after the test procedure. There is a risk of anaphylactic reactions; therefore, DBPCFC often is not used with patients having experienced severe reactions. The DBPCFC is not ethically uncontroversial, and practices differ in different countries for that reason, and because of local traditions and the resources needed.

3.4 Determination of Food-Allergen Exposure

An important part of the diagnostic workout of a suspected food allergic reaction is the determination of food-allergen exposure. The acute exposure assessment has two main components, the *history* of the incident (including reading of labels and getting information from the manufacturer) and *biochemical investigations* of food-allergen content.

For the history, it is important, not only to listen to the patient and others who were present, but also to actively try to find out if other items were consumed than those reported. The patient's story will often be biased towards one particular incriminating agent. Other meal components may be overlooked, like spices, sauces, toppings, snacks eaten before the meal, drinks and so on. The possibility of allergen contamination from foods present on the table, in the kitchen or in the storeroom, but not eaten must be kept in mind (Faeste *et al*., 2003). When relevant, the food package should be examined (labelling, batch number, etc.).

For the biochemical analysis, a sample of the food eaten (including stomach contents) is far better than a sample of the same food delivered from the kitchen or purchased in the store, because random contamination and small-scale manufacturing errors, for example, in the kitchen or a little bakery will be picked up only from a sample of the food eaten (or at least the same preparation batch). Purchased samples (preferably the same production batch as eaten by the patient) will have little value in picking up random contamination, but will be of value in relation to systematic contamination problems, and production and labelling errors. Food-allergen identification and quantification are highly specialized tasks, to be performed by experienced, competent laboratories. We refer to the special literature, and will here only briefly mention some main principles. First, one should be aware that protein denaturation (e.g. by heat, hydrolysis) may cause problems, in particular if immunological methods are to be used for allergen identification. An antibody reacting with the native protein may not bind the denatured protein, and there may be peptides present capable of triggering an allergic reaction even if no proteins or allergenic peptide fragments are detected in antibody-based assays. Further, extraction of the allergen may be a problem, and the food/allergen matrix may interfere with the analysis. Thus, needless to say, the preparation of food samples for analysis is a critical and demanding step. For the allergen assay, three major types of assay will be DNA-based assays, immunological assays (often enzyme-linked immunosorbent assay (ELISA) format) and spectrometric methods. DNA-based assays are suitable for screening and will demonstrate the presence of material from the particular source in question, for example, peanut, wheat or fish, but not the allergen itself. Immunological assays will demonstrate the presence of the allergenic protein, and can be more-or-less quantitative. One frequent problem is immunological crossreactivity (i.e. specificity problems). Increasingly, spectrometric methods are being used for protein/peptide analysis (Goggin *et al*., 2008). For research, and also legal purposes in relation to food fraud or diagnostic investigation of serious allergic reactions, other 'proteomics' methods may additionally be used.

4 MAGNITUDE OF THE PROBLEM: EPIDEMIOLOGY OF FOOD ALLERGY

There are no symptoms that are specific for food allergy, and the diagnosis is often difficult and the procedures resource-demanding, as discussed above. Further, some 5–20 times more people think they have symptoms caused by food allergy than the number that can be verified by currently established medical diagnostic procedures (Altman and Chiaramonte, 1996; Young *et al*., 1994). Finally, the area of food allergy is a playground for many nonscientific self-appointed 'experts', laboratories and organizations, which contributes to the uncertainties about diagnosis and prevalence.

The common general statement about prevalence of food allergy is that 1–4% of adults and 4–8% of children suffer from food allergy. The prevalence of food allergy is age-dependent, gender-dependent and different in different geographical regions. There are few good epidemiological studies on this topic in the literature, first of all because of the complexity of establishing the medical diagnosis of food allergy. Data on the prevalence of seropositivity (specific food IgE to food allergens) and SPT positivity cannot be used as reliable indicators of prevalence, because test positivity (sensitization) is far more common than clinical allergy, and because the relationship between sensitization and clinical allergy will differ between different allergens and in different populations.

The literature on gender differences is scarce, but data suggest that food allergy is more common in females. This is supported by findings in the Norwegian Food Allergy Register, a reporting system for severe allergic reactions. Here, about 60% of the total of reported cases were females and 40% males (Løvik *et al*., 2004); interestingly, among prepubertal children, this appeared to be different with a predominance of boys, which resembles the situation with regard to asthma.

The prevalence of food allergy is highest in small children, and reported to be up to 8%. The most important allergens differ in children and adults. In particular, cows' milk and hens' egg allergies are important in small children and, to a large degree, responsible for the high prevalence of clinical allergy in this age group, but some 80% of the children will outgrow these allergies by school age. Peanut allergy is important in all age groups and is less frequently outgrown, whereas, for example, shrimp allergy is more often found in adults. In principle, all food allergies can be outgrown at all ages, a fact which is important to remember to avoid unnecessary life-long avoidance of allergens to which the person has developed tolerance. Once tolerance has developed in formerly clinically allergic individuals, it seems important that the allergen is eaten to help maintain and reinforce tolerance (tolerance is an active immunological nonresponse). When and how to test for the onset of tolerance to a food must be decided by a doctor, because of the risk of serious reactions.

There are some indications that the prevalence of food allergy in adults has been underestimated, and the upper limit of the probable prevalence rate is now sometimes said to be 4%. This is heavily based upon a study by Sicherer *et al*. (2004), where fish and shellfish allergy alone was reported in 2.3% of the population. Sicherer *et al*. (2003) and Sicherer and Sampson, (2000) reported prevalence rates of peanut and tree-nut allergy of 1.2 and 1.4%, respectively, in a US population. Emmett *et al*. (1999) reported a prevalence of 0.6% of peanut allergy in children 0–14 years of age, and somewhat less in adults. These studies were household surveys. Kanny *et al*. (2001), in a population study in France, found a prevalence of food allergy of 3.5%. Osterballe *et al*. (2005), in an unselected Danish population of children and adults found a prevalence of 3.2% for DBPCFC-verified food allergy. In the Norwegian Food Allergy Register (Løvik *et al*., 2007), the highest incidence of severe reactions reported is among young adults age 20–35 years.

There is a perception among allergologists that the prevalence of food allergy has been increasing, similar to respiratory allergies, but good studies documenting this have not been published. Studies of hospitalization, often cited in this context, may more reflect awareness among doctors and in the population, as well the function and organization of the health care system, than true changes in disease prevalence and severe reaction incidence.

Generally, the prevalence of food allergy appears to follow respiratory allergy. The prevalence of allergies to specific foods can vary geographically, depending on local food habits as well as pollen exposure. For example, buckwheat is important in Asia, rice in Japan, celery in Central Europe, sesame seeds in Israel and North Africa, and walnut and pecan in the USA (Metcalfe *et al*., 1996).

5 FOOD ALLERGENS

There are no known structural features that are characteristic of an allergen (Aalberse, 2000); allergens are defined by their function. An allergen is a molecule that can induce an allergic immune reaction against itself, that is for practical purposes in food allergy, an IgE response. The term 'food allergen' refers both to the complex whole food and to the chemically defined compounds that are responsible for allergenicity. In the regulatory context, one usually deals with foods or classes of foods as allergens (e.g. 'fish and products thereof'). However, the biochemical molecular entity causing most food allergies is protein. Some protein breakdown products, that is, peptide fragments, may conserve part of the allergenicity of the native protein and thus can also be considered as allergens. Food allergens are generally proteins of molecular weight of more than 9 kDa, but sometimes smaller

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

peptides may cause a reaction. Allergenicity of a complex food is rarely due to a single protein component, but rather due to numerous different proteins which constitute the 'allergen repertoire' of the food. Due to the diversity and variability of the human IgE response, all of the allergenic proteins are not always recognized by all patients allergic to this food. Those allergens that are recognized by more than 50% of a population of patients allergic to the food are called *major allergens*. This concept relates only to the frequency of recognition by IgE antibodies, and it is not related to the severity of the clinical manifestations of an allergic reaction. Major allergens may constitute a small proportion of the total protein content of the food concerned; however, food allergens are often among the most abundant proteins in the food. Clinical reactions may be similar whether they are triggered by major or minor allergens.

5.1 The Allergenic Epitopes

The allergenicity of each single protein is due to a number of molecular immunoreactive structures, so-called IgE-binding epitopes. These epitopes comprise only about half a dozen to a dozen amino acids. Epitopes are widespread within the protein molecule. Similar to allergens, not all epitopes are recognized by all the patients allergic to the protein, and some epitopes are immunodominant while others are only recognized by a few patients. Thus, there is room for a tremendous variation between allergic individuals with regard to the precise targets of their allergic responses.

Epitopes are often described as belonging to one of two different classes, continuous or linear epitopes and conformational epitopes. The former consist of a continuous sequence of amino acids along the protein, and these epitopes tend to preserve their allergenicity even during (moderate) denaturation. Conformational epitopes, in contrast, are dependent on the 3D structure created by folding of the protein for their allergenicity, and will lose their allergenicity when protein folding is disorganized during denaturation. This obviously happens with so-called discontinuous epitopes, composed of amino acids in different parts of the protein molecule brought together by protein folding. It has been reported that, in children with milk allergy, reactivity against linear epitopes signifies reactivity that will persist even after a lower pH develops in gastric fluid as the child gets older. These linear IgE-binding epitopes, which may be located in hydrophobic parts of allergenic proteins can thus be used as markers of a persistent food allergy (Beyer, 2003; Chatchatee *et al*., 2001; Järvinen *et al*., 2002; Vila *et al*., 2001). The distinction between linear and conformational epitopes is, however, not absolute, and many 'linear' epitopes are recognized with much higher affinity in the folded protein compared to the isolated peptide.

Most allergenic epitopes consist of amino acids added during transcription/translation of DNA to RNA to protein (translational peptidic epitopes). However, epitopes may also be formed post-translationally, for example, by hydroxylation (hydroxyproline or hydroxylysine), deamidation (formation of glutamate from glutamine), phosphorylation or nitration (tyrosine) and also by addition of carbohydrate moieties.

Stability to processing and resistance to proteolysis by digestive enzymes have been considered a general characteristic of food allergens (Astwood *et al*., 1996). However, recent studies indicate that the relationship between resistance to digestion and allergenicity is less clear-cut than originally thought (Bannon *et al*., 2003; Díaz-Perales *et al*., 2003; Polovic *et al*., 2007).

Allergenicity may be destroyed by processing (e.g. heating) and digestion of the food. However, allergenicity may also be added, because some epitopes may be unmasked and become available after denaturation or hydrolysis of the protein. Further, new immunoreactive structures (neo-allergens) may be created during processing, including heat treatments, for example, by so-called Maillard reactions (Berrens, 1996; Besler, 2001; Besler *et al*., 2001; Davis *et al*., 2001; Hansen *et al*., 2003; Maleki *et al*., 2000; Mondoulet *et al*., 2005; Nakamura *et al*., 2005). For this reason, some but not other allergic individuals tolerate, for example, the cooked food, but not the raw food, but there are also examples that individuals react only to cooked food. Therefore, processing should not be relied on to reduce or remove the allergenicity of a food.

5.2 Crossreactivity

An antibody will match its antigenic epitope very specifically. However, there is some variation between antibodies with regard to how well they match their epitope, and how strongly they will bind. Different antigen molecules may share a very similar epitope, which may lead to the capacity of the same IgE antibody to bind to different allergens (albeit, as a rule, with different binding strength, depending on how good the match is). This phenomenon, that one antibody may bind to different allergens (strictly, to similar epitopes on different allergens), is called crossreactivity. This refers to identical antibody molecules, like monoclonal antibodies. In an immune serum (not purified or incompletely purified with regard to antibody specificities), there will be a potentially wide variety of antibodies, with specificities against a large number of epitopes, and with a potentially large number of antibody clones directed against each epitope. This serum will be able to react with different allergens. Therefore, one may say that crossreactivity, when talking about antigens, is due to highly similar epitopes being present on different (allergen) molecules, whereas

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

crossreactivity of sera and antibody preparations means that antibodies with more or less different epitope specificities are present.

Importantly, serological crossreactivity between allergens (binding of IgE antibodies *in vitro*) does far from always mean that there is also clinical crossreactivity (also called crossallergenicity). For example, peanut-allergic individuals often display serological reactivity to bean proteins, but clinical crossreactivity (crossallergenicity) between peanuts and beans is seldom seen. However, even if crossreactivity between peanut and another legume, soya, rarely is accompanied by clinical symptoms, severe anaphylactic reactions have been reported in a few instances in peanut-allergic patients consuming soya uncontaminated by peanut, and the same applies to crossreactivity between peanut and the legume, lupin.

Many positive allergy tests, both with regard to specific IgE and SPT, are caused by crossreactivity. As a rule, reactivity against the primary sensitizing allergen ('the original allergy') is the strongest, whereas test responses due to crossreactivity tend to be weaker, but the pattern is not always clear. Crossreactivity may lead to clinical reactions, but clinical reactions due to crossreactivity (crossallergy) tend to be weaker than reactions triggered by the primary sensitizing allergen (but unfortunately, not always). Sometimes it is difficult to decide whether there is a case of true crossreactivity or a case of dual sensitization to two apparently crossreacting allergens. Crossallergies to foods may be due to primary sensitization via the skin or airways. A striking example of this is tree and grass pollen allergies leading to clinical allergies to many plant-derived foods (fruits, nuts, berries and vegetables). For example, in the Nordic countries, birch-pollen allergy is associated with allergy to a large number of plant foods, like nuts, apples, carrots and so on. These crossallergies are often (but not always) mild, and manifest themselves as the so-called oral allergy syndrome, with feeling of numbness, itching and swelling in the oral region (see Section 2 on Mechanisms and Symptoms of Food Allergy). Also, this leads to nut allergy in the Nordic countries generally causing milder clinical symptoms than nut allergy in Southern Europe, because in Southern Europe hazelnut allergy will more often be a primary allergy (and be directed against other nut allergens). Another example of crossreactivity due to a pan-allergen (see below) is the crossreactivity between rubber latex and tropical fruits (Wagner and Breiteneder, 2002).

Remarkably, because of crossreactivity (crossallergenicity), a person may experience an allergic reaction to an allergen never encountered before.

Isoallergens are, in common language, variants of the same allergen. Isoallergens are defined by the International Union of Immunological Societies (IUIS)/World Health Organization (WHO) Allergen Nomenclature Subcommittee as molecules from the same species having similar size and identical biological function, and having $\geq$67% amino-acid sequence identity (IUIS/WHO, 1994). Because of their similarity, isoallergens will have a high frequency of crossreactivity.

5.3 Allergen Families and Pan-Allergens

Crossreactivity is caused by similar epitopes being present on molecules in different foods (Aalberse *et al*., 2001). The more resemblance there is between the molecules, developmentally and functionally, the greater is the chance that there will be crossreactivity and crossallergenicity. Allergens are found in only a small subset of protein families (Aalberse, 2000; Chapman *et al*., 2007; Ivanciuc *et al*., 2008; Mills *et al*., 2004; Radauer *et al*., 2008). Plant allergens often are, for example, storage proteins, stress or defence proteins, or LTPs, and the chance that a protein is an allergen is increased if it belongs to such a class of proteins. Certain evolutionally conserved proteins that are allergens in many species are called pan-allergens. Such pan-allergens in plants are, for example, profilins (Asero *et al*., 2008b) and LTPs (Salcedo *et al*., 2004), in fish the muscle protein parvalbumin (Van Do *et al*., 2005), and in crustaceans, molluscs, mites and cockroaches, the muscle protein tropomyosin (Reese *et al*., 1999).

In sum, there are three levels of structures (whole food, protein and epitopes) involved in the interaction with IgE antibodies and responsible for the allergenicity of a given food. Different epitopes, and thereby different proteins and different foods, will respond differently to processing and digestion. Therefore, depending on the immunodominance of the different epitopes in a particular individual, the effect of processing on food allergenicity may also differ between food-allergic individuals. Similarly, crossreactivity of allergens will differ between individuals. Irrespective of this complexity, and the fact that about 200 food allergens have been described, eight allergenic foods are responsible for some 90% of clinical food allergy: peanut, soya, nuts, wheat, milk, egg, fish and shellfish ('the big eight'). Various national and international regulatory bodies may have somewhat expanded lists of allergens that are so important for public health that they should be subject to special treatment with regard to labelling (European Commission, 2007).

6 IS THE NEW FOOD AN ALLERGEN?—TESTING OF POTENTIAL ALLERGENICITY

No single factor has been recognized as a primary identifier of allergenicity. Therefore, in general, a number

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of factors are incorporated into the overall assessment of likelihood of allergenicity by a weight-of-evidence approach (Codex Alimentarius Commission, 2003; FAO/WHO, 2001). Factors considered include the source of the gene or protein, molecular structural similarity of the protein with known allergens, digestibility and specific IgE binding.

Identity or crossreactivity of a food protein with a known allergen may be suspected, for example, if the food is derived from an allergenic food by processing (high temperature, high pressure, enzyme treatment, etc.) or if it has been made by gene transfer from a known allergenic source. Identity or remaining allergenicity, as well as crossreactivity can be assessed by serum screening. In serum screening, binding of IgE to the protein in question in sera from individuals sensitized, either to the corresponding original source protein or relevant protein(s) from organisms more or less broadly related to it, is investigated. Immunochemical methods like dot-blot, ELISA, RAST (radioallergosorbent test) and Western blotting are used. Functional *in vitro* assays are based on activation by the putatively allergenic protein of basophils presensitized with IgEs of relevant specificity. Histamine release or cell-membrane activation markers and flow cytometry can be used (Ebo *et al*., 2008). However, the availability of a sufficient number of well-characterized sera is an important limiting factor. A final test of safety would be double-blind placebo-controlled (DBPCFC) challenge of individuals with the relevant food allergy. However, there are ethical constraints and it is difficult to find a sufficient number of well-characterized volunteers with the relevant allergy.

The assessment of *de novo* sensitization capacity is a difficult task. *In vitro* resistance of the protein to *pepsin degradation* is one component of the assessment (Astwood *et al*., 1996; Thomas *et al*., 2004) according to the Codex Alimentarius guidelines (Codex Alimentarius Commission, 2003; Ladics, 2004). However, opinions are divided with regard to the value of this assay, and it certainly is not a stand-alone assay. The rationale for the assay is that proteins that are rapidly broken down after ingestion are expected to be less likely to be able to sensitize. Many known food allergens show pepsin resistance, but there also are exceptions (Bannon *et al*., 2003; Díaz-Perales *et al*., 2003; Fu *et al*., 2002; Polovic *et al*., 2007). *Animal models* are discussed below; no validated animal models exist, but animal models may give supporting information. *Serum screening* to exclude crossreactivity of a novel protein with known allergens, if suspected, can be performed, but requires that a sufficient number of well-characterized sera are available. The rationale is that a protein that binds IgE, as a rule, will also be a sensitizer.

Bioinformatics or *in silico* methods are much focussed upon as a tool for allergenicity assessment, but there is general agreement that these methods alone cannot answer the question of allergenicity, although there has been rapid development in the field. The reason is that we do not know any structural features of a protein that makes it an allergen. Whether a 'new' protein will turn out to be an allergen cannot be predicted by bioinformatics. Therefore, bioinformatics allow only two questions to be answered: is the protein an existing allergen? Is the protein likely to crossreact with a known allergen? Most of the major food and respiratory allergens have been identified and cloned, and amino-acid sequences for a majority of these allergens have been incorporated into various databases (Brusic *et al*., 2003; Chapman *et al*., 2007; Gendel and Jenkins, 2006; Lucas and Atkinson, 2008; Mari *et al*., 2006). Information about the spatial structure of allergens is, however, only beginning to be mapped and incorporated into databases (Oezguen *et al*., 2008). A problem is that the criteria for including a new allergen into a database are not always clear and well-defined (Lucas and Atkinson, 2008). Examples of databases are the peer-reviewed Food Allergy Research and Resource Program (FARRP) database (*www.allergenonline.com*) and Allergome (*www.allergome.org*).

FAO/WHO (2001) proposed a risk assessment based upon a multiprocedural assessment scheme (**Figure 4**). According to the recommended protocol, a warning flag is raised if either of two criteria is met: a match of six consecutive amino acids to identify contiguous, linear epitopes, or an identity of more than 35% over an 80-amino acid window of the query protein to pick up conformational epitopes (FAO/WHO, 2001), in both cases based on comparison with a documented protein allergen ('sequence homology' in **Figure 4**). The use of 35% identity is 'conservative', because, for crossreactivity to occur, a high degree of homology most often is needed, likely in excess of 50–60% over significant spans of the new protein and the allergen (Aalberse, 2000). However, six amino-acid matches have been found to occur too often between unrelated proteins and therefore this is an unreliable criterion for prediction of allergenic potential (Gendel, 2002; Ladics *et al*., 2006; Silvanovich *et al*., 2006), and neither the Codex Alimentarius Commission nor the EFSA (European Food Safety Agency) adopted the six-amino acid criterion (Codex Alimentarius Commission, 2004; EFSA, 2004a). Eight contiguous amino-acid matches are often used instead, but the value of this approach is also questioned for similar reasons. One approach has been to identify motifs, that is, substructures in a protein connected to function and shared by allergens, and search these for similarity. However, motifs may be specific for protein families, for example tropomyosin, rather than for features connected with allergenicity (Kong *et al*., 2007; Li *et al*., 2004). In conclusion, several approaches alternative to the FAO/WHO protocol have been discussed, including similarity of entire allergens, computationally extracted

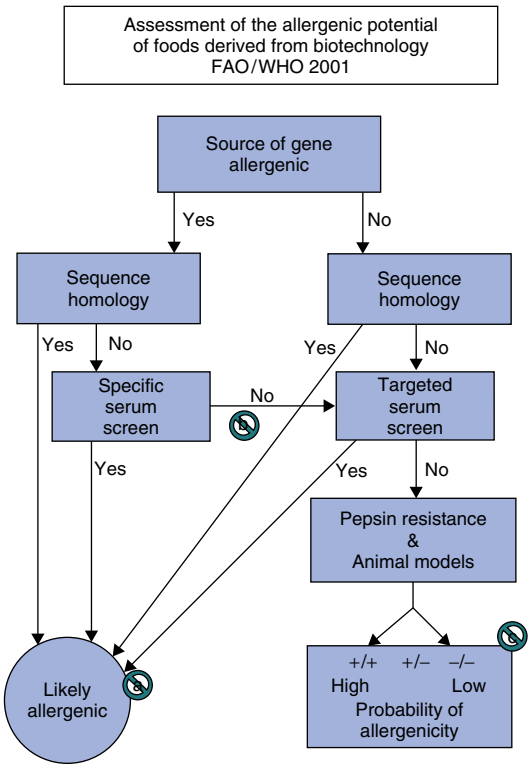

Figure 4 The FAO/WHO 2001 decision tree for possible allergenicity of a novel protein. Stop-sign explanations: (a) Any positive results obtained from sequence homology comparisons to the sequences of known allergens in existing allergen databases or from serum screening protocols, indicate that the expressed protein is likely allergenic. (b) The degree of confidence in negative results obtained in the specific serum screen is enhanced by the examination of larger numbers of individual sera. Conducting the specific serum screen with small numbers of individual sera when larger numbers of such sera are readily available should be discouraged. (c) When positive results are obtained in both the pepsin resistance and animal model protocols, the expressed protein has a high probability of becoming an allergen. If negative results are obtained in both protocols, the expressed protein is unlikely to become an allergen. When different results are obtained in the pepsin resistance and animal model protocols, the probability of allergenicity is intermediate, although rational explanations may be possible in some situations. (Reproduced, with permission, from FAO/WHO, 2001.)

motifs from allergens, similarity to experimentally verified IgE binding epitopes, and amino acid composition.

Finally, it must be remembered that in order to trigger mediator release from mast cells, two IgE-binding epitopes on the same protein molecule are necessary, so that neither a single match of six or eight amino acids between the new protein and the known allergen nor the presence of a conformational epitope may be predictive of capacity to trigger a clinical reaction. For the same reason, IgE binding will not always be associated with mast-cell mediator release or clinical symptoms.

7 ANIMAL MODELS

There is no validated animal model of food allergy for use in a regulatory context, but a number of experimental models are in use or under development for scientific, clinical and regulatory purposes. Basically, two types of model can be discerned, namely models of allergic sensitization and models of allergic reactions and anaphylaxis. Models of allergic sensitization will have as an outcome the specific IgE (or corresponding antibody isotype) response, determined on the protein level (e.g. ELISA) or as functional antibodies (e.g. passive cutaneous anaphylaxis (PCA) testing), or both. Models of allergic reactions will have as an outcome relevant immediate clinical symptoms upon allergen challenge and also atopic-dermatitis-like skin symptoms, symptoms of anaphylaxis, biochemical markers of reaction (e.g. serum histamine, mast-cell proteases, tryptase) or physiological measures of anaphylaxis (lung function and gas exchange, mucosal and vascular permeability, body temperature).

Animal models will, ideally, be helpful for several purposes. These include a number of issues that cannot be readily answered on the basis of human data, like the study of basic immunological mechanisms of food allergy, factors favouring or preventing the induction of food-allergic sensitization, factors favouring the elicitation or prevention of food-allergic reactions and anaphylaxis, the mechanisms of anaphylaxis, role of prenatal exposures and epigenetic factors, adjuvant factors and matrix factors (e.g. fat) in relation to allergy, testing of drugs and natural products for prevention of food-allergic sensitization or the triggering of food allergic reactions, vaccines for prevention or treatment of food allergy, testing of the allergenicity of novel foods, determination of allergenic potency of food components, including novel proteins, the reaction-triggering capacity of food components, immunological and clinical crossreactivity between food allergens, relationships between the serological response and clinical reactivity, and studies of different relevant routes of administration (peroral, inhalation, skin).

What constitutes an ideal animal model certainly will depend upon the purpose of the study and the questions asked, and it is likely that there will not be one single human-like model for universal use. Instead, different models will be the best ones and be used for different purposes. The following ideal criteria of an animal food-allergy model is not likely to be met by one model: IgE as the mast-cell triggering ('reaginic')

antibody isotype, the presence of identified cell types and antibody isotypes homologous to those in man, sensitization induced by eating/peroral administration of the whole food with a minimum of manipulation (adjuvants, immune modulators), alternatively respiratory or skin routes of sensitization, same effect of adjuvants and cofactors as in man, a complete immune response similar to man (T cells and antibody isotypes other than IgE), IgE response to all known food allergens and not to nonallergens, epitope specificity and crossreactivities like in man, potency and potency 'hierarchy' similar to that in man, dose–response and thresholds for sensitization and triggering similar to man, same allergic-reaction mediators as in man (histamine, etc.), and signs, symptoms and other outcome markers similar to man. Clearly, no model will satisfy the ideal criteria listed, but the criteria are important when evaluating the suitability of a model for a given purpose (e.g. if the purpose is to determine allergenic potency for regulatory use, more weight should probably be given to factors related to sensitization (specific IgE) than to triggering of a reaction, although the latter are not irrelevant).

Food allergy occurs naturally in cats and dogs. In dogs, the prevalence has been reported to be about 1% (Day, 2005). There also are some claims that food allergy occurs in other domestic animals like the pig, but this has not been convincingly shown. In the dog, allergens reported to be involved include beef, chicken, milk, egg, wheat and soya bean. Cutaneous symptoms (atopic-dermatitis-like) are common. No spontaneous breed differences have been observed, but genetic factors appear important and atopic dog colonies have been developed with selective breeding.

Experimental animal models with induced food allergy include models in animals naturally developing food allergy (dog), and models in animals that are not known to naturally become food allergic (Helm, 2002; Helm *et al*., 2003; Knippels *et al*., 2004; McClain and Bannon, 2006). The latter include the guinea pig, swine, rats and mice. A problem is that mast-cell activating ('reaginic') antibodies, with the exception of swine, in contrast to man, are not limited to IgE, but include also IgG1a (guinea pig), IgG2b (rat) or IgG1 (mouse).

The guinea pig represents the oldest model for allergenicity testing, but has mostly been used with chemicals, cosmetics and other products, rather than foods or food proteins. There are claims that the oral route of immunization can be used without adjuvants. A problem is the dominating role of IgG1a rather than IgE as the mast-cell activating antibody.

The neonatal swine model (Helm *et al*., 2002) employs newborn piglets from White/Landrace sows. The piglets are sensitized ip (intraperitoneally) with cholera toxin as adjuvant, and challenged by intragastric gavage at one week intervals. Allergens employed have been peanut, chicken ovomucoid, milk, wheat flour and nuts (Helm *et al*., 2002; Rupa *et al*., 2008). This is a challenge model, and clinical outcomes are emesis, lethargy, diarrhoea and respiratory distress, and, in addition, histology of the intestinal mucosa. Symptoms in the piglets are said to be fairly similar to symptoms in man, the same being said about gastrointestinal anatomy and physiology, as well as immune function in the pig, and nutritional requirements of piglets, according to proponents of the swine model, resemble those of human babies. Thus, the swine model may represent a 'human-like' food-allergy challenge model.

The atopic inbred-dog model was introduced by Ermel, Buchanan and Frich (Buchanan and Frick, 2002; Ermel *et al*., 1997; Helm *et al*., 2003). Dogs bred with 'atopy' as a selection marker are injected repeatedly sc (subcutaneously) in the axilla with allergen and alum as adjuvant, up to day 85, and thereafter boostered with a larger dose of allergen with alum bimonthly. Skin tests are performed with Evans blue as a marker of vascular leakage upon allergen injection. Feed challenge is given at age 2.5 years. Clinical outcomes include vomiting, and number and quality of stools. Advantages of the dog model are said to be that the dog represents a species that naturally develops food allergy, and symptoms are 'human-like'. Allergens tested include wheat, barley, cows' milk, beef extract, peanut and tree nuts. Crossreactivity between walnut and Brazil nut was observed, and the allergen 'hierarchy' was reported to be similar to that in man. Thus, the dog also appears to represent a 'human-like' food-allergy challenge model.

Among rats, Brown Norway (BN) rats have been found more suitable for peroral sensitization with food allergens than strains like Wistar, Hooded Listar and PVG rats. Females are said to be more suitable than males for the food allergy model. The BN rat is a high IgE-responder strain, and the animals are immunized at age four to six weeks by daily dosing by gavage without adjuvant (Knippels and Penninks, 2002). Blood samples were drawn after 0, 35, 42 and 49 days, and serum anlysed by ELISA for specific IgG2b and IgE, as well as for functionality, by PCA. Oral challenge is given, and breathing frequency and blood pressure used as outcomes. Among the allergens used are ovalbumin (OVA), cows' milk, egg white, peanut, peanut allergen Ara h 1, shrimp allergen Pen a 1, potato allergen Sol t 1 and beef tropomyosin. Thus, the BN rat model is used both as a sensitization model and a challenge model. Other rat models have been used, for example based on ip immunization with carrageenan as adjuvant.

In the mouse, a variety of models have been used. The mouse has many well-known advantages as an experimental animal, both with regard to practical issues and science. 'Reaginic' antibodies capable of activating mast cells in the mouse are IgE and IgG1. Mostly, inbred BALB/c mice are used for sensitization models and inbred C3H/HeJ mice for challenge (anaphylaxis) models. The BALB/c mouse is a

Table 1 Symptom score for peanut-allergic mice (Li *et al*., 1999)

Score	Symptoms
0	No symptoms
1	Scratching and rubbing around the nose and head
2	Puffiness around the eyes and mouth, diarrhoea, pili erecti, reduced activity and/or decreased activity with increased respiratory rate
3	Wheezing, laboured respiration and cyanosis around the mouth and tail
4	No activity after prodding, or tremor and convulsions
5	Death

good antibody responder, including IgE antibodies. The C3H/HeJ mouse because of a TLR4 receptor deficiency is a lipopolysaccharide (LPS) low-responder. Interesting percutaneous immunization models without adjuvant have been described (Birmingham *et al*., 2007; Strid *et al*., 2004), and investigators employing an ip immunization model in BALB/c mice have reported an allergen potency hierarchy similar to that in man (Dearman *et al*., 2003). In the ip immunization model, the epitope pattern, with β-lactoglobulin, as well as peanut, as allergens has been found to be similar to that in man (Adel-Patient *et al*., 2000; Li *et al*., 1999; 2001). Intranasal and subcutaneous immunization models have also been used. However, most used in the mouse is peroral immunization by gavage, employing cholera toxin as adjuvant, or, recently, acid-neutralizing medications or drugs. Serological outcomes are IgE and IgG1 antibodies (and also other isotypes) determined as protein by ELISA or as functional antibodies by PCA. Clinical outcomes in challenge experiments are clinical symptoms (**Table 1**), diarrhoea, body temperature, mucosal and vascular hyperpermeability, and histological evidence of affected intestinal mucosa and lung, as well as cellular, immunological and biochemical markers, including histamine and mast-cell proteases.

An advantage with the mouse is the detailed knowledge of its immune system and the availability of a wide range of immunological and biochemical reagents, as well as genetically variant mice. The anaphylaxis model in C3H/HeJ mice employs repeated immunizations by gavage up till about 40 days, with cholera toxin as adjuvant (Li *et al*., 1999; 2001). To trigger anaphylaxis, a larger dose of allergen without adjuvant is given. The model has been used with a number of allergens, including peanut, lupin and milk. Lately, a number of publications have documented the capacity of gastric acid neutralization (peroral suspensions or iv (intravenously) administered proton-pump inhibitors) to promote food allergy development to allergens (Untersmayr and Jensen-Jarolim, 2008).

8 REGULATORY ASPECTS OF FOOD ALLERGY—PRINCIPLES AND CONSIDERATIONS

8.1 Introduction

This chapter will discuss some regulatory principles and considerations regarding food allergy. We refer to national agencies and international organizations for the specific documents and regulations (e.g. Codex Alimentarius Commission, 2008; European Commission, 2007; FAO/WHO, 2001).

The development of a food allergic reaction is a two-step process. The first step is the sensitization process, whereby the immune system develops a specific IgE response against the food allergen, thus 'loading the gun'. The second step is a later exposure of the sensitized individual to the food allergen, eliciting the allergic reaction ('pulling the trigger'). The distinction between these two processes is important also in the regulatory context. Most regulatory measures are aimed at preventing the triggering phase, that is, exposure of the sensitized individual to the food allergen. Product labelling is a tool of major importance for this purpose, to make avoidance possible. Only in relation to novel foods, that is, foods that are new to the population (including food from genetically modified organisms), is the prevention of sensitization a regulatory concern.

8.2 The Sensitization Phase to Food Allergens in a Regulatory Perspective

For sensitization to food allergens, exposure to the food allergen (or cross-reacting allergens) is necessary. However, often, we do not know when this sensitizing exposure takes place, but it obviously can happen very early in life and possibly *in utero* or via mother's milk, because there are numerous cases of babies and small children reacting (sometimes fatally) to a food at the first known intake. Such cases are also fairly well documented for allergens for which unknown exposure of the baby through everyday use in the household could not so easily take place, for example, paranuts. It is a fact that very often, we do not know exactly when and how sensitization to food allergens is induced. Further, we do not know the conditions for sensitization in terms of doses and exposure distribution over time. This lack of knowledge constitutes one major obstacle to prevention of sensitization. Another major obstacle is the fact that the allergens most commonly causing severe food allergic reactions in the industrialized world (the big eight), also are among the most important (volume-wise and economically) and are nutritionally valuable foods,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163

like milk, eggs, wheat, fish, peanuts and so on. To ban or strongly limit the use of these traditionally used staple foods with the aim of preventing sensitization and allergy, which either is mostly transient (milk and eggs in children) or affects less than 0.5–1% of the population for each food, would have dramatic social and economic consequences in relation to agriculture, fisheries, trade and food industries. Such a ban of the common allergenic foods also would cause problems with regard to providing a nutritionally adequate diet for the population and, in particular, children. Food tradition is also culturally important. Advice given in particular regarding nutrition in early childhood to tentatively reduce the risk of allergic sensitization is scientifically not very firmly founded. Consequently, prevention of sensitization by regulating the use of traditional allergenic foods is not an issue in regulatory work. This means that with regard to traditional foods, society accepts as a fact of life that a small proportion of the population gets sensitized and allergic, because we have no acceptable means of prevention.

Only with regard to new ('novel') foods, is the prevention of sensitization a regulatory issue. Examples of such foods (for Europe) are foods that have traditionally been used in other parts of the world (e.g. Pacific Islands), but not in Europe, for example nangai nuts (Sten *et al*., 2002), and also foods made by new industrial processes and foods made by genetic modification of organisms. Novel foods do not have a central role in society, and for healthy nutrition, that traditional allergenic foods have. Novel foods have, according to current regulations, to be evaluated for allergenicity to avoid the inadvertent introduction of a new allergen.

Experience is that 'new' foods introduced rarely introduce 'new' allergies, but may still be important food allergens because of crossreactivity with common traditionally used food allergens. Examples of this are lupin, which causes serious reactions in peanut-allergic individuals because of crossreactivity (Lindvik *et al*., 2008), and kiwi fruit (Lucas *et al*., 2003), which causes reactions in part because of crossreactivity with pollen allergens.

8.3 Incidence of Allergic Reactions

The main event of regulatory concern in food allergy is the triggering of allergic reactions. This is an acute event, precipitated by the intake of a sufficient dose of food on one single occasion. A food-allergic reaction, therefore, is comparable to an acute poisoning event; the amount of allergen consumed over a longer period is of limited interest, and then mostly in relation to sensitization and waning of the allergy. The fact that the dose of allergen of concern, in relation to triggering of a reaction, is not the accumulated dose over time, but instead the dose of allergen in one serving of the food, has implications for risk assessment and regulatory work.

The adverse event in relation to food allergy is the allergic reaction, a short-lasting event that cannot be well diagnosed afterwards. The key feature for diagnosis is the sum of clinical symptoms presented during the reaction. There are some biochemical markers of anaphylaxis, like serum *histamine* and *tryptase*, but, in particular, histamine is a short-lived marker present in parallel with the symptoms rather than after the reaction, and is, in practice, difficult to use. Tryptase is somewhat more persistent and can be measured in specimens taken, for example, from autopsied individuals. A key element is the assessment of allergen exposure before the reaction started, the history of allergy, the presence of relevant sensitization and a positive DBPCFC test (see Section 3). However, because the food allergic reaction is a short-lived phenomenon, leaving no lasting traces and, in addition, spans the full gradient of severity from hardly noticeable discomfort to dramatic death, our knowledge of the incidence of allergic reactions in the population to a particular allergen is extremely incomplete. Thus, discussing regulatory measures for foods on the market, we deal with an outcome, the incidence of which is very incompletely known. National or regional reporting systems for (severe) food-allergic reactions would give information of great value for assessing the public-health importance of food allergens (Løvik *et al*., 2004), and a few such reporting systems and registries have been established the last years. Ongoing work in international organizations may lead to more harmonization of food-allergic-reaction reporting systems, and stimulate to the establishment of reporting systems for severe food-allergic reactions in more countries (Björkstén *et al*., 2008).

8.4 Allergen Thresholds

The main regulatory measure to prevent food-allergic reactions is labelling. The basis of the labelling system is the listing of ingredients in the food. Additionally, in the European Union (EU), Annex IIIa (EFSA, 2004b; European Commission, 2007) identifies certain allergens that are of such importance that their presence should be indicated by labelling without exemptions granted for other foods. Labelling is mandatory, both in the presence of the allergenic food component itself and in the presence of 'products derived thereof', and there is no administrative threshold for the quantity of allergen necessary to trigger labelling. However, in the EU, it is possible to apply for exemption from labelling if allergens are no longer present in a product because of removal during the production process or, in principle, extreme dilution. Such exemptions have to be considered on an individual basis for a particular type of product, and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

a number of exemptions have been granted based on documentation that allergens are no longer present in the product in quantities sufficient to cause a problem. However, this has been decided by expert judgement. There have been no defined allergen thresholds and, as a matter of fact, the EFSA has concluded that, at present, there is not a sufficient scientific basis for establishing allergen thresholds (EFSA, 2004b).

Thresholds for labelling are most wanted by the food industry. However, in the population, individual allergen thresholds vary greatly between allergic persons, from less than 1 mg to many grams of the food (Taylor *et al*., 2002). Also, threshold variation from time to time for a given individual must be expected because of natural increase or waning of allergy strength, and because of varying presence of aggravating factors like exercise, mental stress, alcohol, medications and infections. Some individuals are extremely sensitive, and it will probably not be possible to find a common population threshold that will protect even the most sensitive. Instead, agreement on an administrative threshold that protects a great majority of food-allergic individuals may be the solution. Ongoing activities seek to determine thresholds for the foods for which information is best, like peanut.

8.5 Classification of Foods for Regulatory Measures

Novel foods, including genetically modified foods, have to be evaluated with regard to allergenicity. However, with regard to traditional foods, the classification of foods in relation to allergy may seem somewhat arbitrary. First, there are no general rules and recommendations at the national or international level with regard to criteria for which allergens should be labelled. There are a couple of hundred food allergens, many of them obviously of little importance because only one or a very few cases have been reported worldwide, and any regulatory measure would seem out of proportion to the problem. In the other end, some allergens, like peanut, fish and so on, obviously are of great importance and warrant the cost to society, manufacturers and consumers of labelling. The problem with regard to administrative measures is the 'intermediate' food allergens in the gradient from obviously important to obviously trivial. However, some attempts are currently being made to elaborate criteria and a framework for assessing the public-health importance of food allergens, based on the principles of evidence-based medicine (Björkstén *et al*., 2008). If successful and generally accepted, such criteria would make the evaluation of food allergens more similar in different countries and trade regions, would increase predictability in relation to administrative measures and increase transparency of the decision-making process. Key factors for the importance of food allergens are documented incidence of reactions, prevalence of clinical allergy and sensitization, potency of the allergen and exposure factors (extent and mode of use). The prevalence of sensitization to the allergen is a surrogate marker of limited value, because for some allergens (e.g. some legumes) sensitization is rather common, but reactions rarely occur, and, in general, sensitization grossly overestimates the number of people who would react to an allergen (Kagan *et al*., 2003).

Regulatory documents do not appear consistent in their grouping of food allergens. For example, in the EU's Annex IIIa (EFSA, 2004b; European Union, 2007), an 'allergen' that has to be labelled without exemptions is 'molluscs and products thereof'. Molluscs include more than 100 000 species. On the other hand, 'peanuts and products thereof', 'soya and products thereof' and 'lupin and products thereof' are listed separately, instead of combining them in a class called 'legumes and products thereof'. Various other legumes, like peas and beans are foods allergens of minor importance, and many molluscs certainly are also of little or no importance as allergens. Therefore, the grouping of food allergens to be labelled may seem inconsistent with regard to inclusion and limitation criteria. This may be due to the different importance of some foods, or it may reflect the history of allergen labelling.

9 GLUTEN INTOLERANCE

Gluten intolerance causing coeliac disease (gluten-sensitive enteropathy, sprue) is an autoimmune condition triggered by gluten protein, which is found in wheat, rye and barley. Gluten intolerance does not involve IgE and is not an allergy in the classical meaning of the word. Gluten intolerance has a range of different clinical expressions. A life-long gluten-free diet excluding wheat, rye and barley forms the basis for treatment of coeliac disease.

Including classical as well as oligosymptomatic and silent forms in children and adults, the prevalence of coeliac disease in Europe, as well as North and South America, is about 1:100–1:200 (Fasano and Catassi, 2008). Limited data from North Africa and Southwest Asia suggest a similar high prevalence for these areas (Accomando and Cataldo, 2004). The highest reported prevalence worldwide of 5.4% is found in the Sawahari population of North Africa (Catassi *et al*., 2001; Fasano and Catassi, 2008). In central Africa and the Far East, coeliac disease appears to be extremely rare (for references, see Dubois and van Heel, 2008). Disease prevalence mirrors the prevalence of coeliac-disease-associated genes (see below) and broadly also grain consumption (Fasano and Catassi, 2008). An environmental factor suggested to play a role is gastrointestinal viral infections in infancy (for references, see Dubois and van

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Heel, 2008). Countries with low infant gluten consumption (Denmark, Estonia, Finland) have a lower infant, as well as adult, incidence of coeliac disease than countries with a high infant gluten consumption, like Sweden (Mitt *et al*., 1998; Weile *et al*., 1995).

Gluten is the rubbery dough-forming protein which remains after the washing of wheat flour to remove starch. Gluten is a well-defined storage protein with a high content of glutamine and proline, and consists of glutenin and gliadin fractions. Glutenin is a high-molecular-weight fraction insoluble in alcohol, and the toxicity of this fraction in gluten intolerance has not been well characterized. The alcohol-soluble gliadin (mw 28 000–39 000) contains mainly monomeric low-molecular-weight proteins. Both fractions consist of numerous closely related protein components with repetitive peptide units. These repetitive peptide units are found in the α-, γ- and ω-subtypes of gliadin, which have all been shown to elicit the disease equally. A 33-mer peptide has been identified as a primary initiator of the inflammatory response in coeliac disease (Shan *et al*., 2002), and the amino acid sequences of several peptides that form potent T-cell epitopes in gluten intolerance have been characterized.

Wheat, rye and barley all contain gluten and glutenin proteins, collectively called prolamins. Maize, rice, buckwheat, millet and sorghum do not have any of these, whereas oats contain low amounts of prolamins. Consequently, while wheat, rye and barley have been documented to trigger coeliac disease (Wieser, 1996), maize, rice and buckwheat have been found not to be harmful. There is some disagreement about the coeliac toxicity of oats (Janatuinen *et al*., 2002; Lundin *et al*., 2003). Spelt (a primitive form of wheat) has often been claimed by coeliac disease patients to be better tolerated than 'modern' wheat, but spelt is just 'wheat spelt another way' without substantial differences that could explain a significant difference from modern wheat cultivars in relation to gluten intolerance. However, different wheat cultivars differ in their content of proteins, and the ratio of total gluten to gliadin can vary from 1.3 to 1.6. Complete acid hydrolysis abolishes the 'toxicity' of gluten, but partial hydrolysis and enzymatic peptic-tryptic degradation of gluten does not affect gluten intolerance-triggering properties because important peptide units are left unaffected. Heat treatment (baking) does not change gluten 'toxicity', but food technology processes affect extractability and detectability of gluten and thereby affect quantitative gluten measurements (Stern *et al*., 2001).

The normal daily intake of gluten is 15–20 g in the adult European population. The relationship between the amount of gluten ingested and the severity of clinical changes and histological abnormalities is still undefined (EFSA, 2004b). It appears that there is a threshold below which most, if not all, coeliac disease patients would tolerate trace amounts of gluten. However, individual variation and clinical heterogeneity make it difficult to find an acceptable threshold value (Stern *et al*., 2001). Challenge and dietary intake studies have shown that a daily intake of 100 mg of gliadin was sufficient to elicit typical coeliac changes in coeliac-disease patients, whereas a daily gliadin intake of 4–14 mg did not cause any small intestine mucosal damage (for references, see EFSA, 2004b). From a clinical point of view, a threshold value in terms of a daily allowable intake would be preferable to a product-centred mg kg^{-1} limit (EFSA, 2004b).

Cereals containing gluten and products thereof are among the foods on the EFSA 'allergen list', Annex IIIa, foodstuffs that always should be labelled without the exemptions granted most foods (European Commission, 2007). The new Codex Alimentarius Guidelines (Codex Alimentarius Commission, 2008) have a gluten level limit of 20 mg kg^{-1} for 'gluten-free foods', that is foods consisting of naturally gluten-free ingredients that do not contain any prolamin from wheat or *Triticum* grain species, such as spelt, kamut or durum wheat, rye, barley, oats and their crossbred varieties, as well as for foods in which gluten has been removed. Other foods consisting of ingredients with low gluten levels should be labelled 'low-gluten' if the gluten level is less than 100 mg kg^{-1} (effective from 2012) (Codex Alimentarius Commission, 2008).

The sensitivity, specificity and reproducibility of most methods for gluten analysis previously were unsatisfactory (Stern *et al*., 2001). Still, a European gliadin reference is now available, and immunoassays have improved (EFSA, 2004b). However, analytical problems due to heated or hydrolysed material and matrix effects have not been fully overcome.

The diagnosis of coeliac disease relies on small intestinal biopsy showing a severe mucosal lesion with inflammatory cells and flattening of the mucosa, with subsequent restoration of normal morphology and disappearance of symptoms on a gluten-free diet, which forms the cornerstone of coeliac-disease treatment (Fasano and Catassi, 2008; Green and Cellier, 2007; Polanco, 2008). Serological methods, like determination of autoantibodies against endomysium and gliadin antibodies are useful supplements to the diagnostic procedure, and particularly are useful for screening. Coeliac disease is strongly associated with the major histocompatibiliy antigens HLA-DQ2 and DQ8 (Fasano and Catassi, 2008; Marsh, 1992; Schuppan, 2000; Sollid, 2002). The HLA-DQA1*0501, DQB1*0201 gene is found in over 90% of patients. Gluten peptides are presented to immunocompetent cells by DQ2- and DQ8-positive antigen-presenting cells in the small intestine lamina propria. Tissue transglutaminase is released and will potentiate antigen presentation by deamidating or crosslinking gluten peptides (Schuppan, 2000), and T cell activation, cytokine production,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat163
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

inflammation and mucosal destruction occur. Secondary to the cellular immune reaction, production of antibodies against the important endomysial autoantigen tissue transglutaminase and against gliadin takes place. One result of the mucosal damage is malabsorption, which may lead to various deficiency-related symptoms.

The classical picture of coeliac disease with severe diarrhoea, vomiting and failure to thrive becoming manifest at 6–24 months of age is rarely seen today, as a shift from infant and childhood age to adolescent and adult age at diagnosis has taken place (Vivas *et al*., 2008). The classical form of coeliac disease with severe symptoms forms only the 'tip of the iceberg', with relatively silent and latent forms under the 'iceberg' waterline. Less specific deficiency symptoms, abdominal pain, liver disease, osteoporosis, arthritis and dermatologic and neuropsychiatric disease are common, and extraintestinal manifestations should always be considered (Fasano and Catassi, 2008; Vivas *et al*., 2008). There is in coeliac disease an increased risk of intestinal malignancy, and there is evidence that adherence to a strict gluten-free diet reduces this risk and also the risk of bone and autoimmune disease (Haines *et al*., 2008). In particular, coeliac-disease patients who do not respond to a gluten-free diet (so-called refractory coeliac disease, RCD), or rather a subgroup of these (Type 2 RCD) are at high risk of complications such as ulcerative jejunitis and enteropathy-type T-cell lymphoma (Ho-Yen *et al*., 2008). There is an association between coeliac disease and other cell-mediated autoimmune diseases, namely Type 1 diabetes, Graves' disease, rheumatoid arthritis and psoriasis, and, in particular, the association with Type 1 diabetes is striking (Dubois and van Heel, 2008; Farrell and Kelly, 2002; Neuhausen *et al*., 2008; Zhernakova *et al*., 2007). Type 1 diabetes and coeliac disease both appear to have shown rising incidence in recent years (for discussion and references, see Dubois and van Heel, 2008). The association is evident on the gene level (Dubois and van Heel, 2008), and one may speculate that there are also common causative environmental factors, possibly shared with allergic diseases that similarly have shown a marked increase the recent decades.

9.1 Dermatitis Herpetisformis

Dermatitis herpetiformis (DH) is a condition with cutaneous papulovesicular, pruritic lesions on extensor surfaces of the elbows, knees, buttocks, back and scalp. The lesions are precipitated by ingestion of gluten (Leonard *et al*., 1983). The skin eruptions are related to immunoglobulin A (IgA) deposits in the dermal papillae, a phenomenon that is pathognomonic for DH (Zone *et al*., 1996). The granular deposits of IgA are present in perilesional as well as unaffected skin. The concentration of IgA at the affected sites decreases with adherence to a gluten-free diet, and increases again if a gluten-containing diet is introduced (Leonard *et al*., 1983). The antigenic specificity of the IgA is not known, but it colocalizes with epidermal transglutaminase 3 (TG3) (not tissue transglutaminase 2, the target of immune response in coeliac disease) (Hull *et al*., 2008). DH is known nearly always to be associated with coeliac disease, but the intestinal inflammation process in DH is generally less severe than that seen in coeliac disease (Katz and Strober, 1978). Treatment consists of gluten-free diet and the drug dapsone.

10 LACTOSE INTOLERANCE

Lactose intolerance is caused by a reduced capacity to digest lactose, due to primary or secondary lactase (β-galactosidase) deficiency. It is not an allergic or immune-mediated disease.

Lactose is a disaccharide exclusively present in milk and milk products. Lactose cannot be absorbed as such, and is normally hydrolysed in the small intestine by lactase to give glucose and galactose. Galactose is converted into glucose in the liver. If lactose is not hydrolysed, it will exert an osmotic effect and cause accumulation of water and sodium in the intestinal lumen. This will increase the volume of the intestinal content and speed up its transit. Lactose will then reach the large intestine, where it is fermented by the colon microflora. Short-chain fatty acids and gases, including hydrogen and methane will be produced (Pouteau *et al*., 1998), and the fermentation products may cause clinical symptoms. These sometimes start as early as 15 minutes, and generally within 1–3 hours, after lactose ingestion, and consist of stomach and intestinal distention with variable pain, and then flatulence and borborygmia. In more severe cases diarrhoea may follow.

Lactase activity in the enterocytes is regulated primarily by genetic factors in healthy individuals, and is not induced by chronic lactose consumption (Lisker *et al*., 1975). Reduced lactase activity in the intestine can be due to an inherited deficiency in lactase that affects infants (MIM:223000; congenital lactase deficiency, also known as hereditary alactasia or disaccharide intolerance II); however, this form is rare. The most common form of lactase deficiency affects adults, because lactase activity normally is reduced 10- to 20-fold from infantile to adult levels at the age of 3–5 and up to 8–12 years in 75% of the world's population (Beja-Pereira *et al*., 2003). About 25% of the population of the world maintain infantile lactase levels in adulthood (lactase persistence; MIM:2231000) (Scrimshaw and Murray, 1988). Lactase deficiency is inherited as a recessive autosomal trait (Enattah *et al*., 2002), with no gender difference.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

In Europe, 'lactase persisters' are in the majority, and constitute 90–95% of the population in the Nordic countries. A gradient with decreasing prevalence of 'lactase persisters' can be observed as one goes further south in Europe and into Africa and Asia, with the exception of population groups traditionally relying on cattle, and specifically milk products, for food (Bersaglieri *et al*., 2004; Check, 2006; Gudmand-Hoyer *et al*., 1969; Gudmand-Hoyer and Jarnum, 1969; Sahi *et al*., 1983; Sahi, 1994; Swallow, 2003).

Lactose maldigestion thus is a normal physiological response to lactase intake in about 75% of the world's adult population. Symptoms will develop when the capacity of lactose activity is exceeded by the quantity of lactose present in the gut. Doses less than 10 g of lactose, corresponding to about 200 ml of milk (one to two glasses), are tolerated by most lactase-deficient adults. Clinical symptoms will occur in more individuals the higher dose of lactose ingested, and the number of intolerant individuals will decrease when the lactose dose decreases (Marteau *et al*., 2002; Vesa *et al*., 1996a; 2000). The lactose concentration reaching the colon depends largely on the lactose dose ingested, but also on how fast the lactose is consumed, the degree of dilution and the composition of the meal (matrix factors) (Martini and Savaiano, 1988). The relationship between the dose of lactose, the concentration of lactose that reaches the colon and maldigestion symptoms is certainly complex, but experiments have shown that a linear relationship exists in the range of typical serving sizes (6–20 g) (Hertzler *et al*., 1996; Savaiano, 2002). There appears to be some capacity of the colon microflora to adapt and regulate fermentation (Hertzler and Savaiano, 1996), and symptoms of intolerance are minimized in an acidified colon. Some lactase-deficient individuals appear not to have symptoms because their bacterial flora metabolize lactose (Campbell *et al*., 2005). Exogenous lactase added to the food or lactase produced, for instance, in fermented foods like yoghurts may enhance digestion of lactose (Marteau *et al*., 1990; Vesa *et al*., 1996b).

The gold standard in diagnosis of lactase deficiency is the measurement of lactase activity in biopsies of intestinal mucosa, but this is impractical for routine diagnosis. Commonly used is measurement of indirect phenotype markers, namely serum glucose (or galactose) levels after peroral lactose challenge, and H_2 or CH_4 in expiratory air (Arola, 1994). An SNP (single nucleotide polymorphism), C/T-13910 polymorphism, has increasingly been used in the diagnosis of lactase deficiency (Buning *et al*., 2005; Enattah *et al*., 2002). The C/C-13910 genotype corresponds to low or absent adult intestinal lactase activity, while the C/T-13910 and the T/T-13910 genotypes are associated with the presence of full lactase activity. However, some discrepancies between the different methods, including genotyping, and clinical symptoms have been observed in various studies.

In addition to the primary, genetically determined lactase deficiencies, secondary lactase deficiencies occur due to intestinal diseases like, for example, food allergy, coeliac disease and gastroenteritis. Depending on the triggering condition, secondary lactase deficiency will be transient. Secondary lactase deficiency must be considered in diagnostic work.

Iin the EU, products derived from milk have to be labelled according to the rules set down in Annex IIIa (European Commission, 2007). A variety of dietary 'lactose-free' or 'lactose-reduced' food items, which, with standard ingredients or manufacturing procedures would contain (higher levels of) lactose, are commercially available. Also, some milk products contain only low levels of lactose, for example some cheeses, and fermented milk products are in general considered to be better tolerated than nonfermented products.

11 FRUCTOSE INTOLERANCE

11.1 Introduction

Fructose is a monosaccharide common in human food, and a significant source of energy. High amounts are found in many fruits, sweets and confectionery, and some vegetables. Further, fructose is a component of sucrose. Sorbitol can be metabolized into fructose. Mean daily intake of free fructose has been reported to be about 15 g day^{-1}. If fructose in sucrose is added, total fructose consumption in heavy consumers may reach 150 g day^{-1}.

Fructose is not an allergen. However, different forms of fructose intolerance exist. Inborn errors of fructose metabolism involving different enzymes are often grouped into: (i) nonsevere conditions and (ii) severe conditions (EFSA, 2005).

11.2 Nonsevere Fructose Intolerance Conditions

Fructose malabsorption is common, but does not lead to severe symptoms and has been questioned as a disease entity (Rumessen, 1992). It is diagnosed by a breath hydrogen test after an oral fructose load. Fructose malabsorption is often encountered in patients with unspecific diarrhoea, abdominal pain and bloating. The gastrointestinal discomfort usually responds well to reduction of fructose in the diet, and there is no organ pathology (Gomara *et al*., 2008). In addition, there is a rare autosomal condition called isolated fructose malabsorption

which has been linked to a deficiency of the GLUT5 transporter (Rumessen, 1992; Wasserman *et al*., 1996). Benign fructosuria is a deficiency of fructokinase, with no symptoms and no need for therapy (van den Berghe, 2000). In this condition, ingested fructose cannot be metabolized, and increased levels can be found in blood and urine.

11.3 Severe Fructose Intolerance Conditions

Hereditary fructose intolerance (HFI) is a potentially life-threatening condition, due to the absence of aldolase B (Ali *et al*., 1998; Odièvre *et al*., 1978). This leads to liver and kidney accumulation of fructose-1-phosphate and severe toxic symptoms due to inhibited glucose production and depletion of ATP. Prevalence worldwide has been reported to be 1:23 000. Heterogeneity of the condition is indicated by differences in clinical sensitivity to fructose, as well as different mutations of the affected aldolase B gene (Davit-Spraul *et al*., 2008), and some affected subjects remain undiagnosed for a long time. Babies typically do well during exclusive breast-feeding, but after introduction of sucrose, fruits and vegetables develop nausea, vomiting, lethargy and convulsions, together with hypoglycaemia. Severe liver disease and renal failure will follow. Diagnosis is made by assay of liver aldolase activity and DNA analysis. Therapy of HFI involves avoidance of all known dietary sources of fructose, sucrose and sorbitol. There is no scientifically established and generally accepted admissible level for fructose intake, but one recommendation is that a fructose-free diet should contain less than 1.5 g of fructose per day (Bell *et al*., 1987). Affected infants appear more sensitive to fructose than adults. Long-term prognosis on diet is good.

The very rare fructose-1,6-diphosphatase deficiency (FBPase deficiency) is also potentially life-threatening. The metabolic defect is, strictly, not in the fructose pathway, but in gluconeogenesis. About half the patients present in the first week of life with life-threatening acidosis, hypoglycaemia, hyperventilation, convulsions and coma. Acute treatment consists of glucose infusion and treatment of acidoses. Lipid storage causes hepatomegaly. Symptoms are precipitated by febrile conditions and fasting. Whereas treatment includes limitation of dietary fructose, complete avoidance is not necessary. With proper treatment, the long-term prognosis is good.

Fructose, sucrose and sorbitol can be analysed in food by enzymatic methods, as well as high-performance liquid chromatography (HPLC). The limit of detection is dependent on the complexity of the samples and matrix and extraction methods.

In the EU, there are no specific labelling requirements for fructose apart from those for food ingredients in general.

Developmental Immunotoxicology

Rodney R. Dietert

CONTENTS

1 INTRODUCTION

The immune system serves as the bedrock in any consideration of risk of disease and wellbeing of the host. This is based predominantly on its two primary functions: (i) to identify, remove and/or destroy foreign invaders and (ii) to survey tissues and to maintain tissue integrity and homeostasis throughout the body. To perform these functions there are two relatively novel features found in the immune system that are lacking in many toxicological targets: (i) the immune system is fully dispersed throughout the body, with representation in most tissues, including the brain, and (ii) the system is designed to be largely mobile with cells responding to a variety of chemical signals through chemotaxis and relocation within the body.

The immune system is designed such that, when effective, responses against invading pathogens and emerging tumour cells are tailored to the task at hand, including the nature of the disease challenge, the temporal nature of the challenge and the specific location of the challenge. This range of potential responses coupled with a tailoring of an individual response is necessary, since during the course of a lifetime an individual will be exposed to pathogens ranging from small intracellular deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) viruses to large extracellular bacteria and parasites. It is increasingly recognized that inappropriate immune responses in scope, duration, location or specificity have the potential to be as problematic in terms of disease risk as are insufficient immune responses. For this reason, significant environmentally induced modulations of immune response potential represent a likely health risk.

The implications of the disperse nature of the immune system are that all routes of exposures and all local insults have the potential for producing immunotoxicity. Additionally, because the immune system is designed to mobilize cells to sites of tissue/cellular perturbation, local insults have the potential to involve immune cells far removed from the exposure route/location. Local insults (via dermal, oral, inhalation routes of exposure) can sometimes produce adverse immune changes elsewhere in the body (e.g. oral exposures increasing lung inflammatory responses). All of these characteristics of the immune system and its response to the environment have a potential impact on the nature and effectiveness of safety-testing strategies.

2 DEVELOPMENTAL IMMUNOTOXICOLOGY (DIT)

As a subdivision of immunotoxicology, developmental immunotoxicology (DIT) was recently defined as the effects on the immune system resulting from the exposure of the nonadult to physical factors (e.g. ionizing and ultraviolet radiation), chemicals (including drugs), biological materials, medical devices and, in certain instances, physiological factors, collectively referred to as

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat164
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

agents (Luster *et al*., 2008). Clearly, this includes many different categories of environmental factors, including environmental contaminants, as well as drugs. While the focus of this chapter is on toxicants, Dietert and Piepenbrink (2008) suggested the value of considering an integrated womb-to-tomb approach to developmental immune protection given both the diversity of environmental factors (toxicants, diet, microbial exposure) that impact immune development and the life-long health ramifications that are integrally tied to effective immune function.

The study of DIT dates back to at least the 1970s (Luster *et al*., 1978), although a substantial amount of the research has been performed during the last decade. More recently, the focus has been on comparative sensitivity to xenobiotics of the developing immune system vs. that of the fully matured adult (Luebke *et al*., 2006a; 2006b). This has shifted discussion towards strategies to improve protection of the nonadult. DIT has been the topic of several workshops, symposia, reviews and books, where the focus has ranged from health effects to immune-assessment strategies and finally use of developmental immunotoxicity data in risk assessment (Dietert *et al*., 2000; 2002; Holladay and Smialowicz, 2000; Luster *et al*., 2003; 2005; Holsapple *et al*., 2004; 2005; Ladics *et al*., 2005; Dietert, 2005; 2008a; 2008b; 2008c; Holladay, 2005; Dietert and Piepenbrink, 2006; Dietert and Holsapple, 2007; Smialowicz *et al*., 2007; Burns-Naas *et al*., 2008).

The idea that a developing physiological system has critical developmental windows of vulnerability that increase the likelihood of environmentally induced dysfunction is not a concept restricted solely to the immune system. In fact, early-life events seem to exert an unexpectedly significant influence on the later-life functional capacity of several systems, including the immune, neurological, cardiovascular and endocrine systems.

3 EARLY-LIFE ORIGINS OF LATER-LIFE DISEASE: THE BROADER CONTEXT FOR DIT

The idea that foetal environmental programming plays a significant role in later-life disease risk, also known as the Barker hypothesis, has existed for more than a decade and was originally presented to connect intrauterine growth with later-life risk of cardiovascular disease (Barker, 1997). In recent years, this concept has been extended to include the neonatal period of maturation and to involve a broader array of environmental factors (toxicants, diet, infectious agents, physical stressors) impacting a wider range of diseases (Grandjean, 2008). Part of this foetal origin of disease concept is the notion that problematic early-life environmental exposures can cause a rewiring of specific physiological systems, thereby changing the course of ageing and lifelong disease risk. Environmentally induced prenatal–perinatal physiological rewiring has been considered for the immune (McDade, 2005; Phillips, 2006), endocrine (Kajantie, 2008), reproductive (Nijland *et al*., 2008), vascular (Gardiner, 2007) and skeletal (Lanham *et al*., 2008) systems.

Among the diseases with either pediatric or adult onset suggested to have early-life origins and environmental risk are: adult inflammatory bowel disease (Aspberg *et al*., 2006; Danese *et al*., 2007), allergic diseases (Prescott, 2003), Alzheimer's disease (Whalley *et al*., 2006), autoimmune diseases (Brown *et al*., 2006; Peng and Hagopian, 2006; Svensson *et al*., 2004), cardiovascular disease (Barker and Bagby, 2005; Louey and Thornburg, 2005), cerebral palsy (Jacobsson and Hagberg, 2004), lung disease (Landau, 2006), Parkinson's disease (Barlow *et al*., 2004), schizophrenia (Meyer *et al*., 2006; 2008; Ozawa *et al*., 2006), obesity (Krechowec *et al*., 2006), renal disease (Ingelfinger and Schnaper, 2005), metabolic syndrome (Gluckman and Hanson, 2004) and Type 2 diabetes (Jones and Ozanne, 2007).

This chapter considers the potential role of DIT (the prenatal, neonatal, juvenile and adolescent periods of development) in immune dysfunction and disease risks.

4 IMMUNE DEVELOPMENT AND CRITICAL WINDOWS OF IMMUNE VULNERABILITY FOR DIT

Immune maturational events occurring during the prenatal and early neonatal periods of life represent unique processes that lack exact equivalents in the adult. It is during these maturational events that the specialized immune-cell populations arise (e.g. T regulatory cells, Th17 cells, microglia, alveolar macrophages) seed the periphery and then further mature in response to additional gestationally timed physiological factors (e.g. surfactants). For this reason, each immune maturational event is a potential target of environmental disruption, with immune dysfunction as the likely adverse outcome. This dysfunction may take several forms, including not only immunosuppression resulting in an increased risk of infectious disease and cancer, but also misregulation producing an increased risk of allergic diseases and asthma, autoimmune diseases and inflammation-associated neurological disorders.

The novelty of the critical windows of vulnerability for the developing immune system has ramifications that impact hazard identification and risk assessment. First, because many of the key immune-cell maturation events are not replicated in the adult, it is not possible to effectively model whether a potential toxicant might be likely

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat164
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to disrupt prenatal immune events using adult animals or cells. Even *in vitro* effects of known toxicants are different among adult human vs. adult cord-blood-derived immune cells (Mainali and Tew, 2004). Therefore, strategies relying upon the use of adults to predict risk to the developing immune system following xenobiotic exposure or as a trigger for subsequent immunotoxicity testing in the nonadult are flawed and lack both sensitivity and specificity of modelling (Dietert and Piepenbrink, 2006).

The prenatal and neonatal process of immune maturation results in the spectrum of immune effector and regulatory cells that, together, mediate immune responses and regulate the nature, location, type and duration of responses. While genetic background is a factor in later-life immune potential, the environmental condition surrounding immune development plays a critical role in establishing postnatal immune capacity, and, in turn, influences later-life health and wellbeing. For this reason, identification of the risk of xenobiotic exposure to the developing immune system provides an important tool for enhanced disease prevention.

Several reviews have considered the sequence and timing of the novel events that occur during the maturation of the developing immune system, as well as the potential problems that can arise when these events are disrupted by xenobiotic exposure (Holladay and Smialowicz, 2000; Dietert *et al*., 2000; Landreth, 2002; Holsapple *et al*., 2003; Landreth and Dodson, 2005; Leibnitz, 2005; Dietert and Piepenbrink, 2006). More recently, the idea of immune-critical windows relative to DIT has been expanded to include not only those events that have systemic ramification for the offspring (e.g. T-cell clonal selection in the thymus), but also those having more specialized local/regional impact (e.g. microglia seeding, expansion and activation in the brain) (Dietert and Dietert, 2008; Luster *et al*., 2008).

Figure 1 shows a series of systemic and tissue-specific (or local) immune-critical developmental windows, which are maturational benchmarks that impact subsequent distribution and functional capacities of later-life immune-cell populations. Not surprisingly, xenobiotic-mediated disruptions during these intervals are likely to produce the most significant adverse immune

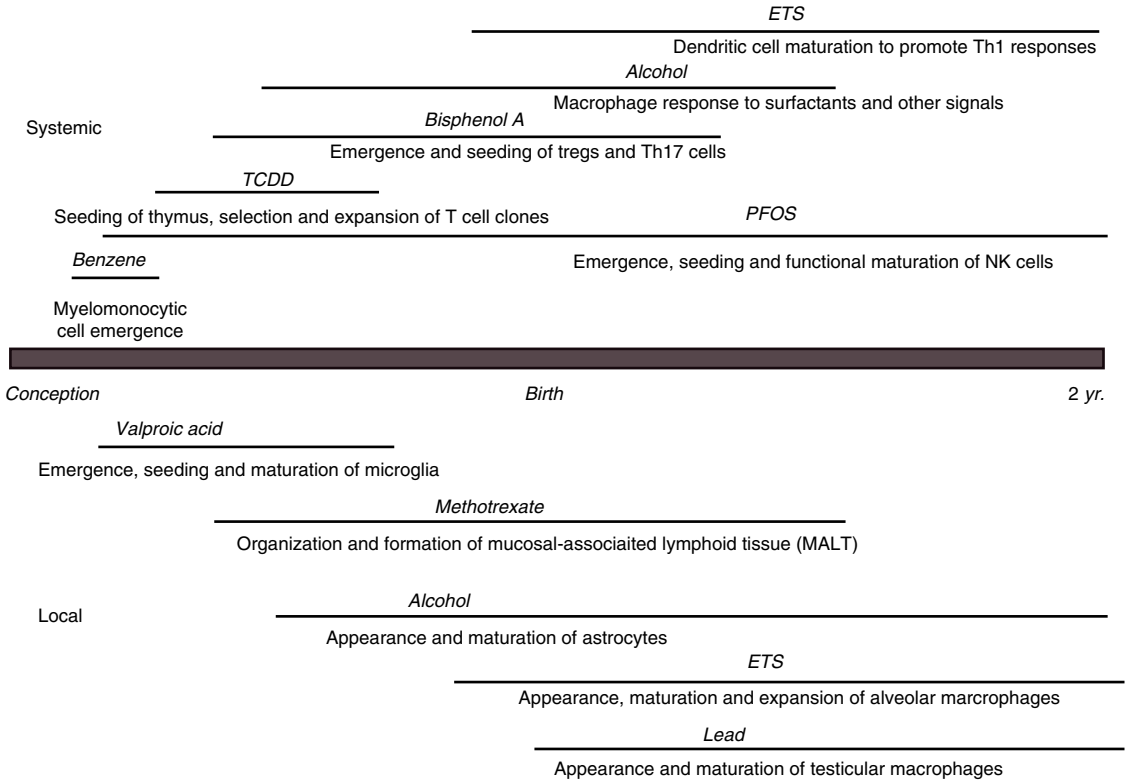

Figure 1 A timeline map of human critical development windows of immune vulnerability is shown from conception until two years after birth. It is divided into two sections. The top section shows six immune maturational processes that are systemic and represent key points of vulnerability for environmental disruption. The bottom section shows five immune maturational processes that pertain to a specific tissue (e.g. brain, lung, testes) or group of tissues (mucosal tissue). A chemical or drug reported to disrupt the specific maturation event is listed above each line segment for the event (e.g. alcohol for the maturation of astrocytes). (Adapted from information in Dietert and Piepenbrink, 2006; Dietert and Dietert, 2008.) Treg = T regulatory cells; Th17 = T helper 17 cell population (which produce Interleukin 17); ETS = environmental tobacco smoke; PFOS = perfluorooctane sulfonate; TCDD = 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.

Trichloroethylene	Peden-Adams *et al*. (2006)
Urethane	Luebke *et al*. (1986)

outcomes. An example of a chemical or drug that has been reported to disrupt the given immune maturational event is shown above each window. For many of these windows several xenobiotics are known to be capable of causing disruption. The idea of systemic critical windows for developmental immunotoxicity dates back for nearly a decade (Dietert *et al*., 2000; Holladay and Smialowicz, 2000; Bunn *et al*., 2001a; Landreth, 2002; West, 2002). However, a more recent expansion of this concept is that resident immune-inflammatory cells in different tissues (e.g. brain, lung, testes) may each have their own critical developmental windows where environmentally mediated disruption can contribute to later-life disease (Dietert and Dietert, 2008). This local or tissue-specific aspect of DIT becomes particularly important in cases where organ cell loss or tissue damage plays a role in specific childhood or adult diseases.

5 CHEMICALS AND DRUGS WITH REPORTED IMMUNOTOXIC ACTIVITY FOR THE DEVELOPING IMMUNE SYSTEM

Not surprisingly, a majority of immunotoxicology research and testing described in the literature is a result of adult animal exposures or the use of adult-derived cells. However, with the concern over early-life origins of later-life disease, DIT research has been increasing. A substantial spectrum of xenobiotics has been reported to produce adverse immune effects following exposure during prenatal, neonatal and/or juvenile periods of development (Dietert and Dietert, 2007). Some of these are connected with specific health concerns (Holladay, 1999; 2005; Gauthier *et al*., 2005a; Heilmann *et al*., 2006; Selgrade *et al*., 2006; Yeatts *et al*., 2006; Goodwin, 2007; Hamada *et al*., 2007; Ohshima *et al*., 2007; Luster *et al*., 2008; Selgrade, 2007; Hertz-Picciotto *et al*., 2008; Wang *et al*., 2007; Wang and Pinkerton, 2008).

Table 1 shows examples of chemicals and drugs with reported capacity to target the developing immune system. Among the most extensively studied xenobiotics affecting the developing immune system are: atrazine (Rooney *et al*., 2003; Rowe *et al*., 2006; 2008), dexamethasone (Eishi *et al*., 1983; Dietert *et al*., 2003; Mainali and Tew, 2004; Mainali *et al*., 2005), diethylstilbestrol (Fenaux *et al*., 2004; Besteman *et al*., 2005; Brown *et al*., 2006), oestrogenic and endocrine-disrupting compounds (Karrow *et al*., 2004; Yoshino *et al*., 2004; Guo *et al*., 2005a; 2006; Yang *et al*., 2008), ethanol (Gauthier *et al*., 2005b; Lazic *et al*., 2007), halogenated aromatic hydrocarbons (Arena *et al*., 2003; Camacho *et al*., 2004; Walker *et al*., 2004), heavy metals (Luster *et al*., 1978; Miller *et al*., 1998; Snyder *et al*., 2000; Sun *et al*., 2003;

Dietert *et al*., 2004; Pace *et al*., 2005; Pilones *et al*., 2007), immunosuppressive drugs (Padgett and Seelig, 2002; Hussain *et al*., 2005; Prakash *et al*., 2007), mycotoxins (Dietert *et al*., 1983; Qureshi *et al*., 1995; 1998; Silvotti *et al*., 1997), organochlorine pesticides (Barnett *et al*., 1990; Theus *et al*., 1992; Chapin *et al*., 1997; Smialowicz *et al*., 2001; White *et al*., 2005), polycyclic aromatic hydrocarbons (Holladay and Smith, 1994; 1995; Rodriguez *et al*., 1999), tobacco smoke (Gilmour *et al*., 2006; Ng *et al*., 2006; Penn *et al*., 2007; Johansson *et al*., 2008; Wang *et al*., 2008) and tributyltin compounds (Smialowicz *et al*., 1989; Tryphonas *et al*., 2004). The diversity of xenobiotic factors affecting the developing immune system provides added incentive to ensure that safety-testing strategies would identify potential developmental immunotoxic outcomes. This is discussed in Section 9.

6 PREGNANCY AND ITS IMPLICATIONS FOR BOTH MATERNAL AND OFFSPRING IMMUNE STATUS

A successful pregnancy requires that the mother carry a semiallogeneic foetus to term without paternal antigen-derived immune rejection. T-cell function and cytokine balance play a critical role in protection of the foetus and maintenance of the pregnancy (Lim *et al*., 2000; Jin *et al*., 2006). Because of the need to suppress allogeneic-driven cell-mediated immune responses, a variety of systemic and uterine-local strategies are used to reduce the likelihood of rejection. These include both Th1 suppression and creation of a Th2-biased environment as well as local uterine efforts to reduce maternal immune stimulation by foreign antigens (Zhu *et al*., 2005; Saito *et al*., 2007; Zenclussen *et al*., 2007).

The creation of a Th2-preferred environment tracks with the likelihood of a successful full-term pregnancy. For example, evidence suggests that women who fail to adequately shift Th cytokines during pregnancy are more likely to have preterm deliveries (Malamitsi-Puchner *et al*., 2006). Additionally, a subset of women who repeatedly miscarry fail to suppress Th1 functional capacity and Th1 cytokine production during pregnancy (Jenkins *et al*., 2000; Wilson *et al*., 2004; Piccinni, 2006). The necessary shift in maternal environment and immune spectrum has implications for the mother and her immune function during the pregnancy (Poole and Claman, 2004).

The shift in immune balance is known to alter the severity of symptoms associated with maternal autoimmune diseases during the pregnancy. Those diseases dependent upon Th1 responses are usually reduced in symptom severity, while those connected with Th2 responses are increased. Pregnancy-associated changes have been reported for lupus (Dhar and Sokol, 2006) as well as rheumatoid arthritis (Doria *et al*., 2006; Ostensen and Villiger, 2007).

The Th2-biased environment of pregnancy also means that the offspring's developing immune system proceeds with a Th2 preference while *in utero*. Th1 responses are suppressed in both the mother and the developing child (McCracken *et al*., 2007). This means that with normal pregnancies, and in the absence of developmental immunotoxicity, children at birth have a Th2-bias capacity (Chen *et al*., 2006) that needs to be shifted towards a more useful balance of functions (Niers *et al*., 2007). These newborns possess immature response capacities that must undergo further maturation to achieve the needed spectrum of host defence. The maturational immaturity includes aspects of both the innate (Satwani *et al*., 2005; Levy, 2007; Sadeghi *et al*., 2007) and acquired (Upham *et al*., 2002; Krumbigel *et al*., 2005; Velilla *et al*., 2006) immune functions and is reflected in cytokine imbalances (Protonotariou *et al*., 2004; Rizos *et al*., 2007). Where developmental immunotoxicity intersects this process is the potential for xenobiotic exposure to interfere with the required perinatal–neonatal shifts in innate and acquired immune functional capacities. The default, should additional neonatal maturation not progress adequately after birth, is a greater likelihood of childhood allergic disease, risk of certain infections and misregulated inflammation (Dietert and Dietert, 2007).

7 GENDER AS A RISK FACTOR WITH DEVELOPMENTAL IMMUNOTOXICITY

Among the findings concerning adverse outcomes following the exposure of the developing immune system to xenobiotics is the importance of gender. Female and male offspring exhibit significantly different immunotoxicity profiles following exposure to a wide array of chemicals and drugs. Most of the studies conducted to date involve rodent models (mice and rats), but the significance of gender in environmentally mediated immune dysfunction also parallels gender differences seen in certain childhood diseases (Lleo *et al*., 2008; Ostman *et al*., 2008). In some cases, low-level exposure may produce immunotoxicity in only one gender for the immune parameters examined (Chapin *et al*., 1997). For other xenobiotics and exposures, both the nature of the adverse outcomes (Bunn *et al*., 2001b) and the postnatal timing for appearance (Rowe *et al*., 2008) can differ between males and females.

Among the xenobiotics reported to produce gender-specific DIT outcomes are atrazine (Rowe *et al*.,

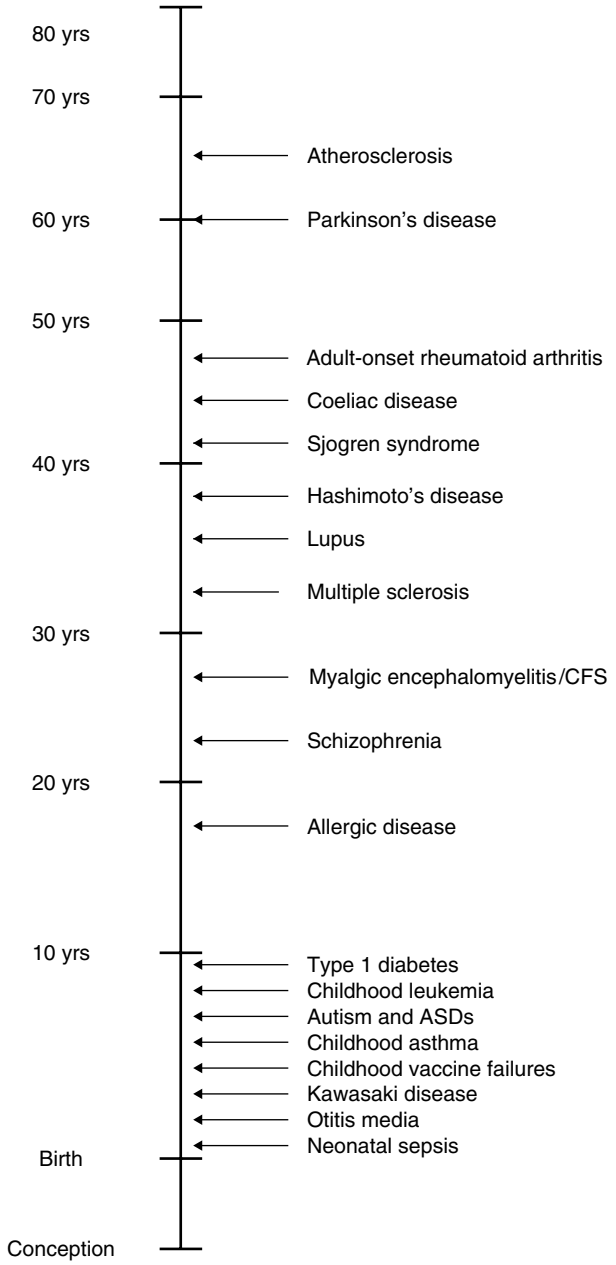

Figure 2 The figure illustrates a timeline of childhood- and adult-onset diseases or conditions that are either directly linked to early-life immune insult or have the potential to be caused by disruption of the developing immune system. As such, these diseases feature both environmental risk factors and immune dysfunction. The timeline presents the approximate average age of onset for each disease or condition.

2006), bisphenol A (Yang *et al*., 2008), cadmium (Pillet *et al*., 2005), chlordane (Blyler *et al*., 1994), cigarette smoke (Ng *et al*., 2006), diethylstilbestrol (Fenaux *et al*., 2004), ethanol (Redei *et al*., 1993), genistein (Guo *et al*., 2005a), lead (Bunn *et al*., 2001b), mercury (Silva *et al*., 2005), methoxychlor (White *et al*., 2005), nonylphenol (Guo *et al*., 2005b), NSAIDs (nonsteroidal anti-inflamatory drugs) (Kushima *et al*., 2007) and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) (Gehrs and Smialowicz, 1999).

8 DIT AND ADVERSE HEALTH OUTCOMES

Research into immunotoxicity, immunity and health risks conducted in the 1980s and 1990s tended to focus on xenobiotic-induced immunosuppression, which was usually accompanied by reduced host resistance to infectious diseases (Selgrade *et al*., 1988; Johnson *et al*., 1989; Smialowicz *et al*., 1991; Luebke *et al*., 1994) This included early DIT studies (Stahlmann *et al*., 1992; Schlumpf *et al*., 1994). But with additional research into DIT and increasing concern over immune-inflammation-related pediatric health risks, immunosuppression is now recognized as only one of several adverse outcomes. In fact, even immunotoxicants known for more than a decade to produce immunosuppression (Faith and Luster, 1979; Gehrs *et al*., 1997) following prenatal and/or neonatal exposures were recently found to concomitantly increase the risk of autoimmunity (Fisher *et al*., 2005; Mustafa *et al*., 2008) and to cause increased risk of inflammation-mediated damage (Vorderstrasse *et al*., 2006; Hogaboam *et al*., 2008). For this reason, it is sometimes more useful to categorize outcomes associated with DIT as pertaining to immune dysfunction or misregulation vs. more restrictive labels. Xenobiotic disruption of immune maturation can produce a myriad of postnatal immune-dysfunction possibilities. These can include increased risk of allergic disease, including asthma, as well as autoimmunity in addition to immunosuppression and misregulated inflammation.

A timeline of childhood and adult onset diseases that are among those relevant to DIT are shown in **Figure 2**. These diseases are established as being directly connected to DIT, have data highly supportive of a connection or have features that make them likely candidates for DIT-influenced risk: immune dysfunction or environmental risk factors for the disease and early-life conditions that contribute to the later-life disease. Among the diseases of greatest interest are conditions associated with infectious agents (neonatal sepsis, otitis media), cancer (childhood leukaemia), allergic diseases (eczema, rhinitis, food allergies, coeliac) including asthma, autoimmune conditions (Type 1 diabetes, multiple sclerosis, systemic lupus erythematosus) and conditions associated with misregulated inflammatory damage-cell loss (schizophrenia, Parkinson's disease, autism).

9 DEVELOPMENTAL IMMUNOTOXICITY TESTING

Immunotoxicity testing using adult animals has a long history spanning several decades (Dean *et al*., 1982; Van Loveren *et al*., 1988; Luster *et al*., 1992a; 1992b; 1994; Hinton, 2000). Effective approaches to adult immunotoxicity testing are based on a tier system for prioritization of testing. Usually the initial tier combines broad-scale functional and nonfunctional end points with subsequent tiers including parameters that provide more detailed information on specific functions (Luster *et al*., 1992a).

In contrast, consideration of developmental immunotoxicity testing has been a recent development that appeared this decade in association with recognition of two fundamental distinctions in toxicology between the developing and the mature immune system: (i) the developing immune system is more sensitive to toxic insult compared to that of the adult (Luebke *et al*., 2006a; 2006b) and (ii) a major disconnect exists in using adult immune exposure as a surrogate to predict risk of prenatal, neonatal or juvenile immunotoxicity (Dietert and Piepenbrink, 2006; Dietert, 2008a; 2008b; 2008c). For this reason, several recent research studies, workshops and reviews have considered effective strategies for developmental immunotoxicity testing (Miller *et al*., 1998; Ladics *et al*., 2000; 2005; Dietert *et al*., 2002; Holsapple, 2002; 2004; 2005; Smialowicz, 2002; Luster *et al*., 2003; Van Loveren *et al*., 2003; Barrow and Ravel, 2005; Dietert and Holsapple, 2007; Dietert, 2008a; 2008c).

The results of this recent literature reflect several points of general agreement, as well as several important points of departure regarding effective approaches to developmental immunotoxicity testing. First, most panels and authors agree that multiple parameters should be evaluated in any immune assessment following exposure of the nonadult and that they are likely to include a mix of functional and nonfunctional end points. This is similar to current immunotoxicity testing approaches in the adult. Additionally, most agree that effective use of animals is a high priority for any testing strategy. A third point of agreement is that for a general DIT screening, chemical or drug exposure across all developmental windows of the nonadult would be used. Finally, most authors agree that the data to date indicate that the developing immune system is more sensitive to xenobiotics than that of the adult.

Figure 3 illustrates a generalized testing schematic for developmental immunotoxicity assessment in the rat. Exposure to the test compound would occur across all developmental windows (prenatal, neonatal and juvenile). Nonfunctional assessment (e.g. histopathology and cell counting) could be conducted at various intervals between birth and adulthood with functional assays using a challenged immune system conducted in the juvenile and young adult.

The general points of agreement on developmental immunotoxicity safety testing reflect the considerable strides that have been made in research on xenobiotics and the developing immune system. However, there are also significant areas where suggested testing approaches diverge. These are: (i) whether use of a challenge

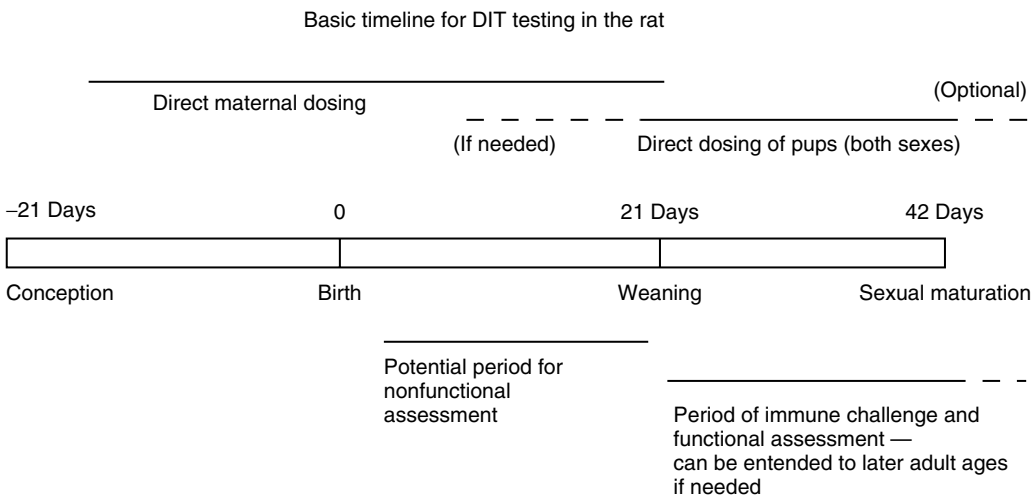

Figure 3 This illustrates a sample timeline for performing developmental immunotoxicity testing using the rat. Exposure to the xenobiotic occurs during all developmental windows of the nonadult and would include maternal dosing during gestation and lactation, with direct pup dosing beginning either postweaning or during lactation as is most relevant for human exposure. Assessment can be performed at various postnatal times. Nonfunctional assessment can begin prior to weaning and extend until the termination of the protocol. Immune challenge and functional assessment would occur after weaning. The protocol can be completed at 42 days after birth or extended longer as needed for the specific xenobiotics exposure, as well as the method of functional assessment. (Adapted from Dietert and Holsapple, 2007.)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat164
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

immune system (animals immunized or challenged with an infectious agent) is required for effective developmental immunotoxicity assessment, (ii) in the tiers, priorities to be given to measuring immune functional assays (e.g. T-dependent antibody response, cytotoxic T-lymphocyte response, delayed-type hypersensitivity response, natural killer cell activity) vs. nonfunctional parameters (e.g. histopathology, cell population counting) and (iii) whether an indication of adult immunotoxicity for a xenobiotic would be necessary before any developmental immunotoxicity testing would be triggered during safety evaluations.

The differences in DIT-related safety-testing philosophies and approaches are evidence in a comparison of Burns-Naas *et al*. (2008) and Dietert (2008a). In the former, histopathology is presented as the core evaluation tool for developmental immunotoxicity testing, with multifunctional testing either relegated to later tiers in the testing process and/or requiring positive indications of immunotoxicity before use. In contrast, Dietert (2008a) proposed that detection of immune dysfunction using multiple assays should be the highest priority in DIT safety assessment, with histopathology and other nonfunctional end points to be conducted in parallel as associated parameters. The latter paper also suggested the benefits of a specific linkage between developmental immunotoxicity safety-testing end points and the diseases of greatest public concern. Namely, that the specific DIT-associated parameters employed should be capable of detecting the immune dysfunctions characteristic of the most prevalent childhood diseases with environmental causes. Such an approach would establish a more direct linkage between immunotoxicity safety testing and the target diseases for anticipated risk reduction.

10 SUMMARY AND CONCLUSIONS

Immune status is well established as a critical factor in host protection against disease. Given the immune-health connection, it is not surprising that DIT is increasingly recognized as an area of research and testing that directly impacts the health and wellbeing of children and adults. Recognition of the developing immune system as an environmental target for postnatal disease fits within the larger multisystem paradigm of early-life origins for later-life disease.

A broad spectrum of chemicals, drugs and other environmental factors are known to disrupt immune development with adverse outcomes dependent upon the level and timing of the exposure. Additionally, the developing immune system is more sensitive to environmental insult than the fully matured immune system of the adult. Therefore, immunotoxic risk identified for an adult is unlikely to provide a good indication of the health risk to a foetus or child. For these reasons, developmental immunotoxicity research and testing have become integrally linked with strategies to reduce the incidence of those chronic childhood and adult diseases featuring immune dysfunction (e.g. allergies, asthma, Type 1 diabetes, multiple sclerosis, lupus, rheumatoid arthritis). Future DIT-related safety testing offers a significant opportunity to minimize problematic environmental exposures that could increase the risk for these diseases. This should result in more cost-effective approaches to address chronic immune-dependent diseases.

ACKNOWLEDGEMENTS

The author thanks Dr. Gary Burleson and Florence Burleson for their helpful discussions, and also expresses appreciation to Janice M. Dietert for her editorial assistance with this chapter.

Drugs of Addiction in the Domestic, Occupational and Sports Environment

Felix K. Adatsi

CONTENTS

1 INTRODUCTION

Throughout recorded history, humans have sought to use drugs for a variety of purposes. The use of wine or other alcoholic beverages for festive celebrations dates back to the Greeks and early Egyptians, and marijuana was used for medicinal purposes in China about 2737 BC. The men of old had a ritualistic use for drugs. Some in the human population still use drugs to express joy or sadness, for pleasure or to null pain, and others use them to gain a competitive advantage in activities which require stamina or endurance. Regardless of the nature of the motivating factor for the initial contact with a drug, if subsequent exposure to the drug becomes frequent and desirable, a gradual problem of addiction develops and becomes evident in the behaviour of the user.

Drug addiction has been described as a compulsion for drug use, even when the continued use goes to the detriment of the proper execution of basic human activities which are considered to be essential for normal social adjustment. The consequences of drug addiction are multifaceted and cut a swath of adverse effects measurable in the despondency, misery and eventual death of the individual. Activities, such as family relationships, work responsibilities and commitment to defined goals, are compromised, as ultimately is the health of the drug user (Hardman *et al*., 2001; Helms *et al*., 2006).

Drug use in modern societies is not a novel activity, but appears to be a natural outcome of our very existence. It should come as no surprise that where two or more people are gathered, drug use could emerge as an expected indulgent activity. It could begin as subtly as sharing a cigarette or a bottle of alcoholic

beverage, and progress to the blatant craving for a drug or sharing a needle filled with heroin. However, unlike primitive societies, the extent of drug use in modern societies is measurable and the consequences are enormous. The 2007 National Survey on Drug Use and Health (NSDUH), an annual survey sponsored by the Substance Abuse and Mental Health Services Administration, issued the following statistics on the use of licit and illicit drugs in the United States (Substance Abuse and Mental Health Services Administration, (SAMHSA) Office of Applied Studies (OAS), 2008). In 2007, an estimated 19.9 million Americans aged 12 or older, representing 8.0% of the population, were current illicit drug users. Illicit drugs include marijuana/hashish, cocaine (including crack), heroin, hallucinogens, inhalants or prescription-type psychotherapeutics used nonmedically. Indeed, the World Health Organization has observed that illicit use of drugs has taken on global dimensions and the extent of the worldwide use of psychoactive substances is estimated at 2 billion alcohol users, and 185 million drug users (World Health Organization, 2009).

The consequences of drug abuse on the individual user are many. Individual drug users may become despondent and their value systems are easily compromised. Users schedule their activities around the drug use, and abandon stimulating family activities. In time, moral norms are compromised and the user becomes vulnerable to a variety of diseases, such as sexually transmitted diseases, hepatitis and HIV/AIDS because of the risk of sharing contaminated hypodermic needles. The effect of drug use on the family is often a disruption of the family structure and creation of varying levels of dysfunction in the family unit. If the user is an adult head of household, leadership roles become murky or nonexistent, and children suffer from lack of discipline and direction.

Currently, in the United States, nearly 7% of full-time adult employees and 9% of part-time employees use illegal drugs (Substance Abuse and Mental Health Services Administration, (SAMHSA) Office of Applied Studies (OAS), 2008). The profile of abusers includes law-enforcement personnel, medical personnel, sports figures, comedians, musicians and scientists. Employers with successful drug-free workplace programmes report improvements in productivity and morale. They also report a decrease in absenteeism, accidents at the workplace, attrition, loss of property and turnover. Sober workers are less likely to change jobs frequently or be late or absent from work. They are more productive, and less likely to file workers' compensation claims.

Several factors must be considered in classifying a drug as a drug of addiction in a particular society. Prominent among them are factors such as the potency of the drug, its prevalence and ease of acquisition in that environment, socioeconomic and political factors, and the overall prevailing culture of drug users in that society. Drug users play a significant role in this classification and it is perhaps their demand for a specific drug that ultimately calls attention to its abuse potential, probable classification as a drug of addiction and its subsequent control.

2 FACTORS INFLUENCING ADDICTION TO DRUGS

The psychosocial factors governing the initial exposure to or indulgence in drugs are complex. They may begin simply as consumers presenting themselves to a physician to seek relief from a lingering ailment, or desiring to be energized following a 'burn-out' feeling or just wishing to experiment with the drug. In the sports arena, subjects might be seeking to enhance their performance or gain a competitive advantage over other competitors in their field. In seeking to obtain relief by using the drug, the unsuspecting user soon becomes attached or 'hooked' to the drug. The effect of some of these drugs is short lived and the user soon develops tolerance to the drug. Overall, environmental factors, such as the availability of a drug, environmental stress, peer pressure, cultural influences and one's inherent susceptibility to drugs, will ultimately influence the selection or the user's propensity to the use of a drug (Kendler *et al*., 2008).

3 DRUGS OF ADDICTION

The main classes of drugs of addiction include stimulants, central nervous system (CNS) depressants and sedatives, opiates and opioid analgesics, hallucinogens and inhalants. Although some of the specific drugs might be grouped in a particular class based on their mode of action, they may cause users to exhibit symptoms which cross over into other classes. Assessment of the extent of addiction to specific drugs in each classification is based on reports from drug-testing laboratories, programmes dealing with self-reporting use of drugs and the frequency of detection from forensic drug-testing laboratories (Cone *et al*., 2008; Office of National Drug Control Policy (ONDCP), 2008; Quest Diagnostics, 2007). Sadly, the recognition and eventual classification of a drug as being a 'drug of addiction' by the scientific community will invariably lag behind the intended use of the drug. It is probably the pattern of inappropriate use imposed on the drug by users which will initiate that classification.

3.1 Stimulants

The drugs in this class include amphetamine, methamphetamine, methylphenidate (Ritalin), Methylenedioxy-

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat165

methamphetamine ('MDMA', 'Ecstasy', 'XTC'), 3,4-methylenedioxymethamphetamine (DMA, 'Ecstasy', 'XTC'), cocaine (as a powder or as 'crack cocaine') and ephedrine. Drugs in this class are abused for their ability to cause excitement, impart a feeling of increased self-confidence, wellbeing and euphoria. Additionally, they offer a feeling of alertness and counter feelings of fatigue. The drugs in this class are popular among truck drivers and workers who must remain alert for jobs or activities requiring endurance and stamina (Logan, 2002). Amphetamines, methamphetamines, cocaine and MDMA are the drugs most commonly encountered within this context. Users who tap into these drugs, soon find that they reach a point of diminishing returns. The same drugs which energize them can also cause them to be fatigued and dysphoric. The central stimulatory effects or 'rush' which results from the use of stimulants is often followed by a 'crash' phase, during which there is depression of the senses (Dackis and Gold, 1985; Gawin and Kleber, 1986).

In general, stimulants such as cocaine and methamphetamine increase neuronal activity in the CNS, resulting in an increased level of the neurotransmitter dopamine (Isenschmid, 2002; Venton *et al*., 2006). This increased level of dopamine is thought to be responsible for the euphoric and excitatory properties of the drugs. With repeated use, stimulants cause some down-regulation of dopamine receptors and users feel an effect that is opposite to that experienced during the excitation phase. Users need to take more and more of the drug in order to experience the same effects they desire. Long-term abuse of these stimulants can result in addiction and users may display features such as violent behaviour, insomnia, auditory hallucinations, paranoia, and suicidal and homicidal intentions. Both cocaine and methamphetamine abuse have been responsible for many other adverse effects resulting in death (National Institute on Drug Abuse (NIDA), 2003; 2005; Kaye *et al*., 2008).

3.2 Central Nervous System (CNS) Depressants and Sedatives

Alcohol continues to be the main representative drug in this class of drugs, in terms of its availability and preponderant use. In many parts of the world, the use of alcohol as a beverage is considered a normal right of passage into adulthood. In Western societies it is so abundant that its use as a social beverage is freely condoned. Nevertheless, it remains a drug and its CNS depressant effects are sometimes taken as a paradigm by which other therapeutic drugs are compared. It is by far the most studied of all drugs in relation to its human effects and consequently the biological and medical effects literature on the subject is the largest single literature in medical science. The other drugs in this class include the barbiturates (amobarbital (Amytal), butalbital (Sandoptal), phenobarbital and secobarbital (Seconal)), benzodiazepines (alprazolam (Xanax), chlordiazepoxide (Librium), clonazepam (Klonopin), clorazepate (Tranxene), diazepam (Valium), estazolam (ProSom), lorazepam (Ativan), oxazepam (Serax) and triazolam (Halcion)) (Physicians' Desk Reference 2008). Other drugs in this class which are recognized for their sedative properties and popular with their demand are carisoprodol (Soma), chlorphenamine (chlorpheniramine, Chlortrimethon), diphenhydramine (Benadryl), gamma hydroxybutyrate (GHB), meprobamate (Miltown), tetrahydrocannabinol (marijuana) and zolpidem (Ambien). In spite of their classification as antihistamines, both chlorphenamine and diphenhydramine are also recognized for their sedative properties in moderate to high doses.

The general effects of these drugs are typified by those encountered in the use of alcohol (Jones, 2003; Garriot, 2003), which is clearly a prototype for the class. The effects and potential hazards posed by these drugs follow a dose–response relationship, with adverse effects increasing with increasing drug blood levels until physiological functions are overwhelmed, resulting in the death of the user. Most CNS depressants have similar pharmacological actions and act by interfering with neuronal activities in the brain. They enhance the actions of the neurotransmitter γ-aminobutyric acid (GABA). By increasing GABA activity, CNS depressants cause a decrease in nervous activities.

Adverse effects associated with this class of drugs span a wide range of psychomotor and cognitive, as well as behaviour changes (Woods and Winger, 1997). In general, learning, thinking and decision-making are impaired, as are activities requiring fine or gross motor skills, depending upon the amount of drug consumed. As CNS depressants, the adverse effects of these drugs also include an increase in reaction time, reduced vigilance, impairment of performance on divided-attention tasks, drowsiness, confusion and unsteady gait. For these reasons, use of CNS depressants drugs impairs driving skills (Ramaekers *et al*., 2004; Bedard *et al*., 2007; O'Hanlon *et al*., 1982; van Laar *et al*., 1992). These adverse effects increase in severity as more drug is consumed. Prolonged use of CNS drugs can cause addiction and despite their beneficial effects as antianxiety drugs, the barbiturates and benzodiazepines are capable of causing drug dependency and fatalities.

3.3 Opiate and Opioid Analgesics

Morphine and codeine, two naturally occurring opiates are found in this class. Other members of this class include buprenorphine (Subutex), dihydrocodeine

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat165
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Synalgos), fentanyl (Duragesic, Sublimaze), heroin, hydrocodone (Vicodin, Lortab), hydromorphone (Dilaudid), meperidine (Demerol), methadone (Dolophine), oxycodone (Oxycontin), pentazocine (Talwin) and propoxyphene (Darvon).

The popularity of opioids among users and the addiction and entrapment of the user in a vicious cycle of dependence on opioids is due to their potent analgesic properties. They are used for the management of moderate to severe pain and chronic pain in cancer or terminally ill patients (Joranson *et al*., 2000; Manchikanti, 2006; Manchikanti and Singh, 2008; Merlo and Gold, 2008; Ballantyne, 2007). Opioids exert their action by binding to specific opioid receptors which are widely distributed throughout the brain, spinal cord and gastrointestinal tract. Three main types of receptors have been identified and are mu (μ), delta (δ) and kappa (κ) receptors (Hardman *et al*., 2001). Specific opioids bind to these receptors, based on their affinities, in their mode of action.

The effects of opioids in humans include euphoria, decreased anxiety, drowsiness, constipation and (pin-point pupil size), which may impair activities such as night driving, and cause life-threatening respiratory depression. A classic feature associated with the use of opioids is the development of tolerance and physical dependence (Hardman *et al*., 2001). For this reason, withdrawal symptoms can be severe when the cessation of drug use is abrupt. Symptoms of withdrawal include restlessness, vomiting, cold flashes, and muscle and bone pain. The extensive reliance on opioids predisposes the user to drug-related fatalities, and instances of accidental opioid fatalities can be found in the scientific literature (Denton *et al*., 2008; Graham *et al*., 2008; Hall *et al*., 2008).

3.4 Hallucinogens

Lysergic acid diethylamide (LSD) is perhaps the classic representation of drugs classifiable as hallucinogens. It enjoys this classification along with drugs, such as phencyclidine (PCP), ketamine, mescaline, and psilocybin/psilocin ('mushrooms'). Tetrahydrocannabinol (marijuana) has been classified as a CNS depressant, however some of its adverse effects warrant its inclusion in this class as well.

Hallucination has been defined as sensory perception without external stimulus of the relevant sensory organ (American Psychiatric Association, 1987). Many pharmacological substances are capable of producing hallucinogenic effects. However, use or mention of drugs such as LSD, peyote, psilocybin and psilocin ('mushrooms'), PCP and ketamine have become synonymous with experiences of a hallucinogenic nature. Most of these drugs are alkaloids and can be obtained from plants. It is no surprise that in certain cultures, chief priests used these plant materials as prized possessions for their hallucinogenic effects during social or religious rituals, and the ensuing induced states of detachment and 'mystical visions' they conferred on them was used to hold a magical sway over others in their tribe. These drugs produce profound drug-induced psychosis, distortions in the user's perception of reality and influence their perception of sound, colour, time and movement.

LSD is the most potent hallucinogenic drug known and produces significant mood- and perception-altering effects at very low doses (Hardman *et al*., 2001). Because of its effectiveness, it is dispensed illegally as 'microdots' or thin stamp-sized squares impregnated with the drug. Law-enforcement personnel seeking to apprehend users of this drug must be aware of these modes of trafficking, and among other clues on a suspect, look for sheets of 'blotter acid' papers or window panes which are thin squares of gelatin soaked with LSD. LSD produces tolerance and psychic dependence (Department of Health and Human Services (DHHS), National Institute on Drug Abuse (NIDA), 2001) and users must take progressively higher doses to achieve a desired effect.

Users of hallucinogenic compounds refer to their experiences with the drugs as 'trips'. A 'bad trip' is a collection of unpleasant and acute adverse effects of the drug which include nightmares, horrifying thoughts, fears of insanity and demonic transformations of surrounding objects (Department of Health and Human Services (DHHS), National Institute on Drug Abuse (NIDA), 2001; Hofmann, 1980). Users of the drug also experience highly intense effects from the senses. Sensory perceptions of smells, colour and sound are magnified. LSD acts on serotonergic 5-HT2 receptors and tolerance develops quickly to the drug (Drummer, 2002). Increasingly larger doses are needed to produce desired effects and this may ultimately lead to addiction to the drug.

PCP was developed for use as a surgical anaesthetic agent in the 1950s. Its use, however, was limited to veterinary medicine because of the extreme adverse effects, such as delirium and agitation experienced by patients when used in human medicine. Repeated use of PCP can result in addiction. Ketamine was developed to replace PCP as an anaesthetic agent and is similar in structure and mechanism of action to PCP. However, it is less potent and has a shorter duration of action. Both compounds are classified as dissociative anaesthetics. Users experience a variety of effects, including 'out-of-body' sensations, detachment from their environment and sometimes complete sensory detachment likened to a near-death experience. Use of ketamine induces amnesia and for this reason has been implicated in drug-facilitated sexual assaults on unsuspecting victims exposed to the drug (Department of Health and Human Services (DHHS), National Institute on Drug Abuse (NIDA), 2001).

3.5 Inhalants

Included in this class of drugs are chemical substances which are gases or possess sufficient vapour pressures to exist in the gaseous state at room temperature. By their very nature, these chemicals are volatile substances and the major route of administration or exposure is by inhalation. They include gases (aerosols, butane, halothane, nitrous oxide, propane), nitrites (amyl nitrite, butyl nitrite, cyclohexyl nitrite) and volatile organic solvents (benzene, chloroform, correction fluids, electronic contact cleaners, ether, gasoline, lighter fluid, methylene chloride, paint thinners, perchloroethylene, toluene, trichloroethylene) (Klaassen, 2007; Balster, 1998). They are inexpensive and their ubiquitous presence as common household chemicals, promote their use by children and young adults. National surveys indicate that more than 22.9 million Americans have abused inhalants at least once in their lives (Substance Abuse and Mental Health Services Administration (SAMHSA) Office of Applied Studies (OAS), 2008).

Users who gravitate towards this class of drugs cut across a broad range of age groups, sexual orientation, citizenry and professional echelons. Those in the medical professions, academia and the food industry are likely to abuse nitrous oxide, partly because of its workplace availability. Young adolescent vagabonds seeking to experiment with drugs are likely to be hooked 'huffing' organic solvents or chemicals commonly found in commercial products such as correction fluids, lighter fluids, spray paints, nail-polish remover, dust off and paint thinners; commercial products which can be cheaply obtained (Kurtzman *et al*. 2001). Nitrites are used as sexual enhancers and are commonly abused by adults (Wu *et al*., 2005). Use of nitrites is common among male homosexuals who reportedly use them for heightened sexual pleasure. In general, these drugs produce a quick and rapid onset of effects and an equally rapid recovery and a sustained 'high' can be obtained by repeated inhalation or sniffing.

Inhalants generally exhibit behavioural effects similar to those of alcohol, barbiturates, benzodiazepines and other CNS depressant drugs (Balster, 1998; Klaassen, 2007). These effects include lightheadedness, loss of inhibition, euphoria, incoordination, drowsiness, dizziness, slurred speech, loss of memory, confusion, delusions and hallucinations. Repeated use of inhalants can lead to addiction, and high concentrations of chemicals in the lungs may result in seizures, coma and death. The volatility of the drugs in this class indicates that a major route of exposure is via the respiratory system. Once in the lungs, these volatile drugs are distributed over a large surface area and displace the air in the lungs. By depriving the body of oxygen, inhalant use may lead to a hypoxic condition. Hypoxia can damage brain cells and impair memory, thinking, learning and decision-making.

Long-term abuse of inhalants, especially those originating from the chlorinated hydrocarbon solvents such as methylene chloride and trichloroethylene, causes widespread and permanent damage to several organ systems including various parts of the nervous system and the brain. It results in the breakdown of the myelin sheaths surrounding nerve fibres. Prolonged destruction can result in paraesthesias, peripheral neuropathies, muscle spasms and tremors. The most serious outcome and hazard of inhalant abuse is a syndrome referred to as 'sudden sniffing death'. Manifestation of this syndrome is common with the abuse of compounds such as butane, isobutane, propane, chemicals in aerosols and 1,1-difluoroethane (Pfeiffer *et al*., 2006; Rohrig, 1997; Sugie *et al*., 2004; Xiong *et al*., 2004), and can result from a single heavy exposure to the inhalant by an otherwise healthy individual.

4 SOURCE AND AVAILABILITY OF DRUGS

4.1 Prescription Drugs

Since the mid 1900s, prescription drugs have increased in their availability to the general public. This increase is due to legitimate commercial production of these drugs and their distribution to hospitals, pharmacies, practitioners, and educational and research institutions (National Drug Intelligence Center, 2009). With this effluence came abuse. Some in the general population sought relief from the use of these drugs while others were tempted to experiment with them. The faint of heart found solace in the temporary relief offered by drugs perceived as 'painkillers' and a pattern of pilgrimage and return from the sanctuary offered by these drugs was established. In the United States, 'doctor shopping' constitutes a major source of availability and abuse of most prescription drugs. In this practice, the drug abuser visits many physicians and presents an ailment which may not exist or exaggerates an existing ailment, in order to obtain multiple prescriptions. Often the drug abuser proceeds to fill the prescriptions at different pharmacies to avoid detection.

Other avenues for access to prescription drugs involve the use of forged prescriptions, posing as a physician and calling in a fictitious prescription, break-ins into clinics and pharmacies, acquisition via internet pharmacy rings and flat-out theft from a sick neighbour, friend or relative. The diversion of prescription drugs can also come from unlikely sources. Unscrupulous medical personnel can author illegal prescriptions or collaborate with corrupt pharmacies to dispense drugs for profit. Finally, employees of pharmaceutical companies and commercial distributors steal prescription drugs from

DOI: 10.1002/9780470744307.gat165
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

their respective inventories and resell the drugs for profit (National Drug Intelligence Center, 2009).

4.2 Cocaine, Heroine, Marijuana, Methamphetamine

These drugs are available through a variety of sources. Domestic production occurs in clandestine laboratories ('meth labs'), and smuggling across the borders accounts for the large amounts usually found in the southern United States. The predominant form of available methamphetamine in the United States is the powder form. Ice methamphetamine is another form of the drug found in the United States and is smuggled into the country primarily from its production sites in Guam and Mexico. Also available is the tablet form of the drug, which is produced in Asia, primarily in Burma (National Drug Intelligence Center, 2009). Powder methamphetamine is usually injected or snorted. Tablet methamphetamine can be ingested orally, smoked, snorted or mixed with water and injected.

4.3 Other Drugs

Drugs in this category arise mainly from syntheses in clandestine laboratories or as a result of novel discoveries and ingenuous ways to use chemicals already in existence. For example, the drug addict may come to perceive nail-polish solvent, γ-butyrolactone (GBL), or 1,4-butanediol (BD) as substances which produce desirable physiological and pharmacological changes, and switch the uses which have been conventionally attributed to these chemicals by society with the newly discovered excitable physiological changes they produce. Consequently, the chemicals jump the line and cross over from their conventional commercial applications to being chemicals which must be regulated because of their abuse potential. Other sources contributing to drugs in this category include the existence of the drug, such as alcohol, as a common beverage, by general acceptance by society. The same type of subjective paradigm exempts the consumption of coffee and tea by society, from being classified as an example of drug abuse. Both coffee and tea contain the stimulant caffeine which is physically addictive.

5 USUAL ROUTES OF EXPOSURE

The usual routes of exposure to many of the drugs listed include oral, intravenous, subcutaneous, intramuscular, inhalation or intranasal application and rectal administration (Hardman *et al*., 2001). In recent times, some in the human population have sought ways to maximize the effect of drugs and deferred to nontraditional methods (Wilson *et al*., 2005) of administering drugs to themselves. For example, rectal administration of drugs is gaining popularity among some of the youth who use this method to maximize the drug's effects and to avoid detection, particularly of drugs such as alcohol which is easily detected on the breath. Cocaine, oxycontin and many other stimulants have all been snorted or used via rectal administration.

6 TYPE OF SPECIMENS AND DETECTION

Blood is the biological specimen of choice to the forensic toxicologist because the presence of a drug in blood indicates that absorption of the drug has taken place. Furthermore, good correlations exist between the blood levels of most drugs and their pharmacological and/or behavioural effects on humans (Levine, 2003; Klaassen, 2007). It provides concrete chemical evidence to the forensic toxicologist in establishing a cause-and-effect relationship between the exposure of a drug and its effect, especially in drunk-driving cases. However, its acquisition for forensic purposes is invasive and hardly desirable for workplace testing.

Urine is the preferred and predominant sample collected at the workplace for testing. In the United States, the mandatory guidelines for workplace drug testing require the use of urine as the specimen of choice (National Institute on Drug Abuse (NIDA), 1988; Mandatory Guidelines for Federal Workplace Drug Testing Programs, 2004). It provides a noninvasive method of determining the presence or absence of a drug in the body of an individual. It is generally available in adequate amounts and contains relatively high concentrations of drugs and their metabolites. It is an easier specimen to analyse using automated immunoassay screening methods in the laboratory without the complication of interfering biochemical and protein substances present in blood. In certain types of acute exposure to a drug, a hidden limitation of urine may be shown in the time lag between exposure (e.g. oral ingestion), absorption, distribution, metabolism and excretion of the drug in the urine. If the lag time is substantial, the urine test result may be negative, although the drug may be building up in concentration in the blood and exerting its effect on the subject by virtue of the circulation of the drug-laden blood to the brain. A major limitation of urine is that it is a waste product of metabolism (Helms *et al*., 2006; Price and Wilson, 1992), and chemical substances found therein must be treated as such. Analysing this biological specimen might not fully answer the specific question on whether or not the individual producing the specimen

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat165
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

was being directly influenced by the drug. However, results obtained from the analysis of a urine specimen will still clarify the forensic issues regarding exposure or use of the drug. For example, the impairing effect of certain drugs, such as alcohol, cocaine or marijuana, might wear off with the active part of the drug being undetectable in blood. Yet some of the active part of the drugs, as well as their metabolite(s), may be present in the urine long after the psychological effects wear off (Verstraete, 2004). The detection of the metabolites in the urine can be taken as evidence of exposure to the parent drug at some time in the past. In recent times, the detection of ethylglucoronide (Bergstrom *et al*., 2003; Rosano and Lin, 2008) and ethylsulfate (Helander and Beck, 2005) in the urine of parolees is gaining popularity as a means of monitoring these individuals for previous alcohol abuse even when they appear sober.

Advances in the analytical technology needed for the chemical testing of small specimen volumes containing low concentrations of drugs and their metabolites have led to the acceptance and increasing popularity of oral fluid (saliva) as a specimen for drug testing (Aps and Martens, 2005; Cone, 1993; Cone *et al*. 2007). In spite of its inherent limitations, saliva offers certain advantages over some traditional biological specimens. Collection is relatively simple, noninvasive and can occur under direct observation of the donor, thereby limiting the potential for adulteration. It can also be collected at any location and time without embarrassing the donor. Its value in alcohol testing for driving-related offences is usually controversial, primarily because of difficulties in connecting saliva alcohol levels to specific degrees of driving impairment. The same is true for drugs other than alcohol. The main challenge appears to arise from lack of harvesting a homogenous mixture of saliva because of differences in the amounts of glandular secretions from the parotid, sublingual and submaxillary glands and problems with oral contamination (Kidwell *et al*., 1998; Crouch, 2005). Additionally, another shortcoming is that certain drugs cannot be detected in saliva a short period after their use, even when the drugs might still be detectable in other biological matrices (O'Neal *et al*., 2000).

Another biological specimen that offers tremendous advantage when it comes to sample adulteration and timeline for the detection of a drug is hair (Cone, 1990; Inoue and Seta, 1992). Its collection, like urine and saliva, is noninvasive, simple and can occur at any time or location without trauma or embarrassment to the donor. Currently, it is the only method for drug testing that can provide up to a 90 day history of drug use in living individuals (Quest Diagnostics, 2007; Villain *et al*., 2004). This of course is unwelcome news to the drug user seeking to remain under the radar of a random workplace drug test programme or preparing for a job interview which may require passing a drug test.

Finally, the use of breath samples for forensic purposes has been well recognized (Garriot, 2003; Dubowski, 1994). Advances in breath testing have led to the manufacture and use of sophisticated breath-test instruments. Since the invention of the simple breathalyzer instrument in 1954, several generations of breath-testing instruments have been manufactured. Included in this group is the BAC Datamaster which is included on the list of instruments deemed satisfactory for the breath testing of alcohol (Conforming Products List of Evidential Breath Alcohol Measurement Devices, 2007). The singular use of breath as a biological sample for the determination of the bodily alcohol content in an individual is codified in legislation around the world. Consequently, its use as a probe for workplace alcohol testing was a foregone conclusion. Today, an investigation of alcohol abuse at the workplace begins, and in many cases, ends with the result of a breath test.

7 DRUGS COMMONLY ENCOUNTERED IN THE OCCUPATIONAL ENVIRONMENT

To some, a mental picture of the workplace is an environment consisting of a secured office setting, air conditioned and shining glass windows. An environment in which workers sporting a white shirt, tie, immaculately tailored suits and clutching laptops walk briskly from office space to office space and say very little as they go about their business. To others, a workplace is an outdoor environment; noisy, with loud music blaring, small talk and a lot of profanity through a haze of cigarette smoke. The choice of and affinity to drugs at these two locations will be different and the types of drugs consumed will be dictated by the prevailing culture of the environment. No single occupational environment, or one from which one derives a means of livelihood, is immune from the scourge unleashed by the indiscriminate use of drugs. From construction workers to truck drivers, pilots and physicians, educators and corporate executives, one encounters abuse of drugs either as prescription medications or in the form of illicit drugs (Wunsch *et al*., 2007; Merlo and Gold, 2008).

The drugs encountered in this environment cover a wide variety of available drugs and use is determined mainly by how much the user is willing to spend in acquiring the drug. Youthful workers might prefer marijuana, cocaine, methamphetamine and some of the newer drugs of addiction, such as prescription opiates. Older workers would use these same drugs, but may add to their cocktail, drugs commonly encountered decades ago, by virtue of their experience. Recently, drug screenings conducted in 2007 show more than a 50% decline in the percentage of positive tests for methamphetamine use at the workplace (Office of National Drug Control Policy

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat165
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(ONDCP), 2008; Quest Diagnostics, 2007). This decline may be due to several reasons, ranging from the lack of availability of the drug to the user, enforcement initiatives at the workplace, to a preference for a readily available alternative. In the United States, for example drugs such as ephedrine and pseudoephedrine, which traditionally could be obtained as an over-the-counter medication, are now difficult to obtain. With such cut in a major substrate in the synthesis of methamphetamine, the turnover rate from 'meth labs' is also reduced.

Among prescription drugs, opioids rank as one of the most abused drugs in the workplace. A major reason for this ranking is the human intolerance for pain. Increased reliance on computers at work, especially in developed nations, causes workers to be more prone to work-related musculoskeletal disorders as a result of repetitive typing or keyboard entries (Wilkens, 2003). Workers are more apt to complain about ailments such as carpal tunnel syndrome. Similarly, sedentary workers are more apt to complain about chronic back and neck pains. Some of these workers turn to opioids and other painkillers for relief. As the pain persists, so does the reliance on drugs for relief. Thus, an increase in the use of opioids due to liberal prescription has occurred, (Kuehn, 2007; Ballantyne and Mao, 2003) with the relevance and efficacy of some of these prescriptions being questionable.

8 DRUGS COMMONLY ENCOUNTERED IN SPORTS

The characteristic profile of the drug user in this group is an individual with a singular objective, to 'win-at-all-cost', and they must have something, such as a medal or a form of recognition, to show for the effort put forth. The usefulness of drugs to the athlete in this group is the real or perceived competitive advantage drugs offer the user over other participants. Adolescents and youths with eyes on playing professional sports and intent upon gaining a competitive advantage over their peers, begin to indulge in drugs in this group (National Survey on Drug Use and Health (NSDUH), 2002). Drugs encountered in this class must improve athletic performance and are therefore classified as performance-enhancing drugs (PEDs). PEDs include anabolic steroids, erythropoietin (EPO) and human growth hormones. Other drugs include amphetamine, taken for its psychic effect for alertness, increased confidence and decreased sense of fatigue. Methamphetamine is similarly taken for alertness, mood elevation, self-confidence and endurance. The appeal of amphetamine to the user is primarily to enhance performance rather than as a training drug. Nevertheless some gymnasts use the drug to suppress appetite and maintain their physical form. Marijuana use is also frequent in this arena, as is GHB, inhalants and narcotics. GHB on the other hand is abused primarily as a training drug and as an adjunct to body-building supplements (Baselt, 2004; Kleimenova *et al*., 1979). The main controlling body in human sport is the International Olympic Committee (IOC). Data generated by IOC-accredited laboratories, indicate that the most commonly abused drugs include those listed above, with steroid use leading in popularity among abusers (Mottram, 1999; Catlin *et al*., 2008).

9 DRUGS COMMONLY ENCOUNTERED IN BARS, CLUBS AND GYMS AND OTHER ENVIRONMENTS

The drugs encountered in this group are collectively termed 'club drugs'. They are generally drugs encountered at 'rave' parties. In their mode of action, these drugs cause stimulation of the senses and also have hallucinogenic effects on the user. Drugs encountered at these locations include 'Ecstasy', amphetamine, methamphetamine, methylphenidate (Ritalin), PCP, GHB, flunitrazepam (Rohypnol, 'Roofies'), ketamine ('Special K', 'Vitamin K') and LSD. The clientele in most bars, clubs and gyms is perhaps the most varied and fluid when compared with those in other environments. Typically, college students, young adults and middle-aged adults unwilling to give up the pleasures of their youth frequent these locations. It is perhaps an understatement to state that adventurous and risky behaviours can be found in most bars and clubs. For this reason, drug users who frequent bars are exposed to a large variety of stimulant drugs and drug-related health risks. Users are expecting to find newer and fast-acting drugs which will cause great stimulation, excitement and altered states, and alcohol is not a significant drug in most of these 'rave' clubs.

10 DRUGS COMMONLY ENCOUNTERED IN THE DOMESTIC ENVIRONMENT

In the domestic environment, alcohol is clearly the drug of choice. The factors leading to its choice include its relatively low cost and availability. It is easy to purchase low-quality alcoholic beverages containing high alcohol content in low-income areas, and around each corner in these areas is a liquor store or a pub. In many societies the consumption of alcohol as a beverage is not frowned upon, but rather extolled. Happiness, satisfaction and expression of joy for other forms of human achievement are celebrated with copious consumption of alcohol. Alcohol is even considered a panacea for human anguish.

Many societies freely condone its consumption and those which write laws to check its use, write what might be considered from the broad perspective of the potential adverse effects of alcohol, protracted ones. In the United States, for example, one can purchase as much alcohol as one can afford, sample the many varieties which abound, and drink as much as can be physiologically tolerated. The restriction, for those with a clean record, is that they must be at least 21 years of age and cannot operate a motor vehicle after such consumption. Therein lies the potential for addiction to this drug. The frequent, plentiful and unrestricted consumption fosters an environment that is conducive to addiction to this drug. A consequence of this type of '*ad libitum'* indulgence in the drug is a myriad of adverse effects impinging on the functionality of family structure in the domestic environment.

This factor has also been largely responsible for the choice of 'crack cocaine' as the major abused drug over cocaine hydrochloride (cocaine powder) by poor inner-city populations. By converting cocaine into 'crack cocaine', these populations were able to smoke the drug and obtain the same 'high' at a price they could afford. The development of 'crack cocaine' lowered the economic barrier for the acquisition of cocaine by low-income populations and bridged the gap that existed between pleasures which hitherto were almost exclusively limited to a relatively small group of affluent population snorting cocaine (Helms *et al*., 2006). The next most frequently abused drug in this environment, and indeed in most of the other environments, is marijuana. Under peer pressure and a need to 'fit in', youths begin to experiment with drugs, which include marijuana, for the first time. In 2007, marijuana was the most commonly used illicit drug among persons aged 12 or older with an estimated 14.4 million users. Additionally, an estimated 2.7 million persons aged 12 or older used an illicit drug for the first time (Substance Abuse and Mental Health Services Administration, (SAMHSA) Office of Applied Studies (OAS), 2008). Correspondingly, most new smokers in 2007 were under age 18. Aside from these drugs, many other drugs, such as pain relievers, psychotherapeutics, inhalants and hallucinogens will also be encountered in the domestic environment. Overall, the prevalence of the various drugs in the various environments is listed in **Table 1** below.

11 SOCIOECONOMIC POLITICAL EFFECTS

Drug abuse has an insidious effect on society that could eventually lead to human resource depletion. Drug users who expose themselves to drugs via the intravenous route place themselves at risk of acquiring diseases such HIV/AIDS and certain types of hepatitis by contact with contaminated hypodermic needles. Pregnant mothers in this group place their unborn children at risk of acquiring the AIDS virus and other diseases. Drugs such as alcohol, 'crack cocaine' and heroin cross the placental barrier and adversely impact the developing foetus *in utero*. At term, these babies have low birth weights and are susceptible to congenital malformations, such as foetal alcohol syndrome, phocomelia and microcephaly. Many are addicted to the drugs used by their mothers and go through harrowing drug withdrawals at birth. They cry easily, are irritable and difficult to comfort, and many become mentally challenged individuals in life (Eriksson *et al*., 1979; Kelly *et al*., 2000).

Drug use has also been implicated in drug-facilitated sexual assaults (date rape) (Kintz *et al*., 2003; McCauley *et al*., 2009). Victims in this drug-related crime are typically adolescent girls. The drugs that are usually encountered are GHB and its congeners, fast-acting benzodiazepines such as flunitrazepam (Rohypnol), ketamine, and alcohol. Unsuspecting victims usually begin by consuming an alcoholic beverage with perpetrators who at some point during the encounter slip the drug into the victim's drink. Under the influence of these drugs, victims have reduced inhibitions and relaxation of voluntary muscles. In their physically incapacitated states they are unable to fight off perpetrators, and succumb to the sexual assault. They have lasting anterograde amnesia of events which occur while under the influence of the drugs (Schwartz *et al*., 2000) and are unable to clearly describe events leading to the assault, making it difficult to pursue and prosecute the perpetrator.

Use of drugs of addiction and trafficking threatens national security and the safety of citizens. Traffickers are able to infiltrate the higher echelon of society and corrupt those in positions of authority. Drug barons are formed within the society and conduct their drug activities with violence and without regard to innocent lives. Many societies in the world today succumb to the vengeance of drug use and some are on the verge of anarchy when it comes to instituting sustainable drug-enforcement initiatives.

Problems in the workplace related to the use of alcohol and other drugs of abuse cost American employers billion of dollars each year. The cost arises from the undue burden placed on the workplace by drug use. Workers who abuse drugs are three and half times more likely to be involved in a workplace accident, resulting in workers' compensation and disability claims. Additionally, healthcare costs are twice as high for employees with alcohol-abuse problems than for other employees. Other factors which might drive up the cost include an increase in absenteeism, which is estimated to cost 500 million lost workdays annually, and lack of productivity (U.S. Department of Health and Human Services (U.S. DHHS), 2008). The overall cost of drug abuse to society is equally very high. According to a study in 1992, the estimated economic cost of alcohol and drug abuse was $245.7 billion. Of this amount,

Oxycodone	High	High	High	High
Propoxyphene	High	High	High	High
Hallucinogens				
LSD	Low	Low	High	High
PCP	Low	High	High	High
Ketamine	Low	Low	High	Medium
Other drugs				
GHB	Low	High	High	Low
Inhalants	Medium	Medium	High	Medium
Marijuana	High	High	High	High
Tobacco	High	High	High	High

[a]High = Drugs that occur with great frequency and positivity; Medium = Drugs that occur with medium/average positivity; Low = Drugs that occur with minimal positivity. Ratings based on data culled from Quest Diagnostics (2007), Drug Abuse Warning Network (DAWN), (2005), Substance Abuse and Mental Health Services Administration, (SAMHSA) Office of Applied Studies (OAS), (2008), Cone *et al*. (2008), Office of National Drug Control Policy (ONDCP) (2008) reports and projections from recognized effects of drugs.

$97.7 billion was due to illicit drugs and those taken for nonmedical purposes (National Institute on Drug Abuse (NIDA), 2008a). The estimated cost represented a 50% increase over the cost estimate in 1985. It is conceivable that the projected cost at the present time would be a much higher figure. A more in-depth look at the breakdown of the cost to society indicates that more than half of the estimated costs were due to drug-related crimes, and about 20% to lost productivity of victims and incarcerated perpetrators of drug-related crimes. The other combined total costs arose from property damage, drug traffic control, legal and correction services, illness and premature deaths of drug users (National Institute on Drug Abuse (NIDA), 2008b).

Theultimate price to be paid by the drug user, whether intentional or accidental, is death. When it comes to the effects of drug abuse on mortality and morbidity, no single group of people in the human population is spared. In this regard, across the entire strata of society, drug abuse causes a 'levelling effect' of misery and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

eventual demise of all those who abuse drugs. From the incarcerated to the decorated, pop stars to movie stars, the ordinary sports enthusiast to sports legends, the ultimate price for drug abuse is the same. Several well-known celebrities succumbed to the adverse effects of drug use. In general, individuals abusing drugs have a higher risk of premature or drug-related deaths when compared with contemporaries who do not use drugs. Jonsson *et al*. (2007) found that drug abuse was directly or indirectly responsible for the deaths of 47% of deceased drug addicts in Sweden in 2002–2003. In the Swedish study, the main drugs detected were ethanol and morphine, and benzodiazepines to a lesser extent. Death due to the use of other illicit drugs is well documented in the literature. Methamphetamine use has been implicated in accidental deaths in Australia (Kaye *et al*., 2008) and use of opiates has been implicated in an overwhelming number of fatalities in the USA in recent years (Hall *et al*., 2008; Paulozzi, 2007). Many other drugs have also been implicated in accidental deaths or death by suicide. Among them are stimulants, such as cocaine and amphetamines (Graham and Hanzlick, 2008; Pilgrim *et al*., 2009), inhalants (Sugie *et al*., 2004) and a variety of CNS depressant drugs, such as alcohol (Theobald *et al*., 2001).

12 MEDICOLEGAL IMPLICATIONS

In societies where law and order are seen as instruments which aid in the settlement of disputes, innocence or guilt associated with an alleged drug use may be determined in a courtroom. As applied to the adverse effects and consequences of drug abuse in these societies, several professionals are usually involved in settling the matter. It is here that the role of the forensic toxicologist becomes important. In addition to acquiring a well-grounded educational training in the field, the forensic toxicologist must have an inquisitive mind, be familiar with a wide variety of drugs, and be conversant with current knowledge regarding the 'drug culture' of the jurisdiction of interest, including the flow, distribution and patterns of use of licit and illicit drugs (Adatsi, 2005). Whatever the requirements might be, once the elements of acceptability are met, ultimately the courts will be looking to the expert to provide direct testimony relating to the specific analyses performed and interpret data that has been generated elsewhere or to provide a spectrum of testimony impinging on what, how much and when exposure to a drug may have occurred. Many judicial systems, including the American judicial system, can be a hostile arena for scientists who agree to serve as expert witnesses. For this reason, a great deal of preparation is needed prior to appearing in court (Furst, 1997; Nowicki and Bright, 2004). Of necessity is adequate knowledge of the discipline in which testimony is sought, and prior communication with the attorney requesting the services of the expert witness. Above all, the expert witness must bear in mind the following famous quote:

> *If the law has made you a witness, remain a man of science. You have no victim to avenge, no guilty or innocent person to convict or save, you must bear your testimony within the limits of science.* ~ *Dr. P.C.H. Brouardel, 19th Century French medicolegalist*

A prominent manifestation of the medicolegal aspect of drug abuse is in the area of drug-related driving offences. In many societies where the automobile is part and parcel of human activity, its operation by the citizenry is considered a privilege. Therefore, safe, proper and normal driving in these societies has a legal component and is regulated. The operation of a motor vehicle is a complex activity requiring the proper functioning of the senses of the CNS. It requires that the driver integrate several functional parameters that are integrated at the level of the CNS. It is a divided-attention task that requires the simultaneous execution of activities requiring thinking clearly, making critical decisions, and monitoring and prioritizing incoming sensory cues. It also requires paying attention to the driving scene, and reacting to perceived events quickly and appropriately. These activities are integrated at the level of the CNS. Many drugs, including alcohol, which affect the CNS or are themselves CNS depressants, impair the proper functioning of the CNS, thereby impairing the driver's ability to operate a motor vehicle in a safe manner.

Drugged driving via drugs other than alcohol is also a public concern that endangers the driver, passengers and other drivers. In 2007, an estimated 12 998 people were killed in alcohol-impaired driving crashes in the United States (National Highway Traffic Safety Administration (NHTSA), 2008). Coming in as a close second to alcohol-related fatalities is the involvement of marijuana. Overall, marijuana has been found to be a prevalent illicit drug in impaired drivers, fatally injured drivers and motor-vehicle crash victims (National Institute on Drug Abuse (NIDA), 2008a; Ramaekers *et al*., 2004; Bedard *et al*., 2007). Many other drugs, from stimulants to CNS depressants have also been implicated in poor driving (Holmgren *et al*., 2007; Jones *et al*., 2008; Logan, 1996; Logan and Couper, 2001; National Institute on Drug Abuse (NIDA), 2008b). Many prescription drugs, such as the benzodiazepines and opiates, come with warnings against the operation of machinery, including motor vehicles, until such time that the user is able to tolerate the drug and can unambiguously determine that they can safely operate a motor vehicle safely (Physicians' Desk Reference (PDR), 2008).

There is a multiplicity of punitive consequences which follow the single misstep of driving under the influence of drugs, as measured by the established rules of proper

conduct within the society of the drug user. Take the case of our hypothetical drug user who spent an evening celebrating a promotion at the job, by drinking with friends at a local beer bar somewhere in the United States of America. Reportedly, he spent most of the evening drinking evenly over a period of three hours. When the bar closed in the early hours of the next morning he got into his car and started to drive home. Quite imaginably, his driving was affected by the 12 beers he reportedly consumed while in the bar. A few drivers with whom he shared the road that night called the police to report his erratic driving. However, before the police got to him, he crashed his vehicle into another, killing its occupant. The criminal aspect of this accident earned him a 15 year sentence for 'operating under the influence of liquor, causing death', this being the applied penalty, pursuant to the statutory violation of the privilege offered him to drive under the laws of the country of his residence.

While in prison, an assessment was made of the grief, and damage and disruption of the life he caused others by virtue of the crash. Here comes the next punitive multiple in the series of consequences which follow this act of bad judgement. The financial liability phase is enormous and spreads to many areas. His own assets, the responsibility of the bar, rehabilitation back into society and the guilt that he is behind the agony and pain being suffered by others for the loss of a loved one in the accident he caused come into focus. Survivors of the deceased mounted a suit against the bar for serving a drunken individual with alcohol, even when it was clear that he may have been visibly intoxicated with alcohol. Serving him with additional alcohol enhanced his drunken state and increased the probability that he might be involved in a traffic accident if he operated a motor vehicle. In the ensuing civil litigation, the action of the bar, in furnishing more alcohol to a visibly intoxicated individual, was judged to contribute to the occurrence of the traffic accident. Subsequently, judgement was against the bar to bear some financial responsibility for the fiscal needs of the surviving next-of- kin of the deceased.

13 CONCLUSION

There is no aspect of our human existence that is not affected by the adverse effects resulting from the use of drugs of addiction in the domestic, occupational and sports environment. Drug abuse is a menace that inflicts damage to society, reduces human resources and threatens national security. It costs billions of dollars in preventive initiatives and treatment programmes. The choice of one drug over another as an addictive drug is governed by its availability, ease of procurement, and cultural and environmental factors, as well as the user's inherent susceptibility to that drug. The list of drugs in each category is by no means an exhaustive one and not intended to represent a comprehensive compilation of all drugs which could belong to that class. Instead it highlights the current knowledge about those drugs commonly encountered and those showing a high abuse pattern.

The types of drugs likely to be found or abused in any environment will be greatly influenced by the culture and complex social orientation of that society. Conceivably, the popularity of today's abused drugs will wane in the years to come. However, it is doubtful that conventional drugs of abuse will totally disappear or lose their appeal to the user. Unfortunately, some of the same drugs which were popular several decades ago will continue to remain on the user's menu and can easily revert to being drugs of choice if vigilance on their control is relaxed. In time, other drugs synthesized for legitimate use or those synthesized in clandestine laboratories will become available and some will be diverted into the wrong hands and gain popularity as drugs of abuse.

Given its long history as being an integral part of human existence, drug addiction will continue to plague society in the years to come, and efforts to identify and curb the use of 'drugs of addiction' will persist. There will always be those drugs which must be consumed to prolong life and assure survival, and those consumed for pleasure or whatever else. As familiarity with each drug becomes well established, a new paradigm will be established to classify drugs into subgroups based on their preponderance, appeal and location of use. Sadly, in this regard, it is the drug user who will perhaps always be a step ahead of the scientific community, as well as society at large, in the recognition or classification of a drug as being a new drug of addiction.

Glutathione and Glutathione-S-Transferase in Detoxification Mechanisms

Xianchun Li

CONTENTS

1 INTRODUCTION

All aerobic organisms, including bacteria, plants, insects and mammals, are subject to oxidative stress resulting from overproduction of reactive oxygen species (ROS), such as free radicals (e.g. superoxide, nitric oxide (NO) and hydroxyl radicals (OHs) and other reactive species (RS) (e.g. hydrogen peroxide, peroxynitrite and hypochlorous acid) (Łukasik and Goławska, 2007). ROS are produced endogenously as a result of aerobic metabolisms, such as oxygen-consuming respiration in the mitochondria and oxygen-producing photosynthesis in the chloroplast. The ROS produced may react with biomolecules, such as DNA, RNA, proteins and lipids, resulting in cell damage and death (Apel and Hirt, 2004; Reed, 1995). Moreover, aerobic organisms also face toxic challenges from various exogenous toxic and/or pro-oxidant xenobiotics present in their diet or environment. Xenobiotics may exert toxic effects by directly disrupting the normal functions of the organisms and/or by generating ROS upon entry to the body or oxidation (Ahmad, 1992; Kalyanaraman *et al*., 1987; Reed, 1995).

To cope with the inevitable oxidative stress from aerobic metabolisms, toxin-rich diets or the environment, aerobic organisms have evolved an integrated detoxification system capable of scavenging ROS and degrading toxic xenobiotics, as well as complex regulatory machinery capable of inducing certain components of the detoxification system when encountering a particular ROS or xenobiotic (Apel and Hirt, 2004; Li *et al*., 2007). This detoxification system heavily depends upon reduced glutathione (γ-glutamyl-cysteinyl-glycine; GSH), an endogenous antioxidant molecule, and glutathione-S-transferase (GST), an antioxidant/detoxification enzyme. GSH and GST are ubiquitous in all living organisms and often exert synergistic actions in detoxifying both ROS and xenobiotics. This chapter presents the current understanding of GSH and GST enzymes, with emphasis on their roles in detoxification, their reaction mechanisms and regulatory control.

2 GLUTATHIONE

2.1 *De Novo* Synthesis of Glutathione

GSH is a water-soluble linear tripeptide of L-glutamine, L-cysteine and glycine (**Figure 1**). It is ubiquitously distributed in the different cellular compartments, including almost 90% in the cytosol (1–10 mM),

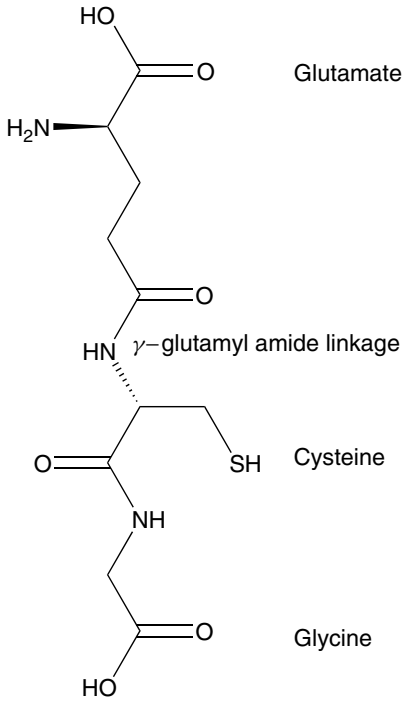

Figure 1 Structure of reduced glutathione. GSH is a linear tripeptide of L-glutamine, L-cysteine and glycine. The electron-donating sulfhydryl (-SH) group on the cysteinyl portion allows GSH to participate in two types of metabolic reactions: oxidation-reduction (redox) and conjugation reactions. The peptidic γ-linkage between the γ-carboxyl group of glutamate and the amino group of cysteine protects GSH from hydrolysis by intracellular peptidases.

approximately 10% in the mitochondria (5–10 mM) and a small percentage in the endoplasmic reticulum and the nucleus (Dalle-Donne *et al*., 2008; Lu, 2000). But all cellular GSH is synthesized within the cytoplasm in a two-step enzymatic process (**Figure 2**; Bukowska, 2004; Franco *et al*., 2007; Wu *et al*., 2004). In the first step, a peptidic γ-linkage is formed between the γ-carboxyl group of glutamate and the amino group of cysteine catalysed by γ-glutamylcysteine synthetase (GCS), also known as glutamylcysteine ligase (GCL). This peptidic γ-linkage protects GSH from hydrolysis by intracellular peptidases. In the second step, GSH synthetase (GS) catalyses the reaction between amine residue of glycine and the cysteine carboxyl from γ-glutamylcysteine dipeptide to form GSH (**Figure 2**; Bukowska, 2004; Franco *et al*., 2007; Wu *et al*., 2004). Both enzymatic steps consume one molecule of adenosine triphosphate (ATP) per catalytic cycle. As GSH levels rise, they self-limit further GSH synthesis because GSH can competitively inhibit the GCS activity. Otherwise, cysteine availability is usually the rate-limiting factor (Dickinson and Forman, 2002; Franco *et al*., 2007; Wu *et al*., 2004).

2.2 Roles of GSH in Detoxification Against Reactive Species and Toxic Xenobiotics

GSH is the most abundant intracellular nonprotein thiol (RSH) molecule. Its high electron-donating sulfhydryl (-SH) group on the cysteinyl portion combined with high intracellular concentration (millimolar levels) generate great reducing power. This characteristic allows GSH to participate in a wide variety of metabolic protection and/or detoxification processes, including oxidation-reduction (redox) reactions and nucleophilic displacement or addition-type conjugation reactions (Franco *et al*., 2007; Meister, 1995a; 1995b; Wu *et al*., 2004). When participating in redox reactions, GSH acts as an antioxidant, and scavenges a wide range of RS, including ROS and reactive nitrogen species (RNS), which are generated endogenously or from exogenous toxic and/or pro-oxidant compounds. As an antioxidant, GSH can directly react with NO to form the relatively stable S-nitrosoglutathione (GSNO) ($GSH + NO + O_2 \rightarrow GSNO + O_2^-$), which can be inactivated by its conjugation to proteins through S-nitrosylation reactions ($GSNO + \text{Protein-SH} \rightarrow \text{Protein -SNO} + GSH$). GSH can also effectively scavenge a number of ROS, including the superoxide anion ($\bullet O_2^-$), $\bullet OH^-$, singlet oxygen ($^1O_2$) and protein and DNA radicals directly, by donating electrons and becoming oxidized to the thyil radical (GS$\bullet$) (**Figure 2**; Franco *et al*., 2007). Moreover, GSH can function as an essential cofactor for GSH peroxidases (GPXs), peroxiredoxins (PXRs), phospholipid hydroperoxide GSH peroxidases (PHGPXs) and GST, to catalytically detoxify cells from hydroperoxides (e.g. H_2O_2), peroxynitrite ($OONO^-$) and lipid peroxides (LOOH) (**Figure 2**; Mates, 2000; Valko *et al*., 2007).

In these direct and indirect (enzyme-catalysing) redox reactions, RS are reduced or inactivated mainly through the generation of disulfide bonds between two GS molecules to form glutathione disulfide (GSSG) (**Figure 2**). This disulfide linkage is reversible and one GSSG molecule can be rapidly reduced to two GSH molecules by the NADPH-dependent glutathione reductase (GR) (**Figure 2**). Changes in the intracellular thiol–disulfide (GSH/GSSG) balance within the cell can be used as an indicator of the redox status of the cells. Under normal physiological conditions, the resulting GSSG can be rapidly reduced to GSH by GR (**Figure 2**), keeping GSSG at ~1% of total GSH concentration (Forman *et al*., 2002; Wu *et al*., 2004). Under severe oxidative stress, GR alone may not be able to keep the cellular GSSG level at ~1% of total GSH concentration and the increased GSSG accumulation can be actively extruded through specific transporters and degraded extracellularly (discussed below).

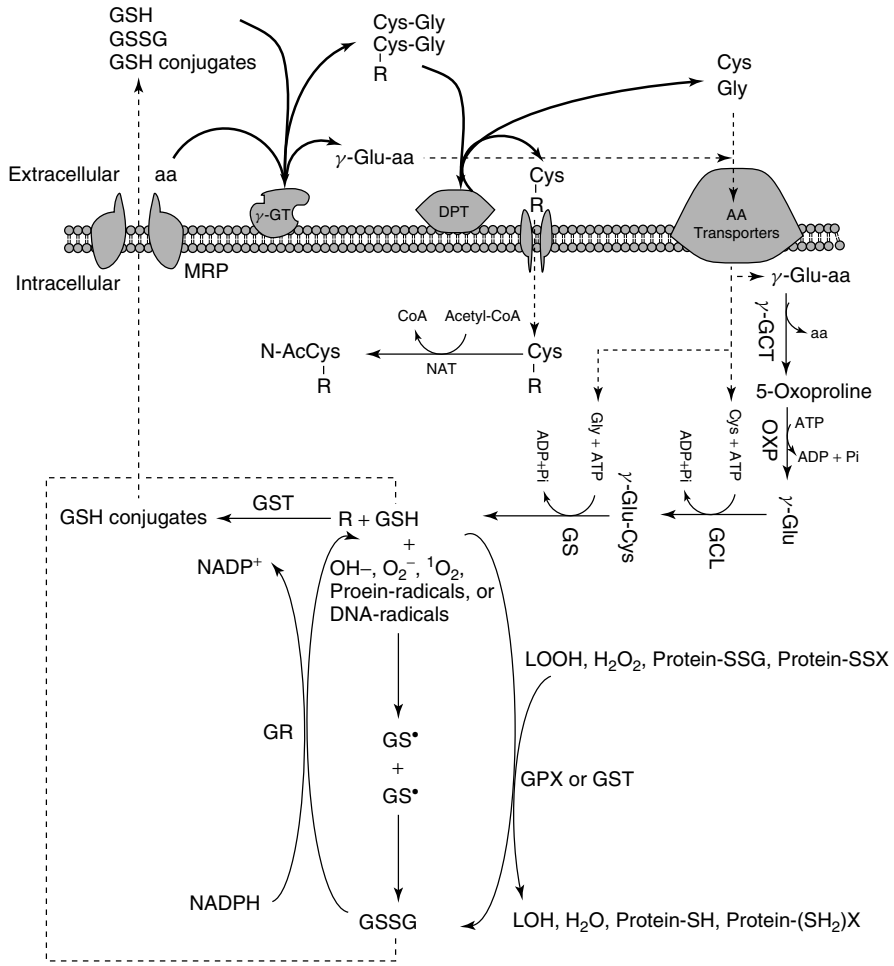

Figure 2 GSH biosynthesis, its utilization and recycling from GSSG and GSH conjugates. GSH is synthesized within the cytoplasm in a two-step enzymatic process catalysed by glutamylcysteine ligase (GCL) and GSH synthetase (GS). GSH can directly or catalytically (by GSH peroxidase (GPX) or glutathione-S-transferase (GST)) reduce various reactive species and oxidants through formation of glutathione disulfide (GSSG). GSH can also conjugate with endogenous and exogenous electrophiles (R), which is largely catalysed by GST. While GSSG can be reduced enzymatically by the NADPH-dependent glutathione reductase (GR) to regenerate GSH within the cells, GSH conjugates must be exported into the extracellular space by ATP-dependent multidrug-resistance protein (MRP) transporters to avoid deleterious effects. MRP may export some GSSG to the extracellular space as well, when the cellular GSSG concentration is too high. The extracellular GSH conjugates, GSH and GSSG are metabolized by γ-glutamyl transpeptidase (γ-GT) and dipeptidase (DPT) to γ-glutamyl-amino acid (γ-Glu-aa), cysteine (Cys), glycine (Gly) and cysteine conjugates ($\overset{\text{Cys}}{\underset{\text{R}}{|}}$, breakdown products of GSH conjugates). The first three products are transported back into the cells by specific amino-acid transporters to serve as substrates for GSH biosynthesis. The cysteine conjugates are taken up into the cells and acetylated by intracellular *N*-acetyltransferases (NAT) to mercapturic acid derivatives ($\overset{\text{N-AcCys}}{\underset{\text{R}}{|}}$) and excreted. Metabolic pathways are depicted by solid lines, whereas pathways showing transport are dashed.

When participated in nucleophilic displacement or addition-type conjugation reactions, GSH plays an essential role in the detoxification and elimination of a great variety of exogenous toxic xenobiotics (e.g. arene oxides, unsaturated carbonyls, organic halides), drugs and endogenous electrophiles (e.g. oestrogen, melanins, prostaglandins and leukotrienes). In these conjugation reactions, the sulfhydryl group of GSH acts as a nucleophile and either displaces another atom (e.g. Cl) or group (e.g. nitro) or attacks an electrophilic site in xenobiotics, endogenous compounds or their reactive metabolism intermediates, to form GSH conjugates (**Figure 2**; Blair, 2006; Franco *et al*., 2007; Meister and Anderson, 1983). GSH conjugation reactions may be spontaneous, but primarily are catalysed by GST, a family of Phase II detoxification enzymes (Meister and Anderson, 1983; Wu *et al*., 2004). To some substrates, GSH conjugation can retain activity

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat166
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of the parent compounds or even activate the parent compounds (Blair, 2006; Monks *et al*., 1990). For example, directly toxic GSH conjugates may be formed from vicinal dihaloalkanes via formation of electrophilic sulphur mustards. Precursor organic thiocyanates and nitrosoguanidines (*N*-methyl-*N*′-nitro-*N*-nitroguanidine) may release toxic agents on GSH conjugation (Monks *et al*., 1990). But, in general, GSH conjugation is considered as an important detoxification mechanism because most of the GSH conjugates produced are more water soluble and less toxic than the parent electrophiles.

2.3 Catabolism of GSSG and GSH Conjugates and Replenishment of GSH

GSH-dependent protection and detoxification of cells against various RS and toxic foreign compounds typically leads to rapid depletion of GSH and formation of GSSG and GSH conjugates (**Figure 2**). While GSSG can be reduced enzymatically by the NADPH-dependent GR to regenerate GSH within the cells, GSH conjugates must be exported into the extracellular space by ATP-dependent transporters to avoid deleterious effects. This is because γ-glutamyl transpeptidase (γ-GT), the only enzyme that can break down the γ-glutamyl amide bond in GSH, GSH conjugates and GSSG, is expressed mainly on the apical surface of cells and located on the external side of the plasma membrane (**Figure 2**). Under severe cellular oxidative stress, too much GSSG may be produced, so that some of them must be transported to the extracellular space as well, for further catabolism (Blair, 2006; Franco *et al*., 2007; Meister and Anderson, 1983). The efflux of GSH conjugates and GSSG (also GSH) across the plasma membrane largely depends on the multidrug-resistance protein (MRP, encoded by ABCC genes), a subfamily of the ATP binding cassette transporters (ABC transporters) (**Figure 2**; Hammond *et al*., 2001; Ballatori *et al*., 2005; Franco *et al*., 2007). The MRP transporters act as cotransporters of organic anions (OA^-) and GSH, GSH conjugates or GSSG. Such MRP-mediated efflux of GSH, GSH conjugates and GSSG is ATP-dependent and requires the presence of GSH (Ballatori *et al*., 2005; Cole and Deeley, 2006; Franco *et al*., 2007). In addition, GSH conjugates may also be transported to the extracellular space by the Ral-regulated effector protein (RLip76, RALBP1), a 76 kDa Ral-binding, Rho/Rac-GAP and Ral effector protein (Awasthi *et al*., 2002; 2003; Sharma *et al*., 2001; 2004). The efflux of GSH conjugates and GSSG confers drug resistance to tumour cells and can protect normal cells from toxic insults (Franco *et al*., 2007).

Two extracellular enzymes, the γ-GT and the cysteinyl glycinase, a dipeptidase (DPT), catalyse the catabolism of GSH, GSSG and GSH conjugates in the extracellular milieu (**Figure 2** and **Figure 3**; Dickinson and Forman, 2002; Franco *et al*., 2007; van Klaveren *et al*., 1997). First, the γ-GT cleaves the γ-glutamyl amide bond to cysteine and transfers the glutamyl residue from GSH, GSH conjugates or GSSG to other amino-acid acceptors (usually cystine), thus producing the common product γ-glutamyl-amino acid (γ-Glu-aa) and substrate-specific products cysteinylglycine (cys-gly, GSH), cys-gly conjugates (GSH conjugates), cys-gly and GSH (γ-Glu-$^{\text{Cys-Gly}}_{\text{Cys-Gly}}$, GSSG) or cystinylbisglycine ($^{\text{Cys-Gly}}_{\text{Cys-Gly}}$, GSSG) (**Figures 2** and **3**; Franco *et al*., 2007; Jones *et al*., 1979). The substrate-specific products are further cleaved by the extracellular DPT, to the common product glycine and the substrate-specific products cysteine (GSH), cysteine conjugates (Cys-R; GSH conjugates) or cystine ($^{\text{Cys}}_{\text{Cys}}$, as an amino-acid acceptor; GSSG). The glycine and cysteine formed are then transported back into the cells by specific amino-acid transporters to serve as substrates for *de novo* intracellular GSH biosynthesis (**Figure 2**). The γ-Glu-aa is also transported back into the cells where it is enzymatically converted to glutamate for GSH biosynthesis through the activity of the γ-glutamyl cyclotransferase (γ-GCT) and the 5-oxoprolinase (OXP) (**Figure 2**). On the other hand, the cysteine conjugate, a breakdown product of GSH conjugates, is taken up into the same cells or into other cell types, where it is acetylated by intracellular *N*-acetyltransferases (NATs) to a mercapturic acid derivative and excreted.

2.4 Homeostatic Regulation of GSH Content

GSH content is under tight homeostatic control, both intracellularly and extracellularly, to maintain a reduced cellular environment. This is achieved by a dynamic balance between GSH synthesis, the utilization of GSH for detoxification against RS, drugs and toxic xenobiotics, and its recycling from GSSG and GSH conjugates. Under normal physiological conditions whereby utilization of GSH is relatively low (only against endogenous RS and electrophiles), the GSH homeostasis system would attempt to keep the cellular GSH content and GSH/GSSG ratio under their upper limit. This is accomplished by the basal levels of the *de novo* synthesis and recycling of GSH, and GSH inhibition of the activity of the rate-limiting enzyme γ-GCL (Dickinson and Forman, 2002; Estrela *et al*., 2006; Franco *et al*., 2007; Wu *et al*., 2004). Upon oxidative stress or electrophilic stimuli, cellular GSH is rapidly used and depleted for protection of cells against these toxic insults, leading to quick and short-term falls in intracellular GSH associated with increased GSSG/GSH conjugate levels (Rahman *et al*., 2005). Accordingly, the GSH homeostasis system would quickly replenish the GSH

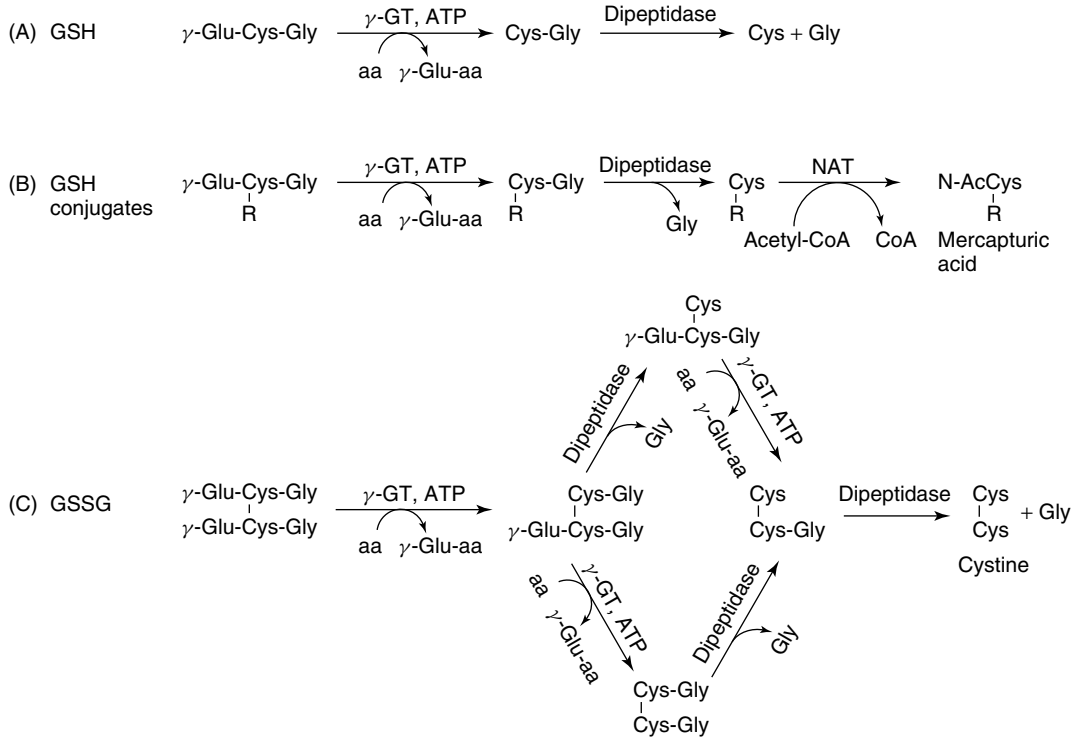

Figure 3 Catabolism reactions and products of (A) GSH, (B) GSH conjugates and (C) GSSG. Cys, cysteine; Gly, glycine; γ-Glu-aa, γ-glutamyl-amino acid; NAT, *N*-acetyltransferases; γ-GT, γ-glutamyl transpeptidase; R, electrophiles.

content and restore the GSH/GSSG ratio back to their normal levels. Depending on cell types and the oxidative and electrophilic stimuli, this can be achieved by increases in *de novo* GSH biosynthesis, GR-mediated GSSG reduction, efflux of GSSG/GSH conjugates, extracellular catabolism of GSSG and GSH conjugates (see **Figure 2**) and/or their combinations. In fact, a large number of compounds, including those forming GSH conjugates and those generating RS, have been shown to cause initial short-term falls in intracellular GSH levels, followed by increases in GSH levels, through induced transcription of the genes involved in *de novo* GSH biosynthesis (γ-GCL, GS) (Dickinson and Forman, 2002; Rahman *et al*., 2005; Shih *et al*., 2003; Trachootham *et al*., 2008; Wild *et al*., 1999; Wu *et al*., 2004; Zhu *et al*., 2008a; Zipper and Mulcahy, 2000), GSSG reduction (GR) (Harvey *et al*., 2008; Ling *et al*., 2008; Shih *et al*., 2003; Zhu *et al*., 2008a; 2008b; 2008c), efflux of GSSG/GSH conjugates (MRP) (Shih *et al*., 2003; Trachootham *et al*., 2008) and/or extracellular catabolism of GSSG and GSH conjugates (γ-GT) (Maher *et al*., 2007; Zhang *et al*., 2005; 2006a).

Recent studies from vertebrate systems indicate that it is the nuclear factor-erythroid-2-related factor 2 (Nrf2)-Kelch-like ECH-associating protein 1 (Keap1) signalling cascade that transduces oxidative and electrophilic stress signals into up-regulation of the above GSH homeostasis gene (γ-GCL, GS, GR, MRP, γ-GT) (**Figure 4**; Harvey *et al*., 2008; Ling *et al*., 2008; Maher *et al*., 2007; Rahman *et al*., 2005; Shih *et al*., 2003; Surh *et al*., 2008; Trachootham *et al*., 2008; Zhang *et al*., 2005; 2006a; Zhu *et al*., 2008b; 2008c). As a member of the NF-E2 family of the basic leucine zipper transcription factors, Nrf2 increases transcription of its target genes by heterodimerizing with small Maf proteins and then binding to a cis-acting element known as the antioxidant responsive element (ARE) or electrophile responsive element (EpRE) within the 5′-regulatory regions of these genes (Motohashi *et al*., 2004). All the GSH homeostasis genes are its target genes, because they have at least one copy of ARE in their 5′- regulatory regions (Erickson *et al*., 2002; Harvey *et al*., 2008; Ling *et al*., 2008; Maher *et al*., 2007; Moran *et al*., 2002; Rahman *et al*., 2005; Zhang *et al*., 2006a). Under normal physiological conditions, Nrf2 is captured in the cytoplasm by the actin-binding protein repressor Keap1 (**Figure 4**; Kobayashi and Yamamoto, 2005; Surh *et al*., 2008; Trachootham *et al*., 2008). Keap1 acts as a substrate adaptor of Cul3-based E3 ubiquitin ligase and targets Nrf2 for rapid degradation by the ubiquitin proteasome (Trachootham *et al*., 2008). Consequently, all GSH homeostasis genes are expressed at their basal levels due to lack of Nrf2-Maf heterodimers for binding to ARE enhancers in the 5′-regulatory regions of these genes (**Figure 4**). Upon oxidative or electrophilic stimuli, the tight Keap1–Nrf2 complex is dissociated due to oxidation or covalent modification of the critical

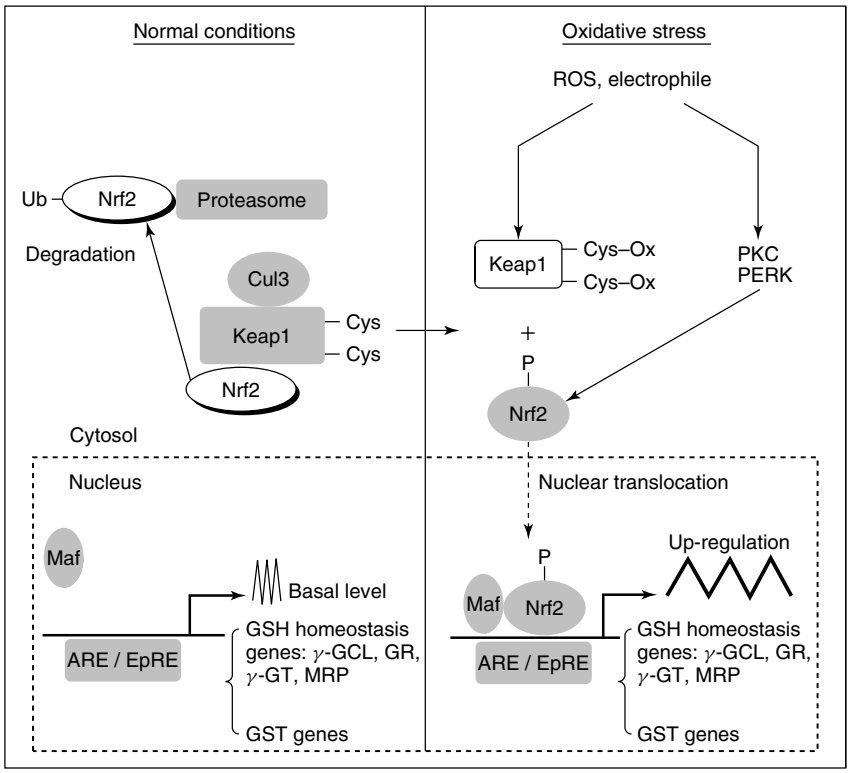

Figure 4 Redox and electrophilic regulation of GSH homeostasis and GST expression. Under normal conditions, Nrf2 is captured in the cytoplasm by the Keap1-Cul3 repressor complex for degradation by proteasome, and GSH homeostasis and GST genes are expressed at basal levels. Upon oxidative stress or electrophilic stimuli, Nrf2 is released from the Keap1-Cul3 repressor complex due to the oxidation/modification of the critical cysteine thiols of Keap1 or phosphorylation of Nrf2 by kinases such as PKC or PERK. The free Nrf2 is translocated to the nucleus, where it heterodimerizes with Maf proteins and then binds to the antioxidant responsive element (ARE) or electrophile responsive element (EpRE) in the 5′ promoter region of GSH homeostasis and GST genes. As a result, transcriptions of GSH homeostasis and GST genes are coordinately up-regulated (induced), leading to a concomitant increase in cellular GSH levels and GST enzymes. Grey, Active forms of the molecules. γ-GCL, glutamylcysteine ligase; GR, glutathione reductase; γ-GT, γ-glutamyl transpeptidase; MRP, multidrug-resistance protein transporter; GST, glutathione-S-transferase. (Modified from Trachootham *et al*., 2008.)

cysteine (Cys-151, Cys-273 and Cys-288) thiols of Keap1 by ROS and electrophiles, or phosphorylation of serine or threonine residues of Nrf2 by the upstream kinases, such as protein kinase C (PKC) and PERK (proline-rich extensin-like receptor protein kinase) (Surh *et al*., 2008; Trachootham *et al*., 2008). Either way, Nrf2 is released from the Keap1, stabilized and translocated into the nucleus, where it forms heterodimers with Maf and up-regulates transcriptions of the GSH homeostasis genes (**Figure 4**). As a result, cellular GSH content and the GSH/GSSG ratio are quickly returned to their normal levels.

3 GLUTATHIONE TRANSFERASE

3.1 Classification and Nomenclature

Glutathione transferases (EC 2.5.1.18), also known as glutathione-S-transferases, are a superfamily of multifunctional enzymes that evolved from a thioredoxin-like ancestor via multiple rounds of gene duplication and subsequent diversification (Hayes and McLellan, 1999; Ranson and Hemingway, 2005). Based on their cellular location, GSTs are grouped into three families: mitochondrial GST, microsomal GSTs, now designated membrane-associated proteins involved in eicosanoid and glutathione metabolism (MAPEG) and cytosolic GSTs. Microsomal GSTs bear no obvious resemblance to mitochondrial and cytosolic GSTs in terms of amino-acid sequence, molecular weight, or tertiary and quaternary structures (Ji *et al*., 2002; Torres-Rivera and Landa, 2008). For example, while mitochondrial and cytosolic GSTs exist as heterodimers or homodimers of subunits of 199–244 (23–27 kDa) and 226 amino acids respectively, microsomal GSTs may exist as monomers, homodimers, heterodimers, homotrimers or multimers of subunits of 14–17 kDa (137–150 amino acids) (Blanchette *et al*., 2007; Hayes *et al*., 2005; Ji *et al*., 2002; Kim *et al*., 2008; Morgenstern *et al*., 1985).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Further classification of cytosolic and mitochondrial GSTs has been an evolving process, initially based on their elution orders from various affinity columns, substrate specificities, immunological properties or isoelectric points, which resulted in different classification/nomenclature systems in different phyla (Blanchette *et al*., 2007; Öztetik, 2008; Ranson and Hemingway, 2005). These biochemical-feature-based classification/nomenclature systems were gradually abandoned, largely because of substrate overlap and failure to reflect subunit composition (Ranson and Hemingway, 2005). Subsequently, a unified classification/nomenclature system that is largely based on the amino-acid identity of each subunit and subunit composition, and to a lesser extent, structural properties (catalytic site and dimer interface), has been proposed to classify and name both mammalian (Mannervik *et al*., 1992) and nonmammalian (Chelvanayagam *et al*., 2001; Edwards *et al*., 2000) mitochondrial and cytosolic GSTs. This system classifies each subunit to a different class, designated by a Greek letter, with members in each class sharing 40% or higher amino-acid identity (Chelvanayagam *et al*., 2001; Edwards *et al*., 2000; Mannervik *et al*., 1992). By this united criteria, the mitochondrial and cytosolic GST subunits currently characterized from all organisms are grouped into ∼15 classes, designated alpha (A), beta (B), delta (D), epsilon (E), phi (F), lambda (L), kappa (K), mu (M), omega (O), pi (P), rho (R), sigma (S), theta (T), tau (U) and zeta (Z) (Blanchette *et al*., 2007; Torres-Rivera and Landa, 2008). Mitochondrial GSTs are quite distinct from cytosolic GSTs and are all grouped into the Kappa class. Among the 14 cytosolic GSTs classes, the mu, alpha, pi, theta, sigma, zeta and omega classes are ubiquitous and can occur in any organism. The remaining seven cytosolic classes are organism-specific GSTs, found only in certain kingdoms or phyla, such as lambda, phi and tau in plants; delta and epsilon in insects; rho in fishes and beta in prokaryotes (Blanchette *et al*., 2007; Torres-Rivera and Landa, 2008; Ranson and Hemingway, 2005).

Under the unified classification/nomenclature system, the name of each GST subunit (or gene) is composed of the initials of the species scientific (nonmammalian species) or common name (mammalian species), followed by the acronym GST, a capital letter for the initial of the class name and a numeral for the individual gene, which is assigned according to the order of gene discovery in each class in that relevant species (Chelvanayagam *et al*., 2001; Li *et al*., 2007; Mannervik *et al*., 1992; Ranson and Hemingway, 2005; Öztetik, 2008). When naming a GST enzyme, two numbers with a dash in between are added after the class name to indicate the subunit composition of the enzyme. Thus AgGSTD2 is the second member of the *Anopheles gambiae* Delta class of GST subunits to be identified. AgGSTD2-2 represents a homodimer enzyme of two AgGSTD2 subunits, whereas AgGSTD1-2 would be a heterodimer GST enzyme made up of a subunit of AgGSTD1 and a subunit of AgGSTD2. And hGSTA2-2 represents a homodimeric GST enzyme of two human GSTD2 subunits.

3.2 Roles of GST in Detoxification against Reactive Species and Toxic Xenobiotics

The functions of GSTs are extremely versatile; this is manifested by the types of reactions they catalyse, the diversity of their substrates, and their noncatalytic activities. As a superfamily of Phase II detoxification enzymes, GSTs function primarily as GSH transferases to catalyse the conjugation of electrophilic endobiotics and xenobiotics (or their metabolites) to GSH (see **Figure 2**; Blanchette *et al*., 2007; Hayes *et al*., 2005; Li *et al*., 2007; Ranson and Hemingway, 2005; Sharma *et al*., 2004). Some GSTs also function as selenium (Se)-independent GSH peroxidase (**Figure 2**), GSH-dependent isomerase and GSH-dependent DDT dehydrochlorinase (DDTase). In addition, GSTs also have noncatalytic activities, functioning as binding and carrier proteins i.e. ligadins of various toxic compounds, modulators of the mitogen-activated protein (MAP) kinase signalling pathway via protein−protein interactions (Blanchette *et al*., 2007; Hayes *et al*., 2005; Sharma *et al*., 2004). As discussed below, most of these activities are essential for cell survival and detoxification against oxidants, RS and toxic electrophiles.

GST plays a pivotal role in cellular protection and detoxification by functioning as GSH transferases. As described in **Figure 2**, GSH confers protection by participating in two types of metabolic reactions: redox reactions for inactivating various oxidants/RS and scavenging the free radicals, and conjugation reactions for detoxifying toxic electrophilic compounds. Both types of reactions, in most cases, require catalysis of antioxidant/detoxificative enzymes. GSTs are the only enzymes that catalyse GSH conjugation reactions with endogenous and exogenous electrophiles. And GSH conjugation is a key stage in the conversion of lipophilic compounds to water-soluble metabolites that are more readily eliminated from the body (Ranson and Hemingway, 2005). Catalysis of GSH conjugations with various electrophiles is the basic function of GSTs. Almost all GSTs can function as GSH transferases although different GSTs may differ in the substrate specificities. Endogenous harmful electrophiles detoxified by GST-mediated GSH conjugations include epoxides, leukotrienes, the arachidonic acid oxidation products oxyeicosanoids (15-deoxy-Δ12,14-prostaglandin J2), the quinone-containing metabolites (aminochrome, dopachrome, noradrenochrome and adrenochrome) from catecholamine oxidation, the lipid peroxidation products,

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

α, β-unsaturated aldehydes (2-alkenals, acrolein, crotonaldehyde, 4-hydroxy-2-alkenals, 4-hydroxy-2(E)-nonenal, 4-oxo-2(E)-nonenal), the cholesterol peroxidation products, cholesterol-5,6-oxide, epoxyeicosatrienoic acid and 9,10-epoxystearic acid, the oestradiol catechol metabolites, 2-hydroxy-oestradiol and 4-hydroxy-oestradiol and oxidized DNA bases (Hayes *et al*., 2005; Blair, 2006). The GSH conjugates formed are further metabolized and finally excreted as mercapturic acid derivatives in mammals (**Figure 2**).

A wide range of exogenous xenobiotics and/or their Phase I metabolites are detoxified by GST-mediated GSH conjugations. These include phytochemicals, therapeutic drugs, industrial intermediates, insecticides, herbicides, environmental pollutants and carcinogens (Hayes *et al*., 2005; Ranson and Hemingway, 2005; Li *et al*., 2007). Dietary phytochemicals that are metabolized by GST-mediated GSH conjugation reactions in animals include flavonoids, organothiocyanates (allyl thiocyanate, benzyl thiocyanate and 2-phenylethyl isothiocyanate) and α,β-unsaturated carbonyls (trans-2-octenal, *trans*-2-nonenal, 2, 4-hexadienal, *trans,trans*-2, 4-heptadienal, *trans,trans*-2, 4-nonadienal and *trans,trans*-2, 4-decadienal) (Li *et al*., 2007). Adriamycin, 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU), busulfan, carmustine, chlorambucil, cisplatin, crotonyloxymethyl-2-cyclohexenone (COMC-6), cyclophosphamide, ethacrynic acid, melphalan, mitozantrone and thiotepa are among the cancer chemotherapeutic drugs detoxified by GSTs (Hayes *et al*., 2005). GST-mediated GSH conjugations are implicated in the detoxification and resistance of some of the organophosphate insecticides and several herbicides including atrazine, fluorodifen, pentachloronitrobenzene (PCNB), propachlor, chlorimuron ethyl (Li *et al*., 2007; Öztetik, 2008). A large number of epoxides, such as the antibiotic fosfomycin and those formed from environmental carcinogens aflatoxin B1, 1-nitropyrene, 4-nitroquinoline, polycyclic aromatic hydrocarbons (PAHs) and styrene, by the actions of cytochrome P450 monooxygenases in the liver, lung, gastrointestinal tract and other organs, are detoxified by GSTs (Hayes *et al*., 2005). GSTs have been also documented to detoxify the ultimate carcinogenic bay- and fjord-region diol epoxides produced from chrysene, methylchrysene, benzo[c]chrysene, benzo[g]chrysene, benzo[c]phenanthrene, benzo[a]pyrene, dibenz[a,h]anthracene and dibenzo[a,l]pyrene, as well as the carcinogenic heterocyclic amines found in cooked protein-rich food (Hayes *et al*., 2005).

In addition to catalysing the conjugation of electrophilic substrates to GSH, many GST enzymes, such as the mitochondrial kappa (K) class GSTs and the cytosolic alpha (A) class GSTs also have a high Se-independent GSH peroxidase activity that allows them to catalyse some of the redox reactions that GSH participates in (Hurst *et al*., 1998; Prabhu *et al*., 2004; Sharma *et al*., 2004; Torres-Rivera and Landa, 2008; Yang *et al*., 2002a). By functioning as Se-independent GPXs, these GSTs provide protection against lipid peroxidation by terminating lipid peroxidation cascade through the reduction of fatty acid hydroperoxides (FA-OOH), and phospholipid hydroperoxides (PL-OOH) (Hayes *et al*., 2005; Sharma *et al*., 2004; Yang *et al*., 2001; 2002b; Zhao *et al*., 1999). Since these GST enzymes (e.g. hGSTA1-1 and hGSTA2-2) can use membrane PL-OOH, such as 1-palmitoyl-2-(13-hydroperoxy-*cis*-9,*trans*-11-octadecadienoyl)-L-3-phosphatidylcholine and phosphatidylcholine hydroperoxide, as substrates *in situ*, they can protect cell membranes at the site of damage (Hayes *et al*., 2005; Hurst *et al*., 1998; Prabhu *et al*., 2004; Sharma *et al*., 2004; Yang *et al*., 2001; 2002a). Furthermore, as oxidative stress and subsequent lipid peroxidation are the common secondary effects of many drugs and xenobiotics, GSTs with Se-independent peroxidases play a crucial role in protection against xenobiotics by reducing lipid hydroperoxides. For example, GSTs with GSH peroxidase activity are implicated in pyrethroid resistance in insects (Vontas *et al*., 2001; 2002) and herbicide resistance in plants (Edwards *et al*., 2000).

Some GSTs can effectively detoxify the organochlorine insecticide DDT by functioning as GSH-dependent DDTase. A number of insect GSTs have been shown to catalyse the dehydrochlorination of the DDT to the noninsecticidal metabolite DDE by using GSH as a cofactor rather than as a substrate (Chen *et al*., 2003; Li *et al*., 2007; Lumjuan *et al*., 2005; Ortelli *et al*., 2003; Ranson *et al*., 2001; Syvanen *et al*., 1996). Besides catalysing conjugation, reduction and dehydrochlorination reactions, GSTs also contribute to intracellular and circulatory transport, sequestration, and disposition of endogenous lipophilic compounds and xenobiotics by acting as binding and transport proteins of hydrophobic nonsubstrates (Hayes *et al*., 2005; Li *et al*., 2007). This nonenzymatic binding activity can reduce the amount of toxic compounds that reaches their target sites (Kostaropoulos *et al*., 2001) and speed up their elimination.

3.3 Structure and Catalytic Mechanism of Cytosolic GSTs

To understand how GSTs catalyse the conjugation reaction of GSH with various electrophiles, three-dimensional (3D) structures have been determined for nearly all cytosolic classes of GSTs (Armstrong, 1997; Öztetik, 2008; Ranson and Hemingway, 2005; Sheehan *et al*., 2001). Although different classes of GSTs share low levels of sequence identity, their overall 3D structures are very similar, with each subunit of a dimeric enzyme consisting of two distinct

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat166
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

domains (Domains I and II) that are separated by a short variable linker region of 5–10 residues (Öztetik, 2008). Domain I resides in the N-terminal one-third of the protein, consists of a β-α-β-α-β-β-α structural motif and provides the binding site for GSH (thus called the G-site) (Armstrong, 1997; Sheehan *et al*., 2001). Domain II, on the other hand, is located in the C-terminal two-thirds of the protein, consists of a variable number of α helices and contains the binding site for hydrophobic substrates (called the H site). Overall, the amino-acid sequences of GSTs are relatively conserved in the N-terminal Domain I, but are quite variable in the C-terminal Domain II (Blanchette *et al*., 2007; Torres-Rivera and Landa, 2008). This is probably because the N-terminal G site always binds and interacts with the same substrate GSH, regardless of GST classes. In contrast, the C-terminal H site often binds to, not one, but a number of different hydrophobic substrates, depending on GST classes and subunit composition. It is the H site that determines the substrate specificity of each GST enzyme.

While cytosolic GSTs are crystallized as a homodimer or heterodimer, at least some of them, if not all, exist as an equilibrium mixture of monomers and dimers in solution (Hearne and Colman, 2006; Huang *et al*., 2008; Vargo *et al*., 2004). The fact that the monomeric form of several human GST enzymes possesses at least partial activity as compared with the dimer (Hearne and Colman, 2006; Huang *et al*., 2008; Vargo *et al*., 2004) demonstrates that each subunit of a dimeric enzyme represents an independent catalytic unit. In other words, all the catalytic reactions between the common substrate GSH and various hydrophobic substrates take place at the subunit level. Nonetheless, dimerization is thought to stabilize the tertiary structure and the catalytic site of each subunit (Erhardt and Dirr, 1995; Huang *et al*., 2008) and to increase the efficiency of the enzyme (Hegazy *et al*., 2004).

The catalytic reactions that occur in each subunit include the G-site–GSH binding, the activation of GSH by the catalytic essential amino acid in the G site, the H-site–hydrophobic-compound binding, and the nucleophilic attack of the activated GS anion on the hydrophobic compound. The key step is the activation of GSH, that is, the ionization of the SH group of GSH by the catalytic essential residue in the G site (Atkins *et al*., 1993; Dirr *et al*., 1994; Liu *et al*., 1992). Depending on the GST class, the catalytic essential residue can be tyrosine (M, P, A and S classes), serine (F, U, D, E, T and Z classes) or cysteine (DHARs, L, B and O class) (Agianian *et al*., 2003; Frova, 2006; Ranson and Hemingway, 2005; Sheehan *et al*., 2001). The catalytic serine and tyrosine function as hydrogen-bond donors via their hydroxyl group to catalyse the ionization of the SH group of GSH, lowering its pK_a to a value of approximately 6–7 from its normal value of around 9.0 (Armstrong, 1997; Sheehan *et al*., 2001). This gets GSH ready for the final conjugation between GSH and the hydrophobic substrate (Torres-Rivera and Landa, 2008). In contrast, the catalytic cysteine residue forms mixed disulfides with GSH, rather than promoting the formation and stabilization of the reactive thiolate anion of GSH. Those GST enzymes bearing a catalytic cysteine residue at the G site often have great peroxidase activity, but poor GSH conjugation activity (Öztetik, 2008).

3.4 Regulation of GST Expression

GST enzymes are expressed at a basal level in normal conditions. Upon exposure to low levels of oxidative stress or a diverse range of endogenous and exogenous harmful electrophiles, expression of GST enzymes is strongly induced (**Figure 4**; Blanchette *et al*., 2007; Cheng *et al*., 2001; Dinkova-Kostova *et al*., 2001; Singhal *et al*., 1999; Surh *et al*., 2008). The electrophilic compounds that induce expression of GST genes are often the hydrophobic substrates of GST enzymes, which include lipid peroxidation products (4-hydroxynonenal (4-HNE)), chemoprotective agents (oltipraz, sulforaphane, 3H-1,2-dithiole-3-thione), phytochemicals (cruciferous sulforaphane, furanocoumarins, indoles, flavonoids, α,β-unsaturated carbonyls and glucosinolates) and various toxicants or pro-oxidants (t-butylhydroquinone, butylhydroxyanisole, thiazoles) (Fukuda *et al*., 1997; Kim and Lee, 2007; Li *et al*., 2007; Surh *et al*., 2008; Wadleigh and Yu, 1987; 1988; Zhang *et al*., 2006b; Zhu *et al*., 2008a). These inducers belong to nine distinct chemical classes, including oxidizable diphenols and quinones, Michael reaction acceptors (olefins or acetylenes conjugated to electron-withdrawing groups), isothiocyanates, hydroperoxides, trivalent arsenic derivatives, divalent heavy metal cations (Hg^{2+}, Cd^{2+}), vicinal dithiols, 1,2-dithiole-3-thiones, and carotenoids and other conjugated polyenes (Dinkova-Kostova *et al*., 2001). Nonetheless, they all can covalently modify sulfhydryl groups by alkylation, oxidation or reduction, which is responsible for the initial 'sensing' of these inducers by the actin-binding protein repressor Keap1, which contains several critical cysteines (Cys-151, Cys-273 and Cys-288) for modification (see **Figure 4** and Section 2.4 for details; Dinkova-Kostova *et al*., 2001; Hayes *et al*., 2005).

Interestingly, induction of GST genes is often paralleled with induction of GSH homeostasis genes (γ-GCL, GS, GR, MRP, γ-GT) (**Figure 4**; Li *et al*., 2005; Shih *et al*., 2003; Surh *et al*., 2008; Zhu *et al*., 2008a; 2008b; 2008c). Such a coordinated induction of GSH homeostasis genes and GST genes (also other Phase 2 detoxification genes) leads to a concomitant increase in cellular GSH levels and GST enzymes, which enables the cell to survive exposure to harmful xenobiotics and oxidative stress (Cao *et al*., 2003; Cheng *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat166
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2001; Dinkova-Kostova *et al*., 2001; Li *et al*., 2005; Singhal *et al*., 1999). Thus, it is not a surprise that GST genes, like GSH homeostasis genes, also contain ARE/EpRE (consensus sequence TGACNNNGC) in their 5′-promoter regions and are regulated by the very same Nrf2-Keap1 signalling pathway (see **Figure 4** and Section 2.4 for details; Hayes *et al*., 2005; Kim and Lee, 2007; Surh *et al*., 2008).

4 CONCLUDING REMARKS

GSH and GSTs are two primary lines of defence that protect human and other organisms from both acute and chronic toxicities of electrophiles and reactive oxygen/nitrogen species. In humans, a wide range of pathological conditions such as AIDS, ischaemia, neurodegenerative, metabolic and inherited diseases, as well as ageing, are associated with reduced/increased GSH levels or deterioration of GSH homeostasis (Estrela *et al*., 2006; Franco *et al*., 2007). Genetic polymorphisms of human GST enzymes (GSTA1, GSTM1) may be associated with increased cancer risk (Reszka *et al*., 2006). As specific GST isozymes (e.g. glutathione S-transferase P (GSTP)) are overexpressed in a wide variety of tumours resistant to drugs, GSTs have emerged as a promising therapeutic target for the development of novel cancer drugs (Burg *et al*., 2006; Tew, 2007; Townsend and Tew, 2003; Townsend *et al*., 2005; Zhao and Wang, 2006). The medical implications of GSH and GSTs are beyond the scope of this chapter and interested readers are encouraged to read the aforementioned reviews.

Much of our knowledge on the structure, catalytic properties and biological functions of GST enzymes are obtained from studies of mammalian cytosolic GSTs. Further work is required to elucidate the catalytic mechanisms and biological functions of the mitochondrial and microsomal GSTs. Historically, much work on GSH and GSTs has been focussed on the roles of GSH and GSTs in cytoprotection against oxidative stress and toxic compounds. More recently, emphasis has been placed on the contribution of GSH and GST enzymes to signalling pathways and the transcriptional regulation of GSH homeostasis genes and GST genes. Although the ARE/Nrf2-Keap1 pathway is elucidated as a key player in controlling transcription of GST and GSH homeostasis genes in mammals, it is yet unclear whether the nonmammalian counterparts are similarly regulated.

Xenobiotic-Induced Inflammation: Pathogenesis and Mediators

Peter J. M. Clements

CONTENTS

1 INTRODUCTION

Inflammation is an extremely complex and fascinating adaptive process by which fluid, electrolytes, plasma proteins and leukocytes accumulate in the extravascular spaces, in response to a variety of noxious stimuli. These inducers of inflammation include trauma, infectious agents, neoplastic cells and xenobiotics. Such stimuli act via complex pathways of intracellular signalling and intercellular mediators to orchestrate the inflammatory process. The cardinal clinical signs of inflammation, redness (rubor), heat (calor), swelling (tumor) and pain (dolor) were initially described 2000 years ago by Celcus, with loss of function (functio laesa) added by Virchow in the nineteenth century.

Inflammation can be divided into acute and chronic phases, characterized by differing morphological and biochemical patterns. It is initially a vascular phenomenon requiring blood supply to deliver leukocytes and plasma proteins from the blood to the site of injury/invasion to destroy micro-organisms, degrade particulates, dilute/flush away toxins and destroy infected, damaged or neoplastic cells, then remove the debris and prepare the site for tissue healing/regeneration.

Due to the influx of inflammatory exudates and the effects of various mediators and effector cells, a properly regulated inflammatory response is beneficial in fulfilling the functions described above. However, dysregulated or prolonged inflammation can lead to ongoing tissue destruction and attempted repair, both of which may result in functional compromise to the affected area or to the whole body, depending on the organ affected.

An understanding of inflammation at the molecular level has led to the development of many therapeutic molecules in order to combat or reduce it. However, inflammation may also be induced by xenobiotics. This can be due to physicochemical properties of the xenobiotic, for example pH or high concentrations at the site of administration, or to local activity in cells at or close to the site of administration. This gives rise to inflammation localized to the point of entry into the body, which may be the alimentary tract (e.g. oral administration), nasal cavity/respiratory tract (intranasal/inhaled delivery), vascular system (intravenous injection/infusion), skin/subcutis (subcutaneous injection), skeletal muscle (intramuscular injection) or

body cavity (peritoneal infusion/injection or intrathoracic administration due to a dosing accident). Inflammation can also be induced/enhanced by variations in experimental dosing techniques. There are risks inherent to a particular form of delivery, for example intravenous injection, or to specific vehicles (e.g. oily depot injections), in addition to direct effects of the xenobiotic being administered.

Xenobiotics may also act directly on cells/tissues, possibly via the production of toxic metabolites, causing cellular injury or death (e.g. via oxidative damage). They may also cause injury indirectly through an exaggerated pharmacology. The site(s) of induced inflammation will then depend on the pharmacodynamics, metabolism or accumulation of the particular xenobiotic (or xenobiotic metabolite) and the ability of the cells to adapt to its presence. Alternatively, xenobiotics may also cause inflammation by interacting with cells of the innate and/or adaptive immune systems, causing the release of proinflammatory cytokines or hypersensitivity reactions, or even by increasing susceptibility to infection by local commensal or pathogenic bacteria, for example in the alimentary or respiratory tract.

In tandem with a knowledge of cell biology, pharmacodynamics and toxicokinetics, examining the complex molecular mechanisms involved in inflammation can give insight into particular ways a xenobiotic may act (or be predicted to act) to induce inflammation. Mechanisms which apply to xenobiotics administered to animals on toxicology studies may or may not also be relevant in the clinical setting.

2 INFLAMMATION

A variety of exogenous and endogenous stimuli, including the effects of xenobiotics, can induce inflammation directly or indirectly. The activity of these *inducers* is recognized or *sensed* by the body, which then acts via a complex, interrelated series of inflammatory *mediators* to bring about changes in tissues and cells, which act as the *effectors* of the inflammatory process. Different patterns of inducers, mediators and effectors will influence the nature and morphologic appearance of the inflammatory response. A summary of the main processes involved in inflammation is shown in **Figure 1**.

Since the main function of inflammation in a tissue involves the delivery of fluid, soluble mediators and effector cells from the systemic circulation, it requires the vascular system for this delivery. Mediators and inflammatory cells may also be delivered to the lymph node draining the site of inflammation, via the lymphatic vessels. Initially, blood flow to the arterioles and capillaries at the site of injury is increased by the vasodilatory/modulatory actions of chemical mediators including vasoactive amines, prostaglandin D2, leukotriene B4 and nitric oxide, a process known as *active hyperaemia*. This produces an increase in hydrostatic pressure and a slowing in blood flow, or even stasis. Increases in the permeability of capillaries and postcapillary venules follow, due to changes in the intercellular junctional complexes of activated endothelial cells (ECs). This results in the selective leakage of plasma fluid and proteins such as albumin and fibrinogen into the extracellular space, a process known as *transudation*. In addition to the above mediators, this phase is influenced by bradykinin, other leukotrienes, platelet-activating factor (PAF), substance P and components of the complement cascade (C3a, C5a). Fibrinogen is an important component of the clotting cascade and polymerizes to form fibrin strands in the perivascular extracellular space. This forms a scaffold which promotes the chemotaxis and migration of inflammatory cells, confines the inciting stimulus/inflammatory response and provides an initial framework for the subsequent healing process. Once activated, ECs along with adjacent mast cells and fibroblasts alter the expression of their surface adhesion molecules (integrins, selectins) and produce cytokines/chemokines (interleukins (ILs)/chemotactic proteins), which act in concert to facilitate the recruitment of leukocytes (neutrophils, lymphocytes, monocytes/macrophages) into the perivascular extracellular space, via an ordered, multistep process called *transmigration*. Leukocytes in the slow-moving plasma of hyperaemic dilated capillaries/venules are able to marginate towards the vessel wall and roll along it, slowing to become firmly adherent, before passing between activated ECs into the perivascular *exudate*. The presence of significant amounts of protein, with or without inflammatory cells, signifies an *exudate*. If endothelial cells themselves are damaged (e.g. by toxins, trauma), the 'pores' created in the vessel walls become large enough to allow the passive extravasation of blood cells, and haemorrhage occurs (which is stemmed by the formation of a fibrin/platelet clot by the clotting cascade). As leukocytes exit the circulation and enter the surrounding tissues, they migrate along a concentration gradient of chemoattractant signals released by microbes, foreign materials, necrotic or neoplastic cells, which serves to appropriately target their activities. Neutrophils are often the predominant type of white blood cell in exudates in the early stages of inflammation. Exudates containing large numbers of viable and nonviable neutrophils are termed *purulent*, or the material itself as *pus*. If a marked neutrophilic response occurs with significant tissue destruction, then *abscess* formation may occur, which may become walled off from the body by the progressive production of fibrous tissue, if the inducing stimulus is not removed and resolution cannot therefore occur. Neutrophils contain prominent cytoplasmic granules composed

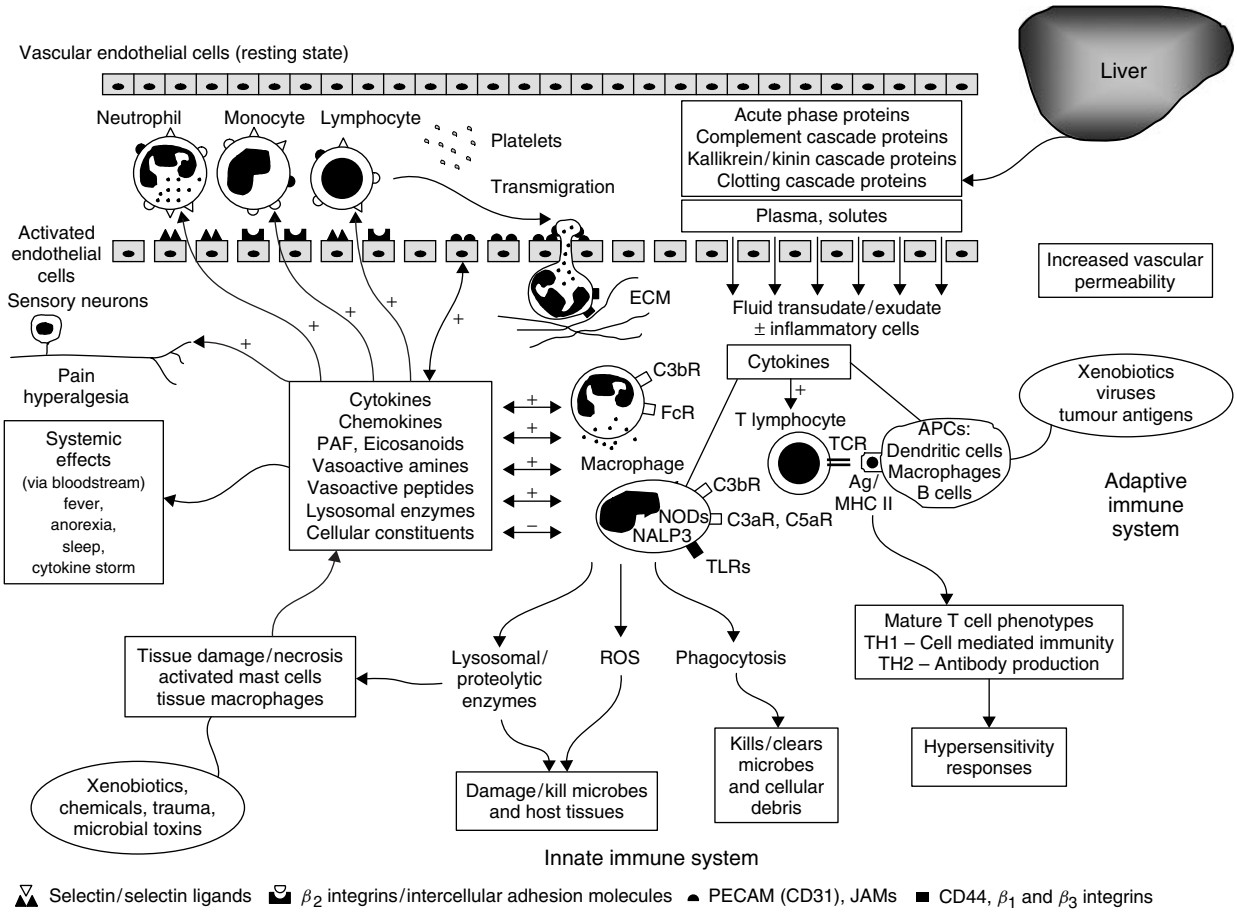

Figure 1 The major processes and classes of mediators involved in inflammation. For detailed explanation, refer to the main text. Expression of cell surface/cytoplasmic proteins as depicted is illustrative and is not as restricted to different cell types as shown. Stimulation of fibroblasts and production of new blood vessels by growth factors/angiogenic factors, to produce vascularized fibrous tissue important in both healing and chronic inflammation, are not shown. Ag—antigen; APCs—antigen presenting cells; C3aR, C3bR, C5aR—receptors for different complement components; ECM—extracellular matrix components; FcR—receptor for Fc portion of immunoglobulins (e.g. IgG); JAMs—junction-associated molecules; MHC II—major histocompatibility complex class II; NALP3—example of an inflammasome; NOD—nucleotide oligomerization domain-like proteins (cytoplasmic pattern-recognition receptors); PAF—platelet activating factor; PECAM—platelet endothelial cell adhesion molecule; ROS—reactive oxygen species; TCR—T cell receptor; TLRs—toll-like receptors.

of various enzymes (lysozyme, cathepsins, matrix metalloproteinases, myeloperoxidases), antimicrobial peptides, designed to kill microbes and degrade foreign material/damaged cells via phagocytosis or secretion of enzymes into the exudates. Monocytes/macrophages and lymphocytes also function to provide a link between the process of inflammation and the innate/adaptive immune response, to remove the inciting cause(s) of inflammation by clearing the debris formed by tissue/microbial destruction. The systemic release of cytokines such as tumour necrosis factor (TNF), IL-1, IL-6 and high-mobility group box 1 (HMGB1) protein also leads to clinical signs of fever and nausea. In order to avoid a potentially detrimental, uncontrolled inflammatory process, cytokines (transforming growth factor beta (TGFβ), IL-10, growth factors), lipoxins and intercellular signalling systems also serve to modify and dampen the inflammatory response and to initiate tissue repair. Once the stimulus has been removed, this allows the proliferation of fibroblasts (fibroplasia, fibrosis), blood vessels (angiogenesis) and epithelial tissues as required in the process of healing.

With minimal tissue damage, resolution may be possible with no permanent morphologic or functional changes. If significant tissue destruction has occurred, then healing through repair with phagocytosis and fibrosis/granulation tissue formation may occur. This will result in a fibrous tissue scar. However, if inciting stimuli/inducers are not successfully removed, for example if a microbe or foreign material persists by evading destruction (e.g. mycobacteria, fungi, parasites, asbestos fibrils, oily vehicles), if exposure to a

xenobiotic is prolonged or repeated, or if an autoimmune reaction occurs, the inflammatory process becomes chronic. This shows distinct morphological appearances and patterns of cytokine/chemokine expression whereby acute inflammation, tissue destruction and repair occur simultaneously. The adaptive immune response will also become involved. Chronic inflammation shows a predominance of lymphocytes, plasma cells and macrophages with granulomatous inflammation rich in macrophages and/or multinucleated giant cells. Associated stimulation of fibroblasts, mesenchymal and epithelial cell types represents ongoing, but incomplete tissue repair. Tissue damage/dysfunction may be exacerbated by the continued destruction of tissue by effector cells and/or the indirect effect of functional compromise due to reduced functional mass or fibrosis (e.g. myocardial fibrosis, hepatic cirrhosis).

2.1 Fluidic/Exudative Phase

Normal fluid dynamics is an active process, and the balance between the amount of water and small molecules within blood (and lymphatic) vessels is influenced by

1. hydrostatic pressure within the vessel. This is the pressure of fluid in the circulation and may be influenced by fluid volume, driven primarily by sodium ions and vascular tone.
2. the colloid osmotic pressure exerted by plasma proteins held within the vessel by capillary walls. This may be influenced by capillary wall permeability, which normally limits egress of proteins, and the concentration of plasma proteins in the circulation (of which the liver is a major source of synthesis).
3. any impedance or obstruction to onward vascular flow, which will tend to increase the pressure upstream.

At the arterial end of a capillary bed, there is normally a net outflow of fluid (water plus electrolytes and small plasma proteins) which remains neutral across the capillary bed with a net inflow via intercellular pores at the postcapillary venules and lymphatics. During the fluidic/exudative phase of inflammation, there is a net fluid outflow at all levels of an inflamed, hyperaemic vascular bed, into the perivascular interstitium. This causes heat, redness and swelling of the affected area and is designed to dilute the stimulus and deliver the appropriate plasma proteins and cells to the site in order to neutralize it. This is achieved by an increase in blood flow to the site through vasodilation of arterioles and capillaries. Activated ECs effect an increase in permeability of the capillaries and postcapillary venules. Fluid, electrolytes, plasma proteins (such as albumin, fibrinogen) and soluble inflammatory mediators pass through as transudation occurs and blood flow slows. Leukocytes then emigrate into the interstitium, which now becomes filled with exudate, acting to contain the stimulus. This is facilitated by chemical mediators, reduced blood flow and altered expression of cell adhesion molecules. The swelling caused by extravasation of fluid/plasma proteins into the extracellular space, plus the influence of algesic chemical mediators (bradykinin, prostaglandin E2) also stretches/sensitizes sensory neural receptors causing pain.

2.1.1 The Importance of Endothelial Cells

Vascular ECs are important in regulating the passage of fluid, electrolytes and cells across the blood-vessel wall. This will vary according to the site of the vascular bed. ECs are polarized, having distinct luminal and basal surfaces, and mediate transmural transport via transcellular pathways (utilizing cytoplasmic vesicles, caveolae or paracellular pathways via cell junctions). Endothelial cells can mediate an extremely rapid increase in vascular permeability in the following ways:

1. Opening of endothelial gaps via junctional complexes between adjacent ECs. This can be mediated by means of EC contraction via actin/myosin filaments, mainly in the cytoplasm of postcapillary venules, where there are high densities of receptors for vasoactive mediators including histamine, serotonin, bradykinin, angiotensin II and leukotrienes. This is the most prevalent mechanism to increase vascular permeability. In addition, reorganization of cytoskeletal microtubules/microfilaments in ECs of postcapillary venules and capillaries also opens junctional complexes, and is induced by cytokines such as IL-1 and TNF, or by hypoxia. These effects are dynamic, lasting between 15 and 30 minutes after a single stimulus.
2. Injury to ECs causing degeneration/necrosis and detachment. This could be caused directly by chemicals, burns, chemotherapeutics or microbial cytotoxins, at any level of the vascular bed (i.e. arterioles, capillaries or venules). Alternatively, ECs may be killed by the action of activated leukocytes, which occurs mostly in venules, or pulmonary capillaries. It is a late response, mediated by the release of lysosomal proteolytic enzymes and reactive oxygen species (ROS) from adherent, activated leukocytes, particularly neutrophils, as they transmigrate out of venules as part of the inflammatory process. Death of ECs, the presence of inflammatory mediators, release of tissue factor and exposure of basement membrane (BM) collagen activate platelets and the clotting and complement cascades.

3. Increased EC transcytosis. This has been associated with vascular endothelial growth factor (VEGF) and may be relevant to histamine and other chemical mediators.
4. Leakage from new blood vessels. Stimulation by angiogenic factors including VEGF results in new blood-vessel formation, which is an important process in normal tissue growth, healing and neoplasia. Immature ECs/blood vessels have a higher permeability than mature ones, which may predispose to perivascular fluid accumulation.

2.2 Cellular Phase

In this phase of acute inflammation, neutrophils, monocytes and lymphocytes are delivered from the circulation to the site of accumulated protein-rich fluid exudate in order to facilitate removal of the inducing stimuli, that is, the killing of bacteria, neoplastic/damaged cells and/or the removal of necrotic cells. This is achieved by

- release of proteolytic enzymes (including matrix metalloproteinases, elastases and cathepsins) from cytoplasmic granules or lysosomes,
- release of chemical mediators,
- generation and release of ROS, and
- phagocytosis.

2.2.1 Leukocyte Migration

Leukocyte migration (also known as extravasation) occurs primarily through capillaries and postcapillary venules, along a chemotactic gradient. It comprises an orderly series of stages which has been termed the leukocyte adhesion cascade. These stages include capture, rolling, activation by chemokines, firm adhesion and migration through the endothelium. As leukocytes migrate from the vasculature, all the different stages of this process may be observed concurrently, from marginated cells 'pavementing' (lining up adjacent to one another) at the endothelial surface, to cells passing through the vessel wall, to those which have entered the perivascular extracellular matrix. Inhibition of any of these steps reduces the number of leukocytes migrating into the perivascular extracellular matrix.

Vasodilation and increased vascular permeability result in a local slowing or even stasis of blood flow. This allows leukocytes to marginate, that is, move to the periphery of the vascular lumen, and come into close apposition with the vascular ECs. This facilitates capture and subsequent rolling of leukocytes along the EC luminal surface. Intercellular adhesion molecules (ICAMs) on the cell surface of leukocytes and luminal surface of ECs play a key role in the migration process, their expression and binding affinity being influenced by chemokines and cytokines. Binding of adhesion molecules to their respective receptors mediates not only leukocyte exit from blood vessels, but also passage into and within the extracellular matrix (ECM).

Cellular adhesion molecules can be divided into different families: the integrins, immunoglobulin superfamily (including selectins and ICAMs) and others, such as the hyaluronic acid receptor CD44 (cluster of differentiation 44). They have a variety of receptor specificities which often overlap, coordinating their interactions to achieve an initially temporary, increasingly stable association, anchoring leukocytes firstly to the ECs, then the scaffolding of the ECM.

The selectins, members of the immunoglobulin superfamily of cell-surface molecules, are important in the initial stages of leukocyte migration. They are expressed on leukocytes (L-selectin) and ECs/platelets (E-selectin/P-selectin). The other members of the immunoglobulin superfamily, the cellular adhesion molecules along with members of the integrin family, play a significant role later in the process of firm adhesion and migration through the endothelium. The capture of leukocytes is mediated by interactions between complex carbohydrate moieties covalently bound to leukocyte surface membrane glycoproteins (e.g. Sialyl Lewis X, E-selectin ligand, P-selectin glycoprotein ligand) and their cognate receptors on ECs (P-selectin and E-selectin proteins). Different selectins are also expressed on leukocytes (L-selectins), which bind to receptors on ECs such as glycoprotein cell adhesion molecule-1 (GlyCAM-1) and others. In the early phase of leukocyte capture these interactions are temporary, helping to maintain a close proximity between leukocytes and ECs. As these interactions become more numerous they result in sustained contact. Leukocytes then roll along the EC surface, propelled by the pressure of the blood flow. Inflammatory mediators also play an important role in facilitating leukocyte migration. Pro-inflammatory cytokines including TNF, IL-1 and IL-6 and the phospholipid-derived PAF are secreted by resident tissue macrophages, mast cells and ECs themselves, in response to inducers of inflammation. These mediators, along with others such as chemokines (concentrated at the EC surface and ECM, bound to proteoglycans), complement proteins C3a and C5a and platelet-derived growth factor (PDGF) enhance the ability of leukocytes such as neutrophils to bind to ECs in two ways:

- Activating leukocytes by promoting the proteolytic cleavage of L-selectin and β_2 integrins. This removes L-selectin, allowing rapid surface expression of the β_2 integrins (Mac-1(macrophage antigen-1)) and other heterodimeric combinations of CD11a, b, c with CD18) in a low-affinity state. Proteolytic cleavage of these integrins causes a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat167
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

conformational change which creates a high-affinity binding state.

- Activating ECs by up-regulating the expression of the receptor for β_2 integrins, intracellular adhesion molecule-1 (ICAM-1) and other ICAM molecules on the luminal surface of activated ECs. ECs are also stimulated by additional inflammatory mediators, including histamine, thrombin and PAF, to redistribute P-selectin from cytoplasmic granules (Weibel-Palade bodies) to their luminal cell surface. These enhanced interactions, plus the presence of chemokines on the EC surface slow the rolling of the neutrophils and facilitate a firm adhesion of leukocytes to the ECs in preparation for the final stages of transmigration.

The presence of a chemokine gradient in the inflammatory exudate is an important factor in leukocyte transmigration or diapedesis. Neutrophils and other leukocytes exit postcapillary venules by moving through interendothelial spaces at the EC intercellular junctions. Platelet endothelial cell adhesion molecule-1 (PECAM-1, CD31), which is present on EC and leukocyte surfaces, is one of a number of ICAMs which are involved in this process. PECAM-1 molecules interact in a homophilic fashion, that is, they bind to other PECAM-1 molecules expressed on adjacent cells. Junctional adhesion molecules (JAMs) are also involved in this process, as are interactions between β_2 integrins/ICAM-1 and E-selectin/leukocyte-expressed ligands. Leukocyte pseudopodia extend between ECs and contact the subjacent BM. Penetration of the endothelial BM is probably achieved by leukocyte collagenase secretion with subsequent exposure to ECM proteins (fibrin, fibronectin, vitronectin, proteoglycans, collagen). Binding to these ECM proteins is mediated partly by the hyaluronic acid receptor (CD44) expressed on lymphocytes, by β_3 integrins expressed on monocytes/macrophages and also by β_1 integrins. In this way, leukocytes (neutrophils, lymphocytes, eosinophils, monocytes and macrophages) are delivered to the site(s) of inflammation from the vasculature in the inflammatory exudates. They are now able to migrate along the chemokine gradient(s) and attempt to neutralize/remove the origin of inflammatory inducers.

2.3 Inducers of Acute Inflammation

Acute inflammation can be stimulated by both exogenous and endogenous factors. As with sensors and mediators of inflammation, there is functional redundancy. Different inducers will stimulate similar functional pathways, and some inducers may also act in a fashion similar to mediators.

2.3.1 Exogenous Inducers

These may be divided into microbial and nonmicrobial groups. Microbes include viruses, bacteria, protozoa (and also metazoan parasites), which stimulate inflammation via common pathogen-associated molecular patterns (PAMPs) and specific virulence factors. PAMPs include lipoprotein, peptidoglycan and lipoteichoic acid from Gram-positive bacteria; lipopolysaccharide (LPS) from Gram-negative bacteria and spirochaetes (e.g. *Leptospira*); single- and double-stranded RNA, unmethylated CpG (cytosine-phosphate-guanine) DNA (from bacterial DNA) and bacterial flagellin from uropathogenic bacteria. Therefore, PAMPs constitute a limited, defined set of conserved molecular patterns carried by micro-organisms of different classes for which cognate receptors (pattern-recognition receptors (PRRs) such as Toll-like receptors (TLRs), C-type lectin receptors and numerous cytosolic Nod-like receptors (NLRs)) have evolved in their hosts. PRRs detect the presence of microbes or other endogenous ligands (see later) and, when activated, lead to the release of inflammatory cytokines (TNF, IL-1) and interferon (IFN). This release occurs via intracellular pathways mediated by a variety of different kinases (including p38, the mitogen-activated protein (MAP) kinase pathway) and transcription factors (including nuclear factor NFκB). An alternative method of signalling employed by certain NLRs is to oligomerize, forming an inflammasome molecule which activates the enzyme caspase-1, also resulting in release of inflammatory cytokines. Damage to the basement membrane separating epithelial cells from mesenchymal cells allows access by pathogens, or even commensal bacteria, to tissue macrophages where they can be recognized via TLRs, leading to the release of inflammatory mediators.

In contrast to PAMPs, virulence factors are pathogen-specific and are not directly sensed, rather they trigger inflammation by their adverse effects on host cells/tissues. For example, Gram-positive exotoxins which form cell membrane pores stimulate inflammation via the resulting efflux of intracellular K^+ ions. This efflux is sensed by one of the NLRs, called the NALP3 (NACHT, leucine-rich-repeat and pyrin-domain-containing protein 3) inflammasome, which leads to pro-inflammatory cytokine release. This mechanism is discussed in more detail later.

Nonmicrobial exogenous inducers include allergens, physical agents (foreign-body material (e.g. hair shafts, plant material), suture materials, implants); mechanical stimuli, including trauma, thermal or freezing injury and electromagnetic radiation of various wavelengths; chemical agents, including acids, alkalis and toxins/poisons; and nutritive factors such as ischaemia or vitamin deficiencies. Both microbial and nonmicrobial inducers may

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat167
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

damage epithelia, for example via irritation. Expulsion and clearance of pathogens/irritants via epithelial barriers, such as the respiratory epithelium via the mucociliary escalator, or the gastric mucosal barrier, are important methods of protection, and breakdown often induces inflammation as the presence of inducers in an inappropriate tissue compartment is sensed. Xenobiotics are classified as exogenous factors although their effects may be varied, including direct chemical, foreign body or toxic effects at the site of application, or systemic absorption and toxicity in target tissues. The presence of foreign materials such as silica or asbestos stimulates accumulation of macrophages to attempt digestion. These cells may fuse to form multinucleated giant cells within granulomas in unsuccessful attempts to digest the foreign material. Resistant microbes such as mycobacteria or fungi also induce a similar macrophage response. Other particulates including diesel exhaust and carbon black are phagocytosed by macrophages which become enlarged and accumulate in the lung, associated with a chronic inflammatory reaction. Reactive metabolites of xenobiotics may be generated *de novo* by particular target cell populations, such as hepatocytes. Xenobiotic activation by Phase I metabolic enzymes may lead, for example, to oxidative cellular damage. Similarly to the effects of microbial toxins (virulence factors), this could lead to the release of products of cell injury and death, which are themselves endogenous inducers. However, the source of reactive metabolite(s) is still external. In addition, a xenobiotic (or its metabolite) may be immunogenic *per se,* or act as a hapten to stimulate an immune response which is directed at cells containing/expressing the xenobiotic at the cell surface. There is evidence to indicate that certain types of skin rashes may be caused in this way (e.g. penicillins, lamotrigine, carbamazepine).

2.3.2 Endogenous Inducers

These are derived internally, and include the factors released from injured or necrotic cells. These are less well defined than exogenous factors, although the way in which they induce inflammation appears to be related to the breakdown in compartmentalization of cells and their components/enzymes/signalling molecules. Such sequestration is normally maintained via the action of various different natural barriers such as epithelia, cell membrane, basement membrane and vascular endothelium. Cellular components such as adenosine triphosphate (ATP), K^+ ions, uric acid, HMGB1 protein and S100 Ca^{2+}-binding proteins (A8, A9, A12), heat shock proteins (HSP60 and HSP70) and endoplasmic reticulum proteins are released by membrane disruption occurring during necrotic cell death. ATP activates nociceptors, sending a neurosensory signal, and it also binds purinoceptors (e.g. $P2X_7$) on the macrophage cell surface. This causes K^+ ion efflux, one of the signals, in addition to the presence of uric acid (urate) crystals, known to activate the NALP3 inflammasome, leading to pro-inflammatory cytokine release. HMGB1 binds to the RAGE (receptor for advanced glycation end-products), which is expressed on vascular endothelia and elsewhere. This RAGE-binding cooperates with multiple TLRs to induce inflammation, a signalling mechanism which is also used by S100 proteins that operate via TLR4. Macrophages stimulated by bacterial LPS, which acts via TLR4, also release HMGB1, demonstrating multiplicity/cooperativity between inducers of the inflammatory process. There is also evidence to suggest that in addition to passive release from necrotic cells, intracellular proteins may be secreted (via a mechanism independent of the endoplasmic reticulum–Golgi pathway) by intact, but stressed cells. This mechanism appears to be regulated by inflammasomes and is mediated by activated caspase-1. Damage to vascular endothelium may significantly influence the extent of both the fluidic/exudative and cellular phases of inflammation. One contributing inducer of inflammation is the exposure of BM collagen and extracellular matrix components. This activates Hageman factor (factor XII), a sensor of vascular damage, which is a key player in the proteolytic cascades of the kallikrein–kinin, coagulation, fibrinolytic and complement systems, generating a variety of inflammatory mediators. Contact with collagen also activates platelets, which produce various inflammatory mediators, including eicosanoids such as thromboxanes, and serotonin.

Endogenous inducers important in chronic inflammation include crystals of monosodium urate and calcium pyrophosphate dehydrate (causing gout and pseudogout in humans), oxidized lipoproteins (high- and low-density) and advanced glycosylation end-products (AGEs), which can accumulate with age and under hyperglycaemic and pro-oxidative conditions. Macrophages detect and phagocytose crystals beyond a certain size, which triggers NALP3 inflammasome activation and IL-1 secretion. Breakdown products of the extracellular matrix also stimulate inflammation. Hyaluronate is a glycosaminoglycan normally present in the ECM as a high-molecular-weight polymer, which is biologically inert. Upon tissue injury, hyaluronate is broken into low-molecular-weight fragments which activate TLR4 via a pathway thought also to involve ROS. Additional ECM-derived inducers include heparan sulfate, fibronectin and fibrinogen. Endogenous inducers may also be secreted, such as surfactant protein A, present in the lung, which stimulates inflammation by binding to surfactant protein receptor 210.

Other endogenous inducers act to cause autoinflammatory responses, that is, those directed at, or which cross-react with, the body's own 'self' antigens, reactions to which are normally suppressed by the immune system. These antigens may derive from degenerate, dysplastic or neoplastic cells, or from xenobiotics, to induce hypersensitivity reactions.

2.4 Sensors and Mediators of Inflammation

Sensors of inflammation are those molecules which recognize the presence of inducers and act via intracellular signalling pathways, to stimulate the production of certain inflammatory mediators.

2.4.1 Sensors of Exogenous and Endogenous Inducers

Pattern recognition receptors are proteins which may be secreted, cell-surface, or intracellular, and have evolved to detect a conserved set of microbe-associated inducers of inflammation known as common pathogen-associated molecular patterns (PAMPs). PRRs are also engaged by specific virulence factors such as Gram-positive bacterial exotoxins, and particulates such as silica and asbestos. Importantly, endogenous inducers such as heparin sulfate, urate crystals, S100 protein and efflux of cellular K^+ ions also have cognate PRRs. PRRs are encoded as part of the germline DNA and are not subject to the somatic gene rearrangements which occur for highly variable recognition molecules in the adaptive immune system, such as T cell receptors (TCRs) and immunoglobulins.

PRRs comprise a variety of sensing molecules. Secreted PRRs include acute-phase proteins such as C-reactive protein (CRP) and serum amyloid protein (SAP), which are synthesized by the liver and present in the plasma. They bind to microbial membranes and, along with mannan-binding lectin (which binds to microbial mannose sugars), they activate complement by the Alternative/Lectin pathways. They can also label microbial membranes for recognition/killing by immune cells, a process called opsonization.

PRRs are also expressed on cell membranes, to detect extracellular inducers. TLRs are a large family of transmembrane proteins which bind a wide variety of exogenous and endogenous ligands. Macrophage mannose receptor binds mannose residues stimulating phagocytosis, whilst CD14 acts as a cofactor for TLRs in detecting LPS and peptidoglycan. PAMPs such as lipoprotein, peptidoglycan and lipoteichoic acid (from Gram-positive bacteria), LPS (from Gram-negative bacteria, *Leptospira*), single-stranded RNA (ssRNA) and double-stranded RNA (dsRNA), unmethylated CpG DNA, and bacterial flagellin from uropathogenic bacteria bind to the extracellular domains of TLRs in the plasma membrane.

Other PRRs are found in the cytoplasm, not on the cell surface. These include C-type lectin receptors, Nucleotide-binding oligomerization domain-like receptors (NLRs) and dsRNA-activated protein kinase. They bind numerous intracellular ligands, including peptidoglycans and dsRNA (characteristic of certain viruses).

When activated by ligand-binding, PRRs lead to leukocyte activation, the release of inflammatory cytokines (TNF, IL-1, IL-18, IL-33) and IFN by a variety of intracellular signalling pathways. For example, activation of TLR4 can be achieved by the binding of (i) exogenous bacterial inducers such as LPS (with the protein cofactors CD14 and MD2 (lymphocyte antigen 96)), or (ii) endogenous inducers such as hyaluronate breakdown fragments, which signal tissue damage. Ligand-binding stimulates intracellular signalling through the cytoplasmic domain of TLRs via a variety of different adapter proteins, including MyD88 (myeloid differentiation primary response gene 88), Toll/IL-1 R adapter protein (TIRAP) and TNF-receptor associated factor 6 (TRAF-6). These adapter proteins link to different kinase pathways, including the mitogen-activated protein kinase pathway (MAP kinase) and TNF-receptor associated kinase pathway (TAK), to activate transcription factors p38, c-Jun/AP-1 and NFκB in the nucleus. The transcription factors mediate pleiomorphic cellular effects, including up-regulation of inflammatory cytokine gene expression (TNF, IL-1, IL-6), defensin and antimicrobial peptide release, stimulation of leukocyte phagocytosis, and dendritic cell activation (which enhances antigen presentation and crosslinks with the adaptive immune system). IFN-β expression is up-regulated by a mechanism independent of the MyD88 adaptor, via a different kinase pathway and interferon regulatory factor-3, although there is cross-talk between these different pathways.

An alternative method of signalling is employed by certain cytoplasmic PRRs responding to cytosolic inducers. NLRs are often involved in recognition of cytosolic PAMPs. Upon ligand-binding, NLRs oligomerize, forming a multisubunit inflammasome molecule which activates the enzyme caspase-1. (This formation of a multisubunit, caspase-activating signalling protein is analogous to the oligomerization of the protein APAF-1 (apoptotic peptidase activating factor-1) to form the apoptosome, one of the processes mediating apoptosis, via a different caspase (−9), which is stimulated by loss of mitochondrial cytochrome C.) Activation of caspase-1 is known to be essential for processing, maturation and release of cytokines IL-1β, IL-18 and IL-33. There is also evidence to suggest that in addition to passive release from necrotic cells, inflammasome-activated caspase-1 mediates secretion of intracellular proteins by intact cells, via a mechanism independent of the endoplasmic reticulum–Golgi pathway. This may be an important mechanism whereby damaged cells initiate inflammation.

One particular type of NLR-inflammasome senses cellular components such as cellular K^+ ions and crystalline monosodium urate and calcium pyrophosphate dehydrate. The presence of these inducers is sensed by the NALP3 inflammasome, one of the NLRs formed by the oligomerization of the protein NALP3. Present

in macrophages, activation of this inflammasome stimulates caspase-1 activation and pro-inflammatory cytokine release (e.g. IL-1). The response to crystals, which is essentially a foreign-body reaction, is also caused by exposure of macrophages to particulate xenobiotics such as asbestos and silica: the NALP3 inflammasome is activated, stimulating cytokine release.

Oxidized lipoproteins (high- and low-density) and AGEs, can accumulate with age and under hyperglycaemic and pro-oxidative conditions. Like HMGB1, AGEs, bind RAGE, which can induce inflammation either directly by intracellular signalling from the cytoplasmic domain of RAGE itself, or via the activation of TLRs and kinase pathways as described above.

Breakdown products of the extracellular matrix can also stimulate inflammation via PRRs. Hyaluronate is a glycosaminoglycan normally present in the ECM as a high-molecular-weight polymer, which is biologically inert. Upon tissue injury, hyaluronate is broken into low-molecular-weight fragments which activate TLR4 via a pathway thought also to involve ROS.

Hageman factor and platelets are important sensors in inflammation. Vascular damage exposes BM collagen (and other extracellular matrix filaments). This activates Hageman factor (factor XII), which is a key player in the proteolytic cascades of the kallikrein–kinin, coagulation, fibrinolytic and complement systems, generating a variety of inflammatory mediators. Contact with collagen also activates platelets, which produce various inflammatory mediators, including eicosanoids such as thromboxanes, and serotonin.

Control of inflammation, which is important in preventing the pathogenic effects of dysregulated, exaggerated responses, also occurs at the level of sensing via PRRs such as the TLRs. Heparan sulfate proteoglycans are expressed ubiquitously on cell surfaces and in the ECM. They bind to and regulate a variety of inflammatory mediators (TNF, IL-2, IL-6, chemokines), but they also attenuate inflammation by binding to inducers such as LPS. They are cleaved from cell surfaces by metalloproteinases associated with ongoing inflammation, and act to bind to LPS and mediators thus modulating the inflammatory process.

2.4.2 Chemical Mediators of Inflammation

Chemical mediators are generated when the presence of inflammatory inducers is sensed. These mediators function as intra/intercellular signalling molecules. They interact in a complex and coordinated fashion to orchestrate the inflammatory response, by influencing their own levels and the functions of various effector cells/tissues. Many of these mediators have overlapping effects on the vasculature and the recruitment of leukocytes, and significant mediators are summarized in **Table 1**. They are derived

1. from the plasma, where they are usually present as inactive precursors synthesized and secreted by the liver, requiring activation to exert biological effects (e.g. clotting, kinin, complement proteins), or
2. from cells present at the site of inflammation, notably mast cells, basophils, platelets, neutrophils and macrophages. They may either be synthesized *de novo* (e.g. prostaglandins, cytokines) upon cellular activation, or preformed and released from cytoplasmic granules or vacuoles (e.g. histamine, serotonin, lysosomal enzymes).

These mediators bind receptors on target effector cells. The effect on these activated cells is often to stimulate the release of further inflammatory mediators, thus forming a potentiating functional cascade.

Mediators already circulating in the plasma generally form part of a proteolytic cascade and require cleavage for activation. Therefore, once the clotting, kinin and complement pathways are initiated, they progress very rapidly, in seconds to minutes. The release of preformed mediators also confers an extremely short response time for the acute inflammatory response: they can be active within seconds of an inducing stimulus.

Mediators which are synthesized *de novo* upon cell activation are released over a longer time-span (hours), as they occur as a result of altered gene transcription and protein expression (e.g. cytokine synthesis, up-regulation of ICAM-1 on vascular ECs) or activation of cellular enzyme pathways (lipid mediators such as prostaglandins, leukotrienes, PAF).

The speed with which the acute inflammatory reaction occurs is rapid. This reaction is also rapidly regulated due to the short half-life of the mediators and the presence/balance of both pro-inflammatory and suppressive molecules. Inherent rapid decay, enzymatic inactivation by kinases or proteases, removal by scavenging systems such as antioxidants, and competition by endogenous inhibitors (e.g. complement inhibitors) all contribute to the short functional half-life of inflammatory mediators. This is important, as acute inflammation can be a destructive process and, if allowed to progress unchecked, can result in significant tissue damage.

Mediators of inflammation, although they express a significant degree of functional overlap, may be classified into different groups on the basis of their biochemical properties.

2.4.3 Vasoactive Amines

Histamine and serotonin (5-hydroxytryptamine) are important, preformed amine molecules which are released from mast cells and platelets upon degranulation, which is an all-or-nothing response. They have complex effects upon the vasculature, depending on the site of the vascular bed, causing increased vascular permeability, vasodilation or vasoconstriction. The

Table 1 Summary of inflammatory mediators and their major effects

Mediator	Vasomodulator (dilation or constriction)	Increase vascular permeability	Leukocyte recruitment/activation/chemotaxis	Other
Plasma protein cascades				
Kinin	√	√	—	Stimulates pain, eicosanoid synthesis
Kallikrein	—	—	√	Hageman factor (XII) senses exposed collagen/extracellular matrix proteins
Clotting/fibrinolysis	—	(√)	(√)	
Complement				
C3a, C5a	—	√	√	Can induce mast cell degranulation
C3b	—	—	—	Opsonin
Acute phase proteins	—	—	—	Microbicidal, opsonins, inhibit proteases
Vasoactive amines	√	√√	(√)	
Substance P	√	√√	√	
Cytokines				
IL-1	√	√	√	Fever
TNF (α)	√	√	√	Acute phase protein synthesis
IFN (γ)	—	—	—	Macrophage activation, Th1 response
Chemokines	—	—	√	
Eicosanoids				
Prostaglandins	√	√	—	Pain, reduce inflammation (PGE_2)
Thromboxanes	√	—	—	Thrombosis
Leukotrienes				
LTB_4	√	(√)	√√	
LTC_4, D_4, E_4	√	√√	√	Stimulate T lymphocytes
Lipoxins	—	—	—	Decrease leukotriene synthesis
Resolvins	—	—	—	Antagonize leukotriene receptors
Platelet activating factor	√	√	√√	
HMGB1	—	—	—	Macrophage activation, anorexia, malaise
Defensins/collectins	—	—	—	Microbicidal, stimulate mast cell degranulation
Reactive oxygen intermediates/nitric oxide	√	√	—	Inhibit mast cell-induced inflammation, regulate chemotaxis

Relative activity shown as: (√), √ or √√. Modified from Ackerman, 2007.

induced vascular effects last for minutes to hours. Histamine effects are mediated via 7-transmembrane (7-TM) domain histamine receptors on leukocytes, ECs and smooth muscle, of which there are various subtypes (e.g. H_1, H_2, H_3). Vasodilation (active hyperaemia) is mediated via binding of H_1 and H_2 receptors on ECs, whereas increased vascular permeability, due to EC contraction (cytoskeletal reorganization) and gap junction formation, is primarily an H_1-mediated effect. Leukocyte activation is also mediated via H_1 and H_2 receptors. Histamine also mediates neural/vagal reflexes, bronchial constriction, release of prostaglandin $F_{2\alpha}$, pain/itching, tachycardia and eosinophil chemotaxis. Serotonin has similar effects to histamine and is also a neurotransmitter. Stimulators of mast cell and platelet degranulation (and hence vasoactive amine release) include contact with BM collagen; thrombin (a product of the clotting cascade, binding to protease-activated receptors (PARs)); adenosine diphosphate (ADP) (released from injured vascular ECs); complement fragments C3a, C4a, C5a; substance P and IgE. If release occurs as a result of binding of antigen to surface IgE on sensitized mast cells (as in Type I hypersensitivity reactions), the profound degree of vascular permeability induced by these amines can cause anaphylactic shock and circulatory collapse.

2.4.4 Vasoactive Peptides

This class of mediators may be preformed and released from secretory vesicles, as for the tachykinins ('fast'-kinins) substance P and neurokinins A and B, or generated from inactive plasma/extracellular fluid precursors as for bradykinin ('slow'-kinin) and fibrinopeptides A and B, fibrin degradation products.

Tachykinins are synthesized by sensory (afferent) neurones and are involved in asthma and allergic reactions. Release of substance P from neurones can be caused by stimulation of vanilloid receptors, which directly induces inflammation and pain. Tachykinins cause similar effects, including vasoconstriction, vasodilation, increased vascular permeability, leukocyte activation and chemotaxis. Substance P also acts directly on mast cells, basophils and eosinophils causing degranulation and release of vasoactive amines (histamine, serotonin).

The other vasoactive peptides, notably bradykinin, which is the major functional product of the kinin cascade, are generated by enzymatic proteolysis. Proteolysis is initiated by activated Hageman factor, kallikrein, thrombin or plasmin, which links the kinin pathways with clotting, fibrinolytic and complement cascades. Vasoactive peptides cause vasodilation and increased vascular permeability, either directly, or by stimulating mast cell degranulation and the release of vasoactive amines (histamine, serotonin). They are also proalgesic (pain-stimulating, a cardinal clinical sign of inflammation), cause smooth muscle contraction/bronchoconstriction and increased arachidonic acid metabolism (resulting in the production of various lipid mediators).

Hageman factor (also known as factor XII in the clotting cascade) is a key inflammatory mediator which coordinates the vasoactive peptide and complement responses by linking the plasma mediator systems of the kinin, fibrinolytic, clotting and complement cascades. As mentioned earlier, Hageman factor is also a sensor of vascular damage (it is activated by the presence of BM collagen and extracellular matrix components) and an inducer of inflammation by stimulating the clotting and kinin cascades.

Regulation of vasoactive peptides is achieved by further proteolysis of bradykinin by the enzyme kininase, whilst earlier in the pathway, plasma kallikrein is inactivated by another protease, serum α_2-macroglobulin, which is one member of a family of serpin proteases. The serpin proteases include α_1-antitrypsin, α_1-antichymotrypsin and antithrombin III, which regulate the clotting and complement systems. Feedback inhibition of tachykinin production is achieved by histamine binding to (inhibitory) H_3 receptors present on nerve fibres synthesizing substance P. In addition, binding of substance P to its receptor (neurokinin 1 receptor (NK1 R)) leads to a reduction in NK1 R expression on target cells (mast cells, ECs, epithelial cells, macrophages), thus decreasing their sensitivity.

2.4.5 Complement

The complement cascade is a pro-inflammatory complex of proteolytic pathways activated via several routes, which generates a variety of intermediates and products that mediate or effect key purposes in inflammation, such as microbicidal effects, chemotaxis, opsonization (labelling of cells for recognition/phagocytosis by innate and adaptive immune systems). The complement cascade can be activated by the presence of (i) antigen-antibody complexes (Classical pathway, demonstrating cross-talk between the innate and adaptive immune systems in acute inflammation), (ii) lectins bound to mannose groups on microbial surfaces (lectin pathway), or (iii) microbial surfaces or products such as lipopolysaccharides (Alternative pathway). It generates the so-called membrane attack complex (C5-9, a multisubunit effector of inflammation), which is inserted into plasma membranes (e.g. bacterial or host cells) forming a pore and causing cell lysis due to unregulated influx of water, electrolytes and small molecules. Several pathways of activation generate complement fragments C3a, C4a and C5a (known as anaphylatoxins). These promote recruitment of granulocytes (neutrophils, eosinophils, basophils), monocytes and induce mast cell degranulation, thus causing vascular effects via the release of vasoactive amines/substance P. Fragment C3b, which is deposited on the surface

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat167

of microbes/cells which activate complement, labels these cells for phagocytosis via recognition of C3b by C3b-receptor expressed on phagocytic cells (e.g. macrophages). Cross-talk between major plasma protein cascades (clotting, kinin, complement, fibrinolysis) also stimulates inflammation by the recognition of thrombin by PARs expressed on leukocytes causing cell activation.

2.4.6 Lipid Mediators

Collectively, these are the eicosanoids and PAF. They are derived from phospholipids in the inner layer of the plasma membrane. Following cell injury or activation by other inflammatory mediators, cytosolic phospholipase A_2 is activated by intracellular Ca^{2+} ions and generates arachidonic acid (eicosatetraenoic acid) and lysophosphatidic acid, which are the precursors of the eicosanoid and PAF classes of lipid. These are synthesized in ECs, leukocytes and platelets in response to physical stimuli and chemical mediators, including complement fragment C5a. Arachidonic acid can also be released extracellularly by the action of soluble phospholipase A_2 (which is inhibited by corticosteroids, accounting for a major component of the anti-inflammatory effect of these therapeutic compounds). Lipid mediators function as autocoids, that is, local hormones, mediating inflammation by acting both as intercellular and intracellular messengers that act on nearly every effector of the inflammatory response (i.e. smooth muscle cells, ECs, platelets, mast cells, eosinophils, epithelial cells, neutrophils and macrophages).

Arachidonic acid is a 20-carbon essential fatty acid. It is metabolized to generate the eicosanoids either by cyclo-oxygenases (COX1 and COX2), forming prostaglandins and thromboxanes, or by lipo-oxygenases, forming leukotrienes and lipoxins.

Cyclo-oxygenase isoenzymes are either constitutively expressed in nearly all tissues (COX1) or may be induced locally by inflammation (COX2), for example in leukocytes and ECs. These enzymes have been major therapeutic targets for anti-inflammatory drugs such as aspirin, ibuprofen, or celecoxib, which is selective for COX2. COX enzymes generate prostaglandin H_2 (PGH_2), which is further metabolized by different enzymes to generate a variety of different mediators. Prostaglandin E_2 (PGE_2) causes vasodilation and, with PGD_2 (a major product of activated mast cells), affects vascular permeability. PGE_2 is a potent hyperalgesic and inducer of fever, along with cytokines. Platelets are major producers of thromboxane A_2 (TXA_2), which is prothrombogenic, and antagonizes the antithrombogenic properties of PGI_2.

Prostaglandin receptors are expressed on a variety of effector cells including eosinophils, basophils, monocytes, dendritic cells and T lymphocytes (coupling inflammation with innate immunity). There are different receptors for different eicosanoids, which orchestrate phenotypic changes such as leukocyte migration, degranulation and release of mediators. They also constitute therapeutic targets to reduce inflammation. For example, PGD_2 receptors are divided into two types, DP1 and DP2 (also known as CRTH2). They are G-protein-coupled receptors which signal through elevation of second messengers cyclic adenosine monophosphate (cAMP) and intracellular Ca^{2+}. In contrast to DP1 (and similar to chemokine receptors—see later), DP2 also signals through inositol triphosphate (IP_3).

Leukotrienes are products of the 5-lipoxygenase (5-LOX) pathway which requires an activating cofactor (5-lipoxygenase activating protein (FLAP)) to colocalize with its substrate, arachidonic acid, forming 5-hydroperoxyeicosatetraenoic acid (5-HPETE). The enzyme activity generates a by-product hydroxyeicosatetraenoic acid (HETE) and an intermediate, leukotriene A_4 (LTA_4), which itself is a substrate for either leukotriene A_4 hydrolase, or leukotriene C_4 synthetase, generating LTB_4 (mainly in neutrophils and macrophages) or LTC_4 (mainly in eosinophils and mast cells and also macrophages). LTD_4 and LTE_4 are formed more slowly upon secretion of LTC_4. Leukotrienes are pro-inflammatory in several ways. Along with the 5-LOX by-product, 5-HETE, they are chemotactic to leukocytes. LTB_4, is most potently chemotactic to the cells responsible for its production, neutrophils and macrophages, and stimulates leukocyte ICAM expression, chemokine production and neutrophil degranulation. This serves to concentrate these cell types at the site of inflammation where they release their destructive enzymes/lysosomal contents. Leukotrienes increase vascular permeability, notably through the action of LTC_4, LTD_4 and LTE_4. These leukotrienes also cause vasoconstriction and bronchospasm and stimulate T-lymphocyte proliferation. Their receptors are also expressed on a variety of cell types including leukocytes (including lymphocytes, and also dendritic cells, again linking with innate immunity), ECs and vascular smooth muscle. Leukotriene receptors, such as the receptor for LTB_4 (called BLT1) are 7-TM domain, G-protein-coupled receptors, similar to chemokine receptors.

PAF is generated via the acetylation of lysophosphatidic acid and transfer of phosphocholine in a variety of cells including ECs, platelets, leukocytes and mast cells. It has potent biological activity and mediates vasodilation, vasoconstriction, increased vascular permeability, platelet activation/aggregation and leukocyte recruitment/adhesion/chemotaxis. PAF effects are mediated by binding a G-protein-coupled receptor expressed in target cells including ECs, leukocytes and smooth muscle. PAF stimulates release of vasoactive amines from platelet granules and via mast cell degranulation. In addition, PAF increases eicosanoid synthesis and neutrophil oxidative burst following phagocytosis.

Lipoxins are products of the 12-LOX pathway active in platelets, using as its substrate LTA_4 transferred by direct contact from leukocytes, particularly neutrophils. This generates lipoxins A_4 and B_4 (LXA_4, LXB_4). Lipoxins are generally anti-inflammatory, inhibiting neutrophil adhesion and chemotaxis and decreasing production of pro-inflammatory cytokines by a wide variety of cell types. They may also endogenously regulate the pro-inflammatory leukotrienes, since levels of lipoxins and leukotrienes show an inverse relationship. Such regulatory activity is shown by prostaglandins PGE_2 and PGI_2, which can stimulate lipid-mediator class switching in leukocytes from LTB_4 synthesis to LXA_4. Metabolism of eicosanoids derived from omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) gives rise to an additional lipid series called resolvins and protectins. These act via chemokine-like receptors and antagonize leukotriene receptors to attenuate signalling (e.g. via NFκB) and reduce the production of TNF and other pro-inflammatory signals. With the lipoxins, resolvins and protectins stimulate nonphlogistic macrophage recruitment from plasma (i.e. without the elaboration of pro-inflammatory mediators) and phagocytosis of micro-organisms/apoptotic cells, whilst increasing the exit of phagocytes via the lymphatics. This is important in the clean-up of microbes/damaged tissue in preparation for resolution/healing. They also inhibit neutrophil and eosinophil infiltration/chemotaxis, showing dual pro-resolution in addition to anti-inflammatory activity.

Regulation of lipid inflammatory mediators is also achieved through the short half-life of these lipid metabolites (either via decay or enzymatic destruction). An autoregulatory function may also exist for PAF. The target cells for PAF activity not only synthesize PAF, but can also degrade it via PAF acetyl hydrolase, thus limiting its pro-inflammatory activity.

2.4.7 Cytokines

This comprises a large group of soluble, short-acting protein mediators produced mainly by activated lymphocytes and macrophages, but also by a wide variety of cells including other leukocytes, ECs, epithelial cells and fibroblasts, which modulate the functional phenotype of target cells (effectors of inflammation). Most members of this group belong to the interleukin class of molecules and have a wide spectrum of effects on different cell types, that is, they are pleiotropic. For example, IL-12 mediates growth and differentiation of not only T lymphocytes, but also B lymphocytes and natural killer (NK) cells. Much is known about the major function of cytokines in adaptive immunity and in addition they function as inflammatory mediators, also playing key roles in innate immunity. This is another example of the functional interplay between inflammation and both arms of the immune system at the biochemical level.

Depending on the distribution of their cognate receptors, cytokines can act in one or all of three ways. Firstly in an autocrine fashion, binding to receptors expressed on the surface of the cells secreting the cytokine, as occurs for activated T cells, potentiating their own growth. Secondly, in a paracrine fashion by binding to receptors expressed on cells in the immediate vicinity, and thirdly in an endocrine fashion, by acting on targets distant from the site of production. The systemic acute-phase responses of fever, decreased appetite (anorexia), sleep and increased production of acute-phase proteins induced by IL-1, IL-6 and TNF are examples of endocrine effects important in inflammation.

Cytokines are important in mediating acute and chronic inflammation. TNF, IL-1 and IL-6 are the principal functional cytokines which promote leukocyte recruitment and inflammatory responses, but others also have key roles to play in innate and adaptive immunity against intracellular pathogens (IL-12, IFN-γ). They can activate macrophages (IFN-γ), eosinophils (IL-5), neutrophils and ECs (TNF). IFN-γ is produced mainly by activated T lymphocytes and NK cells and is an important cytokine involved in macrophage activation. TNF and IL-1 are in turn produced primarily by activated macrophages, illustrating the importance of this cell type in mediating acute inflammation. Macrophages are not the sole source of these cytokines: for example, lL-1 is secreted by activated lymphocytes and other cell types. Production can be stimulated by a variety of inducers as mentioned previously (including stimulation of TLRs and subsequent MAP kinase activation, or via inflammasome pathways). The principal functional effects of TNF and IL-1 are on ECs, leukocytes, fibroblasts and the induction of systemic acute-phase reactions. In ECs, TNF and IL-1 induce cellular activation, which involves an increase in transcription and expression of genes encoding cell adhesion molecules, cytokines, chemokines, growth factors, cytoskeletal remodelling, enzymes involved in the production of lipid mediators (eicosanoids) and nitric oxide. This increases the 'stickiness' and thrombogenicity of ECs and increases vascular permeability, facilitating leukocyte adhesion and transmigration. TNF also primes neutrophils, increasing their responsiveness to other inflammatory mediators; it enhances IL-1 and IL-6 produced by leukocytes (autocrine/paracrine effects) and stimulates fibroblasts to proliferate and remodel collagen (promoting both collagen degradation and synthesis).

Cytokines are also important mediators in the adaptive immune response. Lymphocyte activation, proliferation and maturation to different functional phenotypes is mediated largely by interleukins (IL-2, 4, 5, 7, 9, 10, 12–29). IL-2 is a key growth factor for T cells; differentiation of T cells to Th1 (T helper 1) or Th2 phenotypes is mediated by IL-12 and IL-4, respectively; IL-15 stimulates NK cell growth and activity. Interleukins (IL-4, IL-10) are also important in modulating interactions of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat167
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

T cells with dendritic cells (antigen-presenting cells) which are important in antigen recognition at epithelial surfaces. Other cytokines (erythropoietin, various colony-stimulating factors, IL-3) function as stimulators of haematopoiesis.

Activation of NK cells, which are important effector lymphocytes involved in antibody-dependent killing of target cells, is also mediated by cytokines. NK cells can be stimulated by the haematopoietic cytokine Flt3 (fms-like tyrosine kinase-3) and also IL-4, IL-12, IL-15 and IL-21, which induce cell differentiation, expression of the IgG receptor required for target recognition (CD16) and IFN-γ release (which activates macrophages). IL-21 also controls the extent of this activation by initiating a delayed programmed cell death in the activated NK cells.

Cytokines form two main biochemical structural classes (I and II) and bind to their cognate receptors, which have similarly evolved into two classes and are expressed on the target cell surface. Many of the Class I cytokines (including IL-2 to 7, IFN and erythropoietin) bind their cognate receptors and signal through a pathway involving janus kinases (JAKs) and signalling molecules (STAT, signal transducer and activator of transcription). The activated STATs dimerize, translocate to the nucleus and stimulate pro-inflammatory gene transcription, mediating cell activation, proliferation and cytokine production. Consider the T lymphocyte as a target cell, for example: stimulation via IL-2, leading to proliferation and differentiation is a key event in switching on the adaptive immune response and is blocked when the IL-2 receptor is inhibited (e.g. by a monoclonal antibody (mAb)). Different isoforms of JAKs and STATs convey subtly different signals and result in different phenotypes: for example, JAK1 is important in lymphocyte development and STAT6 mediates Th2 responses. Signalling via the JAK/STAT pathway can also be inhibited intracellularly by various mechanisms: at the level of the cytokine receptor, by proteins called suppressors of cytokine signalling (SOCS); at the level of kinase-mediated STAT activation by phosphatases which cleave the activating phosphate groups; and at the level of gene transcription by an inhibitory protein, PIAS (protein inhibitor of activated STAT), which binds to activated STATs in the nucleus.

TNF-receptors, in contrast, are homotrimers which act via a different pathway. Similar to TLRs, TNF-receptor binding increases nuclear levels of the transcription factor NFκB, but it acts through a different pathway, via phosphorylation of IκB (inhibitory protein κB). IκB normally inhibits NFκB activity by binding to it and trapping it in the cytosol. Phosphorylation of IκB releases it from binding, allowing NFκB translocation to the nucleus, where it can function as a transcription factor. In activated cells, transcription is increased for a wide variety of inflammatory genes, including pro-inflammatory cytokines like IL-1, as well as genes mediating cell adhesion, proliferation and apoptosis.

HMGB1 functions in a cytokine-like manner. This nuclear protein is one of a range of factors released from necrotic cells. It binds to RAGE, which is expressed on vascular endothelia and macrophages. The RAGE-HMGB-1 conjugate cooperates with multiple TLRs to stimulate the production of other cytokines. HMBG1 is also secreted by activated macrophages and is an important mediator of elements of the acute-phase response such as fever, anorexia and malaise.

2.4.8 Chemokines

Chemokines are often considered as a subgroup of cytokines which function primarily as chemotaxins, promoting lymphocyte, neutrophil and macrophage migration. Chemokines are produced from almost all cell types and fall into structurally distinct subfamilies, most of which are represented by the CC and CXC families, depending on the position of cysteine residues. Activated macrophages, and tissue cells, are major sources of CXC chemokines, whilst CC chemokines are produced largely by T lymphocytes. Other important chemokines include the C-chemokine (lymphotoxin) and the CX3C chemokine, fractalkine. Cytokines functioning as chemotaxins in inflammation are often termed 'chemotactic protein' or 'inflammatory protein', with the cell target or source specified in the name (e.g. granulocyte chemotactic protein-2, macrophage inflammatory protein-1). Another chemokine, CXCL12 has been implicated in recruitment of macrophages to hypoxic tissues. Other 'homing' chemokines are also responsible for mediating lymphocyte partitioning to specific areas of lymphoid tissue, conferring the characteristic anatomical structure of lymph nodes, or splenic white pulp. These are usually expressed constitutively in lymphoid tissues. The main functional difference between these chemokines is in the population of cells attracted by their presence, which is largely determined by receptor distribution. Receptor distribution is itself a function of the cell type and differentiation state, which are relevant to partitioning of different lymphocyte types and mature vs. immature cells in lymphoid tissue. Activation state of the target cell (e.g. in inflammation) also influences the level of receptor expression and will determine how sensitive a cell is to chemotactic signals. Chemokine receptors are 7-TM domain proteins (the same class of receptor as the vasoactive amines histamine, dopamine and serotonin), which are specific to different chemokine families but will often bind several different chemokines within each family. For example, the CCR1 receptor binds CCL chemokines 3, 7, 9, 15, 16 and 23. Such receptor promiscuity is another example of functional overlap for inflammatory mediators. Receptor–ligand binding signals through a receptor-coupled G protein, which in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat167
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

turn activates phosphodiesterases (PDEs), generating second messengers such as cAMP and IP_3. These second messengers mediate intracellular calcium levels via protein phosphorylation and can also mediate gene expression by activating transcription factors. Regulation of signalling is achieved by the internalization and degradation of receptor–ligand complexes.

2.4.9 Acute-Phase Proteins

These are plasma proteins which are mostly synthesized by the liver. Concentrations of these proteins may increase dramatically as part of the inflammatory response. These proteins function as part of the innate immune system. Some have microbicidal and opsonizing properties which act to remove inflammatory inducers such as microbes and cell debris. They also function as mediators of inflammation, and some can be measured in blood as circulating, clinical pathologic indicators of inflammation. Acute-phase proteins include CRP, fibrinogen, haptoglobin, α_1-acid glycoprotein, α_1-antitrypsin, complement proteins (C3 and C4) and serum amyloid A protein (SAA). Their production is stimulated by pro-inflammatory cytokines: CRP and fibrinogen are increased by IL-6, whilst IL-1 and TNF increase levels of SAA. Since the principal source of these proteins is the liver, it is important to note that increases in acute-phase proteins are caused by sufficiently high levels of these cytokines in the systemic circulation, not as a local effect. Complement proteins are involved in inflammation by the generation of factors C3a and C4a, which mediate recruitment of granulocytes (neutrophils, eosinophils, basophils) and monocytes, and induce mast cell degranulation. In contrast, protease inhibitors such as α_1-antitrypsin act to limit inflammation by inhibiting the activity of proteolytic enzymes released primarily by neutrophils, thereby reducing the extent of tissue damage caused by these enzymes.

2.4.9.1 Defensins and Collectins

Defensins are cationic proteins with antimicrobial properties, which also function as inflammatory mediators. Alpha and beta defensins, along with anionic peptides including histatins and dermacidins, are produced by epithelial cells and neutrophils. They are active against microbes such as bacteria, fungi and some enveloped viruses, probably by forming membrane pores. Defensins also stimulate mast cell degranulation, function as chemotaxins, stimulate cell activation (including T lymphocytes, macrophages and dendritic cells), cell proliferation, cytokine synthesis/release (e.g. IL-8) and wound repair.

Collectins are fibrillar proteins with a lectin-binding domain which can bind and aggregate bacteria/viruses but which can also mediate inflammatory responses. Collectins, like surfactant proteins A and D, found in lung surfactant, can stimulate macrophages and regulate production of TNF and ROS.

2.4.9.2 Reactive Oxygen Intermediates and Nitric Oxide

The production of various free radicals is a significant effector of inflammation in activated neutrophils and macrophages, related to the killing of microbes or infected/neoplastic cells. Reactive oxygen intermediates may also be generated by the metabolism of xenobiotics. These highly reactive molecules, which include superoxide anion, hydroxyl radicals and reactive nitric oxide intermediates, notably peroxynitrite, will react biochemically with a variety of different cellular molecules (proteins, lipids, nucleic acids), generating various cell molecule intermediates which are themselves highly reactive, and propagate further damaging reactions. Cell membrane phospholipids will be attacked, forming lipid peroxides; DNA adducts and strand breaks may be formed; protein crosslinking and oxidation of signalling molecules may occur. These changes compromise membrane and nucleic acid integrity, gene regulation/cell cycle, protein structure/function and intracellular signalling, possibly resulting in the release of additional inflammatory mediators/cell necrosis. If affected cells are ECs, then vascular permeability may be increased. Intracellular antioxidant systems exist to combat the generation of ROS. These include enzymes such as catalase, superoxide dismutase, glutathione peroxidase, proteins such as transferrin and melatonin, and essential dietary factors such as vitamins A, C, E, lycopenes and flavonoids. These defend against ROS by reducing the free radicals, but may be depleted by excessive/prolonged generation of ROS, as may occur with certain xenobiotics, and significant cell damage ensues. The presence of superoxide intermediates may be indicated by measurement of reduced glutathione levels, or by immunohistochemistry to detect the presence of inducible nitric oxide synthase (iNOS), glutathione *S*-transferase Pi, or 8-hydroxydeoxyguanosine (8-OHdG).

Nitric oxide itself is a powerful, though short-lived inflammatory mediator, which is produced by the enzyme nitric oxide synthase (NOS). There are different forms of NOS: neural, inducible and endothelial. The action of endothelial NOS in generating NO derivatives causes vascular smooth muscle relaxation. NO also exhibits anti-inflammatory activity by inhibiting mast cell-induced inflammation, platelet aggregation/adhesion, by oxidizing lipids and by regulating leukocyte chemotaxis.

2.4.9.3 The Acute-Phase Response and Cytokine Release Syndrome

The acute-phase response is an important systemic manifestation of malaise associated with inflammation, and is due to the (endocrine) activity of IL-1, TNF and IL-6, acting mainly on sensory nerve fibres, ECs

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(particularly in the brain) and macrophages/microglia (influencing prostaglandin levels, notably PGE_2). This response influences the hypothalamus/various brainstem nuclei, inducing fever, decreased appetite and increased sleep/unconsciousness. Neutrophilia (release of neutrophils into the circulation) and stimulation of the corticosteroid endocrine axis are also part of the acute-phase response. Haemodynamic shock, an effect associated particularly with TNF, is circulatory hypotension (reduced blood pressure) as a result of systemic effects on vascular resistance (also increased vascular permeability), and is associated with increased heart rate and acidosis (decreased blood pH). TNF also promotes mobilization of lipids and proteins (catabolism); along with suppressed appetite this can lead to sustained weight loss and anorexia (cachexia). Other mediators, such as HMGB1 proteins, feature in the acute-phase response.

The signs/symptoms typical of the acute-phase response, mediated largely by cytokines, are also known as a 'cytokine storm'. At the molecular level, this is characterized by an excessive release of pro-inflammatory cytokines. Historically, it has been described in graft-versus-host disease, as part of the pathogenesis of pancreatitis in man, following significant tissue trauma and associated with certain viral pathogens and particularly with sepsis. Depending on the particular inducer(s) and pattern of cytokines expressed, clinical manifestations can vary, but the broad pathogenesis is one of massive cytokine release leading to widespread inflammatory effects such increased vascular permeability and hypovolaemic shock. Certain Gram-positive bacterial toxins with very high biological potency have been termed superantigens. Such superantigens are able to activate T lymphocytes by binding cell surface major histocompatibility complex (MHC) class II/TCR molecules, but in a way that is not restricted to antigen-specificity. Thus, large numbers of immune-competent cells can be activated in an antigen-independent fashion, leading to systemic release of pro-inflammatory cytokines including IL-1, TNF and IFN. Septicaemia and endotoxic shock are not dissimilar in their pathogenesis. Specific bacterial-toxin cytotoxic effects and/or the specific LPS-mediated activation of TLRs represent differences in the specific pathogeneses, but the end-result is a similar systemic inflammatory reaction, with significant release of cytokines and other inflammatory mediators including eicosanoids, PAF and kinins. The various effects of these mediators, discussed earlier, lead to vasodilation/vasoconstriction, leakage of plasma proteins into the extracellular space, activation of the complement, kinin and clotting cascades and sequestration of activated leukocytes and platelets. Activation of the plasma protein cascades may lead to disseminated intravascular coagulation and depletion of factors which may then predispose to haemorrhage. Hypoperfusion may result in local tissue hypoxia which is also pro-inflammatory, resulting in production of the chemokine CXCL12 (or stromal-derived factor-1), which can recruit macrophages to the injured tissue. If severe/widespread, these changes may result in circulatory shock and multiple organ failure, which can be fatal even if aggressively treated. The superantigen/superagonist mechanism is also related to xenobiotic-induced inflammation, as some protein therapeutics (notably the anti-CD28 monoclonal antibody TGN1412) can cause this phenomenon, which has led to significant morbidity in the context of clinical trials.

2.5 Effectors of Inflammation

The action of inducers and mediators of inflammation is to alter the phenotype of effector cells. The changes in these cells, which may be in the synthesis/expression of certain molecules or mediators, change in cell shape, migration, phagocytosis or release of cytoplasmic granules, are responsible for the functional alterations which characterize an inflammatory response.

2.5.1 Endothelial Cells

The importance of vascular ECs in mediating vascular permeability and leukocyte transmigration has already been mentioned. Via changes in cell morphology and expression of cell adhesion molecules (including the selectins, ICAM-1, PECAM-1 and JAMs), synthesis of cytokines, and so on, they function as important effectors, themselves responding to inducers and mediators in order to regulate local blood flow, ensure the accumulation of a cell-rich transudate at the site(s) of inflammation and form new blood vessels if required as part of the healing process. This is mediated by various growth factors, including VEGF.

2.5.2 Mast Cells

Mast cells are generally located adjacent to small blood/lymphatic vessels, particularly close to epithelial surfaces, and are important in the initiation and early stages of the inflammatory response. They express cell surface receptors for the Fc-region of IgE and become coated with IgE molecules, the antigen-specific regions of which face the extracellular environment. Crosslinking of these IgE molecules by allergens or parasites (e.g. Type I hypersensitivity response) stimulates degranulation and the release of the potent mediators contained therein. Mast cell degranulation can also be induced by substance P released from sensory nerve endings and from macrophages, defensins and complement factors C3a, C4a, C5a. Granules contain preformed substances including TNF, vasoactive amines (histamine, serotonin), proteoglycans (e.g. heparan), neutral proteases, tryptase, chymase and stem cell factor. Proteolytic enzymes can

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat167
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

degrade protein toxins/mediators and also extracellular matrix, which contributes to remodelling but can also cause damage, particularly if degranulation is excessive. Tryptase is also mitogenic to epithelial cells, which contributes to healing. Mast cells can also synthesize various inflammatory mediators such as leukotriene C_4, PAF, prostaglandin D_2, cytokines and chemokines (e.g. eosinophil chemotactic factor, which can play a major role in recruitment of eosinophils associated with mast cell activation).

2.5.3 Neutrophils

These cells are derived from the bone marrow and are circulated in the blood. They are a key effector cell in acute inflammation, functioning principally to kill/phagocytose bacteria or foreign materials (recognized by membrane-expressed C3b or Fc receptors) and to release preformed lysosomal enzymes (proteases, phosphatases, phospholipase A2, myeloperoxidases), antimicrobial molecules (lysozyme, lactoferrin, defensins) and inflammatory mediators (leukocyte adhesion molecules, defensins, plasminogen activators) from their cytoplasmic granules to degrade protein/extracellular matrix and enhance the inflammatory reaction. Cytoplasmic granules can be classified as 'specific' and 'azurophil', based on their appearance, and their contents differ slightly. Both types of granules are discharged into phagosomes to degrade microbes/foreign material, or they can be released into the surrounding ECM. The enzymes either degrade cellular constituents or generate superoxide bursts (e.g. myeloperoxidase) designed to kill phagocytosed microbes. However, these enzymes when released into the ECM will also cause local tissue/cellular damage or liquefaction, which will itself stimulate the inflammatory process and may lead to the formation of pus/an abscess.

Increased production and release from the bone marrow (and in rats, notably the spleen) is stimulated by cytokines (IL-1, TNF, IL-3 and granulocyte/macrophage colony stimulating factor (GM-CSF)) and increased levels of circulating neutrophils (plus increases in acute-phase proteins such as fibrinogen and CRP) can be clinical pathological indicators of an ongoing inflammatory response. Neutrophils are short-lived, only surviving a few days once they leave the systemic circulation. They express receptors for many different classes of inflammatory mediator. In addition to C3b and Fc receptors, they also express receptors for cytokines, substance P, PAF and chemokines. Ligand binding of these receptors and cell surface adhesion molecules (e.g. selectins and β_2-integrins such as Mac-1 (CD11b/CD18 heterodimers)) activates neutrophils by mechanisms discussed earlier, resulting in up-regulation of those cell surface molecules involved in transmigration from the blood stream, activation of eicosanoid pathways and cytoskeletal changes facilitating formation of pseudopodia for cell movement (chemotaxis), phagocytosis and degranulation.

2.5.4 Eosinophils

With neutrophils, eosinophils are collectively termed granulocytic cells. They are also recruited from the circulation to sites of inflammation, and are particularly prominent in inflammatory reactions to allergens or parasites and in locations such as the alimentary tract. Eosinophil chemotactic factor (from mast cells), histamine, C5a, cytokines (IL-4, IL-5, IL-13) and other chemokines (CCL5, CCL11 or eotaxin) are all involved in the recruitment and activation of eosinophils. Their heterogeneous cytoplasmic granules are notably eosinophilic (in contrast to neutrophils in most species); primary granules contain major basic protein (MBP), which is toxic to host cells/parasites and stimulates vasoactive amine release (e.g. histamine). Secondary granules (specific granules) contain a cationic protein with similar properties to MBP and also microbicidal peroxidase, neurotoxin and various proteases (e.g. collagenases, metalloproteases) which degrade the ECM. Excessive activation of eosinophils is associated with significant cell/connective tissue damage. A variety of cytokines are also produced by activated eosinophils, including ILs 1–6, 8, 10, 12, 16, TGF, GM-CSF, chemokines and eicosanoids, notably LTC_4. Catalase/phosphatase enzymes are also released from eosinophil granules, which influence the inflammatory response by inactivating leukotrienes.

2.5.5 Monocytes/Macrophages

Monocytes are produced in the bone marrow and circulate in the blood. Independent of inflammation, these cells migrate to tissues, where they differentiate to become tissue macrophages or histiocytes; these cells adopt a surveillance function and if activated by a local insult can become important sources of mediators early in the inflammatory response. Dendritic cells are also part of the monocyte/macrophage cell lineage and are recruited preferentially to lymphoid tissues and external interfaces like skin and mucous membranes of the gut and respiratory tracts. Monocytes can also become activated and recruited from the circulation as part of the inflammatory response, differentiating to become macrophages upon transmigration into tissue. Activation signals for macrophages include those mediated via TLRs (binding of microbial inducers, or from contents of damaged/necrotic cells possibly by RAGE complexing); via cytokines (particularly IFN-γ from activated T lymphocytes and IL-12 associated with cell-mediated immunity/Th1 responses, and IL-4 and IL-13 associated with Th2 responses). These macrophages are important sources of inflammatory mediators such as cytokines

(TNF, IL-1) and play an important part in phagocytosis of microbes and foreign materials which may be recognized by C3b receptors or Fc receptors in the macrophage surface. This recognition also serves to activate macrophages and is important in the innate immune response, for example, in the lung, where macrophages phagocytose particulates which are carried beyond the mucociliary escalator of the respiratory epithelium (e.g. environmental 'nuisance dusts', or lactose used in inhalation studies).

Different forms of activation result in different phenotypic changes, ranging from phagocytosis, to a respiratory burst and the release of ROS/nitric oxide to kill cells/microbes, to up-regulation of MHC expression for antigen presentation, and to release of IL-1 and TNF. Inert particulates, foreign materials or resistant microbes (e.g. fungal hyphae, mycobacteria) can continue to stimulate a macrophage response, via cytokines, microbial proteoglycans, integrins and other cell surface receptors mediating cell fusion. These signals, which may in part be sensed intracellularly via the NALP3 inflammasome, result in a macrophage-rich granulomatous inflammatory infiltrate or granuloma, which may contain macrophages fused into multinucleated giant cells in an attempt to remove the inducing stimulus.

Macrophages are also important in causing tissue damage and in stimulating fibrosis. ROS, nitric oxide proteases, eicosanoids and chemokines from activated macrophages will either damage tissue directly, or attract neutrophils. This is important in removing microbes and damaged or necrotic tissue to make way for healing. Activated macrophages also release growth factors including PDGF, fibroblast growth factor (FGF) and TGFβ. These stimulate fibroblasts to produce collagen and also angiogenesis, both of which are required for the healing process/production of granulation tissue.

In addition to their role in innate immunity, macrophages are also key effector cells for the adaptive immune system, and influence chronic inflammation by antigen presentation (a function both of dendritic cells and activated macrophages), T lymphocyte help resulting in the proliferation of reactive T cells, which may stimulate cell mediated immunity (Th1 phenotype) or the differentiation/proliferation of B lymphocytes and antibody production (Th2 phenotype).

2.5.6 Lymphocytes and Plasma Cells

These cells are important in adaptive immunity and are a feature of chronic inflammation, generally being recruited to tissues at 24–48 hours, later than neutrophils. Naive lymphocytes locate from the circulation to specific compartments of the lymphoid tissues, exiting the circulation via the high endothelial venules. This process is mediated by chemokines (CCL19 and 21, CXCL12 and 13) and ICAMs acting via their cognate receptors expressed on the lymphocytes. Mucosal lymphoid tissue targets cells using a specific adhesion molecule, mucosal adressin cell adhesion molecule (MadCAM). Mature, activated lymphocytes are recruited to sites of inflammation in a similar fashion to other leukocytes.

Once located at the site of inflammation, T lymphocytes expressing the classical α/β TCRs and CD4 on their cell surface (helper T lymphocytes) orchestrate chronic inflammation according to different phenotypes, Th1, Th2 or Th0. Th1 responses (cell-mediated responses) are facilitated by a pattern of cytokines, including IL-12 released by dendritic cells, which results in the recruitment of macrophages via release of IFN-γ and TGFβ from the activated T cells. Th2 responses (humoral responses) are characterized in particular by IL-4, IL-5 and IL-10 from Th2-type CD4 lymphocytes, which stimulate B lymphocytes to produce antibodies and will also activate eosinophils and mast cells. These responses may be seen where the basis of stimulation is allergic. Th1 and Th2 phenotypes are not mutually exclusive although each tends to inhibit the other. This lack of phenotype exclusivity is due in part to the presence of Th0 lymphocytes, which are able to secrete patterns of cytokines common to both phenotypes. The predominant form of T lymphocyte response can also be influenced by dendritic (antigen-presenting) cells and another class of T lymphocyte, the regulatory T cell which can inhibit the dendritic cells themselves. Lymphocytes expressing CD8 cell surface molecules (and classical TCR heterodimers) are known as suppressor/cytotoxic T cells. These cells can kill target cells expressing foreign antigens (e.g. virus- or xenobiotic-derived) via specific recognition of these antigens in conjunction with MHC Class I.

B lymphocytes are responsible for antibody production (and differentiation into a mature plasma cell antibody-secreting phenotype), but these cells can also stimulate other lymphocytes by taking up and presenting antigen.

NK cells are a subset of lymphocytes which do not express TCRs or surface immunoglobulins but do bear Fc receptors (CD16 molecules) and a variety of other costimulatory and inhibitory molecules. These cells contain cytoplasmic granules and are important in the recognition and removal of cells/microbes coated with IgG and cells expressing stress-induced or viral proteins. They are regulated by a variety of cytokines and also secrete cytokines themselves, including TNF and IFN-γ.

This participation of the adaptive immune system influences the nature of the induced chronic inflammatory response and is important in some types of xenobiotic-induced inflammation, where the xenobiotic acts to induce a specific immune response which may either cross-react with endogenous antigens (molecular mimicry) or else target cells expressing the (complexed) xenobiotic at the cell surface.

2.5.7 Fibroblasts

These cells secrete collagen, other ECM components, cytokines, chemokines and proteases (matrix metalloproteases) and are important physiologically in providing stromal support/scaffolding/compartmentalization in normal tissues. In inflammation, fibroblasts play a significant role in the regulation, production, vascularization and remodelling of an intercellular matrix. This is important both in containing a chronic inflammatory response (e.g. abscess formation) and in the production of bridging fibrovascular (granulation) tissue which may fill a tissue defect caused by damage/inflammation as part of the healing process. Growth factors such as PDGF, FGF, TGFβ and VEGF, produced by macrophages and other cell types in inflammation, activate fibroblasts.

References to recent reviews and articles covering the morphological, functional and molecular aspects of inflammation, at a level of detail which is beyond the scope of this chapter, are included in the 'Further Reading' section.

3 XENOBIOTIC-INDUCED INFLAMMATION

Xenobiotics can cause inflammation by a variety of mechanisms with differing pathogeneses and morphologic patterns of change. Xenobiotic-induced inflammation may be associated with

- the point of entry or administration of the xenobiotic
- systemic toxicity in different target tissues
- the indirect effects of pharmacology
- intracellular or extracellular accumulation
- the induction of cytokine release
- stimulation of an adaptive immune response.

In many cases xenobiotics will cause cytotoxicity/necrosis in target cells which may result in the release of cellular contents in abnormal tissue compartments. As previously discussed, the presence of these cell contents acts as an inflammatory inducer which is sensed and leads to the release of inflammatory mediators. Cellular damage may occur as a result of physicochemical properties of a xenobiotic which may be influenced by the site of administration/experimental procedure. It may also occur as a result of direct cellular toxicity, which may arise through a number of different mechanisms. These mechanisms may serve to exacerbate inflammation by generating pro-inflammatory mediators such as nitric oxide derivatives or ROS; however a similar endpoint of cellular degeneration and/or necrosis is achieved. In addition, cells may be injured in an indirect fashion as a result of exaggerated pharmacology. Xenobiotics may also cause inflammation by acting on cells/signalling pathways which are themselves involved in the processes of inflammation and immunity. They may do this by excessively stimulating pro-inflammatory pathways leading to cell activation and release of inflammatory mediators, or alternatively by inducing an adaptive immune response which may result in chronic inflammation.

3.1 Inflammation Associated with the Point of Entry

Administration of xenobiotics can be an important factor in initiation of inflammation. Xenobiotics may exacerbate inflammation as a result of the route of administration, for example intravenous administration, which may itself be influenced by variations in operator experience, technical equipment or duration of administration. Intravenous administration will cause a degree of trauma to the vessel (and overlying subcutis/skin), which will be associated with a degree of perivascular haemorrhage, fibrin and inflammatory cells, as a result of the activation of pro-inflammatory processes and release of mediators. Duration of intravenous access is also a factor. Indwelling venous cannulae can cause prolonged irritation and activation of the clotting cascade, leading to inflammation and thrombus formation. Over time, chronic thrombi may show fibroplasia/fibrosis ('organization') and mineralization in control animals (**Figure 2**) in addition to those receiving xenobiotic. Therefore, it is always important to review the variation of background inflammation/haemorrhage to reveal exacerbation of the inflammatory response, which may be caused by irritant xenobiotics. Irritant effects include necrosis of the vessel wall/surrounding tissues, with enhanced oedema, inflammatory cell infiltration and thrombus formation. Barbiturate anaesthetic agents are examples of irritants which can cause significant vascular and extravascular tissue damage and even sloughing of necrotic tissue due largely to the high (alkaline) pH of formulations. Intraperitoneal injection can also cause inflammation of the peritoneal cavity and serosal surface of abdominal viscera by chemical irritation in rats and dogs (Brady *et al*., 2004; Kanter *et al*., 1994). Accidental deposition of oral formulations into the pleural cavity as a result of dosing accidents and oesophageal perforation will cause significant, often fatal intrathoracic inflammation. Introduction of fluid into the pleural space will interfere with lung ventilation and perfusion, but inflammation is related to the irritant effect of oral formulations when exposed to the sensitive pleural membranes and also the efflux of food material through the perforated oesophagus.

Oral administration results in the deposition of xenobiotic into the stomach, directly if administered by gavage tube. If this compromises the normal defence of the gastric mucosal barrier (which constitutes the superficial mucous layer and the gastric epithelium), or the relatively

Figure 2 Inflammation in the heart, vasculature and lung. (A) Normal rat heart showing close apposition of normal myofibres (original magnification ×200). (B–E) Progression of acute inflammation in rats following a single subcutaneous dose of isoprenaline. (B) Early changes in acute inflammation. Note the central necrotic myofibre (arrow), interstitial oedema (seen as increased clear space between cardiomyocytes) and predominantly neutrophilic inflammatory cell infiltrate (original magnification ×200). (C) Note the predominantly mononuclear inflammatory cell infiltrate into the interstitium and phagocytosis of necrotic cardiomyocytes (original magnification ×200). (D) Later stage (48 h postdosing) showing the presence of mononuclear inflammatory cells and remaining cardiomyocyte cytoplasmic debris, but note the plump spindle-shaped nuclei in the interstitium, indicating activation of interstitial cells including fibroblasts. (E) At this more advanced stage, healing by fibroplasia/fibrosis is becoming more established. Necrotic cardiomyocyte debris has been phagocytosed, removed and the interstitium is expanded by plump, proliferating interstitial cells, with some remaining mononuclear inflammatory cells (lymphocytes/monocytes/macrophages). Collagen is being laid down by the fibroblasts (original magnification ×400). (F) Inflammation in a canine arteriole. This is an example of idiopathic canine polyarteritis ('Beagle Pain Syndrome'), a spontaneous condition. Note the margination (arrow) and transmigration of inflammatory cells through the arteriolar wall and into the perivascular interstitium (original magnification ×200). (G) Inflammation related to experimental procedure. Vena cava from a control rat with an indwelling cannula. The site of the cannula is shown by the ovoid clear area in the lower right quadrant of the image. It is surrounded by a large thrombus showing features of chronic inflammation, with fibroplasia, lymphohistiocytic inflammatory cell infiltrate and multifocal necrosis/mineralization (arrows). The thrombus is adherent to the vessel wall on the right hand side and there is a narrow crescentic space on the left, containing red blood cells, which represents the remaining lumen of the vena cava (original magnification ×20). (H) Chronic inflammation in the rat lung associated with phospholipid accumulation in alveolar macrophages. Alveoli are filled with vacuolated macrophages, cellular debris, eosinophilic proteinaceous material and cholesterol crystals (needle like clefts in the section). There is a mixed inflammatory cell infiltrate and alveoli have become lined by Type II pneumocytes (cuboidal epithelium). There is also perialveolar fibrosis (arrows).

hardy squamous epithelium of the rodent forestomach, then it will expose the subepithelial compartment to inflammatory inducers including the normally acid conditions of the stomach contents, which will produce further damage, exacerbating the inflammation. This may occur as a topical/irritant effect of direct administration. Physicochemical factors such as pH and buffering capacity of administered formulations will be important considerations but administration of ethanol, hyperosmolar glucose, salt solutions and also stress, protein restriction or starvation have been reported to induce inflammation/ulceration in the rat forestomach and/or glandular stomach (Goldberg, 1973; Puurunen *et al*., 1980). Inflammation and the milieu of inflammatory cytokines, particularly IL-1, IL-2 and TNF, can enhance both antigen presentation by dendritic cells/macrophages, and the induction of an adaptive immune response. This is illustrated in the experimental induction of alimentary tract hypersensitivity to tribenzenesulfonic acid (a sulfonamide) by administration of alcohol, which breaks down the mucosal barrier and induces inflammation (Bertram, 2002). The hypersensitivity response causes granulomatous inflammation in the colonic mucosa. The mechanisms of hypersensitivity will be discussed later.

Oral gavage administration may also give rise to necrosis and inflammation in the upper respiratory tract. In rats, lesions in the nasal cavity of multifocal olfactory and respiratory epithelial necrosis and inflammation have been associated with oral but not parenteral administration of xenobiotics (Pino *et al*., 2006). Changes are also usually present in the nasopharynx and represent reflux or convection of oral formulation in animals which are obligate nasal breathers. This is also considered to be a result of topical irritancy of oral formulations to the more sensitive nasal epithelia.

Delivery by the inhalation route may also cause toxicity related to topical irritancy. Due to anatomical factors, the nasal airways and larynx are common sites of irritancy. Many inhaled xenobiotics cause degeneration/necrosis and inflammation in the nasal cavity and airways including formaldehyde, cigarette smoke, ammonia, ozone, chlorine (Harkema *et al*., 2006). The regional distribution of lesions, including inflammation, reflect local dose, water solubility, epithelial susceptibility and local metabolism. Squamous epithelium is more resistant than respiratory or olfactory epithelia. Erosion or ulceration of squamous epithelium causes inflammation due to compromise of this epithelial barrier and presumably exposure of inflammatory inducers either to other keratinocytes or to the underlying tissues. Oxidants like chlorine and ozone are less irritant but can cause inflammation associated with the less resistant transitional epithelium: exudation of neutrophils into the epithelium and airway is a feature and may be linked to the rapid increase in mucus secretion. With continued exposure to ozone, a chronic inflammatory reaction develops. Formaldehyde affects the respiratory epithelium, and the continued cycle of inflammation and attempted repair, with epithelial cell replication (presumably as part of the growth factor-driven inflammation/repair process) is thought to play a part in the induced nasal tumours (Harkema *et al*., 2006). In the larynx, inhaled irritants can also cause respiratory epithelial compromise, such as loss of cilia and degeneration associated with inflammation. Susceptible sites are usually at transitions from squamous to other, more susceptible types of epithelium, including respiratory epithelium of the ventrolateral epiglottis, and the ventral pouch (Lewis, 1991). A protective hyperplastic/metaplastic response is associated with irritancy.

Route of administration may also influence concentrations of xenobiotic in local tissues and therefore, target-tissue toxicity. A good example of this is the 'topical' effect of anti-inflammatory agents following oral administration, which can lead to gastric erosion/ulceration and inflammation. Oral anti-inflammatory drugs (including alcohol, aspirin, corticosteroids), histamine H_2 receptor antagonists and proton pump inhibitors have been shown to alter the make-up of normal gastric mucous layer, reducing the content of protective sulfomucins and prostaglandin PGE_2 (Greaves, 2007). This compromise of the normal protective effects of the gastric mucous layer may predispose to mucosal damage. The nonsteroidal anti-inflammatory drugs (NSAIDs) indomethacin (indometacin) and ibuprofen produce gastric mucosal erosion and ulcers with associated inflammation (Shriver *et al*., 1975). The initial stages are neutrophil-independent, then tissue damage is exacerbated by neutrophil influx. In the early stages, NSAIDs are readily absorbed into the mucosa, a process which is dependent on the physicochemical properties of the NSAID (versus its antiprostaglandin effect). Important factors in the pathogenesis of mucosal damage include lipid solubility, acidity, which mediate interaction with cell membrance phospholipids and their ability to uncouple mitochondrial oxidative phosphorylation once 'trapped' in the cell (Bjarnason *et al*., 2003), in addition, the pharmacological activity of COX inhibition blocks the production of protective prostaglandins (mucus content and mucosal blood flow mediated by vasodilators such as PGE_2). The inhibition of COX enzyme is also associated with an increase in the 5-LOX pathway, generating the pro-inflammatory leukotrienes (e.g. LTB_4). The penetration of cellular constituents, LTB_4, gastric acid and bacteria attract neutrophils (e.g. via TLRs/PRRs) which themselves cause tissue damage and exacerbate the inflammatory reaction by the release of lysosomal enzymes including myeloperoxidase, the generation of superoxide radicals, eicosanoids such as LTB_4, proteases and other inflammatory mediators (Bertram, 2002). This reaction can progress to form penetrating ulcers and peritonitis due to the presence of powerful inflammatory inducers (irritant

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

materials, inflammatory cells, bacteria) and mediators in the peritoneal cavity.

Certain inhaled xenobiotics cause degenerative/inflammatory lesions in olfactory epithelium of the nasal cavity due to high local concentrations, coupled with metabolism to generate products toxic to the overlying epithelium. Xenobiotics including 3-methylfuran when given by inhalation, or systemic acetaminophen, can cause necrosis of the olfactory epithelium as a result of metabolism by the cytochrome P450 enzymes expressed in this epithelium (Harkema *et al*., 2006).

Inflammation caused by adenoviral vectors also varies depending on the route of administration. Adenovirus causes pneumonitis by inhalation, hepatitis by intravenous injection and myositis by intramuscular injection (Schnell *et al*., 2001). Viral capsid has been shown to be important in stimulating this initial inflammatory response via the release of pro-inflammatory cytokines (Liu and Muruve, 2003) and is discussed in more detail later.

3.2 Inflammation Caused by Systemic Toxicity

Xenobiotics can cause direct toxicity to target cells by a number of different mechanisms, leading to cellular dysfunction and death. If this results in the release of inflammatory inducers then it will result in inflammation. The site and severity of inflammation will depend on the target cell population, which is itself dependent upon a combination of absorption, level of expression of the pharmacologic target, metabolism and cellular adaptation mechanisms. It may be restricted to a single tissue or organ or, if the vasculature is affected, inflammation may occur in a variety of different locations.

3.2.1 Organ- and Tissue-Specific Inflammation

Paraquat causes acute damage to Type I and II alveolar epithelial cells via redox cycling, depletion of reduced nicotinamide adenine dinucleotide phosphate (NADPH) and the generation of ROS, notably hydroxyl radicals. Following systemic administration, paraquat is concentrated in the lungs by a receptor-mediated uptake mechanism (Haschek *et al*., 2002), and the high oxygen levels present here contribute to the severity of damage (Lock and Wilks, 2001). Although damage does not directly affect the pulmonary capillaries, they are intimately associated with alveolar epithelial cells which are an important component of the blood–air barrier. Alveolar epithelial necrosis leads to alveolar oedema, haemorrhage and extensive alveolar, interstitial and perivascular inflammatory cell infiltration which can be fatal (Clark *et al*., 1966). Surviving animals show chronic inflammation with extensive fibroplasia and attempted alveolar epithelial regeneration (Kimborough and Gaines, 1970). Interstitial inflammation in the lung also occurs as a result of ozone-induced damage, treatment with chemotherapeutic drugs such as bleomycin and busulfan, and hypersensitivity reactions, with fibroplasia a feature of chronic lesions (Haschek *et al*., 2002). Bleomycin also induces pulmonary interstitial pneumonia and fibrosis, and TNF (α) has been implicated in the pathogenesis of these changes to the end-stage of fibrosis (Piguet and Vesin, 1994).

The distribution of the pharmacological target of a xenobiotic may influence the distribution of induced inflammation. In rats, inflammation of the caecum associated with indomethacin inhibition may indicate a protective effect of normal COX2 expression. COX2 is present at high levels in macrophages and other interstitial cells at the ileocaecal junction. Inhibition by xenobiotics or in transgenic mice with the *COX2* gene deleted may have a preferentially deleterious effect on these cells, accounting for the distribution of the observed ulcerative/inflammatory lesions (Haworth *et al*., 2005). Necrosis of lymphoid tissue may also occur as a direct effect of xenobiotic administration, leading to inflammation and haemorrhage. Inhibitors of p38 kinases (involved in the MAP kinase signalling pathway) may cause acute intestinal toxicity in dogs. The primary change of lymphoid necrosis and inflammation is considered to lead to mucosal haemorrhage visible macroscopically at necropsy. Affected animals show signs of neutrophilia and fever, which are associated with systemic effects of various inflammatory mediators. High levels of expression of p38 kinase have been demonstrated in canine B lymphocytes (but not in rodents), and inhibition is thought to cause a species-specific necrosis of B lymphocytes and inflammation in the dog (Davis, 2008).

The nature of the target tissue may also influence the pathogenesis of the inflammatory response. The acinar cells of the exocrine pancreas contain proenzymes which are normally activated when they reach the lumen of the gastrointestinal tract. Xenobiotic-induced inflammation can be caused by a variety of drugs including corticosteroids, antibiotics, anti-inflammatory agents and anti-HIV drugs (Trivedi and Pitchumoni, 2005). Although the precise mechanisms are unclear, when these cells are damaged by xenobiotics, there is release and activation of proteases/lipases contained within. These enzymes then exacerbate tissue damage and thus increase the generation of inflammatory inducers.

Xenobiotics which generate reactive metabolites can also lead to cell injury/necrosis and ensuing inflammation. The site of inflammation may then depend on the presence of metabolic enzymes required for activation and/or the endogenous protective mechanisms which may

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be more or less effective. Carbon tetrachloride is metabolized preferentially by centrilobular hepatocytes, generating trichloromethyl radicals, which bind covalently to lipids and proteins causing oxidative stress, lipid peroxidation, structural damage to membranes and enzyme inhibition, notably that of microsomal ATPase. Cells undergo ballooning degeneration, and necrosis, releasing cellular enzymes (e.g. alanine aminotransferase, which is measured in blood samples) and many other cellular constituents including ATP, K^+ ions, and so on, which act as inducers of inflammation.

Kupffer cells (specialized hepatic macrophages) are important in detecting these inducers and mediating influx of neutrophils (Edwards *et al*., 1993), in addition, the oxidative stress induced by carbon tetrachloride increases NFκB levels in the nucleus, which also promotes expression of pro-inflammatory cytokines (Liu *et al*., 1995). Cytokines, including tumour necrosis factor alpha (TNF-α), IL-1β, IL-6 and iNOS, plus growth factors such as PDGF isoforms, are up-regulated and play an important part in acute and chronic inflammation caused by carbon tetrachloride (Lee *et al*., 2008; Borkham-Kamphorst *et al*., 2008). Apelin is a protein which is important in the pathogenesis of carbon tetrachloride-induced inflammation and fibrosis. It enhances vascular dilation after endothelial nitric oxide synthesis via the extracellular receptor kinase (ERK) pathway, and may also initiate angiogenesis. In rats, apelin expression is regulated by TNF and it is increased in hepatic stellate cells in inflamed/fibrotic liver (Principe *et al*., 2008).

Systemic absorption of compounds and their distribution around the body can lead to inflammation related to bioactivation in the skin. Phototoxicity results from the absorption of visible light by xenobiotics (e.g. 8-methoxypsoralen, sulfonamides, fluoroquinolones) or endogenous porphyrins accumulating due to hepatotoxicity. Absorption of light triggers complex reactions resulting in the formation of free radicals which cause dermoepidermal erythema, oedema and necrosis (Klein-Szanto and Conti, 2002). Inflammation is induced, which is exacerbated if ulceration of the epidermis occurs, leading to exposure of subepithelial cells to (self-) trauma, environmental irritants, microbes, cellular debris and the effects of proteolytic enzymes from infiltrating neutrophils.

Xenobiotic-mediated inhibition of excretory mechanisms can also cause cellular toxicity and inflammation. Interference with the normal bile salt transport and excretion mechanisms can lead to hepatocellular damage, necrosis and subsequent inflammation. Drugs including rifampicin, ciclosporin (cyclosporine) and troglitazone directly inhibit ATP-dependent taurocholate transport by competitively binding to BSEP (bile salt export protein), the major hepatocellular bile salt efflux system (Pauli-Magnus *et al*., 2005). In mice, administration of lithocholic acid also causes cholestasis, hepatocellular necrosis and inflammation (Staudinger *et al*., 2001). Necrosis of hepatocytes will release cellular constituents which can act as inflammatory mediators. Damaged/stressed cells may secrete cellular proteins by a non-Golgi-mediated pathway (Medzhitov, 2008) but it is not known if this is part of the pathogenesis of cholestasis. Bile salts are themselves irritant and may induce inflammation if they escape their normal tissue compartments as they accumulate.

Route of excretion can also influence the pathogenesis of inflammation in target tissues. Cyclophosphamide is an alkylating agent which causes haemorrhagic inflammation of the bladder. Hepatic metabolism of cyclophosphamide generates acrolein, which is excreted in the urine and enters into the uroepithelial cells. Acrolein then activates intracellular ROS, nitric oxide production and cytokine (TNF, IL-1) expression (directly or through NFκB and c-Jun/AP-1), depleting cellular antioxidant defence mechanisms such as glutathione, and driving peroxynitrite production. Finally, the increased peroxynitrite level damages lipids (lipid peroxidation), proteins (protein oxidation) and causes DNA strand breaks, leading to activation of poly(adenosinediphosphate-ribose) polymerase (PARP), a DNA repair enzyme. PARP overactivation results in the depletion of oxidized nicotinamide adenine dinucleotide phosphate (NADP) and ATP, and consequently in necrotic cell death. Such cell damage/death will (i) cause haemorrhage if ECs are affected, and (ii) release intracellular contents into the mucosa and the urine. These pro-inflammatory cytoplasmic constituents and cellular proteases, can then cause further tissue damage and exacerbate the inflammatory reaction (Korkmaz *et al*., 2007). Renal tubular excretion of xenobiotic and crystal formation in the kidney tubules is an example of extracellular accumulation and is discussed later.

3.2.2 Vascular Lesions at Multiple Sites

Drug-induced vascular injury can act via a variety of mechanisms, which may be complex/multifaceted, but which directly affect the vessel and which lead to perivascular inflammation. Necrotizing vasculitis may be induced by a number of xenobiotics (e.g. phenylpropanolamine, methamphetamine), usually in small-to-medium calibre arterioles (Van Vleet *et al*., 2002). Whilst the mechanism is largely unclear, necrosis which would immediately increase vascular permeability and liberate cellular inducers of inflammation is associated with an initial neutrophil-rich infiltrate and thrombus formation. PDE IV inhibitors have been developed as anti-inflammatory/antiasthma drugs (Souness *et al*., 2000), but cause vascular injury and inflammation in preclinical studies. The proposed mechanisms include increases in intracellular cAMP and nitrate stress, physical stress due to local vasodilation and also activation of pro-inflammatory pathways. In

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat167
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

rats, mesenteric vessels showed plasma insudation (in the vessel wall) and exudation, arterial haemorrhage and fibrinoid necrosis/mural fibrin, inflammatory cell infiltration in vessel walls and mesenteric oedema. Morphological evidence of mast cell activation, degranulation and EC activation were also observed (Zhang *et al*., 2008b). Similar morphological changes are also seen in monkeys (Losco *et al*., 2004). In rats, PDE IV inhibitors (SCH 351591 and SCH 534385) caused activation of mast cells, ECs, macrophages and the formation of the potent oxidant peroxynitrite (which is a reaction product of nitric oxide and superoxide anions) in ECs and macrophages (Zhang *et al*., 2008b). Peroxynitrite formation may be a common pathway in drug-induced vascular injury and is thought to contribute to oxidative damage of macromolecules (e.g. DNA) and the induction of apoptosis in ECs and vascular smooth muscle cells (Mihm *et al*., 2000). It is also important in inflammation (Pacher *et al*., 2007), mediating L-selectin shedding, up-regulation of Mac-1 (CD11b/CD18) on neutrophils and increased expression of E-selectin, P-selectin, ICAM-1 and VCAM-1 (vascular cell adhesion molecule) on ECs (Zhao *et al*., 2004; Sohn *et al*., 2003), thus enhancing the association of ECs and neutrophils (Sohn *et al*., 2003). Induction of peroxynitrite in ECs may therefore be an early inducer of inflammation in PDE IV inhibitor-induced vascular injury. Mast cell activation/degranulation is also pro-inflammatory via the release of various pro-inflammatory mediators, including vasoactive amines, proteases, VEGF (which increases vascular permeability) and bFGF (basic fibroblast growth factor, important in fibroplasia). All of these will act to increase vascular permeability, exudation, recruitment of leukocytes and activation of fibroblasts present in inflammation. In the rat, the vascular changes were reflected in circulating biomarker changes indicative of inflammation, including CRP, haptoglobin, thrombomodulin, α_1 acid glycoprotein, IL-6 and VEGF (Weaver *et al*., 2008).

Similar morphological changes have been reported for PDE III inhibitors in dogs (Clemo *et al*., 2003). These vasoactive compounds have also been shown to increase the local production of iNOS, nitrotyrosine and peroxynitrite by mast cells and ECs, which are molecular/cellular events associated with the vascular necrosis/apoptosis and inflammation observed in mesenteric blood vessels of rats (Zhang, 2008b).

3.3 Inflammation as an Indirect Consequence of Pharmacology

A wide variety of agents cause direct toxic damage resulting in myocardial necrosis, including ionophores, gossypol, allylamine and fungal toxins, all of which induce inflammation (Van Vleet *et al*., 2002). The myocardial injury caused by β adrenergic stimulation is an example of cell degeneration/necrosis and inflammation as a primary result of exaggerated pharmacology. Although multiple mechanisms have been proposed for the action of isoprenaline (isoproterenol), it is generally accepted that the pharmacologically mediated tachycardia results in increased oxygen demand (Dhalla *et al*., 1992), and this is well documented in the rat as a model of an infarct-like myocardial lesion. The temporal progression of inflammatory changes is shown in **Figure 2**. Myocardial necrosis occurs primarily in the left ventricle and is associated with elevations in circulating myocardial proteins such as cardiac troponins (York *et al*., 2007) and an inflammatory response which is initially characterized by oedema and neutrophil infiltration, followed by monocytes/macrophages which remove cardiomyocyte debris, and healing by formation of fibrous tissue by adjacent interstitial fibroblasts/perimysial cells. The release of cellular components from degenerate/necrotic cells would be expected to induce an inflammatory response and myocardial gene expression analysis has shown that IL-6 is up-regulated early in this process, along with MAP kinase and NFκB signalling, which are implicated in inflammatory signalling, necrosis and apoptosis (Mikaelian *et al*., 2008). Increases in iNOS are also correlated with lesion severity (Zhang *et al*., 2008a). Together these data highlight the prominence of pro-inflammatory processes in the pathogenesis of cardiomyocyte injury in this model.

Vasodilating antihypertensive agents, such as minoxidil and hydralazine, cause myocardial necrosis associated with a fall in blood pressure. Hypotension, hypoperfusion and tachycardia cause myocardial necrosis and subsequent inflammation (Van Vleet *et al*., 2002).

NSAIDs can cause interstitial nephritis and papillary necrosis in the kidney in rats and dogs. Whilst these compounds are anti-inflammatory, the mechanism of inhibition of prostaglandin synthesis via effects on cyclo-oxygenase enzyme activity is thought to cause a variety of changes. Interstitial nephritis is observed as a chronic change: the mechanism is not known, though it may be due to an inflammatory reaction driven by other eicosanoids not produced via COX pathways (i.e. leukotrienes, lipoxins). A cell-mediated specific immune response may also occur since the predominant infiltrating lymphocytes are CD8+ T cells with low numbers of B cells. In the medulla, the mechanism underlying papillary necrosis is thought to be an alteration of blood flow related to the vascular effects of changes in normal prostaglandin synthesis. Interstitial cells are the earliest cell type affected, followed by congestion, local tissue hypoperfusion, hypoxia, endothelial degeneration and necrosis (Khan and Alden, 2002). These lesions are often characterized by a rim of infiltrating inflammatory cells at the border between the hypoxic/ischaemic tissue and adjacent tissue with a functional blood supply, or as vascular supply is restored

following degeneration/necrosis (Gopinath *et al*., 1987). This indicates that an intact vascular supply is required to transport plasma/inflammatory cells to the site of inflammation, which may be stimulated by a combination of factors including damage to ECs, the presence of cytoplasmic components from necrotic cells and the release of mediators associated with tissue hypoxia such as hypoxia-induced factor.

3.4 Inflammation as a Result of Intracellular or Extracellular Accumulation

Accumulation of xenobiotics in cells may result in cytotoxicity but can also stimulate inflammation without causing cell death.

3.4.1 Particulate Accumulation

Inert xenobiotics, such as silica, asbestos, carbon black and para-aramid fibrils, cause chronic and/or granulomatous inflammation in the lung when inhaled (Medzhitov, 2008; Levy, 1995; Nikula *et al*., 1995; Warheit, 1995). In rats, the macrophage/chronic inflammatory response to inhaled particulates is particularly marked (Levy, 1995). These materials accumulate and are associated with an increase in the numbers of pulmonary macrophages. The lack of 'self'-receptors (e.g. MHC molecules, CD47) and physical nature and size inhibit phagocytosis (Medzhitov, 2008). Xenobiotic particulates such as asbestos and silica have been shown to regulate inflammation via activation of the NALP3 inflammasome in macrophages. This is associated with granulomatous inflammation/granuloma formation (Cassel *et al*., 2008; Dostert *et al*., 2008). In addition it is also known that inhaled diesel particles and carbon black accumulate in macrophages in the rat lung. This accumulation appears to inhibit macrophage scavenging and motility and is probably associated with a similar mechanism to silica, since they both cause a similar pulmonary macrophage accumulation and chronic inflammation when administered by inhalation to rats (Nikula *et al*., 1995; Levy, 1995). Accumulation of particulates in macrophages has also been associated with additional molecular evidence of inflammatory processes. Following exposure to indium phosphide powder, oxidative stress, increased macrophage levels of iNOS, COX2 expression and oxidative DNA damage (8-OHdG formation) have all been demonstrated in rats showing alveolar granulomatous inflammation and proteinosis (Gottschling *et al*., 2001). Continuing exposure to inhaled particulate with ongoing macrophage accumulation and associated chronic granulomatous inflammation is thought to lead to pulmonary squamous metaplasia, atypical hyperplasia and neoplasia (Gottschling *et al*., 2001).

3.4.2 Phospholipid Accumulation

A different form of intracellular accumulation is caused by phospholipid accumulation, or phospholipidosis (PLD), which is commonly associated with cationic amphiphilic compounds across diverse pharmacologic targets (Kacew *et al*., 1997; Nonoyama and Fukuda, 2008). PLD is generally indicative of an adaptive response of the target cell to an inhibition in the normal pathway of lysosomal function and subsequent lysosomal accumulation of xenobiotic in multilamellar bodies. Uncommonly, PLD can lead to cytotoxicity and associated inflammation, although there is little evidence to suggest that this is a direct result of PLD, rather accumulation of the drug/metabolites (Reasor and Kacew, 1996). Examples include amiodarone and chloroquine. Despite the absence of lung inflammation in preclinical species, in the clinic, amiodarone has been associated with PLD in alveolar macrophages, ECs and other cell types. This was associated with chronic inflammation/fibrosis, causing obliteration of airways. Various mechanisms are postulated, from cytotoxicity, hypersensitivity to generation of free radicals and/or modulation of the inflammatory response, with the major metabolite desethylamiodarone being implicated (Reasor and Kacew, 1996; Malhotra *et al*., 2003).

Spinosad® (spinosyn A and spinosyn D), an insecticide, causes PLD (vacuolation on standard light microscopy) in a variety of cell types, some associated with cellular degeneration/inflammation on long-term administration (Yano *et al*., 2002). These inflammatory changes were seen in the lung and thyroid gland, the two most sensitive tissues for PLD. In the lung, alveolar histiocytosis (macrophages were vacuolated) was associated with chronic inflammation (visible macroscopically). In the thyroid, chronic inflammation was associated with vacuolated epithelial cells, necrotic cellular debris and the production of fibrous tissue (Yano *et al*., 2002). Here, the inflammation is associated with tissue necrosis. In long-term rat studies where pulmonary inflammation is associated with PLD, the presence of nuclear pyknosis and cholesterol clefts, indicative of foamy alveolar macrophage necrosis, may be observed (**Figure 2**), providing a link between inflammation and cytotoxicity. Similarly, Elmiron® (pentosan polysulfate sodium), a synthetic glycosaminoglycan, also caused multifocal alveolar chronic active inflammation associated with vacuolated macrophages and cholesterol clefts (NTP (National Toxicology Program), 2004).

Accumulation of phospholipid in bile duct epithelium in rats treated with an antirheumatism agent causes apical vacuolation at low doses, but at increased severity is associated with necrosis of bile duct epithelial cells. Epithelial cell death will cause the release of cellular components which are capable of acting as inducers of inflammation. In addition, these components need to be exposed to sensing mechanisms, which indicates

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat167
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

that there is also compromise of the bile ductular BM, allowing egress of necrotic cellular debris, and probably small amounts of bile, into the ECM. Bile itself is an irritant which will also act as an inducer of inflammation if not properly compartmentalized. The precise mechanism is not clear, but bile duct epithelial necrosis is associated with an inflammatory cell infiltration (Nonoyama and Fukuda, 2008). Aminoglycoside antibiotics cause acute renal toxicity due to tubular necrosis. Mitochondrial enzyme inhibition and peroxidation of phospholipids have been associated with this effect (Mingeot-Leclercq and Tulkens, 1999). If the tubular BM remains intact, little or no inflammatory response is observed; however at its most severe, tubular necrosis can lead to an inflammatory cell infiltration.

3.4.3 Crystal Formation

Extracellular accumulation of uric acid also induces inflammation. Cytotoxic drugs, diuretics, salicylates, ethambutol and nicotinic acid are associated with arthritis. These xenobiotics cause hyperuricaemia and the deposition of uric acid crystals in joints. Uric acid/urates are known to induce inflammation. The mechanism of inducing inflammation appears to be similar to that triggered by environmental xenobiotic particulates. Macrophages detect and phagocytose crystals beyond a certain size, which triggers NALP3 inflammasome activation and IL-1 secretion (Martinon *et al*., 2006; Medzhitov, 2008). Crystal formation in renal tubules, with associated tubular dilation, and inflammation of the tubules, renal interstitium and renal pelvis, are caused by oxalate and sulfonamide administration (Gopinath *et al*., 1987). Although the mechanism is unclear, tubular dilation may compromise the normal BM integrity, and the inflammatory reaction can be marked with tissue damage and mediator release presumably caused by inflammatory cells, particularly neutrophils.

3.5 Systemic Inflammation due to the Induction of Cytokine Release

Induction of excessive systemic release of pro-inflammatory cytokines (the so-called 'cytokine storm') is an important mechanism by which xenobiotics can cause hypovolaemia and shock.

Immunostimulatory mAbs designed to stimulate the immune response are being developed as cancer therapies. However, these can also cause autoimmunity and systemic inflammation. As these mAbs are designed to be as humanized as possible in their protein sequences, they are usually immunogenic in preclinical species, in addition to their pharmacologic activity which should be maintained in relevant species used for toxicity studies. MAbs can increase co-stimulation of T lymphocytes, such as anti-CD28, which results in the activation, cytokine up-regulation and proliferation of these cells (Melero *et al*., 2007). Classically, T lymphocyte activation requires specific interactions between the TCR and antigen presented in association with MHC Class I or II, plus a host of additional co-stimulatory (or inhibitory) molecules (including CD40, CD28) which modulate the signal and response. Some anti-CD28 mAbs can stimulate T lymphocyte activation in the absence of the primary TCR/MHC-mediated signal. This so-called 'superagonist' effect was observed when such a mAb (TGN1412) was administered to normal volunteers on a clinical trial (Suntharalingam *et al*., 2006), but only low levels of cytokine release were observed in primates on toxicity studies (Dayan and Wraith, 2008). Administration of TGN1412 caused cytokine release syndrome ('cytokine storm'), with increased circulating levels of TNF-α, IL-1β, IL-12 and IL-6. It is likely that neutrophils, monocytes and plasma cells were also affected, contributing to the pathogenesis of T lymphocyte activation, culminating in multiorgan failure due to massive angioedema and disseminated intravascular coagulation (Suntharalingam *et al*., 2006; Melero *et al*., 2007; Mehrishi *et al*., 2007) as a result of increased vascular permeability and activation of the clotting/fibrinolytic plasma protein cascades.

Other mAbs, such as the anti-CD20 rituximab, have also been associated with cytokine release, possibly mediated by crosslinking of antibody to target-cell receptors followed by the engagement and activation of complement by binding to the biologically active Fc region of the antibody (Winkler *et al*., 1999).

Administration of adenoviral vectors (generally based on human adenovirus Type 5) in gene therapy can also result in the activation of the innate immune system and an acute cytokine response in a variety of species from mice, through nonhuman primates, to man. Elevation of TNF, IL-6 and IL-12 is observed in mice as an early event following intravenous injection of adenovirus, concomitant with macrophage, dendritic cell and EC activation, plus increased chemokine production (Zhang *et al*., 2001; Liu *et al*., 2003). This initial reaction is mediated, at least in part, by the presence of adenoviral capsid (Liu *et al*., 2003). A similar response occurs in nonhuman primates, following intraportal administration, causing thrombocytopaenia, disseminated intravascular coagulation, petechial haemorrhages, elevated TNF, IL-12, IL-6, and macrophage/dendritic cell activation, with sinusoidal neutrophilic aggregates observed in the liver (Schnell *et al*., 2001). This neutrophilic infiltration pays a significant role in the hepatotoxicity associated with adenovirus vectors (Muruve, 2004). Pathways involving TLRs, although important in microbial detection/inflammation, have not been specifically implicated, although common signalling pathways appear to be involved. The adenovirus capsid binds to its receptor on the cell surface, along with the β_2-integrin CD11b, which activates

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat167
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

pro-inflammatory signalling, including the p38-MAP kinase and extracellular signal-regulated kinase (ERK) pathways, leading to NFκB-mediated up-regulation of pro-inflammatory cytokines, chemokines and cellular adhesion molecules. The stimulation conferred by this initial innate inflammatory response can be sufficient to induce an adaptive immune response in the absence of viral replication (Liu and Muruve, 2003; Muruve, 2004). In man, intravenous administration of adenoviral vector has also been associated with a systemic inflammatory response, elevation of serum IL-6 and IL-10, with disseminated intravascular coagulation and fatal multiple organ failure (Raper *et al*., 2003).

The initiation of adaptive immune responses is controlled by innate immune (pro-inflammatory) signals. Adjuvants are included in vaccines specifically to stimulate the adaptive immune system to respond to the relevant antigen and generate a protective, specific immune response. Immunostimulatory adjuvants, like Freund's, containing microbial components (such as LPS, unmethylated CpG DNA), act via the stimulation of TLRs to initiate a pro-inflammatory cytokine response which in turn enhances interactions between antigen-presenting cells and T lymphocytes (Medzhitov, 2008). Granulomatous hepatitis has also been reported in man following treatment with bacillus Calmette-Guérin (BCG) as an immune modulator (Lamm *et al*., 1986). Aluminium adjuvants, commonly referred to as 'alum', are particulates which stimulate immune responses via the induction of pro-inflammatory cytokines. These particulates aggregate, are readily phagocytosed by macrophages and have been shown to stimulate IL-1b and IL-18 production *in vitro*. Similar to silica and asbestos, alum adjuvants activate the NALP3 inflammasome, resulting in the release of these cytokines (Eisenbarth *et al*., 2008). Bacterial elements of DNA plasmids contain unmethylated CpG DNA and can therefore also exert a pro-inflammatory effect. Probably acting via TLRs, these can stimulate release of TNF, IL-2, IL-6 and IFN-γ (macrophage activating factor) from effector leukocytes, which may contribute to the pathogenesis of glomerulonephritis in mice, caused by the production of IgG antibodies to bacterial DNA (Dempster and Haworth, 2008).

3.6 Inflammation due to Adaptive Immune Responses

The morphological hallmark of autoimmune disease and allergy is inflammation. However, there are no specific morphological features which facilitate distinction between chronic inflammation as a consequence of specific antigen-mediated responses and other types of chronic inflammation. Vasculitis or dermoepidermal inflammation may be suggestive of a hypersensitivity response, and immunohistochemistry is important in defining the lymphocyte subsets present.

3.6.1 Hypersensitivity Responses

Many different xenobiotics can cause hypersensitivity responses, and notable examples include aspirin, cephalosporins, penicillins, sulfamethoxazole, halothane, lamotrigine and carbamazepine (Park *et al*., 1998). Hypersensitivity responses are classically categorized into four different types. These types are not mutually exclusive and a particular xenobiotic can cause multiple types of reaction. For example, penicillin causes reactions in all four categories (Naisbitt *et al*., 2000). The underlying prerequisite is that there is an adaptive immune response towards the xenobiotic in question and that antidrug antibodies (ADAs) and/or T lymphocytes specific to cells expressing drug-associated antigens are produced. Specific adaptive immune responses will give rise to immunologically based inflammatory reactions upon (re-) exposure to the drug (or its haptenated metabolites).

- Type I hypersensitivity: if ADAs in the form of IgE are present on the surface of mast cells, then rapid mast cell activation and degranulation is stimulated by antigen binding. This results in the release of the plethora of vasoactive/pro-inflammatory mediators including vasoactive amine, eicosanoids, PAF, cytokines, chemokines. These immediate responses cause allergic (anaphylactic) reactions and can result in hypotensive shock if the vasodilation/plasma transudation is sufficiently severe/widespread.
- Type II hypersensitivity: if ADAs target antigen expressed on the cell surface, then cytotoxicity of the target cells may occur via the recruitment of NK cells and phagocytic cells (e.g. macrophages) or complement fixation and assembly of a membrane attack complex (C5-9). These interactions are mediated via Fc receptors.
- Type III hypersensitivity is associated with the formation of soluble antigen/antibody complexes which are deposited throughout tissues, notably the walls of small blood vessels. Again, Fc receptors are targeted by complement and phagocytes which can exacerbate inflammation (vasculitis/arteritis) by the production of ROS.
- Type IV (cell-mediated) hypersensitivity reactions take longer to evolve, requiring antigen presentation in association with MHC. This stimulates a T lymphocyte (Th1) response recruiting macrophages (and the release of pro-inflammatory Th1 cytokines) and mediating specific cytotoxicity via TCR-mediated recognition of cells expressing antigen complexed with MHC Class I (CD8+ cytotoxic T cells). These reactions often affect the skin (Naisbitt *et al*., 2000).

3.6.2 Generation of Xenobiotic-Specific Antigens

Metabolism of the xenobiotic is usually a key step in antigen formation for small molecules, as the generation of reactive intermediates is required for protein binding. Macromolecules may be antigenic in themselves, but small molecules (usually <1 kDa) are not immunogenic *per se* and require to be linked to larger (cell-derived) ones in order for immune recognition to occur (Park *et al*., 1987). For example, benzylpenicillin is metabolized to penicillenic acid, which is then conjugated to the anime group of proteins, which then becomes antigenic either directly, or when a xenobiotic-conjugated peptide is presented in conjunction with MHC to T lymphocytes (Naisbitt *et al*., 2000). Different patterns of inflammation can reflect target cells where this metabolism/conjugation occur and may be initiated/enhanced by the presence of so-called danger signals. These are co-stimulatory signals, such as pro-inflammatory cytokines, which increase both antigen presentation and T lymphocyte activation (Matzinger, 1994). Halothane can cause liver necrosis and inflammation associated with the presence of ADAs and autoantibodies in patients (Uzmalinoglu *et al*., 1970; Kenna *et al*., 1984; Homberg *et al*., 1985). Studies in the guinea pig provided evidence of protein adducts presented to T lymphocytes by Kupffer cells (Furst and Gandolfi, 1997).

3.6.3 Hypersensitivity Reactions in Specific Tissues

Immune-mediated inflammation in the skin is also associated with some of the xenobiotics listed above. The skin reactions are usually accompanied by systemic signs of inflammation/immune activation such as fever and lymphadenopathy. There is a dermal and epidermal infiltration of T lymphocytes: both helper (CD4+) and cytotoxic (CD8+) phenotypes have been demonstrated for sulfonamides, phenytoin and carbamazepine. Cytotoxic T lymphocytes lyse target cells via pore-forming perforins (Mauri-Hellweg *et al*., 1995; Naisbitt *et al*., 2000). Benzo[a]pyrene (BAP) is a polycyclic aromatic hydrocarbon (PAH) which is metabolized to a reactive diol epoxide. This metabolite binds cellular macromolecules including protein and DNA (Klein-Szanto and Conti, 2002). Binding to the latter is associated with genotoxicity characteristic of this class of xenobiotics, but contact hypersensitivity also associated with PAHs may reflect binding to the former. PAHs can up-regulate various cytokines/chemokines including IL-1, IL-2 and TNF. BAP has been demonstrated to increase expression of the chemokine CCL1 (N'Diaye *et al*., 2006). These may provide important co-stimulatory signals to promote allergic contact hypersensitivity seen in man.

Hypersensitivity vasculitis occurs as a result of immune activation and inflammation. Lesions are characterized by a predominantly lymphohistiocytic infiltrate in the absence of medial/fibrinoid necrosis and thrombus formation (in contrast to acute xenobiotic -induced vascular necrosis/injury discussed earlier). Immune-mediated vascular injury, similar to other hypersensitivity responses, shows no dose-relationship and has been associated with antimicrobials (penicillin, ampicillin, sulfonamides, tetracyclines) and other xenobiotics, including propylthiouracil, phenylbutazone (Van Vleet *et al*., 2002; Naisbitt *et al*., 2000). Hypersensitivity reactions may also be associated (e.g. for penicillin) with immune-mediated arthritis (Woodard *et al*., 2002).

Some of the mAbs designed to interfere with co-inhibitory signals similar to the CD28 signal, such as cytotoxic T lymphocyte-associated antigen-4 (anti-CTLA-4), have also caused transient, reversible autoimmune effects. Clinically these manifest most frequently as skin itchy (pruritic) eczema/rashes and inflammatory bowel syndromes with moderate to severe diarrhoea, although inflammation of the pituitary gland and uveal tract of the eye have also been described (Blansfield *et al*., 2005). No autoantigens have yet been identified, and it may be that the inflammatory bowel syndromes could be due to inappropriate immune responses to commensal flora (Melero *et al*., 2007).

Adenoviral vectors, in addition to the initial inflammatory/innate response stimulated by capsid-mediated pro-inflammatory cytokine release, induce a delayed, specific immune-mediated inflammation two to seven days later in mice (Liu *et al*., 2003). This phase requires viral gene transcription in infected cells, and is associated with adenovirus-specific cytotoxic T lymphocyte infiltrates in the liver and a second peak of cytokine mRNA (messenger RNA) expression (e.g. TNF). Chronic inflammation is thus induced as a consequence of a specific, cell-mediated immune response to the viral vector.

3.7 Conclusions

Xenobiotics can induce inflammation by a variety of different mechanisms, many of which result in cell injury, degeneration and/or necrosis, either directly or indirectly, by parent or metabolite. This cytotoxicity may be related to pharmacology or to the generation of toxic intermediates in the affected cells. Xenobiotics may also activate inflammatory/immune cells to release inflammatory mediators in nonspecific ways or by stimulating a specific immune response. The pattern of morphologic and functional changes induced by these mechanisms differs according to the target cell population affected and persistence of inducing stimuli. Inflammation itself can also cause tissue damage, resulting in an exacerbation of the initial insult, and can enhance adaptive immune responses. Much is known about the molecular events involved in inflammation itself and has been

shown to apply to inflammation induced by xenobiotics. It is important to note that superantigen-mediated cytokine release, or immune-mediated mechanisms of inflammation may be poorly predicted by preclinical toxicity studies. A detailed knowledge of the pathogenesis and molecular mechanisms involved in inflammation can facilitate the design of *in vitro* or *in vivo* studies to predict or investigate these responses associated with xenobiotic administration.

Medicolegal and Ethical Issues in the Practice of Toxicology: A British Perspective

Denis A. D'Auria

CONTENTS

1 INTRODUCTION

A legal system provides a country with a means of resolving disputes, where the parties may be individuals, companies, public bodies or even the Government itself. In achieving this end, the Law also relies on science to provide advice to the courts on issues in contention at any time. The courts are unlikely to decide disputes involving scientific and medical issues unless they receive appropriate advice from a suitably authoritative source.

Toxicological advice might be critical to the outcome of a case concerning a work-related accident involving an acute release of a chemical or indeed chronic release. In product liability claims, a toxicologist will advise parties about issues that might relate to causation. Toxicological advice may assist in resolving labour disputes concerned with working conditions related to toxic substances in use in the workplace.

It is said that law brings order to everyday life and affects the very fabric of our society. It is inevitable, that toxicologists and the practice of toxicology will be heavily influenced by law and this chapter will explore some of those areas of interaction, using the law in England and Wales as a basis for the discussion. The law in Scotland is different. However, since most UK law especially in the fields of public health, occupational health and safety and toxic substances control is European in origin, it will include a brief review of relevant European Union-wide law and where appropriate, mention will be made of key principles drawn from relevant other jurisdictions. This review is not exhaustive, but it begins with a brief overview of the legal system in England and Wales.

2 SOURCES OF LAW IN ENGLAND AND WALES

To provide something of a background, this section will briefly review the legal system and its operation.

2.1 The Common Law and Precedent

The United Kingdom is a parliamentary democracy. The principal legislative power lies with parliament, which is responsible for the provision of law through statute. However, not all statutes are applicable throughout the United Kingdom and may be limited to one or more jurisdictions, for example, England, Wales, Scotland and Northern Ireland.

The law in England and Wales has never been codified. To deal with this situation, the traditional approach has been that the courts seek to identify similar cases that have occurred in the past and argue whether or not these can be distinguished from the current case before the court. The doctrine of precedent, as it is known, enables the judiciary to make legal rules without reference to parliament. This form of law is known as common law and is based on historical practices of the judges, journeying between towns and cities to deal with cases in each place.

The outcome was based on what decisions were made in similar cases elsewhere in the jurisdiction, as well as who rendered the judgement in what court. Thus, precedent value was on similar circumstances being judged in the same level or higher court. This apparent complexity confers the advantage of significant flexibility, which is of immense value in areas of contract and civil liability.

Criminal law is about keeping order in society, as opposed to resolving disputes between parties, although others argue that the disputants are the criminals on the one hand and society on the other. The resolution of such disputes becomes so important for the good of society that the prosecutions are pursued by the state in the name of the people. As one might expect, criminal law is generally enacted in statute.

Within the legal system therefore, judges serve two quite different roles. They declare and develop the common law by analysing the legal arguments put before them. To do this, they are entitled to resolve both questions of law and questions of fact. They also interpret the meaning of acts of parliament and regulations, though to a much lesser extent than one might have originally believed.

2.2 Binding Precedent

Much legal analysis is based on distinguishing the present case from those similar cases that have been heard previously. As indicated above, this process is far from

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

simple and indeed it can only work if one is bound by former decisions. This is the nature of so-called binding precedent. For example, the opinions of those judges sitting at the top of the hierarchy of the courts count for more than those in the lower courts. The highest court in the United Kingdom is the Judicial Committee of the House of Lords. The decision of this court binds all lower courts. Decisions of the next echelon, the Court of Appeal binds all lower courts, but not the House of Lords, which is of course, superior to it. Ultimately, every judge in a parliamentary democracy must yield to elected representatives, who can overturn any judgement by simple statute.

2.3 Primary and Delegated Legislation

Current legislative practice is to establish broad principles in a parent act giving power to a minister to make regulations. Once drafted and finalized, these are laid before parliament and are only debated if objections are raised.

Both primary and delegated legislation carries binding legal obligations and sanctions. If this continues for decades, the law can become overly complex and impenetrably obscure. For these reasons, regulations, which are made under powers in a parent act, are reviewed and updated periodically. An example of this is the Control of Substances Hazardous to Health Regulations first brought into force in 1984 and updated at various times, most recently in 2002.

2.4 The Approved Code of Practice

A newer device relevant to making regulations an effective tool for enforcement is the Approved Code of Practice. These are drafted by the appropriate department of government and are attached to acts of parliament or enacted regulations. They direct courts and tribunals to refer to them in attempting to interpret relevant acts and regulations. They are particularly used in the occupational health and safety field. When consulting these publications, which are widely available, care must be taken to ensure that the document being studied is indeed an Approved Code of Practice, which is normally clearly stated on the front cover or in the introduction. They are not themselves law, being described as quasi-legislation, but they are effective in providing advice in readily understandable terms. Failure to follow the advice contained therein is regarded as prima facie evidence of a breach of law. However, it may be open to a defendant to prove that the countermeasures adopted, had the same effect as those recommended in the Approved Code of Practice.

2.5 Civil and Criminal Law

As mentioned above, criminal law provides for sanctions against those who offend against society.

Criminal prosecutions are brought by public officials such as the Crown Prosecutions Service or Health and Safety Executive inspectors. In Scotland, it is the procurator fiscal.

Unless qualified for legal aid, the defendant bears the costs of the defence. Penalties awarded to those found guilty range from fines at various levels, through community service, to imprisonment. Both companies and individuals can be subject to criminal sanction. Money paid in fines, is, for the sake of clarity, retained in the Court Service and is not paid out in compensation.

The principal function of civil law is to compensate the victim of a noncriminal wrongdoing. The claimant (formerly known as the plaintiff; or the pursuer in Scotland) is the individual who is harmed by the unlawful act. They sue for compensation for what they have suffered in the civil courts or occasionally in the tribunals.

The claimant may also seek a court order similar to an injunction (or an interdict in Scotland). This will be addressed to the defendant and direct them to return the situation to legality. Breach of any such order will be a contempt of court and will be punished according.

2.6 Sources of Law in the European Union

The United Kingdom is now a member of the European Union and as such has ceded much of its legislative power in certain fields to it. The power to make new law is given to the Council of Ministers and the European Commission. One minister from each member state attends Council meetings. Depending on the items set out in the agenda, this may be the Foreign Minister, Agriculture Minister and so on. The administrative arm of the Union is the Commission, located in Brussels. The judicial power is conferred on the Court of Justice of the European Community, based in Luxembourg. Procedures in this Court are very different from those in common-law jurisdictions. There is reliance on written representations and limited oral examination. The Court bases its procedures on French administrative law (*le droit administratif*). A key official of the Court is the Advocate General who provides advisory opinions to the judges.

Each member state sends one judge to the Court. Its principal task is to interpret the treaties and any secondary

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

legislation made with its authority. European Court of Justice rulings must be recognized and enforced by the courts of member states, but there is no appeal from its decisions.

2.7 Legislation in the European Union

Secondary legislation takes the form of regulations, directives and decisions. Regulations are mandatory. They have the force of law throughout the community, without the need to be ratified by the legislatures of each member state. Directives are binding as to the results to be achieved, but leave the choice of method of achieving the objectives to the member states. They, therefore, require domestic implementing legislation. The Consumer Protection Act 1987 was the main statute that implemented the principles set out in the Product Liability Directive.

These directives are frequently delayed in their implementation by member states. It is therefore not unusual for the Commission to bring the erring member state before the European Court of Justice for failure to implement a directive.

In Marshall vs. Southampton Health Authority (1986), the Court of Justice held that an individual employed by a government could sue that government under the provisions of an unimplemented directive as though it had been implemented, a privilege not available to nongovernment employees. In other words, the directive is directly enforceable in emanations of the state without 'domesticization' by implementing legislation.

The Court of Justice further developed the law in Francovitch vs. Italy (1992) when it was held that an individual may, in some circumstances, sue a government for damages for failure to enact a directive within the specified period.

Decisions are rulings, given by the Commission, in individual cases and may be addressed to a state, an organization or an individual. However, they are binding only upon the state, organization or individual to whom they are addressed.

Recommendations are persuasive, but not legally binding. The process of harmonization amongst the European Union states encompassed occupational health schemes. A case before the European Court of Justice (Grimaldi vs. Fonds des Maladies Professionelles, 1990) highlighted the plight of expatriate workers who developed conditions compensatable under the law of their homeland, but not in the country in which they are working. The Commission had made recommendations about compensation and called upon member states to introduce legislation to provide compensation to those affected by conditions with a proven causal link to work. However, the European Court of Justice held that the recommendation cannot confer rights on individuals, but must be taken into account by national courts when interpreting domestic legislation. A further recommendation included a list for governments to consider and called for immediate legislation to deal with scientifically recognized, occupationally related conditions. Almost 50% of that list was chemicals, and specifically metals, including cadmium, chromium, mercury, manganese and nickel.

The European law, therefore, affects issues of public health and safety, as well as toxic-substance control. Nowhere is this more obvious than in the new regulations that came into force, the so-called, REACH Regulations, which will be discussed next.

3 THE REACH REGULATIONS: A EUROPEAN UNION APPROACH

The so-called REACH Regulations are set to have a major impact on the European Communities chemical manufacturers, suppliers and users, not only in the European Union, but far beyond its borders. The acronym stands for 'Registration, Evaluation and Authorisation Regulations'. It is probably the European Union's most comprehensive and complex piece of legislation yet produced.

3.1 Background

Chemical-control laws have existed in Europe for many decades. One of the early directives applied to classification, packaging and labelling, dating from Council Directive 67/548/EEC (1967). In addition, there are over 40 additional Community-level laws which also regulate chemical safety. A principal advantage of the REACH Regulations is that it simplifies the complexity and confusion surrounding the prior legal framework for chemical-substances control and incorporates it into a single piece of legislation, dealing, at the same time, with the difficulties with implementation and enforcement. Cynics amongst us would wish to add a qualifier, 'allegedly'. The regulations run to over 800 pages and there is currently a United Kingdom government-sponsored consultation over enforcement, which is likely to involve a minimum of three separate agencies, an enforcement environment where multiple agency jurisdiction is not popular. Obligations involving information and registration were not introduced until 1981, but these requirements were only applied to substances brought to the market since then. The difference is not small, since an estimate of over 100 000 substances in significant production was left largely unreviewed. In the absence of testing and a review of usage, it is impossible to determine whether or not these chemicals are indeed being handled responsibly. Manufacturers may have sketchy knowledge of environmental and human

safety. Material safety data sheets may overstate the case. Frequently, downstream users receive inadequate information about the substances and their associated risks. Indeed, they may not be equipped to recognize the significance of those risks. This lack of information often results in environmental and health-protection problems. It is a widely held belief that chemicals cause a considerable measure of ill health. A lack of information makes it difficult to deal with the focus of public-health concerns. Many chemical entities and others of a more complex nature have been the focus of controversy, including bisphenol A, phthalates, brominated flame retardants and perfluorooctanoic acid.

The previous regulatory system was not conducive to innovation because of the different rules that apply to existing and new substances. REACH Regulations eliminates this discrepancy and establishes a single, and indeed, unique, legal framework for all chemicals in use in the European Community territory.

3.2 The REACH Regulations: An Overview

These regulations are to be distinguished from the normal sets of regulations in the British legislative environment. These are of EU origin. REACH Regulations has been described as one of the European Union's largest legislative projects. Without a doubt extensive, it is also complex and difficult to understand. However, that difficulty is primarily a function of its length.

The new regulations provide a unified framework for the control of toxic substances on the European market. The main purpose of the REACH Regulations is to improve environmental and health protection standards. Whilst these are most laudable objectives, one of industry's principal concerns is the high cost of compliance.

The basic principles of the REACH Regulations are set out below.

3.2.1 Registration

The centrepiece of the regulations is the requirement for registration. REACH Regulations will provide systematic information about relevant chemicals. The regulations define a substance broadly; it includes chemical elements and raw compounds in either natural or manufactured forms, including process-related impurities.

A manufacturer or importer of a substance is required to submit a registration dossier to the new European Chemical Agency based in Helsinki in Finland, if at least 1 tonne (the equivalent of 1000 kg) is manufactured or imported.

There are, however, certain exemptions to the registration procedure. For example, pharmaceutical preparations for human or veterinary use, or substances added to foodstuffs or feeds, as these are already regulated at the Community level to protect environmental and human health in equivalent ways.

The annexes to the REACH Regulations contain two lists of chemicals that are exempted from registration requirements. Annexe IV contains substances about which available information is sufficient to indicate that they pose only a minimal risk. This list includes such substances as carbon, nitrogen, water and sunflower oil. The list in Annexe V contains substances for which registration is considered irrelevant or unnecessary and includes minerals, ores and noble gases.

Manufacturers and importers must include in their information dossiers data about the chemical identity of the substance in question, its physicochemical, toxic and ecotoxicological properties, its classification and labelling, and the ways in which it is used. For chemicals with an annual production of 10 tonnes, a chemical safety report must be provided.

Not surprisingly, the data to be provided in the dossier is determined by the annual production or importation levels. The largest group is produced or imported in quantities of 1–10 tonnes per annum. There are four categories set out in the REACH Regulations:

- 1–10 tonnes per annum;
- 10–100 tonnes per annum;
- 100–1000 tonnes per annum;
- Excess of 1000 tonnes per annum.

The greater the quantities in question, the more stringent are the information requirements for the dossier. Only data on the substance's physicochemical properties, and on a few acute impacts on the environment and human health must be submitted for production or import of 1–10 tonnes per annum. Extensive testing is required if levels in excess of 1000 tonnes are produced or imported.

The aim of registration is to offer manufacturers the opportunity of proving that their product is safe in use. Testing requirements follow logically and are not inflexible protocols tiered rather than tailored to risk. Certain tests can be waived where appropriate to the circumstances. If, for example, there is no relevant exposure for expected employees or consumers, chronic toxicity testing may be waived.

Registration imposes obligations on manufacturers and importers, since they are the parties responsible for the safety of their chemicals. Importers and manufacturers therefore must seek to prove that their products are indeed what they claim to be, that is, safe to use. A second objective is that the results of testing may ultimately lead to the adoption of available control measures for safe use of the substances along the supply chain.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There is a suggestion prima facie, that this is a reversal of the burden of proof. As legalistic as this might sound, this is not so. It is illustrative of a basic principle. Under the old system, authorities of the member states determined the risks associated with any substance, with a view to justifying any protective measures which were to be prescribed. This process had to be of limited effectiveness, given the vast numbers of chemicals involved in modern business, limited competent staff available and resources of the authorities concerned.

Implementation of REACH Regulations will lead eventually to the development of a broad information base, which will be of great value to all stakeholders. New findings will be disseminated to stakeholders at relevant times. Manufacturers may be encouraged to improve their products, and users, their handling procedures.

There may also be a legal impact outside the general area of toxic substances control. For example, water- and soil-quality regulations are based on toxicological hazard criteria. Data in REACH Regulations will facilitate actions relative to such related areas. The position is, to some extent, analogous to the relationship between the regulations for consumer protection and occupational health and safety.

REACH Regulations introduces obligations for the transfer of information about toxic substances, properties and risk management measures throughout the supply chain. Under these requirements suppliers of a substance or a preparation must provide downstream customers with a relevant data sheet if the substance or preparation is classified as:

- Dangerous
- Persistent, bioaccumulative and toxic (PBT)
- Very persistent and very bioaccumulative (vPvB).

As under previous requirements, safety data sheets need to include information about potential hazards, first-aid measures to be taken in response to exposure cases, measures to be taken in case of fires, requirements pertaining to handling, storage, disposal and transport, physicochemical and toxicological properties. REACH Regulations therefore differs remarkably from the requirements under Section 5 of the UK Health and Safety at Work Act, and so on, since many of these dossiers will be subject to professional scrutiny and published information will hopefully be more likely to be based on firm evidence. In addition, the information requirements have a slightly different emphasis. Hopefully, the effect will be to have less 'over-anxious' reporting of hazards and precautions.

Under REACH Regulations, safety data sheets must incorporate exposure scenarios, based on the uses identified by the party who was subject to their registration obligations. These exposure scenarios are to include information about what types of exposure are to be expected by downstream users and about relevant risk-management procedures to be adopted in each case.

A party subject to registration obligations needs access to information about experience gained with use of the respective substance or substances. For this reason, REACH Regulations introduces requirements whereby downstream users in the supply chain must provide information to the manufacturers and others located upstream. In cases where the downstream user does not wish to inform a manufacturer, then they are not obliged to do so. One reason may be, for example, loss of competitive advantage. Whilst this might appear a gap in the flow of information, the use information must be provided to the European Chemicals Agency.

3.2.2 Evaluation

The European Chemicals Agency is the new Community institution responsible for the technical, scientific and administrative aspects of REACH Regulations. The Agency will be responsible for evaluation, together with the relevant national authorities. These procedures for evaluation are particularly worthy of note.

Two procedures can be distinguished, known as dossier evaluation and substance evaluation. The dossier procedure involves the Agency checking whether or not a registration dossier conforms to all applicable requirements, for example, whether or not it contains all necessary tests, or whether the data supplied are of adequate quality. Substances that provide reasons for concern are assessed thoroughly by the competent authority in the member state from which the registration originated. Such evaluations can result in the issue of substance prohibitions or restrictions required by the European Chemicals Agency.

3.2.3 Authorization

REACH Regulations provides for authorization procedures for substances of special concern. This group includes those classified as PBT and vPvB, as well as those with carcinogenic, mutagenic and reprotoxic properties. How precisely these will be applied in practice remains to be seen and in particular, whether or not one returns to a mechanism similar to the Delaney clause. Additional substances can be subjected to this authorization procedure if initial assessments indicate that serious impacts on human health or the environment are likely. The regulations indicate that this is particularly likely in the event of a substance being found to have endocrine-disruptive properties.

Workloads arising from this procedure, no one is in any doubt, will be significant. A practical management device, which will be applied, will limit the workload by use management. Thus, only uses of those substances that are listed in the annex to the regulations will be subject to authorization procedures. At a time to be decided,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

nonauthorized uses of chemicals on that list will be prohibited. The structure of the authorization procedure has given cause for considerable discussion. As a result authorizations will not be limited in time, but will be regularly reviewed to determine whether conditions for authorization are still being fulfilled. Thus, the door is ajar for the application of future research.

Within the REACH Regulations framework, the issue of substitution has, of course, become significant. Every application for authorization must include both an analysis of possible substitute substances or procedures, as well as an analysis of its technical and economic feasibility. Decisions on authorizations, similarly, will take into account the possibilities for substitution. This, of course, will be of relevance only in situations where risks are not being adequately controlled.

The concept of adequate control applies only to substances for which there is a 'derived no-effect level' (DNEL) or a 'predicted no-effect concentration (PNEC) value' cannot be determined from Annex I of REACH Regulations. Substitution obligations will not be imposed, therefore, in all cases. The authorization procedure itself will also provide incentives for substitution. After all, authorization procedures create costs and uncertainties for business. The market's response to a chemical which fails authorization, or perhaps incurs heavy restriction, might well illicit considerable negative publicity for a supplier. In contrast, alternatives which do not require authorization may develop considerable market benefits. There seems, therefore, a considerable business advantage to investment in REACH Regulations obligations.

Prohibitions or restrictions on substances and their usage are permitted under REACH Regulations. These measures certainly existed under earlier chemical control regimes. The procedures under REACH Regulations, however, are considerably simplified. Restrictions are intended to act as a safety net and their implementation is far more rapid than has been the case in the past.

3.3 The Impact of REACH Regulations

It is likely that REACH Regulations will bring advantages for innovation. Substance information collected within the registration procedure will be deposited in the European Chemical Agency's database, but unlike the Community's former ECDIN (Environmental Chemicals Data and Information Network) project, this will be available on the internet and to the public, with the exception of confidential information placed with the Agency during the process. Published information will include commercial designation, physicochemical properties, results of toxicological and ecotoxicological studies, and relevant DNEL and PNEC levels. Composition of commercial preparations, and information about relationships between manufacturers or importers and downstream users will not be included on grounds of confidentiality and commercial sensitivity.

A legislative initiative, such as this, will inevitably raise many concerns. The impact of REACH Regulations that is of most concern is the financial burden on industry. Although there may be business incentives for investing in obligations under REACH Regulations, some studies have also considered the benefits from environmental and human-health protection. Some Community-sponsored studies indicate potential savings within the healthcare sector of 50 billion euros in the next 30 years (Council Directive 67/548/EEC, 1967; European Commission, 2003). Such savings result from decreased rates of skin disorders, allergies and cancer. Environmental benefits were predicted as significant, but were not quantified in these studies.

In the past, special regulation was applied whenever it was deemed necessary. Historically, priorities were determined rather more on the detection of chemicals in new media or biological samples. The right priorities, it must be admitted, were not always made. The availability of key information at an early stage in the life cycle of the chemical is not believed to provide more explicit and valid bases for future regulatory action.

Decision-making in this area has always depended on advances in chemical analysis. Organochlorine compounds could not easily be detected until electron capture became available. The availability of analytical methodology and relevant information will both be regarded as significant contributors to accurate and reliable regulatory decision-making in the future. This must be potentially huge, given advances in microelectronics and improvements in the sensitivity of analytical methods.

Perhaps, the most meaningful impact of REACH Regulations will be its ability to introduce what is essentially a preventive regime to toxic-substance control. No longer will it be necessary for a substance to cause a problem before it is subject to regulation. REACH Regulations therefore, employs the combined benefits of anticipatory regulation and effective monitoring.

The 15 year ongoing testing process will have a significant impact in the science sector, specifically, toxicology and ecotoxicology, as well as industrial hygiene. Impact and exposure data worth in excess of an estimated 10 billion euros will become available. The insights gained from these effect-monitoring exercises will lead potentially to increased understanding of underlying pathogenic mechanisms and structure–activity relationships.

During implementation of REACH Regulations, there will be an increased demand for animal testing, but also it is hoped, an enhanced understanding of alternatives to animal experimentation. It is likely too, that an impetus will be given to computer simulation, QSAR (quantitative structure–activity relationship)-driven assessments

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and *in vitro* methods as the only techniques available to complete the necessary workload. The forthcoming databases may contribute to the validation of alternative methodologies. All such methods, however, will have clear limitations and should only be used within an appropriately defined context to achieve results consistent with the underlying philosophy of REACH Regulations. It is hoped that appropriate research will be stimulated to underpin the REACH Regulations concept and its future applications.

Industry will respond by promoting the development of safe chemicals and their application. REACH Regulations will provide the data for the emergence of a chemical market with minimal adverse impact on human health and environment. The availability of REACH Regulations data may provide a significant competitive advantage. Surprisingly, REACH Regulations is becoming viewed almost as a 'brand' for a safe chemical, as contributing to a competitive advantage for European manufacturers.

REACH Regulations simplifies the framework for moving research chemicals to actual applications and eventually to market. As it requires a systematic approach, this perhaps forms its greatest benefit. In keeping with its regulatory intent, existing substances will be subject to a broad range of prohibitions, restrictions and conditional authorizations, resulting in pressure to move towards substitution whenever practical.

The coupling of globalization and rapid information exchange reshapes the regulatory environments in many of the EU states and is likely to be continued as the implementation of REACH Regulations gathers pace. Moreover, the publicly available information, the wealth of new assessments and the exposure evaluations required will have an impact across the EU. It is, perhaps, for this reason that regulations, rather than a directive, have been chosen as the most appropriate legislative instrument.

REACH Regulations is likely to have a far-reaching effect on legal systems through its impact on liability. Assessment of liability may vary throughout different legal systems. However, issues of predictability of chemical damage remain key to these considerations. Such information will be readily available. When these requirements are violated, a defence against employee or consumer legal action becomes less plausible. This may affect producers and users both within and external to the EU and will be especially true for REACH Regulations substances under prohibition.

The European Chemical Agency will check dossiers for completeness and quality. When grounds for concern exist, the Agency can require intensive testing and can impose additional requirements. Through this process, contaminants may emerge which may help clarify decision-making going forward. The intervention of professionally qualified staff becomes important to the philosophy of REACH Regulations.

An authorization procedure is expected to apply to a substance producing a high level of risk. The list contained in Annex XIV will contain about 1000 substances and will provide candidates for environmental analysis. The outcome of this process will further refine the list.

3.4 Enforcement

It is said that there is no law without enforcement, and truly REACH Regulations cannot fulfil its declared intent without enforcement. REACH Regulations can only be enforced by competent national authorities. Each authority has a number of responsibilities under the regulations:

- Provision of advice to stakeholders through a 'help desk' facility
- Enforcement of compliance within their jurisdiction, at least reacting to 'whistle-blowing'
- Conduct of in-depth evaluation of selected prioritized substances and preparation of draft decisions
- Propose harmonized classification and labelling
- Identification of substances of very high concern for authorization
- Proposal of restrictions
- Nomination of candidates for membership of the European Chemical Agency's, committees on risk assessment and socioeconomic analysis
- Appointment of members to the forum for information exchange and meetings to monitor enforcement matters
- Liaison with enforcing organization in relation to downstream responsibilities.

Currently, the Department of the Environment, Food and Rural Affairs (DEFRA) is the lead government department on REACH Regulations for all policy matters, including enforcement, acting with the Department of Business Enterprise and Regulatory Reform (BERR), the Environment Agency, the Health and Safety Executive and the devolved administrations of Wales, Scotland and Northern Ireland. A second consultation paper, setting out the proposed process for enforcement and enforcing authorities, is currently under way. Briefly, it is proposed that elements concerning registration will be enforced by the Health and Safety Executive as competent authority. Supply-chain-related matters are likely to be enforced by the Health and Safety Executive and the Health and Safety Executive of Northern Ireland up until the point of retail sale. Thereafter, enforcement will be carried out by trading standards and consumer protection agencies. Use-related duties will be enforced by a range of enforcing authorities, using the existing regime, and enforcing authorities for health, safety and environment

legislation. The consultation will close in August 2008 and a report is expected by December 2008. It is likely that the report will set out powers, as well as specify the REACH Regulations offences and penalties for noncompliance.

The REACH Regulations will have significant impact on science, industry and commerce from the start of the phasing-in period. However, the adverse impacts perceived by industry are being pragmatically addressed through the phased implementation. Moreover, it has the promise of reduced environmental damage and improved human- health protection. Those promises will not be achieved without an effective and efficacious enforcement system, in the absence of which this immensely complex piece of legislation will fall into just another piece of Brussels bureaucracy.

4 THE TOXICOLOGIST AND EXPERT EVIDENCE

The evidence of experts may be crucial to the resolution of a dispute that is the subject of the case being heard by the court. Lay witnesses may only testify as to the facts that they have observed. As experts have special knowledge, they are permitted to give opinion evidence. A lay witness cannot say that a man was drunk, only that he was observed walking unsteadily and smelling of alcohol. A toxicologist is equally not permitted to say that a man was drunk, but he can say that he was able to estimate a blood alcohol of 140 mg per 100 ml in his laboratory and this was consistent with unsteady gait. Thus, expert witnesses are allowed, and even expected, to express an informed opinion on the matters referred to them. The toxicologist could, therefore, be justified in informing the court that the behaviour was consistent with the measured blood alcohol concentration.

4.1 Historical Background

The legitimacy of experts giving opinion evidence was settled once and for all in Folkes vs. Chadd (1782) where the defendants argued that the plaintiff's expert, one Thomas Smeaton, an engineer, gave an opinion, whereas the jury had to base their verdict on fact. The trial judge, Lord Mansfield, thought differently:

> *Mr Smeaton's … opinion is deduced from the facts, which are not disputed—the situation of banks, the course of tides and of winds and the shifting of sands … [he] understands the construction of harbours, the causes of their destruction and how remedied. In matters of science, no other witnesses can be called. … Of this, such men as Mr Smeaton alone can judge. Therefore, we are of the opinion that his judgement, formed on the facts, was very proper evidence.*

Lord Mansfield's decision achieved two things. First, he acknowledged the usefulness of expert witnesses and their evidence. Second, he accorded them a special place in legal proceedings, whilst at the same time, removing from them all vestiges of the role they had in deciding technical matters. Their place was in the witness box and not alongside the judge.

The increasing technical nature of civil disputes has led to an increase in the use of expert evidence. Increasingly, experts are called upon to act as advisors to barristers in drafting pleadings, in assessing the merits or otherwise of the case, and in directing cross-examination. In this section, the role of the expert in UK law will be reviewed. Toxicologists may be involved in many areas of law, but notably personal injury arising out of chemicals, occupational health and safety, product liability, employment law and a lot more besides. They may well be involved in criminal matters, including drink driving, traffic law, drug enforcement, criminal-liability issues, rape and murder, as well as criminal sanctions arising out of breaches of health and safety law.

External to the judicial forum, toxicologists may be involved in risk-assessment exercises and their subsequent management, as well as alternative dispute resolution (ADR) through expert determination and even mediation.

Before turning to the principles of the expert evidence, a brief review of some legal aspects might be of value.

4.2 The Law of Tort

The area of personal injury is a part of the law of tort, which means a civil wrong. This covers, generally, two specific areas, that of negligence and breach of statutory duty. The majority of tort actions are in negligence. However, the plaintiff, or more correctly, in today's terminology, the claimant, may only recover damages when there is negligence on the part of the defendant. Thus, the classic tort formula is as follows:

- The defendant owes a duty to the claimant
- There has been a breach of that duty
- Damage must have been incurred as a result of that breach.

The first element is usually easy to determine, for example, in the context of, say, employer/employee relationships. The second element is usually the subject of expert evidence.

The third element has a number of aspects to consider. First, the resultant damage must be directly caused by the putative chemical. Second, that damage must be

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

direct and not too remote. Third, the damage must be foreseeable.

There is extensive case law setting the parameters of the tort formula, as well as its subelements concerning damage. These however, are beyond the scope of this chapter.

Once the elements of the formula are satisfied, the judge will award the damages. Similarly, the calculus used is complex, being covered by a complex mixture of common sense, obscure rules and case law. Thankfully, it too goes beyond the scope of this chapter.

4.3 The Ikarian Reefer Principles

The principles of expert evidence have been set out in a classic case by Mr. Justice Cresswell (National Justice Compania Naviera SA vs. Prudential Assurance Co Ltd, 1993). These principles have become generally accepted as the classic statement of good practice. They were eventually incorporated into the Civil Procedure Rules, 1998, which swept away the old-style approach to expert evidence and is now the underpinning set of rules in UK practice. We will examine these principles in turn.

4.3.1 The First Principle

The first principle is set out in Mr. Justice Cresswell's judgement:

> *Expert evidence presented to the court should be, and should be seen to be, the independent product of the expert, uninfluenced as to the form or content by the exigencies of litigation.*

Few would object to this principle at first glance. However, form cannot be uninfluenced by litigation. The content demanded by judges today will contain certain elements, such as the report author's curriculum vitae to lay out the groundwork for the oral evidence of the person who will be subject to examination-in-chief and cross-examination in the witness-box. Similarly, the precise nature of the proceedings will direct the report-writer to address certain matters upon which the expert evidence is required. It is usual practice for lawyers to set the questions for the experts, the result being a sharply focussed report, with greater relevance to the court's needs. The involvement of lawyers in the drafting of the report was the subject of comment by Lord Denning, the Master of the Rolls (Whitehouse vs. Jordan, 1980). He was commenting on a joint report of two claimants' experts:

> *In the first place, their joint report suffers, to my mind, from the way it was prepared. It was the result of long conferences between the two professors and counsel in London and it was actually 'settled' by counsel. In short, it wears the colours of a special pleading, rather than an important report. Whenever counsel 'settle' a document, we know how it goes: 'We had better put this in'; 'We had better leave this out'; and so forth.*

The case went on appeal to the House of Lords, where Lord Wilberforce (Whitehouse vs. Jordan, 1981) commented on this judgement in the following words:

> *While some degree of consultation between experts and legal advisers is entirely proper, it is necessary that expert evidence presented to the court, should be and be seen to be, the independent product of the expert, uninfluenced as to form or content by exigencies of litigation.*

Thus the principle of independence is confirmed by the UK's highest court. Whilst it is quite proper for a lawyer to ask for a passage to be omitted, whether or not the expert should accept this instruction depends on the implications. Asking for a passage to be omitted is perfectly justified if the issues covered are not included in the pleadings. It would not be so justified, if removal of the passage distorted the report-writer's true meaning. The difficulty arises when lawyers ask 'catch-all questions' and the expert must report on an issue which may bring the case to an end. In this situation, the expert must remain true to their belief, on the evidence available, but be content to have avoided significant public expenditure.

It is also permissible, for lawyers, for a draft report to be clarified or for material to be developed further or the content to be arranged differently. This is sometimes needed to assist in presenting the case to the judge, whilst the expert is undergoing oral examination in court. The expert is best advised to confine themselves, as far as possible, to the questions posed by the lawyers. Throughout the scrutiny of their report by counsel, the expert has a duty to maintain a proper balance of truth.

4.3.2 The Second Principle

Cresswell sets out the second principle in the following terms:

> *An expert witness should provide independent assistance to the Court by way of objective unbiased opinion in relation to matters within his expertise (See Polivitte Ltd—v- Commercial Union Assurance). An expert witness in the High Court should never assume the role of an advocate.*

The fact that this warranted a comment at all suggests that biased opinions and reports that bordered on advocacy were common occurrences. Certainly there were 'hired guns', but these are now far fewer than before.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There are a number of expert bodies beginning to develop professional standards among experts so that the court may have confidence in their integrity.

Giving unbiased opinions is not equivalent to giving 'independent assistance' for the court. Experts are appointed by parties and paid by one of them or jointly. They are engaged by the parties to provide oral evidence, advice on case management and trial litigation. A more balanced case was put forward by Garland J in: Polivitte Ltd vs. Commercial Union Assurance Ltd (1987)

> *I have almost considered the role of an expert to be two-fold: first, to advance the case of the party calling him, so far as it can properly be advanced on the basis of information available to the expert in professional exercise of his skill and experience; and secondly, to assist the Court, which does not possess the relevant skill and experience in determining where the truth lies.*

4.3.3 The Third Principle

The third principle is set out in the following words:

> *An expert witness should state the facts or assumptions upon which his opinion is based. He should not omit to consider the material facts which detract from his concluded opinion.*

This principle is fine, provided that it is qualified by a statement limiting it to the questions posed to the expert. An expert is not required to speak out or report issues that are not pleaded in the case. This can place experts in very difficult situations. It is a common mistake that is easily avoided.

4.3.4 The Fourth Principle

That experts should stay within their expertise is a statement of the obvious, but it is very difficult in modern science and toxicology is no different. The fourth principle is:

> *A witness should make it clear when a particular question falls outside his experience.*

This principle has become something of a *cause célèbre* in the UK. The problem arises when, say, toxicologists have to consider toxicological evidence. Mere skill in assessing epidemiological data may be sufficient. But toxicologists may find themselves in difficulty when discussing epidemiological literature. The issue appeared in a Scottish case before a senior judge, the Lord Ordinary (Main vs. McAndrew Wormald Ltd, 1988). The case concerned a man, now deceased, who had been exposed to asbestos during his lifetime. During the appeal, it was held that it was permissible for experts to refer to literature and in particular, to rely on epidemiological literature, though they were neither epidemiologist nor statisticians.

In his judgement, Lord Nimmo Smith in McTear vs. Imperial Tobacco Ltd (2005), delivered a full résumé of the expert evidence in a matter where the pursuer (the claimant in England and Wales) sought damages against a tobacco company for the death of her husband from lung cancer. He failed to accept the decision in the Main case as authority for introducing evidence not within the expertise of those experts so instructed. He said that there was still a requirement that published material fell within the expertise of the witness and that would be decided on the facts of the case. He highlighted the need for epidemiology to be fully and properly tested.

4.3.5 The Fifth Principle

The fifth principle was enunciated in Cresswell 's judgement in the following words:

> *If an expert's opinion is not properly researched before he considers that insufficient data is available, then this must be stated with an indication that the opinion is no more than a provisional one. In cases where an expert witness who has prepared a report could not assert that the report contained the truth, the whole truth and nothing but the truth, without some qualification, that qualification should be stated in the report.*

This latter notion was drawn from the remarks of Staughton LJ in Derby vs. Weldon (1994), which are as follows:

> *I do not think that an expert witness, or any other witness, obliges himself to volunteer his views on every issue in the whole case when he takes an oath to tell the whole truth. What he does oblige himself to do is to tell the whole truth about those matters which he is asked about.*

This principle improves, therefore, the transparency, as well as the management of the litigation. It reminds the witnesses of the need to tell the truth and in this simple admonition attempts to remove the last vestiges of a 'combat' metaphor. This is not a fight, just an attempt to dispense justice.

4.3.6 The Sixth Principle

The sixth principle is set out as follows:

> *If after the exchange of reports, an expert witness changes his view on a material matter having read the*

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

other side's expert's report or for any other reason, such a change of view should be communicated (through legal representatives) to the other side without delay and when appropriate, to the court.

Curiously, it is apparent that when this judgement was written, disclosure of the change of opinion to the other side was not mandatory. Counsel had up to the last minute to decide whether to summon a witness or to rely on a report. However, as stated, the principle was an aspiration of Cresswell J, the judge, and has now been incorporated into current practice.

4.3.7 The Seventh Principle

The seventh and last principle is set out in the following terms:

Where expert evidence refers to photographs, plans, calculations, analyses, measurements, survey reports or other similar documents, these must be provided to the opposite party at the same time as the exchange of reports.

This, of course, is another statement of good practice aimed at promoting transparency.

5 THE CIVIL PROCEDURE RULES

The Ikarian Reefer principles set out above are all regarded as good practice and have been met with approval by the judiciary in their incorporation into the Civil Procedure Rules, 1998. Prior to this date, there was considerable judicial unease about the behaviour of several experts in civil cases. The need for experts was certainly recognized, but they were seen as a source of excessive expense, delay and redundancy.

This brought the old subject to the attention of Lord Woolf, who chaired a committee providing a report to Government, seeking to improve access to justice and reducing the costs of litigation (Lord Woolf, 1996). The Civil Procedure Rules, 1998 apply throughout the civil, as distinct from the criminal, jurisdiction in the UK. For example, they apply in County Court, the High Court and the Court of Appeal, as well as in lesser tribunals. Their aim is to increase cooperation between the parties in the conduct of proceedings and thus, lead to the swift dispensing of justice.

Exposure to lawyers, in both reality and the media causes one to hear such phrases as: 'the judge's track record'; 'beating my learned colleague'; 'my strategy' or 'the tactics for the case'. The lay person would be forgiven if this has led them to the impression that pursuing a legal action is nothing more than a game of skill. Lord Donaldson, Master of the Rolls (MR), has some advice for anyone harbouring such thoughts (Davies vs. Eli Lilley & Co, 1987):

Litigation in this country is conducted 'cards upon the table'. Some people from other lands regarded this as incomprehensible. 'Why,' they ask, 'should I be expected to provide my opponent with the means of defeating me?' The answer, of course, is that litigation is not a war, or even a game. It is designed to do real justice between the appearing parties and if the court does not have all the relevant information, it cannot achieve this objective.

Most people seek a 'fix' to their grievance. Very few deliberately set out to provoke litigation. Consequently, it may be a considerable time before the notion of legal action becomes relevant. At this stage, an expert report may help by assessing the strength of the case or providing advice on settlement terms to the claimant.

5.1 Experts Under the CPR

The Civil Procedure Rules (CPR) strictly limit the number of experts called by each side, often to one medical and one other. Consequently, some lawyers appoint so-called 'shadow' experts to assist in assessing the case and even settling the pleadings.

Communications between expert and legal advisor are, of course, privileged and should not be disclosed without consent.

The functions of the expert are set out below:

- To act as advisor to one party and provide a preliminary report
- To act as an expert witness and provide a written report to the court
- To help draft pleadings
- To advise on documents for, or provided during, disclosure
- To comment on draft questions for the opposition's experts
- To narrow outstanding issues in discussions with experts
- To advise on negotiating a settlement.

Once litigation has commenced, the CPR apply, especially if a report is made to the court. If the expert was previously involved in the case as an advisor, fresh instructions must be issued.

Under Rule 35.4 of the CPR, the court's permission is required to appoint experts. This usually follows an early case conference or a pretrial review. These are normally conducted by a district judge and occur at intervals during the pretrial process. Under Rule 35.5 (i), the report must be written.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Today, the expectation of the court is that a single expert will be appointed to advise the court. The authority to do this is set out under Rule 35.7. There is opposition to this relatively new departure in expert-witness management from the legal profession. If parties cannot agree to the so-called 'single joint expert' under Rule 35.8, the court is empowered to select an expert from the list provided by the parties or to direct appointment by some other means.

Objections are usually dealt with by the district judge. Occasionally the Court may make other directions to the expert, which will be set out in a written order. These might include, for example, permitting the parties to ask written questions, or more often to direct that experts meet. The single joint expert will have their neutrality and independence recognized and is therefore unlikely to be attacked in court. Communications between a single joint expert and the parties are not privileged for obvious reasons.

If parties agree and there are sufficient reasons to support the view a district judge may permit the appointment of separate experts for each side. The days of the 'professional' expert witness are long gone. An expert with standing in their primary profession as a toxicologist, or whatever, are more likely to be appointed than one who was not.

In the case of party-appointed experts, each party bears their own costs with respect to their experts. In the case of a single joint expert, the parties are jointly and severally liable for the costs.

Changes in the justice system in the UK now permit lawyers to accept instructions on the basis of what is known as conditional fee arrangements. Broadly speaking, lawyers accept cases and legal expenses insurance covers the costs of the litigation. Naturally, for the lawyers, the strength of the case becomes crucial. Experts should not accept instructions under these arrangements and their fees should be guaranteed in full. To do otherwise would bring their independence into doubt.

It is clear that the court is determined to control expert evidence and therefore, places considerable emphasis on the written report. The powers to restrict expert evidence are set out in Rule 35.4. The court's permission is required under 35.4.1. Applications for employment of expert evidence must identify the specific field of expertise and where practical, the expert, as set out in Rule 35.4.2 (a-b). Lastly, the report must, of course, be written.

5.2 Accepting Instructions

The importance of the written report is underlined by the often-quoted advice that experts should never accept instructions for which they cannot deliver the report in due time. To do so risks judicial displeasure, which is inevitably not conducive to contentment. In deciding whether or not to accept instructions, the reader might wish to consider:

- Are the issues in dispute their professional knowledge, experience and competence?
- Is the reader confronted by any relevant personal or professional matters?
- Is the reader's evidence likely to help the court?
- Can the reader meet the timescales involved within their personal and professional schedules? Booked holidays are not an excuse acceptable to a judge.

If the answers to these questions are in the affirmative, then the report can be accepted.

5.3 Writing the Report

The report should be written in simple language and with wide margins. This permits marginal notes by both the judge and counsel. A suggested format is set out below, though not all sections are relevant or necessary on all occasions. A case reference number should be included on the cover sheet. Qualifications and experience of the writer should be included, as well as any relevant literature, any detailed experiments carried out and a list of those who assisted in their conduct. Paragraphs should be numbered to facilitate reference. This writer's personal preference is for numbering sequentially. The report should contain a table of contents and be page-numbered. Finally, it should contain the expert's declaration, which is set out below. As can be seen, this is a statement of compliance and truth.

The report format is designed to be judge-friendly. Being what is today called 'CPR-compliant', the use of this format is not a surreptitious marketing tool, but a characteristic that is sought by judges. If the report is not CPR-compliant, this may well influence the weight given by the judge to the report in assessing the evidence.

Once the report is completed and submitted, questions may be asked from either side to clarify or seek to correct factual issues. If appointed as a single joint expert, the replies need to be copied to the other party.

As far as the format of the report is concerned, the following sections are needed:

- Cover sheet
- Table of contents
- Headers—name of expert, date, field
- Chronology
- Introduction
- Background to dispute
- Issues for consideration—expert's instructions
- Method of enquiry
- Documentation

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Discussion/commentary
- Conclusion
- Opinion
- Declaration.

There are various versions of the expert's declaration and the one below has been used by the writer for some years:

I, … (Name), declare that:

I understand that my duty included in my providing written reports and giving evidence is to help the court and that this duty overrides any obligation to the part who has engaged me.

I confirm that I have complied with my duty.

I believe that the facts I have stated in this report are true and that the opinions I have expressed are correct.

I have endeavoured to include in my report those matters of which I have knowledge, or of which I have been made aware, that might adversely affect the validity of my opinion.

I have indicated the sources of all information I have used.

I have not, without forming an independent view, included or excluded anything which has been suggested to me by others and, in particular, my instructing lawyers.

I will notify those instructing me immediately and confirm in writing if, for any reason, my existing report requires any correction or qualification. I understand that:

- My report, subject to any corrections before swearing as to its correctness, will form the evidence to be given under oath;
- I may be cross-examined on my report by a cross-examiner, assisted by an expert;
- I am likely to be the subject of public adverse criticism by the judge, if the court concludes that I have not taken reasonable care in trying to meet the standards set out above.

I have not entered into any arrangement where the amount or payment of my fees is in any way dependent on the outcome of the case.

5.4 Case Management

Thereafter, involvement of experts will depend on the outcome of the pretrial review, conducted in the High Court by a master or a district judge. This review seeks to limit, or conversely, extend the expert evidence. By this approach, the court seeks to avoid unnecessary evidence or witnesses. From this point on, the report cannot be edited. The practice of side letters has also been swept aside.

At this point, the court directs deposition and exchange of documents. Disclosure of documents used to be the basis of an application. Nowadays, it is the outcome of a pretrial review, which, in effect, is a court order. It applies to all documents under the control of the parties upon which they intend to rely. The documents in one party's possession may affect their own case adversely or another party's. Conversely, it may support it. In essence, the disclosure is no longer automatic and its implementation is strictly controlled in both its nature and extent, by the court.

5.5 Conference in Counsel's Chambers

At some time prior to trial, there will be a meeting of the principal individuals involved in each counsel's chambers. This is termed a 'conference' and may involve a wide-ranging discussion of evidence and specifically reports, approaches to the case, liability, risks and so on. The conference will be attended by each party concerned, any insurance representative, instructing solicitors and, usually, as many experts as are involved. This helps everyone concerned to get a better view of the case's strengths and weaknesses. The presence of the experts ensures that all parties are fully informed about the risks involved. More particularly, the discussion may throw up issues for discussion, at the next, and often final, stage of the process—the meeting of experts.

5.6 The Meeting of Experts

The notion of the meeting of experts prior to a case is not new, they were often held under the 'without prejudice' rule. They were usually controlled by lawyers, either through the agenda or even chairing the meeting. They were exceptional. Under the CPR, they are very much more routine and help move the case towards agreement. The agenda is usually set by the experts and not the lawyers. Lawyers are not usually present at the meeting, but they may ask for specific issues to be discussed. Unless the case is particularly complicated, a meeting need not necessarily take place. Under these circumstances, the experts can rely on an extended telephone conversation.

The aim of this exercise is to agree a memorandum of what issues are agreed between the experts and what are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

not. Thus, in most cases, experts have concluded their work at this point and advise the court. This avoids the unnecessary expense of serving a summons and bringing them to court, not to mention the significant additional costs involved.

5.7 Summary

Whilst it is very much a personal matter whether one wishes to enjoy this work or not, there are certain important considerations. First, involvement in expert-witness work helps develop a rigorous approach to problem-solving skills. Second, it improves research and critical appraisal skills. Third, one has made a contribution, which can be seen to influence policy. Fourth, one's knowledge can be subject to the rigorous scrutiny of a barrister, trial lawyer or even a judge. Notwithstanding the financial rewards, involvement in expert evidence work is very much worthwhile.

6 WHISTLE-BLOWING AND THE PUBLIC INTEREST

Consider the toxicologist, employed by a chemical supplier. His employers have decided to begin importing a pesticide that is to be used for aerial spraying of crops. During his preparation of the REACH Regulations dossier, his team becomes aware of two issues. First, there have been reports of outbreaks of unexplained neurological disorders in three countries, where the pesticide has been used. Second, there is some laboratory evidence of ecotoxicity.

He considers the evidence significant and notifies his senior management of his very serious concerns. However, the response to his briefing paper comes back indicating that the company executive management has pinned their forecasts for company profits on the import of this substance and need therefore, to bring it as quickly as possible to the European market place. His senior manager tells him in no uncertain terms that his loyalty to their mutual employer is expected and the likelihood of his concerns actually coming to fruition is generally regarded as minimal. The dossier is required and he is told not to include the adverse human-health effects or ecotoxicity.

Our company toxicologist is left in something of a moral dilemma. His own moral compass will probably encourage him to lean more towards disclosure on the grounds of public safety. However, he will also ask about his relationship with the company and the small matter of the confidentiality clause that the company inserted into his contract. Then there are other matters.

He needs to support this wife and three children. With his youngest child joining his older siblings at university in the next academic year, he cannot afford to lose his job. When the dossier is sent to the Health and Safety Executive and the European Chemical Agency, there is no mention of neurological disorder or ecotoxicological issues.

6.1 An Ethicist's View

How should he have behaved? He has tried talking to his senior management, but to no avail. What should he do now? Should he distance himself from the situation and accept it as a *fait accompli,* a situation beyond his ability to intervene? Should he disclose the true situation to the Health and Safety Executive, the competent authority and/or the Agency in Helsinki? He wants to do the right thing, but what is the correct way to handle the situation and how does he get there? A philosopher and applied ethicist, Steare, has suggested a simple framework to help decide what is right (Steare, 2007). Steare sets out the following five questions:

- What are the rules?
- How do we act with integrity?
- Who is this good for?
- Who could be harmed?
- What is the truth?

A useful starting point for our toxicologist might be to apply these questions to the situation.

The rules and laws about public disclosure are drafted to cover a large range of situations. They are therefore, of necessity, indistinct. Breaching the company confidentiality agreement may not be illegal, but this does not mean that it is right. If the law is silent on the subject, an ethical statement might help.

The preamble to the Code of Ethics adopted by the Society of Toxicology on 31 January 1985 and revised on 1 June 2005, reads:

> *The Society of Toxicology is dedicated to developing and communicating knowledge to improve the health and safety of living beings and to promote the environment upon which we depend. … To obtain this objective, each member must maintain high ethical standards, recognise a duty to share this knowledge with the public and be a thoughtful advocate for human, animal and environmental heath. To this purpose, this Code requires a personal commitment.*
>
> (Society of Toxicology, 1985).

The Code of Practice attached to the Victorian Occupational Health and Safety Act, 2004, requires the professional occupational health and safety member to point out to senior management the problem, potential

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

consequence and the member's ethical and legal obligations. The professional member is then exhorted to inform the third party, having sought the advice of senior colleagues and informed their senior management of his action. Professional members are then protected by the Whistleblowers Protection Act (2001). There appears to be added weight to the protections of our whistle-blowing toxicologist in the State of Victoria, where they have the very clear protection of a legal framework.

The Eurotox Code of Practice requires it members to communicate:

> *in a timely and responsible manner with regard to the significance and credibility of available data, abstain from professional judgements influenced by conflict of interest, economic as well as "academic" in connection with special interest groups…*
>
> (Eurotox, 2009).

This has been a brief review of several ethical statements. It seems that the principal theme remains constant, however, that a professional toxicologist should not participate in any attempt to distort the meaning of any scientific communication either by action or inaction. The professional view seems, therefore, to argue in favour of public disclosure.

One might expect professional toxicologists to act with integrity. What precisely does that mean? Every individual has a series of values or principles, which drives their view of life. This is often called, by the psychoanalyst, their 'world view'.

These principles guide us to what is right. When our behaviour is consistent with our 'world view', we act with integrity. If those principles are just 'talk', we behave with hypocrisy. Law and rules of ethical behaviour are imposed from external sources, whether state or professional organizations, but our integrity comes from within.

We now come on to more familiar ground, as we have to deal with the calculus of benefit or harm. For each course of action, whom would our toxicologist harm and whom would he benefit? The difficulties of carrying out this calculus are the limits that need to be set. It is only really helpful if they are balanced across the widest possible range of stakeholders and thus, our toxicologist needs to identify that range of stakeholders before setting out the harms and benefits. This, of course, is the fundamental thinking behind the so-called 'stakeholder analysis'.

Lastly, there is the matter of truth. One is reminded of Mahatma Gandhi's famous quotation:

> *There is no God higher than truth.*

Disclosure does not depend on whether these reports are convincing or not. The actual decision-making lies outside the company and should not be usurped by it. If the reports were flawed, our toxicologist should point this out and a critique of the evidence be included. Most readers would agree that the right thing is to disclose.

However, increasingly, society is recognizing the value of this activity called whistle-blowing as a form of internal policing and, as we have seen, is giving the disclosure, under certain circumstances, statutory protection. In the UK, this is provided generally by the Public Disclosure Act, 1998. This section will provide an overview of the Act and whistle-blowing in general.

6.2 Whistle-Blowing: The UK Position

The media will have provided a general appreciation of the nature of whistle-blowing through their coverage of high-profile cases. At its most simplistic, whistle-blowing occurs when an employee or other worker provides certain types of information, usually to the employer or a regulator, which has come to their attention through work. The whistle-blower is not usually directly personally affected by the danger or illegality. Whistle-blowing occurs, therefore, when a worker raises concern about danger or illegality that affects others, for example, members of the public.

The key piece of legislation is the Public Interest Disclosure Act, 1998. In general, workers should be able to make disclosures about wrongdoing to their employer, so that problems can be identified and resolved quickly within the organization. The Act mainly takes the form of amendments to the Employment Rights Act, 1996 and contains provisions about the kinds of disclosures which are protected and the persons offered protection by the Act.

6.2.1 Protected Persons

The provisions introduced by the Act seek to protect most workers from being subject to detriment by their employer. Detriment may include denial of promotion, facilities or training opportunities, which the employer might otherwise have offered. If dismissed, employees may make an application before an employment tribunal for unfair dismissal, if they have made a protected disclosure.

Contracted workers are not employees and may not therefore apply for unfair dismissal before an employment tribunal. They may, however, complain of being subject to detriment.

With limited exceptions, the provisions protect the following categories:

- Those working under contracts of employment
- Those who work personally for someone else, a so-called 'worker's contract', but are not self-employed in the proper meaning of the word

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Home workers;
- Certain agency workers
- National Health Service practitioners
- Certain categories of trustees.

The list of protected persons may be revised at any time, usually through an Order in Council. This is a flexible way of updating a statute without the necessity of drafting a bill or finding time within the parliamentary session. When seeking information, therefore, it is important to obtain the current position as the scope of these measures can equally be changed by case law.

6.2.2 Qualifying Disclosures

Qualifying disclosures are disclosures of information, which the worker reasonably believes tend to show that a specified event took place at some time in the past, was happening in the present or is likely to happen in the future. These events include:

- A criminal offence
- A breach of a legal obligation
- A miscarriage of justice
- A danger to the health and safety of any individual
- Damage to the environment
- Deliberate covering up of information tending to show any of the above five matters.

Most of these will be relevant to the toxicologist, with a possible exception of the miscarriage of justice.

The employee making the disclosure must have a reasonable belief that the information tends to show one of the events identified above for it to constitute a 'relevant failure'. That belief, however, need not be correct. The worker must, however, demonstrate that it was reasonable to hold that belief at the time of disclosure, given all the circumstances.

Even if the relevant failure took place oversees, or where the relevant law was not that of the United Kingdom, the Act still applies. If the worker committed an offence in making a disclosure, as might be the case if he were statutorily forbidden to do so, for example, under the Official Secrets Act, 1989, the disclosure does not qualify for protection.

Any information acquired, relevant to potential litigation, is privileged and should not be disclosed. If that information was disclosed by a legal advisor, in the course of managing a case, it would be protected. However, if it was made by a secretary, it would not.

6.2.3 Protected Disclosures

A qualifying disclosure would be a protected disclosure when it is made:

- To the worker's employer; either directly to the employer or by procedures authorized by the employer for that purpose
- To another person whom the worker believes to be solely or mainly responsible for the relevant and
- The worker acts in good faith.

Disclosure to the employer may well lead to rapid resolution of the problem by the individual best placed to do so. However, an authorized procedure may be adequate. Many companies now have whistle-blowing policies, designed to facilitate confidential disclosures by staff, often through the human-resource department or mediated via a nominated director. A slight variation of this occurs in some companies in Europe who appoint, say, an external academic, as an ombudsman. This particular mechanism works extraordinarily well. Simple procedures that are easy to use, readily accessible and promoted by the company are more likely to result in internal disclosure to the employer in preference to externally. In drawing up these procedures, negotiators must take account of the best way to secure trust and confidence in their staff, to ensure that their procedures will be used. For these reasons, joint negotiation will ensure participation by the workforce and their representatives.

6.2.4 Making a Qualifying Disclosure to a Prescribed Person

Under the Public Interest Disclosure Act, workers concerned about wrongdoing or relevant failures can make disclosures to a person or a body which has been prescribed for the purpose of receiving disclosure about the matters concerned. A qualifying disclosure will become protected, provided that:

- The disclosure is made in good faith
- The individual making the disclosure reasonably believes that the disclosure and any allegation arising from it are substantially true
- They reasonably believe that the matter falls within the description of matters for which the person or body has been prescribed.

In the case of our toxicologist, the Health and Safety Executive might be responsible for the people receiving the pesticide, storing, transporting and applying it. In respect of the community impacted by the spraying, the Environment Agency would be appropriate. Space does not permit detailing the persons/bodies and the relevant areas of concern. An interested reader is referred to the original Act. If a disclosure is made to a lawyer in the course of obtaining legal advice, provided it is qualified, it will be protected without further condition. If the employee is on the staff of a government organization, including a nondepartmental public body, any qualifying disclosure made under the conditions set out above, to a

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

government minister, will be treated as protected, whether made directly or through government officials.

6.2.5 Serious Failures

Conditions are varied when making a qualifying disclosure about an exceptionally serious failure. It would be a protected disclosure if the person:

- Makes the disclosure in good faith
- Reasonably believes that the information disclosed, any allegation contained therein is substantially true
- Does not act for personal gain.

It must be reasonable for the disclosure to be made in all circumstances, having regard, in particular, to the person to whom the disclosure is made. The relevant failure must be exceptionally serious as a matter of fact and not simply that the person making the disclosure reasonably believed that this was so.

6.2.6 Conditions for the Protection of Disclosures

Qualifying disclosures become protected when the appropriate conditions are met. First, the person making the disclosure must:

- Make the disclosure in good faith
- Reasonably believe that the information and any allegations contained therein are substantially true
- Not act for personal gain.

In addition, one or more of the following conditions must be met:

- The individual reasonably believed that he would be subject to a detriment by his employer, if the disclosure were to be made to his employer or to a prescribed person
- In the absence of an appropriated prescribed person, the person making the disclosure reasonably believed that disclosure to the employer would result in the destruction or concealment of information about wrongdoing
- The person making the disclosure had previously disclosed substantially the same information to his employer or to a prescribed person
- It must be reasonable for the disclosure to be made in all the circumstances.

In reaching decisions about statutory protection, the employment tribunal needs to consider a large number of factors to determine whether or not the disclosure was reasonable. The first might be the identity of the person to whom the disclosure was made. Thus, it may be reasonable, under the circumstances, to disclose to a professional body with responsibility for professional standards in a particular field, for example, toxicology and medicine. Second, an obvious consideration is the seriousness of the relevant failure and whether or not this is continuing, or is likely to recur. It may be significant if the disclosure breaches the employer's duty of confidentiality to others, for example, confidentiality about a client and proposed purchases which might directly impinge on market advantage, a recognized concern under REACH. Third, an employment tribunal might consider what action might have been taken had disclosure been made previously to the employer or a prescribed person. Last, whether or not the worker complied with any internal procedures, approved by the employer, may be considered in the context of the tribunal.

6.2.7 Health and Safety Matters

The Employment Rights Act, 1996 provides, in Sections 44 and 100, protection for employees who, in certain circumstances, raise concerns about, or take action in connection with health and safety matters. Under these provisions it would be unfair to dismiss employees who act to protect themselves or others from serious and imminent danger. The new provisions under the 1998 Act, therefore, simply complement those contained in the earlier 1996 Employment Rights Act.

6.2.8 Contractual Duties of Confidentiality

Our toxicologist was concerned about the confidentiality clause in his employment contract. Any provision in an agreement between an employer and an employee that prevents the latter from making disclosures protected by the 1998 Act is void. This applies to any agreement between the two parties and includes, therefore, a contract of employment or separate agreement and this, in turn, includes agreements settling claims under the Public Interest Disclosure Act, 1998.

6.2.9 Dispute Resolution

The Employment Dispute Resolution Act came into force on 1 October 2004. It requires employers to follow a minimum three-step process to promote internal resolution of the dispute, whether or not it concerns dismissal, disciplinary or grievance issues. Where both parties have failed to adhere to these procedures, employment tribunals will impose financial penalties. However, it differentiates between a grievance and protected disclosures. A formal grievance is not a necessary prelude to making a protected disclosure. The statutory minimum grievance procedures only apply to a protected disclosure if the employee actually intends that the disclosure constitutes the substance of a grievance to raise with his employer.

6.2.10 Employment Tribunals and Remedies

The provisions of the Public Interest Disclosure Act protect both employees and workers. Both can complain that they have been subjected to detriment by their employer for making a protected disclosure. An employee who is dismissed can make a claim for unfair dismissal. In the case of a worker who is not an employee, whose contract was terminated in view of his protected disclosure, a complaint can be made of having been subjected to detriment. The complaint must be made within three months, but the time is extended in connection with the statutory dispute-resolution process. It can also be heard if the tribunal believes it was not reasonably practicable to have the complaint made within the three month timeframe and it has nonetheless been made within a time period which they consider to be reasonable.

For unfair dismissal claims, interim relief is available, where the complaint is made within seven days from the effective date of termination. Where such a complaint is upheld, it is open to the tribunal to order reinstatement or redeployment, as well as payment of compensation. If a worker's claim is regarded as well founded, the tribunal may make a declaration to that effect and order compensation.

7 CLAIMS MANAGEMENT

The advent of increased access to justice and other aspects of deregulation have led to the evolution of a claims-management industry. One particular measure of interest is the ability to refer cases to other solicitors for a fee. This is not reflected, for example, in the medical profession. Nightly, on television, there are advertisements encouraging those who have had an accident or developed an illness attributable to work to pursue the person or company responsible on a 'no win, no fee' basis. Viewers are given the impression that claimants have nothing to lose and the potential of a huge financial windfall to come. They have become, in the UK, the pariahs of the law. Claims farmers have become the butt of much criticism, particularly when the Lord Chancellor blames the rise of compensation on their activity.

Many of the cases they offer to bring on the part of clients have little merit and are not really likely to get to trial. Some claims farmers exploit their client's misfortunes to encourage them into pursuing the flimsiest of law suits. Advertisements are to be found in shopping centres, on television, on the back of passing busses and on the pavements of our cities.

Many claims farmers are not lawyers, but entrepreneurs who refer to a captive panel of solicitors, who cut their cost for a guaranteed flow of cases. The essence, of course, is to reduce costs and this is often achieved through the use of nonlawyers and administrative staff to carry out the routine, day-to-day and low-level work, referring to professional lawyers when necessary. In the UK, they are often seen representing clients in tribunals, which is perfectly legal.

The worst kind of claim farmer is the one who encourages their client to take out expensive cost-insurance to cover the eventuality of having to pay their opponent's costs. In the event of a case collapsing, the claimant is left with costs, which may outweigh any compensation that may have been obtained.

In the USA, the descriptor 'ambulance chaser' is given to those lawyers or their representatives who haunt hospital corridors for people who are victims of accidents or injury, so that they can sue the person liable on their behalf. In many ways, one can describe this activity as fundamentally more honest than appears the case in the UK. Once instructed, ambulance chaser or not, the legal advisor in the USA works on their client's behalf, in stark contrast to many claims farmers operating today in the UK.

In any period of legal reform, changes must be made sustainable and maintain confidence in the justice system. The Lord Chancellor spoke at a conference of personal injury lawyers in 2007 (Eurotox, 2009). He referred to inadequate and generally suboptimal information given by claims-management companies to claimants, indicating a frequent failure to include low-cost options. He pointed out that the most serious complaints came from the unregulated companies—those who used hard selling techniques, cold calling and advertised in family-practitioner surgeries and healthcare facilities. In short, the industry was placed well and truly in his regulatory sights.

Before examining the claims-management industry and the Compensation Act, a brief review of how we arrived at the present position is relevant.

7.1 Access to Justice

Section 58 of the Courts and Legal Services Act 1990 allowed the use of conditional fee agreements in such types of cases as specified by the Lord Chancellor. These, however, were subject to requirements made by Section 58 (10), which exclude all criminal and family law proceedings from these arrangements.

Conditional fee agreements allow clients to agree with their lawyers, that the lawyer will not receive all or part of their usual fee or expenses if the case is lost. If it is won, the client pays an up-lift to the lawyers in addition to the usual fee.

In 1995, conditional fee agreements were permitted for a limited range of cases, including personal injury and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cases before the European Court of Human Rights. The maximum up-lift in the event of success was set at 100%. In addition, the Law Society recommended that lawyers should voluntarily limit the up-lift to 25% of the damages obtained if that was lower than the 100% up-lift of the fee.

At the same time, insurance policies were developed, which allowed the client to take one insurance to cover the costs of the other party and the client's own costs, other than their lawyers' fees. If the case should be lost, the up-lift and the premium were taken from any damages that might be recovered by the client. In July 1998, the Government extended the availability of conditional fee agreements to all civil cases, excluding family law.

Since the introduction of fees, the common law has been developed and two important cases are worthy of note. In Thai Trading Company (a Firm) vs. Taylor (1998), Lord Falconer (2007), the Court of Appeal held that there were no longer any public policy grounds to prevent lawyers agreeing to work for less than their normal fees in the event that they were unsuccessful, provided that they did not try to receive more than their normal fees, if they were successful. The latter was only permissible in those proceedings in which conditional free agreements were allowed. In another case (Thai Trading Company (a Firm) vs. Taylor, 1998) the Vice Chancellor held that it was also lawful for a conditional fee agreement to apply in a case which was to be resolved by arbitration under the Arbitration Act, 1950, even though these were not formally court proceedings, provided all the requirements specified by regulation as to form and content of conditional fee agreements were complied with. In addition, it is now possible for someone contemplating litigation to take out an insurance policy in the event that the case is lost, to cover the costs of the other party, as well as their own legal costs, including their lawyers' fees, if these were not subject to a conditional fee agreement. Some of these policies had indeed been developed to support the use of conditional fee agreements, but others had been used to meet lawyers' fees charged in the traditional way. The Act makes premiums paid for protective insurance recoverable in costs. The principles behind the Government's desire are very simple. They are designed to increase access to justice for, in the words of the eminent judge, Lord Denning, 'the man on the Clapham omnibus'(Lord Chancellor's Department, 1998).

7.2 The Compensation Act 2007

From the above, it is clear that many claims management businesses were found to engage in adverse practices to the detriment of the consumers, the claimants and the public interest. These included aggressive marketing techniques applied at sensitive times, encouragement of a frivolous claim, which contributes to the perception of a compensation culture, giving consumers misleading information about options available to them, providing poor quality advice and dropping claims when they did not appear financially lucrative. Following a report by the Better Regulation Task Force (2004), the Government stepped in with the Compensation Act, 2007. The Act received the Royal Assent on 25 July 2006 and came into force on 23 April 2007.

Within the Act, the definition of claims-management regulation is so wide that it can apply to almost any claim for compensation. It is now suitably restricted by a Statutory Scope Order, which narrows the definition to specified activities and sectors. Any person carrying out the activities listed below connected to making a claim for compensation for: personal injury; industrial injuries disablement benefit; criminal injuries; employment; housing disrepair; or financial products or services must be authorized to do so. The activities regulated include:

- Advertising for seeking out or direct marketing to persons who may have a claim
- Advising a claimant or potential claimant in relation to his claim or cause of action
- Referring details for a fee, of a claim or claimant, or a cause of action or potential claimant to another person, including a person having a right to conduct litigation
- Investigating or commissioning the investigation of circumstances, merits or origins of a claim with a view to using the results in pursuing the claim
- Representing a claimant, whether in writing or personally, to a tribunal body or person.

Toxicologists are most likely to be caught in the penultimate category. A statutory order exempts certain persons from the need to be regulated if they are already regulated for the management of claims services, as for example, are lawyers and insurers. Charities, not-for-profit agencies and independent trades unions are also exempted.

7.3 Issues for the Toxicologist

It is likely that toxicological evidence is potentially featured in personal injury, criminal cases, employment and industrial injury disablement cases. Depending on the circumstances, expert evidence is more likely to be required for the first three categories. Indeed, there is an argument to suggest that cases are more likely to need toxicological expertise because the area is so little understood. Paradoxically, a rigorous attention to expert evidence is sometimes lacking in these cases, which leads

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to difficulties later in the case. Therefore, one possibility is that expert evidence may render the case nonviable and this would not be what a claims-management company might wish for their own purposes.

Environmental medicine, (formerly known as clinical ecology and also sometimes called nutritional medicine) is a convincing mix of orthodox clinical medicine and toxicology. For those practitioners who sincerely hold beliefs in relation to the ideas of clinical ecology, there is an overriding obstacle, which is simply that there is relatively little conventional evidence underpinning their theory and more particularly, their practice. There will be an immediate clash between conventional, clinical and toxicological evidence, on the one hand, and those who practise environmental medicine on the other.

Dealing with unregulated claims management companies can place the toxicologist at risk from two areas. First, one's professional reputation can be damaged through simple association with a company who is criticized in the press for being the subject of enforcement procedures, under the Compensation Act. Second, such companies may have a risk of going out of business with relatively little notice. They may be placed in that position, not only as a result of business pressure, cash flow difficulties and the like, but also as a result of enforcement procedures. The result, of course, is that the toxicologist may not get paid.

When clients instruct a lawyer and their claim is managed under a conditional free agreement, this should have no effect on the fee paid to a toxicologist. The fee paid to a toxicologist for expert advice should under no circumstances be determined by the potential success or otherwise of the case. In UK law, the toxicologist is appointed to advise the Court, not the parties. If the fee is to be influenced by the conduct of the case, then it would be hard to defend the expert's impartiality.

Many lawyers maintain in-house panels of experts, including toxicologists, with whom they build up a relationship, each party developing an understanding of the other's 'needs' and 'wants'. This is to be applauded and will be of considerable benefit to both claimant and defendant. However, it would be wrong for the toxicologist either to reduce their fee or extend credit terms beyond their usual terms of business in return for an entry on their database or a promise of increased referrals.

8 SOCIAL RESPONSIBILITY AND PUBLIC STATEMENTS

Many codes of ethical standards reflect the normality of our society in seeking to give back something positive to the community in which we live. This thought is encapsulated in the tendency for large corporations to have spin-off charitable foundations or active social participation. Social responsibility is often seen as a fundamental necessity in today's marketing strategy. This being so, it is not surprising to have these notions reflected in codes of ethics for toxicologists (Society of Toxicology, 1985).

It is true to say that the public has a colossal appetite for information about toxicology, whether it concerns adverse effects on human health or the environment. Given also the range of toxicological issues from acrylamide in food to cranberry juice, the stage is set for a rigorous exchange of information with the public. However, this brings with it duties on the part of toxicologists which are not necessarily explicitly set out ethical standards.

At the very essence of the relationship between toxicologists and society is their professional and scientific responsibility to the community in which they work and live. They apply and make public their knowledge of toxicology in order to contribute to human welfare. They are concerned about and work to mitigate the cause of adverse health effects in humans and the environment.

It is an ethical imperative that toxicologists should at all times work to advance the cause of human welfare and the science of toxicology. Toxicologists should also strive to avoid misuse of their work, to comply with the law and to encourage the development of law and social policy.

Tacit acceptance of misunderstanding by journalists and the media should not be tolerated and therefore, toxicologists should make themselves available to journalists to help them to avoid this. There are several organizations that promote this sort of dialogue and university press offices can play a major role in this. Credibility might be enhanced on the part of the toxicologists by the occasional acceptance of *pro bono* work. In dealing with statements made by others, toxicologists must retain professional responsibility for any statements made on their behalf. They must prevent others making deceptive statements and correct any that are made, whenever practicable.

Toxicologists should avoid false or deceptive statements, avoiding assertions which lack any credible evidence base. Where it is limited or flawed, these should be explained. Public statements may be false, deceptive, misleading or fraudulent, because of what they state, convey or suggest, or because of what they omit, concerning research practice or other work activities or other persons or affiliations.

False or deceptive statements which specifically should be avoided include:

- Training, experience or competency
- Personal academic degrees
- Credentials
- Institution or association affiliations
- Services offered

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Scientific bases for, or results of, or degree of success of their services
- Their fees
- Publication of research findings
- Providing participants with information.

One should only claim as credentials, earned degrees and those used as the basis for licensure or specialist accreditation. All statements made to the press and media must be based on the appropriate toxicological literature and practice, whether they are on or off the record. Unless experienced in dealing with journalists, care should be taken in making 'off the record' comments, despite conventions that protect this form of communication. It is always worthwhile assuming that 'off the record' comments may well find their way into print, justified by reported speech. Statements should always be consistent with the toxicologist's integrity and the speciality's ethical principles.

Following assistance to the press or other media with a particular story, journalists should never be left with the impression that they now have a special relationship with the toxicologist.

9 ALTERNATIVE DISPUTE RESOLUTION

ADR may be defined as a range of procedures which serve as alternatives to the adjudicatory procedures of litigation and arbitration, for the resolution of disputes generally, but not necessarily involving the intervention and assistance of a neutral third party who helps to facilitate such a resolutions. Arbitration, originally an alternative procedure, is now generally viewed as being closer to litigation in its approach, and part of mainstream practice, leaving the term ADR to refer mainly, but not necessarily exclusively, to consensual rather than adjudicatory processes.

9.1 Types of ADR

The development of ADR in the UK has its principal origins in the dissatisfaction of many people with the way in which disputes are traditionally resolved. This is reflected in the criticisms of the courts and perhaps, more commonly, the legal profession, as well as sometimes a sense of alienation from the entire justice system. There are three primary categories of dispute resolution, which include both the traditional and alternative approaches. Negotiation is probably the most common, with disputants resolving their difficulties by communication. There are various styles and theories of negotiation, for example, positional bargaining or principled negotiation, but it is usually a skill learned by experience. Adjudication is a dispute process in which a neutral has, and exercises, authority to hear the respective positions submitted by the disputants and to make a decision on their dispute which will be binding on them. This may be by litigation or:

- Arbitration: a privately chosen neutral is paid by disputants and follows rules employed by statute or arbitral organization
- Administrative or statutory tribunal: in matters such as industrial injury benefit, criminal injury compensation and others
- Expert determination: in which the parties appoint an expert to consider their issues and to make a binding decision or an appraisal without an enquiry following an adjudicatory process
- Private judging: a process not yet widely used in the UK, where cases are referred to a referee, chosen by the parties to decide some or all of the issues or to establish specific facts.

Mediation is the third category. It is a process by which disputants engage the assistance of a neutral third party to act as a mediator, a facilitating intermediary, who has no authority to make binding decisions, but uses various procedures, techniques and skills to help parties resolve their dispute by negotiated agreement without adjudication. The mediator is a facilitator who may, in some models of practice, make an appraisal of some merits of each party's case, but does not make a binding decision. The theory remains that the parties resolve their own dispute. Mediation is by far the commonest form of ADR practised in the UK today.

9.2 Hybrid Processes

Each of these primary processes can be used in its own right without adaptation. But, the experienced ADR practitioner will devise a permutation of various procedures which makes a better fit with all the nuances with all the parties' needs in a case without being constrained by prescribed rules.

Certain common combinations have evolved in this way and form a distinct category which is known as hybrid processes. The so-called 'mini-trial' is a form of evaluative mediation, which is followed by negotiation, and the so-called 'med-arb', which commences with mediation, but continues with arbitration in the event of the dispute not being resolved, are two examples.

Two particularly interesting forms include the neutral fact-finding expert and the early neutral evaluation. The former involves an investigation by a neutral expert into certain specific issues of fact, technical matters and law and thereafter, if required, a mediatory role and eventual participation in an adjudicatory process. The

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

latter requires a neutral evaluator to meet the parties at an early stage of the case in order to make a confidential assessment of the dispute, partly to help them narrow and define the issues and partly to promote efforts to arrive at a settlement.

9.3 Issues for Toxicologists

A toxicologist may be involved in a number of these processes from time to time, especially if they undertake a great deal of medicolegal work. Processes of particular interest to the toxicologist will be expert determination, neutral fact-finding and early neutral evaluation. They may also be involved in providing expert evidence for the purposes of arbitration or, indeed, as an adjunct to mediation.

Mediation, and indeed arbitration, requires special training. Mediation training is relatively short and can well be regarded as an important life skill. Whilst toxicologists trained in mediation are rare, the combination can be particularly useful in mediation involving complex toxicological issues. However, the success of mediations does not usually depend specifically on the employment of a subject specialist.

Instructions to the toxicologist may not make it clear at the outset whether or not the toxicologist is to be involved in an ADR process or simply in the provision of an expert opinion. If, given the circumstances, an ADR process is a possibility, then the toxicologist would be well advised to seek clarification from those appointing him.

9.4 Expert Determination

In this ADR process, an expert is appointed by parties to undertake a specific resolutive function, for example determining safety measures are adequate for workers exposed to a toxic substance. The expert's functions and authority arise from contract and are different from those of an arbitrator. In these circumstances, the toxicology expert may be liable in negligence if the case is not in the context of a legal action. If it were, they would have immunity for their opinions. The opinion of an arbitrator may be appealed to the courts.

An expert determination can be set aside on certain grounds and these have been the subject of judicial comment, as in Campbell vs. Edwards, where Lord Denning MR, stated:

> *It is simply the law of contract. If two persons agree that the price of property should be fixed by a valuer on whom they agree, and he gives that valuation honestly and in good faith, they are bound by it. If there were fraud or collusion, of course, it would be very different. Fraud or collusion unravels everything.*
> (Campbell vs. Edwards, 1976)

Thus, in principle, the parties are bound by their own agreement that the task to be undertaken should be entrusted to the person whom they have nominated. The parties:

> *... made the [expert] their judge on that point. They thought proper to confide in his judgement and skill and must abide by it unless they could have made it plainly appear that he had been guilty of some gross fraud or partiality.*
> (Belchier vs. Reynolds, 1978)

In other words, the agreement to refer the dispute to an expert is as binding on both parties as any other term of their contract.

There is some precedent for predicting the court's responses to challenges for expert determination. First, the court would need to determine what parties have agreed to remit to the expert, that is, to what his or her terms of determination will be considered. If the expert has departed from his contractual instruction in any material respect, it will be open to either party to contend that the determination is not binding on the grounds that the expert had not done what he was appointed to do. If, on the other hand, the expert has carried out his contractual functions and instructions, then the parties would not have a basis for challenging his determination (Nikko Hotels (UK) Ltd vs. MEPC plc, 1991; Jones vs. Sherwood Computer Services Ltd, 1992). It is clear from these authorities that it is in everyone's interest to specify as clearly as possible in the terms of reference what they require the expert to undertake and if possible, the means by which they are to arrive at their determination. This will hopefully result in a consonance between the wishes of the parties and the means by which the expert achieves them. The process clearly has value in circumstances which lend themselves to independent determination, for example, safe use of chemicals, toxicological safety and so on.

9.5 Early Neutral Fact-Finding Expert

This simple process is not in wide use in the UK, but bears some similarity with 'shadow experts' under the CPR. A neutral expert investigates legal or technical issues and submits a nonbinding report. This may assist the parties to reassess their position and may assist the court if it is agreed between the disputants to be so used. Alternatively, another expert may be appointed for litigation purposes.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat168
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The initial purpose of the neutral expert is to investigate the technical matters and report to the parties jointly. If the parties require, the neutral's role can be changed to that of a facilitator of subsequent negotiations. The process is suitable for cases with technical issues which would benefit from neutral expert appraisal and reporting. These may include occupational health and safety, product liability and related matters. It is not appropriate where there are no specialist issues requiring expert involvement. Neither is it appropriate where witness credibility is at issue and would render technical appraisal irrelevant.

9.6 Early Neutral Evaluation

This is a process which began in the USA in 1985. An experimental programme involved cases being selected and referred to a third party lawyer for evaluation some six months prior to the commencement of litigation. This process is rarely encountered in any formal sense in the UK, but it is used from time to time. The idea is somewhat analogous to the 'advisor' under the CPR in the UK.

The mandate of the early neutral evaluator is, not only to look at the strengths and weaknesses of the case, but also to consider how best to conduct the litigation rapidly and economically.

Initially the scheme was designed to force parties to confront the merits of the case more carefully and to develop an efficient appraisal to the issues and to discovery. Facilitation of a settlement was later added to the scheme. The evaluator was given the authority at the evaluation session to help the parties, in joint or separate meetings, to explore the possibilities of settlement. Another function is to consider alternatives to litigation to help in resolving the case effectively and expeditiously. The material used in the evaluation is 'privileged', as is the record of discussions in sole or joint sessions.

Positive benefits include making parties and their lawyers examine the case more effectively and systematically, giving them a better understanding of the issues, improving communications and creating opportunities for early settlement discussions.

In the UK, it is rarely used under the description of the early neutral evaluation. However, it is occasionally used to deal with some disputes characterized, again, with high scientific and technical content. Communication of the science and technical issues by a credible expert can often diffuse the impact of the dispute.

10 CONCLUSIONS

This chapter has been a review of the areas in which the professional skills of the lawyer and toxicologist overlap. The result has been something of an eclectic mix. Some areas have been excluded, such as occupational health and safety legislation and in particular, the Control of Substances Hazardous to Health Regulations. The reason for their exclusion is that they are the province of laboratory managers rather than toxicologists in the formal sense. Similarly, although toxicologists can be very much involved in criminal law, fewer of them become engaged in this area unless they are forensic specialists and the nature of their tasks is fairly self-evident. The areas that have been covered reflect a fascinating area which can offer considerable challenge to the toxicologist interested in making toxicology truly a science that serves our community. It has been a cook's tour, but hopefully, with sufficient depth for the interested reader.

1 INTRODUCTION

We leave as we came, and God willing as we shall return, with peace and hope for all mankind.
Eugene Cernan (Commander of last Apollo mission), December 17, 1972

Human exploration of space came at just the right time for many of us to be real-time witnesses to the achievement of placing human footprints in the ancient dusts of the lunar surface. For millions of earthlings, this achievement inspired us and radically changed how we viewed the moon. This sojourner of the night was no longer the mysterious, unreachable orb that it had been since man first looked skyward. It had become part of who we were and where we could go; it had become a target for human exploration. After the remarkable series of Apollo missions in the late 1960s and early 1970s, the space-faring nations failed to seize the momentum and pulled back to achieve a series of low-earth-orbit missions. These missions were most remarkable for the bridges that were built between nations that were not politically similar. The first of these was the Apollo–Soyuz demonstration project in 1975, and much later this was followed by the Shuttle–Mir (see **Figure 1**) missions of the late 1990s, and now the International Space Station (ISS) has become an outpost for many countries to explore the cosmos. Most recently, mankind's heart has returned to the romance and challenge of walking again on the moon and reaching out for the first time to another planet.

The unfolding of human space exploration involves many serious risks to those bold enough to step forward and become astronauts or cosmonauts. More often than we would like, those risks have turned into tragedy before the eyes of millions of people watching launches and landings on television. Among the risks that must be managed in space are those of a harmful exposure to toxic compounds such as carbon monoxide (CO), fixatives or reactive dusts. Toxic compounds have presented major problems during a few missions. These include the accumulation of carbon dioxide (CO_2) during the ill-fated Apollo 13 mission, the exposure of the Apollo crew to nitrogen tetroxide during the descent of the capsule, the fires aboard Mir in the late 1990s and the noxious products from regeneration of the metal-oxide canisters aboard the ISS.

Space toxicology has much in common with its parent discipline; however there are unusual facets of the subdiscipline of space toxicology that distinguish it from other subdisciplines:

1. Exposures to compounds in space are continuous and can go on for months from the accumulation of slowly released toxicants or from accidental releases of compounds that are difficult to remove from the air. We must also pay attention to the possibility that toxic compounds can be created in the air revitalization systems (ARSs) from relatively less harmful compounds.
2. Astronauts undergo an array of physiological changes that make them potentially more susceptible to the effects of toxic compounds. These may be caused by reduced gravity, stress or isolation. The space-adaptation effects include loss of red-cell mass, loss of bone, cardiovascular sensitivity and effects on the immune system. In addition, radiation exposures can be much greater during spaceflight when the mission goes beyond low-earth orbit.
3. Exposures to compounds in space are often continuous for the duration of the mission; however, routine activities or accidents can elevate exposures for a period of hours or a few days. Exposures are best viewed as a steady-state component perturbed by episodes of elevated pollutants. The crewmembers have extremely limited escape options when compared to earth-based populations, although there is always a contingency for abandonment of the vehicle if the risk to the crew were clearly life-threatening. Submariners are the only earth-based population with similar exposures to space crews, and their escape options are also somewhat limited.
4. Space habitats and vehicles are equipped with systems to scrub the air, and also recover and purify the water. These air and water systems are intimately linked because water-soluble air pollutants are inevitably recovered in the water and these pollutants must be removed before the crew consumes the water. Certain air pollutants can poison filter systems in either the air scrubbers or the water purifiers, so the space toxicologist must be alert to this possibility.
5. The ethnic and racial population of humans undertaking space missions has broadened to include almost all earth-based groups. With the noteworthy exception of the historic flight of Senator John Glenn at the age of 77 years, all persons launched into space have been middle-aged, and known to be in good health. The ethnic diversity means that the space toxicologist must be aware of the possibility that certain crewmembers may be unusually susceptible to pollutants. On the other hand, the fact that all crewmembers are healthy adults and not pregnant gives the space toxicologist a bit more flexibility in interpreting exposures that on earth could be harmful to the elderly, the unborn or the infirm.

In this chapter, we provide a resource of information for toxicologists interested in the field of space

toxicology, as well as those with a special interest in the future of space exploration.

2 HISTORY OF SPACE TOXICOLOGY

> *We choose to go to the moon. We choose to go to the moon in this decade and do the other things, not because they are easy, but because they are hard, because that goal will serve to organize and measure the best of our energies and skills, because that challenge is one that we are willing to accept, one we are unwilling to postpone, and one which we intend to win, and the others, too.*
>
> President John F. Kennedy (35th President, United States of America)

The National Aeronautics and Space Administration (NASA) recognized from the earliest days of human spaceflight that maintenance of air quality required stringent control of materials (Osbon, 1963) and that standards for two weeks of continuous exposure were needed for lunar missions (Edgerley, 1964). Within a few years, the Space Science Board had set provisional limits on a handful of compounds for emergencies (one hour exposure), 90 days of exposure and 1000 days of exposure (NAS (National Academy of Sciences), 1968). The documentation of each value was limited. A much longer list of compounds was considered by the Panel on Air Quality in Manned Spacecraft for exposures of one hour, 90 days and six months (Committee on Toxicology, 1972); 10 minute, 'special area', exposures were set for six compounds. These limits were suitable for missions to the lunar surface and for prolonged stays in Skylab, which orbited the earth in the 1970s; however, as the concept of a reusable, earth-orbiting space-shuttle vehicle matured, limits were established for seven and 30 days of exposure based on recommendations from the National Academy of Sciences (Dietlein, 1976).

In the 1990s the approach to setting spacecraft limits was expanded to include one hour and 24 hour exposure guidelines for contingency (emergency or accidental) exposure scenarios. NASA asked the National Research Council (NRC) to form a committee specifically for spacecraft guidelines. The committees formed were first the Subcommittee on Spacecraft Maximum Allowable Concentrations (SMACs) for air standards, and later the subcommittee on Spacecraft Water Exposure Guidelines (SWEGs) for water consumption. These committees consist of appropriate peers in air and water quality from various discipline specialties within the field of toxicology and human-risk assessment. While NASAs space toxicologists set the air-exposure values, the NRC subcommittee on SMACs stringently reviews and works in collaboration with NASA toxicologists, who present and defend all values to the committee, before approval and publication. During this process, long-term chronic exposure limits expanded from seven and 30 days to include 180 days and, in the new millennium, 1000 days air exposure values were added, to respond to longer-duration missions. NASA toxicologists later endeavoured to develop water-consumption guidelines. These water guidelines are also peer reviewed and formalized using the Subcommittee on SWEGs. The water consumption standards are one day, 10 days, 100 days and 1000 days.

3 THE DISCIPLINE OF SPACE TOXICOLOGY

Perchance, coming generations will not abide the dissolution of the globe, but, availing themselves of future inventions in aerial locomotion, and the navigation of space, the entire race may migrate from the earth, to settle some vacant and more western planet.... It took but little art, a simple application of natural laws, a canoe, a paddle, and a sail of matting, to people the isles of the Pacific, and a little more will people the shining isles of space. Do we not see in the firmament the lights carried along the shore by night, as Columbus did? Let us not despair or mutiny.

Henry David Thoreau

What is the difference in the effect, once it is encountered by a space-faring explorer as opposed to someone on Earth? Once man decided to venture past our protective earth's atmosphere and explore space, astronauts would interact with chemicals (liquid, vapour or particulate). Thus, NASA would find it a great medical and life-support technology challenge, as it still does, to sustain life and human functions in an optimal manner for the tasks required for space exploration (Gardner, 1999). While NASA had early space guidelines for air quality, in the 1990s NASA began to consider how the mode of action of a chemical would differ when introduced into a physiologically altered human. Exploring beyond the outer atmosphere and gravitational field of our planet to the moon and throughout our solar system presents us with a number of complex and unique environments. Many of these distinct worlds all present a rich collection of chemical, geological and possibly biological systems that we journey to discover and explore, not only for the sake of curiosity, but for the desire to gain further scientific understanding of a vast and unexploited milieu. To accomplish the intricate and exciting goals of man working and living in space, space toxicology has materialized with the primary objective of protecting man from potentially harmful environmental contaminants that are inevitable in the living and working environment of astronauts. The following are key considerations of space toxicology, some of which may also apply to the parent discipline of toxicology:

1. Chemicals, chemical by-products and their mixtures must come in contact with tissue(s) and or organ(s) for which they have specific ability to cause damage (Ballantyne *et al*., 2000).
2. Chemicals behave differently in zero-gravity and reduced-gravity environments, which often dramatically increases the ability of a chemical to come into physical or structural contact with tissue(s) and/or organ(s).
3. The observed toxic effect or end point should be quantitatively related to the degree of exposure (concentration and duration) to the chemical(s) or chemical mixture(s). (Ballantyne *et al*., 2000).
4. The target of space toxicology studies and assessments is to determine the potential for harmful effects in the human that is living in an altered physiological state in a closed-loop environment for time-based exposures.
5. Acceptable risk criteria set by NASA for human spaceflight are also considered for off-nominal or accidental acute exposures.

Space toxicology is a unique and targeted discipline for spaceflight, space habitation and occupation of celestial bodies, including planets, moons and asteroids. Astronaut explorers face distinctive health challenges and have access to limited resources for rescue and medical care during space operations. The inherent changes in health caused by spaceflight, such as stress factors, anaemia and bone loss may also modify overall susceptibility to toxic effect. The ultimate goal of space toxicology is to protect the health of the astronaut by assessing potential chemical exposures during spaceflight and setting safe limits that will protect the astronaut, in a physiologically altered state, against chemical exposures.

When you look at the stars and the galaxy, you feel that you are not just from any particular piece of land, but from the solar system.

Kalpana Chawla (late US Astronaut STS-107)

The space environment is quite distinctive from our Earth's environment. Space is a near-perfect vacuum allowing stars and planetary bodies to move in accordance to gravitational forces on various scales. The atmospheric protection found on Earth is not present in the space environment. These and other distinct environmental conditions of space influence the potential toxic effect of chemical exposures and complicate the steps that must be taken to effectively maintain astronaut health. Altered gravity (reduced or zero gravity) and the closed-loop living environment further complicate the task of safeguarding crew health, since the habitat (vehicular or settlement) must be carefully regulated and monitored so that harmful amounts of toxicants do not build up within the enclosed volume. Keeping the quality of air and water consumed safe and healthy is an increasingly complex task as longer-term space expeditions are undertaken.

Astronaut explorers are a diverse group selected from the world population. NASA stringently screens the health of potential crewmembers prior to induction into the astronaut corps. This elite group of healthy individuals is selected to withstand the physiological, mental and environmental changes that are inherent to space exploration. Prior to selection for specific spaceflights,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat169
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

individuals are screened for susceptibility biomarkers with respect to mission specific and/or innate adverse reactions resulting from spaceflight adaptation. One example is an increase in probability of renal-stone formation during space habitation; therefore individuals with a history of renal stone formation may be excluded (James, 2008). The health screening process minimizes the interindividual variability among this population.

The fundamental nature of space toxicology is that it is a discipline concerned with studying and predicting the potential of chemicals and chemical mixtures, in air and water, to produce harmful effects in humans, in an altered gravity environment. Space toxicology is a study of the interaction between chemicals in microgravity and humans in order to determine the potential for chemical(s) to produce injury which results in adverse health effects and to investigate the type, frequency, mechanism of action and production factors influencing their development and pervasiveness and the permanence or reversibility of these adverse effects. The definition of this discipline may be stated succinctly; however, implementation of this science can be complex.

The space toxicologist will assess the potential for adverse health effects by taking into consideration the amount of individual chemicals, as well as the content of each chemical in mixtures, human physiological changes, route of exposure, chemical by-products (if these by-products are formed prior to exposure, such as pyrolysis products) and potential contact time in order to assign toxicity hazard rating. All chemical-containing materials must be assessed before they are allowed to be utilized during spaceflight operations. The broad scope of chemical-containing materials, including liquids, gases and particulates, and types of chemical exposure scenarios, must all be deliberated in order to assign toxicity assessment values, as well as in setting spaceflight standards. Spaceflight standards are set for a number of chemicals for human exposure in air and water. These standards are time-weighted averages and consist of short-term and long-term permissible exposure guidelines. These guidelines should not be exceeded during nominal space operations, since they are intended to protect astronauts from acute and chronic health effects.

4 TOXICOLOGY STANDARDS FOR HUMAN SPACE EXPLORATION

Since the beginning of manned spaceflight, NASA has considered the overall health of astronaut crew members as vital for individual performance and well-being, as well as overall mission success. This was the impetus for the birth of space toxicology. Humans interacting with chemical constituents in enclosed or closed-loop environments are intrinsic to spaceflight; therefore these chemical exposures must be controlled and maintained at a level that is not detrimental to crew health. Despite engineering efforts, hundreds of chemicals will potentially be encountered in the closed-loop environment during spaceflight. Some chemicals that must be considered are those produced by the crew members, as well as those originating from vehicular components, payload experiments and use of utility compounds.

Most environmental pollutants in spacecraft do not have appropriate regulatory limits. NASA cannot apply earth-based standards to spaceflight since they do not consider the various physicochemical changes of spaceflight. Therefore when setting spacecraft standards, the space toxicologist must prioritize amongst the chemicals that crewmembers are likely to be exposed to and develop a standard that can be applied to acute and chronic exposures.

4.1 Spacecraft Maximum Allowable Concentrations

The first time the spacecraft maximum allowable concentrations (SMACs) were compiled into a formal NASA publication, the document only listed the seven-day SMAC values and did not provide any rationale for these concentrations (Coleman and James, 1990). As the Space Station Programme was being defined and redefined, it became apparent that exposures of 180 days could be anticipated, so NASA once again turned to the NRC for assistance in setting values for contingencies (one hour and 24 hours) and long-duration exposures up to 180 days (James, 1995). The need for contingency SMACs was validated because real-time, on-board air analysers were being developed to quantify pollutants accidentally released into the air (Limero *et al*., 2000) or from accidental combustion of polymers (Beck *et al*., 1991). A combination of short-term exposure limits and on-board analysers, along with flight rules, facilitated the management of toxicological events when they occurred. An array of SMACs was set for approximately 50 compounds and thoroughly documented in four volumes from the NRC (National Research Council (NRC), 1994; National Research Council (NRC), 1996b; National Research Council (NRC), 1996a; National Research Council (NRC), 2000a). A few years ago it was recognized that revised standards were needed for many compounds and 1000-day standards were essential in anticipation of long duration missions to Mars, hence a fifth volume containing revised values and 1000-day SMACs was published (National Research Council (NRC), 2008).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat169
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.2 NASA Acceptable Risk for SMAC Values

For contingency chemical release events one and 24 hour SMACs are utilized; NASA has defined acceptable risk as a concentration of a substance in air that may be tolerated during the performance of specific tasks during emergency conditions lasting for less than one hour or less than 24 hours (National Research Council (NRC), 1992; Khan-Mayberry, 2008b). The one and 24 hour SMACs could include reversible effects that do not impair judgment and do not interfere with proper responses to the emergency, such as shutting a valve, closing a hatch, removing a source of heat or ignition, or using a fire extinguisher (National Research Council (NRC), 1992; Khan-Mayberry, 2008b). For example, exposure at the one and 24 hour levels may produce effects such as increased respiratory rate from increased CO_2, headache or mild central nervous system (CNS) effects from CO, and respiratory tract and eye irritation from ammonia or sulphur dioxide (National Research Council (NRC), 1992; Khan-Mayberry, 2008b).

In contrast to one and 24 hour SMACs, which are intended to guide exposures during emergencies, SMACs lasting up to 180 days, and now 1000 days, are intended to provide guidance for operations during those time periods (180 days in an environment like the Space Station and 1000 days for extended stays on the lunar, Martian or other planetary surfaces) including transit time. Accounting for accumulation, detoxification, excretion and repair of toxic injuries is important in determining long-term SMACs (National Research Council (NRC), 1992; Khan-Mayberry, 2008b). Whether a material has a cumulative effect must be taken into account for long-duration SMACs. Neuropathologic regeneration or repair of toxic injuries occurs more readily in intermittent than in continuous exposures, making repair important in setting long-term SMACs (National Research Council (NRC), 1992; Khan-Mayberry, 2008b).

4.3 Spacecraft Water-Exposure Guidelines (SWEGs)

Water is a precious resource during human spaceflight and as NASA attempts to recover as much water as possible from humidity condensate and urine, the need for spaceflight-specific standards became apparent. NASA had been using the Public Health Service Environmental Protection Agency's maximum contaminant levels (MCLs) as guidelines for definition of acceptable water quality; however, experts agreed that unique limits were needed for people engaged in spaceflight because of the different exposure conditions in space (National Research Council (NRC), 2000a). Some of the problematic compounds in spacecraft water were of no concern for earth-based populations, so limits had never been set for these compounds. In cooperation with the NRC, NASA has developed spacecraft water-exposure guidelines (SWEGs) for approximately 30 compounds for ingestion periods of one day and 10 days, contingency values, along with 100 and 1000 days for long-term ingestion (National Research Council (NRC), 2000b). These should not be applied to earth-based activities and are not appropriate, because the astronaut population is to a good extent different than earth-based populations and the risks acceptable to NASA tend to be quite different than for other populations. At present, the only water component with a SWEG that can be quantified in orbit is total organic carbon, but NASA plans to be able to monitor many more compounds during exploration missions involving prolonged stays on distant celestial bodies. Presently, the SWEGs serve as design goals for engineers as they develop water purification systems to ensure a supply of potable water throughout missions.

4.4 NASA Acceptable Risk for SWEG Values

For contingency events one and 10 day SWEGs are utilized; NASA has defined acceptable risk as a consumption of a chemical dissolved in water that may be tolerated during the performance of specific tasks during rare emergency conditions lasting for time periods up to 24 hours or 10 days contingent upon the specific event (National Research Council (NRC), 2000a). The one day SWEG is expected to prevent irreversible hazardous health effects and degradation in crew performance. This contingency value allows for temporary discomfort providing there is no adverse effect on judgement, performance or the ability to respond to an emergency. The longer-term SWEGs are meant to prevent immediate or delayed adverse health effects and degradation in crew performance that would result from continuous exposure for up to 1000 days. These long-term SWEGs are written to provide guidance for oral (consumption) exposure during nominal operations (National Research Council (NRC), 2000a).

5 IDENTIFIABLE SOURCES OF TOXICANTS

There are a substantial number of particulate and volatile space contaminants that have been identified and quantified by NASA's toxicology laboratory. Chemicals that are of greatest concern when assessing for potential toxicity are those that target organs or organ systems

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat169
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

that are already compromised by spaceflight-induced physiological changes. The primary sources of contaminants come from human metabolism and materials off-gassing. Off-gassed components are from nonmetal surfaces which contribute steady low-level compounds to the breathable airspace. This chronic exposure is of particular interest to the space toxicologist, since the closed-loop environment does not provide ventilation of the air to the external environment. Acute exposures from evolving off-nominal catastrophic events such as fires, accidental release of chemicals from instrumentation or payload experiments may occur. Utility compounds such as lubricants, adhesives and personal hygiene products also contribute to the array of air pollutants. Therefore chemicals brought into the space environment are assessed for potential toxicity prior to approval for spaceflight use.

5.1 Metabolic Sources of Contamination

The enclosed volumes of inhabited space vehicles and habitats may contain 'pockets' of obstructed flows and poorly ventilated areas. This amplifies the concern for concentrated areas of isolated chemical release. The crewmember could potentially enter a 'pocket' inadvertently and receive an acute adverse exposure if the environment is not properly controlled. Metabolism is usually the greatest source of low-level contamination aboard spacecraft (Coleman and James, 1994). Potential opportunities for build-up of toxic levels of metabolic contaminants occur during nominal space operations, such as maintenance activities in restricted or confined areas, gathering of several crewmembers in small areas to perform experiments and other day-to-day activities.

CO_2 is the most commonly thought of contaminant introduced into the cabin atmosphere as a result of metabolic production. According to calculations by NASA (National Aeronautics and Space Administration) (1987) each crewmember produces 0.76–1.15 kg (1.67–2.58 lb) of CO_2 per day, contingent upon physical activity (operational tasks and exercise) (Coleman and James, 1994). Production of CO_2 in humans is through oxidative metabolism of carbohydrates, fatty acids and amino acids (Wong, 1996). This CO_2 is quickly released into the space environment via respiratory elimination.

Metabolically manufactured acetaldehyde is also introduced into the space habitat or vehicle. It was estimated that acetaldehyde is produced at a rate of about 83 μg day^{-1} per human (Olcott, 1972; Wong, 1994b). Acetaldehyde is oxidized primarily in the liver to acetic acid by aldehyde dehydrogenase, aldehyde oxidase and xanthine oxidase (Wong, 1994b).

Ammonia is introduced into the closed-loop volume via metabolism. While NH_3 is mainly eliminated in urea, a minor elimination pathway is via exhalation (Wong, 1994a). Ammonia production occurs by catabolism of amino acids, amines, nucleic acids, glutamine and glutamate in peripheral tissues and from dietary amino acids (Cornell, 2008). High-protein meals and stringent exercise can increase ammonia production and metabolism (Cornell, 2008) and should be considered if NH_3 levels ever become elevated without a known source of contamination.

There is no way to prevent these types of contaminants from entering spacecraft or space habitats, so the ARS Air Revitalization System is utilized to sustain good air quality, as well as utilizing preventative measures, such as limiting how long crew members are in small, tight or confined spaces.

5.2 Off-Gassing

An off-gassed product is a compound evolved as a gas from a material or assembled article. Polymeric materials are known to release gases via breakdown of the polymer and volatilization of the products, or through the liberation of gases trapped during the process of manufacturing or cleaning of materials (Coleman and James, 1994). In order to minimize the risk of toxic contamination to the crew by flight articles, NASA requires that off-gas acceptability testing be performed as a mandatory step before flight acceptance is conferred (NASA (National Aeronautics and Space Administration), 1991b).

Alcohols, aldehydes, aliphatic hydrocarbons, CO, chlorinated hydrocarbons and siloxanes may be a result of materials off-gassing (Coleman and James, 1994). At the end of an off-gas test (72 hours, 120°F) the atmosphere of the sealed test chamber is determined by analytical instrumentation that allows for separation, identification and quantification of all off-gassed products according to NASA standards. An individual flight article, the assembled flight articles or multiple numbers of a flight article are determined for acceptance by their toxic hazard index or toxicity (T) value. The T value is defined as, 'the dimensionless ratio of the projected concentration of each off-gassed product to its seven day SMAC value and summing the ratios for all off-gassed products without separation into toxicological categories' (International Organization for Standardization, 2000).

The T-value calculation:

$$T_{\text{total}} = C_1/\text{SMAC}_1 + C_2/\text{SMAC}_2 + \ldots + C_n\text{SMAC}_n \quad (1)$$

C_1 = concentration of contaminant 1 and SMAC_1 = 7d SMAC of contaminant 1.

The T_{total} for any test item should not exceed 0.5 if it is to be deemed acceptable for flight (Coleman and James, 1994; International Organization for Standardization, 2000). If the test article does not meet this criterion,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat169
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

it may undergo treatment to reduce off-gassing levels, such as 'baking' the article at an elevated temperature before undergoing additional off-gas testing. NASA can also assign a rating that allows a certain mass of the material to be used. NASA may opt to replace the failed material with another type of material that has passed off-gas requirements.

In years past, NASA has attempted to summarize the off-gassing from all materials inside a module, but this has proven to be inaccurate. Beginning with the ISS, NASA has tested each US module on the ground for aggregate off-gassing. This is because first entry into sealed modules that are attached to the ISS can pose a distinct toxicity hazard. While modules are assembled with materials determined to be safe by off-gas testing, once assembled, new volatile chemicals could be introduced via adhesives, sealants or other chemicals used in assembly process, therefore it is necessary to off-gas-test assembled modules with at least 75% by mass of its launch contents. These modules are also sealed for many days (typically 100 days) prior to launch. The off-gas test should be at least one fifth of the time between the last clean air purge and the first entry of the crew. Results of a whole-module off-gas test can be used to predict the level of pollution the crew will encounter when first entering the module.

5.3 Payload Chemicals

Chemicals are also introduced into the habitable space environment through payload experiments. Potentially toxic or known toxic chemicals are routinely employed in biological and chemical studies. There are a vast number of chemicals used in payloads such as buffers, fixatives, acids, preservatives and proteins. The space toxicologist must assess every chemical contained in a payload and assign a toxicity hazard level (THL) value based upon its inherent toxicity, the amount that could possibly be released into the cabin volume and the ability of the crew to remediate the contaminant from the area.

5.4 Thermodegradation

Even a small fire or pyrolysis event can pose a serious and frightening hazard inside a sealed spacecraft. NASA utilizes fire-resistant materials on its spacecraft, especially in the insulation of wiring; the most commonly used insulations are Teflon and Kapton. While unlikely to burn, these polymeric materials pose unique concerns due to the highly toxic materials that are released during pyrolysis. These highly toxic chemicals include hydrogen cyanide (HCN), hydrogen fluoride (HF), hydrogen chloride (HCl), CO and nitrogen dioxide (NO_2). While NASA has restrictive flammability standards in place to safeguard against the introduction of thermodegradation contaminants, most nonflammable materials that undergo smouldering from high heat will release highly toxic pyrolysis products (NASA (National Aeronautics and Space Administration), 1991b; Coleman and James, 1994). It is noted that in the absence of gravity, convection does not occur, so combustion products are not transported from the fire and combustion events may be oxygen-poor leading to high production of CO.

Despite best efforts during spaceflight, there are a few examples of pyrolysis products being released. Arcing and pyrolysis of wire insulation made of Kapton and Teflon sleeves; electrical-wire fusion of Kapton–poly tetrafluoroethylene electrical-wire insulation; thermodegradation of electronic components of data display units, and thermodegradation of Delrin housing and Stepan foam insulation of a refrigerator unit. The refrigerator incident in particular caused the crew members to temporarily seal off this area and enter a different module for fresh air (Coleman and James, 1994). Fortunately none of the documented thermodegradation events released life-threatening levels of toxic products; however, they highlight the concern of potential hazards associated with these types of incidents (Coleman and James, 1994).

5.5 Combined Effect of Radiation

Radiation itself can be a toxic hazard to space explorers. High levels of ionizing radiation can have deleterious and even fatal effects if not properly managed (Eckart, 1996; Gardner, 1999). Radiation has the ability to potentiate the toxicity of volatile and other airborne chemicals (Gardner, 1999). Radiomimetic chemicals and drugs must be carefully evaluated during spaceflight (Coleman and James, 1994). Much more research on radiation effects on chemicals in microgravity is needed in order to fully elucidate radiation's role in the potential toxic effect of chemicals in physiologically compromised astronauts.

6 UNUSUAL PHARMACOKINETICS OF COMPOUNDS IN ASTRONAUTS

Absence of gravitational forces (or altered gravity) must be considered when assessing pharmacokinetics, chemical reactivity, behaviour and settling times (particulate). Studies have shown that chemical kinetics are altered during microgravity (Berinstain *et al*., 1999). Due to the known physiological changes in the body resulting in changes in fluid shift, organ shape and enzymatic activity, it can be expected that pharmacodynamics (measurement of quantifiable drug responses as a function of drug concentration) and pharmacokinetics (time course of a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat169
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

chemical/drug and its metabolites in the body) of chemical compounds would be altered Derendorf (1994). It is stated by Levy (1991) that studies of pharmacodynamics of drugs on animal and human test subjects subjected to physiological perturbations will lead to an increase in the understanding of chemical reactions and the biological system. Derendorf (1994) further discussed the mechanisms that will affect drug efficacy including clearance (excretion), change in enzyme activity and renal changes, binding (absorption) to tissues and proteins, blood flow (distribution) and bioavailability (potential efficacy). These variables are arduous to predict (and a source of much debate amongst regulatory toxicologists) under normal terrestrial conditions, making the need for further research in this area very useful for long-term space exploration. In 2004, Graebe *et al*. summarized the current state of knowledge in regard to pharmacokinetics and pharmacodynamics. This article addressed the lack of data in these areas and summarized current procedures in place to predict the effect of drugs in microgravity. Prior to flight, astronauts test all medications that are frequently used during spaceflight before mission assignment to identify potential side effects, performance-related problems and individual therapeutic effects; this evaluation tool is not precise for determination of how these chemicals react in space, but they have proven to be useful in the absence of true data (Graebe *et al*., 2004).

7 ASTRONAUTS AS A SUSCEPTIBLE POPULATION

We hope someday, having solved the problems we face, to join a community of galactic civilizations.
President Jimmy Carter, 1977 (39th President of the United States of America)

Astronauts engaged in spaceflight must physiologically adapt to the absence of gravity and the stresses associated with intense work and isolation. Post-flight physiological evaluations of astronauts and flight experiences have revealed a number of ways that astronauts are changed from their earth-based health status. The mechanism of these changes is often not understood, but the target organ or system involved in change is clear. A potentially toxic compound that adversely affects the same system or organ may be more potent in space because of the spaceflight-induced changes. That is, the crew is more sensitive to the toxic compound than they would be on earth.

7.1 Haematotoxicants

Based on immediate, post-flight measurements after missions of varying duration, the loss of approximately 10% of red-cell mass occurs within a week of in-orbit operations and persists at this level of loss throughout the time a crewmember is in orbit (Huntoon *et al*., 1989). In setting SMACs, experts agreed that exposure of crewmembers to a compound that reduces red-cell mass or other red-cell parameters should not have an exposure limit as high as would be estimated for earth-based exposures. The mechanism of the spaceflight reduction in red-cell mass is not clearly elucidated and often the mechanism of action of a given haematotoxicant is unknown. Expert judgment suggested that a reduction of the standard for an earth-based exposure of threefold would be sufficient to protect astronauts in orbit, even with their spaceflight-induced loss of red-cell mass. This factor has been applied in setting SMACs for 2-ethoxyethanol, benzene, nitromethane, indole and isoprene.

7.2 Cardiotoxicants

Episodic reports of cardiac arrhythmias during spaceflight, and especially during extravehicular activities (EVAs), suggest that exposures to cardiotoxicants on orbit should be more constrained than for earth-based populations (Buckey and Buckey, 2006). Arrhythmias, such as preventricular contractions, have been reported during stressful times, such as during EVA, and also at times when the crew was known to be potassium-depleted (Leguay and Seigneuric, 1981). Such arrhythmias can have serious and sudden medical consequences; therefore, the experts engaged to set exposure limits determined that a factor of five was appropriate for reduction of any earth-based exposure standard for cardiotoxicants to one suitable for spaceflight. Compounds for which this factor was used include the following: bromotrifluoromethane (shuttle fire extinguishant), CO and several Freons.

7.3 Immunotoxicants

A number of changes in the immune system during and immediately after spaceflight have been demonstrated; however, these cannot be uniformly characterized as adverse effects. Methodological differences appear to play a major role in the outcome variations of research investigations and clinically significant functional changes have not been demonstrated (Borchers *et al*., 2002). Many factors may contribute to immune changes, including isolation, confinement, loss of gravity, radiation, sleep irregularities and poor nutrition (Sonnenfeld and Shearer, 2002). Postflight immune changes include altered cytokine production, natural-killer (NK) cell function, monocyte function and granulocyte function,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat169
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

whereas, in-flight studies have demonstrated reactivation of latent herpes viruses and altered cell-mediated immunity (Crucian *et al*., 2008). Experiments on animals flown in space and on humans in bed-rest studies have also contributed to our understanding of the potential effects on the spaceflight-stressed immune system. Collectively, the term immunologists use to describe these changes is 'immune system dysregulation'. Such effects clearly suggest that any exposure limit for an immunotoxicant ought to be reduced to compensate for the possibility that an astronaut's immune system is compromised. The safety factor for this concern has been set at three by NASA and the NRC Committee on Toxicology.

7.4 Ethnic Diversity in Sensitivity to Toxicants

Science, for hundreds of years, has spanned the differences between cultures and between countries.
Laurel Clark (US Astronaut)

Human spaceflight involves persons from a wide variety of racial and ethnic groups. In setting exposure limits for certain toxicants we must account for differences that could make certain groups more susceptible to those toxicants. NASA does not use any general safety factor for intraspecies variability, as some agencies do, because the astronauts comprise a healthy, middle-aged population; however, factors are used when data show that a specific subpopulation is sensitive to the toxic effects of a compound. When the SMACs were set for ethanol, the issue of the 'flushing response' that occurs in certain Asian subpopulations after oral consumption of ethanol was considered as a separate end point (James, 1996). This enabled the SMAC to be protective of this subpopulation of astronauts. For other compounds a factor of three has been used when a sensitive subpopulation is known or postulated to exist. For example, the formaldehyde SWEG was reduced by a factor of three due to the potential for increased sensitivity of a subpopulation related to genetic polymorphisms in formaldehyde dehydrogenase (McCoy, 2007).

8 AIR REVITALIZATION AND WATER RECOVERY

The air- and water-quality systems are critical for ensuring the safety of air and water. As stated by Waligora *et al*. (1994), astronauts are not expected to dedicate significantly more time towards life support activities than they would on Earth; therefore the broad goal in the development of life support systems is to provide an unassuming, reliable unit that requires minimal crew involvement.

8.1 Air Revitalization System

Air quality is of particular importance for protecting the health of astronaut explorers in a closed loop. Coleman and James (1994) describe air 'scrubbing' as having particular importance after a release of toxic chemicals or after thermodegradation. The ARS is the primary tool for keeping air pollutants at safe levels and plays a pivotal role in health, safety and mission success. NASA has a long-standing process for the development for the ARS that has been utilized on board manned spacecraft and space habitats such as Skylab and the ISS (NASA (National Aeronautics and Space Administration), 2008b). Several options exist for providing a practical design for the ARS, each option affects crew comfort and safety, reliability, weight and cost (Waligora *et al*., 1994). Multiple iterations of the ARS have been engineered throughout the history of manned spaceflight, from Project Mercury through to the ISS. All of the ARS systems show a spectrum of process technologies and hardware for purification and management of spacecraft cabin atmospheres (NASA (National Aeronautics and Space Administration), 2008b). NASA describes the primary processes for air revitalization or scrubbing as separation or reaction processes. Separation processes that have been employed by NASA include physical adsorption, absorption and filtration. Chemical adsorption, oxidation, reduction and electrochemistry are some of the reactive processes employed. The major function of the ARS is removing trace contaminants such as volatile organic compounds (VOCs), particulate matter (PM) and CO_2 from the cabin atmosphere. The ARS serves as resource recovery and recycling, and atmospheric gas production, distribution and storage, such as CO_2 reduction to methane and carbon products, and atmospheric gases from *in situ* resources (NASA (National Aeronautics and Space Administration), 2008b).

The course taken for the removal of CO_2 during the Mercury, Gemini, Apollo and Shuttle Programmes employs consumable LiOH canisters. The current US Shuttle vehicles, use two LiOH canisters for CO_2 absorption. Each canister contains 2.3 kg of LiOH and at least 85 g of charcoal (Coleman and James, 1994; NASA (National Aeronautics and Space Administration), 1989). The LiOH canisters, in addition to CO_2, are also able to adsorb HF, HCl, HCN, NO_2 and other gases produced by fire (Coleman and James, 1994). The charcoal in these canisters traps VOCs released by crew metabolism and off-gassing. These canisters must be replaced at 6–12 hour intervals depending upon the size of the crew

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat169
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Coleman and James, 1994). NASA has operated molecular sieves regenerated by vacuum swing and/or thermal swing for CO_2 removal during the Skylab and ISS Programmes (NASA (National Aeronautics and Space Administration), 2008b). NASA has gained some insight through the use of immobilized amines that are regenerated by a vacuum swing process. However, even though the process has been demonstrated on multiple Shuttle missions, this procedure is still being studied and has not been employed for routine use on manned spacecraft (NASA (National Aeronautics and Space Administration), 2008b).

Granular activated carbon (GAC) and a variety of oxidation catalysts is used by NASA for the removal of trace chemical contaminants. The GAC is normally derived from coconut shells. Specialized forms of GAC are specially treated to remove contaminants such as NH_3 and CH_2O (NASA (National Aeronautics and Space Administration), 2008b). GAC, along with thermal catalytic oxidation, is used to eliminate CH_4 and CO for long-duration missions. Shorter missions employ an ambient-temperature catalytic oxidizer (NASA (National Aeronautics and Space Administration), 2008b).

Mechanical filtration is utilized to remove PM commonly found during spaceflight. The ISS utilizes high-efficiency particulate air (HEPA) filters that remove respirable range particles while the shuttle uses a filter rated for 40 microns nominal and 70 microns absolute size particles (NASA (National Aeronautics and Space Administration), 2008b).

8.2 Water Recovery System

Clean water is vital for the protection of crewmembers from waterborne contaminants found in potable and hygiene water. For long-duration missions, it would be impossible to carry all of the water needed by crewmembers living in space, therefore the water revitalization and recovery systems are in place to supply this precious commodity. During early spaceflight missions, water supplies were transported on board for short-duration flights during the Mercury and Gemini eras. Apollo flights introduced water created as a by-product of electrical power fuel cells. This water was used for consumption and food reconstitution; however, personal hygiene was kept to a minimum (Waligora *et al*., 1994; Sauer and Calley, 1973. Skylab did not employ fuel cells, since the mission length did not make their use feasible. The Shuttle uses fuel cells to supply water for consumption, food reconstitution and personal hygiene (Waligora *et al*., 1994). Recycled water is needed for housekeeping, personal hygiene and consumption; each of these tasks increase in criticality as flight duration increases (Waligora *et al*., 1994). The water required is estimated at 2.2 l per person per day for drinking, hygiene and food preparation, 1 l per person per day for water regeneration and up to 0.3 l per person per day for flushed water; these basic needs require the capability to recover and recycle safe water during sustained presence in space. Water reclamation systems are designed to supply specified amounts of water at a specific quality (National Research Council (NRC), 2000a).

NASA has found that the hundreds of chemicals identified in the closed-loop atmosphere may end up in the recycled water. The in-orbit water recovery hardware on the ISS has humidity condensate collection systems, as well as equipment for the recovery of humidity condensate (NASA (National Aeronautics and Space Administration), 2008a). All of the CO_2-removal equipment in use on the ISS has been engineered towards working in harmony with the optimal closed-loop ARS; this system operates by reacting CO_2 with H_2 produced by an onboard water-electrolysis unit. The interaction between these processes recovers a significant amount of water (NASA (National Aeronautics and Space Administration), 2008a). Future plans for urine treatment include regenerative environmental-control life-support system (ELCSS) hardware. This equipment will be deployed on the ISS and will have the capacity to increase the recovery of wastewater by processing pretreated urine in a vapour compression distillation (VCD) subsystem (NASA (National Aeronautics and Space Administration), 2008a). This water processing assembly (WPA) will treat urine distillate and humidity condensate via combined adsorption and ion-exchange processes, and thermal catalysis. Once in use on the ISS, NASA estimates that approximately 93% of wastewater will be recovered to potable standards, leaving the remaining wastewater as a concentrated brine solution (NASA (National Aeronautics and Space Administration), 2008a).

9 SPACE TOXICOLOGY ASSESSMENTS

Space toxicology combines our understanding of the adverse health effects of environmental pollutants with our conception of how these pollutants behave differently in space and how humans may be more sensitive to exposures during times of space exploration. Our goal when assessing toxicity is to manage the health risks that would potentially be derived from toxic exposures during spaceflight, habitation of outposts and exploration of celestial bodies. Within this century we hope this will include a sustained presence on our moon, followed by placing explorers in outposts on Mars, the tiny moons of Mars and perhaps nearby asteroids. Toxicological risks must be assessed and managed within the context of extreme isolation, continuous exposures, reuse of air and water, limited rescue options and the need to use highly

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Figure 2 Astronaut conducting a spacewalk: the life-support system contains several batteries. (Reproduced from NASA.)

toxic compounds for propulsion. As we begin to explore other celestial bodies *in situ*, other toxicological hazards, such as inhalation of reactive mineral dusts, must also be assessed for risk.

Space toxicology assessments are risk-assessment tools used by NASA engineers, flight surgeons and flight directors to ascertain the potential toxicity of a chemical, chemical mixture or chemical by-product being flown in space. Data on chemical and biological materials to be flown in the pressurized volumes of habitable spacecraft and habitats are needed by space toxicologists to assess the toxicity and assign hazard levels (NASA (National Aeronautics and Space Administration), 2006). These levels may be used as a means to decide whether or not a chemical-containing payload will be safe enough to fly during manned spaceflight missions. It is up to the toxicologist to determine the chemical THL in the specified space vehicle or habitat module in which the proposed chemical(s) will be housed during spaceflight or space habitation. If this includes more than one risk scenario, each hazardous scenario must be assessed and rated separately. THLs are assessed only for chemicals, and the space toxicologist must understand the mission environment and be aware of all chemical hazards contained in the habitable volume of the spacecraft or space habitat in order to address the concurrent exposures to a variety of airborne chemicals.

Any apparatus that is scheduled to enter the pressurized or habitable volume and contains chemicals or off-gassed chemical contaminants must be assessed for health hazards. Payload experiments often contain toxic chemicals involved in materials processing, tissue fixation, fluid behaviour and other types of experiments (Coleman and James, 1994). The vast and varied numbers of chemicals that will be introduced into the habitable volume by a multitude of instrumentation and operational equipment, all required for spaceflight operations, must be evaluated for their potential to introduce chemicals in the closed-loop environment. Use of materials that have been deemed safe by off-gas testing is not always possible when designing new instrumentation or devices necessary for specific flight tasks. At times the toxicologist will also come across unusual toxicity requests for compounds not intentionally flown in space (e.g. CdO dust from corroded connectors).

Batteries contain toxic or corrosive chemicals that serve as electrolytes or active ingredients. Several batteries are used to power devices such as laptops and space-suit life-support systems (see **Figure 2**) aboard space vehicles and habitats. There are several hundred batteries currently in use on the ISS. Each type of battery in use must be assessed for toxicity. For the Space Shuttle, all toxicological assessments for batteries are housed in one NASA document (NASA (National Aeronautics and Space Administration), 1991a).

The THL rating scale is numerical and has unique criteria for each number. The scale ranks from 0 (nonhazardous) to 4 (catastrophic). A THL of 0, or nonhazardous, is defined in NASA guidelines as a chemical that may be a gas, solid or liquid, which may or may not be containable, that will cause zero to no greater than slight irritation that will last less than 30 minutes, which requires no therapy and causes no systemic effects.

The critical or level 1 THL is defined as a gas, solid or liquid, which may or may not be containable, that results in slight to moderate irritancy that lasts greater than 30 minutes and will require therapy. The systemic effects will be minimal with no potential for lasting internal tissue damage.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat169
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

All THLs rated 2–4 are considered catastrophic hazards and distinguished as follows. A catastrophic level 2 THL is either a solid or nonvolatile liquid that can be contained, cleaned and removed by crewmembers, which has no systemic effects and causes moderate to severe irritation that has the potential for long-term performance decrement and will require therapy. It also may cause permanent eye damage.

The catastrophic level 3 THL is a solid or nonvolatile liquid that can be contained, cleaned and removed by crewmembers, that would cause appreciable effects on perception, coordination, memory or the potential for long-term (delayed) critical injury (cancer) or may result in internal tissue damage. Irritancy alone does not constitute a level 3 hazard.

The highest THL, catastrophic level 4 is a gas, volatile liquid or fumes if released or escapes, that are not containable, that would result in moderate to severe irritancy. THL 4 exposures have the potential for long-term decrement of crew performance, would cause appreciable effects on perception, coordination, memory or the potential for long-term (delayed) critical injury (cancer) or may result in internal tissue damage. If the chemical is an eye-only hazard, there may be a risk of permanent eye damage. THL 4 exposures will require therapy for the affected crewmembers.

NASA is committed to not flying or limiting any toxicity level 4 hazards from being used in the crew's habitable volume during manned spaceflight. However, certain THL 4 chemicals may be deemed critical for spaceflight and therefore every effort is made to isolate THL 4 chemicals from the crewmembers during spaceflight.

The THLs have become essential for all manned spaceflight operations. These toxicity ratings are utilized by a number of groups throughout NASA in support of planning, design and decision-making for each mission. Hardware may be designed to ensure THL levels are not exceeded, payload developers must ensure that their payload does not introduce a catastrophic hazard into the habitable volume, safety engineers make containment and labelling decisions based in part upon THLs for the protection of ground personnel and crewmembers. NASA flight surgeons make preflight and real-time decisions for operations decisions and treatment, if necessary, of crewmembers in the event of off-nominal exposures and releases.

10 RISK-BASED ENVIRONMENTAL MONITORING

The space toxicologist will assess risk by taking into consideration the amount of individual chemicals or, if applicable, the content of each chemical in mixtures, human physiological changes, route of exposure, chemical by-products (if deemed appropriate) and potential contact time, in order to assign toxicity hazard rating. All chemical-containing materials must be assessed before they are allowed to be utilized during spaceflight operations. The broad scope of chemical-containing materials, including liquids, gases and particulates, and chemical exposure scenarios, must all be deliberated in order to assign toxicity assessment values, as well as in setting spaceflight guidelines or standards. Spaceflight guidelines/standards are set for a number of chemicals for limiting human exposure in air and water. These values are time-weighted averages and consist of short-term and long-term permissible exposure limits. These quantities should not be exceeded during nominal space operations since they are intended to protect astronauts from acute and chronic health effects.

10.1 Predictable Risks

Since we know the compounds present aboard any spacecraft, we can make plausible predictions about which of them might become a toxic hazard. At the present time NASA uses an array of instruments to manage predictable risks of air pollution in the ISS or Shuttle. These instruments provide real-time and archival (returned to earth for analysis postmission) monitoring of chemical contaminants. Propellants are monitored using a gold-salt method in the air lock (a small compartment through which astronauts must go to gain access to the vehicle exterior) in case some of this material contaminates the EVA suits and is brought back into the air lock (Bacal *et al.*, 2008). If propellants are detected, then flight rules dictate procedures for removing residual propellants, such as baking out in sunlight or brushing off the offending crystals. Ammonia can be monitored inside the ISS using detector tubes in the remote possibility that this heat-exchange material breaches several barriers and migrates from the external thermal loops into the cabin. Again, flight rules dictate procedures based on ammonia-monitoring results. CO_2 is monitored using a hand-held infrared spectrometer, referred to as the carbon dioxide monitoring kit (CDMK), to determine if pockets of this anthropogenic gas have formed or if whole-module analysers are accurate (Limero *et al.*, 2000).

10.2 Unpredictable Risks

We can expect combustion events to occur episodically in spaceflight; in that sense these events are predictable; however, the toxic threat caused by a fire is unknown without specific air monitoring. NASA employs a hand-held device known as the compound specific analyser—combustion products (CSA-CP) using electrochemical sensors for CO, HCN and HCl to assess the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Figure 3 Crewmember operating and air monitor on the Shuttle. (Reproduced from NASA.)

toxic risk from a fire if it occurs, and to assess the air revitalization as air quality is recovered after an event. Flight rules, based on the results of monitoring, govern the crew actions in dealing with a fire. Because the ISS has become a sprawling complex, four such analysers are deployed in selected modules throughout the ISS to deal with any combustion event.

Volatile organic compounds can accumulate slowly in spacecraft atmospheres or be suddenly released as a result of accidents. Such unpredictable sources require a broad-spectrum capability to monitor VOCs at trace levels (see **Figure 3**). For several years the ISS has depended on a volatile organics analyser (VOA) based on gas chromatography/ion mobility spectrometry to monitor the atmosphere *in situ* (Limero *et al*., 2003). This large instrument proved valuable in characterizing the impact of nominal regeneration of Metox canisters and in characterizing the pollutants released when seals in the Elektron (an oxygen generator) were overheated during a repair (James, 2003). Since the VOA is well past its design lifetime and shows signs of imminent failure, replacement instruments are being developed. One promising instrument based on commercial technology is a gas chromatograph/differential mobility spectrometer that is hand-held (Limero *et al*., 2008).

11 DUST AS A TOXICITY HAZARD

11.1 Nuisance Dust

During ordinary spaceflight operations dust is seldom a problem aboard the ISS or the Shuttle. HEPA filters remove virtually all particles that could be a problem aboard the ISS. This does not mean that the ventilation ducts do not occasionally become obstructed with 'dust bunnies'. When this happens, the ability of the air revitalization to remove pollutants can be significantly reduced. Improved materials management has reduced the early problems of floating lint and debris aboard the Shuttle. When new modules are brought to the ISS, the crew is warned to wear eye protection when first entering it because the dust and debris that had settled during ground-based processing becomes airborne in the absence of gravity.

11.2 Reactive Dust

In addition to nuisance dust, spacecraft can sometimes have reactive dust in the air. The prime source for this is the LiOH dust that can come from canisters designed to remove CO_2 from the air by reacting with it. Aboard the Shuttle a single canister lasts for approximately one day depending on the size of the crew. The ARS contains two canisters in parallel that can be changed out on an alternating schedule. Occasionally, if the canisters are old, LiOH dust will have contaminated the outside of the canisters and the person changing the filter may receive a slight, irritating exposure to this reactive dust. Some crews report that when a new filter has been placed in line they sense a very slight degree of mucosal irritation for a few minutes, presumably from LiOH dust swept into the airstream as it passes through the interior of the fresh reaction bed.

11.3 Lunar Dust

During the Apollo flights to the moon, and especially when the lunar lander returned to the command module while it was orbiting the moon, the absence of gravity enabled the accumulated dust to float freely in the

Figure 4 Apollo astronaut exploring the lunar surface during the Apollo missions. The open design contributed to lunar dust contamination of the suits of the astronauts. The main sources of lunar dust contamination came from exploration on foot and taking lunar samples. (Reproduced from NASA.)

air. Typically, the dust proved to be no more than a nuisance to the crew; however, in at least one instance an allergic-like reaction occurred to the dust. By the time the crew received these exposures to the dust it had been aged in the habitable environment for many hours or several days. Lunar geologists have described the surface of pristine lunar dust as highly reactive due to solar wind bombardment and micrometeoroid impacts (see **Figure 4**). Lunar dust also has a very large surface area for a given dust grain size. These properties suggest that fresh lunar dust could be more toxic than the aged dust encountered by the Apollo crews. NASA has investigated the toxicological properties of lunar dust stimulants (Lam *et al*., 2002) and is in the process of testing authentic lunar dust. The problem is confounded by the fact that there are different types of lunar dust (mare and highland) and each of these types can be in various degrees of 'maturity'. In anticipation of prolonged stays on the lunar surface, NASA is developing a database from which evidence-based exposure standards can be established.

11.4 Martian Dust

Martian dust is likely to present a very difficult problem for the first humans to reach that exotic environment. Planet-wide dust storms have been observed in the past few years and small 'dust devils' have been photographed as they dance across the Martian surface raising dust spouts and etching the terrain with grooves. The chemical reactivity of Martian dust was demonstrated by experiments aboard the Viking spacecraft (Oyama, 1977). In fact, it was this reactivity that led some scientists to propose that this was evidence of life (Oyama and Berdahl, 1977). At the time of writing NASA has landed a spacecraft in a crater near the north pole of Mars and is testing surface samples of dust *in situ* to assess its reactivity. The results could elucidate the type and magnitude of the reactivity of Martian dust. Of course we face the potential problem of the heterogeneity of the dust in various locations; however, planet-wide dust storms may have resulted in a relatively uniform surface covering by the dust.

12 THE VISION FOR SPACE EXPLORATION

This cause of exploration and discovery is not an option we choose; it is a desire written in the human heart.

President George W. Bush (43rd President, United States of America)

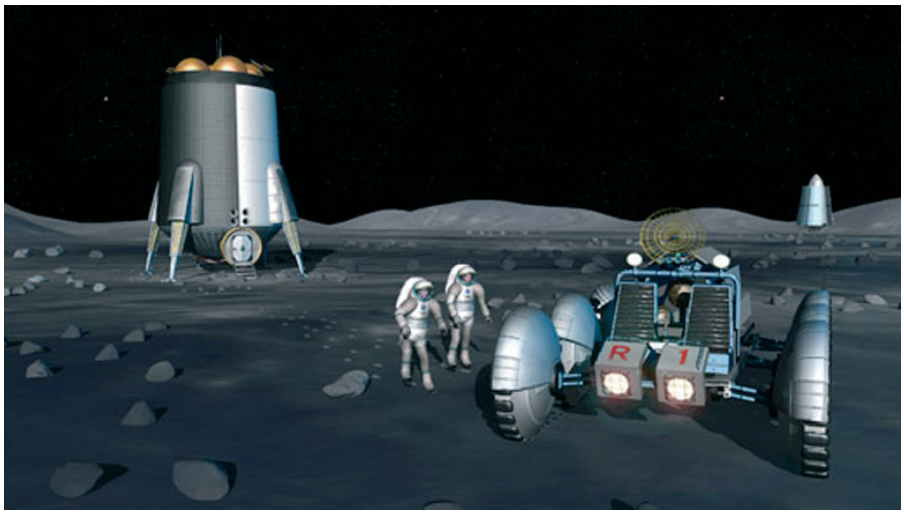

Figure 5 Computer depiction of future lunar missions. (Reproduced from NASA.)

We end with a brief look ahead to the future of space exploration. Space toxicology will support the programmes of the future and embark upon supporting crew health as we venture to distinct and uncharted locations. The future of space operations involves intense isolation, greater challenges with air and water reclamation, reuse and conditioning, chronic chemical exposures, exposure to reactive mineral dusts and limited return and rescue options.

In 2004, NASA published its *Vision for Space Exploration*; this document outlined the United States' plans for retiring the shuttle, completing the ISS and returning to the moon and exploring beyond. The goal to advance scientific, economic and security interests is described as fundamental for the United States (NASA (National Aeronautics and Space Administration), 2004). In order to accomplish this incalculable ambition, NASA has embarked upon multiple projects. These include implementing a human and robotic programme for exploration of the solar system and beyond, extending the human presence across the solar system by returning to Moon in preparation for human exploration and habitation of other celestial destinations (see **Figure 5**), such as Mars, its moons and perhaps nearby asteroids, developing technologies and infrastructures to support future exploration and promoting international and commercial participation (NASA (National Aeronautics and Space Administration), 2004). As NASA prepares to return to the lunar surface in 2018, space toxicologists labour to support these efforts through an array of projects. These include (but are not limited to):

- Supporting the successful retirement of the Shuttle programme with continued toxicology analysis and real-time support during missions.
- Working with international partners to ensure the maintenance of a safe living and working environment on the ISS
- Conducting lunar dust toxicity research and developing guidelines and risk criteria for human exposure (Khan-Mayberry, 2008a).
- The adaptation and development of next-generation environmental monitoring equipment, to improve our real-time monitoring capabilities of air and water quality
- Providing subject-matter expertise and toxicological analysis in support of the design and development of spacecraft, spacesuit and habitat designs supporting all new manned spaceflight programmes.

Space exploration entails cooperation with the best and brightest across technical disciplines from public, educational and private industries; this keeps our field of space toxicology interesting and filled with diverse opportunities for those with an interest in collaborative efforts.

ACKNOWLEDGEMENTS

I would like to express gratitude and recognize my coauthor, NASA chief toxicologist Dr. John T. James, along with my fellow space toxicologists Dr. Hector Garcia, Dr. Chiu-Wing Lam, Dr. Shannon Langford and Dr. Raghupathy Ramanathan, who work tirelessly to protect the health of our astronauts. I dedicate this chapter to anyone that looks to the stars for inspiration, knowledge and understanding. To my family who sustains me and friends who inspire and encourage me. Finally, to all the women and men of the National Aeronautics and Space Administration who take on the challenges of space exploration to answer the call for scientific and philosophical understanding.

Long-term Adverse Health Consequences from Exposure to Products Generated from Major Disaster Sites

Matthew P. Mauer

CONTENTS

1 INTRODUCTION

Major disasters have been a constant reality since ancient times. From the destruction of Pompeii in AD 79, to the Chicago fire in 1871, to the World Trade Center (WTC) disaster in 2001, major disasters have repeatedly caused disruption, illness and death. A variety of natural and human-made events may be characterized as major disasters. Some examples include the cataclysmic eruption of Krakatoa in 1883, the San Francisco earthquake in 1906, the explosion of the atomic bomb at Hiroshima in 1945, the deadly smog events in Donora in 1948 and in London in 1952, the toxic gas release at Bhopal in 1984, the nuclear disaster at Chernobyl in 1986, the Oklahoma City bombing in 1995, the Indian Ocean tsunami in 2004 and Hurricane Katrina in 2005.

By definition, disasters are emergencies of a severity and magnitude resulting in deaths, injuries, illness and/or property damage that cannot be effectively managed by the application of routine procedures or resources (Landesman, 2001). Disaster has also been defined as a situation of massive collective stress (Kinston and Rosser, 1974). Leonard and Teitelman (1991) have defined a disaster as 'any community or regional event that disrupts community function and activities and causes concern for the lives, health and property of the citizens of a community'.

Epidemiological approaches to disasters usually focus on the immediate post-impact period with emphasis on surveillance of injuries, outbreaks of infectious and communicable diseases, illness due to environmental hazards, and mortality (Logue *et al*., 1981). However, it is important to recognize that disasters may result in long-term health consequences, including effects on mortality and morbidity one or more years after the event (Logue *et al*., 1981). The physical health of survivors of major disasters may be adversely affected for years, particularly in technological disasters, such as those involving chemicals and radiation (Noji, 2005). Thus, epidemiological studies of disasters must account for several issues, including characterization of the population at risk and/or exposed to the disaster, estimation of the exposure to the disaster, identification of short-term adverse health outcomes, and identification of long-term

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

adverse health outcomes (Dominici *et al*., 2005). It has been noted that evidence for long-term consequences of disasters, both physical and emotional, through the use of cohort studies with sufficient follow-up time is somewhat lacking (Ibrahim, 2005). Galea (2007), in discussing the findings of one study of long-term health effects after a disaster, stated that 'thinking only about the acute population-health consequences of disasters is essentially considering only the tip of the iceberg'. Furthermore, he explained that persistent illness after a disaster may result in an increase in use of physician services and changes in the patterns of need for medical care, which can extend well beyond the immediate aftermath of a disaster. He went on to state that 'recognition that physical symptoms may persist for several years after exposure to a disaster, then, has implications for clinicians—perhaps primarily for primary care providers'. Long-term health effects can thus result in substantial personal, economic and societal burdens. When one considers that long-term health effects may include lingering, chronic effects as well as latent diseases such as cancer, the importance of studying such effects after a major disaster becomes clear.

This chapter will review reports of long-term health effects from a selection of major disasters, from several different disaster categories. Specifically, this review will cover the physical effects of exposures, as opposed to psychological effects. While not all major disasters for which pertinent literature exists can be covered, those discussed have been selected to provide an overview of a wide range of exposures. For some more recent disasters, such as the WTC disaster, there is a large and growing body of evidence regarding long-term health effects. For other disasters, the evidence is more limited. Overall, this review is intended to offer insights into the spectrum of long-term health effects that may be considered when planning epidemiological studies in the aftermath of future disasters. In addition, by illuminating some of the limitations of our knowledge in this area, this review may help encourage future disaster planners and researchers to emphasize the study of long-term health consequences from major disasters.

2 TYPES OF DISASTERS

According to the web site of the United States Department of Homeland Security's Federal Emergency Management Agency (FEMA), there are 17 categories of disaster (**Table 1**). Disaster types can also be grouped into 'natural disasters' and 'technological disasters' (Landesman, 2001). Natural disasters are unpreventable and, for the most part, uncontrollable. They include earthquakes, floods, heat waves, hurricanes, landslides, thunderstorms, tornadoes, tsunamis, volcanoes, wildfires and winter storms. Technological or human-made disasters are also unpredictable, may be unpreventable, and may have limited physical damage while having long-term effects (Landesman, 2001). Technological disasters include dam failure, fire, hazardous materials incidents (chemical, biological or radioactive), nuclear power plant emergencies and terrorism. They may also include explosions, building or bridge collapses, transportation crashes, and breaks in water, gas or sewer lines (Landesman, 2001).

Table 1 Types of disasters

3 TERRORISM-RELATED DISASTERS

3.1 The World Trade Center Disaster—11 September 2001

The WTC disaster represents one of the worst technological disasters in history. The 11 September 2001 terrorist attacks in New York City resulted in the destruction of the WTC towers and the destruction of or damage to many other surrounding buildings. The magnitude of the destruction and resulting wreckage was unprecedented (**Figure 1**). Tragically, thousands lost their lives, including passengers on the involved commercial aircraft, community residents, office workers, and heroic rescue and response personnel.

On the morning of 11 September 2001, each of the WTC towers (North Tower and South Tower) sustained a direct hit from a jet airliner laden with jet fuel. The combustion of over 90 000 l of jet fuel in the two airliners initiated fires that reached a maximum temperature of 750–800 °C, resulting in the collapse of the towers (Eagar and Musso 2001). The collapses destroyed an estimated 1.2 million tonnes of construction material, an estimated 50 000 desktop computers,

Figure 1 Lower Manhattan, New York City, just after the collapse of the first World Trade Center tower, 11 September 2001. (Reproduced from USEPA.)

Figure 2 The cloud of dust and debris enveloping lower Manhattan immediately after the collapse of the World Trade Center towers, 11 September 2001. (Reproduced from USEPA.)

300 mainframe computers, and large amounts of plastics, PVC-coated copper cable, office furnishings, fluorescent lights and other materials (Nordgren *et al*., 2002). Two utility substations containing approximately 500 000 l of polychlorinated biphenyl (PCB)-contaminated transformer oil were also destroyed. In addition, approximately 380 000 l of heating and diesel fuel, and fuel from several thousand automobiles stored in subterranean structures, were burned in the postcollapse fires (Nordgren *et al*., 2002).

The collapse of the towers produced an immense dust cloud, which enveloped much of lower Manhattan, penetrating many buildings in the area (Chen and Thurston, 2002) (**Figure 2**). Fires at the site continued to burn for approximately three months, until late December 2001. Emissions from the site from 11 September 2001 through early 2002 affected lower Manhattan as well as immediately adjacent areas in Brooklyn and New Jersey (Lioy *et al*., 2002; Wolff *et al*., 2005). The most intense exposures occurred during the collapse and in the following two days. Thereafter, the fires weakened and much of the resuspendable dust was washed from outdoor surfaces by rain (Lioy *et al*., 2006). Reports indicated that, from late September onward, the fine-particle mass levels in the area were generally within the limits of the United States Environmental Protection Agency (US EPA) National Ambient Air Quality Standard in effect at that time, averaged over a 24-hour period (Thurston and Chen, 2002). However, intermittent smoke plumes from ongoing fires, and resuspended dust from debris-removal activities, continued to impact the area for months (Lioy *et al*., 2006; Cahill *et al*., 2004) (**Figure 3**). For weeks, an acrid cloud hung over lower Manhattan until the fires were extinguished (Landrigan *et al*., 2004). An additional issue of concern was the dust that had infiltrated offices, businesses and residential buildings (Lioy *et al*., 2006).

Figure 3 Plumes of smoke rise from the debris at Ground Zero—fires burned at the site for over three months after 11 September 2001. (Reproduced from NOAA.)

3.1.1 Exposures

The dust and combustion products generated from the destruction of the World Trade Center consisted of a complex mixture of a variety of compounds. Lioy *et al*. (2002) studied three bulk samples of the total settled dust and smoke, collected from weather-protected locations east of the WTC site in September 2001. The samples consisted primarily of construction materials, soot, paint and glass fibres. Hydrocarbon levels indicated partially burned or unburned jet fuel, plastic, cellulose and other ignited materials. Analyses identified metals, radionuclides, ionic species, asbestos, polycyclic aromatic hydrocarbons (PAHs), PCBs, polychlorinated dibenzodioxins, polychlorinated dibenzofurans, pesticides, phthalate esters, brominated diphenyl ethers and other hydrocarbons. The vast majority of particles in the samples were greater than 10 μm in diameter (Lioy *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2002). McGee *et al*. (2003) studied the toxicity of fine particulate matter ($PM_{2.5}$) from samples collected on 12 and 13 September 2001. Their analyses indicated that the main components were construction materials such as cement, concrete aggregate, ceiling tiles and wallboard. Their results showed high levels of calcium and sulphur, and much lower levels of transition metals and other elements (McGee *et al*., 2003). Larger size dust particles were found to be caustic and alkaline, which could be irritating to mucous membranes (Chen and Thurston, 2002).

Cahill *et al*. (2004) analysed aerosols generated at a collection site roughly 1.8 km from the WTC site and 50 m above ground level. Samples were collected between 2 and 30 October 2001. The results demonstrated that WTC-derived plumes occasionally swept over lower Manhattan, resulting in intense aerosol impacts lasting several hours at any given site (Cahill *et al*., 2004). Size fractions above 1 μm consisted of finely powdered concrete, gypsum and glass, with sootlike coatings and anthropogenic metals, but little asbestos. The very fine size range was dominated by sulfuric acid and organic matter, including PAHs and their derivatives, and glasslike silicon-containing aerosols (Cahill *et al*., 2004). The authors concluded that 'a person could, in a few hours, be subject to materials in amounts and composition that they would not have had to endure in years of typical ambient conditions'.

Pleil *et al*. (2004) predicted PAH air concentrations on 14 September 2001 that were among the highest reported from outdoor sources. They concluded that the initial high concentrations resulted from the fires that diminished over the next 100 days. During most of that period, the PAH levels were primarily from diesel sources, with levels slowly declining to background levels (Pleil *et al*., 2004). Wolff *et al*. (2005) reported that the highest levels of polycyclic aromatic hydrocarbon-deoxyribonucleic acid (PAH-DNA) adducts were found in women whose blood was collected closest to 11 September 2001.

Olson *et al*. (2007) investigated concentrations of volatile organic compounds (VOCs) from four locations near the WTC site between September 2001 and January 2002. They found that concentrations of total VOCs and most individual VOCs decreased from the time period when fires were burning to the time period after the fires were finally extinguished, in late December 2001.

Edelman *et al*. (2003) reported on biomonitoring results from New York City firefighters who responded to the WTC disaster. Blood and urine specimens from 321 firefighters were analysed for 110 potentially fire-related chemicals. Specimens were collected three weeks after the disaster. Most chemical concentrations were found to be generally low and not outside of reference or background ranges. However, Special Operations Command firefighters had more than twice the level of urinary 1-hydroxypyrene, a PAH metabolite, than other exposed firefighters or control firefighters. Heptachlorodibenzodioxins and heptachlorodibenzofurans were found in significantly higher levels in exposed firefighters when compared with control firefighters. Firefighters on site during the collapse of the towers had significantly higher urinary antimony levels than firefighters who arrived on site postcollapse, or controls. The urinary antimony adjusted geometric mean for Special Operations Command firefighters was twice as high as for other exposed firefighters or controls. In addition, lead levels were significantly higher in exposed firefighters than in controls, though the increase was considered to be far below clinically significant levels (Edelman *et al*., 2003).

Tao *et al*. (2008) reported on biomonitoring conducted for New York State personnel who responded to the WTC disaster. Specifically, they reported on results of testing for eight perfluorochemicals including perfluorooctanesulfonate (PFOS), perfluorooctanoic acid (PFOA), perfluorohexanesulfonate (PFHxS) and perfluorononanoic acid (PFNA). These compounds are used in soil- and stain-resistant coatings on upholstery, carpets, leather, floor waxes, polishes and in firefighting foams, and were potentially released during the collapse of the towers. Plasma samples from 457 responders were analysed based on reporting of lower-respiratory symptoms (symptomatic vs. asymptomatic), and based on exposure groupings determined using an exposure assessment method (Herdt-Losavio *et al*., 2008). The exposure groupings were: more dust exposed (MDE), less dust exposed (LDE), more smoke exposed (MSE) and less smoke exposed (LSE). PFOS, PFOA, PFHxS and PFNA were consistently detected in almost all samples. PFOA and PFHxS concentrations in WTC responders were approximately twice as high as concentrations reported for a USA general population. Concentrations of PFHxS were significantly higher in the MDE group than in the LDE group. Concentrations of PFNA were significantly higher in the MSE group than in the LSE group. These results suggest that perfluorochemicals were released as a result of the collapse of the WTC towers, and that individuals exposed to the resulting smoke and dust are at risk for a higher body burden of these compounds, though the potential health implications of these findings are unknown (Tao *et al*., 2008).

3.1.2 Health Effects

A number of health effects have been reported in different cohorts with WTC exposures, including responders, community residents and office workers. Though not a focus of this review, it should be noted that a major health impact in this population was psychological effects, including symptoms of post-traumatic stress disorder (PTSD) and depression (Galea *et al*., 2002; Trout *et al*., 2002; Tapp *et al*., 2005; Brackbill *et al*., 2006; Perrin *et al*., 2007; Mauer *et al*., 2007).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.1.2.1 Effects in Response Personnel

Prezant *et al*. (2002) provided the first reports of clinical findings in New York City firefighters who were exposed at the WTC site. They defined the term 'World Trade Center cough' as a persistent cough that developed after exposure to the WTC site and that was accompanied by respiratory symptoms severe enough to require medical leave for at least four weeks. They defined exposure based on time of arrival at the disaster site and found that 8% of firefighters with a high level of exposure, 3% of firefighters with a moderate level of exposure, and 1% of firefighters with a low level of exposure exhibited WTC cough. Symptoms of dyspnoea were present in 95%, 87% had gastro-oesophageal reflux disease, and 54% had nasal congestion. Of the firefighters who underwent post-bronchodilator spirometry, 63% demonstrated a response to bronchodilator and 24% of those who had challenge testing demonstrated bronchial hyper-reactivity. Chest radiography was unchanged from baseline in 96% of the firefighters with WTC cough. Among 78 of those subjects with normal findings on chest radiography who underwent high-resolution computed tomography (CT) during inspiration and expiration, 51% demonstrated air trapping and 30% demonstrated bronchial wall thickening. There was little evidence of parenchymal changes. The authors concluded that 'intense, short-term exposure to materials generated during the collapse of the World Trade Center was associated with bronchial responsiveness and the development of cough. Clinical and physiological severity was related to the intensity of exposure'. Banauch *et al*. (2003) followed with a report on spirometry and methacholine challenge testing in a representative sample of New York City firefighters with no history of respiratory disease or current smoking, stratified by exposure intensity (high, moderate and control). Exposure was defined based on time of arrival at the disaster site. They found that hyper-reactivity of the airways at one, three and six months postcollapse was associated with exposure intensity. Six months postcollapse, highly exposed firefighters were 6.8 times more likely than moderately exposed workers and controls to be hyper-reactive. In addition, hyper-reactivity persisted in 55% of those who were hyper-reactive at one and three months. The authors concluded that 'development and persistence of hyperreactivity and reactive airways dysfunction were strongly and independently associated with exposure intensity.' Banauch *et al*. (2006) conducted a longitudinal study of pulmonary function in 12 079 New York City Fire Department rescue workers who were employees on or before 11 September 2001. Spirometries from 1 January 1997 through 11 September 2002 were analysed. Adjusted average forced expiratory volume in one second (FEV1) and forced vital capacity (FVC) were analysed to compare results during the first year after, and the five years before, 11 September 2001. They found that WTC responders experienced a substantial reduction in adjusted average FEV1 during the year following 11 September 2001 (372 ml). This FEV1 decrement equalled 12 years of ageing-related decline in FEV1. In addition, exposure intensity as characterized by initial arrival time at the disaster site correlated linearly with FEV1 reduction in an exposure–response gradient. They reported that similar findings were observed for adjusted average FVC. The authors concluded that 'World Trade Center exposure produced a substantial reduction in pulmonary function in New York City Fire Department rescue workers during the year following 9/11/2001.' Izbicki *et al*. (2007) reported on their investigation of sarcoidosis or 'sarcoid-like' granulomatous pulmonary disease. During the five years after 11 September 2001, they evaluated enrolees in the Fire Department of New York (FDNY) World Trade Center Monitoring and Treatment Program who had chest radiographs suggestive of sarcoidosis. They conducted chest CT imaging, pulmonary function tests (PFTs), provocative challenge tests, and biopsy. They compared annual incidence rates to the 15 years prior to the WTC disaster. They found pathologic evidence consistent with new-onset sarcoidosis in 26 patients. During the first year after the disaster 13 were identified (incidence rate of 86/100 000) and 13 were identified during the next four years (average annual incidence rate of 22/100 000), as compared to 15/100 000 during the 15 years before the disaster. They concluded that 'post-World Trade Center the incidence of sarcoidosis or "sarcoid-like" granulomatous pulmonary disease was increased among FDNY rescue workers.'

Salzman *et al*. (2004) reported on a cohort of police first-responders who were evaluated through January 2002. Respiratory symptoms occurred in almost 78%, but resolved or improved by the time of the evaluation in three-fourths of subjects. The most commonly reported symptom was cough (62.5%). Spirometry results were abnormal in approximately 29% and the abnormalities were mild. Buyantseva *et al*. (2007) reported on lower-respiratory symptoms in New York City police officers at 1 month and 19 months after the WTC disaster. They found that prevalence of cough was the same at both the initial and follow-up assessments (43.5%). However, the prevalence of phlegm, shortness of breath and wheeze all increased significantly from the initial to the follow-up assessments.

Herbert *et al*. (2006) reported results from an ongoing medical monitoring programme for WTC responders in 2006. Among all responders in this cohort ($N = 9442$), almost half reported any new or worsened lower-respiratory symptom while working at the WTC site. Almost two-thirds reported any new or worsened upper-respiratory symptom. The most prevalent lower-respiratory symptom was dry cough (28.7%). The most common upper-respiratory symptom type was nasal-related symptoms (48.4%). Among those responders reporting any respiratory symptom while performing WTC work (68.8%), symptoms persisted to the time of examination in 59%. Abnormal spirometry was observed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in 29%, with low FVC in 21% and obstruction in 6%. Among nonsmokers, 28% had abnormal spirometry in comparison with 13% in the general United States population. PFT abnormalities and respiratory symptoms were associated with early arrival at the disaster site. The authors concluded that 'World Trade Center responders had exposure-related increases in respiratory symptoms and PFT abnormalities that were persistent up to 2.5 years after the attacks.'

Mauer *et al*. (2007) reported results from an evaluation of health effects in a cohort of New York State personnel who responded to the WTC disaster. They found that nearly half reported any new or worsening lower-respiratory symptom. A similar, though slightly lower percentage of study participants reported any new or worsening upper-respiratory symptom. The most common lower-respiratory symptom was dry cough (30.5%) and the most common upper-respiratory symptom was throat irritation (27.9%). Almost 14% reported acid stomach or heartburn symptoms. Some respiratory symptoms were associated with having been caught in the cloud of dust on 11 September 2001. PFT results revealed abnormalities in only a small percentage of this cohort, and clinical laboratory test results (blood chemistry and complete blood count) did not reveal any significant abnormalities in the overall cohort. This cohort deployed somewhat later than first-responders. Thus, they probably experienced moderate overall levels of exposure in comparison to groups such as the firefighters and New York Police Department (NYPD) first-responders. The authors concluded that 'this cohort generally reported fewer symptoms than most other more highly exposed responder cohorts. Results suggest that being present when the buildings collapsed was associated with reported symptoms.'

Skloot *et al*. (2004) reported that, in a cohort of ironworkers who responded to the WTC disaster, lack of a respirator with a canister was a risk factor for large airways dysfunction, as determined by forced oscillation (FO) testing. The FO data also showed a substantially higher prevalence of abnormal airflow resistance after exposure than was seen with spirometry. Oppenheimer *et al*. (2007) reported that symptomatic individuals with presumed WTC exposure and normal spirometry results demonstrated elevated airway resistance and frequency dependence of resistance determined by Impulse Oscillometry (IOS), elevated reactance area on IOS and frequency dependence of compliance (FDC), and reversibility of these functional abnormalities after bronchodilator. They concluded that these abnormalities likely reflect dysfunction in airways more distal to those evaluated by spirometry.

Herbstman *et al*. (2005) reported on a study of respiratory health effects in 183 WTC clean-up and recovery workers, conducted in December 2001. They stated that approximately one-third reported cough and one-quarter reported phlegm. Prevalence rates of symptoms were related to the number of days spent working at the WTC. The prevalence rates of upper-airway symptoms exceeded those of lower-respiratory symptoms. Tapp *et al*. (2005) described symptoms in a cohort of New York City transit employees, 7.5 months after the WTC disaster. They found that workers in the dust cloud at the time of the collapse had significantly higher risk of persistent lower-respiratory and mucous membrane symptoms. Wheeler *et al*. (2007) described newly diagnosed asthma among WTC site workers and volunteers in the World Trade Center Health Registry. They found that newly diagnosed asthma was reported in approximately 4% of this population. The risk of newly diagnosed asthma was 12-fold higher than the expected three-year risk in the general population. Earlier arrival time, longer duration of work, exposure to the dust cloud, and working on the pile were all significant risk factors. Among workers who arrived on 11 September 2001, longer delays in use of respiratory protection were associated with increased asthma risk. Tao *et al*. (2006) investigated respiratory health among clean-up workers 20 months after initial exposure, in comparison with a group of workers who were never at the WTC site. They found that the clean-up workers were more than three times as likely to report any lower-respiratory symptoms. In a 2008 case report, de la Hoz *et al*. (2008a) reported the clinical characteristics of 10 symptomatic WTC workers who were diagnosed with vocal cord dysfunction. Most of the patients had hoarseness, dyspnoea not associated with bronchial hyper-reactivity, or dyspnoea associated with asthma. The authors concluded that 'vocal cord dysfunction appears to be part of the spectrum of airway disorders caused by occupational exposures at the World Trade Center site.'

3.1.2.2 *Effects in the Community*

Trout *et al*. (2002) evaluated concerns related to health effects and occupational exposures among a population of office workers in a building close to the disaster site, three months after the disaster. Constitutional and mental health symptoms were evaluated in comparison with a group of office workers in Dallas, Texas. Symptoms, including cough, shortness of breath, wheeze, chest tightness, and others, were reported more frequently in the New York City workers. Fagan *et al*. (2002) reported results from a telephone survey of Manhattan residents five to nine weeks after the disaster. Among residents with asthma (13%), 27% reported experiencing more severe asthma symptoms after 11 September 2001. Increased severity was more common in residents who reported psychological distress and/or difficulty breathing due to smoke and debris from the disaster. Szema *et al*. (2004) reported on a retrospective review of charts from 205 paediatric patients with established asthma from a clinic in Chinatown, for the year before and the year after 11 September 2001. They found that,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

after 11 September 2001, these children had significantly more asthma-related clinic visits and received significantly more prescriptions for asthma medications. Those who lived within 5 miles (8 km) of the disaster site had more clinic visits after the disaster. In addition, mean %predicted expiratory flow rates declined for the patients who lived within 5 miles (8 km) of the disaster site, during the three months after the disaster.

Reibman *et al*. (2005) investigated lower-respiratory symptoms and screening spirometry results in residents in an 'exposed area' and in a 'control area', approximately one year after the disaster. They found that new-onset lower-respiratory symptoms were more frequent among residents from the 'exposed area', as were persistent new-onset lower-respiratory symptoms. No differences in screening spirometry results were detected. In the same study population, Lin *et al*. (2005) reported on upper-respiratory symptoms. They found that residents in the affected area reported higher rates of new-onset upper-respiratory symptoms after 11 September 2001. Most of these symptoms were persistent one year later. They also found that residents in the affected area who were previously healthy had significantly more respiratory-related unplanned medical visits and more new medication use after the disaster. Wagner *et al*. (2005) reported on their investigation of the asthma status of Medicaid managed care enrolees who may have been exposed as a result of the disaster. They conducted a mailed survey among enrolees living in New York City. Of survey respondents, 45% reported worsened asthma after the disaster. Those who reported worsened asthma were more likely to have utilized health services for their asthma. Residence in lower Manhattan and Western Brooklyn was associated with worsened asthma. Brackbill *et al*. (2006) reported on health effects among survivors of collapsed and damaged buildings (excluding those involved in rescue and recovery), from data in the World Trade Center Health Registry. Almost two-thirds were caught in the dust and debris cloud. More than half of those studied (56.6%) reported experiencing new or worsening respiratory symptoms after the disaster. In addition, almost one-quarter reported heartburn/reflux. Survivors caught in the dust and debris cloud were more likely to report any respiratory symptom, severe headaches, skin rash/irritation, hearing problems/loss, heartburn and diagnosed stroke. The authors concluded that 'two to three years after 11 September, survivors of buildings that collapsed or that were damaged as a result of the World Trade Center attack reported substantial physical and mental health problems.'

Lederman *et al*. (2004) reported on their assessment of the impact of gestational stage at the time of the disaster, and distance from the WTC in the four weeks after 11 September, on birth outcomes among 300 nonsmoking women who were pregnant at the time of the disaster. They found that term infants born to women who were pregnant at the time of the disaster and who were living within 2 miles (3.2 km) of the disaster site during the month after the event demonstrated significant decrements in term birth weight and birth length, after controlling for sociodemographic and biomedical risk factors. Furthermore, women in the first trimester of their pregnancy at the time of the disaster delivered infants with significantly shorter gestation and a smaller head circumference, regardless of the distance of their residence or worksite from the disaster site. The authors concluded that 'the observed adverse effects suggest an impact of pollutants and/or stress related to the World Trade Center disaster and have implications for the health and development of exposed children.' Perera *et al*. (2005) described their efforts to learn whether PAHs, as measured by benzo[*a*]pyrene-DNA adducts (PAH-DNA adducts), from the WTC disaster affected birth outcomes in pregnant women, and their newborns. They found no independent foetal growth effects due to PAH-DNA adducts, but adducts in combination with *in utero* exposure to environmental tobacco smoke were associated with decreased foetal growth. An assessment of possible effects on child development was reported by Perera *et al*. (2007). They found a significant interaction between PAH-DNA adducts and *in utero* exposure to environmental tobacco smoke on mental development index score at three years of age. They concluded that 'results suggest that exposure to elevated levels of PAHs in conjunction with prenatal environmental tobacco smoke exposure may have contributed to a modest reduction in cognitive development among cohort children.'

3.1.3 Summary

The evidence in the literature suggests that WTC-related exposures have resulted in a variety of health outcomes, including lower- and upper-respiratory effects, gastro-oesophageal reflux disease, psychological effects, and possibly adverse birth outcomes and sarcoidosis in some cohorts. Some of these health symptoms have been persistent over time in some populations. The precise reasons for this are still unclear. With the exception of sarcoidosis, interstitial lung diseases have not been reported in any WTC cohorts, but single case reports of eosinophilic pneumonia (Rom *et al*., 2002), bronchiolitis obliterans (Mann 2005) and granulomatous pneumonitis (Safirstein *et al*., 2003) have been published (Prezant, 2008). In a study of the range of clinical characteristics in a group of workers representative of the widest possible range of occupations at the WTC site, de la Hoz *et al*. (2008b) reported on five predominant diagnostic categories in their analysis: upper-airway disease (78.5%), gastro-oesophageal reflux disease (57.6%), lower-airway disease (48.9%), psychological illness (41.9%), and chronic musculoskeletal illness (17.8%). A combination of the first three categories was the most frequent pattern of presentation (29.8%). The main respiratory health

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

consequence from the WTC disaster has been the 'World Trade Center Cough Syndrome', which involves chronic rhinosinusitis, asthma and/or bronchitis, often complicated by gastro-oesophageal reflux dysfunction (Prezant, 2008).

Lower-respiratory effects have been consistently reported in both response workers and in community residents. Studies have indicated that exposed cohorts have experienced reduced lung function with declines in FEV1 and FVC, significant responses to bronchodilators, and significant responses on provocative challenge tests (Prezant *et al*., 2002; Banauch *et al*., 2003; 2006; Salzman *et al*., 2004; Herbert *et al*., 2006). In addition, Oppenheimer *et al*. (2007) concluded that IOS and FDC abnormalities likely reflect dysfunction in airways more distal to those evaluated by spirometry.

The precise nature of the pulmonary effects experienced by those with WTC exposures is complex, and has not yet been fully elucidated. Typically, a pattern representing obstructive impairment might be expected from an irritant-induced airway injury. However, an unexpectedly high proportion of WTC responders have demonstrated declines in FEV1 and FVC with preservation of the FEV1/FVC ratio (Mendelson *et al*., 2007). Herbert *et al*. (2006) reported that the most common spirometric abnormality seen among their responder cohort was a low FVC. These findings could be interpreted to represent restrictive impairments, such as might be found with parenchymal lung disease (Mendelson *et al*., 2007; Herbert *et al*., 2006). However, these findings may result from air trapping, causing a 'pseudorestrictive' pattern (CDC 2004; Herbert *et al*., 2006). Herbert *et al*. (2006) reported that 19% of WTC workers and volunteers demonstrated a partial reversal of their low FVC following bronchodilator, which can be seen with low FVC due to air trapping. Prezant *et al*. (2002) reported that among responders who underwent high resolution computed tomography, half demonstrated air trapping. Mendelson *et al*. (2007) reported results from high-resolution computed tomography scans in 29 WTC workers with lower-respiratory symptoms. Air trapping was demonstrated in 25 of the 29 patients, and there was a significant correlation between air trapping and duration of dust exposure. They concluded that 'air trapping from small airways disease may account for some of the reported clinical and pulmonary function abnormalities in World Trade Center dust-exposed workers.'

Further evidence of the potential lower-respiratory effects of exposure to WTC dust was provided in a study of the effects of WTC-derived $PM_{2.5}$ on the respiratory tract in mice (Gavett *et al*., 2003). The authors found that 'exposure to high levels of WTC $PM_{2.5}$ can promote mechanisms of airflow obstruction in mice.' They concluded that 'high-level exposure to WTC $PM_{2.5}$ could cause pulmonary inflammation and airway hyper-responsiveness in people.'

3.1.4 Ongoing Concerns

Looking towards the future, the primary concerns for populations with a history of WTC exposure relate to possible long-term and persistent health effects, as well as onset of health effects with longer latency periods, such as cancer. Some commonly reported health effects, such as upper- and lower-respiratory symptoms, have demonstrated persistence over time. Aerodigestive inflammatory syndrome, which consists of 'World Trade Center' cough, irritant asthma or reactive airways dysfunction syndrome (RADS), rhinosinusitis or reactive upper-airways dysfunction syndrome (RUDS), and gastro-oesophageal reflux disorder, is a major consequence of exposure (Lioy *et al*., 2006). These effects must be monitored in the future. Furthermore, ongoing studies to help clarify the precise physiological mechanisms responsible for the respiratory effects of WTC exposure will be necessary.

A variety of compounds that could potentially cause cancer were present in the dust and smoke resulting from the disaster. For most cancers, the typical latency period is approximately 12–25 years, though it can range from as short as three years (radiation- or toxin-induced leukaemias) to as long as 40 years (asbestos-induced mesothelioma) (Rugo, 2004). Thus, studies to investigate cancer incidence among WTC responders and residents will become increasingly important as more time passes. Further studies of possible adverse developmental effects in children born to mothers who were pregnant at the time of their WTC exposure may also provide important information.

4 CHEMICAL DISASTERS

4.1 Bhopal Gas Leak Disaster—2–3 December 1984

What has been referred to as the 'World's Worst Industrial Disaster' (Dhara and Dhara, 2002) occurred on the night of 2–3 December 1984 in Bhopal, the capital city of one of the largest states in India. The Department of Relief and Rehabilitation, Government of Madhya Pradesh, has stated that more than 200 000 persons were exposed to a toxic cloud of methyl isocyanate gas, and that more than 6000 deaths resulted. Some independent agencies estimated the death toll to be as high as 15 000 to 20 000 deaths. It is estimated that approximately 50 000 persons are suffering from long-term health effects (Dhara *et al*., 2002).

4.1.1 Exposures

Methyl isocyanate is an intermediate product in manufacturing carbaryl, which is a carbamate pesticide. This

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

pesticide was being manufactured at the Union Carbide plant in Bhopal when the accident occurred. Dhara and Dhara (2002) reported that the toxic cloud was released from the plant due to the introduction of water into a methyl isocyanate storage tank resulting in an uncontrollable reaction. Safety systems, such as a flare tower and a caustic soda scrubber, failed to contain the reaction. Approximately 27 tonnes of methyl isocyanate escaped from two tanks within 1–2 hours. The gas was not able to disperse quickly due to adverse atmospheric conditions (inversion and low wind speed). It was reported that the gas cloud enveloped the area and moved slowly. No air monitoring occurred at the time of the incident or later, but the estimated mean methyl isocyanate concentration in the cloud was 27 ppm. That concentration is 1400 times higher than the United States Occupational Safety and Health Administration's workplace standard (Dhara and Dhara, 2002).

Dhara and Dhara (2002) reported that the acute irritant effects of the exposure resulted in panic, anxiety and disorientation, which caused people to run out of their homes and into the gas cloud, resulting in even greater exposures. The primary exposures involved the eyes and the respiratory tract, though some skin exposure and presumably ingestion exposure, due to the chemical dissolving in saliva, also occurred. Most of the immediate mortality that followed the gas leak was attributed to direct, irritative toxicity to the lower respiratory tract, and resulting hypoxia (Cullinan *et al*., 1996).

4.1.2 Health Effects

4.1.2.1 General Effects

Cullinan *et al*. (1996) reported on health effects approximately 10 years postdisaster among a representative sample of gas-exposed persons in comparison with a reference group of unexposed persons from the same city. A random sample of those surveyed also underwent neurological testing. Exposed persons reported more general health problems, more episodes of fever, more adverse pregnancy outcomes and more respiratory symptoms than unexposed persons, with a strong gradient by exposure category. Persons in high-exposure categories reported neurological symptoms more frequently, and this was generally confirmed with neurological testing. Ocular symptoms also showed a similar pattern.

Ocular studies, conducted nine months to two years after exposure, revealed chronic irritant symptoms including persistent eye watering, burning, itching and redness. The primary chronic lesions included conjunctivitis, deficient tear secretion, and persistent corneal opacities (Andersson *et al*., 1986; Raizada and Dwivedi, 1987; Khurrum and Ahmad, 1987). A three-year postexposure follow up survey was conducted among previously surveyed exposed and unexposed Bhopal residents (Andersson *et al*., 1990). The results indicated an increased risk of eye infections, hyper-responsive phenomena, excess cataracts, and resolution of corneal erosions in exposed persons. This constellation of symptoms was characterized as 'Bhopal Eye Syndrome'. The authors stated that 'in its response to methyl isocyanate, the eye should be considered a sentinel organ for more general phenomena in the body.' In summary, Dhara and Dhara (2002) stated that 'the single acute exposure seems to have resulted in a chronic inflammatory process' in the eye.

4.1.2.2 Respiratory Effects

Kamat *et al*. (1992) reported on exposed subjects who were followed with clinical, lung function, radiographic and immunologic tests up to 24 months postdisaster. Dominant symptoms included exertional dyspnoea, cough, chest pain, sputum, and muscle weakness. Radiographically, interstitial deposits were found to be persistent changes. PFTs showed primarily restrictive changes with small-airway obstruction. The small-airway findings persisted. They also found signs of alveolitis in bronchoalveolar lavage (BAL) fluid on fibre optic bronchoscopy. In 11 cases, positive methyl isocyanate-specific antibodies to IgM (immunoglobulin M), IgG and IgE were found. The authors felt that earlier evidence of interstitial restrictive lung pathology with small-airway disease was confirmed. They went on to explain that 'the airway component seems to have progressed, leading to a fluctuating course with persisting disability.'

Vijayan *et al*. (1995) reported on initial BAL results in a group of exposed persons, approximately five years postdisaster, and repeat lavage results (approximately 2.7 years postdisaster) in a group of exposed persons who had the test done previously. All subjects had persistent respiratory symptoms. They found that among those undergoing repeat lavage, lower-respiratory tract inflammation had progressed from macrophage alveolitis to macrophage-neutrophilic alveolitis. Among those undergoing lavage for the first time, five years postdisaster, macrophage-neutrophilic alveolitis was the common finding. The authors suggested that, because alveolar macrophages and neutrophils are capable of promoting lung injury and fibrosis, inhaled toxic gas might produce permanent damage to pulmonary parenchyma. They concluded that 'the persistence of clinical, radiological, and pulmonary function abnormalities in this study as well as in previous studies may be due to the consequences of macrophage-neutrophilic alveolitis.'

A study of the relationship between lung inflammation, changes in lung function, and severity of exposure among Bhopal victims included BAL and PFTs, conducted one to seven years after the disaster (Vijayan and Sankaran, 1996). The PFTs included FEV1, FVC and FEV1/FVC ratio. The authors found that total lung inflammatory cells and absolute numbers of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

macrophages and lymphocytes increased significantly as severity of exposure increased. FEV1/FVC ratio was significantly lower as severity of exposure increased. BAL neutrophils showed significant negative correlations with FEV1 %predicted, while neutrophil percentage was negatively correlated with FEV1/FVC ratio. Absolute lymphocytes were negatively correlated with FVC %predicted. Radiographic abnormalities were associated with decline in FEV1 %predicted. The authors concluded that 'pulmonary function abnormalities occur in gas-exposed subjects as a consequence of an abnormal accumulation of lung inflammatory cells.' Furthermore, they suggested that, because pulmonary function decline was associated with radiographic abnormalities, injury following toxic-gas exposure can lead to irreversible lung damage.

Cullinan *et al*. (1997) reported on respiratory morbidity 10 years postdisaster. Respiratory symptoms (cough or phlegm for greater than three months, dyspnoea, wheeze in past year) were significantly more common among exposed persons versus unexposed persons. The frequency of symptoms decreased as exposure decreased, with exposure characterized by distance lived from the plant. Pulmonary function was also assessed, including FEV1, FVC, FEV1/FVC ratio and forced expiratory flow (FEF) between 25 and 75% of vital capacity (FEF25–75). All pulmonary function indices were lower among those in the higher-exposure categories. The authors concluded that 'the symptoms reported, and the differences in lung function detected, are compatible with chronic airflow limitation and particularly with disease of the small airways.'

Dhara *et al*. (2002) reported on long-term health effects in survivors of the Bhopal disaster, nine years later. They found that for subjects reporting any versus no exposure, prevalence ratios were elevated for most respiratory and nonrespiratory symptoms. Respiratory symptoms included shortness of breath, cough for at least three months, asthma and phlegm. Mucous membrane symptoms included nose pain, eye redness and eye pain. Systemic symptoms included fever in the last 12 months, fatigue, chest pain, taste problems and loss of appetite.

4.1.3 Summary

Chronic inflammatory ocular symptoms were reported to be persistent for several years after the Bhopal disaster. One author dubbed the symptoms 'Bhopal Eye Syndrome'. However, the primary persistent health effects noted in survivors of the Bhopal gas leak involved the lower respiratory tract. Persistent lower-respiratory effects included declines in PFTs with indications of small-airways disease. Studies reported findings of alveolitis, abnormal accumulation of inflammatory cells in the lungs, and interstitial lung disease, up to 10 years postdisaster.

4.2 Seveso Accident—10 July 1976

On 10 July 1976, substantial amounts of 2,3,7,8-tetrachlorodibenzo-*para*-dioxin (TCDD) were accidentally released from a chemical plant near the town of Seveso, Italy, impacting an area with a large residential population. The accident occurred due to an uncontrolled exothermic reaction during the production of trichlorophenol. A fluid mixture entraining approximately 2900 kg of organic matter was released through an exhaust pipe. This mixture included a substantial amount of TCDD. The exhaust was then driven by prevailing winds as far as 6 km south of the chemical plant (Pesatori *et al*., 2003).

4.2.1 Exposures

Pesatori *et al*. (2003) indicated that the most heavily contaminated area covered approximately 87 ha, and average levels of TCDD in soil samples ranged between 15.5 and 580.4 $\mu g\,m^{-2}$. This has been designated zone A and had approximately 750 inhabitants. A further contamination zone with levels not exceeding 50 $\mu g\,m^{-2}$ covered 270 ha. This has been designated zone B and had approximately 5000 inhabitants. A third area with levels generally below 5 $\mu g\,m^{-2}$ covered 1430 ha. This has been designated zone R, with approximately 30 000 inhabitants. Bertazzi *et al*. (1997) reported that a total of 180 families comprising more than 700 individuals were evacuated from zone A and that residents in zones B and R had to comply with regulations aimed at avoiding continuing exposure through consumption of local crops, dairy food and meat products.

4.2.2 Health Effects

Bertazzi *et al*. (1993) described an evaluation of cancer incidence over a 10-year period after the accident. This and subsequent follow-up studies used the population of a surrounding noncontaminated area as a reference group. In zone B, hepatobiliary cancer was significantly elevated, especially in those living in the area for over five years. Males had a significant increase in lymphoreticulosarcoma, and women had a significant increase in multiple myeloma. Results from a 15-year follow-up mortality study (Bertazzi *et al*., 1997) indicated that, in zone B, males demonstrated significantly increased mortality from rectal cancer, pleural cancer and leukaemia. Women demonstrated significantly increased mortality from multiple myeloma. They found no increase for all-cancer mortality.

A 20-year follow-up mortality study also reported no increase in all-cancer mortality (Bertazzi *et al*., 2001). In zone B, males demonstrated significantly increased mortality from rectal cancer. Lymphohaematopoietic neoplasms were significantly increased in both genders. This was also demonstrated for Hodgkin's disease.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Females demonstrated a significant increase in diabetes. In zone A, chronic rheumatic heart disease and chronic obstructive pulmonary disease were significantly increased. The authors concluded that 'results support evaluation of dioxin as carcinogenic to humans and corroborate the hypotheses of its association with other health outcomes, including cardiovascular- and endocrine-related effects.'

Consonni *et al*. (2008) reported results from a 25-year follow-up mortality study. They found a significant excess of lymphohaematopoietic neoplasms in zone B, and a significant excess of non-Hodgkin's lymphoma and multiple myeloma in zone A. They also reported a significant increase in chronic rheumatic heart disease and chronic obstructive pulmonary disease in zone A, as well as a significant increase in diabetes among females in zone B. The authors concluded that 'a toxic and carcinogenic risk to humans after high TCDD exposure is supported by the results of this study.'

Warner *et al*. (2007) report on results from the Seveso Women's Health Study, which assessed reproductive health among 363 women who had resided in zone A or zone B and who had adequate stored sera collected soon after the accident. They examined the relationship between 1976 serum TCDD levels and ultrasound-detected ovarian follicles among 96 women in the menstrual follicular phase, and serum hormone levels among 129 women in the menstrual luteal phase at follow-up. The authors concluded that the results provided no clear evidence of an association of high exposure to TCDD with quality of ovarian function, approximately 20 years postaccident.

4.2.3 Summary

The long-term mortality studies that have reported results up to 25 years postaccident suggest that high exposure to TCDD is associated with mortality due to some types of cancer, including lymphohaematopoietic neoplasms overall and rectal cancer in males. Results also suggest that mortality due to some chronic cardiac, pulmonary and endocrine conditions might be associated with high TCDD exposure in this cohort.

5 NUCLEAR DISASTERS

5.1 Chernobyl Accident—26 April 1986

The Chernobyl nuclear power plant, located in Ukraine approximately 10 km south of the border with Belarus, was the scene of the worst disaster in the history of the nuclear industry. On 26 April 1986 two explosions destroyed the core of unit 4 of the plant and the roof of the building (Hatch *et al*., 2005). A complete meltdown of the reactor took place, with an estimated 150–200 million curies of radioactive materials subsequently released into the atmosphere over the next 10 days (Tronko *et al*., 1999). The International Atomic Energy Association classified the event as a 'major accident', and the release of radionuclides greatly exceeded those in all previous atomic power station accidents (Tronko *et al*., 1999). Fallout levels were extremely nonuniform (Likhtarov *et al*., 2006). During the first 10 days of releases, wind direction changed frequently, so all areas surrounding the reactor received some fallout. Rainfall occurred in an irregular pattern, also contributing to varying degrees of deposition (Hatch *et al*., 2005). Over 450 different radionuclides were released over Ukraine, Belarus and Russia, which were the most contaminated areas (Tronko *et al*., 1999; Hatch *et al*., 2005; Howe, 2007). The radioactive cloud spread to the Baltic States, as well as Scandinavia and other parts of Western Europe. Contamination of the ground was found to some extent in every country in the Northern Hemisphere, even on the North American continent (Tronko *et al*., 1999; Hatch *et al*., 2005; Howe, 2007).

5.1.1 Exposures

There were three primary cohorts exposed to radioactive contamination as a result of the Chernobyl disaster. Emergency response workers or clean-up workers, also referred to as liquidators, included approximately 600 000 individuals. Roughly 240 000 liquidators worked at the reactor site and within 30 km of the site in 1986 and 1987, when doses were highest (Cardis *et al*., 2006; Howe, 2007). Residents who were evacuated or relocated during 1986 included approximately 116 000 individuals, in Ukraine, Belarus and Russia. An additional 220 000 residents were relocated after 1986 (Cardis *et al*., 2006; Howe, 2007). Residents in contaminated areas that were not evacuated include more than 5 million individuals (Cardis *et al*., 2006; Howe, 2007). Doses ranged from 10 mSv among the least exposed, nonevacuated residents to 100 mSv for liquidators in 1986 and 1987 (Cardis *et al*., 2006).

Releases from the site included gases, aerosols and finely fragmented nuclear fuel particles (Hatch *et al*., 2005). Exposures included short-lived radioactive iodines, most importantly iodine-131 (^{131}I), external exposure from radionuclides deposited on the ground, and ingestion of radioactive caesiums, particularly caesium-134 (^{134}Cs) and caesium-137 (^{137}Cs) (Cardis *et al*., 2006; Nuclear Energy Agency, 2002; United Nations Scientific Committee on the Effects of Atomic Radiation, 2000). The most important exposures for liquidators were from external radiation, primarily from gamma-emitting radionuclides (Hatch *et al*., 2005). The most important pathways of exposure for residents

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in contaminated areas were external exposure from radionuclides deposited on the ground and internal exposure from ingestion of milk and other foods contaminated with ^{131}I, ^{134}Cs and ^{137}Cs. In the first few months, the thyroid was the most exposed organ, due to ^{131}I, with the primary exposure pathway being from pasture to cow to milk (Hatch *et al*., 2005). Adequate prophylactic measures against radioiodine exposure with ingestion of stable iodine salts were not instituted after the disaster (Tronko *et al*., 1999).

Following either internal or external radiation exposure, children are the most vulnerable exposed group, because thyroid sensitivity to radiation is high and they have a longer lifespan to develop effects (Tronko *et al*., 1999; Hatch *et al*., 2005).

5.1.2 Health Effects

5.1.2.1 Cancers

Antonelli *et al*. (1996) reported on a study of thyroid cancer among 64 children aged 4–16 years in an area of Belarus. Previously, among children under age 15 in this area, there was one case of thyroid cancer observed from 1981 to 1985, 21 cases from 1986 to 1990 and 143 cases from 1991 to 1994. Among the 64 subjects, more than 90% were less than 6 years of age. The authors reported that there appeared to be no correlation between aggressiveness of the tumour and the age of the subjects. Astakhova *et al*. (1998) conducted a case–control study to test a possible association between the Chernobyl disaster and an increase in thyroid cancer among children in national therapy centres in the Minsk area of Belarus. Cases were matched with two sets of controls and the results indicated a strong relationship between thyroid cancer and estimated radiation dose. Tronko *et al*. (1999) reported data from a registry of thyroid carcinoma cases at the Institute of Endocrinology and Metabolism in Kiev. During the five years prior to the disaster, 59 cases of thyroid carcinoma were identified among children and adolescents 18 years of age or younger. The total number of cases in Ukrainian children and adolescents between 1986 and 1997 was 577. The group most affected included children who were less than six years of age in 1986. Morphologically, the tumours were generally aggressive with a high frequency of lymph node metastases, venous invasion and extrathyroidal spread. Davis *et al*. (2004) reported on a case–control study of radiation exposure and thyroid cancer risk among children and adolescents aged 0–19 years at the time of the disaster, residing in the more highly contaminated areas of the Bryansk area of Russia. They found a statistically significant trend of increasing risk with increasing dose, suggesting that exposure to radiation from Chernobyl is associated with risk of thyroid cancer and that the relationship is dose dependent. Likhtarov *et al*. (2006) conducted an ecological study to investigate the relationship between ^{131}I thyroid dose and thyroid cancer. The study included 301 907 individuals who were between the ages of 1 and 18 at the time of the disaster and were living in an area in Northern Ukraine. Cases included 232 thyroid cancers diagnosed between 1990 and 2001. The estimated relative risk per Gray was significantly elevated. The authors concluded 'in broad terms, these estimates are compatible with results of other studies from the contaminated areas, as well as studies of external radiation exposure.' Tronko *et al*. (2006) studied a cohort of over 13 000 individuals younger than 18 years of age who lived in the most heavily contaminated areas in Ukraine at the time of the disaster. They identified 45 pathologically confirmed cases of thyroid cancer during the 1998–2000 screening, as compared to 11.2 cases that would have been expected in the absence of the disaster. The authors concluded that exposure to radioactive iodine was strongly associated with increased risk of thyroid cancer among those exposed as children and adolescents.

Inskip *et al*. (1997) conducted thyroid examinations for 2000 liquidators from Estonia, nine years after the disaster. The workers had been sent to the site between 1986 and 1991 and served for an average of three months. The authors found that the workers did not experience a significantly increased risk of nodular thyroid disease associated with exposure to external radiation. They concluded 'possible reasons for the apparent absence of effect include low radiation doses, the protracted nature of the exposure, errors in dose measurement, low sensitivity of the adult thyroid gland, or the insufficient passage of time for a radiation effect to be expressed.' Rahu *et al*. (2006) studied two cohorts of liquidators, from Estonia and Latvia, between 1986 and 1998. Each cohort was followed using nationwide population and mortality registries. A statistically significant excess of thyroid cancer cases was found, though there was no evidence of a dose response. The authors discussed the possibility that the excess cases observed might be due to screening.

Risk for leukaemia was investigated in several studies. Konogorov *et al*. (2000) estimated the radiation-induced risk of leukaemia in 162 684 liquidators using data from the Russian National Medical and Dosimetric Registry. They found no significant association between risk of leukaemia and various measures of exposure. The International Consortium for Research on the Health Effects of Radiation (2006) reported on a population-based case–control study that investigated whether acute leukaemia was increased among children from Belarus, Russia and Ukraine who were *in utero* or less than six years of age at the time of the Chernobyl disaster. They found a statistically significant increase in leukaemia risk with increasing estimated radiation dose to the bone marrow. This finding was most evident in children from Ukraine, but not found in children from Belarus or Russia. The authors felt this may, at least in part, represent an overestimate of risk in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Ukraine. They concluded that the study provided no convincing evidence of an increased risk of childhood leukaemia related to exposure to Chernobyl radiation. Ivanov (2007) presented preliminary results from a study using the Russian National Medical and Dosimetric Registry. He reported that, during the first 10 years after the disaster, the relative risk of leukaemia was statistically significant among liquidators with higher exposure doses in comparison with liquidators with lower exposure doses. Hatch *et al*. (2005) stated that 'to date, the available data support a measurable increase of leukaemia among cleanup workers.' Howe (2007) evaluated empirical studies for evidence relating to Chernobyl radiation exposure and leukaemia risk. He concluded that 'possibly apart from Russian cleanup workers, no meaningful evidence of any statistical association between exposure and leukaemia risk as yet exists.'

With regard to solid cancers, other than thyroid, Hatch *et al*. (2005) reported that little could be said, most likely due to the longer minimum latency period and lower risks per dose. Cardis *et al*. (2006) stated that 'apart from the large increase in thyroid cancer incidence in young people, there are at present no clearly demonstrated radiation-related increases in cancer risk.' They noted that studies of such cancers are few, and have methodological limitations. Furthermore, due to inadequate latency, they felt it was too early to evaluate the full radiological impact of the disaster. Ivanov (2007) reported preliminary results indicating that in 1991–2001, among Russian liquidators, the excess relative risk for incident solid cancers was statistically insignificant.

5.1.2.2 Genetic Effects

A number of studies have looked at genetic effects from exposure to Chernobyl-related radiation. While the clinical implications of these effects may be uncertain, these findings still merit discussion. Weinberg *et al*. (1997) reported on an analysis of DNA isolated from the blood of experimental and control subjects, involving offspring born before and after the disaster, and their parents. They used genome fingerprinting simple sequence repeat-anchored polymerase chain reaction (PCR) amplification and random amplified polymorphic DNA PCR. They detected new bands that appeared in children born after the disaster, while no such bands appeared in children born in the same family before the disaster or in children from control families who were not exposed to the radiation.

Dubrova *et al*. (1997) conducted an analysis of germ-line mutation rate at human minisatellites among children born in heavily contaminated areas of Belarus. Data confirmed a two-fold higher mutation rate in exposed families in comparison with nonexposed families from the United Kingdom. Within the Belarus cohort, mutation rate was significantly greater in families with higher parental radiation dose. Weinberg *et al*. (2001) screened for the appearance of new fragments using multisite DNA fingerprinting among children born to liquidator families conceived after parental exposure. They found a seven-fold increase in the number of new bands in comparison with controls. There was a strong tendency for the number of new bands to decrease with elapsed time between exposure and offspring conception. The authors concluded 'these results indicate that low doses of radiation can induce multiple changes in human germ-line DNA.' Livshits *et al*. (2001) measured the frequency of inherited mutant alleles at seven hypermutable minisatellite loci in children born to liquidators and controls. There was no significant difference in the frequency of inherited mutant alleles between the two groups. The exposed group was then divided into those who were conceived within two months of their father having worked as a liquidator and those who were conceived at least four months after their father stopped working as a liquidator. The frequencies of mutant alleles were higher for the majority of loci for the former group than for the latter group.

Dubrova *et al*. (2002) reported that a statistically significant increase in mutation rate was found in the germ line of exposed fathers, whereas the maternal germ-line mutation rate in exposed families was not elevated. They concluded that elevated minisatellite mutation rate can be attributed to post-Chernobyl radioactive exposure. Kiuru *et al*. (2003) compared minisatellite mutation rates of children born to Estonian liquidators after the disaster with those of their siblings born prior to the disaster. They found that the minisatellite mutation rate was not significantly elevated among children born after the accident. Slebos *et al*. (2004) also studied whether radiation exposure can cause paternal genetic mutations that are transmitted to offspring, among families of liquidators. They found that children conceived before and children conceived after their father's exposure showed no statistically significant differences in mutation frequencies. Their results did suggest a modest increase in germ-line mutations in tetranucleotide repeats.

5.1.3 Summary

There is evidence that exposure to radiation from the Chernobyl disaster resulted in elevated risk for thyroid cancer among children and adolescents. There is some suggestion of elevated risk for leukaemia among clean-up workers or liquidators, though the evidence for this is more equivocal. There is inadequate evidence for an association with other cancers, though until recently the latency period would be considered inadequate. There is also some suggestion in the literature that exposure to Chernobyl radiation has resulted in genetic mutations in some offspring conceived after or born after parental

exposure, though the potential clinical significance of these changes is uncertain.

6 VOLCANIC DISASTERS

6.1 Mount St. Helens Eruption—18 May 1980

Mount St. Helens, dormant since 1857, catastrophically erupted on 18 May 1980, releasing approximately 4 km^3 of rock and ash into the atmosphere, and covering much of Washington State with a layer of fine volcanic ash up to several centimetres deep (Vallyathan *et al*., 1983; Baxter, 1986). Volcanic ash erupted to an altitude of 60 000 ft (over 18 km) and was deposited eastward, impacting not only Washington State but also Idaho and Montana (**Figure 4**). In Spokane County, Washington, volcanic ash persisted in depths up to 2 inches (5 cm) for several weeks after the initial event (Kraemer and McCarthy, 1985). Subsequent eruptions and resuspension of ash by wind and human activities resulted in exposure of over 1 million people in the northwestern USA (Vallyathan *et al*., 1983).

6.1.1 Exposures

Mineralogical analysis demonstrated that the majority of the ash was composed of silicate minerals of the plagioclase class (Fruchter *et al*., 1980; Green *et al*., 1982). Most of the ash particles were within the respirable range, or less than 10 μm in diameter (Green *et al*., 1982). Dollberg *et al*. (1986) reported that crystalline silica was identified as being present in the Mount St. Helens volcanic ash at levels of 3–7% by weight.

6.1.2 Health Effects

There were some variable reports of cellular effects of the volcanic ash from Mount St. Helens. Volcanic ash was reported to inhibit superoxide anion release from zymosan-stimulated rat alveolar macrophages (Castranova *et al*., 1982). Because superoxide is an antibacterial substance, this result might suggest that exposure to volcanic ash could impair antibacterial host defence mechanisms by adversely affecting the ability of alveolar macrophages to protect the lung from infection (Castranova *et al*., 1982; Green *et al*., 1982). Martin *et al*. (1986), in a review of the existing literature, suggested that evidence indicated that antibacterial defences against pyogenic organisms and viruses were not impaired by ash exposure. Green *et al*. (1982) reported that *in vitro* biologic tests using various concentrations of ash indicated the ash was mildly fibrogenic, which was confirmed *in vivo*. Vallyathan *et al*. (1983) reported on the pulmonary response among rats to intratracheal administration of 1 or 10 mg of ash. At 28 days, the intra-alveolar aggregates of mononuclear cells had condensed to form granulomas. The granulomas enlarged in size from 28 to 180 days, with progressive increase in the amount of collagenous tissue. The authors concluded 'volcanic ash may pose a risk for pneumoconiosis in heavily exposed human populations.' Adler *et al*. (1984) reported that their studies of the *in vitro* interactions of ash with epithelial cells of rodent respiratory airways suggested that volcanic ash from Mount St. Helens interacted minimally with respiratory mucosal cells. In their review, Martin *et al*. (1986) stated 'the data indicate that volcanic ash, even in high concentrations, causes little toxicity to lung cells *in vitro* and *in vivo*, as compared to the effects of free crystalline silica, which is known to be highly fibrogenic.' They did allow that volcanic ash is not entirely inert, probably due to the low concentrations of free crystalline silica present in the ash. They concluded 'humans without lung disease who are exposed to volcanic ash are probably at very little risk for pulmonary toxicity unless the exposure is extremely heavy and prolonged.'

In a study of childhood asthma hospitalization rates in Spokane County, Washington, Kraemer and McCarthy (1985) reviewed medical records from seven hospitals for children up to 19 years of age. They reported a nearly two-fold increase in paediatric asthma admissions over seasonally expected rates from April through June 1980. They also reported an increase in asthma admissions during the weeks following the eruption, when levels of suspended volcanic ash particulates were at their highest. Buist *et al*. (1986a) reported results from a four-year follow-up of a cohort of loggers exposed over an extended period to varying levels of volcanic ash from Mount St. Helens. They found that a significant, exposure-related decline in FEV1 occurred during the first year after the eruption. However, by the fourth year

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat170
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the decline was no longer significant. A similar pattern was noted for self-reported symptoms including cough, phlegm and wheeze. The authors stated that 'findings are consistent with the hypothesis that the inhaled ash caused mucus hypersecretion and/or airway inflammation that reversed when the exposure levels decreased.' In a review conducted by Buist *et al*. (1986b), they reported that long-term or chronic effects of exposure to the volcanic ash included irritation and inflammation of the upper and lower respiratory tracts while low-level chronic exposures continued, or after intense short-term exposure.

Olenchock *et al*. (1983) studied the effects of volcanic ash exposure on the level of humoral immune factors IgG, IgA, IgM, C3, C4 and antinuclear antibody (ANA) in volcanic-ash-exposed loggers in comparison with nonexposed loggers. C3 and C4 were significantly lower among exposed loggers shortly after the eruption and also one year later. Exposed loggers also demonstrated a significant decrease in serum IgG and IgA levels one year after the event. The authors concluded that 'exposure to volcanic ash may affect humoral immunologic parameters.'

6.2 Soufriere Hills, Montserrat Eruption—19 July 1995

In July 1995, the Soufriere Hills volcano on the Caribbean island of Montserrat began erupting, and it has continued to be active since that time. The eruptions have deposited large quantities of ash, particularly on the southern part of the island that is downwind of the volcano. The capital, Plymouth, was evacuated in April 1996, though the port was kept open and people were allowed into the area during safe periods to clear ash from their properties (Searl *et al*., 2002). All activities in Plymouth ceased after a major eruption on 25 June 1997 when 19 people were killed. Continuing high levels of volcanic activity during the summer and fall of 1997 resulted in the evacuation of areas in the central part of the island. Since 1997, approximately 4500 of the original 12 000 residents have remained on the island, in the northern areas (Searl *et al*., 2002). The eruptions have involved the growth of a lava dome in the old crater that periodically produces large ash emissions, often in the form of pyroclastic flows, when it collapses or explodes (Forbes *et al*., 2003).

6.2.1 Exposures

The remaining population of the island has been exposed to ash from the periodic ash falls as well as from resuspension of ash particles by wind and human activity. Searl *et al*. (2002) reported that individual exposures were related to occupation. The highest exposures occurred among gardeners, cleaners, roadworkers and police at roadside checkpoints. Individual exposures for some of these workers in 1997 included concentrations of cristobalite (silicon dioxide) that exceeded the American Conference of Governmental Industrial Hygienists (ACGIH) recommended occupational exposure limits. Analysis of the ash in 1996 demonstrated high levels of crystalline silica (15–20% by weight), as well as substantial quantities of particles smaller than 10 μm (13–20% by weight) (Searl *et al*., 2002). The silica was present as cristobalite (Baxter *et al*., 1999). Freshly erupted ash also contained water-soluble sulfates, chlorides and fluorides adsorbed on particle surfaces. The surface acidity of these particles could result in irritant effects on the airways (Searl *et al*., 2002).

6.2.2 Health Effects

Forbes *et al*. (2003) studied the effect of ash exposure on the respiratory health of children on Montserrat. They found that children aged 12 and under who had ever lived in areas with moderate or heavy ash exposure had a significantly higher prevalence of reported wheeze ever, and wheeze in the past 12 months, in comparison with children who had always lived in low exposure areas. They also found that the risk for exercise-induced bronchoconstriction, defined as a 10% decline in peak expiratory flow rate, was almost four-times higher in children who currently lived in areas with moderate or heavy ash exposure in comparison with children who currently lived in low-exposure areas. In a report for the Institute of Occupational Medicine, Cowie *et al*. (2002) gave results from an October 2000 survey of workers from occupations with potentially high exposures to volcanic ash. They also conducted spirometry and chest radiography. They found that the risks of reporting symptoms of asthma and breathlessness were significantly associated with exposures from heavy ash clearing activities. In addition, among men, FVC and FEV1 results were significantly reduced in subjects who had ever worked as gardeners or roadworkers. There were few signs of abnormalities on the chest radiographs. The results suggested exposure to volcanic ash had some mild effect on respiratory health among the Montserratian workers, though there was no evidence of an accelerated or severe silicotic reaction to ash exposure. There was no evidence of any effect of residential exposure or exposure from domestic cleaning tasks on study participants' health. Cowie *et al*. (2003), in another report for the Institute of Occupational Medicine, calculated risks of silicosis for six different population groups and four locations on the island. They reported that risk estimates for most groups are 1 in a 100 or less after up to 20 years of volcanic activity. The exceptions to this included gardeners (2–3 per 100) and children

(5 per 100). The authors did note that the risk calculation methods used could lead to over-estimation of risk.

6.3 Summary

Studies related to the two examples of volcanic disasters presented here suggest there may be two types of exposure most likely to result in ongoing, potentially long-term respiratory health effects. First, individuals with ongoing exposure to ash falls and/or resuspended ash may experience lower-respiratory symptoms such as shortness of breath, cough and wheeze, as well as declines in PFT results. This may be most prominent for those with higher levels of exposure, such as certain occupational groups, and in more vulnerable populations, such as children. These effects may eventually resolve if exposure ceases. The other exposure group of concern involves those individuals with the heaviest, most acute and intense exposures. It is plausible, though not yet confirmed, that these individuals may experience lingering respiratory symptoms and declines in pulmonary function. Some individuals with these high exposures may also be at some, probably low, risk for the development of silicosis.

Hansell (2003) has noted that despite the fact that over 455 million people worldwide live within exposure range of a volcano active within recorded history, there has been relatively little epidemiological research published on the health effects of volcanic emissions. The International Volcanic Health Hazard Network was created in 2003 to help determine the health effects of volcanoes, as there has been limited long-term monitoring of exposed populations (Jones, 2006). One reason more studies are needed is because there may be important differences between exposures and thus effects from different volcanoes as well as between different events involving the same volcano, in terms of eruption pattern, gaseous emissions, base composition of ash, compounds adsorbed onto ash particles, the percentage of respirable particles, and toxicological activity (Hansell, 2003). Using the two examples presented in this chapter, most respirable ash in Montserrat has been generated from pyroclastic flows, with cristobalite concentrations measured at up to 20% by weight. However, Montserrat ash derived from phreatic explosions has had lower concentrations of cristobalite (8.6% by weight) (Housley *et al*., 2002). In comparison, cristobalite concentrations were noted to be approximately 4.2% by weight for ash from the Mount St. Helens eruption (Baxter *et al*., 1999). As noted by Hansell (2003), other volcanoes, such as Sakurajima, Japan, may have ashfalls accompanied by sulphur dioxide emissions (Uda *et al*., 1999) or, in the case of Kilauea, Hawaii, may involve predominantly sulphur dioxide emissions (Mannino *et al*., 1996).

7 CONCLUSIONS

This review presents epidemiological evidence for long-term adverse health consequences from a selection of major disasters, which represent some of the more thoroughly studied events in history. While it provides an overview of outcomes expected from several types of disasters, it also illustrates the gaps in knowledge that exist for some of these events. For instance, studies of health effects related to the World Trade Center disaster have been numerous and are expected to continue for many years. This represents one of the most thoroughly studied disasters in history, though even for these studies there have been significant methodological obstacles (Savitz *et al*., 2008). Conversely, long-term health effects from volcanic disasters have not been as thoroughly studied, despite their regular occurrence throughout history.

Among disaster types not covered in this review, floods and hurricanes offer another brief example of the relative lack of data that exists regarding long-term adverse health consequences of disasters. While floods account for approximately 40% of natural disasters, and may become even more frequent and severe due to global warming and increasing urbanization and deforestation (Landesman, 2001), knowledge of long-term health effects of flooding is less complete than is knowledge of immediate post-event effects (Reacher *et al*., 2004). Some studies have attempted to evaluate this issue (Bennet, 1970; Abrahams *et al*., 1976; Tapsell and Tunstall, 2008), but overall the literature is somewhat lacking. Hurricane disasters have not generated many long-term health studies either. Hurricane Katrina resulted in a truly monumental disaster including failure of the levees in New Orleans and subsequent flooding of 80% of the city (Rabito *et al*., 2008). There have been a number of reports of short-term, post-event health effects (Centers for Disease Control (CDC), 2006; Tak *et al*., 2007; Rath *et al*., 2007; Cummings *et al*., 2008; Rabito *et al*., 2008). However, to date there are few published reports of long-term physical health effects among populations affected by this disaster.

For the majority of disaster types, there is relatively little information available regarding long-term health outcomes among disaster victims (Cook *et al*., 2008). In many cases this may be due to inherent methodological challenges in tracking displaced populations, accurately identifying responder and community cohorts, identifying exposures of concern, and in establishing causal links between such exposures and specific health outcomes, both in the short term and long term. Savitz *et al*. (2008) note that the unanticipated nature of a disaster makes it more difficult to carefully define the population of interest, measure exposure and prepare for longitudinal health studies. In some cases, there may be insufficient resources available to develop and sustain longitudinal studies. Many organizations responsible for disasters do

not have an adequate process or authority structure for coordinating long-term population health surveillance that may last for months or years after a disaster (Fenig and Cone, 2005).

Though the World Trade Center disaster was a unique and unprecedented event, the epidemiological response that has been ongoing, in the form of health monitoring and longitudinal studies, can serve as an example of how, given adequate resources, postdisaster research may be effectively pursued despite ever-present methodological challenges. Ideally, national and local health services should be equipped to provide health surveillance systems and resources in the weeks, months and years after a disaster (Cook *et al*., 2008). Disaster response planning should include the study of long-term health impacts as an integral part of the overall response plan for disasters, and efforts should be made to ensure the availability of resources for such response activities. However, even without adequate resources, any attempt to identify affected populations and track postdisaster health impacts over time may provide valuable knowledge, given the relative lack of published data on this issue for many disaster types.

ACKNOWLEDGEMENTS

I offer my sincere thanks to Munyaradzi Masawi for his valuable assistance with reviewing the literature and with the preparation of this review.

Biological Correlates of Low-Level Electromagnetic-Field Exposure

Jitendra Behari

CONTENTS

1 INTRODUCTION

During the last four decades or so there has been growing concern about the effects of electromagnetic radiation on biological systems. This is because of electronic devices, for communication, the air surveillance system, industry, and diagnostic and therapeutic purposes in medicine, emitting microwaves/radiofrequency (RF) waves. In view of this, the importance of the electromagnetic radiation pervading the environment is now increasingly realized. This has added to the list another pollutant in the environment (electropollution) after air, water, soil and noise. The effects are broadly classified into two: thermal and nonthermal, though the line of demarcation between the two is not very clear. While the former leads to an increase in body temperature, the latter does not. The nonthermal effects are attributed to the induced electromagnetic fields (**Figure 1**).

While the issue is still being debated, devices emitting these radiations have found their use in everyday life. These principally include mobile phones and microwave ovens, to name a few. Microwaves are emitted by mobile phones of the GSM type (global system for mobile

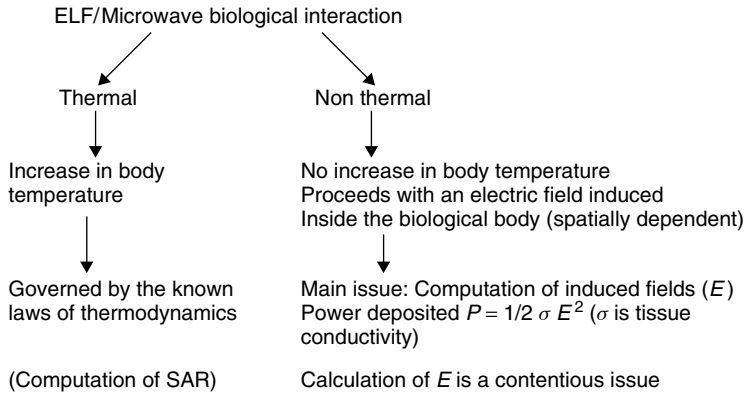

Figure 1 The boundary line between thermal and nonthermal effects is thin and not yet well defined. ELF: extremely low frequency; SAR: specific absorption rate; E_i: induced field; P: power deposited; σ: tissue conductivity.

telecommunication). It is an extremely low frequency (ELF) modulated pulsed microwave carrier. This is not the case for analogue radio and television. It can be argued that digital mobile phones transmit information in bursts of microwaves. This raises a question regarding its negative effect on human health. It has been observed that the two low-frequency sine waves (8.3 and 217 Hz, respectively) act on the composite pulsed GSM signal.

There are reports indicting adverse health effects of cell phones which emit electromagnetic radiation, with a maximum value of 50% of their energy being deposited when held close to the head. Also there is a likelihood that fields emanating from base stations (though very weak), would create a health hazard, though the issue is still being debated. It would therefore be useful to explore and understand the mechanism of electromagnetic-field effects over a wide frequency band at the existing level of RF/microwave exposure from various devices and in the environment.

While the thermal effects of microwaves are not commonly detected, nonthermal effects, if undetected, may have negative effects on human health. It is understood that RF electromagnetic fields (EMFs) from base stations to which humans are exposed (far-field exposures) are well below the allowed values. In a recent survey, it was reported that around 4% of people claim that they are sensitive to RF EMFs to some degree (Eltiti *et al*., 2007). The biological effects also depend upon the intermittency of the exposure, may be accumulative, and may include membrane interactions that affect the ion fluxes, the modulation of neuronal impulse activity and possibly induce arrhythmia in isolated heart. Behavioural effects and those on reproductive patterns are also possible at low levels of microwave exposure. There are important biomedical considerations associated with long-term exposure to any environmental factor capable of tissue interactions. These include effects specifically attributable to wave type, duration, intermittency, frequency of recurrent exposure, interactions involving simultaneous exposure to multiple factors, age at onset of exposure and may also reflect ethnicity. While examining the biological effects, it was realized that it is not the external field, but the fields within the tissue and the body that are important.

Taking cognisance of the above, several governments have imposed limitations on the fields radiated by power systems. Biologists and the physicians have conducted many clinical tests over many years and have proposed a set of maximum values for the radiated fields, depending on the frequency.

2 THE PHYSICS OF THE PROBLEM

Biological bodies are inhomogeneous, having tissue-specific dielectric properties and a complex shape, making the computation of the induced field rather difficult. The fields induced inside the body depend upon, but are not limited to, the following parameters:

1. The location of the field with respect to the surroundings, for example, if there are metallic objects around, the person is grounded or otherwise
2. Polarization of the incident wave with respect to the orientation of the human body
3. Size of the human body (L) with respect to the wavelength (λ) of the incident radiation (L/λ)
4. The portion of the body
5. The electrical properties of the tissue in question.

In free-space propagation of an electromagnetic field, the power density is given by:

$$\text{Power density} = E^2/1200\,\Pi \text{ mW cm}^{-2} \qquad (1)$$

where E is the electric field strength.

Figure 2 illustrates how the average body specific absorption rate (SAR) is size and frequency dependent (free-field exposure level of 10 mW cm^{-2}, Gandhi

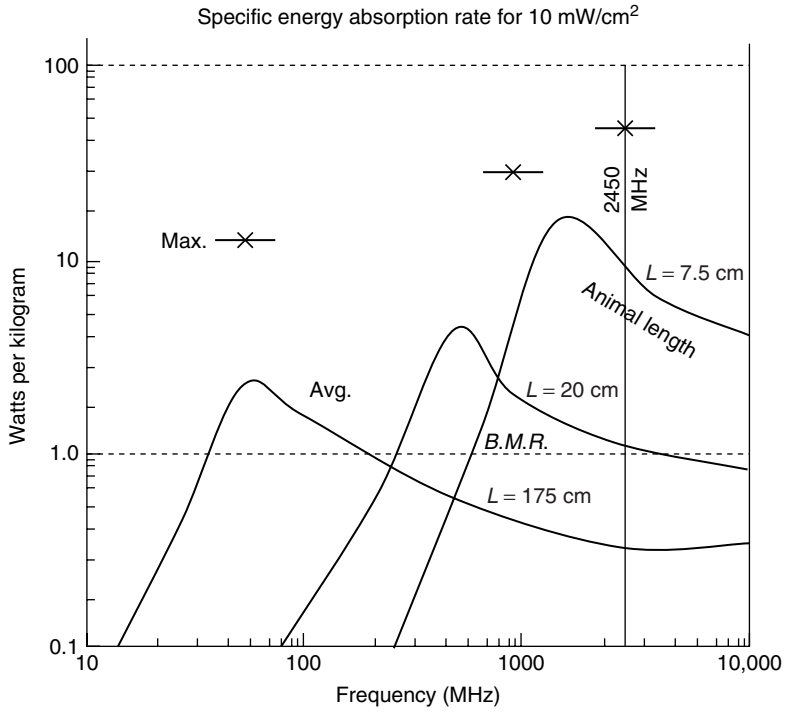

Figure 2 Average SAR in prolate spheroidal models of biological subjects exposed to electromagnetic radiation as a function of frequency. (Reproduced from Gandhi *et al.*, 1979. © IEEE.)

et al., 1979). The absorption characteristics for a prolate spheroridal model representing a man, 175 cm long, oriented parallel to an incident electric field (maximum absorption) is shown. It indicates that the average SAR, for a man model, exposed to radiation at frequencies from 10 to 10 000 MHz, first increases as the square of the frequency, reaching a peak of $2\,W\,kg^{-1}$ at about 70 or 80 MHz, then gradually approaches an asymptotic value of approximately $0.16\,W\,kg^{-1}$. In the upright position, the grounded body has longitudinal resonance around 35 MHz (Gandhi and Rozzell 1975). In the transverse and anteroposterior axes, maximum absorption occurs at frequencies from 135 to 163 MHz. This configuration may be obtained in a far-field exposure. However, near-field patterns of energy absorption, as in the case of a user of a mobile phone near to the head, will be dominated by regional peaks determined by the proximity of the transmitting antenna to specific body parts and their relative orientation.

When a smaller body (simulating a rat), 20 cm long is exposed, the maximum absorption shifts towards a higher frequency, 650 MHz, and when a still smaller 7.5 cm long body (simulating a mouse) is exposed, the maximum absorption is within the microwave frequency range (2450 MHz). From simple biophysical considerations, each body therefore has a characteristic resonant frequency, depending upon the length of the long axis. Correspondingly, for the same level of incident exposure, the average value of the SAR is dependent upon the length of the body, the degree of decoupling decreasing the average value of SAR by more than an order of magnitude. It is suggestive that absorbed RF energy can be converted into other forms of energy and can cause interference with the functioning of biological systems. A significant portion of this energy is converted into heat (absorption). However, the effects are frequency dependent. At frequencies, below 100 kHz, the induced fields can even stimulate nervous tissue.

3 THE HEAD AS A RECIPIENT OF ELECTROMAGNETIC ENERGY

The waves falling on the biological objects may not necessarily penetrate through the entire body, but are limited to a distance determined by the skin depth. The depth to which microwaves can penetrate inside the tissue depends on the electric and magnetic properties of the tissue and of the microwave frequency. In general, at a given frequency, the lower the water content of the tissue, the greater the wave penetration and vice versa. As of now, reliable data are available on the dielectric constants of biological tissues and the assessment of biointeraction mechanisms can be quantified to an appreciable extent.

Out of all the organs, the head is the targeted recipient of electromagnetic energy from many wireless systems (e.g. mobile phones), whose impulses are also transmitted to other organs and parts. Thus, its physical and biological properties have been well investigated. For the

head, the resonant frequency is a function of head size, decreasing from around 700 MHz in infants to 400 MHz in adults (Gandhi and Hagmann, 1977). Early studies using thermalizing far-field exposure levels identified sites for preferential deposition of electromagnetic energy (hot spots) within the head. These hot spots occur inside lossy spheres, as models for brain tissue, with radii $0.1 < r > 8$ cm for frequencies between 300 MHz and 12 GHz (Kritikos and Schwan, 1972; 1976). However, at lower frequencies and much higher frequencies, heating occurs primarily at the surface of the sphere facing the source. Heat conduction and convection from a central brain hot spot have been modelled, with inclusion of a factor for blood flow, which accounts for heat removal (Kritikos and Schwan, 1979). For a spherical head 10 cm in diameter, exposed to a 1.0 GHz, 10 mW cm^{-2} field with a central hot spot 2 cm in diameter, the expected temperature rise would be 0.5 °C, with normal blood flow and heat conduction (Adey, 1997).

For a given incident field flux, the heating potential in the hot spot decreases rapidly with increasing head radius (Kritikos and Schwan, 1972; 1975; 1976). Thus, in man, the expected temperature rise would be lower at this 1.0 GHz field frequency than seen in the 10 cm model. There are strong differences in convective capacities between cerebral grey and white matters, attributable to substantially higher densities of blood-vessel capillary beds in central cortical grey matter (Ranck, 1964). For the human head, simulated as a sphere 15.0 cm in diameter with three layers representing brain, fat and skin, a 2.45 GHz (or higher frequency) field is rapidly absorbed at the surface of the head.

4 DOSIMETRY

At lower frequencies (<100 kHz), many biological effects are quantified in terms of current density in tissue and this parameter is most often used as a dosimetric quantity. At higher frequencies, many (but not all) interactions are due to the rate of energy deposition per unit mass. This is why the SAR is used as the dosimetric measure at these frequencies. It is expressed as W kg^{-1}. The SAR is thus the absorbed power by the absorbing mass. The most obvious approach towards dosimetric analysis is to experimentally determine the SAR distribution in phantoms simulating animal and human bodies, as well as in real cadavers. One way of determining the local or whole-body SAR is by temperature measurements. The SAR is proportional to the temperature increase only when the effects of heat diffusion can be neglected.

With these limitations in mind, the SAR concept has proven to be a simple and useful tool in quantifying the interactions of RF/microwave radiation with living systems, enabling comparison of experimentally observed biological effects for various species under various exposure conditions. This provides (as of now) the only means, however imperfect, of extrapolating the animal data into potential hazards to humans exposed to RF radiation, and facilitating, planning and effectively executing therapeutic hyperthermic treatment (Stuchly and Stuchly, 1996).

The SAR is defined as the time derivative of the incremental energy dW absorbed by or dissipated in an incremental mass dm contained in a volume element dV of a given density ρ (WHO, 1993; NCRP, 1981). An equivalent method is to take a temperature measurement. The SAR is proportional to the temperature increase ΔT, when the effects of thermal conduction, convection and radiation are negligible, in the time interval Δt.

$$\mathrm{SAR} = -\left(\frac{\mathrm{d}}{\mathrm{d}t}\right)\left(\frac{\mathrm{d}W}{\mathrm{d}m}\right) = \left(\frac{\mathrm{d}}{\mathrm{d}t}\right)\left(\frac{\mathrm{d}W}{\rho(\mathrm{d}V)}\right) = C\frac{\Delta T}{\Delta t} \tag{2}$$

The same can also be evaluated, using the Poynting vector theorem for sinusoidal varying electromagnetic fields:

$$\mathrm{SAR} = \left(\frac{\omega\varepsilon_0}{2\rho}\right) - |E_\mathrm{i}|^2 = \left(\frac{\varepsilon}{2\rho}\right) - |E_\mathrm{i}|^2 \tag{3}$$

where $|E_\mathrm{i}|^2$ is the peak value of the internal electric field (in V m^{-1}). SAR is also dependent upon if the wave type, that is, square, sine or triangular. The power of the square is larger than the other two. The average SAR is defined as the ratio of the total power absorbed in the exposed body to the mass in which it is absorbed, which is not necessarily that of the total body. The local SAR refers to the value within a defined unit volume or unit mass, which can be arbitrarily chosen.

To better understand experiments in microwave exposure, as well as their relation to safety standards; it is useful to refer to the diagram in **Figure 3**. In this diagram, with log–log coordinates of power (or power density or SAR) on the ordinate and time on the abscissa, it is possible to draw the threshold for various effects and hazards. For example, to heat a finite sample to a given temperature, the threshold is a constant SAR for long periods of time, while, for short periods of time, during which no heat is lost from the sample, the threshold curve is a line of constant specific absorption (SA = SAR − time) which is at 45° from the horizontal. The intersection of the two lines, constant SAR and constant SA, determines the applicable thermal time constant and associated 'average time' in setting exposure standards (Osepchuk and Petersen, 1996).

As evident by Equations (2) and (3), both approaches (temperature/field) have some common requirements. Any measurable field disturbance caused by the intrusion of the probe must be avoided. A further requirement is that any signal, picked by any part of the probe, other

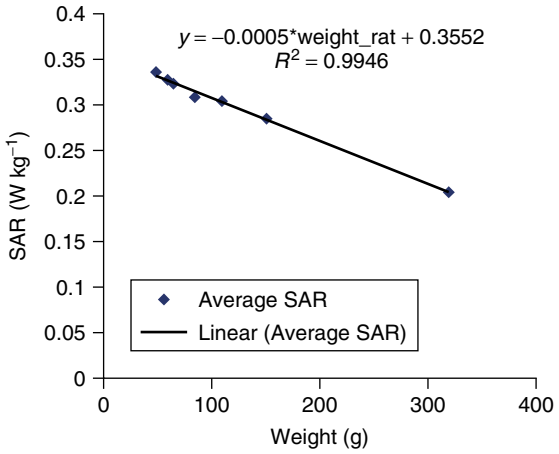

Figure 4 The linear-regression model of the SAR as a function of weight of the rat.

than the signal itself should be sufficiently suppressed. Further, the spatial resolution should be better than the smallest spatial dimension of any local field maxima or minima, in order to enable accurate assessment of the SAR distribution. Determination of the SAR distribution requires measurements in the tissue volume of interest. In larger volumes, with greatly nonuniform distributions, SAR varies from place to place, demanding measurements in several places, and the location of the sensor must be precisely known.

In animal experimentation (particularly in the developing stage) it is clear that as the animal age increases (and hence the weight) the SAR values change and dosimetric estimation becomes uncertain. On the basis of theoretical formulation from Durney *et al*. (1979), weight/age increases for the rat as shown in **Figure 4**. It is found that SAR in the foetus is strongly dependent on the geometrical relationship between the foetus and the EM source, while the average SAR for the foetus is always lower than the RF safety guidelines under the exposure conditions (Togashi and Ryder, 2007). The single-value concept of SAR thus has many uncertainties.

Also, the concept of SAR is not sufficient when one is looking for biological effects not dependent upon absorption. This raises questions about using these parameters for evaluating effects that may be of another nature. The possibility of nonthermal effects is thus a controversial one and the problem of dosimetry becomes much more complex. SAR may be a valid quantitative measure of interactions other than absorptive ones, when the mechanism is dependent on the intensity of the electric field, except, however, when the direction of the field is of importance with respect to the biological structure. Similarly, the SAR concept may not be sufficient for direct interactions with the E field. Further, there is always a level of uncertainty about perceived field strength and actual RF exposure.

The extrapolation of results from animal experiments (mostly) to humans is used in a reduced form, termed frequency scaling. The approach essentially enables us to use results from one model experiment and to predict results in another biological object, differing only by a scale factor. The frequency-scaling principle can be applied to determine the equivalence between the exposure of a man of height l_m and an animal of a length l_a, with both man and animal having the same orientation with respect to the exposure field, using the relationship:

$$f_m l_m = f_a l_a \tag{4}$$

where f_m and f_a are the frequencies at which man and animal are exposed, respectively (Durney and Christensen, 2000). It should be mentioned that the SAR distribution in the two cases will be similar in the two bodies (but may not be the same). This may be valid for low losses, which is not always be the case for biologic structures.

5 BIOLOGICAL EFFECTS

While considering the biological effects of electromagnetic-field exposure, the evidence for nonthermal effects has been gathered under two headings: (i) *in vitro*: altered cell responses and (ii) *in vivo*: results of chronic exposure in animals. The data available on biological effects of electromagnetic-field exposure are immense and at times contradictory. These effects may not always produce adverse health impacts. There is an element of uncertainty across various mobile frequency bands and also on whether the target under investigation is brain or muscle tissue. Living systems are

electrochemical systems that use EMFs in everything from protein folding, through mobile communications, to nervous system function. If we expose a living system to a weak external signal it will interact and may interfere with normal physiological functioning (Parker and Winters, 1992). It is this aspect of EMF–biological interaction that has aroused interest in recent years. Some of the physiological systems that have been targeted for investigation are discussed below.

5.1 The Blood–Brain Barrier (BBB)

The blood–brain barrier (BBB) protects the mammalian brain from potentially harmful compounds in the blood. It is a selectively permeable, hydrophobic barrier that is readily crossed by small, lipid-soluble molecules. It serves, not only to restrict entry of toxic polar molecules into the brain, but also as a regulatory system that stabilizes and optimizes the fluid environment of the brain's intracellular compartment. A dysfunctioning BBB allows influx of normally excluded hydrophilic molecules into the brain tissue. This might lead to cerebral oedema, increased intracranial pressure and, in the worst case, irreversible brain damage. Opening of the BBB may subject the central nervous system (CNS) to assault from extraneous micro-organisms. It is thus a natural defence system that maintains the physicochemical environment of the brain within certain narrow limits that are essential for life.

The BBB has thus been a subject of investigation because of its vicinity to the radiation source and its central function in the human brain. Because of its penetration, exposure of an electromagnetic field could cause significant alteration in BBB behaviour. The emission intensity of sodium fluorescein in brain tissue exposed to an EMF for 30 minutes was larger than that without such exposure (Williams *et al*., 1984). In a study on the transport of D-mannitol across the BBB, it was observed that a higher power (larger SAR) generally yielded larger permeability, and a pulse wave was more effective in permeability enhancement than a continuous wave (CW) (Oscar and Hawkins, 1977). Further, for higher electromagnetic frequencies, the conductivity was larger, with a correspondingly higher SAR (Equation 3), hence producing a greater permeability. Larger modulation also induces greater permeability. In addition, the conductivity at a depth of 50% was larger than that for 0% for an AM (amplitude modulation) wave with a modulation of 16 Hz (Albert *et al*., 1987). A twofold increase in the BBB permeability of sucrose was obtained after exposure to an EMF of 1.8 GHz over four days (Schirmacher *et al*., 2000). From all these observations, it can be concluded that permeability enhancement was not because of temperature increase, as it was within the variation of 1 °C in daily rhythm.

This selective permeability has the disadvantage that agents and drugs that are effective in treating diseases in other parts of the body may not be able to gain entry into the brain to combat infection. The ability to selectively open the BBB suggests the possibility of using microwave regional hyperthermia to facilitate chemotherapy for brain tumours and facilitate the delivery of anticancer drugs such as methotrexate. This drug is often used for high-dose chemotherapy.

A series of investigations on BBB permeability have revealed changes at a very low level of microwave exposure. As a specific example, effects of microwave fields on the BBB have been investigated by exposing male and female Fisher 344 rats in a transverse electomagnetic (TEM) line chamber to 915 MHz CW microwaves, as well as pulse-modulated waves with repetition rates of 8, 16, 50 and 200 per second. The SAR varied between 0.016 and 5 W kg^{-1}. The rats were not anaesthetized during the two hours of exposure. The results show that both continuous and pulsed microwaves have the potential to open up the BBB for albumin passage, with no significant difference between the two (Salford *et al*., 1994).

5.2 The Nervous System

Due to the proximity of a mobile phone to the head, most research efforts have been concentrated on estimating the potentially toxic effect of RF on the CNS. This is largely because the nervous system is the body's main control and integrating network. Its activities are divided into two parts: sensing and then responding. In the first category it serves two functions: sensing intrinsic and extrinsic (environmental) stimuli, and interpreting and integrating these signals. In the second phase, it responds to interpretation by initiating actions in the form of muscular contractions or glandular secretions. The nervous system of vertebrates is composed of two primary parts: the central nervous system composed of brain and spinal cord and the peripheral nervous system, composed of all nerves outside the CNS. When the nerves or brain are perturbed, for example by RF radiation, morphological, electrophysiological and chemical changes will take place. These include transient minor effects on a electroencephalogram (EEG), on sleep structure and on cognitive processes in human subjects (Mann *et al*., 1997. A significant change in these can lead to a change in overall behaviour. It has been further reported that different areas of the brain have different sensitivities to RF radiation (Lai *et al*., 1989; Ray and Behari, 1988). Exposure of the brain to a mobile phone may lead to an increase in temperature to the extent of 0.1 °C (Van Leeuwen *et al*., 1999; Wainwright, 2000), after taking into consideration the high blood-perfusion rate.

This, in contrast to skin blood perfusion, was significantly elevated after exposure to mobile phone frequencies (Monfrecola *et al*., 2003). Under some conditions, such as when the handset operates at full transmitter power because of a long distance to the next base station, local SAR values in the brain are reported to be in the range of $1\,W\,kg^{-1}$ or more (Huber *et al*., 2003).

6 THE ROLE OF CALCIUM

6.1 Effects on Metabolism

Lerchl *et al*. (2008) have shown that chronic RF exposure (383, 900 and 1800 MHz) leads to frequency-dependent increase of body weight in Djungarian hamsters at moderate SAR values. These authors have concluded that this is indicative that metabolic processes may be affected by such exposures. It is possible that molecular processes involved with the brain energy metabolism of the rat may be perturbed by radiation in the microwave frequency region. It has been reported that there are divalent iron atoms and two divalent copper atoms in the molecules of the respiratory chain (Lehninger, 1965). Each of these is essential to the respiratory function at the molecular level. Charged particles like these, if not otherwise constrained, undergo translational motion in an electric field. Such a group of particles would possibly respond to an oscillating electric field over a wide range of frequencies, starting from natural RF oscillations up to the highest values to which natural process react (Sanders *et al*., 1984). Nicotinamide adenine dinucleotide (NADH), adenosine triphosphate (ATP) and creatine phosphate (CP) are key compounds in brain energy metabolism. ATP is a key compound in energy metabolism because it is the carrier of energy for the processes in living cells. NADH is oxidized to produce ATP in the mitochondria, while brain ATP concentration is maintained at the expense of CP. When demand for ATP is higher than the mitochondrial production capacity, CP is rapidly converted to ATP to sustain ATP levels and a significant decrease in CP levels is observed prior to any decrease in ATP. The changes in these compounds are frequency dependent.

Another effect on metabolism of electromagnetic radiation is the leakage of free calcium ions, either through the cell's external membranes or those surrounding internal 'calcium stores'. This can have dramatic effects on many aspects of metabolism and explains results like the stimulation of growth and increased risk of cancer, symptoms suffered by electrosensitive humans. Calcium concentration inside the cell controls the rate of many metabolic processes, for example, the activity of many enzyme systems and the expression of genes. Ca^{+2} ions use special channels to cross the membrane along the concentration gradient. The concentration of calcium ions in the cytosol is normally kept about a thousand times lower than that outside by metabolically driven ion pumps in the membranes. Electromagnetic-field stimulation increases membrane leakiness, causing unregulated amounts of extra calcium to flood in. The actual effects depend on the programmed state of the cell at that instant of time; for example, the growth rate, the repair rate after injury or the rate of healing can be enhanced. On the other hand, if there are mutant precancerous cells present, it may also lead to tumour promotion.

6.2 Calcium Release from Cell Membranes

Ca^{+2} ions are able to bind without causing deformations to either membrane proteins or soluble proteins of the cytoplasm or organelles. They have several ion-binding sites and, by changing their configuration as a function of the occupied site, they are capable of exciting a specific target enzyme. The Ca^{2+} ion has been identified in relaying electrochemical messages to the cell surface and thus is the most critical target for microwave exposure. It is known that Ca^{2+} signalling has extreme sensitivity to coherent excitation by very low field energies within specific amplitude and frequency windows (Gartzke and Lange, 2002). This causes a large electrostatic force to be generated at the cell surface. The lowest level of exposure could be $0.00015\,W\,kg^{-1}$ ($0.08\,\mu W\,cm^{-2}$) with a 16 Hz signal modulated at 240 MHz (Schwartz *et al*., 1990). The mechanism of action of gonadotrophin releasing hormone (GnRH) on the anterior pituitary gonadotrophin reveals that Ca^{2+} functions as a second messenger in the GnRH-activated signal-transduction cascade (Jennes *et al*., 1995; Haisenleder *et al*., 2001; Liu *et al*., 2003).

Ca^{+2} ions use special channels to cross the membrane along the concentration gradient. These voltage-gated channels are normally closed in excitable cells, but they open in response to an action potential. There has always remained a question of whether the cell membrane (calcium ion channel), is directly involved in electromagnetic-field interactions (Liburdy, 1992). This is important because the receptor sites and ion channels are located in the cell membrane and are first involved in the signal-transduction processes. Another question is if alterations in the calcium fluxes are propagated down the signal-transduction cascade to alter events such as gene activation. Further, changes in the calcium ion second messenger are linked to induction of c-myc messenger RNA, a mid-stage signal-transduction marker, which, in turn, travels down the signal-transduction cascade to alter gene activation events and cell proliferation.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

6.3 Brain Function and EMF Effects

The role of calcium in the control of brain function has been under investigation and was found to be influenced by a range of modulating frequency. A statistically significant increase in net $^{45}Ca^{2+}$ transport was observed for modulating frequencies of 6–16 Hz, followed by a fall over the frequency range 20–35 Hz (Bawin *et al*., 1978). The nonlinear effect of modulated waves on chicken cerebral tissue has also been demonstrated with $^{45}Ca^{+2}$. The animals were exposed to 0.8 mW cm^{-2} at 147 MHz, amplitude modulated by a sinusoidal signal (0.5–35 Hz). The existence of frequency windows was confirmed (Blackman *et al*., 1979) for an incident power flux of 1 mW cm^{-2}; there was a positive response when the modulation lay between 6 and 12 Hz, but little response at 0.5 and 20 Hz. A power window was also shown to exist at constant frequency; when the chicken cerebral tissue was submitted to a 450 MHz carrier wave modulated at 16 Hz there was a significant increase in power levels of 0.1 and 1 mW cm^{-2}, while no effect was observed for power levels of 0.05 and 5 mW cm^{-2}. Similar results in terms of frequency and power windows were reported by Kunjilwar and Behari (1993) who exposed rats to 112 MHz, amplitude modulated at 16 Hz (SAR 0.1 W kg^{-1}), and reported changes in acetylcholineste rase activity and Na^+/K^+ phosphatase activity (Behari *et al*., 1998). They observed no significant changes when the CW was changed to 73.5 and 36.75 MHz with a modulating frequency of 76 Hz. The limits of the frequency and power windows were 6–20 Hz and 0.1–1 mW cm^{-2}, respectively (Gandhi, 1982). The carrier frequency was shown to be less than 1 GHz, but itself had little effect, while the modulating frequencies were more controlling. For avian brain tissue under an AM wave, conductivity at a modulation of 16 Hz was 1.2 times that for 3 Hz (Albert *et al*., 1987). For human brain, conductivity also increases with an FM modulation increase from 9 to 16 Hz (Blackman *et al*., 1979).

Bawin *et al*. (1975) have found that exposing brain tissue to weak VHF (very high frequency) radio signals modulated at 16 Hz released calcium ions bound to the surfaces of cells. Blackman *et al*. (1982) concluded that weak fields were often more effective than strong ones. Without these ions, cell membranes are weakened and are more likely to tear under the stresses and strains imposed by the moving cell contents. Although the resulting holes are normally self-healing, they will increase leakage while they are open and this can explain the bulk of the known biological effects of weak electromagnetic fields. Leaks in the membranes surrounding lysosomes can release digestive enzymes, including DNAse (an enzyme that destroys DNA). Panagopoulos *et al*. (2007) showed that exposing adult *Drosophila melanogaster* to a mobile phone signal for just six minutes a day for six days broke the DNA in the cells that give rise to eggs into fragments, and half of the eggs died. Diem *et al*. (2005) also found significant fragmentation after exposing cultured rat and human cells to a simulated mobile phone signal for 16 hours. They showed that exposing human cells for 24 hours to simulated phone signals gave DNA fragmentation similar to that due to the gamma rays emitted from a radioactive isotope.

7 ELECTROMAGNETIC-FIELD EXPOSURE AND ENZYME ACTIVATION

7.1 Ornithidine Decarboxylase (ODC)

Ornithidine decarboxylase (ODC) is an enzyme essential for cell growth and DNA synthesis. It is a rate-limiting enzyme in the synthesis of polyamines. Polyamines (putrescine, spermadine, spermine, cadaverine) are long-chain molecules that are positively charged (polycationic). They have the highest charge/mass ratio of any biomolecule. High ODC activity occurs in the unregulated growth of tumour cells, as in the malignancy prostate cancer (**Figure 5**).

RF exposure has been shown to induce ODC activity, levels of which are often elevated during cell growth and tumour promotion. The exposure of mouse fibroblasts to amplitude modulated microwaves at an SAR of 3 W kg^{-1} increase ODC activity (Penafield *et al*., 1993), but to a much lower level than treatment with a chemical promoter. Litovitz *et al*. (1993) have examined the modulation frequency dependence of ODC activity in cultured cells (fibroblasts), determining the minimal duration that a single ELF modulation frequency must be sustained (coherence time) in order to elicit an ODC response. Using a 915 MHz field, switching modulation frequencies from 55 to 65 Hz at a coherence time of one second or less abolished enhancement of ODC responses, while coherence times of 10 seconds or longer produced full enhancement. These microwave coherence effects and pulsed effects are similar to those observed in ELF fields.

In an investigation in murine L929 cells, ODC was activated by an AM wave at 845 MHz, though it was not affected by frequency modulation (FM) at the same frequency (Penafield *et al*., 1993). ODC synthesizes polyamines, which promots the permeability of superoxide dismutase (SOD) across animal cell membranes (Poduslo and Curran, 1996).

7.2 Protein Kinase C Activity

Protein kinase C (PKC) plays a key role in a variety of pathologic states, including oncogenesis (Harvey

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat171
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

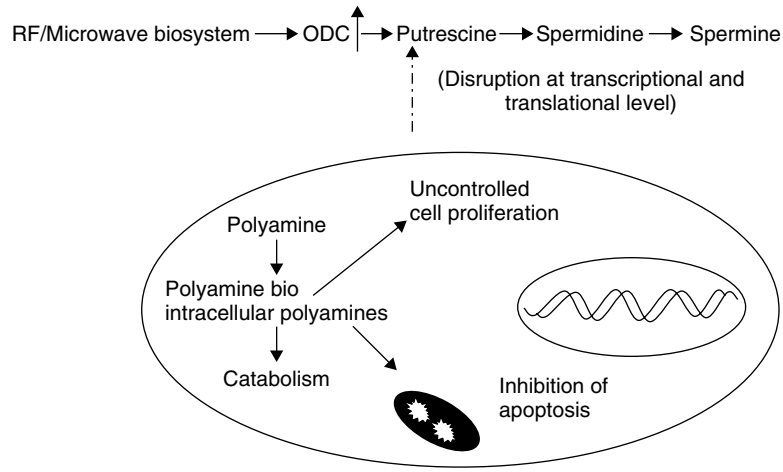

Figure 5 Mode of RF/microwave interaction with biological system in tumour promotion.

and French, 2000; Nishizuka, 1986), and in mediating cellular responses to extracellular stimuli involved in proliferation, differentiation, apoptosis and exocytotic release in a number of non-neuronal cells (Ohkusu *et al*., 1986). Several lines of evidence suggest that PKC modulates ion conductance by phosphorylating membrane proteins such as channels, pumps and ion-exchange proteins, besides its role in extrusion of Ca^{2+} immediately after its mobilization into cytosol. The enzyme has also been implicated in phosphorylation of several neuronal proteins, which are thought to regulate neurotransmitter release and long-term potentiation in memory formation (Suzuki, 1994).

The activation of this enzyme is thought to be biochemically dependent on Ca^{2+}. Tumour-promoting phorbol esters have a structure very similar to diacylglycerol and activate protein kinase C directly, both *in vitro* and *in vivo* (Castagna *et al*., 1982). It has been variously reported that protein kinase C is the receptor for tumour promoters (Parker *et al*., 1984). Tumour promoters, such as phorbol esters, increase the affinity of the enzyme for Ca^{2+}, resulting in its full activation at physiological Ca^{2+} concentration. TPA has a specific membrane receptor in the cell membrane (Hunter *et al*., 1984; Niedel *et al*., 1983). In order to stimulate cell proliferation in cells, growth factor and PKC are needed to induce the signal pathways. Byus *et al*. (1984) reported a decrease in the activity of this enzyme following exposure of human lymphocytes for a period of 15–30 minutes to 450 MHz, amplitude modulated at 16 Hz.

8 GENOTOXIC EFFECTS

The photon energy of RF radiation (10^{-3}–10^{-6} eV) is much less than the energy required to break chemical bonds (hydrogen bonds ~0.5 eV) and therefore it is believed that this radiation does not damage DNA. However, it is possible that certain cellular constituents are altered by exposure to EMF, such as free radicals. Free radicals are able to interact with DNA or other cellular components and are involved in cell regulatory processes.

8.1 Electromagnetic Fields and DNA

- Since nerve cells do not divide and are not likely to become cancerous, more likely consequences of DNA damage in nerve cells are changes in function and cell death, which could either lead to or accelerate the development of neurodegenerative diseases.
- EMF-induced DNA damage could be blocked by treating rats with antioxidants, including melatonin, immediately before and after exposure. Melatonin is a hormone secreted from the brain's pineal gland. As a potent antioxidant, it effectively eliminates free radicals inside cells.
- The effect of RF radiation on DNA could conceivably be more significant on neurons than on other cell types, because these nerve cells have a low capability for DNA repair.

DNA damage may lead to increased mutation frequency and could be linked to gene mutations. A gene is a section of DNA containing the information needed to make a particular protein or enzyme. There is also a section that can turn the gene on or off in response to outside signals. The growth of an organism from a fertilized egg involves a hugely complex pattern of switching genes on and off that regulates growth, cell division and differentiation into specific tissues. DNA damage can sometimes give unregulated growth to form

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

tumours. However, the effect may not be immediate and may take years before it is fully replicated.

In most studies, genotoxic effects have been investigated after short-term exposure (Moulder *et al*., 1999; Vijayalaxmi and Obe, 2004). Diem *et al*. (2005) reported DNA strand breaks (by comet assay) in human diploid fibroblasts and cultured rat granulose cells after RF field exposure (1800 MHz, SAR 1.2 or 2 W kg^{-1}; different modulations; duration 4, 16 and 24 h; intermittent 5 minutes on/10 minutes off or CW), but it is not clear if continuous exposure of nonmodulated or modulated 1800 MHz was used. A statistically significant increase in micronucleus formation and in chromosomal aberrations were observed in fibroblasts as well. Speit *et al*. (2007) used CW with intermittent exposure (1800 MHz, SAR 2 W kg^{-1}), applied using the same cell system and reported negative results. Nikolova *et al*. (2005) reported, after six hours, but not after 48 hours RF field exposure, a low and transient increase in DNA strand breaks in embryonic stem-cell-derived neural progenitor cells.

When mice were exposed to 2.45 GHz fields at an SAR of 1.18 W kg^{-1} for two hours per day for 120, 150 and 200 days, structural genomic rearrangement were observed in brain and testes cells (Sarkar *et al*., 1994). Lai and Singh (1995), (1996) reported that rats exposed to pulsed (two-second pulses, 500 pulses per second) or CW 2.45 GHz fields with SARs of 0.6 or 1.2 W kg^{-1} for two hours increased the number of single- and double-strand breaks in brain cell DNA when assayed four hours after RF exposure. Lai and Singh (1997) also reported that treatment of rats immediately before or after exposure with either melatonin (1 mg kg^{-1}) or PBN (*N*-*t*-butylphenylnitrone, 100 mg kg^{-1}) blocks the formation of DNA breaks by RF fields. These experiments challenge the belief that RF fields are unable to break molecular bonds. Epigenetic events may be involved. Paulraj and Behari (2006) studied the same phenomena at other frequencies and low dose level, and confirmed DNA strand break; they also concluded that the hippocampus is the targeted site of such interactions.

While damage to DNA strands has been confirmed by several workers, it is argued that its repair is an ongoing process and the damaged chromosomes can be reconstituted. However, this proposition is not without risk. There is no guarantee that these will replicate in the manner they were originally present. Pieces may be left out (deletions), joined in backwards (inversions), swapped between different parts of the chromosome (translocations) or even attached to the wrong chromosome. The effect may also be frequency dependent. In most cases, the new arrangement can work for a while, if most of the genes are still present, and any metabolic deficiencies can often be made good by the surrounding cells. However, things may be different when it comes to meiosis. During meiosis, the chromosomes line up in pairs (one from each original parent) along their entire length so that corresponding parts are adjacent and can be exchanged. Malformed pairs are torn apart in the later stages of meiosis so that eggs or sperms that have an incomplete or unbalanced set of genes may not function properly, and so reduce fertility and other physiological functioning. There is a possibility that this may lead to permanent genetic damage, which although it may not be visible in the first generation, may be evident thereafter.

8.2 Fertility Patterns

For some time there has been a debate about whether exposure to RF electromagnetic fields is associated with an elevated risk in reproduction. Radio waves from mobile phones may have an effect on the process of spermatogenesis. According to one study, lifestyle can decrease semen quality (Kilgalton and Simmons, 2005) and prolonged use of mobile phones can have negative effects on sperm motility chacteristics (Fejes *et al*., 2005). It has been shown that sperm DNA damage is not repaired, because of the chromatin structure (Singh and Stephens, 1998).

Concerns are growing about the possible hazardous effects of RF electromagnetic waves (EMW) emitted by household electronic gadgets on human health. Nakamura *et al*. (2003) found that exposure of pregnant rats to 2.45 GHz CW microwaves at 2 mW cm^{-2} power density for 90 minutes decreased uteroplacental blood flow and increased progesterone and $PGF_2\alpha$ (placental growth factor). Dasdag *et al*. (2003) reported a decrease in seminiferous tubule diameter in male rat testes after exposure. They used a commercially available 890–915 MHz global signal module with 0.141 W kg^{-1} whole-body SAR. More recently, Aitken *et al*. (2005) found significant damage to mitochondrial and nuclear genomes in epididymal spermatozoa of mice, when exposed to RF 900 MHz EMW, 12 hours a day for seven days. Several authors (Fejes *et al*., 2005; Ji-Geng *et al*., 2007; Kesari and Behari, 2008) have also observed that carrying the mobile phones near reproductive organs for a longer time may have negative effects on sperm motility and male fertility.

Forgacs *et al*. (2006) have reported that repeated whole-body 1800 MHz GSM-like microwave exposure (0.018–0.23 W kg^{-1}) below the maximum permissible exposure (MPE) level recommended by the International Commission for Nonionizing Radiation Protection (ICNIRP) is able to increase the serum testosterone level, RBC (red blood cells) and VPRC (volume of packed red blood cells) in male mice, although still within physiological limits. These authors further reported that the unaltered *in vitro* steroidogenic capacity of Leydig cells obtained from microwave-exposed mice suggest that Leydig cells are not the primary targets of the applied microwave exposure or the direct action is transient only and confined to the period of exposure. This suggests that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat171
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the main target of action is probably located at the higher regulation level of the hypothalamic-pituitary-gonadal axis. It is known that prolonged use of GSM mobile phones may lead to reduced melatonin production (Burch *et al*., 2002; Jarupat *et al*., 2003). Melatonin exerts an antigonadotrophic effect mainly at the level of the hypothalamus and pituitary (Jackson *et al*., 1984; Bittman *et al*., 1985; Vanecek, 1998) and directly decreases the testosterone secretion in Leydig cells too (Valladares *et al*., 1990; Kus *et al*., 2002).

Sun *et al*. (2005) investigated the effects of electromagnetic radiation emitted by computers on human sperm quality and did not find any adverse effects. Reactive oxygen species (ROS), such as superoxide anions ($O_2^{\bullet -}$), hydroxyl radicals ($OH^{\bullet}$) and hydrogen peroxide (H_2O_2) may influence the structural integrity and function of sperm, such as motility, capacitation and sperm–oocyte fusion (Griveau *et al*., 1995). Spermatozoa are particularly vulnerable to oxidative stress because their plasma membrane is rich in polyunsaturated fatty acids (PUFAs) and membrane bound NADPH oxidase. ROS have been shown to correlate with reduced male fertility (Iwasaki and Gagnon, 1992), cause perioxidative damage to the sperm plasma membrane (Hughes *et al*., 1996), and induce both DNA strand breakages and oxidative base damage in human sperm (Kodama *et al*., 1997). A decrease in total antioxidant capacity of seminal plasma has been correlated with a reduction in sperm quality, such as concentration, motility and morphology (Smits *et al*., 1998).

The issue that biological effects of RF radiation are genotoxic is still not fully resolved, though some of the available results do not discount such a possibility. Some *in vitro* data show effects that are negative, while others are positive, close to the guidelines levels for safe exposure.

9 NONGENOTOXIC EFFECTS

Several studies reported the effect of RF fields on cell-cycle kinetics, but in the majority of the investigations no effects were detected (Vijayalaxmi *et al*., 2001; Higashikubo *et al*., 2001; Zeni *et al*., 2003; Miyakoshi *et al*., 2005; Lantow *et al*., 2006c). Alteration of cell proliferation was described in only a few reports (Pacini *et al*., 2002; Capri *et al*., 2004b).

Apoptosis is an important mechanism of protection against cancer. Several studies have reported RF field effects on human peripheral blood mononuclear cells (Capri *et al*., 2004a), lymphoblastoid cells (Marinelli *et al*., 2004), epidermis cancer cells (Caraglia *et al*., 2005), human Mono Mac 6 cells (Lantow *et al*., 2006c) and Molts 4 cells (Hook *et al*., 2004). No difference in apoptosis induction was detected between sham-exposed and RF-field-exposed cells (Hook *et al*., 2004). On the other hand, Marinelli *et al*. (2004) have reported a better survival rate of T lymphoblastoid leukaemia cells exposed to 900 MHz nonmodulated RF fields and Caraglia *et al*. (2005) found apoptosis induction in human epidermoid cancer cells after exposure to 1.95 GHz fields. The REFLEX study (Nikolova *et al*., 2005) reported no effects of RF fields on cell cycle, cell proliferation, cell differentiation, apoptosis induction, DNA synthesis and immune cell functionality. These authors described some effects on the transcript level of genes, after RF exposure, related to apoptosis and cell-cycle control; however, these responses were not associated with detectable changes in cell physiology. Analysis of whole-genome compementary DNA arrays show alterations in gene expression after various RF exposure conditions using different cell types, but no consistent RF signature, such as stress response, could be identified (Remondini *et al*., 2006).

Heat-shock proteins act primarily as molecular chaperones to eliminate unfolded proteins, which can also appear from cellular stress. This stress response can be induced by many different external factors, including temperature, chemicals, oxidative stress, heavy metals, ionizing and nonionizing radiation and ultrafine carbon black particles. Hsp70 has been shown to interfere with postmitochondrial events to prevent free-radical-mediated apoptosis (Gotoh *et al*., 2001). An increased expression level of Hsp70 can thus offer protection against stress. Heat-shock proteins are also involved in oncogenic processes (Jolly and Morimoto, 2000; Inoue *et al*., 1999; French *et al*., 2001). Some investigators have described increased heat-shock-protein levels after RF exposure (Leszczynski *et al*., 2002; Kwee *et al*., 2001; de Pomerai *et al*., 2000). However, these results are controversial, because there are negative findings also (Cotgreave, 2005). It may be that data on Hsp70 awaits further confirmation, at different frequencies and power levels.

Nikolova *et al*. (2005) described modulation in gene regulation after RF-field exposure at an SAR of $1.5\,W\,kg^{-1}$ in p53-deficient embryonic stem cells. Proteomic analyses of human endothelial cell lines showed RF fields induce changes in the expression and phosphorylation state of numerous proteins, including Hsp27.

Another important parameter is to measure neurotransmitters in various parts of the brain (Zhou *et al*., 1986). Neurons transmit information across the synapses using a range of neurotransmitters. Calcium plays an essential role in this, because a small amount of calcium must enter the neuron every time before it can release its neurotransmitters. If the electromagnetic field causes extra calcium to leak inside the cell (neuron), it increases the background level and may trigger an early release of neurotransmitter. It has been shown that the excitation of acupuncture points by microwaves (0.2–3 GHz) may produce an efficient analgesic effect, as shown by

the corresponding increase in the pain threshold (Teng *et al*., 1989). Furthermore, respective variations in pain threshold and neurotransmitter release in the center of pain reception in the brain are proportional (Van der Vorst *et al*., 1992).

Particular interest has also been expressed in the biological effects of pulsed modulated RF and microwaves on the ear. The human ear can perceive pulsed modulated radiation between 200 MHz and 6.5 GHz as a buzzing or clicking noise, depending on the modulation characteristics. The effect is attributed to the thermoelastic expansion of the brain tissue, following the small ($\ll 1\,^{\circ}C$), but rapid, increase in temperature on the absorption of the incident energy, generating a sound wave in the head that is detected by the hair cells (cochlea) (Sienkiewicz *et al*., 2005). However, its clinical potential is yet to be fully utilized.

10 MECHANISM OF ENERGY TRANSFER AND AMPLIFICATION

10.1 Macromolecular Resonance

Electromagnetic-field effects in biology and their variability are suggestive of the possibility of resonance effects. So far resonance conditions are characterized in terms of narrow 'windows', of frequency and amplitude ranges only (Blackman *et al*., 1995).

There are two broad situations: when collisional perturbations are very short and when they are long in comparison with the field period. In the former case, every collision is quite effective in interrupting the molecule's radiation absorption–emission process. In a fluid with a high rate of collisions, a collisional broadened relaxation-type spectrum results. In the later case, whene collisions are of long duration compared to the EMF period, the spectrum becomes resonant. The collision time in a macromolecular fluid is a function of temperature, and therefore the EMF frequency determines the kind of spectrum (rotational or resonant). Water is a broad-band attenuator of microwave (MW) fields, which also shields other possible bimolecular absorption processes. Experiments suggest resonant absorption in growing cells at 41 GHz fields and in DNA at 11 GHz (Grundler *et al*., 1977; Azanza and Del, 1994). However, the significance of these resonance frequencies in biological systems is yet to be established.

The nonthermal, pulsed microwave effects are connected with the transfer of information from the irradiating field to the live organism, through the latter's ability to identify certain frequencies of radiation, then its ability to absorb energy from the field (Hyland, 2001). The intensity of radiation needed for this recognition is many orders of magnitude below even that currently associated with nonthermal effects.

10.2 Stochastic Resonance

Fields millions of times weaker than the membrane potential gradient of $10^7\,V\,m^{-1}$ modulate cell processes to surface-stimulating molecules. This may underline the ability of biological systems to amplify small signals in noisy environments. Viewed in this manner; it is possible to imagine an information-processing system in which the presence of an ongoing noise-like activity enhances information-handling capacity. Low-level effects are attributed to the direct interaction between neuron membranes and the local electric fields. Power levels of 0.1 and $1\,mW\,cm^{-2}$ correspond to free-space values of 61 and $194\,V\,m^{-1}$, respectively. This field is negligible compared to the static transmembrane potential of $\sim$90 mV ($\sim 10^7\,V\,m^{-1}$) across a membrane of thickness 4 nm. However, this is larger than the field due to slow brain waves ($1\,V\,m^{-1}$) or from terrestrial fields (10^{-3}–$10^{-6}\,V\,m^{-1}$) (**Figure 6**).

10.3 Cell-Surface Glycoproteins as Possible Sites for EM-Field Interactions

Cells in tissue are separated by narrow fluid channels, typically not more than 150 A° wide, that act as windows on the electrochemical senses surrounding each cell. These channels are preferred pathways for intrinsic and environmental electromagnetic fields in tissue, since they offer a much lower electrical impedance than cell membranes. Functional measures of brain electrical impedance are thus an index of conductance in this extracellular space and have been correlated with brain tissue physiological states in health and disease (Adey *et al*., 1963; 1965; Porter and Bocke, 1965). These intercellular channels are also the sites of electrochemical sensors that protrude as protein strands from within the cell membrane. They form a strongly negatively charged glycocalyx on the cell surface (**Figure 7**). They act as specific receptors for hormones, antibodies, neurotransmitter molecules, certain chemical cancer promoters and, maybe, EMF signals. Their amplified signals to the cell interior elicit enzymatic responses regulating metabolism, messenger functions and cell growth. McConnell (1975) noted that intrusion of the phospholipid tails are constrained and they behave more rigidly.

It is now established that cell Ca^{2+} signalling has extreme sensitivity for coherent excitation by field energies within specific amplitude and frequency windows (Schwartz *et al*., 1990). Membranes are identified as sharply partitioning each cell from its neighbour, by reason of their high content of fat molecules (phospholipids). The structure is identified as double layer of phospholipid molecules, the plasma

membrane. The cell membrane is thus a physical and an electrical barrier. Since generally accepted physiological findings have revealed sensitivities to induced tissue electric gradients from ELF environmental fields and from ELF-modulated fields, it is anticipated that power amplification mechanisms are operative in transductive coupling of these weak stimuli from fluid surrounding cells to the cell interior.

In search for a general mechanism of interaction of EM field with cells, Na^+-K^+ ATPase, the 'ion-pump' enzyme in cell membranes has been studied (Behari *et al.*, 1998; Blank and Soo, 1992; 1991). Changes in enzyme activity in either electric or magnetic fields show that the most important factor affecting signal transduction is the level of enzyme activation, the maximum biological (ATP-splitting) activity of the enzyme under a given set of conditions (i.e. ion concentration, temperature). Enzyme function involves communication between ATP-splitting catalytic sites and ion-binding sites in different parts of the molecule in a coordinated sequence; ion-binding sites in enzymes are essential and are probably brought about by charge movements during function. Such movements have been observed in the microsecond range. Ion fluxes via effects on ion pumps such as Na^+K^+ ATPase in human red blood cells exposed to RF and microwave radiation (Allis and Sinha-Robinson, 1987; Liu *et al.*, 1990; Christiansen, 1989), pointed out dependence of the optical properties on membrane excitation. States may determine the stability of dark soliton propagation as a means of transmembrane signalling. This is summarized in **Figure 6**.

11 BIOMARKERS OF TUMOUR PROMOTION

From physical considerations it is suggestive that RF exposure is not mutagenic and is therefore unlikely to initiate cancers. Animal studies have demonstrated

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat171

that microwaves and RF fields can be called cocarcinogenic since they increase chemically induced skin cancer (Szmigielski *et al*., 1982a). Cellular studies have verified that these carcinogenic effects are mediated by DNA, since relatively weak fields increase DNA synthesis (Liboff *et al*., 1984) and can modulate DNA repair (Meltz *et al*., 1987). Some studies have also demonstrated that electric fields could break or nick DNA strands (Tamiya *et al*., 1988), and the change in secondary structure (conformation) of DNA, a phenomena associated with cancer (Kitchin *et al*., 1989). It should be mentioned that these field emissions were largely at low EM field strengths, the safety limits for the public at large.

Intracellular processes occurring under the influence of power-line magnetic fields, related to free radicals and signal transmission, may determine the biological effects. An uncontrolled oxygen radical release (oxidative stress), may cause protein oxidation, enzyme inactivation and lipid peroxidation within the cellular membranes, causing structural and functional abnormalities. SOD plays a key role in the system protecting the body from destructive free-radical activity. A decrease in SOD and glutathione peroxidase activities, with an increase in catalase (CAT) activity, has been reported in powerline frequency-generated magnetic fields (Kula *et al*., 2002) and in RF-field exposure alike (Kesari and Behari, 2008). It is possible that magnetic fields interact with the free radicals formed, rather than inducing them.

Szmigielski *et al*. (1982b) and Szudzinski *et al*. (1982) reported that chronic exposure of mice to RF (2.45 GHz, 2–3 or 6–8 $W\,kg^{-1}$, two hours a day, six days a week for up to 12 months; 40 or 100 animals per group) accelerated the development of sarcoma colonies in the lung after subcutaneous injection of sarcoma cells; mammary tumours in mice having a normally high incidence of these tumours by painting the skin with a known chemical carcinogen. Szmigielski *et al*. (1988) reported that exposure to RF fields (2.45 GHz CW,4–5 $W\,kg^{-1}$, two hours a day, 5–6 days a week for a few months; 40 animals per group) increased the number of chemically induced hepatomas and sarcomas, and increased the number of skin tumours in mice given a subcarcinogenic dose of benzo[a]pyrene. The authors suggested that the acceleration of tumour development may have resulted from a direct effect on immunocompetent cells. However, no such effect was reported when exposed to a low-level microwave field after doses of 7,12-dimethylbenz[o]anthracene, a known carcinogen (Paulraj, 2000).

These results and other investigations are not without contradictions. Salford *et al*. (1993) reported no effect on the progression of tumour cells injected into rat brain after exposure to continuous or pulsed 915 MHz RF fields (CW exposure, 1 W per pulse,1.67 $W\,kg^{-1}$, 0.41 $W\,kg^{-1}$ for 217 Hz modulation, pulse width 0.52 ms, 2 W per pulse, 62 animals per group). Santini *et al*. (1988) found that the progression of subcutaneously implanted melanoma cells in mice was unaffected by daily exposure to pulsed or CW exposure to RF fields (2.45 GHz CW and pulsed, 10 $W\,m^{-2}$, 1.2 $W\,kg^{-1}$, 2.5 hours a day, six days a week for the lifetime of the animal). Wu *et al*. (1994) reported no effect of RF exposure (2.45 GHz exposed three hours a day, six days a week for five months; average SAR 10–12 $W\,kg^{-1}$) on chemically induced colon cancer in mice. Rotkovska *et al*. (1993) found that the exposure of mice to low-level RF fields from police radar (34 GHz) did not affect biological parameters that could initiate any pathologic process. Repacholi *et al*. (1997) reported a 2.4-fold increase in the incidence of lymphomas in transgenic mice exposed to up to 900 MHz fields pulsed at 217 Hz with pulse widths of 0.6 seconds. The time to lymphoma development was also shorter in the RF-exposed animals.

The studies undertaken so far do not show any significant variation in the melatonin levels due to continuous RF-EMF exposure (Vollrath *et al*., 1997; De Seze *et al*., 1999; Sukhotina *et al*., 2006).

It can be concluded that there are various indicators of tumour promotion due to electromagnetic-field exposure, including

1. Increase in ODC and PKC activity
2. Increase in Ca^{2+} efflux
3. Altered antioxidant enzyme activity
4. DNA strand breakage (single and double)
5. Na^{+}/K^{+} phosphatase activity
6. Decreased melatonin levels. ↓ Cancer promotion (Stress development/RF/MW syndrome)

It is quite intriguing that the mode of EMF interaction with biological system is multifold. There is ample evidence that low-level electromagnetic fields cause DNA strand breakage in brain cells and sperm. The application of pulsed electromagnetic fields to induced fracture and osteoporosis in rats causes accelerated healing (Behari, 1991) and deceleration in ovariectomized and neuroectomized rat (bones) (Lochan *et al*., 2005; Jayanand *et al*., 2003).

Some recent investigations (Prakash, 2008) have revealed that the synergistic effects of nanoparticles and pulsed electromagnetic radiation can prevent microgravity-induced osteoporosis. This is evidenced by an increase in bone mineral content, bone mineral density and morphological changes. Results indicate that the extremely low frequency field components of clinical pulsed elecromagnetic field (PEMF) signals are far more capable of stimulating bone remodelling activity than higher-frequency components. This is because the pulsed signals carry a multiplicity of messages to the biological systems compared to continuous ones. This in contrast to other low-level field effects, which are often implicated in tumour promotion. In contrast to high power, the use of weak electromagnetic fields to study

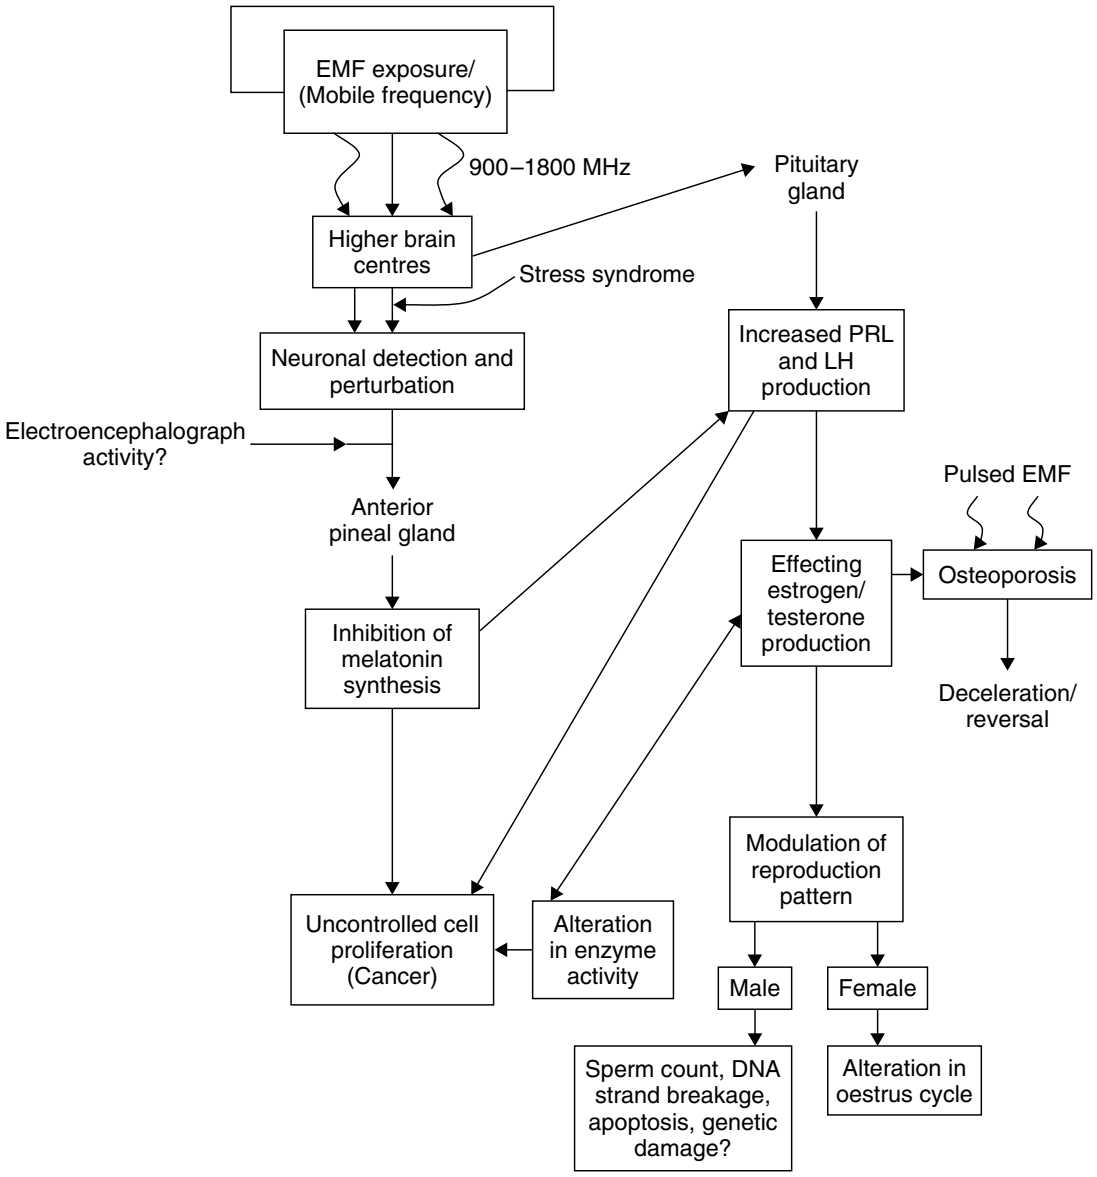

Figure 8 Proposed model of EMF exposure: influence on brain cells, promotion of the growth of initiated tumour cells, osteoporosis and reproduction patterns.

the sequences and energetic events that couple humoral stimuli from surface receptor sites to the cell interior has identified cell membranes as a primary site of interaction with these low-frequency fields in pericellular fluid. A summary of the modes of EMF biointeraction is shown in **Figure 8**.

Long-term biological consequences of repeated microwave irradiation depend on the parameters of irradiation. Experiments have shown that changes in cholinergic receptors, after repeated microwave exposure, also depend on the endogenous signals in the brain. The microwave effects could be blocked by pretreatment, before each session of daily exposure, with the narcotic antagonist naltrexone. It is apparent from these results that endogenous opiods may play a mediating role in some of the neurological effects of microwaves (Lai, 1992). The microwave effects can be summarized as follows: (i) microwaves enhance morphine-induced catalepsy in the rat; (ii) narcotic antagonist blocks a transient increase in body temperature after microwave exposure; (iii) microwave-induced changes in high-affinity muscarinic cholinergic receptors in the brain after repeated sessions of microwave exposure can be blocked by pretreatment with a narcotic antagonist and (iv) the three major subtypes of opiod receptors, μ, δ and κ are involved in mediating the effect of microwaves in the brain.

The hypothesis that low-intensity pulsed microwave exposure can be a source of stress has been investigated by giving low intensity, single and repeated exposure to benzodiazepine receptors in three areas of brain: the cerebral cortex, the hippocampus and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat171
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the cerebellum (Lai, 1992). The cerebral cortex and hippocampus are known to play significant roles in stress responses and, along with the cerebellum, contain high concentrations of benzodiazepine receptors. The authors investigated the effects of single (45 minutes) and repeated (10 × 45 minute sessions daily) microwave exposure (2.45 GHz, 1 mW cm^{-2}, average whole-body SAR 0.6 W kg^{-1}, pulse 500 ppm with pulse-width 2 ms) on the concentration and affinity of benzodiazepine in the cerebral cortex, hippocampus and cerebellum of the rat. The mechanism by which acute stress affects benzodiazepine receptors in the brain is not yet fully understood.

The similarity of the effects of microwaves and those of established sources of stress led to the speculation that microwave irradiation is a 'stressor' (Salford *et al*., 1994). The effects of absorption of electromagnetic energy on brain tissue and cell membranes depend on the type of electromagnetic field (modulation). These effects appear to be important at frequency and amplitude modulations below 300 Hz, although conclusive evidence has yet to emerge. The effect of these frequencies is important to examine, as these fall close to EEG frequencies, though their direct coupling is unlikely (Takashima *et al*., 1978). Whole-body exposure of rats at 30 mW cm^{-2} (SAR 25 W kg^{-1}) causes an increase in EEG activity (the sum of EEG wave frequency bands) immediately after exposure and a slight increase in delta waves (0.5–4.0 Hz) of the EEG recording (Thuróczy *et al*., 1994).

12 HEALTH IMPLICATIONS AND POSSIBLE REMEDIATION

The increasing use of electromagnetic fields for a variety of purposes (domestic, occupational and industrial) raises the problem of their health implications. Various functional properties of DNA (including DNA synthesis (Liboff *et al*., 1984) and repair (Meltz *et al*., 1987) are altered by EM fields. Direct effects on DNA may be mediated by its conformational state. Conformational states, in turn, are controlled by hydrogen bonds, which hold together the folded secondary structure of biomolecules (Takano *et al*., 1999). Mobile phones speed up DNA rewinding, suggesting an increase in hydrogen-bond formation. If mobile phone radiation is found to have effect on hydrogen bonds, it will have serious implications in biology. This hypothesis, however, contradicts other data suggesting that the primary site of EMF biointeraction is the plasma membrane and/or the ions that bind to various protein receptors within the plasma, conditions requiring a complex interaction with the EM field from the mobile phone. In systems where two EM fields interact, the strength and orientation between the two fields is critical in order to obtain resonance conditions.

Some technologies have emerged, utilizing a concept that one type of EM field can reverse or neutralize the biological effects produced by another type. Industry-frequency magnetic fields are important because of the biophysical influence on the cell. (Kula and Drozdz, 1996; Kula *et al*., 2000). One of the major molecular effects of magnetic fields is their influence on the nuclear spins of paramagnetic molecules (Grissom, 1995). This mechanism plays an important role when in the course of a chemical reaction the chemical bond is disrupted and two molecules with unpaired electrons are formed (a pair of radicals). Depending on their electron spin orientations, radical recombination or diffusion and formation of free radicals (e.g. oxygen radicals) may take place. A DC field neutralizes the effect of a pulsed magnetic field on nitrite outgrowth in neuronal cellular studies (Blackman *et al*., 1996). Another related study has been the use of incoherent noise fields to neutralize magnetic-field effects on ODC induction (Farrell *et al*., 1998). In the case of mobile-phone frequency exposures, it has been demonstrated that they increase the number of fruit-fly offspring, as well as some biochemical markers. It also increases the levels of transcription factors which are known to activate DNA synthesis. This effect can be reversed when a commercially available aluminium shield is added to the mobile phone. Syldona (2007) have demonstrated that mobile-phone-induced changes in DNA rewinding are completely reversed when an Aulterra Neutralizer is added to the mobile phone. This effect is seen 77% of the time, yielding a statistically significant result. The evidence supports a set of sequential interactions between ELF and ELF-modulated RF fields and some regulatory mechanisms.

Some experiments suggest that the Aulterra Neutralizer contains a highly paramagnetic mineral. A magnetoresistance response (Meissner effect) is induced when the neutralizer is in the presence of a magnetic field generated from mobile phones. Thus, paramagnetic shielding (in addition to ferromagnetic shielding) is probably the reason for the ability of the Neutralizer. RF exposure causing increased DNA damage in cells is cumulative. Various evidence suggests that responses of the central nervous system to this radiation could lead to a stress response (Lai, 1992; Lai *et al*., 1987). Stress effects cumulate over time and involve first adoption and then an eventual breakdown of homeostatic processes when they persist. The results of major reports (WHO (World Health Organization), 2005; Seitz *et al*., 2005; Rubin *et al*., 2005) seem to support these findings.

In leukocytes, physiological activation is associated with the onset of phagocytosis and leads to increased formation of ROS. These cells exert a wide variety of functions including the regulation of the immune response (pro- and anti-inflammatory processes), scavenging of senescent cells, phagocytosis of infected or

malignant cells, wound healing, repair and detoxification. The generation of free radicals enhances important physiological processes, for example, signal-transduction processes of various membrane receptors and further immunological functions. An imbalance between excessive formation of ROS and the limited antioxidant defence system may take place. However, several authors (Lantow *et al*., 2006a; 2006b; Simko *et al*., 2006) reported no increase in free-radical level.

13 GUIDELINES FOR SAFETY LIMITS

The question of laying down the criteria for safe exposure is a problematic one, because the dose needs to be assessed, not just as external field intensity, but also as cumulative exposure, as well as SAR, for specific anatomical sites. This demands the need to have an accurate knowledge of RF exposure. This radiation is termed a silent killer; its impact is not immediately visible. Any epidemiological studies over a long period (10 years or more) are difficult to carry out and control. Moreover, the basic restrictions are expressed in quantities that are internal to the body and are not measured, such as SAR. On the other hand, the reference levels are expressed (measured) in the free-space situation, such as for the electric field. Such data are not always available.

Nonetheless, attempts to draw up safety limits and their criteria have long been in operation. RF exposure limits are defined by the ICNIRP (1998) and are set to $0.08\,W\,kg^{-1}$ for the general public and $0.4\,W\,kg^{-1}$ for occupational exposure. The guidelines for whole-body exposure on humans is based on responses to animals at levels sufficient to produce behavioural changes, but not thermal damage to the tissue. It is possible that, because of the large interspecies differences among the small animals (rodents) and primates, the former may not be representative of human responses under identical exposure conditions over the whole body.

However, the latest basic restriction for localized exposure is $2\,W\,kg^{-1}$ for most parts of the body (Lin, 2006). For the extremities (arms and legs distal from the elbow and knees, respectively, including the fingers, toes, hands and feet) and for pinnae, the basic restriction expressed in terms of SAR is $4\,W\,kg^{-1}$. The value of SAR is obtained by averaging over some specified time periods (i.e. 6–30 minutes) and by averaging over any 10 g of tissue.

For frequencies between 3 and 100 GHz, the basic restrictions are the same as the derived limits of the MPE. The value of the MPE is obtained by averaging over some specified time periods that vary from 2.5 to 30 minutes for different frequencies.

The new Institute of Electrical and Electronics Engineers (IEEE) standard includes several major differences from the 1991 edition. First and the foremost, the IEEE standard instituted an exclusion for the pinnae or the external ears by relaxation of the abovementioned basic SAR restriction from 2 to $4\,W\,kg^{-1}$. Further, the SAR value has been raised from $1.6\,W\,kg^{-1}$ averaged over any 1 g of tissue, to $2\,W\,kg^{-1}$ over any 10 g of tissue. This effectively means relaxing the criteria, because deposition of energy over 10 g would be inherently lower, compared to the SAR over 1 g. This revised choice (10 g in the shape of a cube) would permit depositions of RF or microwave energy in different parts of the eye that exceed the basic SAR restriction by a large margin, while keeping the SAR for the entire eye below the prescribed limit ($2\,W\,kg^{-1}$).

In the 1991 edition, the MPE between 30 and 300 MHz, was $10\,W\,m^{-2}$. The new MPE in terms of power density is $2\,W\,m^{-2}$ between 30 and 400 MHz, the region most susceptible for human exposure. It ramps up from 2 to $10\,W\,m^{-2}$ between 400 and 2000 MHz. For frequencies greater than 2000 MHz, the MPE is $10\,W\,m^{-2}$. Also, the designated frequency bands and the MPE are different. In the 1991 edition, they were $10\,W\,m^{-2}$ between 30 and 300 MHz. The ramp up from 10 to $100\,W\,m^{-2}$ took place between 300 MHz and 3000 MHz. For frequencies greater than 3000 MHz, the MPE was $100\,W\,m^{-2}$ (**Figure 9**). In general, the new IEEE standards are more restrictive between 30 MHz and 100 GHz. Furthermore, new IEEE guidelines state that the maximum spatial power density should not exceed 20 times the square of the allowed spatially averaged peak values for frequencies below 400 MHz, and should not exceed $40\,W\,m^{-2}$.

The major differences also include the tissue mass and the time period over which the SAR values are to be averaged, and the applicable frequency bands for the MPE. Also, the most significant difference is the exclusion of pinnae from the head by IEEE, which made it possible to allow a higher local SAR value for the basic restriction at $4\,W\,kg^{-1}$. In the ICNIRP guidelines, pinnae are not excluded and are treated as an integral part of the human head.

Moreover, localized SAR values in the ICNRP guidelines are averaged over any 10 g mass of contiguous tissue. ICNIRP guidelines do not specify a cubic volume of tissue as the averaging mass. In addition, all SAR values are averaged over a six minute period in the ICNIRP guidelines, in contrast to the 2.5–30 minutes stipulated in the new IEEE standards.

The IEEE standards are not identical to the ICNIRP guidelines. This may also be true for frequencies used in mobile communications and wireless devices and systems. Global harmonization of RF exposure standards for the general public would be a future goal. Some of the points of contradiction, as mentioned above, will continue to be a point of investigation, and should also include more accurate assessment of SAR values, more reliable

Susceptibility of Neonatal Rats to Xenobiotics

Mutsuko Hirata-Koizumi, Ryuichi Hasegawa, Akihiko Hirose and Makoto Ema

CONTENTS

1 INTRODUCTION

Children, particularly neonates, are in the process of rapid development and growth (Scheuplein *et al*., 2002). Such developing organisms experience many complex, integrated events involving the regulation of cell growth, differentiation and morphogenesis. Many environmental factors, including nutritional adequacy (e.g. protein, vitamin and folic-acid availability), maternal smoking and alcohol consumption, prescription drugs and chemical contamination with substances such as lead and organic mercury, can interfere with these events, through mutagenesis or through altered cell division, hormone activity, enzyme function or energy sources, which may exert significant irreversible adverse effects by disrupting normal development. On the other hand, the immaturity of immunological, metabolic and elimination functions, especially during the early postnatal period (Alcorn and McNamara, 2002; Holsapple *et al*., 2003), can lead higher susceptibility to chemical toxicity, compared with adults. When the effects of chemicals on human health are evaluated, the possible greater risk to such sensitive groups should be fully taken into account.

Current risk assessments of xenobiotics, especially industrial chemicals, are usually performed based on animal studies. In order to cover different developmental stages, multiple types of toxicity studies are conducted. In repeated-dose toxicity studies for the evaluation of general toxicity, dosing of chemicals to rodents begins as soon as possible after weaning and any case, before the animals are nine weeks old (OECD, 1998; 2008). Prenatal developmental toxicity studies involve the administration of chemicals to pregnant animals, and developmental toxicity, including teratogenicity, is evaluated (OECD, 2001a). In reproductive toxicity studies, chemicals are usually given to rats from the premating period thorough the mating, gestation and lactation periods (OECD, 1983), with, in multiple generation studies, direct administration to pups after weaning (OECD, 2001b). Combination of the results from these studies would appear to enable the evaluation of health effects of chemical exposure in any period during the lifetime. However, evaluation of the effects of chemical exposure during the early postnatal period may be inadequate because preweaning animals are only exposed to chemicals indirectly through maternal milk during nursing, or directly through small amounts of food or water containing chemicals in the late lactation period in cases of test substance administration via diet or drinking water, in reproductive toxicity studies (OECD, 1983; 2001b). Quantitative evaluation is impeded, because it is unclear how much test material is ingested by preweaning animals, in such studies. For chemicals that are not excreted in maternal milk, toxic effects from direct chemical exposure during the early postnatal period would not be detected. In the recently adopted Organization for Economic Cooperation and Development (OECD) test guidelines for developmental neurotoxicity, it is noted that direct dosing of pups

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

should be considered in those cases where there is a lack of evidence of continued exposure to offspring through the maternal milk (OECD, 2007). In order to evaluate the toxic effects and dose–response during the preweaning period, it is necessary to administer chemicals directly to neonatal animals. Although various factors such as ethical limitations, limited human and economic resources, or handling difficulties, do not make it easy to conduct such studies and there has been a lack of sufficient information regarding the susceptibility of neonatal animals to the toxicity of chemicals; some information has been accumulated in recent years.

In this chapter, special attention is directed to the susceptibility to chemical toxicity during the early postnatal period from the standpoint of risk assessment for susceptible groups such as neonates and infants. We introduce comparative analysis of the toxic susceptibility to 20 chemicals between neonatal rats and young rats as examples, and discuss the possible causes of differences and the adequacy of uncertainty factors for the risk assessment of neonates or infants. In the comparative analysis, preweaning rats were directly administered with chemicals, and the toxic susceptibility evaluated. For detailed information on the methods and results on 18 chemicals, please refer to our previous publication (Hasegawa *et al*., 2007). We re-evaluate the neonatal susceptibility to 20 chemicals, by adding the recent new data on two chemicals (Hirata-Koizumi *et al*., 2007; 2008a; 2008b; 2008c) to it, in this chapter.

2 Comparative Analyses of the Toxic Susceptibility of Neonatal and Young Rats to 20 Chemicals

In this section, we summarize comparative analysis results of the toxic susceptibility in neonatal and young rats for 20 chemicals. Here, 'neonatal rat study' means an 18-day repeated-dose toxicity study targeting the preweaning period, in which male and female rats were administered with chemicals by oral gavage from postnatal days 4 to 21. The results of neonatal rat studies were compared with the findings in young rats, mainly the results of 28-day repeated oral-gavage studies using five- or six-week-old young rats ('young rat study'). For comparison of the toxic susceptibility between rats of differently ages, presumed no observed adverse effect levels (pNOAELs) were estimated for 20 chemicals. The pNOAEL is defined as the most likely no adverse-effect dose. In most cases, this value is equal to the no observed adverse-effect level (NOAEL), the highest dose at which no adverse effects are observed, but it is not always adequate for an accurate comparison of the toxic susceptibility, because the NOAEL is dependent on the dose spacing. Therefore, in some cases, a more realistic no adverse-effect dose was estimated as a single value or range.

Table 1 shows the pNOAELs of 20 chemicals in neonatal rats and young rats, and their ratios (pNOAEL for young rats/pNOAEL for neonatal rats). Of the 20 chemicals, pNOAEL ratios were estimated for 18 chemicals. The mean ratio was 2.35, and all values demonstrated differences of fivefold or less. The ratios showed that neonatal rats were clearly more susceptible (twice or greater) to 11 chemicals (61.1%), and less susceptible (half or less) to six chemicals (33.3%). Exceptionally, tetrabromobisphenol A (TBBPA) showed toxicity only in the kidneys of neonatal rats, and the nephrotoxicity is considered to be a highly specific toxicity in neonatal rats rather than a difference in the sensitivity to the same toxic end point between ages.

2.1 Chemicals with Higher Susceptibility in Neonates

2.1.1 Nitrophenols (4-Nitrophenol and 2,4-Dinitrophenol)

The major toxic effect of 4-nitrophenol and 2,4-dinitrophenol was clinical signs such as convulsions, a decrease in locomotor activity and prone/lateral positioning, followed by death, in both neonatal rats and young rats (Koizumi *et al*., 2001). In the neonatal rat study, 4-nitrophenol induced deaths at 230 mg kg^{-1} and above, and most of the rats exhibited convulsions before death. This chemical also induced one death in 36 animals in the 160 mg kg^{-1} group, and no adverse effects were observed at 110 mg kg^{-1} or less. In the young rat study, 4-nitrophenol caused the death of most males and females at 1000 mg kg^{-1}, and was not toxic at 400 mg kg^{-1} except for male-rat-specific renal toxicity, which is considered not to be relevant for other species. The pNOAELs for 4-nitrophenol were concluded to be 110 mg kg^{-1} day^{-1} in neonatal rats and 400 mg kg^{-1} day^{-1} in young rats.

As with 2,4-dinitrophenol, clear clinical signs of toxicity and death were found at 30 mg kg^{-1} in the neonatal rat study and at 80 mg kg^{-1} in the young rat study (Koizumi *et al*., 2001). Administration of 20 mg kg^{-1} 2,4-dinitrophenol also lowered the body weight of neonatal rats. This effect was not observed in the young rat study, so it appears that this may be because rapid weight gain occurs during the neonatal period (Koizumi *et al*., 2001; 2002; 2003; Hirata-Koizumi *et al*., 2005a; 2008b; Takahashi *et al*., 2006). Such higher susceptibility regarding neonatal body-weight gain was also found for 2,4,6-trinitrophenol (Takahashi *et al*., 2004), 1,1,2,2-tetrabromoethane (Hirata-Koizumi

Table 1 Comparison of pNOAELs for 20 industrial chemicals in neonatal and young rats

Chemical name	Neonatal rats (mg kg^{-1} day^{-1})	Young rats (mg kg^{-1} day^{-1})	Ratio[a]
4-Nitrophenol	110	400	3.6
2,4-Dinitrophenol	10	20	2.0
3-Aminophenol	80	240	3.0
2-Chlorophenol	40[b]	200	5.0
4-Chlorophenol	100	100	1.0
3-Methylphenol	60–80[b]	300	4.0–5.0
3-Ethylphenol	100	300	3.0
4-Ethylphenol	30	100	3.3
2-*t*-Butylphenol	20	100	5.0
2,4-Di-*t*-butylphenol	5	20	4.0
p-(α,α-Dimethylbenzyl)phenol	30	100	3.3
1,3,5-Trihydroxybenzene	100	300	3.0
2,4,6-Trinitrophenol	40–50[b]	20	0.4–0.5
(Hydroxyphenyl)methylphenol	100	40	0.4
Trityl chloride	60	12	0.2
1,3-Dibromopropane	50	10	0.2
1,1,2,2-Tetrabromoethane	50	6	0.1
HDBB	0.5[c]	0.1[d]	0.2
DBHCB	—[e]	—[f]	—
TBBPA	40	—[g]	—

This table reproduces the data in **Table 2** of Hasegawa *et al*., 2007, by adding new data on HDBB and DBHCB.
HDBB, 2-(2′-hydroxy-3′,5′-di-*t*-butylphenyl)benzotriazole; DBHCB, 2-(3′,5′-di-*t*-butyl-2′-hydroxyphenyl)-5-chlorobenzotriazole); TBBPA, Tetrabromobisphenol A.
–Appropriate values were not able to be given
[a]Ratio of the pNOAEL for young rats to that for neonatal rats, showing comparative toxic susceptibility of neonatal rats to young rats.
[b]A realistic no adverse-effect dose was speculated because the NOAEL selected from established dose levels was considered to be inadequate for precise comparison.
[c]In the neonatal rat study, histopathological examination was conducted only for the liver and heart, and the haematology and developmental parameters, such as reflex ontogeny and external and sexual development were not examined.
[d]The value was estimated based on the results of a 52-week repeated-dose toxicity study using young rats because adverse effects were observed at the lowest dose in a 28-day study (young rat study). Since the estimated pNOAEL was markedly different between sexes, the lower value was given.
[e]The pNOAEL could not be estimated because adverse effects were observed even at the lowest dose of 250 mg kg^{-1} in the neonate.
[f]The pNOAEL could not be estimated because the young rat study was conducted only at a single dose.
[g]No accurate values for the pNOAEL could be generated because any adverse effects were not observed, even at the highest dose.

et al., 2005a) and 2-(3′,5′-di-*t*-butyl-2′-hydroxyphenyl)-5-chlorobenzotriazole (DBHCB) (Hirata-Koizumi *et al*., 2008c), as discussed below. Since the pNOAELs of 2,4-dinitrophenol are considered to be 10 mg kg^{-1} day^{-1} in neonatal rats and 20 mg kg^{-1} day^{-1} in young rats, the toxicity of nitrophenols in neonatal rats seems to be 2.0–3.6 times greater than in young rats.

2.1.2 3-Aminophenol

In the neonatal rat study, tremors, depression of body-weight gain and hypertrophy of thyroid follicular epithelial cells were observed at the highest dose of 240 mg kg^{-1}, and no definitive toxicity was found at 80 mg kg^{-1} (Koizumi *et al*., 2002). In the young rat study, in addition to the similar changes observed in neonates, anaemia and hyaline droplets in the proximal epithelium of kidneys were found at 720 mg kg^{-1}. Although slight pigmentation in the renal proximal tubular epithelium was observed at 240 mg kg^{-1}, this is not considered to be an adverse effect because of the lack of changes in haematological parameters at this dose. It is concluded that the pNOAEL was 80 mg kg^{-1} day^{-1} in neonatal rats and 240 mg kg^{-1} day^{-1} in young rats, and, therefore, the susceptibility of neonatal rats to 3-aminophenol was three times higher than that of young rats.

3-Aminophenol induced anaemic changes only in young rats. Similar anaemic effects only in young rats were found for 2,4,6-trinitrophenol and 1,3-dibromopropane (Hirata-Koizumi *et al*., 2005a;

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat172
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Takahashi *et al*., 2004), as described below. Although methaemoglobin levels were not determined in the young rat studies, it was reported that methaemoglobin reductase levels in young rats were distinctly lower than in neonates (Gruener, 1976; Lo and Agar, 1986), which may be the reason for the higher susceptibility to anaemic effects in young rats.

2.1.3 Chlorophenols (2-Chlorophenol and 4-Chlorophenol)

Chlorophenols mainly induced behavioural toxicity both in neonatal and young rats (Hasegawa *et al*., 2005). In the neonatal rat study of 2-chlorophenol, tremors, hypoactivity and abnormal gait were observed at 300 mg kg^{-1}. Basophilia of the renal tubules was also observed at that dose. Tremors were also found at 50 mg kg^{-1}, but only once during the dosing period and in one of 12 females. Therefore, the pNOAEL for neonatal rats was estimated to be 40 mg kg^{-1} day^{-1}, a little below the 50 mg kg^{-1}. In the young rat study of 2-chlorophenol, in addition to the behavioural changes observed in neonatal rats, slight centrilobular hypertrophy of hepatocytes were found at the highest dose of 1000 mg kg^{-1}. The pNOAEL was concluded to be 200 mg kg^{-1} day^{-1}, and therefore, neonatal rats are considered to be five times more susceptible to 2-chlorophenol toxicity than young rats.

In the case of 4-chlorophenol, clinical signs, including tremors, bradypnoea/tachypnoea and hypoactivity, were found at 300 mg kg^{-1} and above in neonatal rats and at 500 mg kg^{-1} mg/kg in young rats (Hasegawa *et al*., 2005). There were no other adverse effects in either study. The pNOAELs for 4-chlorophenol were concluded to be 100 mg kg^{-1} day^{-1} in both neonatal and young rats; the toxic susceptibility to this chemical was similar regardless of age.

2.1.4 3-Methylphenol

In the neonatal rat study, various clinical signs, such as deep respiration, hypersensitivity on handling, tremors under contact stimulus and depression of body-weight gain were observed at 300 mg kg^{-1} (Koizumi *et al*., 2003). At 100 mg kg^{-1}, the hypersensitivity and tremors were also noted in a small number of males only on single days during the dosing period. The pNOAEL is considered to be slightly lower than 100 mg kg^{-1}, at which the incidence of clinical signs was very low. In the young rat study, clear clinical signs and depression of body-weight gain, as observed in neonatal rats, appeared at 1000 mg kg^{-1}. Since the pNOAEL for young rats was considered to be 300 mg kg^{-1} day^{-1}, differences in the toxic susceptibility to 3-methylphenol could be concluded to be four to five times.

2.1.5 Ethylphenols (3-Ethylphenol and 4-Ethylphenol)

In the neonatal rat study of 3-ethylphenol, the only adverse effect was a slight lowering of body weight at the highest dose of 300 mg kg^{-1} (Takahashi *et al*., 2006). On the other hand, in the young rat study, 3-ethylphenol caused clinical signs of toxicity such as staggering gait and prone/lateral positioning, increase in liver weight, with alteration of the related blood biochemical parameters, and hyperplasia of the squamous cells in the forestomach at 1000 mg kg^{-1}. Although the toxicity profiles of both ages were not similar, it is considered to be due to inadequate high-dose setting in the neonatal rat study. The pNOAELs for 3-ethylphenol were concluded to be 100 mg kg^{-1} day^{-1} in neonatal rats and 300 mg kg^{-1} day^{-1} in young rats.

4-Ethylphenol caused more severe changes than 3-ethylphenol. In neonatal rats, deaths, clinical signs of toxicity, such as hypoactivity and deep respiration, and inhibition of body-weight gain were observed at 300 mg kg^{-1} (Takahashi *et al*., 2006). Since the delay in righting reflex was found even at 100 mg kg^{-1}, the pNOAEL for neonatal rats was concluded to be 30 mg kg^{-1} day^{-1}. In the young rat study, 4-ethylphenol caused clinical signs of toxicity, lowering of body weight and slight hepatic effects at 1000 mg kg^{-1}, and pathological changes in the forestomach at 300 mg kg^{-1} and above; therefore, the pNOAEL was concluded to be 100 mg kg^{-1} day^{-1}. These results show that neonatal rats have three times higher susceptibility to the toxicity of ethylphenols than young rats.

Following administration of 3- and 4-ethylphenols, squamous cell hyperplasia in the forestomach was observed in young rats, but not in neonatal rats. In the neonatal rat study of 4-ethylphenol, this change was not found even at high toxic doses. *p*-(α,α-Dimethylbenzyl)phenol and (hydroxyphenyl)methylphenol also affected the forestomach, only in young rats (Hasegawa *et al*., 2005), as discussed below. Generally, phenols have similar toxicological effects, due to their actions as extremely corrosive protoplasmic poisons (Manahan, 2003; Bloom and Brandt, 2001). In neonatal rats, the epithelium of the gastrointestinal tract would be more quickly renewed than in young rats because of more active body metabolism in the developing process. In addition, the low capacity of neonates to secrete gastric acid might explain the lower sensitivity to the effects on the forestomach.

2.1.6 t-Butylphenols (2-t-Butylphenol and 2,4-Di-t-butylphenol)

In the neonatal rat study of 2-*t*-butylphenol, clinical signs of toxicity, such as ataxic gait and decrease in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat172
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

locomotor activity, and slight hypertrophy of hepatocytes with increased liver weight, were observed at 60 mg kg^{-1} and above (Hirata-Koizumi *et al*., 2005b). The pNOAEL was concluded to be 20 mg kg^{-1} day^{-1}. In the young rat study, similar clinical signs of toxicity and increase in the liver weight were found at 500 mg kg^{-1}, and the pNOAEL was concluded to be 100 mg kg^{-1} day^{-1}.

As for 2,4-di-*t*-butylphenol, various histopathological findings were detected in the liver and kidneys, both in neonatal and young rats (Hirata-Koizumi *et al*., 2005b). Since slight hepatic changes were observed at 40 mg kg^{-1} in neonatal rats and at 75 mg kg^{-1} in young rats, the respective pNOAELs were concluded to be 5 and 20 mg kg^{-1} day^{-1}. Based on these findings, the susceptibility of neonatal rats to 2-*t*-butylphenol and 2,4-di-*t*-butylphenol was thought to be four to five times higher than that of young rats.

2.1.7 *p*-(α,α-Dimethylbenzyl)phenol[a]

In the neonatal rat study, dilation of renal tubules and papillary ducts were observed at 100 mg kg^{-1} and above (Hasegawa *et al*., 2005). In the 300 mg kg^{-1} group, such changes were accompanied with increased level of urinary volume or blood urea nitrogen, and no complete recoveries were found in the renal changes after a nine-week recovery-maintenance period. Toxic effects on reproductive organs were also noted in neonatal rats; testicular weight at 300 mg kg^{-1}, and ovarian weight at 100 mg kg^{-1} and above were lowered, and increased numbers of atretic follicles were found in the ovaries of 300 mg kg^{-1} group. After the recovery-maintenance period, in addition to similar follicular changes, decreased numbers of corpora lutea and hypertrophy of uterine endometrial epithelium were detected. In the young rat study, renal effects, as observed in neonatal rats were found at 300 mg kg^{-1} and above. In addition to deaths, lowering of body weight, squamous hyperplasia in the forestomach and bile-duct proliferation in the liver were found in the 1000 mg kg^{-1} group. No effects were detected on the reproductive organs in young rats. The pNOAELs were concluded to be 30 mg kg^{-1} day^{-1} for neonatal rats and 100 mg kg^{-1} day^{-1} for young rats; therefore, the susceptibility of neonatal rats to *p*-(α,α-dimethylbenzyl)phenol was considered to be 3.3 times higher than that of young rats.

2.1.8 1,3,5-Trihydroxybenzene[b]

In neonatal rats, hypertrophy of thyroid follicular cells was observed with increased thyroid weights at 500 mg kg^{-1} (Hasegawa *et al*., 2005). Although the liver weights were also increased at this dose, it was not accompanied by any histopathological alterations. The pNOAEL is concluded to be 100 mg kg^{-1} day^{-1} in neonatal rats. In the young rat study, similar effects on the thyroids and liver were found at 1000 mg kg^{-1}, and the pNOAEL is concluded to be 300 mg kg^{-1} day^{-1}. Based on these findings, the susceptibility of neonatal rats to 1,3,5-trihydroxybenzene appears to be three times higher than that of young rats.

2.2 Chemicals with Lower Susceptibility in Neonates

2.2.1 2,4,6-Trinitrophenol

In the neonatal rat study, the only observed adverse effect was a slight lowering of body weight at the highest dose of 65.1 mg kg^{-1} (Takahashi *et al*., 2004). In the preliminary dose-range-finding study conducted over the same dosing period, deaths and clinical signs of toxicity, as well as lowered body weight, were found at 81.4 mg kg^{-1}. The pNOAEL for neonatal rats was considered to be 40–50 mg kg^{-1} day^{-1}, slightly lower than 65.1 mg kg^{-1}. In young rats, haemolytic anaemia (i.e. decreased red blood cells and haemoglobin, extramedullary haematopoiesis and haemosiderin deposition in the spleen) and testicular toxicity (i.e. atrophy of seminiferous tubules in the testis and decrease in numbers of sperm in the epididymis) were observed without any deaths or changes in body weight at the highest dose of 100 mg kg^{-1}. In the prior 14-day dose-finding study, 2,4,6-trinitrophenol caused deaths at 500 mg kg^{-1}. The pNOAEL for young rats was concluded to be 20 mg kg^{-1} day^{-1}; therefore, it is considered that young rats have 2.0–2.5 times higher susceptibility to the toxicity of 2,4,6-trinitrophenol than neonatal rats. This is quite the opposite result from that found in the comparative studies for other phenols (see above).

2,4,6-Trinitrophenol demonstrated a qualitatively different toxicity in neonatal and young rats. Lowering of body weight only seen in neonatal rats would come from the rapid weight gain during the early postnatal period in the control group, and anaemic effects only in young rats might be due to lower methaemoglobin reductase levels, as mentioned above (see Sections 2.1.1 and 2.1.2). In the rat testes, the seminiferous cords contain only undifferentiated Sertoli cells and gonocytes at birth (Sjöberg *et al*., 1986). The Sertoli cells proliferate rapidly during the early postnatal period, and then slow down and cease multiplying by approximately postnatal day 20 (Orth, 1982; Orth, 1984; Toppari *et al*., 1996). Most gonocytes have differentiated into spermatogonia at about 10 days of age, and the first primary spermatocytes appear at days 12 or 13 after birth (Sjöberg *et al*., 1986). At 24 days of age, the first meiotic divisions are observed, but not until 44 days of age are the mature spermatids found in the testes. The testicular toxicity of 2,4,6-trinitrophenol in young

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat172
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

rats might be due to the effect on the maturation of spermatids.

2.2.2 (Hydroxyphenyl)methylphenol[c]

In the neonatal rat study, the highest dose of 100 mg kg^{-1} did not cause any changes, but in the preliminary dose-range-finding study performed using the same method of administration, half the animals of the 200 mg kg^{-1} group died and the final body weight was lowered in this group (Hasegawa *et al*., 2005). Histopathological examination was not conducted in this preliminary study. In the young rat study, one female became moribund and the final body weights of males were decreased at 1000 mg kg^{-1}. All animals of this dose group showed squamous hyperplasia in the limiting ridge of the forestomach, and two-thirds of the animals featured centrilobular hypertrophy of hepatocytes. Hepatic pathological changes were also found with low incidences at 200 mg kg^{-1}. The pNOAELs were concluded to be 100 mg kg^{-1} day^{-1} in neonatal rats and 40 mg kg^{-1} day^{-1} in young rats, showing a 2.5-times higher susceptibility in young rats.

2.2.3 Trityl Chloride[d]

Similar hepatic effects were observed in neonatal and young rats (Hasegawa *et al*., 2005). In the neonatal rat study, centrilobular hypertrophy of hepatocytes was observed with increased liver weight in the 300 mg kg^{-1} group. In the preliminary dose-range-finding study, in addition to more evident increase in the liver weight, one female death and a lowering of body weight were found in the 600 mg kg^{-1} group. In the young rat study, centrilobular hypertrophy of the hepatocytes accompanied with increased liver weight was observed at 60 mg kg^{-1} and above. In the 300 mg kg^{-1} group, soft faeces and mucosal thickening of the cecum were found in most animals with more extensive hepatic changes. Based on these findings, the pNOAELs were concluded to be 60 mg kg^{-1} day^{-1} in neonatal rats and 12 mg kg^{-1} day^{-1} in young rats, showing that young rats have five times higher susceptibility to the toxicity of trityl chloride than neonatal rats.

2.2.4 Bromoalkanes (1,3-Dibromopropane and 1,1,2,2-Tetrabromoethane)

1,3-Dibromopropane caused lowering of body weight and centrilobular hypertrophy of hepatocytes at 150 mg kg^{-1} in neonatal rats (Hirata-Koizumi *et al*., 2005a). The pNOAEL was concluded to be 50 mg kg^{-1} day^{-1}. In young rats, in addition to findings similar to those observed in neonates, slight anaemic changes, including decreased haemoglobin and increased reticulocyte ratio were found at 250 mg kg^{-1}. Since centrilobular hypertrophy of the hepatocytes was also observed at mg kg^{-1}, the pNOAEL for young rats was considered to be 10 mg kg^{-1} day^{-1}.

In the neonatal rat study of 1,1,2,2-tetrabromoethane, increased liver weight with slight elevation of blood total protein at the highest dose of 50 mg kg^{-1} was not considered adverse because of the lack of histopathological changes (Hirata-Koizumi *et al*., 2005a). In the preliminary dose-range-finding study, lowering of body weight and a marked increase in the liver weight was noted at 200 mg kg^{-1}, but histopathological examination was not conducted in this preliminary study. In the young rat study, while body weight was not affected, even at the highest dose of 200 mg kg^{-1}, centrilobular hypertrophy of the hepatocytes was observed in the liver at 20 mg kg^{-1} and above. Hypertrophy of follicular cells was also found in the thyroids at 60 mg kg^{-1} and above. The pNOAELs were considered to be 50 and 6 mg kg^{-1} day^{-1} in neonatal and young rats, respectively. Based on these results, it can be concluded that young rats have 5–10 times higher susceptibility to the toxicity of 1,3-dibromopropane and 1,1,2,2-tetrabromoethane than neonatal rats.

2.2.5 Benzotriazole Ultraviolet Absorbers (2-(2′-Hydroxy-3′,5′-di-t-butylphenyl) benzotriazole[e] and 2-(3′,5′-Di-t-butyl-2′-hydroxyphenyl)-5-chlorobenzotriazole)[f]

In the young rat study of 2-(2′-hydroxy-3′,5′-di-*tert*-butylphenyl)benzotriazole (HDBB), toxic effects were observed mainly in the liver, such as hypertrophy and vacuolar degeneration of the hepatocytes, focal necrosis and bile duct proliferation (Hirata-Koizumi *et al*., 2007). HDBB also affected the heart, kidneys, thyroids and blood. These adverse effects were found even at the lowest dose of 0.5 mg kg^{-1} in males, but in females, they were detected only at 12.5 mg kg^{-1} and above. In the 52-week repeated-dose toxicity study using young rats, the pNOAEL of HDBB was concluded to be 0.1 mg kg^{-1} day^{-1} in males and 2.5 mg kg^{-1} day^{-1} in females, based on histopathological changes in the liver (Hirata-Koizumi *et al*., 2008a). There was a marked gender-related difference in the HDBB toxicity in young rats. In the neonatal rat study, hepatocellular findings were found at 2.5 mg kg^{-1} and above in both sexes (Hirata-Koizumi *et al*., 2008b). Interestingly, the gender-related difference was not detected in the toxic susceptibility of neonates to HDBB. The pNOAEL of HDBB for neonatal rats is concluded to be 0.5 mg kg^{-1} day^{-1} in both sexes. These findings suggest that the toxic susceptibility of males to HDBB is five times higher in young rats than neonatal rats, but conversely, five times higher susceptibility of neonates was found for females.

Similar phenomena were found for the structural analogue, 2-(3′,5′-di-*t*-butyl-2′-hydroxyphenyl)-5-chlorobenzotriazole (DBHCB) (Hirata-Koizumi *et al*., 2008c).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat172
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

In young rats to whom 250 mg kg^{-1} DBHCB was administered, the relative liver weight increased to more than twice that of the control in males, while the change in relative liver weight was less than 10% in females. On histopathology, hypertrophy of the hepatocytes was observed in males, but not in females. In neonatal rats, inhibition of body-weight gain and histopathological changes in the liver were observed, as well as increased liver weight and blood biochemical changes at 250 mg kg^{-1} and above in both sexes. These findings clearly show the lack of gender-related differences in the DBHCB toxicity in neonatal rats. Unfortunately, it is not possible to compare the susceptibility of neonatal and young rats to the DBHCB toxicity because the dose setting in both studies were inadequate to estimate the pNOAELs.

2.3 Neonatal-Specific Toxicological Profiles

2.3.1 Tetrabromobisphenol A[g]

In the neonatal rat study, tetrabromobisphenol A (TBBPA) induced nephrotoxicity characterized by the formation of polycystic lesions at 200 mg kg^{-1} and above, while some deaths occurred at 600 mg kg^{-1} (Fukuda *et al*., 2004). After the nine-week recovery-maintenance period, such nephrotoxic lesions were still present. The pNOAEL was concluded to be 40 mg kg^{-1} day^{-1}. On the other hand, in the young rat study, the kidneys showed no histopathological changes even at the highest dose of 1000 mg kg^{-1}, and no chemically related changes were found in other examined parameters, either. In order to investigate the specificity of the nephrotoxicity induced by TBBPA in neonatal rats, an additional 18-day repeated-dose toxicity study using young rats was conducted at the higher doses. The results revealed no histopathological changes in the kidneys up to 6000 mg kg^{-1} in young rats. These findings clearly indicate that the nephrotoxicity of TBBPA is specific for neonatal rats, although the toxic dose level was relatively high.

Such specific renal toxicity in neonatal rats has also been reported for other chemicals, such as chlorambucil (Kavlock *et al*., 1987), 2,3,7,8-tetrachloro-1,4-dibenzodioxine (Couture-Haws *et al*., 1991) and difluoromethylornithine (Gray and Kavlock, 1991). In the kidneys of rats, nephrogenesis occurs at a rapid pace between birth and 8 days and is complete by 11 days of age, and tubular differentiation continues until the time of weaning (Zoetis and Hurtt, 2003). Developing renal tubules during the early postnatal period might show higher sensitivity to the induction of renal polycystic lesions associated with hyperplasia of the tubular epithelium in response to cellular damage.

2.3.2 p-(α,α-Dimethylbenzyl)phenol[a]

Although the major target of *p*-(α,α-dimethylbenzyl)phenol was the kidney in both neonatal and young rats, this chemical also affected the reproductive organs, but only in neonates (Hasegawa *et al*., 2005) (see Section 2.1.7). In females, ovarian follicular changes did not show recovery, and additional changes were found in the ovaries and uterus after the recovery-maintenance period. Follicle stimulating hormone (FSH) is a major survival factor for early antral follicles, the stage during which a majority of follicles undergo atresia under physiological conditions (Chun *et al*., 1996; McGee and Hsueh, 2000). Deprivation of gonadotropins by hypophysectomy leads to atresia and apoptosis of developing follicles, whereas FSH treatment of cultured early antral follicles prevents the spontaneous onset of follicular apoptosis (Nahum *et al*., 1996; Chun *et al*., 1996). In the neonatal rat study, *p*-(α,α-dimethylbenzyl)phenol decreased the number of the FSH-positive pituitary cells. In rats, ovarian follicles become subjected to strong gonadotropin control during the second week of postnatal life (Beckman and Feuston, 2003); therefore, decrease in FSH stimulation during this critical period might be associated with the specific ovarian toxicity of *p*-(α,α-dimethylbenzyl)phenol in neonatal rats.

3 POSSIBLE CAUSES OF THE DIFFERENCES IN TOXIC SUSCEPTIBILITY OF NEONATAL AND YOUNG RATS

Higher susceptibility of neonatal rats was found for 11 phenolic compounds, most of which induced clinical signs, suggestive of the effects on the central nervous systems, as the major toxicity. From available published data, several factors could be hypothesized as potential contributors to the increased susceptibility in neonates. For example, it has been reported that 2,4-dinitrophenol is eliminated much more rapidly from the serum in mature rabbits than in neonates (Gehring and Buerge, 1969), and this might be due to immature hepatic metabolic or renal excretory functions during the neonatal period (Gow *et al*., 2001; Rich and Boobis, 1997; Zoetis and Hurtt, 2003). For 4-nitrophenol, more concrete data are obtained. This chemical is mainly excreted as the glucuronide and sulfate in urine in young/adult rats (Machida *et al*., 1982). Since uridine diphosphate (UDP)-glucuronyltransferase and sulfotransferase activities for 4-nitrophenol are lower in microsomes or cytosols prepared from the livers of neonatal rats (Matsui and Watanabe, 1982), a higher level of 4-nitrophenol would be expected in the blood of neonatal rats than young rats treated with this chemical. A similar

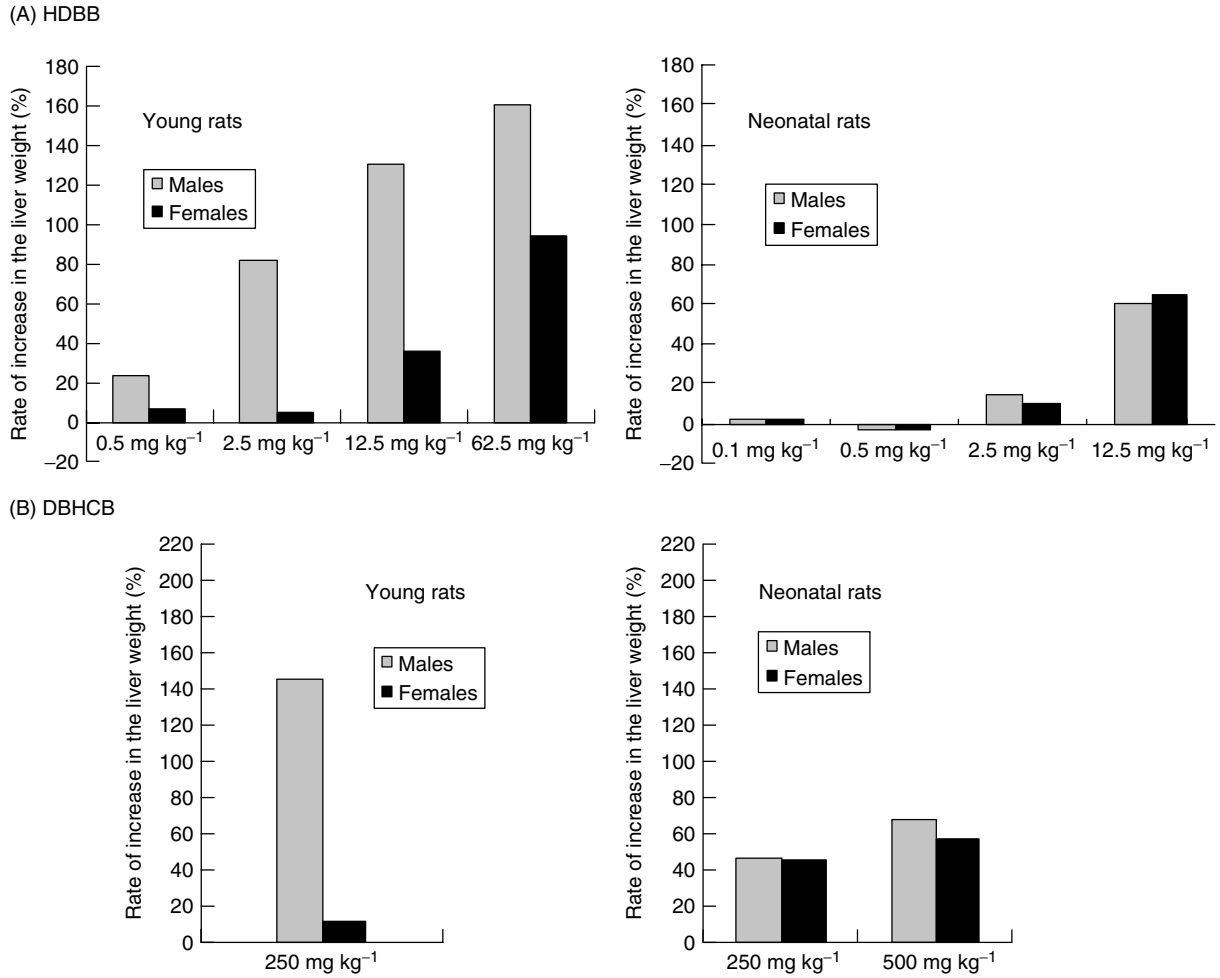

Figure 1 Rate of increase in the liver weight in young and neonatal rats administered with HDBB or DBHCB. (A) HDBB was given by gavage to young rats for 28 days (Hirata-Koizumi *et al.*, 2007), and to neonatal rats from postnatal days 4 to 21 (Hirata-Koizumi *et al.*, 2008b). (B) DBHCB was given by gavage to young rats for 28 days, and to neonatal rats from postnatal days 4 to 21 (Hirata-Koizumi *et al.*, 2008c).

phenomenon could occur for 3-methylphenol, because this chemical is known to be predominantly conjugated with glucuronide or sulfate and excreted in the urine (Bray *et al.*, 1950). In this manner, the higher toxic susceptibility of neonatal rats might be associated with the higher level of administered chemicals in the blood. In rats, it is also known that the blood–brain barrier does not completely form during the early postnatal period (Vidair, 2004), which might result in further elevation of phenolic compounds in one of the possible target organs, the brain.

While the above-mentioned 11 phenols are considered to have direct actions on their target organs, six chemicals showing lower susceptibility of neonatal rats may need metabolic activation to exert toxic effects. For example, following administration of 1,3-dibromopropane to adult rats, mercapturic acid conjugates were detected as the major urinary metabolites (James *et al.*, 1981; Jones and Wells, 1981; Onkenhout *et al.*, 1986). The chemical structures of the metabolites suggest that oxidative biotransformation by cytochrome P450 would occur before or after glutathione conjugation, as is common for dihaloalkanes (Zoetemelk *et al.*, 1986; Tornero Velez *et al.*, 2004; IARC (International Agency for Research on Cancer), 1999a; 1999b; Guengerich *et al.*, 1991; ATSDR (Agency for Toxic Substances and Disease Registry), 1992). In the metabolic process, it is considered that some active metabolites, including episulfonium ions and bromoaldehydes, are generated, and they might contribute to the emergence of 1,3-dibromopropane toxicity. Similarly, it has been suggested that 1,1,2,2-tetrabromoethane requires an oxidative metabolism by cytochrome P450 to produce active intermediates (Kennedy *et al.*, 1993; Ahr *et al.*, 1980; Hales *et al.*, 1987; Wolf *et al.*, 1977). In neonatal rats, expression levels and activities of hepatic cytochrome P450 and glutathione S-transferase is low, especially in the early days after

birth (Borlakoglu *et al*., 1993; Cresteil *et al*., 1986; McCusker *et al*., 1989); therefore, production of active metabolites would be significantly lower in neonatal rats.

Benzotriazole ultraviolet absorbers showed interesting results in that the marked gender-related differences in the toxicity in young rats was not observed in neonatal rats. A comparison of the degree of change in the liver weight clearly shows this phenomenon (**Figure 1**). Sexual variations in the toxic susceptibility of young rats have been documented for many other chemicals (Muraoka and Itoh, 1980; Knuckles *et al*., 2004; Agarwal *et al*., 1982; Carlson and DuBois, 1970; Coleman *et al*., 1990; Stern *et al*., 2007; Wang *et al*., 2001), and the various causes are indicated mainly for toxicokinetic determinants. In particular, many mechanistic studies have been reported on the metabolic enzymes cytochrome P450s (Waxman and Chang, 2005). In rats, a subset of hepatic cytochrome P450s is expressed in a sex-dependent fashion, and interestingly, the difference between sexes is not apparent until puberty. If such metabolic enzymes have an intimate involvement in the toxic activation or detoxication of benzotriazole ultraviolet absorbers, a lack of sex differences in the toxicity in neonatal rats could be explained. On the other hand, recently, it has been shown that certain key transporter-protein mRNAs are expressed differentially between sexes in sexually mature rats and that certain of these differences develop during the period of sexual maturation (Buist *et al*., 2002; 2003; Buist and Klaassen, 2004; Kudo *et al*., 2002). Another possible explanation for benzotriazole ultraviolet absorbers exerting equivalent effects on the liver of male and female neonatal rats might be the contribution of these transporters to the uptake or excretion.

4 DOSE–RESPONSE CURVES IN NEONATAL RATS AS COMPARED WITH YOUNG RATS

Comparison of the pNOAELs revealed that neonatal rats were clearly more susceptible to 11 chemicals and less susceptible to six chemicals, as mentioned above (see **Table 1**). In order to compare the clear toxic doses in neonatal rats with those in young rats, we also estimated the presumed unequivocally toxic level (pUETL), which is defined as the clear toxic dose giving similar severity for both neonatal and young rats, for 20 chemicals, and compared the values between ages. **Table 2** shows the pUETLs of neonatal and young rats, and their ratios (pUETL for young rats/pUETL for neonatal rats). The comparison of pUETLs showed different results from that of the pNOAELs. Especially for 2,4,6-trinitrophenol, (hydroxyphenyl)methylphenol, 1,3-dibromopropane and 1,1,2,2-tetrabromoethane, while the pNOAELs were higher in neonatal rats than in young rats, the pUETLs were paradoxically lower in neonates. These findings suggest a difference in the slope of the dose–response curve between neonatal and young rats.

In **Table 3**, ratios of the pUETL to the pNOAEL in neonatal rats and young rats are shown for each chemical. The values for 17 chemicals were obtained, and among them, 2,4,6-trinitrophenol, (hydroxyphenyl)-methylphenol, trityl chloride, 1,3-dibromopropane and 1,1,2,2-tetrabromoethane demonstrated much larger ratios in young rats than in neonatal rats. The dose–response curve of these chemicals must be much steeper in neonatal rats than in young rats, as shown in **Figure 2A**. A major reason for variation in shapes of the dose–response curve is unclear. One possible explanation might be a low capacity for protection against deleterious oxidative stress in the neonatal rats, when the toxic chemical burden crosses a threshold in the liver. Actually, it has been reported that hepatic activities of superoxide dismutase, catalase and glutathione peroxidase are extremely low in neonatal rats, compared with the adults (Yoshioka *et al*., 1982). Other 12 chemicals showed almost the same pUETL/pNOAEL ratios in both ages. The dose–response curve would show a parallel shift from right (young rats) to left (neonatal rats) or in the opposite direction, as shown in **Figure 2B**.

5 INCORPORATION OF NEONATAL SUSCEPTIBILITY INTO RISK ASSESSMENT

The aim of dose–response assessment in risk assessment is to derive reference values, such as acceptable daily intakes (ADIs) or tolerable daily intakes (TDIs). The points of departure, the NOAELs or benchmark dose lower bounds (BMDLs) are usually based on the results of toxicity studies using experimental animals. In such toxicity studies, uniform experimental animals are typically used as the study population. Risk assessment needs to target sensitive subpopulations, such as neonates and infants.

In current risk assessments, two uncertainty factors are generally applied to the NOAELs or BMDLs, one for extrapolation from animal to human and the other for potential variation in sensitivity among members of the human population, each with default values of 10-fold. There are some data which allow consideration of whether the 10-fold factor for intra-human variability is adequate for the risk assessment of neonates or infants (Dourson *et al*., 2002; Hasegawa *et al*., 2007), as follows. In human data analyses, most studies targeted comparison of toxicokinetic/pharmacokinetic parameters (Ginsberg *et al*., 2002; Naumann, 2001; Renwick, 1998;

Table 2 Comparison of pUETLs a for 20 industrial chemicals in newborn and young rats

Chemical name	Neonatal rats (mg kg^{-1} day^{-1})	Young rats (mg kg^{-1} day^{-1})	Ratio[a]
4-Nitrophenol	230	600–800	2.6–3.5
2,4-Dinitrophenol	30	80	2.7
3-Aminophenol	240	720	3.0
2-Chlorophenol	200–250	1000	4.0–5.0
4-Chlorophenol	300	500	1.7
3-Methylphenol	300	1000	3.3
3-Ethylphenol	—[b]	—[b]	—
4-Ethylphenol	200–250	1000	4.0–5.0
2-*t*-Butylphenol	100–150	500	3.3–5.0
2,4-Di-*t*-butylphenol	100	500	5.0
p-(α,α-Dimethylbenzyl)phenol	300	700–800	2.3–2.7
1,3,5-Trihydroxybenzene	500	1000	2.0
2,4,6-Trinitrophenol	65	100	1.5
(Hydroxyphenyl)methylphenol	140–160	1000	6.3–7.1
Trityl chloride	400–500	300	0.6–0.8
1,3-Dibromopropane	150	250	1.7
1,1,2,2-Tetrabromoethane	200	300–400[c]	1.5–2.0
HDBB	12.5[d]	2.5[e]	0.2
DBHCB	—[f]	—[f]	—
TBBPA	—[b]	—[b]	—

This table reproduces the data in **Table 2** of Hasegawa *et al*., 2007, by adding new data on HDBB and DBHCB.
–Appropriate values were not able to be given.
[a]Ratio of pUETL for young rats to that for neonatal rats.
[b]The pUETL values were not able to be given because clear toxic effects were not observed even at the highest dose in neonatal or young rats.
[c]These range values were estimated on the basis of all relevant toxicity data, including single-dose toxicity data in young rats (the lowest mortality dose was 722 mg kg^{-1} for males and 852 mg kg^{-1} for females) (MHLW (Ministry of Health, Labour and Welfare of Japan), 2003).
[d]In the neonatal rat study, histopathological examination was conducted only for the liver and heart, and haematology and developmental parameters, such as reflex ontogeny, and external and sexual development were not examined.
[e]Since the pUETLs were markedly different between sexes, the lower value was given.
[f]The pUETL could not be estimated because the young rat study was conducted only at a single dose.

Renwick *et al*., 2000; Skowronski and Abdel-Rahman, 2001), and only Glaubiger *et al*. (1981) analysed the comparative susceptibility to the overall toxicity between children and adults, showing that the variance is quite small, on the basis of comparing maximum tolerated doses for 17 anticancer drugs. For animal data analyses, Charnley and Putzrath (2001) demonstrated that younger animals are less susceptible to 47% and more susceptible to 40% of the tested chemicals in carcinogenesis studies. Calabrese (2001) also reported that younger animals have greater sensitivity than older animals in 54% (more than 10-fold in 14%) by LD_{50} (median lethal dose) ratio analyses for 313 chemicals. All these reports suggested that the sensitivity of children/younger animals against adults to most chemicals may be within 10-fold, meaning that the 10-fold uncertainty factor as a human variability might be enough to cover the sensitivity of children/younger animals, but these analytical results did not target the early postnatal periods. Sheehan and Gaylor (1990) and Goldenthal (1971) targeted this period, and compared the LD_{50} values between neonatal and adult animals for a large number of chemicals. However, these analyses are also inappropriate for evaluating an adequacy of the uncertainty factors because the factors are usually applied to the NOAELs or BMDLs estimated from repeated-dose results.

The above mentioned comparative analysis on 20 chemicals is the first trial to evaluate the susceptibility of neonatal rats to chemicals based on the results of repeated-dose toxicity studies, and the analytical results show the importance of studying the early life-stage sensitivity to toxic insult. When toxicity studies using neonatal animals determine the critical effects of chemicals, then ADIs or TDIs should be estimated based on their findings. When such neonatal studies do not determine any critical effects, then the ADIs or TDIs are appropriately estimated based on the critical effects found in other studies, and then the neonate is protected. It is when toxicity studies for the neonatal period have not been conducted that the uncertainty factors must be invoked to protect the neonate. The analytical results on 20 chemicals suggest that an uncertainty factor of 10-fold for human

Table 3 Comparison of pUETL/pNOAEL ratios for 20 industrial chemicals in neonatal and young rats

Chemical name	Neonatal rats	Young rats
4-Nitrophenol	2.1	1.5–2.0
2,4-Dinitrophenol	3.0	4.0
3-Aminophenol	3.0	3.0
2-Chlorophenol	5.0–6.3	5.0
4-Chlorophenol	3.0	5.0
3-Methylphenol	3.8–5.0	3.3
3-Ethylphenol	—	—
4-Ethylphenol	6.7–8.3	10.0
2-*t*-Butylphenol	5.0–7.5	5.0
2,4-Di-*t*-butylphenol	20.0	25.0
p-(α,α-Dimethylbenzyl)phenol	10.0	7.0–8.0
1,3,5-Trihydroxybenzene	5.0	3.3
2,4,6-Trinitrophenol	1.3–1.6	5.0
(Hydroxyphenyl)methylphenol	1.4–1.6	25.0
Trityl chloride	6.7–8.3	25.0
1,3-Dibromopropane	3.0	25.0
1,1,2,2-Tetrabromoethane	4.0	50.0–66.7
HDBB	25.0	25.0
DBHCB	—	—
TBBPA	—	—

–Appropriate values were not able to be given because pNOAELs or pUETLs were not estimated in neonatal and/or young rats.

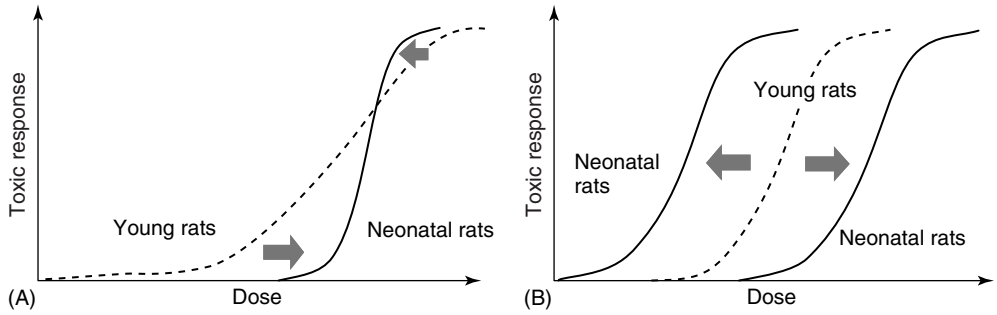

Figure 2 Illustration of two patterns of shift of dose–response curves from young to neonatal rats. (A) Change in the slope: a steeper shaped curve in neonate rats than young rats. (B) Parallel shift from right (young rats) to left (neonatal rats) or in the opposite direction.

variability can be considered appropriate for risk assessment, unless knowledge of particular toxicity in neonates or infants is present, or if not present is discountable due to other credible information on the chemical. Finally, it should be noted that these repeated-dose studies targeting neonatal animals are available only for a limited group of chemicals, and therefore conducting further studies and the gathering information for a greater variety of chemicals are strongly desired.

NOTES

In this chapter, we use IUPAC names for most chemicals, but more general names are used for the others. These compounds are indicated by superscript lowercase letters, and the IUPAC names are given below.

[a] 4-(2-Phenylpropan-2-yl)phenol
[b] Benzene-1,3,5-triol
[c] Methylenediphenol
[d] [Chloro-di(phenyl)methyl]benzene
[e] 2-Benzotriazol-2-yl-4,6-di-*tert*-butylphenol
[f] 2-(5-Chlorobenzotriazol-2-yl)-4,6-di-*tert*-butylphenol
[g] 2,2′,6,6′-Tetrabromo-4,4′-isopropylidenediphenol

1 INTRODUCTION

Consideration of the components of toxicity in risk assessment settings has perhaps been limited by one of toxicology's basic guiding principles—that the dose makes the poison. Toxicity is necessarily a function of exposure which has components not only of total dose, but also of time or duration (e.g. dose rate). The consideration of duration as an element of toxicity in risk-assessment settings has a long, but nonetheless scanty history, especially in comparison to dose–response relationships. It is likely that at least part of this imbalance is due to the risk-assessment scenarios often being for a lifetime at a presumably average exposure concentration, where the evaluation is often of different doses all applied in a continuous manner such that duration is not a variable. The importance and occurrence of shorter-term exposure scenarios, where time and dose are essentially equal covariables, are of increasing interest, not only for occupational settings **Occupational Toxicology**, but for scenarios affecting the general population (e.g. evacuation and re-entry in emergency-response scenarios) **Acute Toxicity**; **Chemical Incidents-Emergency Planning, Preparedness, Response and Recovery. Community Considerations**.

Probably the most commonly cited and utilized relationship between exposure concentration and exposure duration (time) leading to a response is the mathematical relationship $C \times t = k$, which has come to be known as Haber's Law (Haber, 1924). Haber established that a simple relationship of concentration multiplied by the duration of exposure (usually in minutes) equalled a constant (k) when applied for short durations to warfare gases used in World War I. Later studies established that the relationship also worked with a number of solvent chemicals (Flury and Wirth, 1934). A more utilitarian form of this relationship was developed by ten Berge *et al*. (1986) where the equation is refined and expressed as $C^n \times t^b$ allowing for empirical derivation of the relationship between C and t (**Figure 1**) to explain deviations from Haber's rule seen with some common chemicals (e.g. ammonia). Haber's rule can be seen as a special case of the ten Berge model, where the exponents of concentration (n) and time (b) are both unity. **Figure 1** also shows the outcome (note a log–log scale) of setting the value of $n = 1$ and to a relatively large value of 3. Time/duration relationships different from that of Haber's rule (i.e. where $n = 1$) would result from this range of 'n's. Extrapolations to a given duration under these different relationships could produce remarkably disparate values.

It is well established that many levels of complexity exist in relating dose to toxicity **Environmental and Endogenous Factors Determining the Expression of Toxicity**; **Dose-Response Analysis in Experimental Toxicology and Risk Assessment**; however, it is perhaps

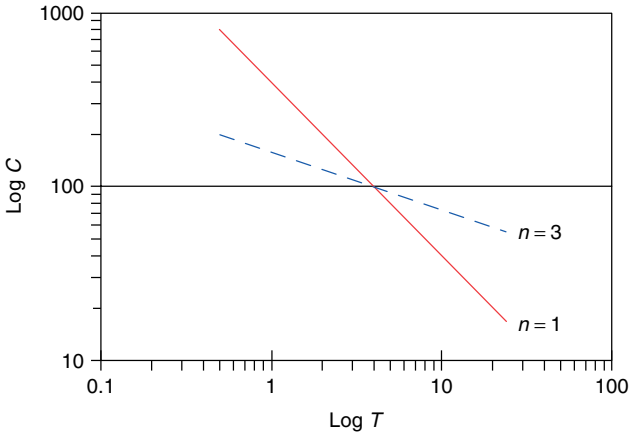

Figure 1 The concentration (C) times duration (t) relationship $C^n \times t = k$ on a log–log plot. The exponent n is actually a composite variable from the probit equation relating concentration and time, $Y = b_0 + b_1 \ln C + b_2 \ln t$, with $n = b_1/b_2$. (Reproduced from ten Berge *et al.*, 1986.)
Plots for different values of n are illustrated.

not as well appreciated that many of the same complexities are in play in relating exposure duration to toxicity. The complexities for dose and toxicity are founded in the areas of kinetics, dynamics, repair, adaptation and so on. Only recently has it become understood that these same elements affect the relationship between exposure duration and toxicity (Rozman and Doull, 2000; Rozman, 2000). Examples of these complicating factors include comparisons between one-time-only exposures to recurrent exposures at different intervals (daily, weekly, etc.), in relating the length of time from exposure to an adverse response and in extrapolations along the temporal continuum (short to long durations, or vice versa). There are, additionally, numerous examples in the literature where responses are not accurately defined by the $C \times t = k$ prediction, likely to be due to various complexities, obvious or latent (ten Berge *et al.*, 1986; Sommerville *et al.*, 2006; Dalbey *et al.*, 1998; Rajini *et al.*, 1993; Boyes *et al.*, 2003).

The association of time/duration of exposure to kinetics, dynamics, repair and so on has been demonstrated convincingly for several chemical compounds. For example, Stahl *et al.* (1992) noted that 1,2,3,4,6,7,8-heptachlorodibenzodioxin (HpCDD), toxicity (death up to 70 days after a single acute exposure) observed a strict $C \times t = k$ relationship, whereas the closely related 2,3,7,8-tetrachlorodibenzodioxin (TCDD), did not. Rozman (1999) demonstrated that these differences are due in large measure to the observation that the biological $t_{1/2}$ of a single dose to HpCDD (at 200 days) essentially established and maintained a near steady-state condition for an adequate duration (70 days) within which toxicity occurred; whereas with TCDD ($t_{1/2}$ of 20 days), a single exposure did not. As such, the difference in toxicokinetics between these two related chemicals resulted in a confounding of an underlying $C \times t = k$ relationship. This confounding was affirmed by experimentally establishing a $C \times t = k$ relationship for TCDD with augmented dosing (once every four days) that maintained a 'quasi' steady state (i.e. an effective dose over an adequate duration). These investigations have presented solid evidence affirming that $C \times t = k$ may be operable when all variables, complexities and confounders are known and can be controlled (e.g. where the timescale in steady state is long compared to the timescale of toxicity) and therefore, useful as a predictive model under these circumstances. The fact remains, however, that exposures dealing with or related to a $C \times t$ relationship will likely not occur under such controlled conditions and that knowledge of contributing complexities, such as kinetics, will be lacking. Under these usually occurring conditions of limited understanding of variables, more pragmatic approaches for estimating the $C \times t$ relationship are required.

In cases where more detailed data have been available, physiologically based toxicokinetic (PBTK) models have been applied in elucidating $C \times t$ relationships. The nature of these models allows for extensive and expandable incorporation of numerous parameters allowing for consideration of biological and kinetic sources of complexity, all in an integrated manner. The few duration studies available with these highly parameterized models demonstrate that they can closely approximate empirical information, including instances that do not follow the Haber relationship (Simmons *et al.*, 2005; Bruckner *et al.*, 2004; Lu *et al.*, 2008). These models thus affirm the complexity of $C \times t$ relationships and imply that consideration of variables, such as those related to physiology and biochemistry, allows for at least partial resolution of this complexity. Development of such models, however, is labour intensive, requires knowledge about the toxicologically active form of the chemical (parent or metabolite), the identity of the known or assumed target tissue and, of course, rare duration–response data against which the model may be evaluated. Thus this approach, although having considerable scientific merit, is likely not to be a practical alternative in exploring the $C \times t$ relationship for a majority of chemicals. Again, simpler methods and approaches are needed.

Acute lethality is the toxicity end point for which $C \times t = k$ data is most often available for modelling (and on which much of the historical basis for $C \times t$ relationships are established). In most risk-assessment applications, however, the concern will be for toxicity at a much lower severity than mortality. Application of the $C \times t = k$ relationship for lethality to other nonlethal end points engenders considerable uncertainty, unless the mechanism causing the toxicity is the same or similar enough for both end points. With certain end points, such as sensory-based irritation, scientific justification for application of lethality-based results may be lacking altogether (Shusterman *et al.*, 2006). End-point-specific

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat173

$C \times t$ data and information would thus be desirable, as would a better understanding of the $C \times t$ relationship for longer durations and/or repeated exposures.

Methods and approaches to evaluate the $C \times t$ relationships from empirically observed nonlethal responses are especially relevant for acute exposure-duration scenarios. This work presents case studies, along with, for each, various methods and approaches for evaluating the $C \times t$ relationship, with varying amounts of observed data, with lethal and nonlethal end points, as well as with relevant ancillary information affecting this relationship. The methods include application of the US Environmental Protection Agency's (EPA) version of severity-based categorical regression, CatReg (US EPA, 2006; *http://epa.gov/ncea/catreg*), the EPA's version of the ten Berge software (US EPA, 2008; *http://www.epa.gov/ncea/bmds/dwnldu.html#berge*) and benchmark dose (BMD) software (US EPA, 2009; *http://ww.epa.gov/ncea/bmds/*), and methods (US EPA 2000; *www.epa.gov/nceawww1/pdfs/bmds/BMD-External_10_13_2000.pdf*) as well as a proposed default approach for evaluation of the $C \times t$ relationship in minimal data situations. The case studies also highlight the practical utility, strengths and limitations of these methods and approaches. They are provided as a resource for the reader to evaluate $C \times t = k$ with varying levels of data and ancillary information. Future directions for research on $C \times t$ relationships and duration extrapolation are also discussed.

2 CASE STUDIES AND APPROACHES TO C x t EVALUATION

2.1 Phosgene Case Study

2.1.1 General

An acid chloride, phosgene is a highly reactive poisonous gas with known and investigated progression of effects leading to lethality via pulmonary collapse. Much has been written on local pulmonary interactions of phosgene, particularly with the surfactant system, that mixture of lipids and proteins situated at the air–liquid interface of the alveolus necessary for maintaining alveolar stability and preventing pulmonary oedema (Jugg *et al*., 1999; Pauluhn *et al*., 2007). The induction of surfactant abnormalities following phosgene exposures is presumed to be a key pathophysiological event leading to pulmonary oedema and sequelae (Pauluhn *et al*., 2007). Protein levels in bronchoalveolar lavage (BAL) fluid have been shown to be among the most sensitive end points characterizing these early, acute effects of phosgene exposure (Hatch *et al*., 1986; Sciuto, 1998; Pauluhn, 2006a; 2006b; 2006c).

In their study of the $C \times t$ relationship of pulmonary responses to high lethal exposures to phosgene Rinehart and Hatch (1964) concluded that 'there was no indication that concentration contributed more than exposure time to the magnitude of change in pulmonary performance over the range of $C(x)T$ values studied'. The work of Pauluhn (2006a; 2006b) indicates that this should be approximately true for both lethal and nonlethal exposures, with the latter referring specifically to end points indicative of a transient perturbation of the blood–air barrier (Pauluhn, 2006b).

2.1.2 Issue: C × t and End Point

Phosgene has a relatively robust database of $C \times t$ information, especially on target tissue end points of the respiratory tract. The issue examined in this case study is comparison of two approaches on data utilization in estimating the $C \times t$ relationship. One approach involves utilization of all available data, inclusive of a range of target-tissue end points measured in several different species and multiple studies, some of which employ and report on only a single duration; this approach was implemented using the US EPA version of categorical regression software, CatReg (US EPA, 2006). In contrast, the second approach is the use of a single data set in a single species (rat) examining the timecourse for expression of a single highly sensitive respiratory tract end point, BAL-fluid protein levels in a refined dose–response analysis using BMD analysis. These analytical methods and tools are described only generally here, with references given to more in-depth methodological sources.

2.1.3 Methods

2.1.3.1 CatReg: Severity-Based Categorical Regression

The US EPA developed CatReg to perform categorical regression analysis with the categorical component representing response severity (Guth *et al*., 1997; Strickland and Guth, 2002; US EPA, 2006). Response severity data are obtained from judgment-based evaluations and assignments of the responses observed in various toxicity studies. It is these individual categories of responses that may be evaluated by CatReg with respect to concentration and duration and other variables of the data.

For example, the severity response category scheme used by CatReg for the phosgene database was as follows: no adverse effect assigned severity 0; a mild adverse effect assigned severity 1; a severe adverse effect assigned severity 2; lethality assigned severity 3. The assigned severity category and other information associated with the specific response, such as the gender, species and, of course, the concentration and duration of exposure, all may be recorded for each individual response. An attribute of this severity assignment is that it can be applied to responses irrespective of study, species,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat173
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

or gender. Outputs from CatReg analysis of such data may then be used to define $C \times t$ relationships for a specific category of severity derived simultaneously from a large number of different studies that may comprise many different species and end points. Outputs may also be examined from the perspective of any subset of the entered data, such as examining the $C \times t$ relationship for a severity 1 (mild adverse) effect in a specific species or the $C \times t$ relationship for a category severity 2 effect either for an individual species or for all species with both genders.

Regression lines generated in CatReg concentration–duration plots commonly have a negative slope with respect to increasing durations, reflecting the general tenet that exposures of greater durations and lower concentrations result in a similar severity of response. The regression lines generated by CatReg are actually probability functions relating the likelihood of observing an effect for a specific severity category over a range of exposure durations. For example, the regression line presented in this example analysis of phosgene represents the 10% (extra) risk of observing a particular severity category or higher over a range of concentrations (C) and durations (T) and for that reason are designated as 'ERC-T10%' lines for any given severity category. These lines are estimations of the probability (or likelihood) than an effect of a certain severity will occur at various concentrations and durations of inhaled phosgene at this level of risk.

Other outputs from the CatReg regression important to the $C \times t$ relationship include model estimates for the coefficients of both concentration (β_1) and duration (β_2) for a given severity category that are analogous to coefficients in the ten Berge equation (see legend to **Figure 1**). When the concentration and time terms in the model are log transformed, β_1/β_2 represents n in $C^n \times t$.

Further in-depth specifics in the statistical and procedural aspects underlying CatReg are available at the web site (*http://cfpub.epa.gov/ncea/cfm/nceatools_human.cfm*) and via a number of supporting references (Guth *et al*., 1997; Dourson *et al*., 1997; Strickland and Guth, 2002; Brown and Strickland, 2003; Brown and Foureman, 2005; US EPA, 2006).

2.1.3.2 Benchmark Dose

The BMD approach is an alternative to the NOAEL–LOAEL (no/lowest observed adverse-effect level) approach for estimating a threshold-type dose in data sets. Rather than the risk assessor designating a single dose in a data set as an NOAEL, based on some measure of response, BMD fits a mathematical model to the entire dose–response data set for any given end point. The model allows the risk assessor to designate a certain level of response (e.g. 10% extra risk or one standard deviation from the mean, SD) and then to estimate the dose that corresponds to that benchmark response (BMR), in the context of the entire range of dose–response available. This feature allows all dose–response groups to be compared on a common basis (i.e. that exposure required to produce the same BMR) rather than being restricted to designation of an actual dose, as in the NOAEL–LOAEL, for which response information may be judged only from contiguous doses. The terms BMD_{10} and BMD_{SD}, usually refer to the central estimate of the dose at the BMR, with the corresponding statistical 95% lower bound on dose designated as $BMDL_{10}$ and $BMDL_{SD}$, respectively. The analysis done here for each concentration–duration point is with the central estimate, actually the maximum likelihood estimate (MLE), the BMD. When the BMD approach is applied to air concentrations, as in the next example, the parallel term benchmark concentration (BMC) is used. Also, extra risk, the type usually used by the US EPA, is defined as the estimated increased risk over background ($P_d - P_0$) divided by the maximum risk with background excluded ($1 - P_0$).

2.1.4 Phosgene Concentration–duration Information and Analysis

The following tables are included to demonstrate the type of data utilized in these two analytical methods.

Although not exhaustive in its data listing, **Table 1** serves to demonstrate the variety and scope of data available on the respiratory tract on the $C \times t$ relationship for phosgene. As can be seen, these data comprise information from end points ranging in adversity from alterations in cofactor levels (decreased nonprotein sulfhydryls) to lethality from five different species. The table also indicates the severity categorization assigned for the CatReg analysis, ranging from phosgene exposure without effect, severity 0, up to lethality, severity 3.

Table 2 shows the end-point-specific analysis on BAL-fluid protein data obtained from phosgene-exposed rats two days post-exposure by Diller *et al*. (1985). US EPA benchmark dose software (BMDS) models and a BMR level of one SD increase of BAL protein levels were used to estimate the exposure concentrations giving a 1 BMC_{SD} over the range of response between the control value and the values noted at the exposure durations listed in **Table 2**. Pauluhn (2006b) reported that 'the $C \times t$-dependent changes of phosgene-induced pulmonary injury appear to be described best by elevation in BAL fluid protein concentration one day following exposure', as opposed to BAL fluid protein or other end point measurements taken as late as three months post-exposure. Using duration-specific dose–response data sets describing the relationship between BAL-fluid protein concentration and exposure concentration, benchmark measures were estimated for the various exposure durations. The slope of the resultant BMC-duration plot was then used to derive the value of n in C^n. Further

Table 2 BMC_{SD} estimates (from a linear polynomial model) for the response of increased lung-lavage fluid protein ($\mu g\,ml^{-1}$) in male rats two days post-exposure to various phosgene exposure durations. The interpretation of these data is (upper column) that a BAL-fluid level of 107 (69+38) $ug\,ml^{-1}$ is estimated to result from exposure to an air concentration of 6.1 mg phosgene m^{-3} for 20 min (0.33 h)

Exposure ($mg\,m^{-3}$)	BAL fluid, $\mu g\,ml^{-1}$, mean ± SD		Duration (h)	BMC_{SD} ($mg\,m^{-3}$)
	Control	Exposed		
10.1	69 ± 38	355 ± 255	0.33	6.1
4.0	117 ± 97	288 ± 29	0.83	1.6
0.4	69 ± 38	90 ± 39	4.17	0.71
0.4	117 ± 97	255 ± 78	8.3	0.24
0.4	69 ± 38	301 ± 133	8.3	0.16

These data are from **Table 2** in Diller *et al*., 1985.

specifics on the analysis of the Diller data via BMC are given in **Table 2**.

As can be seen from these tables, both the extent of data and the evaluation of the response of the Diller *et al*. (1985) data differed between the CatReg and BMD analyses. In the CatReg analysis, all animals from all duration-exposure groups were included in the analysis (see the listing for Diller in **Table 1**), nearly all of which were noted and recorded as being at a response level at or below severity 1 (mild adverse) defined as a 2× increase over concurrent control BAL-fluid protein levels. In the BMC analysis, however, the shortest dose/duration group of 10 minutes (0.17 hours) was eliminated from the analysis (see explanation below). Also, as noted above, the threshold level was set for a specific significant response at 1 SD from the concurrent control value. The reasoning for these differences is based upon additional information gained from the test species and about the end point.

In his analysis of breathing patterns of rats exposed (nose-only) to relatively high phosgene levels ($40\,mg\,m^{-3}$ and higher), Pauluhn (2006a) noted a marked and reproducible transient depression in ventilation parameters 10–15 minutes from the start of exposure. Accordingly, it was considered justifiable to exclude results for these short exposure durations from his analysis and the same data (10 minutes or 0.17 hours) were excluded from this end-point-specific BMC analysis of the Diller data. Regarding the BAL end point, Hatch *et al*. (2001) noted BAL-fluid protein levels in rodents were relatively insensitive indicators of mortality, whereas other reports suggest BAL-fluid protein to be a much more sensitive indicator of mortality in humans (Pittet *et al*., 1997). It was thus considered appropriate to further refine the response level at which this end point may be considered to have an effect, hence the assignment and determination of 1 BMC_{SD} in the BMC analysis for the BAL-fluid protein end point vs. the mildly adverse criterion described above for the CatReg analysis.

Figure 2 shows the composite CatReg solution for nearly all phosgene concentration–duration data for respiratory tract end points and is inclusive of those data shown in **Table 1**. As would be anticipated, the placements of the ordinate values at any given point on the duration axis for severity 3 (lethality) data points are higher in concentration than the values for severity 2, which is likewise higher than for severity 1, with severity 0 data points having the lowest ordinate values. The ERC-10% curve for a severity 1 response is shown with confidence limits and is situated lower on the axis (and further from the actual severity 1 data points) than would a higher-probability curve, such as an ERC-30% or ERC-70%, which would be progressively nearer to the severity 1 data. Also as anticipated, the placement of data points for any given severity with increasing duration define a negative slope. This observation was confirmed by the CatReg regression analysis and solution for the severity 1 respiratory effects (the ERC-T10% curve along with its confidence bounds) for combined species (rats, guinea pigs and mice) in **Figure 2**. These observations indicate that components of both concentration and duration have a role in characterizing the $C \times t$ relationship to phosgene responses.

2.1.5 Comparison of Results

The overall and comprehensive analysis made possible by the nature of the CatReg method is highlighted in **Figure 2**. Data points from over 20 studies, representing five different species for many different respiratory end points each of which has been judged with respect to severity, are all directly represented on **Figure 2**. The normalization of these data through the severity categorization scheme discussed above demonstrates the meta-analytic nature and value of CatReg for this type of analysis. This example case study does not show the versatility of CatReg in utilizing capacities to further sort, filter and analyze all data through a spectrum of permutations. Rather, the data were utilized here collectively to estimate the probability of a severity 1 effect, along with its statistical boundaries through the $C \times t$ relationship represented by these data. Direct outputs from CatReg (i.e. β_1/β_2) were used to determine the value of n (in C^n) at 1.4. A meta-analysis such as this can provide an investigative starting point, but may need to be refined

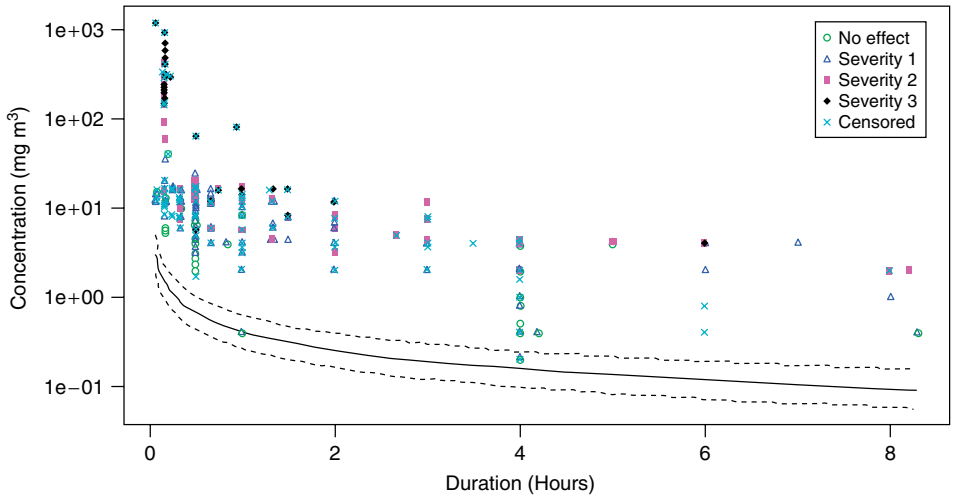

Figure 2 A sample concentration–duration plot from the CatReg analysis of respiratory tract effects from phosgene exposure. The effects have been graded for severity (grades 0–3 with 0 being 'no effect' and 3, lethality). The cumulative odds model, log-probit link function, provided the best fit to rat, mouse and guinea-pig respiratory effects (for details of on these models see the latest CatReg Software Documentation, US EPA, 2006). Data points may represent more than one subject, depending on the number of subjects in an experimental group responding with a particular severity. Groups with individuals in more than one severity category are represented by more than one symbol per the key shown above. When a response does not clearly fit into a single severity category, either because insufficient information is available or because the adversity of the effect is uncertain, the effect is 'censored' over two or more categories. The mathematical approach used for censoring is detailed in the CatReg Software Documentation (US EPA, 2006). Solid line = ERC-T10% for mild adverse effects (severity 1); Dotted lines = 95% one-sided lower and upper bound confidence limits.

based on biological information or sensitivity analyses to remove data (e.g. time points, test species or end points) that confound rather than inform or may be less relevant to the potential for human lung irritation from acute phosgene exposures, as is seen in the accompanying BMD analysis of the Diller *et al.* (1985) data.

Figure 3 shows the analysis for n on the calculated BMC_{SD} using the selected end point of BAL-fluid protein data from the rat study by Diller *et al.* (1985). As explained above, this analysis is based on specific information, further refined using ancillary information and shows that: (i) BAL is the most sensitive end point in inhalation exposures to phosgene, (ii) BAL end point information one to two days post-exposure is most representative of damage and (iii) ventilatory parameters in the early stages of exposure (10–15 minutes for rats) are unstable. The value for n in this refined analysis, at 1.0 differed from that determined with the more broad inclusive CatReg analysis.

The values of n derived from these two approaches both indicate that duration is a major determinant in the $C \times t$ relationship of nonlethal effects from acute inhalation exposure to phosgene. Both of these values are relatively far from those values of n (i.e. >1) that indicate a predominance of concentration over duration (e.g. note the decreased slope of the $C \times t$ line at $n = 3$ in **Figure 1** above). It is also to be noted that phosgene was one of the agents used to establish Haber's rule at $n = 1$ (see Pauluhn *et al.*, 2007). The most likely reason the CatReg analysis with phosgene presented in this review is not totally concordant with Haber's rule is that, as discussed above, some data included in this meta-type analysis may have an inordinate or unexpected influence on the results. Different species may have competing kinetic and dynamic influences, different end points may vary in their sensitivity and different exposure regimens used in studies can cause variability. In this case, the reflex apnea seen in rodents exposed to high concentrations of irritating chemicals for up to 15 minutes led to the decision to drop the 10 minute duration from the BMC analysis; this refinement was not done with the CatReg analysis. Consideration of these factors in assessing risks from exposure to environmental chemicals is the reason this report was written.

2.2 Ethylene Oxide Case Study

2.2.1 General

At room temperature and pressure, ethylene oxide (EO) is a colourless, highly reactive gas. EO serves as a feedstock in the manufacture of ethylene glycol and surfactants, and is used as a sterilant for heat-sensitive materials and products, especially in the healthcare industry (e.g. in hospitals). Trace amounts of EO are produced from the combustion of carbon-based compounds, but the main sources of potential exposures for humans are from industrial applications or its use as a sterilizing agent.

DOI: 10.1002/9780470744307.gat173
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

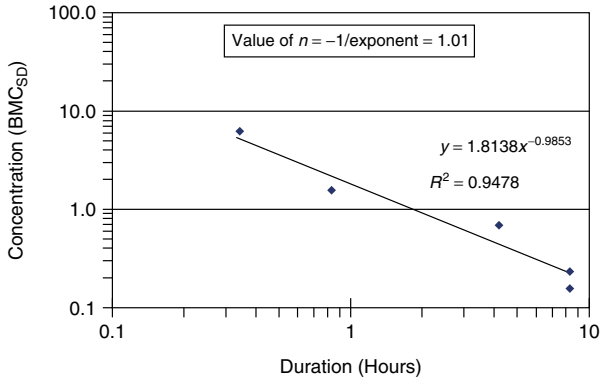

Figure 3 A log–log plot of benchmark dose estimates for increases in lung-lavage protein levels after various durations of exposure to phosgene. (Reproduced from Diller *et al.*, 1985.) The dose–response data at each exposure duration were analyzed using a linear model to obtain the benchmark for a response level of 1 standard deviation from concurrent controls (BMC_{SD}). These BMC_{SD} estimates are plotted against duration and fit to a model in the form of $C = m \times t^b$. This model was transformed to the $C^n \times t = k$ equation where values of m are related to k (where $m = k^{1/n}$) and values of b are related to n (where $b = -1/n$). The value for the exponent n in this analysis is $-0.9853 = -1/n$, such that $n = 1.01$. The actual transformation is: $C^n \times t = k$; $C^n = (kt^{-1})$; $C = (kt^{-1})^{1/n}$; $C = k^{1/n} \times t^{-1/n}$.

Health effects associated with exposure to EO include potential cancers of the haematopoietic system; developmental and foetal toxicity; dermal, ocular and respiratory tract irritancy and effects on neurological function (Agency for Toxic Substances and Disease Registry (ATSDR), 1990).

2.2.2 Issues

The data sets available for concentration–duration analysis with EO include several based on the lethality end point, and one study that also substantiated nonlethal developmental effects in mice from single exposures at varying concentrations and exposure durations, showing a $C \times t$ relationship. These data sets allow for demonstrating: (i) the application of existing software implementing the $C^n \times t$ approach and (ii) the consequences of different values of n in an applied scenario.

2.2.3 Methods

All calculations of the value of n in this section (referring to the exponent n in the $C^n \times t = k$ equation) were determined using the statistical software DoseResp developed by ten Berge (2006), a version of which is available at the following web sites, *http://www.epa.gov/ncea/bmds/dwnldu.html#berge* or *http://home.planet.nl/~wtberge/doseresp.html*.

2.2.4 Data and Analysis

Three sets of inhalation lethality data were available for EO and used in this analysis. A composite data set on rats was constructed from the studies by Jacobson *et al.* (1956), Nachreiner (1991) and Nachreiner (1992). This composite data set comprised rats of two strains (Wistar and Sprague–Dawley) exposed over a relatively wide range of EO concentrations (882–6161 ppm) at two durations (60 or 240 minutes). A second composite data set was created from the two Nachreiner studies alone, in which only Wistar rats were used. The third data set was from the developmental study in mice by Weller *et al.* (1999). In this study, pregnant mice were allocated to exposure groups (50–70 in each concentration/duration group). There were five time points (90, 105, 120, 180 and 360 minutes) for observations of lethality available for analysis in the Weller study, with exposure concentrations ranging from 350 to 1800 ppm. Further specifics on these data sets are available in **Table 3** below. The point to be noted here is that this approach to elucidating $C \times t$ requires relatively little data, as compared to other approaches such as CatReg.

2.2.5 Results and Implications

Qualitatively, the values of the exponent n derived from these three data sets are consistent in that they are between 1 and 2 (**Table 3**). As mentioned before, the value of n gives an indication of the relative role and prominence of duration or concentration in the effect observed. As shown in **Figure 1**, values of $n > 1$ (e.g.

Table 3 Summary of $C \times t$ data for ethylene oxide

Group size	End point	$C^n \times t = k$ data			n
		No. of ($C \times t$) combinations	Duration range (min)	Concentration range (ppm)	
5–10	Lethality	23	60 or 240	882–6161	1.2 ± 0.06
5	Lethality	17	60 or 240	1021–6161	1.4 ± 0.13
14–70	Lethality	8	90–360	350–1800	1.7 ± 0.2

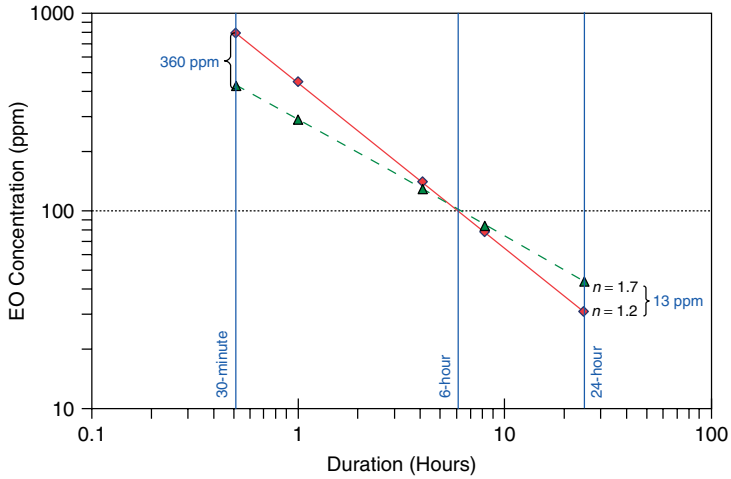

Figure 4 Comparison of results in extrapolating using different values of n in the equation $C^n \times t$. The figure compares two different values of n derived from lethality results in animals exposed to ethylene oxide. The extrapolation depicted is from a known effect level (NOAEL of 100 ppm), duration (six hours), and extends to a shorter (30 minutes) duration and to a longer (24 hours) duration using the values of n indicated. The ppm values noted at the ends of the two curves represent the divergences in concentrations at the durations indicated.

3) define increasingly shallow slopes on the $C \times t$ relationship indicating that the effect noted has a prominent concentration component with duration being a less determinative factor. Values of $n < 1$ yield increasingly steeper slopes on the duration–concentration curve thereby indicating duration to be more determinative in elicitation of the response. Thus the EO results for n consistently indicate duration to be a major determinant in the concentration–duration relationship for EO, at least at high concentrations and with mortality as an end point.

Quantitatively, however, parameters expressed as exponents by their very mathematical nature may be expected to be critical and highly sensitive elements in characterizing relationships. As such, it is instructive to examine the results for n obtained for the EO data in **Table 3** from the aspect of its intended utility (i.e. quantitatively extrapolating to different intersections of the concentration–duration curve). **Figure 4** is constructed to demonstrate both the sensitivity and the manner in which extrapolations would be affected by seemingly small differences in n. This example assumes observation of an NOAEL occurring at 100 ppm, six hour exposure to EO, with the requirement to extrapolate to an NOAEL concentration at a shorter duration of 30 minutes. Application of the most disparate values of n from **Table 3**, 1.2 and 1.7, shows the quantitative differences as a consequence of this difference in n. The higher concentration value dictated by the lower value of n (1.2) results in an extrapolated value of 793 ppm. This is over 360 ppm higher than the value of 431 ppm obtained with the higher value of n (1.7). If the direction of this extrapolation is changed from six hours to 24 hours (i.e. from a shorter to a longer duration), the resultant concentrations due to these different values of n at 24 hours are 31 ppm for $n = 1.2$ and 44 ppm for $n = 1.7$. (The maths for the former condition would be $C^n \times t = k$, $(100^{1.2}\text{ ppm}) \times 6$ hours $= 1507$ ppm/hour $= 3014 \times 0.5$ hours $= (793^{1.2}\text{ ppm}) \times 0.5$ hours; $(100^{1.7}\text{ ppm}) \times 6$ hours $= 15071$ ppm/hour $= 30142 \times 0.5$ hours $= (431^{1.7}\text{ ppm}) \times 0.5$ hours.)

For scenarios such as health-based risk assessment, projecting exposures, through a highly uncertain process such as extrapolation, bears considerable liability, especially if it leads to higher and higher concentrations. In this example of extrapolating from a longer to a shorter duration, the marginally lesser value of n of 1.2 resulted in a much higher extrapolated concentration, nearly two-fold higher (763/431 ppm), than did the greater value of n at 1.7. To complicate this situation further, it can be seen that the converse of this situation occurs when the extrapolation proceeds from shorter to longer duration. Here the slightly greater value of n at 1.7 resulted in a 1.4 fold higher (44/32 ppm) value than did the lesser value of n of 1.2.

This example serves to point out further considerations in performing duration extrapolation, including the consequences of the existing differences in the value of n derived from the $C^n \times t$ approach, and further, the temporal direction in the application of different values of n. In applying these results to this example of EO, for example, justification could be made for applying an n of 1.7 when extrapolating from longer to shorter duration and for applying an n of 1.2 when extrapolating from a shorter to a longer duration. This leads us to a discussion of an approach to avoid underestimation of risk when faced with conflicting data or uncertainty.

2.3 The '*n*' Boundary Approach

2.3.1 General Issue: Variability and Minimum Data Default

A general issue common to most all concentration–duration data sets and their analysis, including these case studies, is their attendant uncertainty and variability reflected in the exponent n. The type of data necessary for elucidating the actual relationship and the nature of the variability would require multiple pairing of various concentration–duration experiments, data that is currently a rarity. For both phosgene and the EO case studies discussed here it is demonstrated that uncertainty/variability in n can lead to quite widely disparate results in exposure levels derived for a common duration and that the greater the extent of extrapolation, the intended application of these analyses, the greater the resultant differences. With EO, for example, extrapolation with the relatively small variability of the estimated n over a moderate range of duration (0.5–6 hours) resulted in concentration values that were nearly doubled. Yet another complicating aspect of the uncertainty/variability is that the outcome of extrapolation is influenced by the temporal direction of the extrapolation (i.e. from longer to shorter or from shorter to longer durations). The EO case study demonstrated clearly that extrapolations from longer to shorter durations resulted in increasingly higher differences in concentrations related to the value of n, with the converse relationship between values of n occurring in the extrapolation from shorter to longer durations. Extrapolating health-based values to high concentrations that have not been examined directly or well characterized may have increasing liability.

2.3.2 Toxicity Information

The data sets examined by ten Berge (1986) did not examine variability or uncertainty around estimation of an individual n. These authors, however, did report the range over which n varied in those data sets examined as being 1–3. This range of values has, in general, been affirmed by others (e.g. see Sommerville *et al.*, 2006).

2.3.3 Analysis and Results

A plot of these values defining this range of 1–3 is given in **Figure 1** above. Examination of these simulations (relative to a fixed time point) reveal how the $n = 3$ curve is shifted towards paralleling the x (duration) axis, that is, produces relatively small changes in C through a range of values for t. From this figure it can also be seen how the $n = 1$ curve is shifted towards paralleling the y (concentration) axis instead and yields relatively large changes in C through a smaller range of values for t. Thus these curves each address a different liability of duration extrapolation. The $n = 3$ curve serves to restrict extrapolation to higher concentrations when proceeding from longer to shorter durations. The $n = 1$ curve provides for a diminution of the $C \times t$ product when proceeding from shorter to longer durations.

A modification of **Figure 1** is presented below as **Figure 5**, highlighting the aspects and points discussed above. Curves corresponding to $n = 1$ and 3 are shown based on a hypothetical NOAEL of 100 ppm at a duration of four hours, which forms the intersection between

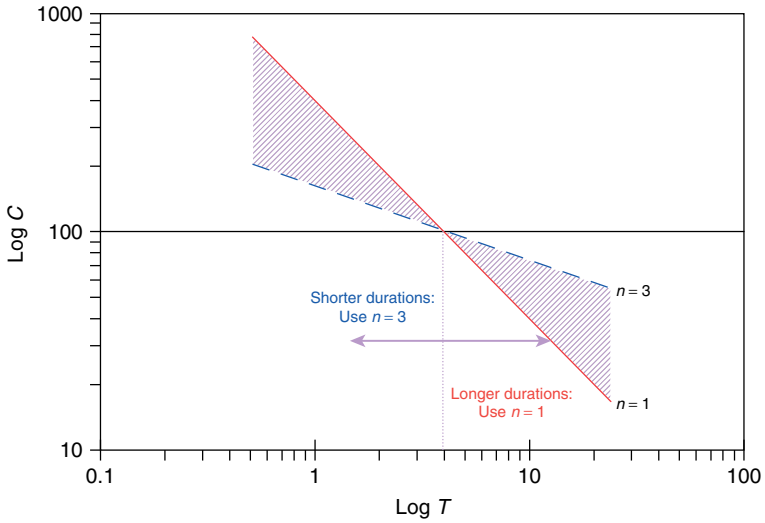

Figure 5 Duration extrapolation with a composite n in $C^n \times t = k$. The solid line corresponds to the $C \times t = k$ relationship at $n = 1$ (steep) and the dashed line at $n = 3$ (more shallow), which intersect at the duration indicated on the x-axis. The recommendation is to use the lower boundary of the shaded portion between these straight lines, using the portion of the line for $n = 3$ for shorter durations and the portion of the line for $n = 1$ for longer durations when extrapolating from observed data.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat173
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

these two curves. The areas of intersection between these curves have been crosshatched and may be described as follows. The area to the left of the common duration intersection is bounded on the lower portion by the $n = 3$ curve and on the upper portion by the $n = 1$ curve and corresponds to the progressively higher concentrations that would result from utilizing values of $n < 3$ in extrapolating from longer to shorter durations. The area to the right of the common duration intersection is bounded on the lower portion by the $n = 1$ curve and on the upper portion by the $n = 3$ curve. This area corresponds to the progressively lower concentrations that would result from utilizing values of $n > 1$ in extrapolating from shorter to longer durations. As discussed above, it is these hatched areas of extrapolation that are typically most problematic in defining a concentration–duration relationship, especially for purposes such as risk assessment and establishing health-effect reference values.

When represented in this manner it can be readily seen that, unless there are data to help elucidate the correct value of n, these problematic areas could be excluded from the extrapolation process by adopting a composite curve for extrapolation that would consist of a value of $n = 3$ for shorter durations and a value of $n = 1$ for longer durations. In extrapolating from longer to shorter durations, application of the lower portion of the $n = 3$ curve can be seen to result in less rapid rates of concentration increase than the corresponding portion of the $n = 1$ curve. In extrapolating from shorter to longer durations, application of the value of $n = 1$ curve can be seen to result in more rapid rates of concentration decrease than the corresponding portion of the $n = 3$ curve.

2.3.4 Implications and Use of Default

This composite curve would have considerable utility. As the values used are at the practical limits of n (1 and 3), the composite curve could be used to project and define the upper range of concentration and duration values that may be considered for purposes of investigating or establishing health-effect end points. This curve could also be reasonably adapted to serve as a manner by which a concentration–duration relationship could be established for a minimal-data situation. This approach has been adopted by the National Academies of Science's National Research Council (NRC, 2001) as a default procedure for establishing and bounding concentration–duration curves under conditions of minimal information (see *http://www.epa.gov/oppt/aegl/pubs/sop.pdf*).

3 DISCUSSION/SUMMARY

Considerable scientific attention has been given to both concentration and duration as aspects of dose in acute settings using the concept of toxic load (TL). The application of the TL concept in characterizing the amount of toxic material received and in the production of specified responses in a population has recently been reviewed (Sommerville *et al.*, 2006). Proponents of TL acknowledge the wide range of variables, including variance of the tested species/individuals due to underlying physiological and biochemical differences, batch effects, experimental error and character of exposure that may complicate the accurate estimation of a TL relationship. Efforts to more accurately estimate TL has lead to a series of models put forth or developed to consider one or more of these variables. TL models are all based more on empirical observations than on basic biological theories, including models described by Griffiths and Megson (1984) and Ride (1995). Also, sophisticated PBTK models highly parameterized to accommodate many of these variables can accurately predict empirical data, thereby implying the confounding role of these variables in the concentration–duration relationship (Bruckner *et al.*, 2004; Simmons *et al.*, 2005).

Rozman (2000) and others (Rozman *et al.*, 1996; Rozman and Doull, 2000; 2001; Doull and Rozman, 2000) have presented evidence that, in the absence of, or by mitigating, the confounding variables, such as those acknowledged by the proponents of TL, Haber's product $C \times t$ (i.e. $C^1 \times t = k$) may be the most precise relationship between the concentration and time components. With that acknowledgement, however, is counterposed that exposure to environmental chemicals routinely occurs under less than ideal conditions for matching a simple $C \times t$ relationship and those factors that force deviation from the ideal and are influencing the $C \times t$ relationship in some manner are not likely to be accounted for in real-world situations.

Whether acute exposures to toxic airborne agents occur to humans under occupational or nonoccupational scenarios, or to laboratory animals under controlled conditions, all are likely to be inclusive of elements of variability that will induce variance from the precise relationship between concentration and duration. It is on this basis that these case studies of empirical data are presented, along with the various methods and techniques for analysis and evaluation of their $C \times t$ relationship.

It may be instructive at this point to consider again the procedures employed and discussed above in addressing the situation when minimal information is available on which to derive $C \times t$ relationships, referred to herein as the n-boundary approach. Viewed generally, application of this approach reasonably advocates the use of values of n that are dependent on the temporal direction of the extrapolation; designating higher values of n such as 3 when extrapolating to shorter duration (to higher concentrations) and lower values of n such as 1 when

Table 4 A summary of empirical methods and approaches for use in characterizing the $C \times t$ relationship of toxicity responses

Method/ approach	Source	Description	Data requirement	Attributes	Limitations
PBTK models	Open literature	Highly sophisticated models capable of estimating internal dose at target tissues associated with response. Used for various purposes, including $C \times t$ relationships	Highly parameterized for a single data set	Highly sophisticated, accommodates many variables to characterize definitive $C \times t$	Information intensive. Requires many parameters to develop as well as duration-dose data for validation of model.
CatReg	*http://epa.gov/ncea/catreg*	US EPA version of categorical regression based on severity. Results from different studies, species and gender may be normalized based on severity category. Concentration– duration analysis conducted for any severity category	May utilize many data sets in an integrative analysis	Meta-analytic feature of categorization allows for extensive compilation and integration of data sets.	Requires extensive data analysis and documentation.
ten Berge (software)	*http://www.epa.gov/ncea/bmds/dwnldu.html#berge*—Excel least-square equations used for calculating trendlines from response data	Software version of ten Berge model	A single multipoint concentration–duration data set	Ease in application.	Analysis limited to single data sets.
BMD analysis	*http://epa.gov/ncea/bmds*	US EPA version of benchmark dose software	Preferred minimum of three data sets from which individual benchmark concentrations may be derived for three different durations.	For refined analysis of dose–response data and common response level when available for individual durations	Analysis limited to single data sets
n-Boundary	This work and *http://www.epa.gov/oppt/aegl/pubs/sop.pdf*	A version of $C^n \times t$ where the value of n is set based the temporal direction of extrapolation. Design and intent is to extent limit extrapolations to higher concentrations for shorter durations and to lower concentrations for longer durations	Minimum data. May be applied with a single initiating $C \times t$ data point for which response is defined	Ease in application. Results in low or conservative estimates of concentration, that is, those that likely err on the side of safety	High attendant uncertainity.

extrapolating from shorter to longer durations (to lower concentrations), in the absence of any chemical-specific information to help inform these extrapolations. This approach and reasoning, in which extremes of extrapolations resultant from temporal directions are minimized through assignment of values of n, could be considered as a means to accommodate data-based uncertainty and variability in the value of n such as encountered in these examples. The values of 1 and 3 used for n above were based on the historical range reported, mainly from the historical study of ten Berge *et al*. (1986) and others. Another option for a range of values that could be considered to fit this purpose would be to examine a range of empirically derived n values for use in extrapolation such that the higher or highest values of n be used in extrapolating from longer to shorter durations and the lower or lowest value of n be used in extrapolating from shorter to longer values. With the EO case study, for example, the n value of 1.7 would be used for extrapolating from shorter to longer durations and the n value of 1.2 would be utilized for extrapolating from shorter to longer durations.

As has been emphasized, however, any and all results from such procedures for evaluation of the $C \times t$ relationship need to be evaluated from the aspect of the entire database and information available for both reasonableness and appropriateness. As demonstrated above with phosgene, this evaluation applies to specifics of end points reported such that actual data sets may be justifiably modified for evaluating and refining the $C \times t$ relationship. This evaluation may apply to the overall character of certain end points. For example, results analyzing the response of sensory-based irritation (in humans), gives clear indications that exposure concentration has a proportionally greater effect for this end point than does exposure duration (see review by Shusterman *et al*., 2006). Other observations with this response indicates that this characterization may be even further complicated with time-effects disappearing or even reversing.

The methods and approaches presented in this work for evaluating $C \times t$ relationships are listed in **Table 4**. This listing of methods and approaches is provided as a set of tools, each tool useful for approaching specific situations requiring resolution and evaluation of $C \times t$ relationships. These tools are designed especially for use in acute inhalation scenarios and involving both lethal and nonlethal end points. It is also acknowledged that these approaches and methods are based largely on mathematical and statistical principals and only peripherally on any underlying biological models. It is hoped and anticipated, however, that application of these methods to various data sets may help in the syntheses of new hypotheses, whose testing would support existing biological theories on $C \times t$ relationships or provide a basis to formulate new ones.

Toxicological Considerations in Relation to the Regulatory Safety Evaluation of Medical Devices

Raju Kammula

CONTENTS

1 INTRODUCTION

Medical devices and their component materials are potential sources of toxins that may produce undesirable local and/or systemic toxic responses when used clinically. The evaluation of toxic responses of medical devices using various toxicological test methods is also called biocompatibility evaluation of medical devices. Biocompatibility evaluation of medical devices is carried out to determine that a device performs as intended and presents no significant harm to the patient or user. This assessment is generally considered to be the determination of the biological interaction of the medical-device materials with host tissues. This interaction should not result in a toxic, injurious or immunological response in the person receiving the device. Therefore a safe medical device

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat174
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

should be biologically compatible (biocompatibility) with the patient by not producing toxic responses.

Historically, evaluating the toxicity (biocompatibility) of medical devices has been a complex task. This complexity arises from the fact that devices are made of diverse range of materials and have various intended uses, with body contact ranging from transient skin contact to permanent implantation. The biocompatibility of medical devices is demonstrated by testing of device materials and their leachable chemicals and degradation products, using toxicological test methods.

The safety and effectiveness of medical devices marketed in the United States (USA) is regulated by the Center for Devices and Radiological Health (CDRH) of the US Food and Drug Administration (FDA). The medical devices marketed in the European Union (EU) are required to comply with EU Medical Devices Directive 93/42/EEC (EU, 1993), which specifies requirements for safety assessment. There are several national and international standards that address the toxicological evaluation of medical devices. In recent years the FDA—in particular, the CDRH uses and accepts toxicological data generated using the national and international biocompatibility standards to evaluate the safety of medical devices. The EU and Japan (Ministry of Health Labor and Welfare: MHLW, 2003 Notification No. 0213001) also uses and accepts toxicological data, generated using international standards.

This chapter is an introduction to a relatively new and rather complicated field in toxicology—the toxicological testing of medical devices. It discusses the toxicological considerations to establish the safety of medical devices to meet the requirements of regulatory agencies. The guidelines for testing of medical devices are discussed and a general description of the various test procedures are given. Developments in the field of biocompatibility regarding international harmonization and the potential for new methodologies are also addressed.

2 REGULATION OF MEDICAL DEVICES

In US the FDA is the regulatory agency primarily responsible for the regulation of medical devices. The Federal Food, Drug, and Cosmetic Act (1938) provided the first authority to the FDA to regulate devices because of the concerns about fraudulent or quack devices. The statue did not provide provisions for premarket clearance of medical devices, because of the belief that such products played little role in health care. As device technology developed, and devices such as Intrauterine devices, heart valves, vascular grafts, renal dialysis, and so on, became more important in health care, it was realized that devices should be subject to more comprehensive regulation, including premarket review. The 1976 amendments to the US Food, Drug and Cosmetic Act, provided FDA with authority to require that medical devices intended for human use demonstrate reasonable assurance of safety and effectiveness—including material toxicity (biocompatibility). The Safe Medical Devices Act (1990) and the Medical Device Amendments (1992) further amended the Act. Additional modifications resulted from the Food and Drug Administration Modernization Act (FDAMA) of (1997), which, among other important reforms, allowed FDA to recognize consensus standards including biocompatibility standards established by national and international standards-development organizations.

Medical devices to be marketed in the EU are required to comply with EU Medical Devices Directive 93/42/EEC (EU, 1993), which specifies requirements for safety assessment issues. The purpose of the directive is to promote a single European market for trade in medical devices, while ensuring that users and patients are not exposed to unnecessary risks.

3 CLASSIFICATION OF MEDICAL DEVICES IN THE UNITED STATES

The Medical Device Amendments of (1976) put into place a classification scheme for medical devices. The various types of devices are placed into one of three classes, depending on the degree of risk they present and the level of regulatory control needed to provide reasonable assurance of their safety and effectiveness.

Medical devices designated as Class I require the lowest level of regulatory control, and this designation is intended for those devices for which there is sufficient information to conclude that safety and effectiveness can be ensured by general controls alone. General controls provide enforcement authority for misbranding, adulteration, registration and listing, banned-device authority, consumer notification and recall, product reporting and good manufacturing practice (GMP).

Medical devices designated as Class II are devices for which general controls alone are not sufficient to ensure safety and effectiveness, but for which there is sufficient information to establish special controls to provide this assurance. Therefore, in addition to the provisions for general controls, these devices are subject to one or more special controls that may include performance standards, guidelines, patient registries or postmarket surveillance.

Class III devices entail the highest level of regulatory control. For such devices, there is insufficient information to demonstrate that either general or special controls can provide a reasonable assurance of safety and effectiveness. Because of a lack of valid scientific data, these devices present the most risk and are therefore subject to

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

general controls, as well as premarket approvals (PMAs) prior to marketing.

The requirements for medical devices to enter into commercial distribution in the USA vary according to the regulatory class of the device. Premarket notification (510(k)) and PMAs are the primary pathways to market for new devices, yet their regulatory requirements differ. All Class III devices are subject to PMAs, and must demonstrate a reasonable assurance of safety and effectiveness, as shown by valid scientific evidence. A significant-risk device that is not yet cleared for marketing through a 510(k) or approved through the PMA process can be tested in humans only when an investigational device exemption (IDE) application has been approved by the agency.

4 TYPES OF REGULATORY SUBMISSIONS TO THE FDA

4.1 Premarket Notification (510(k))

Unless exempt, Class I and Class II devices are subject to Section 510(k) of the FDAMA, which requires anyone wishing to introduce a device into commerce to notify the FDA at least 90 days in advance. A 510(k) notification is used to determine whether a new device is, or is not, substantially equivalent to a pre-amendments device or to a reclassified postamendments device. Substantial equivalence is based on an assessment of the device's intended use, technical characteristics and factors of safety and effectiveness. A new device that has been found to be substantially equivalent may be marketed immediately, whereas a new device that is not substantially equivalent may be marketed only through an approved PMA application. Devices reviewed under a 510(k) notification are not 'approved' by the FDA; rather, these devices are cleared for marketing as being substantially equivalent to legally marketed devices (Premarket Notification 510(k), 2008).

4.2 Premarket Approval (PMA)

All devices placed into Class III are subject to PMA requirements. A class III device is 'for use in supporting or sustaining human life or for a use, which is of substantial importance in preventing impairment of human health, or presents a potential unreasonable risk of illness or injury'. PMA is a process of scientific review to ensure the safety and effectiveness of Class III devices. A PMA submission must contain valid scientific evidence from which it can be concluded that there is reasonable assurance of the safety and effectiveness of the device under its conditions of use.

A PMA submission must have sections, among others, devoted specifically to laboratory, animal and clinical data. The laboratory and animal data sections must contain detailed descriptions of all laboratory and animal testing for the safety and effectiveness of the device performed by or for the applicant. This includes descriptions of materials of components, methods and results of analysis of contaminants and leachables and all *in vitro* and animal toxicology tests. Information on nonclinical laboratory studies must include a statement that each study was conducted in compliance with the Good Laboratory Practice (GLP) regulation (Good Laboratory Practice Regulations, 2008) or a statement of reason for noncompliance (Premarket Approval Application (PMA), 21 CFR 814, 2008).

4.3 Investigational Device Exemptions (IDEs)

A significant-risk device that is not yet cleared for marketing through a 510(k) or approved through the PMA process can be tested in humans only when an IDE application has been approved by the agency. A significant-risk device is one that presents a potential for serious risk to the health or welfare of a patient and is: (i) an implant, (ii) used in supporting or sustaining human life or (iii) substantially important in diagnosing, curing, mitigating or treating a disease, or in preventing impairment of human health. An IDE application must contain sufficient evidence of the device's safety, including results from toxicity tests and a reasonable expectation of effectiveness to warrant its testing in humans. Although non-significant-risk devices do not require an approved IDE application, they are still subject to the IDE regulation (Investigational Device Exemption (IDE), 21 CFR 812, 2008).

4.4 Product Development Protocols (PDPs)

Section 515(f) of the Federal Food, Drug and Cosmetic Act provides this alternative to the PMA process for Class III devices. An approved product development protocols (PDPs), established early in the device's development, defines the types of data and specific safety and performance levels that must be attained for market clearance. Marketing may commence following FDA verification that the device meets all safety and performance levels. This process allows FDA to effectively regulate Class III medical devices from initial development to marketing (Product Development Protocol (PDP), 21 CFR 814.19, 2008).

4.5 Humanitarian Device Exemption

The Safe Medical Devices Act of 1990 provides an incentive for the development of humanitarian-use devices (HUDs). An HUD is a device that is intended to benefit patients by diagnosing or treating a disease or condition affecting fewer than 4000 individuals in the United States per year—circumstances under which a device manufacturer's research and development costs for a product could exceed its market returns.

The humanitarian device exemption (HDE) application is similar in form and content to that for PMAs, but is exempt from the effectiveness requirements. Specifically, an HDE application is not required to include the results of scientifically valid clinical investigations demonstrating that the device is effective for its intended use. However, the application must contain sufficient information, including preclinical toxicology data, for the FDA to determine that the device does not pose unreasonable risks and that the probable benefits to health outweigh the risks (Humanitarian Use Devices, 21 CFR 814, sub part H, 2008).

5 BIOCOMPATIBILITY EVALUATION OF MEDICAL DEVICES

Biocompatibility evaluation of medical devices is performed to determine the potential toxicity of device materials resulting from contact of the device with the body. The device materials should not—either directly or through the release of their material constituents—produce adverse local or systemic effects, be carcinogenic, or produce adverse reproductive and developmental effects. Therefore, evaluation of any new device intended for human use requires data from systematic testing to ensure that the benefits provided by the final product will exceed any potential risks posed by device materials.

One of the first steps in the manufacture of a medical device involves the selection of suitable biocompatible materials. This is an essential step because the types of tests required for evaluation of a device depend on the physical and chemical nature of its materials in addition to the nature of the device's exposure to the body. A specific material may appear suitable on the basis of its physical properties, cost and availability, but might contain toxic chemical components. Therefore, it is prudent to perform full chemical characterization of the candidate materials at an early stage to eliminate those that have potential to release toxic leachable chemicals, and select those that are sufficiently biocompatible or nontoxic for their intended use.

Detailed chemical characterization of the device/materials, which includes identification and quantification of potential leachable chemicals and their potential toxicity will aid in the toxicity risk assessment of the device. It will also facilitate in many cases the elimination of some of the toxicological tests to evaluate the biocompatibility of the device. The International Standards Organization (ISO) standard 10993, Part 18 gives detailed guidance on performing chemical characterization of medical-device materials (ISO, 2005).

Many believe that the FDA and other regulatory agencies, in addition to regulating devices themselves, approve the materials used in medical products and maintain a list of approved or acceptable biomaterials. In a very few instances, biomaterials are used as final products (e.g. injectable collagen, certain dental composites or bone cements); in such cases the FDA regulates these materials as devices. But, in general, the FDA neither approves materials nor maintains a list of approved materials (Kammula and Morris, 2001).

The suggested toxicologic/biological tests to evaluate the biocompatibility of medical devices include cytotoxicity, acute systemic toxicity, subchronic and chronic toxicity; irritation to skin, eyes and mucosal surfaces; sensitization; haemocompatibility; short-term implantation effects; genotoxicity; and carcinogenicity and effects on reproduction, including developmental effects. However, in certain cases, depending on the varying characteristics and intended uses of devices, as well as the nature of their body contact, these general tests may not be sufficient to demonstrate the safety of some specialized devices. Additional tests for specific target-organ toxicity—such as neurotoxicity and immunotoxicity—may be necessary for some devices. For example, a neurological device in direct contact with brain parenchyma and cerebrospinal fluid (CSF) may require an animal implant test to evaluate its effects on the brain parenchyma, propensity to induce seizure, or effects on the functional mechanism of the choroid plexus and arachnoid villi to secrete and absorb CSF. Thus, the specific clinical application of the new device determines which tests are most appropriate (FDA, 1995).

6 GUIDANCES AND STANDARDS TO EVALUATE BIOCOMPATIBILITY OF MEDICAL DEVICES

In 1986, the FDA, Health and Welfare Canada, and Health and Social Services UK issued first guidance to evaluate the biocompatibility of medical devices, the Tripartite Biocompatibility Guidance for Medical Devices. This Guidance has been used by FDA reviewers, as well as by manufacturers of medical devices, in selecting appropriate tests to evaluate the adverse biological responses to medical devices. Since that time, the ISO, in an effort to harmonize biocompatibility testing, developed a standard for biological evaluation of medical

Table 1 The ISO standard 10993, consists of the following parts[a], under the general title Biological Evaluation of Medical Devices

—Part 1: Evaluation and testing
—Part 2: Animal welfare requirements
—Part 3: Tests for genotoxicity, carcinogenicity and reproductive toxicity
—Part 4: Selection of tests for interactions with blood
—Part 5: Tests for *in vitro* cytotoxicity
—Part 6: Tests for local effects after implantation
—Part 7: Ethylene oxide sterilization residuals
—Part 8: Selection and qualification of reference materials for biological tests
—Part 9: Framework for identification and quantification of potential degradation products
—Part 10: Tests for irritation and sensitization
—Part 11: Tests for systemic toxicity
—Part 12: Sample preparation and reference materials
—Part 13: Identification and quantification of degradation products from polymeric medical devices
—Part 14: Identification and quantification of degradation products from ceramics
—Part 15: Identification and quantification of degradation products from metals and alloys
—Part 16: Toxicokinetic study design for degradation products and leachables
—Part 17: Establishment of allowable limits for leachable substances
— Part 18: Chemical characterization of materials

[a]Future parts will deal with other relevant aspects of biological testing.

devices (ISO 10993). The scope of this 18-part standard is to evaluate the effects of medical device materials on the body (**Table 1**). The first part of this standard 'Biological Evaluation of Medical Devices: Part 1: Evaluation and Testing', provides guidance for selecting the tests to evaluate the biological response to medical devices. Most of the other parts of the ISO standard deal with appropriate methods to conduct the biological tests suggested in Part 1 of the standard.

The ISO Standard, Part 1, uses a similar approach to Tripartite Guidance in style, format and content. It uses a tabular format (matrix) for laying out the test requirements based on the various factors discussed above. It sets forth several fundamental principles similar to those in Tripartite Guidance (**Table 2**) for the evaluation of medical devices and provides a framework for their application. This part of the standard divides medical devices into three main categories: surface devices, externally communicating devices and implant devices. Each category is further divided into subcategories according to the type of contact the patient is exposed (**Table 3**). The selection of appropriate tests for a device in a given category depends also on the duration of contact. Three different time periods are given: limited contact (<24 hours), prolonged contact (24 hours to 30 days) and permanent contact (>30 days). The standard lists a series of biological tests that must be considered for each category in a test matrix to demonstrate a particular device is safe for its intended use (**Table 3** and **Table 4**). These tests include *in vitro* cytotoxicity, dermal irritation and intracutaneous reactivity, skin sensitization, acute systemic toxicity, subchronic toxicity, chronic toxicity, carcinogenicity, mutagenicity, implantation and haemocompatibility.

Parts 2 to 18 of ISO 10993 contain guidelines and test methods to conduct various recommended tests. In some cases, parts 3 to 18 are specific and prescriptive, whereas others provide general directions and crossreference more standards and published test methods.

Most of the participating countries in the ISO harmonized the requirements or modified the standards to mesh with the regulatory infrastructure and their national standards. The EU retained many of the standards as harmonized, since these standards meet the EU Medical Devices Directive 93/42/EEC (EU, 1993), which specify requirements for safety assessment. Japan adopted ISO 10993-1 as published, but made some changes in the conduct of the individual biological tests (MHLW, 2003).

7 THE FDA BIOCOMPATIBILITY REQUIREMENTS AND USE OF STANDARDS

Section 204 of the FDAMA of 1997, allows the FDA to recognize consensus standards established by national and international standards-development organizations. There are several national and international

Table 2 Principles for the evaluation of medical devices

1. The selection and evaluation of any material or device intended for humans requires a structured biological evaluation programme. The biological evaluation shall be planned, carried out and documented by knowledgeable and experienced individuals capable of making informed decisions.
2. The evaluation programme shall include documented informed decisions that assess the advantages/disadvantages and relevance of: (i) the physical and chemical characteristics of various candidate materials; (ii) any existing toxicology and other biological safety data on product and component materials, breakdown products and metabolites; (iii) any history of clinical use or human exposure data and (iv) test procedures.
3. In the selection of materials to be used in device manufacture, the first consideration should be fitness for the purpose with regard to characteristics and properties of the material, which include chemical, toxicological, physical, electrical, morphological and mechanical properties.
4. The following should be considered for their relevance to the overall biological evaluation of the device: (i) the material(s) of manufacture; (ii) intended additives, process contaminants and residues; (iii) leachable substances; (iv) degradation products; (v) other components and their interactions in the final product; (vi) the performance and characteristics of the final product and (vii) physical characteristics of the final product, including but not limiting to, poracity, particle size, shape and surface morphology.
5. The choice of tests and the data required in a biological evaluation, and their interpretation, should take into account the chemical composition of the materials, including the conditions of exposure as well as the nature, degree, frequency and duration of exposure of the medical device or its constituents to the body, enabling the characterization of devices to facilitate the selection of appropriate tests. The rigour necessary in the biological evaluation is principally determined by the nature, degree duration and frequency of the exposure and the toxicological hazards identified for the material.
6. All potential biological hazards should be considered for every material and final product, but this does not imply that testing for all potential hazards will be necessary or practical. The range of possible biological hazards is wide and can include short-term effects such as acute toxicity, irritation to the skin, eye and mucosal surfaces, haemolysis and thrombogenicity, as well as long-term or specific toxic effects such as subchronic and chronic toxic effects, sensitization, genotoxicity, carcinogenicity and effects on reproduction including teratogenicity.
7. Selection of any *in vivo* and *in vivo* tests should be based on end-use applications. Appropriate good laboratory practices should be applied in the conduction of tests and competent informed persons should evaluate the test data. Whenever possible, *in vitro* screening should be carried out before *in vivo* tests. Test data, complete to the extent that an independent analysis could be made, shall be retained.
8. The materials or final product should be considered for biological re-evaluation if any of the following occurs: (i) any change in the source or in the specification of the materials used in the manufacture of the product; (ii) any change in the formulation, processing, primary packaging, or sterilization of the product; (iii) any change in the final product during storage; (iv) any changes in the intended use of the product and (v) any evidence that the product may produce adverse effects when used in humans.
9. The biological evaluation should take into account the nature and mobility of the chemical constituents in the materials used to manufacture the device and other information, other non-clinical test, clinical tests and post-market experience for an overall assessment.

consensus standards that address the biological evaluation of medical devices to evaluate their toxicity. Such standards are typically developed by consensus, with the participation of industry, healthcare professionals and academic and government scientists.

The CDRH recognizes those standards that help provide a reasonable assurance of the safety and effectiveness of medical devices and do not conflict with any legislation or regulation under which the Center operates. Therefore, information submitted regarding conformance with recognized standards would have a direct bearing on the evaluation of biological safety made during the review of IDEs, HDEs, PMAs and PDPs. In the case of 510(k)s, information on conformance with CDRH-recognized consensus standards may help establish substantial equivalence of a new device with a legally marketed device.

If a manufacturer elects to conform to a recognized consensus standard to satisfy premarket review requirements, the manufacturer must submit either a declaration of conformity to the standard or state how conformance to that standard will be achieved. When acceptance criteria are clearly specified by a standard, the FDA's need to review actual data is eliminated. However, the manufacturer must maintain all records relating to the conformity to the standard for a period of two years after approval, or for the expected lifetime of the device, whichever is longer.

		B	X	X	X	X	X	X	X	X
		C	X	X	X	X	X	X	X	X

This table is a framework for the development of an assessment programme and is not a checklist.
X indicates data end points that can be necessary for a biological safety evaluation, based on a risk analysis, where existing data are adequate, additional testing is not required (ISO 10993-1).
O additional tests, may be applicable in U. S. (FDA Bluebook Memorandum #G95-1)
[a]Tissue includes tissue fluids and subcutaneous spaces.
Reproduced from the FDA, 1995.

Conformance with recognized consensus standards in itself, however, may not always represent a sufficient basis for regulatory decisions. A specific device may raise additional safety or effectiveness issues not addressed by a recognized consensus standard, or FDA regulations may require additional information beyond what the consensus standard provides. Under such circumstances, conformity with a recognized standard will not satisfy all requirements for investigating or marketing the product in the United States.

This table is a framework for the development of an assessment programme and is not a checklist.
X indicates data points that can be necessary for biological safety evaluation, based on a risk analysis, where existing data are adequate, additional testing is not required (ISO, 2003).
O additional tests, which may be applicable in the USA FDA, 1995.
[a]Tissue includes tissue fluids and subcutaneous spaces.
Reproduced from FDA, 1995.

For example, as noted above, even though the FDA have recognized Part 1 of ISO 10993-1, dealing with biological test selection, the standard does not address several tests required to evaluate devices contacting nervous-system tissue and devices that may affect the immune system. Therefore, many of these devices, if tested according to ISO 10993-1 alone, could raise additional safety issues not addressed by the standard.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat174
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Figure 1 Decision flowchart for reviewers performing biocompatibility evaluations for the 510(k) process. (Reproduced from FDA, 1995.)

The modifications documented in the FDA's Blue Book Memorandum (FDA, 1995), address these additional safety concerns.

The Blue Book Memorandum contains an FDA-modified matrix (**Tables 3** and **4**) designating additional tests that may be needed for various device categories—and recommending specialized testing for neurotoxicity and immunotoxicity of certain devices. It also includes a decision flowchart for the selection of toxicity tests for 510(k)s (**Figure 1**).

The flowchart was designed to help FDA reviewers to determine whether the biocompatibility information provided in a 510(k) submission for a device under review is sufficient. The flowchart helps reviewers in the determination of substantial equivalence by directing them to specific review criteria about device materials, their chemical composition, manufacturing processes and sterilization methods. The chart also advises reviewers to consult device-specific guidances and, if necessary, to seek assistance from senior toxicologists in the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat174
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Center, as well as to consider information from other sources, such as master files and published literature. In addition, reviewers are advised to consider any scientific or risk-analysis justifications for not conducting some of the suggested tests. Finally, if the data and analyses provided do not resolve all the questions concerning the biocompatibility of a subject device, the chart advises reviewers that additional toxicology testing is required and that such testing should be conducted according to the FDA-modified test matrix (FDA, 1995).

The FDA has also recognized other parts of ISO 10993, several of which contain protocols for carrying out the tests suggested in Part 1. In addition, the FDA has recognized several standards developed by the United States Pharmacopeia (USP) and the American Society for Testing and Materials (2008) that present specific protocols for conducting various biological tests. A list of these recognized standards and the dates they were recognized, together with information detailing the extent of their recognition by the FDA, can be obtained from the CDRH web site (*http://www.fda.gov/cdrh/stdsprog.html*). Also available on the site is supplemental information on the data requirements or modifications for particular standards that may be necessary to support the regulatory requirements of premarket submissions. Often, recognized standards entail test protocols, which the Center may recognize; however, if the standard does not include any acceptance or rejection criteria for the assessment of test results, it is necessary for the manufacturer to submit the actual data for assessment by the Center's review staff (FDA, 1995).

8 TOXICOLOGY TESTING OF MEDICAL DEVICES

This section will address the toxicology testing methods commonly used to evaluate biocompatibility of medical devices and their materials. For detailed methods and protocols for the tests discussed, the reader should consult the numerous published references.

Medical devices and their component materials are potential sources of toxins that may produce undesirable local and systemic effects when used clinically. Therefore, evaluation of any new device intended for human use requires systematic testing to ensure that the benefits provided by the final product will exceed any potential risks produced by device materials.

Medical devices are primarily made from high-molecular-weight polymers, metals and ceramics held together by screws, clips, adhesives and heat seals. They, in general, tend to be solids and do not achieve their intended activity by chemical action within or on the body. Most components of medical devices contain mixtures of polymers, and additives, such as catalysts, antioxidants, colourants, plasticizers, stabilizing agents and lubricants. In addition they also contain residual products of sterilization.

The toxicological testing of device materials has unique constraints, which limit the applicability of classical protocols and procedures. Classical protocols are designed to obtain quantitative dose–response data on pure chemicals and drugs. In the case of synthetic device materials, complete chemical composition is often not available. In addition, synergistic reactions among the components can cause a toxic reaction, even though the individual additives are considered nontoxic. In general, the toxicity testing of device/materials is directed towards the assessment of the potential toxicity of the device/material under specific conditions, particularly under end-use conditions. The relative significance of acute, subacute, subchronic and chronic toxicological responses to the health of patients has been established for drugs and chemical agents, and it is in that context that empirical toxicological data generated on the devices and their materials should be assessed.

Logically, the toxicity testing should take place at two points in the development of medical devices. First, as soon as the material is identified as a candidate material and second, as soon as end-use configuration of the material is determined and the final device is available for testing. As stated earlier, end-use testing of a device will carry certain constraints unique to the final configuration and application of the device. Sterilization may degrade the device material or react with nontoxic additives in the device to increase the toxic potential of the device; therefore all toxicity testing should be done on the final sterilized device.

The process of obtaining the toxicity profile of a medical device may require various modifications to standard or classic toxicity testing procedures, as well as utilizing new and innovative approaches. In practice the toxicity profiles of medical devices is obtained by conducting a battery of toxicity tests which include acute, subchronic and chronic toxicity; irritation to skin, eyes and mucosal surfaces; sensitization; haemolysis; thrombogenicity; genotoxicity; carcinogenicity; and effects on reproduction, including developmental effects. However, depending on varying characteristics and intended uses of devices, as well as the nature of contact, these general tests may not be sufficient to demonstrate the safety of some specialized devices. Additional tests for specific target-organ toxicity, such as neurotoxicity and immunotoxicity may be necessary for some devices. Also, for some implanted devices, a material-mediated pyrogenicity test in rabbits is suggested. The specific clinical application of the new device determines which tests are more appropriate (FDA, 1995).

9 TEST ARTICLE AND SAMPLE PREPARATION

Before selecting the test methods it is important to decide what the test article really is, since medical devices are very complex, with many components, primarily made from high-molecular-weight polymers, metals and/or ceramics held together by screws, clips, adhesives and heat seals. The ideal test sample is the intact medical device that has been processed and sterilized in the same manner as the medical device that will be used in humans. It is however, not always practical to use the intact medical device because of the design constraints inherent in the biological test methods. In cases where a medical device comprises several components made from different materials, the ideal and practical procedure from a toxicological point of view would be to test extracts of the components separately. In some cases, however, an evaluation under normal-use conditions is mimicked by using the device or a piece of the device directly. When extracts are tested, the extraction media should constitute both polar and nonpolar solvents to ensure the extraction of components of widely different solubility properties. The most commonly used extraction media are physiological saline, vegetable oil, dimethylsulfoxide and ethanol. Other extraction media such as polyethylene glycol (PEG) or aqueous dilutions of ethanol may be selected in certain cases. For *in vitro* cytotoxicity testing, complete cell-culture medium is most often employed.

The extraction temperatures vary depending on the physicochemical properties of the device materials. Some leachable compounds may be chemically altered at high temperatures and it is now generally recommended that extraction be conducted at 37 °C, simulating body temperature, for 72 hours. However, depending on the nature of the device materials, higher temperatures (50 °C for 72 hours, 70 °C for 24 hours and 121 °C for one hour) have been used to exaggerate extraction process. For *in vitro* cytotoxicity tests, extraction at 37 °C for 24 hours is usually recommended, since certain constituents of the media are relatively labile.

The amount of leachable substances released in to the extraction media is also related to the surface area and thickness of the product to be extracted. The ratio of surface area to the volume of the extracting fluid varies depending on the size and shape of the product. When surface area cannot be determined due to the configuration of the specimen, it is recommended to use of 0.1 g of elastomer or 0.2 g of plastic or other polymer for every 1 ml of extracting fluid. Generally moulded elastomeric closures are tested intact. For a better understanding of extraction principles and methods, refer to the US Pharmacopeia (2008a) and ISO 10993 Part 12 Sample preparation and reference materials (ISO, 2006e).

10 TOXICITY TESTS FOR BIOLOGICAL EVALUATION

10.1 Cytotoxicity

The aim of *in vitro* cytotoxicity tests is to detect the potential ability of a device or its materials to induce sublethal or lethal effects, such as lysis of cells (cell death), the inhibition of cell growth, colony formation and other effects, as observed at the cellular level. Three types of cell-culture assays that are commonly used to screen medical devices and materials; the elution test, the direct-contact test and the agar diffusion test. These methods are known to be sensitive, economical and quick to conduct. Several types of cell cultures are available for testing; two cell strains, L-929 and Wl-38, are most commonly used. The ISO 10993 standard, Biological Evaluation of Medical Devices—Part 5: Tests for *in vitro* cytotoxicity (ISO, 1999a), gives a detailed description of all three methods. In the elution test, an extract (elute) of the material is prepared and added in varying concentrations to the cell cultures. Growth inhibition is a widely used parameter, but others may also be used. In the direct-contact test, pieces of test material are placed directly on top of the cell layer, which is covered only by a layer of liquid cell-culture medium. Toxic substances leaching from the test material may depress the growth rate of the cells or damage them in various ways. In the agar diffusion test, a piece of test material is placed on an agar layer covering a confluent monolayer of cells. Toxic substances leaching from the material diffuse through the thin agar layer and kill or disrupt adjacent cells in the monolayer. The selection of an appropriate test method is based on the physical and chemical properties of the test material and the potential clinical use of the device.

There is usually a good qualitative correlation between results from cell-culture tests and studies performed *in vivo* with respect to cytotoxicity vs. primary tissue effects. It is important to recognize, however, that although cell-culture toxicity is, in general, a good and sensitive indicator of primary tissue compatibility, exceptions may arise in cases where leaching substances cause tissue damage *in vivo* through more complex mechanisms. At present, the *in vitro* cytotoxicity assays are used as screening tests and considered primarily as supplements to the various *in vivo* tests.

10.2 Irritation

The ISO 10993 standard, Biological Evaluation of Medical Devices-Part 10: Tests for irritation and delayed-type hypersensitivity (ISO, 2002) describes irritation tests for both single and repeat-use exposure to a device. Based on the route of exposure irritation,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat174
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

tests are subclassified into, skin, intracutaneous, eye and mucus membrane irritation tests. The preferred animal species for irritation tests is the albino rabbit, whose highly sensitive, light skin makes it possible to detect even very slight skin irritation caused by a substance. Skin-irritation tests of medical devices are performed with two extracts obtained with polar and nonpolar solvents or with the device material itself. In the single-exposure test, rabbits are treated for several hours, whereas for the cumulative or repeat-use test, the same procedure is repeated for several days. All extracts and extractants are applied to intact skin sites. Skin reaction is seen as redness or swelling and is graded according to a specified classification system.

In the primary skin irritation study, patches of device materials are applied to fur-free skin of six rabbits. However, for most topically used devices, three rabbits consistently showing little or no response is adequate proof that dermal irritation is not a potential hazard. If the results are equivocal, three additional rabbits can be added, for analysis of a large sample (Derelanko *et al*., 1993). For medical-device materials, the occluded patches should stay for 24 hours. The treated skin should be observed for erythema and oedema at 1, 24, 48 and 72 hours after the removal of the patches. A primary skin-irritation index is calculated by adding all scores and dividing by the number of dosed sites.

The intracutaneous injection test, described in the US Pharmacopeia (USP, 2008b) is widely used. This test, conducted in rabbits, simulates the irritation which can occur in humans upon exposure of breached skin to a foreign irritating device or when a device is introduced subcutaneously. The test measures signs of inflammation as erythema, oedema, ulceration and necrosis. Device extracts are injected into the skin and the degree of irritation is measured at 24, 48 and 72 hours. Skin reactions are scored and evaluated, based on the severity of erythema and oedema.

Mucus membrane irritation assays are used to evaluate dental and personal hygiene devices (Chvapil *et al*., 1979; Eckstein *et al*., 1969). Eye irritation assays are used in evaluating contact lenses, and other devices that contact the ocular tissue (FDA, 1988). ISO 10993-10 (ISO, 2002) provides detailed guidance for mucusmembrane irritation assays.

10.3 Sensitization

Sensitization assays are described in ISO 10993 standard, Biological Evaluation of Medical Devices—Part 10: Tests for irritation and delayed-type hypersensitivity (ISO, 2002). The sensitization reaction is also known as allergic contact dermatitis, which is an immunologically mediated cutaneous reaction. This is in contrast to irritant contact dermatitis (skin irritation)—a skin reaction caused by the primary and direct effect of a substance on the skin. In animals, the sensitization reactions manifest themselves as redness (erythema) and swelling (oedema).

The preferred animal species for sensitization testing is the albino guinea pig. All available guinea-pig methods have certain features in common: an induction (sensitization) phase, when the potential allergen is presented to the organism, followed by a rest period, and a subsequent challenge phase to determine whether or not sensitization has occurred. One of the most recognized and validated assays is the guinea-pig maximization test (GPMT). The GPMT (Magnusson and Kligman, 1969) is widely used for assessing the sensitizing potential of medical devices/materials. In the maximization test, both polar (saline) and nonpolar (vegetable oil) extractions are prepared from devices or component parts of the device according to methods described in ISO 10993-12 (ISO, 2006e) and USP 31 (US Pharmacopeia, 2008b). During the induction phase of the test, the animals are treated with intradermal injections and topical application of the extract alone, the adjuvant alone, and the extract and adjuvant mixture. A minimum of 10 animals are used with each extract and a minimum of five animals are maintained as untreated controls. A week later, the same site is pretreated with a surfactant, sodium lauryl sulfate to eliminate any skin barrier to a topical patch of the material extract to be applied at the same site on the following day. Two weeks after the second induction, the test animals, as well as animals in the control group for each extractant, are challenged with a topical application of the appropriate extract to the flank and covered with an occlusive patch for 24 hours. Skin reactions at the test site are rated for erythema and oedema at 24, 48 and 72 hours after application of the extract. A positive reaction at the test site not observed at the control site could be indicative of sensitization reaction.

The second commonly used method is the repeated-patch test published by Buehler (1965). In this test the material to be evaluated is cut into 2.5×2.5 cm sections for each patching. Liquids, gels and pastes are applied as a 0.5 ml or 0.5 g dose. A group of 10 animals is patched either three times in one week or once a week for three weeks. Each treatment consists of six hours occluded patching. After a week recovery period, all test and control animals are challenged by topical patching. Any response, such as redness and swelling seen in the test animals, but not seen in control animals is indicative of sensitization reaction.

Predictive tests in guinea pigs are important tools in identifying the possible hazards to a population repeatedly exposed to a substance. Nevertheless, results from sensitization tests in guinea pigs have to be evaluated carefully. A positive test result in this assay may rate a substance as a stronger sensitizer than it appears to be during actual use. On the other hand, a negative result in such a sensitive assay ensures a considerable safety margin regarding the potential risk to humans.

DOI: 10.1002/9780470744307.gat174
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Recently, an alternative test method, the mouse local lymph node assay (LLNA), was developed to replace the use of guinea pig sensitization test to identify potential sensitizing materials (Kimber *et al*., 2002). The basic principle underlying the LLNA is that sensitizers induce proliferation of lymphocytes in the lymph node draining the site of chemical application, and this proliferation is proportional to the dose applied, providing a means of obtaining an objective, quantitative measurement of sensitization.

This method has been validated for chemicals, both in the USA and Europe by the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) and European Committee on the Validation of Alternative Methods (ECVAM) respectively. However, it has not been validated for chemical mixtures and metals; therefore, at present its utility in the evaluation of medical devices/materials is limited.

10.4 Acute Systemic Toxicity

Acute systemic toxicity is an adverse effect occurring within a short time (less than 24 hours) after administration of a single dose of a substance. Systemic toxicity assays for medical devices are listed in ISO 10993 standard, Biological Evaluation of Medical Devices—Part 11: Tests for Systemic Toxicity (ISO, 2006d). The standard covers tests for single (acute) and repeated-dose toxicity and contains a list of recommendations for other standard tests for oral, dermal, intravenous, intraperitoneal and inhalational routes of administration. Single-dose (acute) systemic toxicity tests are designed to determine if the leachable materials induce mortality, body-weight changes or clinical signs of toxicity. The acute-toxicity test in mice, which is described in the US Pharmacopeia 31 (2008c), is commonly used to evaluate medical devices. In this test, the test material is extracted in 0.9% saline, 5% ethanol in saline, vegetable oil and PEG 400. The first two extracts are injected intravenously and vegetable oil and PEG 400 extracts are injected intraperitoneally into mice. Animals are observed for a minimum of three days. Adverse reactions generally appear within the first 24 hours after dosing. Clinical signs such as lethargy, hyperactivity, convulsions, body-weight loss and death are some of the parameters monitored and compared to a vehicle control group of mice.

Determining acute systemic toxicity is usually an initial step in the assessment and evaluation of the toxic characteristics of a substance. By providing information on health hazards likely to arise from short-term exposure, the acute systemic toxicity test can serve as a first step in the establishment of a dosage regimen in subchronic and other studies, and can also supply initial data on the mode of toxic action of a substance.

10.5 Genotoxicity

Genotoxicity assays are described in ISO 10993 standard, Biological Evaluation of Medical Devices—Part 3: Tests for Genotoxicity, carcinogenicity and reproductive toxicity (ISO, 2006a). Genetic toxicology tests are used to investigate device materials for possible mutagenic effects—that is, damage to the body's genes or chromosomes. Mutagenesis can occur as a result of interaction between mutagenic agents and the genetic material of the organism. Mutations can be classified into two general types: gene mutations and chromosomal mutations. Gene mutations are changes in nucleotide sequences at one or several coding segments within a gene; chromosomal mutations are morphological alterations or aberrations in the gross structure of the chromosomes. The tests that are used to evaluate the genetic toxicity are diverse and include *in vitro* tests using micro-organisms and cells from multicellular animals, as well as *in vivo* tests using insects, plants and mammals. Both *in vitro* and *in vivo* tests can be further grouped, on the basis of the end point detected, into three major groups: (i) forward and reverse mutations (e.g. point mutation, deletion mutation, etc.), (ii) clastogenicity assays detecting structural and numerical changes in chromosomes (e.g. chromosome aberrations, micronuclei, etc.) and (iii) the assays that identify DNA damage (e.g. DNA strand breaks, unscheduled DNA synthesis (UDS), etc.). For medical devices, the ISO standard recommends *in vitro* testing in one nonmammalian system (bacterial) and two mammalian cell systems, for effects on DNA, gene mutations and chromosomal aberations. Assays may be performed with extracts of the device materials. Physiological saline and dimethyl sulfoxide are recommended as extracting media. The extracts are prepared at 37 °C for a minimum of 24 hours using the highest possible surface area (ISO, 2006a). The ISO 10993-3 standard (ISO, 2006a) recommends the test methods published by the Organization for Economic Cooperation and Development (OECD) for chemicals.

The standard recommends the Ames assay, the most widely used genotoxicity test, which uses *Salmonella typhymurium* strains for screening potential carcinogens (OECD, 1981). This is one of the established tests in which large number of chemicals representing a variety of chemical classes have been tested. It is a very sensitive assay to determine the potential of a test material to induce the genetic mutation of histidine reversion using five strains of *Salmonella typhymurium* (TA 98, TA 100, TA 1535, TA 1537 and TA 102) that are sensitive to DNA-damaging agents in the presence or absence of the S-9 mammalian microsomal enzyme.

The standard also recommends several *in vitro* mammalian cell systems to detect gene and chromosome mutations. It specifically recommends the mouse lymphoma assay (OECD, 1997c), incorporating colony

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat174
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

number and size determination in order to cover both end points (clastogenicity and gene mutations). It also recommends an *in vitro* mammalian cytogenetic test for clastogenicity. If any of the *in vitro* tests are positive, the standard recommends an *in vivo* test on the basis of most appropriate end point identified in the *in vitro* tests. The *in vivo* tests have advantage of taking into account absorption, distribution and excretion, processes that are not functional *in vitro* systems. The most commonly used *in vivo* tests are the micronucleous test in rodents (OECD, 1997a), the metaphase analysis in rodent bone marrow (OECD, 1997b) and the UDS test with mammalian liver cells *in vivo* (OECD, 1997d).

10.6 Implantation

Implantation tests are designed to assess acute and long-term *in vivo* tissue reaction to device materials. It is considered one of the most pertinent and direct tests to evaluate device materials and their leachable components. When a device material is implanted into a muscle or subcutaneous tissue, leachable components from the implant diffuse into surrounding tissue and the severity of the tissue response depends on the toxic nature of the leachables. Tissue samples taken from the implanted site are evaluated by macroscopic and microscopic examination for the nature and degree of inflammatory responses around the implant site. These responses are compared with the tissue response caused by an established standard reference material. Most of the implantation methods used are based on the original US Pharmacopeia rabbit muscle method (US Pharmacopeia, 2008f) which lasted only three to five days, the implant tests used to study the effects of various device materials may be conducted for any length of time up to the lifespan of the animal. The biological parameters assessed include: the presence of inflammatory cells, such as polymorphonuclear leukocytes, lymphocytes, plasma cells, macrophages and giant cells. In addition, tissue changes such as necrosis, neovascularization, fibrosis and fatty infiltration are evaluated.

In cases where an implanted material degrades *in vivo*, a delayed response may occur; for this reason subchronic and chronic implantation tests are carried to study the effects of potential degradation products of the material.

ISO 10993 standard, Biological Evaluation of Medical Devices—Part 6: Tests for local effects after implantation (ISO, 2006c), contains a description of general guidelines and more detailed descriptions of methods for implantation in subcutaneous tissue, muscle and bone. The standard gives guidance on the implantation of solid degradable and nondegradable materials, as well as nonsolid materials such as liquids, pastes and particulates.

10.7 Haemocompatibility

The purpose of haemocompatibility testing is to look for possible undesirable changes in the blood caused directly by a medical device or chemicals leaching from a device. Undesirable effects of device materials on the blood may include haemolysis, thrombus formation, alterations in coagulation parameters and immunological changes. ISO 10993 standard, Biological Evaluation of Medical Devices—Part 4: Selection of tests for interaction with blood (ISO, 2006b) gives guidance for evaluating interaction of medical devices with blood. The standard lists recommended test methods to evaluate blood–device interactions for devices externally communicating with the blood path, for devices communicating with circulating blood and for implanted devices in the cardiovascular system. Haemocompatibility test methods are categorized by the primary process or system being measured, as thrombosis, coagulation, plates and platelet functions, haematology and immunology.

10.8 Subchronic Toxicity

Subchronic toxicity is the potentially adverse effect that can occur as a result of the repeated daily dosing of a substance to experimental animals over a period of time, up to 10% of their lifespan. In the assessment and evaluation of the toxic characteristics of a chemical, the determination of subchronic toxicity is carried out after initial information on toxicity has been obtained by acute testing, and provides data on possible health hazards likely to arise from repeated exposures over a limited time. Such testing can furnish information on target organs and the possibilities of toxin accumulation, and provide an estimate of a no-effect exposure level that can be used to select dose levels for chronic studies and establish safety criteria for human exposure. The route of exposure and the length of exposure depends on the animal model to be used. No standard protocols exist for subchronic evaluation of medical devices. The ISO standard 10993 Part 11: Tests for systemic toxicity (ISO, 2006d), references several classical toxicology methods that have been established for the safety evaluation of drugs and chemicals. Modifications to the established methods are necessary to make them applicable to devices.

In subchronic toxicity studies using established methods for drugs and chemicals, one or two animal species are dosed daily, usually for a period of three to six months; the rat is the standard animal species

of choice. The animals are given the test substance in increasing doses. The dose level of the low-dose group should be at the level of human exposure. When extracts of medical devices are employed, one dose level (the highest practically applicable volume) is often sufficient, since strong toxicity is generally not expected. Therefore, in general, subchronic studies are conducted with one test and one control dose level.

One key element to keep in mind in the design of subchronic test protocols for medical devices is that the treatment or implant should mimic the end use. In repeated exposure (extracts) or constant exposure (implants) studies, evaluation of both local and systemic adverse effects should be part of the study design. The implant studies that have both test and control materials implanted in the same animal to study the local effects of the device are not acceptable as true systemic subchronic studies.

10.9 Chronic Toxicity

ISO 10993, Part 11: Tests for systemic toxicity (ISO, 2006d), gives guidance to conduct chronic systemic toxicity of medical devices, but it provides no test protocols or references to conduct chronic toxicity studies. Chronic toxicity is defined as effects of either single or multiple exposures to medical devices, materials and/or their extracts during a major period of the lifespan of the test animal (greater than 10% of animal lifespan). For implanted devices the standard suggests that the chronic toxicity test protocol may be expanded to include an implantation test protocol to evaluate both chronic systemic and local effects. Chronic implanted studies are required for all devices in contact with the body for 30 days or longer, regardless of exposure site (**Table 4**), and every attempt should be made to ensure that test conditions approximate the end-use conditions.

10.10 Carcinogenicity

The objective of carcinogenicity studies is to observe test animals over a major portion of their lifespan to detect any development of neoplastic lesions (tumour induction) during or after exposure to various doses of a test substance.

ISO 10993 Standard, Biological Evaluation of Medical Devices, Part 3: Tests for genotoxicity, carcinogenicity and reproductive toxicity (ISO, 2006a), gives guidance on carcinogenicity assays for medical devices. There are very few medical devices for which this test can be justified.

The ISO standard suggests three situations where a carcinogenicity assay should be considered:

1. Reabsorbable materials and devices, unless there are significant and adequate data on human use and exposure
2. Materials and devices where positive results have been obtained in genetic toxicity testing on mammalian cells
3. Materials and devices introduced into the body and/or its cavities with a permanent or cumulative contact for 30 days or longer, except when significant and adequate human-use history is available.

Carcinogenicity testing in drugs and chemicals is normally conducted with oral or inhalation dosing. For implants and medical devices, some modifications to the standard procedures may be necessary. These modifications are primarily in the test sample preparation and dosing.

Carcinogenicity studies are usually performed in rodents, starting at six to eight weeks of age and continued for the lifetime of the species, which is approximately two years. OECD Guidance 451 (OECD, 1981) provides general guidance for testing of chemicals, which can be applied for extracts of medical devices. In these studies, mice and rats are dosed with device extracts every day for 18–24 months. At the completion of the dosing period, all surviving animals are sacrificed and their organs and tissues examined microscopically for the presence of tumours. An increased incidence of one or more category of tumours in the dosed group would indicate that the product tested has the potential to induce tumours and could be considered a possible carcinogen in humans.

The American Society for Testing and Materials (ASTM) Standard F1439-03 gives specific protocols for the performance of lifetime bioassays for the tumorigenic potential of implant materials (ASTM, 2008). These lifetime implant studies are generally conducted in rodents by subcutaneous implantation of device materials. However, these studies have raised some concern, because the data is not predictive of human experience with the same materials. In rodents, solid implanted materials (synthetic polymers, glass and metal films), independent of their chemical composition, induced tumours (primarily sarcomas). This phenomenon, which often manifests itself in rodents, is known as solid-state or foreign-body carcinogenesis, and is due to the size, shape and surface characteristics of the implant and duration of implantation. This phenomenon does not occur in guinea pigs and chickens. Because of the issues associated with carcinogenicity studies in rodents, the FDA advises manufacturers to initiate discussions with the appropriate review division in the Office of Device Evaluation, CDRH, prior to the initiation of expensive, long-term testing of any new device materials, to ensure the proper testing with the appropriate animal species (FDA, 1995).

11 REPRODUCTIVE AND DEVELOPMENTAL TOXICITY

ISO 10993 Standard Biological Evaluation of Medical Devices, Part 3: Tests for genotoxicity, carcinogenicity and reproductive toxicity, (ISO, 2006a) gives guidance for conducting reproductive and developmental toxicity tests. The standard recommends these tests for: (i) long-term contact devices contacting reproductive tissue or the ebmryo/foetus (intrautrine and contraceptive devices); (ii) resorbable materials and devices that are used in women of child bearing age.

None of the traditional methods for the study of reproductive effects have been widely used with devices. The available protocols for chemicals and drugs to study reproductive and teratological studies can be used for device extracts, but should be modified for implants based on the nature of device materials and intended use. The standard recommends OECD guidelines 414 (OECD, 2001) and 415 (OECD, 1983) to conduct teratogenicity and one-generation reproductive toxicity studies. Since these guidelines are not intended for medical devices, the standard recommends appropriate modification to the protocols based on the nature of the device materials and intended use.

11.1 Biodegradation

Biodegradation is defined as an alteration of the medical device material involving the release of degradation products, as well as loss of integrity or performance of the device in a physiological environment. Biodegradation assays are described in ISO 10993 standard, Biological Evaluation of Medical Devices—Part 9: Degradation of materials related to biological testing (ISO, 1999b). The test methods for degradation studies are given in parts 13, 14 and 15 of ISO 10993 Standards, for polymers (ISO, 1998), ceramics (ISO, 2001) and metals (ISO, 2000) respectively. Part 9 of the standard (ISO, 1999b) describes methods for studying *in vitro* degradation and techniques for identification and quantification of *in vivo* degradation products from implanted medical devices.

11.2 Toxicokinetics

Toxicokinetic studies evaluate the kinetics of absorption, distribution, biotransformation and excretion of toxic chemicals in the whole organism. In the medical device evaluation it is applied to leachable and extractable chemicals, as well as biodegradation products from device materials. The leachable and extractable components include additive chemicals, monomers and low-molecular-weight components of polymeric materials. In addition they also include residual chemicals from sterilization processes (e.g. ethylene oxide). The ISO 10993 Standard Part 16: Toxicokinetic study design for degradation products and leachables (ISO, 1997) gives guidance on evaluating the biological disposition of extractable chemicals *in vitro* and biodegradation *in vivo*.

11.3 Pyrogenicity

Pyrogenic reactions are generally associated with bacterial endotoxins that may remain on the devices after sterilization. However, certain materials are able to cause febrile reactions in humans and animals, similar to endotoxins from Gram-negative bacteria. *In vitro* and *in vivo* tests have been developed to determine the presence of endotoxins. The bacterial endotoxins test, also known as the Limulus amoebocyte lysate (LAL) test, measures the concentration of endotoxins using either a turbidimetric or calorimetric end point (US Pharmacopeia, 2008d). The LAL test would not detect certain device materials that are pyrogenic. In such cases, the rabbit pyrogenicity test is used. The rabbit pyrogen test involves measuring the rise in temperature of rabbits over a three hour interval following the intravenous injection of the extract from of the device material (US Pharmacopeia, 2008e). The sample passes the test if no rabbit shows an individual rise in temperature of 0.5 °C or more above its respective control temperature. ISO 10993 Part 1 (ISO, 2003), does not require this test, however, the FDA requires rabbit pyrogenicity tests for all implanted devices to evaluate the material-mediated pyrogenicity (FDA, 1987).

Phototoxicology

J. Frank Nash

CONTENTS

1 INTRODUCTION

Exposure to sunlight is essential to human life. The beneficial/healing properties of sunlight are documented throughout the history of mankind (Zanolli, 2003). Examples of physiological and psychological benefits of sunlight, alone and in combination with exogenous test materials, are diverse, ranging from the production of pre-vitamin D and psychological benefits in patients with seasonal affective disorder to treatment of psoriasis, that is, PUVA therapy. However, as is the case with any test material/pharmacological agent, too much sunlight has deleterious effects on human skin (Ichihashi *et al*., 2003). Moreover, such harmful effects may be exacerbated in the presence of exogenous test materials. It is this latter context which gives rise to the field of phototoxicology.

Phototoxicology, in the most basic terms, is the study of the biological consequences resulting from the interaction of light and a chromophore. In most cases, the chromophore is an exogenous test material but it can also be an endogenous compound. There exist a variety of *in vitro* and *in vivo* test methods that may be used to access acute and chronic phototoxicological hazard potential of a material/chemical.

It should not be surprising that in the twenty-first century, the assessment of light with exogenous chromophores is an important part of a human safety evaluation, particularly for those products applied topically to sun-exposed parts of the body. What may be surprising is that the field of phototoxicology has been developed, in part, out of 'crisis', or in a reactionary manner to clinical findings in humans, rather than a pragmatic, systematic approach. For example, in the early 1960s, tetrachlorosalicylanide (TCSA) was incorporated into hand soap, which lead to many cases of photoallergenicity (Harber *et al*., 1966; Sams, 1968). Likewise, there is a long list of drugs and other ingredients which are known to produce photoirritation in humans; many of these discovered after human exposure. Finally, in the 1990s, severe photo-related toxicities were observed in patients treated with fluoroquinolones (Norrby and Lietman, 1993; Urbach, 1997; Ferguson and Dawe, 1997). Borne out of these clinical experiences and other similar events were many of the photo-methods and activities in regulatory communities aimed at

proactively determining phototoxicological potential of compounds.

The objectives of this paper are to: (i) review methods available to assess phototoxicological hazard potential of test materials, and (ii) recommend an approach for conducting a phototoxicological risk assessment.

2 PHOTOTOXICITY: MECHANISTIC OVERVIEW

Any consideration of phototoxicology starts with photochemistry and the Gotthaus-Draper principle: *only absorbed light is active photochemically or photobiologically.* For a molecule to have a direct photobiological effect, it must absorb photons and dispense with this gain of energy in some manner. **Figure 1** provides an oversimplified mechanistic pathway of this process. In this illustration, a chromophore absorbs photon energy and becomes excited. In one case, this excited-state molecule rapidly (i.e. in picoseconds) returns to ground state, harmlessly emitting energy as, for example, heat or phosphorescence. However, in some cases, the singlet excited state forms a longer-lived triplet state which loses energy at a slower rate and may form photoproducts or free radicals. This latter sequence is thought to play an important role in direct photobiological/toxicological effects.

Beyond the direct photochemical events, any impact of a xenobiotic on ultraviolet radiation (UVR)-induced responses in the skin would be attributed to some secondary mechanism or response modifier; for example, changing structure/function of the skin thereby increasing the 'dose' of light or suppressing the immune response. Thus, understanding the potential mechanism(s) of the interaction between UVR and a chemical is critical when considering the phototoxicological impact of a response and, arguably, most important in human risk assessment.

3 DEFINITION OF LIGHT

The common point of initiation for any biological response to light is absorption of photon energy by a chromophore. The probability of light absorption is dependent on the molecular structure of the chromophore and the wavelengths of light. For the purposes of phototoxicology, the wavelengths of light of greatest interest are nonionizing UVR (290–400 nm), visible radiation (400–760 nm) and, to a lesser extent, near-infrared (760–1300 nm). The solar UVR spectrum is divided somewhat arbitrarily into UVC (100–290 nm), UVB (290–320 nm) and UVA (320–400 nm). Because wavelengths below 290 nm are absorbed by the ozone layer and do not reach the surface of the earth, UVC radiation from sunlight is of little concern when considering phototoxicological potential of test materials.

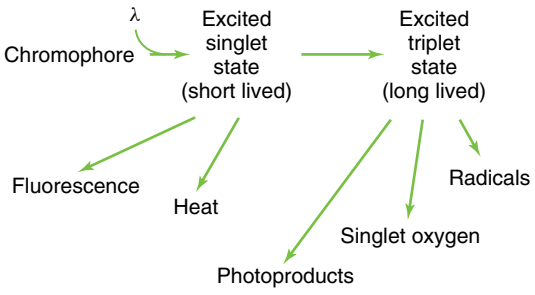

Figure 1 Mechanistic model of phototoxicity.

Because light is a dependent variable in all phototoxicological studies, it is critical to understand a few basic terms. First, *spectrum* is used to describe a range of continuous wavelengths of light coming from a source, for example xenon arc solar simulator or sun. Because energy of UVR is inversely proportional to its wavelength and different wavelengths have vastly different biological effects (e.g. 1000× difference in potency between 300 and 400 nm UVR on erythema in human skin), it is essential that the spectrum of light is known. Joule (J) is the unit of energy used to express the amount of light energy. *Irradiance* is the rate of delivery of energy per unit area expressed as $mW\,cm^{-2}$ or $W\,m^{-2}$, and *fluence* is the amount of energy delivered to an area of tissue, in $mJ\,cm^{-2}$ or $J\,m^{-2}$. Fluence, commonly referred to as the 'dose', and irradiance are related: fluence ($J\,m^{-2}$) = irradiance ($W\,m^{-2}$) × time (s). These terms and very simple relationships are most helpful when interpreting phototoxicological studies or in preparing a photo-related risk assessment.

4 DETERMINATION OF UV/VISIBLE LIGHT ABSORPTION

Determination of the UV/visible absorption spectrum is a starting point when considering the need for phototoxicological testing. The purpose for such a determination is to have some knowledge of the wavelengths at which a chemical may absorb energy and its molar extinction coefficient (MEC). Such information provides insights regarding the wavelengths at which a test material is affected by light, that is, photodegradation or photoactivation. At a minimum, these data can be used to better tailor the design or interpretation of phototoxicological studies, in the event that such investigations are necessary.

The absorption spectrum of any molecule in solution can be empirically determined using a spectrophotometer. This UV/visible absorption spectrum of a solution is a function of the concentration of all absorbing species,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat175
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the path length of the spectrophotometric cells and the MEC of each species. This absorption spectrum is unique for any given molecule and is the probability that a photon will be absorbed plotted against the wavelength. The absorption spectrum for a molecule shows regions of absorption referred to as 'absorption bands'. Importantly, the vehicle used will have some influence on this absorption spectrum. This point has ramifications with regard to phototoxicology.

Whereas there is no one single approach for measuring the absorption of UV/visible light of a molecule or product, the Organisation for Economic Co-operation and Development (OECD) Guideline for testing Chemicals entitled 'UV-VIS Absorption Spectra (Spectrophotometric Method)' (*http://lysander.sourceoecd.org/vl=788910/cl=13/nw=1/rpsv/ij/oecdjournals/1607310x/v1n1/s1/p1*) may be used as a starting point or reference. It is worth noting that there are other methods for determining the absorption spectrum of a compound or test product.

The most comprehensive and important work related to the interpretation of absorption data was performed by Henry (2006) and reported at the American Society for Photobiology meeting (Henry, 2006). In this study, the MEC of 37 known photoirritants representing multiple chemical classes was determined. All known human photoirritants had at least one absorption band with an MEC $>10001\ mol^{-1}\,cm^{-1}$. Stated differently, compounds with an MEC $<10001\ mol^{-1}\,cm^{-1}$ over the range of 290–760 nm are unlikely to have phototoxicological concerns. As Henry (2006) noted, however, many compounds have MEC $>10001\ mol^{-1}\,cm^{-1}$ and, even so, this says nothing about the biological impact of the test material. Nonetheless, determination of absorption profiles is relatively cheap and reproducible, and, as such, serves as a convenient starting point in considering phototoxicological potential of a test material.

5 OVERVIEW OF PHOTOIRRITATION

Photoirritation is the name used to describe the event produced by the interaction between UV or visible radiation and a chemical resulting in an acute, adverse skin reaction (Allen, 1993; Gould *et al*., 1995). This acute adverse reaction is also referred to as a 'phototoxic' response or 'cutaneous phototoxicity' or 'part of a photosensitization reaction', which has lead to some confusion. For the purpose of this review, the term photoirritation will be used.

In the context of phototoxicology, photoirritation is a high-frequency reaction with a rapid onset (e.g. minutes to hours following exposure to light). Symptoms include erythema (redness), burning, prickling, pain and pigment changes (i.e. hyper or hypopigmentation). Whereas photoirritation is typically not a serious (i.e. life-threatening) adverse event, it can be quite serious and painful. In most cases, the symptoms are reversible, resolving within days. However, pigmentary changes may take several months to resolve.

A photoirritation reaction can be evoked in all subjects, provided the concentration of chemical and 'dose' of light are appropriate. The action spectrum for most photoirritant reactions is 320–400 nm; that is, UVA light. Classes of compounds known to be phototoxic in humans are psoralens, sulfonamides, phenothiazines, tetracyclines, fluoroquinolones, coal tar derivatives, anthracene, acridine, porphyrins and dyes (Moore, 2002; Stein and Scheinfeld, 2007). Generally, such chemicals are often polycyclic with many unsaturated bonds, absorb long-wave UVA (320–400 nm) or visible light and become photoactivated, accounting for their phototoxic properties. Photoirritation is prevented by protection from or avoiding light exposure.

5.1 Approaches Used to Assess Photoirritation

5.1.1 *In Vitro*

Many photoirritation *in vitro* methods have been proposed and evaluated for both screening and mechanistic purposes (Lovell and Sanders, 1990; Spielmann *et al*., 1995; Pape, 1997; Lovell and Jones, 2000). During the 1990s, the European Centre for the Validation of Alternative Methods (ECVAM) together with the European Cosmetics trade association (Colipa) undertook the task of validating an *in vitro* photoirritation assay (Spielmann and Liebsch, 2002). The 3T3 *n*eutral *r*ed *u*ptake *p*hoto*t*oxicity (3T3 NRU-PT) assay was carefully selected based on its sensitivity and selectivity using known human photoirritants. The 3T3 NRU-PT assay was evaluated extensively and shown to be highly predictive of human clinical phototoxicity (Spielmann *et al*., 1998).

Table 1 presents an overview of the 3T3-NRU-PT assay. Presently, this study consists of incubating 3T3 mouse fibroblast cells with various concentrations of the compound of interest. Following this incubation, the cells are exposed to $5\ J\,cm^{-2}$ UVA. The %inhibition of growth is compared against cells exposed to chemical but not to UVA light. A photoirritation inhibitory factor (PIF) and mean photo effect (MPE) are calculated using IC_{50} (half maximal inhibitory concentration) and weighted values from concentration–response curves, respectively. Based on the validation study results, a test substance with a PIF < 2 or an MPE < 0.1 predicts: 'no phototoxicity'. A PIF > 2 and < 5 or an MPE > 0.1 and < 0.15 predicts: 'probable phototoxicity', and a PIF > 5 or an MPE

Table 1 OECD Test No. 432: *in vitro* 3T3 neutral red uptake phototoxicity test

3T3 NRU-PT	Comment
General design	Mouse fibroblast, 3T3 cells (monolayer) Apply various concentrations of solubilized test material Expose to 5 J cm^{-2} UVA (320–400 nm) Add neutral red dye Measure neutral red uptake Use known positive and negative control materials
Measures	%Inhibition of growth as compared to vehicle
Data interpretation	Calculate photoirritation inhibition factor (PIF) value using IC_{50} values. PIF $\geq$ 5.0 predicts 'phototoxicity'; PIF $<$ 2 predicts 'no phototoxicity'; PIF $>$ 2 and $<$ 5 predicts 'probable phototoxicity' Calculate mean photo effect (MPE) using weighted average of concentration response curves. MPE $>$ 0.15 predicts 'phototoxicity'; MPE $<$ 0.1 predicts 'no phototoxicity'; MPE $>$ 0.1 and $<$ 0.15 predicts 'probable phototoxicity'
Key references	(Spielmann *et al*., 1994; 1995; 1998)

$>$ 0.15 predicts: 'phototoxicity' (Peters and Holzhutter, 2002).

The 3T3-NRU-PT assay has been accepted by the European Union (Spielmann *et al*., 1995; 1998) and endorsed by ECVAM's Scientific Advisory Committee. Moreover, at the request of the European Commission DG (Directorate General) Enterprise, their experts, the Scientific Committee on Cosmetic non-Food Products (SCCNFP), proposed the use of the assay as the standard method for testing the UV light-absorbing cosmetic ingredients or mixtures of ingredients for phototoxic (photoirritation) potential. This led to the formal acceptance of the assay in the European Directive (Commission Directive 2000733/EC of April 25 2000), and in 2004 publication of an OECD Test Guideline No. 432.

As with any method, the 3T3-NRU-PT assay is not perfect. The test material used in the 3T3-NRU-PT assay must be soluble. This is an issue for many topically applied finished products. To overcome this challenge, organotypic skin cultures have been evaluated with some success (Edwards *et al*., 1994; Liebsch *et al*., 2005). The assay does not provide potency or 'rank order' of photoirritation potential. As well, the 3T3-NRU-PT assay is a hazard-based study and it is difficult to extrapolate results, for example positive 'photoirritation', to human risk. This has been particularly problematic for pharmaceutical test materials, many of which may have photoirritation potential as determined in 3T3-NRU-PT assays, but pose little or no human risk as a result of exposure. Notwithstanding these concerns, the 3T3-NRU-PT assay represents a useful and relevant means of evaluating photoirritation potential and, after the absorption profile is determined, the next step in a phototoxicological assessment.

5.1.2 *In Vivo Animal Models*

Photoirritation testing has been done in several animal species including mice, rabbits and guinea pigs (Harber, 1981; Nilsson *et al*., 1993; Lambert *et al*., 1996). From the preceding discussion, *in vitro* photoirritation studies have several shortcomings. To this end, the *in vivo* guinea pig photoirritation test (Nilsson *et al*., 1993) is preferred and may be useful if (i) the test material cannot be tested *in vitro*; (ii) a No Observed Effect Level (NOEL) is needed for human risk assessment; or (iii) the test is required by a regulatory agency.

An overview of the guinea pig photoirritation assay is summarized in **Table 2**. Briefly, guinea pig skin is exposed to the test chemical. After 2 h of exposure to the test or control material, half of the test sites are exposed to 10 J cm^{-2} UVA while the remaining sites are shielded. Visual grading is performed at 1, 24 and 48 h after UVA exposure. An incidence and severity index are calculated, comparing treated sites to control (untreated) or vehicle-treated site.

The guinea pig photoirritation test can be used to evaluate systemically administered test materials. For such studies, measures of plasma and/or skin concentrations of test material may be helpful in determining the time between drug and light exposure to maximize the interaction (Horio *et al*., 1994).

In addition to the guinea pig, mouse models have been developed for *in vivo* photoirritation testing (Gerberick and Ryan, 1989a; Shimoda *et al*., 1993; Marutani *et al*., 1993). The mouse models have been used to assess the photoirritation potential of topical or systemically-administered test materials. In the mouse ear-swelling model (Gerberick and Ryan, 1989a), the end point is easily quantitated, that is, measurement of swelling, and is more objective than models based on subjective evaluation of skin changes. Both mouse and

Table 2 *In vivo* guinea pig photoirritation test method

In vivo phototoxicity test	Comment
General design	Albino guinea pigs (n = 18), hair removed 2 h exposure to test and control materials using Hilltop chamber patches Expose half of the test sites to 10 J cm^{-2} UVA, keep other half covered Grade all sites at 1, 4, 24 and 48 h after exposure Use 8-MOP as control
Measures	Visual skin grading by trained personnel evaluating incidence and severity indexes
Data interpretation	Determination of photoirritation is based upon the differences in skin response at the UVA-exposed and UVA-shielded test sites after exposure to the respective application of the test material in comparison to controls
Reference	(Nilsson *et al.*, 1993)

guinea pig models have been shown to identify known human photoirritants.

5.1.3 In Vivo Human Testing

The method used to evaluate photoirritation in humans is described in **Table 3**, following the procedure of (Kaidbey and Kligman, 1978). This clinical phototoxicity test method can be used to assess compounds/products administered topically or systemically. In the latter case, the study is modified by administration of the chemical at the standard therapeutic dosage either once or repeatedly over several days. This method differentiates between reactions that are induced by (i) UV, (ii) test material or (iii) test material + UV (true photoirritation response).

Specific wavelengths of UVR may be used depending on the absorption profile of the test material, or a standardized artificial light source, filtered to emit UVA, may be used. In each subject, a minimum erythema dose (MED) is determined for the light source, generally on the back of the subjects, before dosing and at various points during dosing. A photoirritation response is considered positive if a significant decrease in the ratio of MED before and after dosing is observed (Ferguson and Johnson, 1993; Ferguson and Dawe, 1997).

5.2 Summary of Photoirritation Testing

The *in vitro* 3T3 NRU-PT assay should be the first test used in assessing photoirritation potential of a test material. This assay will provide a yes/no answer regarding the photoirritation *potential* of the test material. Animal models of photoirritation are available to define NOEL and for testing materials incompatible with *in vitro* conditions. Finally, human photoirritation testing may be used to confirm the absence of photoirritation response under specific exposure conditions. Considering the frequency and human relevance of photoirritation, testing for this adverse event should be conducted in standard phototoxicological risk assessments.

6 OVERVIEW OF PHOTOALLERGY

Photoallergy is a cell-mediated immunologic reaction to a chemical that has been made antigenic by the interaction with light (Allen, 1993; Gould *et al.*, 1995). This reaction is analogous to allergic contact dermatitis, but differs in that the test material requires activation by light to elicit the response. Clinically, photoallergenic skin responses resemble photoirritation reactions with a similar action spectrum. There are several differences between photoallergy and photoirritation, including (i) onset, with photoallergic responses taking at least 24 h to develop, (ii) distribution of lesion, with some 'bleedover' to unexposed skin in photoallergic responses, and (iii) histologically, the photoallergic response is characterized by epidermal oedema and vesicle formation and a dense perivascular infiltrate. Photoallergenic responses are less frequent than photoirritation reactions.

Many of the known human photoallergens are also photoirritants (Stein and Scheinfeld, 2007). Antimicrobial agents, fragrances, plant derivatives, sunscreens and some drugs have been reported to produce photoallergy in humans (Bryden *et al.*, 2006). Specifically, halogenated phenolic compounds, coumarins, musk ambrette, promethazine, chlorpromazine, ketoprofen and *p*-aminobenzoic acid have been reported to be photoallergenic in humans. As is the case for photoirritation, these chemicals absorb light and become photoactivated. The photoactivated molecule may be identified as foreign by the immune system or it may serve as a hapten, interacting with a larger biomolecule such as protein which may then initiate an immunologic response. As is the case for photoirritation, photoallergic responses can be prevented by protection from or avoiding light exposure.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat175
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 3 Human photoirritation and photoallergy test methods

Human photoirritation and photoallergy tests	Comment
General design	**Photoirritation** Ten subjects that meet inclusion/exclusion criteria. Test material patched for 24 h prior to UV exposure UV exposure: UVB = 1/2 MED; UVA = 10 J cm^{-2} Three test sites: 1. test material + UV exposure 2. nonirradiated control site (test material only) 3. irradiated control site (no test material) Test sites read at 10 min, 24 h and 48 h after UV exposure **Photoallergy** Twenty-five subjects that meet inclusion/exclusion criteria. Test material patched for 24 h prior to UV exposure Induction phase –24 h patch followed by UV exposure, twice per week for 3 wk –UV exposure: UVB = 3×MED; UVA = 4 J cm^{-2} –nonirradiated control site (test material only) –irradiated control site (no test material) –final induction followed by 2-wk rest period Challenge phase –single 24 h patch application followed by UV exposure –UV exposure: UVB = 1/2 MED; UVA = 4 J cm^{-2} –naive site –three test sites (see photoirritation) Sites read at 24, 48 and 72 h following UV exposure
Measures	Visual reading by trained personnel; 0–4 scale for objective irritation with additional notations for sensory response
Data interpretation	For the interpretation of results, it is important to compare the response of the test material + UV exposed site to both control sites—test material only and UV only. If the response pattern is not clearly indicative of sensitization vs. clinical irritation, it may be necessary to follow up with a rechallenge and/or prospective/provocative use test.

6.1 Approaches Used to Assess Photoallergenicity

6.1.1 In Vitro

There are no *in vitro* assays for assessment of photoallergy. The closest *in vitro* approach is the determination of binding to serum albumin following UV exposure (Lovell and Jones, 2000). This photobinding technique has been evaluated but, at this time, has not been advanced as a method for validation (Moser *et al*., 2001). Beyond photobinding, there are knowledge-based screens such as DEREK (Deductive Estimation of Risk from Existing Knowledge) with structural alerts for photoallergens and photoirritants (Barratt *et al*., 2000).

Very recently, an *in vitro* photoallergy test using THP-1 cells exposed to UVA has been reported (Hino *et al*., 2008). THP-1 cells, derived from human monocytic leukaemia cells, express co-stimulatory molecules CD86 and CD54 as well as major histocompatibility complex (MHC) class II molecule. When THP-1 cells are cultured with known allergens, these surface markers are expressed and can be measured. This approach has been modified by Hino *et al*. by exposure of THP-1 cells to test material followed by UVA, and reported to identify select photoallergens. This promising approach may be useful as a means of identifying potential photoallergens and/or distinguishing photoirritants from photoallergens.

6.1.2 In Vivo Animal Models

At present, photoallergy can be assessed preclinically using *in vivo* methods. The preferred animal species is the guinea pig (Ichikawa *et al*., 1981), although the mouse ear model is used also (Gerberick and Ryan, 1990). As presented in **Table 4**, the guinea pig photoallergy

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

Table 4 *In vivo* guinea pig photoallergy test methods

In vivo photoallergy test	Comment
General design	Albino guinea pigs (n = 25–45), hair removed Inject Freund's complete adjuvant to define test sites Remove stratum cornea by tape stripping test sites 2 h exposure to test and control materials using Hilltop chamber patches Expose half of the test sites to 10 J cm^{-2} UVA, cover other half repeat on days 2, 4, 7, 9 and 11 (excluding injection of Freund's adjuvant) On day 21 conduct primary challenge Grade at 24 and 48 h after UVA exposure Use 8-MOP and musk ambrette as controls
Measures	Visual grading by trained personnel Incidence and severity indexes determined
Data interpretation	Determination of photoallergy is based upon the differences in skin reactions at the UVA-exposed and UVA-shielded test sites after exposure to the respective challenge dose of test material in comparison to controls
Key references	(Ichikawa *et al.*, 1981; Gerberick and Ryan, 1989b)

assay consists of two phases: the induction and challenge phases (Harber *et al.*, 1982; Gerberick and Ryan, 1989b). During the induction phase, test sites are injected with Freund's adjuvant to designate the test areas. These test sites are repeatedly tape stripped to remove the stratum corneum, followed by application of the test or control material for 2 h. After treatment with the test materials, half of the test sites are exposed to 10 J cm^{-2} UVA while the remaining sites are shielded. This procedure is repeated, except for Freund's adjuvant injection, on days 2, 4, 7, 9 and 11. On day 21, nonirritating doses of test or control materials are applied to the sites for 2 h, followed by exposure to 10 J cm^{-2} UVA. Visual grading is undertaken at 1, 24 and 48 h following UV exposure, and incidence and severity indexes calculated in comparison to controls.

More recently, Ullrich, Vohr and colleagues have introduced a modification of the local lymph node assay (LLNA) termed photo-LLNA or UV-integrated model for the differentiation of skin reactions (UV-IMDS) (Vohr *et al.*, 1994; 2000; Homey *et al.*, 1995; Neumann *et al.*, 2005). In brief, groups of mice are treated with test material or vehicle on the dorsum of both ears on three consecutive days. Immediately after application of test material mice are exposed to 10 J cm^{-2} UVA light. For the comparison of induction and challenge responses, mice are treated on the shaved back with test material or vehicle alone on three consecutive days (induction-phase treatment). Twelve days after the last induction-phase exposure, mice are challenged with test material or vehicle on the dorsum of both ears for a further three days (challenge-phase treatment). Lymph nodes are excised 24 h after the last challenge-phase treatment. Lymph node weight, cell counts and stimulation indices, which were defined as the ratio of mean lymph node cell counts from groups treated with test compound to corresponding results of control groups, are determined. This approach holds promise and may replace current models for photoallergenicity testing. It will be necessary for a more comprehensive evaluation of photo-LLNA, together with refinement of the testing procedure, to advance this test method.

6.1.3 *In Vivo Human Models*

Table 3 provides an overview of the method used for clinical photoallergy testing of topical compounds based on the work of Kaidbey and Kligman, (1980). The design of this photoallergy test is based on human repeat-insult patch testing, designed for confirmatory evaluation of contact sensitizers. This method can be adapted for testing chemicals administered by other routes by replacing the patch induction phase with dosing of the subjects with the therapeutic dose and route over a similar period of time. The chemical can be administered by patch testing for the challenge phase.

6.2 Summary of Photoallergenicity Testing

Photoallergy is a rare event even in a phototoxicological context. It can be distinguished from photoirritation based on incidence, time of onset after exposure, clinical appearance and distribution of reaction relative to site of product application. There are no validated *in vitro* approaches for evaluating photoallergenic potential of test materials. The *in vivo* guinea pig photoallergenicity study is a mainstay for such testing. However, the UV-IMDS (i.e. photo-LLNA), may become a replacement for the guinea pig at some point in time. Like photoirritation, there is a human clinical photoallergenicity test that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat175
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is used to confirm the absence of photoallergenicity. Determination of photoallergenicity is, in general, not a routine evaluation in phototoxicological risk assessment unless there is a positive photoirritant evaluation.

7 OVERVIEW OF PHOTOGENOTOXICITY AND PHOTOCARCINOGENICITY TESTING

To date, the area with the most uncertainty in phototoxicology risk assessment is photogenotoxicity and photo co-carcinogenicity testing. This is largely attributable to the lack of documented human photo co-carcinogens, aside from the combination of 8-methoxypsoralen (8-MOP) and UVA (PUVA) therapy used to treat psoriasis (Stern, 1984; Stern and Laird, 1994). Even if data from rodent photo co-carcinogenicity studies are considered, as is often the case in toxicology when human data are not available, the database remains small and controversial with few positive and even fewer negative substances having been tested. The lack of an appropriate dataset of rodent photo co-carcinogens and non-photo co-carcinogens makes validation of a short-term *in vitro* test, such as photogenotoxicity, at best challenging if not unachievable (Jacobs *et al*., 1999). As such, the use of existing models of photogenotoxicity and photo co-carcinogenicity, are research tools with uncertain relevance in a human phototoxicological risk assessment.

7.1 Photogenotoxicity/Photo Co-carcinogenicity: Parallels to Genotoxicity and Carcinogenicity Testing

When considering the carcinogenic potential of a chemical, it is often helpful to initially evaluate its genotoxic properties. If a compound is genotoxic, it is potentially carcinogenic (Ennever and Rosenkranz, 1987; Sato and Tomita, 2001). The same theoretical relationship exists between photogenotoxicity and photo co-carcinogenicity. For instance, the only known human photo co-carcinogen, that is, 8-MOP, is photochemically activated, leading to DNA lesions (Hara *et al*., 2007), which may be responsible, in part, for its long-term tumorigenic properties (Forbes *et al*., 1976). However, the strength of the relationship between photogenotoxicity and photo co-carcinogenicity cannot be accurately determined due to the absence of known human photocarcinogens or co-carcinogens. Nevertheless, the cause and effect relationship is logically sound and theoretically appealing.

An important difference between standard genotoxicity/carcinogenicity testing and photogenotoxicity/photo co-carcinogenicity testing is that in the latter cases we examine the effects of two agents and their potential interactions, namely UVR, a known carcinogen, and the test material. Such interaction may be direct, for example photochemical activation of the test substance to a genotoxic substance, or indirect, for example pseudo-photoclastogenic (Lynch *et al*., 2008). The potential for a test substance to have indirect effects that enhance the activity of UVR is quite possible in both photogenotoxic and photo co-carcinogenicity studies. The possibility that indirect mechanisms account for positive results complicates interpretation of these studies, even if some indirect effects may be relevant to human risk assessment, for example immunosuppression.

7.2 Photogenotoxicity Testing

Photogenotoxicity is defined as the genotoxic effect induced by and dependent on the concomitant exposure to a chemical and solar-simulated UV (Brendler-Schwaab *et al*., 2004). Two photogenotoxicity approaches have been used. One is an *in vitro* photomutagenicity assay and the other is an *in vitro* photocytogenetics assay. The photomutagenicity assay measures small DNA changes that result in gene mutation. The photocytogenetics assay measures larger DNA changes that result in chromosome damage.

The current tests used to assess photogenotoxicity of test materials are based on existing genotoxicity methods with the inclusion of UVR exposure. The studies are: (i) photo-Ames, a test for point mutations (Chetelat *et al*., 1993); (ii) photo-chromosome aberration using mammalian cells such as Chinese Hamster Ovarian (CHO) and V79 cells (Itoh *et al*., 2002); and (iii) photo-comet assay using human keratinocytes and V79 cells (Chetelat *et al*., 1996). The conduct and interpretation of these studies is detailed in reviews by Brendler-Schwaab, Müller, Kasper (Müller *et al*., 1998; Kersten *et al*., 1999; Gocke *et al*., 2000; Brendler-Schwaab *et al*., 2004) and Meunier *et al*. (2002).

It is important to point out that methods for measuring photogenotoxicity are not yet as standardized around the world as routine tests; there are, however, ongoing international efforts to harmonize photogenotoxicity methods. Most important, the predictive validity of photogenotoxicity testing has not been established and, as such, the value in human phototoxicological risk assessment is uncertain.

7.3 Photo Co-carcinogenicity Testing

Photo co-carcinogenicity testing is defined here as the study of how chemicals modulate the development of

skin tumours induced by solar-simulated UVR. Up to this point, the assessment of acute or subacute interactions of a drug and UVR has been considered. In contrast, modulation of photo co-carcinogenicity represents a chronic toxicity that is not amenable to human testing.

The induction of UVR-induced tumorigenesis has been studied for several decades using hairless mice, a species that develops a nonmelanoma skin cancer equivalent to human squamous cell carcinoma (Forbes, 1981). What has been demonstrated is that tumour induction is dependent on the dose, the time or duration of exposure and the wavelength of UVR (Forbes *et al*., 1978; 1981). For murine nonmelanoma skin cancers, the wavelengths of importance are in the short-wave UVB (290–320 nm) and are up to 1000 times more potent than long-wave UVA in inducing skin tumours in mice.

In the process of understanding the relationship between UVR and skin cancer development, there have been a number of experiments that have shown that drugs can modify this interaction *vis-à-vis* multiple mechanisms (Mukhtar *et al*., 1999). These mechanisms include direct photoactivation of a chemical resulting in DNA adduct formation, and the universe of indirect mechanisms including promotion, immunosuppression, skin irritation, dietary changes, and so on, all of which can modify UVR-induced skin cancer formation (Forbes and Urbach, 1974).

Forbes and colleagues have introduced test methods for evaluating the photo co-carcinogenicity potential of test materials (Forbes *et al*., 1993; 2003; Sambuco *et al*., 2003). The animal model used in the photo co-carcinogenicity study is the SKH1 albino hairless mouse. The hairless mouse has the advantage that it does not require clipping, hair being a very good UV protectant. Furthermore, hairless skin allows easy detection of skin lesions as they arise (Forbes and Sambuco, 1998). The key design characteristics include use of a UV solar simulator that emits the full spectrum of UVR present in sunlight. In one version, the test substance is applied before UVR on Monday, Wednesday and Friday and after UVR on Tuesday and Thursday for 40 weeks with no treatment on Saturday and Sunday, followed by a 12-week observation period without dosing. The reason for this pattern of exposure is that, in theory, it allows detection of photochemically activated substances, as well as those that may modulate photocarcinogenesis but are photo-labile. Generally, separate groups receiving either high or low UVR serve as benchmarks for groups that are dosed with low UVR and the test substance. The repetitive low doses of UVR will induce tumours in all mice, and the higher UVR dosing regimen will induce tumours with a shorter latency. The end point measures that are evaluated generally are lesion (i.e. squamous cell papillomas and/or carcinomas), tumour prevalence (incidence), tumour yield (multiplicity) and time to tumour (latency). This is not a model for basal cell carcinoma, the most common human skin cancer, or melanoma, the most deadly and aggressive skin cancer in humans.

The key finding in the SKH1 albino hairless mouse photosafety study is whether the test substance alters the time of appearance of tumours or increases the number of tumours per mouse (Molefe *et al*., 2005). Agents that cause tumours to appear more rapidly or in increased numbers are defined as 'photo co-carcinogens'. Agents that delay the onset of tumours or decrease the number of tumours are photo-protective (e.g. sunscreens). Strictly speaking the photo co-carcinogenesis protocol discussed here is a co-carcinogenesis design, because the test substance is administered along with a known carcinogen (i.e. UVR). The assay is also referred to as simply photocarcinogenesis study.

As an experimental paradigm, there is some validity in assessing chemical modification of photocarcinogenicity. However, when considering risk assessment and using this as a model or requesting this for evaluation of chemicals, consideration of the limitations is necessary. As with all *in vivo* rodent carcinogenicity assays, there are likely to be both qualitative and quantitative differences between responses observed and possible effects in humans. The SKH1 hairless mouse is fairly sensitive to UVR-induced tumour formation, and its epidermis is at most one-third as thick as human epidermis, allowing for increased penetration of both UVR and topically applied chemicals. Importantly, there are multiple mechanisms by which chemicals might act as co-carcinogens with UVR. These include photochemical activation, inhibition of DNA repair, immunosuppression, altered optical properties of the skin, and tumour promotion. The photo co-carcinogenicity study may provide little mechanistic understanding and be heavily dependent on the exposure conditions used in the study.

A common problem associated with all *in vivo* tests used in cancer hazard identification is the uncertainty of extrapolating results from animal models to humans. This is a particular problem when nongenotoxic effects such as tumour promotion are involved in the tumorigenic mechanism. In general, skin tumour promotion in laboratory animals shows substantial strain and species specificity, which makes interspecies extrapolation of results uncertain, and no human skin tumour promoters have been unequivocally identified. Therefore, effects observed in the hairless mouse photo co-carcinogenicity study may not be predictive of human responses.

Another problem is that there is only one chemical that has been clearly identified as a human photo co-carcinogen, namely 8-MOP. The immunosuppressive agents, such as ciclosporin and azathioprine, are human skin carcinogens, and probably exacerbate the risk of UVR-induced skin cancer, but other factors such as papillomavirus infection may contribute to the mechanism of increased cancer risk. The lack of chemicals that are known human photo co-carcinogens means that the

photo co-carcinogenicity assay can not be readily validated for human risk assessment and its predictivity is uncertain.

7.4 Summary of Photogenotoxicity and Photo Co-carcinogenicity Testing

In vitro photomutagenicity or photoclastogenicity assays may be used in an attempt to understand the photogenotoxicity potential of a test material. Despite all the limitations currently associated with these testing schemes, *in vitro* photogenotoxicity is addressed using relatively inexpensive tests that hold the most promise as a means to quickly and inexpensively assessing potential mutagenic/clastogenic effects of chemicals. If *in vivo* photo co-carcinogenicity testing is required, there is currently a single model using SKH1 albino hairless mice that has a history at least within the US Food and Drug Administration (FDA). Again, it cannot be overemphasized that the current rodent photo co-carcinogenicity study results may have little or no bearing on human heath risk. As such, we cannot fully assess what the relevance of the rodent studies is to human health risk.

8 REGULATORY GUIDANCE FOR PHOTOTOXICOLOGICAL ASSESSMENT

Prior to 2000, there were discussions occurring in the USA and Europe regarding approaches to be used for evaluation of phototoxicological potential of drugs and cosmetic products. This culminated in guidelines issued by the FDA in the USA (*www.fda.gov/cder/guidance/3640fnl.htm*) and European Agency for the Evaluation of Medicinal Products (EMEA) (*www.emea.europa.eu/htms/human/humanguidelines/nonclinical.htm*). These guidance documents provide a decision tree for photosafety testing, focussed on pharmaceuticals. In general, the FDA and EMEA approaches share a similar yes/no decision tree but differ rather significantly in the area of photogenotoxicity and photo co-carcinogenicity testing. The FDA has not found photogenotoxicity results to be particularly robust and, as such, has leaned towards *in vivo* photo co-carcinogenicity testing (Ellis, 1998; Jacobs *et al*., 1999). On the other hand, the EMEA has requested *in vitro* photogenotoxicity data in lieu of *in vivo* photo co-carcinogenicity studies. Nonetheless, and consistent with Section 7 of this chapter, the EMEA has recently reconsidered some photogenotoxicity studies, with their Committee for Proprietary Medicinal Products/Safety Working Party (CPMP/SWP) stating:

> *Oversensitivity and the occurrence of "pseudo-effects" with* in vitro *models recommended by the current guideline, in particular the mammalian cell test for photo-genotoxicity have become a major problem. Therefore the use of these test models for regulatory purposes can no longer be justified and need to be replaced by more appropriate approaches.*[a]

In summary, there are regulatory guidelines for photosafety testing which provide a structured approach in the evaluation of test materials. It would be prudent to seek some additional perspective from regulators before embarking on expensive and time-consuming testing as there are still some uncertainties in the value of some data.

9 SUMMARY

At the second ECVAM workshop on phototoxicity testing (Spielmann *et al*., 2000), a structured flowchart was developed which provides guidance in phototoxicological evaluation of test materials. Now, it is suggested that the basic approach towards human phototoxicological risk assessment should include, first the determination of the absorption spectrum and second, photoirritation testing, using *in vitro* 3T3 NRU-PT (OECD 432) methods and, if needed, *in vivo* preclinical or, for confirmatory testing, human. These data will answer the two basic questions: (i) does the test material absorb UV? and (ii) is the material photoactivated, and what is the biological consequence (i.e. photocytotoxicity)? If a material is photoactivated, there may be the need to understand the photoallergenic potential and long-term consequences of use/exposure. In the case of photoallergenicity, there are animal models that exist and, in the future, perhaps an *in vitro* test may emerge. To understand potential photogenotoxicity and photo co-carcinogenicity, there are experimental approaches including adaptations of standard *in vitro* genotoxicity tests and a photo co-carcinogenicity study using SKH1 hairless mice. For photogenotoxicity and photo co-carcinogenicity testing, there remains a level of uncertainty regarding the outcome of such studies. This is particularly true as it relates to risk assessment. Finally, there are regulatory guidance documents for photosafety testing which may require some testing to forego or address labelling questions related to photosafety.

Phototoxicology is an important consideration for all test materials. However, given the dependence of such events on exposure to UVR, common sense and practical approaches should be considered in the context of testing needs. Clearly a material that is not exposed to UVR should not be a phototoxicological risk. By the same token, systemically administered materials are not exempt

from testing as they may represent a phototoxicological risk. In the end, the end points and test methods identified herein should provide the tools needed to conduct a robust phototoxicological risk assessment.

Biomarkers of Exposure to Carcinogens

Paul T.J. Scheepers

CONTENTS

1 INTRODUCTION

In human exposure assessment a biomarker is a parent substance, metabolite or addition product (adduct) that can be measured in blood, urine or exhaled air. Sometimes hair, skin and nails are also used as tissues for isolation of biomarkers. For isolation of DNA adducts there is some experience with the use of exfoliated epithelial cells isolated from the buccal mucous or from urine. A biomarker provides information on the internal exposure to a substance, in contrast to external exposure monitoring that can be provided by personal air sampling or skin-contamination testing.

The use of biomarkers in a human biological monitoring campaign can be a good way to evaluate exposure to carcinogenic substances on the workplace or in the general environment.

If the parent compound is used as a biomarker of exposure, information on uptake of a substance from various different sources and via different routes can be obtained. Use of a metabolite or adduct to DNA or proteins will also provide information on bioavailability and metabolic activation.

Even if the biomarker is not identical to the substance a person is exposed to, it may still contain chemical-structure information, such as an addition product that can be linked to this parent substance. This makes a biomarker very useful for assessment of exposure.

The half-life of biomarkers determines the moment of sample collection relative to time of exposure. Elimination from the lungs is usually fast (minutes to hours), elimination from plasma and urine is fast (hours to days), elimination from blood cells is much longer (weeks to months) and the half-life of adducts to macromolecules depends on many factors, but may vary from hours to days for most DNA adducts to weeks or months for some specific DNA adducts and their repair products (Henderson *et al*., 1989). Adducts to proteins may have a longer lifespan (weeks to months), depending on the turnover of the protein or of the cell, such as in the case of haemoglobin (Hb) in erythrocytes (Scheepers, 2008).

It must be noted that the excretion pattern is not just dependent on the terminal half-life of a substance, but is also dependent on the pattern of exposure and the *porte d'entrée*. Biomarker levels will show a different pattern in workers as opposed to subjects exposed in the general environment. Inhalation exposure will show a pattern of excretion that is different from that after dermal absorption.

There are many specific chemicals that are very persistent due to specific properties like high lipophilicity or noncovalent binding to proteins (e.g. halogenated substances like polychlorinated biphenyls (PCBs), dioxins and also some metals like cadmium and lead).

Metabolites and adducts are usually mechanism-based and provide useful information on the formation of metastable intermediates that are involved in genotoxic activity. Most biomarkers reflect systemic bioavailability rather than a target dose, which sometimes limits the interpretation in terms of assessment of cancer risk.

Some biomarkers have been used to study exposure to carcinogenic substances in the general population or to reconstruct exposures after chemical incidents involving carcinogenic substances.

Based on evaluations by the International Agency for Research on Cancer (IARC) to 2003 it is estimated that workers are exposed to carcinogenic substances in 18 occupations and industries. These exposures involve 28 substances classified as definite human carcinogens, 27 probable carcinogens and 113 agents classified as possible occupational carcinogens (Siemiatycki *et al*., 2004).

In this chapter parent compounds will be discussed in Section 2, metabolites in Section 3, adducts to proteins in Section 4 and DNA adducts and their products of enzymatic repair in Section 5. In Section 6 the use of biomarkers in human biological monitoring studies will be discussed.

2 PARENT COMPOUNDS

For those substances that can exert their toxicity without any metabolic activation, a parent compound is suitable as a biomarker. For the large group of volatile organic compounds (VOCs), the primary toxic effect may be neurotoxicity, whereas a metabolite may represent a genotoxic substance. For this reason parent substances are often determined as relevant biomarkers of exposure in body fluids and exhaled air. Biological monitoring of metals will also be discussed.

2.1 Body Fluids

VOCs can be determined from blood by headspace analysis. In this analysis of the sample the analyte is exchanged between the liquid and gas phase until equilibrium. In the gas phase the concentration is determined and the concentration in the liquid is then calculated using a blood–air partitioning coefficient. The advantage of such an approach is a clean matrix for gas chromatographic analysis. Parent organic compounds and inorganic compounds can also be analysed from urine if they are readily soluble in water. An important group of carcinogens that is normally determined as a parent compound from body fluids is metals (Nordberg *et al*., 2007).

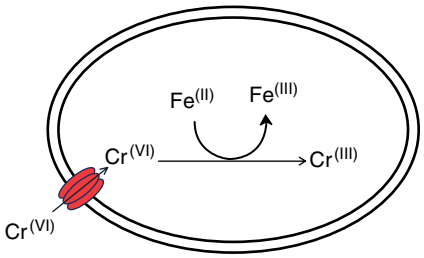

Figure 1 Cr(VI) enters the erythrocyte through an ion transporter for phosphate and sulfate. In the red blood cell Cr(VI) is reduced to Cr(III) by Fe(II) in oxyhaemoglobin that is converted to methaemoglobin. Cr(III) cannot pass through the membrane, causing accumulation of chromium in the cell. (Reproduced from Lewalter *et al*., 1985. © Springer.)

2.1.1 Blood

Most organic substances can be analysed from full blood or plasma. For volatile organic substances a headspace analysis may be used. In plasma, metals can be free or bound to metallothioneins, for example. Metals may also be determined from different types of blood cells, such as erythrocytes and granulocytes. An interesting application is the determination of chromium from erythrocytes, for example, in workers who are exposed chromate-containing primers or by inhalation of fumes from stainless-steel welding. Chromates containing hexavalent chromium may enter blood cells using ion channels (**Figure 1**). In this way chromium becomes trapped in the erythrocyte and the systemic exposure to hexavalent chromium can be evaluated by isolation of the erythrocytes and determination of the total chromium content. Also, the plasma levels of chromium in welders are related to the type of metal that is welded and the composition of the electrodes used (Scheepers *et al*., 2008).

2.1.2 Urine

Urine can also be analysed for the parent substance, such as in the case of organic solvents (Fustinoni *et al*., 1999), but if the carcinogenicity involves enzymatic activation, a downstream metabolite may be selected as a biomarker

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat176
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(see Section 3). Urine is also a good matrix for detection of metals. Some knowledge about speciation and kinetics is needed in order to interpret urinary metal excretion.

In the analysis of arsenic, speciation between inorganic and organic arsenic is useful because of differences in the origin and toxicity. Inorganic As can be derived from drinking water and is a known human carcinogen, whereas organic arsenic compounds, with a much lower toxicity, originate primarily from the diet, in particular seafood (Buchet *et al*., 1996).

In biological monitoring of chromium, kinetics are important. Stainless-steel welders are exposed to welding fume particles that contain chromates. Chromium leaches very slowly into the circulation due to the sparse water solubility of some of the chromates that are deposited deeply in the lungs (Schaller *et al*., 2007). This explains why the preshift urine sample of a welder may still contain considerable levels of chromium compared to a nonexposed worker (Scheepers *et al*., 2008). In this case exposure during the work shift can be evaluated by comparing preshift and postshift values of urinary chromium excretion.

2.2 Exhaled Air

End-exhaled air is defined as the last 300–400 ml at the end of a prolonged exhalation and is equivalent to the alveolar fraction. It can be easily and noninvasively collected in both adults and children. In this air volume the chemical substance equilibrates almost instantly with arterial blood, ruled by the blood–air partition coefficient. With this parameter, the concentration in the arterial bloodflow that takes the substance to the brain can be calculated.

End-exhaled air can be collected in a ~100 ml container. This container must be equipped with a one-way valve to prevent ambient air being drawn in if the subject starts to inhale at the end of the deep exhalation. There are commercial systems such as the BIO-VOC that can be used for the routine collection of end-exhaled air samples in adults and children (**Figure 2**). In the analysis, compared with body fluids, exhaled air is a very clean matrix that enables ultrasensitive detection of VOC down to pmol l^{-1} for chlorinated hydrocarbons.

3 METABOLITES

Biotransformation leads to detoxification for most chemical substances. However, metabolism may also lead to formation of reactive intermediates and more- or less-stable metabolites that can exert a specific toxic effect that may be different from the toxicity of the parent compound.

Figure 2 Exposure to benzene can be investigated using breath analysis. End-exhaled air was collected by children attending primary school in Turkey. The volatile organic solvents are transferred to a solid phase by the investigator directly after sample collection. In this way the organic compounds are well preserved for later analysis. (Reproduced with permission from J. Konings.)

As a parent compound, styrene can be determined in end-exhaled air or urine (Teixeira *et al*., 2008). Styrene is metabolized to styrene-7,8-oxide, which is a genotoxic metabolite. Styrene-7,8-oxide and phenylethyleneglycol can be determined in blood (Christakopoulos *et al*., 1993). In urine, mandelic acid, phenylglyoxylic acid, phenylglycine and 4-vinylphenol are possible urinary biomarkers (**Figure 3**). It is also possible to determine the secondary metabolites 1- or 2-phenyl-2-hydroxyethylmercapturic acid derived from a glutathione conjugate (Fustinoni *et al*., 2008). Some metabolites or conjugates are less useful because they are not specific for styrene. For example, benzoic acid (not shown in **Figure 3**) is not specific for styrene exposure since this substance also used as a food additive (E210). Hippuric acid, besides being a reaction product of benzoic acid, is also a conjugate formed following exposure to toluene.

4 PROTEIN ADDUCTS

Peptides and proteins contain numerous nucleophilic groups that can be targets for electrophilic attack by reactive intermediates to form adducts (**Figure 4**). These are mostly electrophilic, but not only alkylating substances. Törnqvist *et al*. (2002) point out that not all of these adducts are exclusively of post-translational origin, like N-terminal valines, that are much used as biomarkers (**Table 1**).

Intracellular proteins such as Hb follow zero-order kinetics, leading to a steady-state level that is determined by the turnover of the cells. In the case of Hb, the lifespan

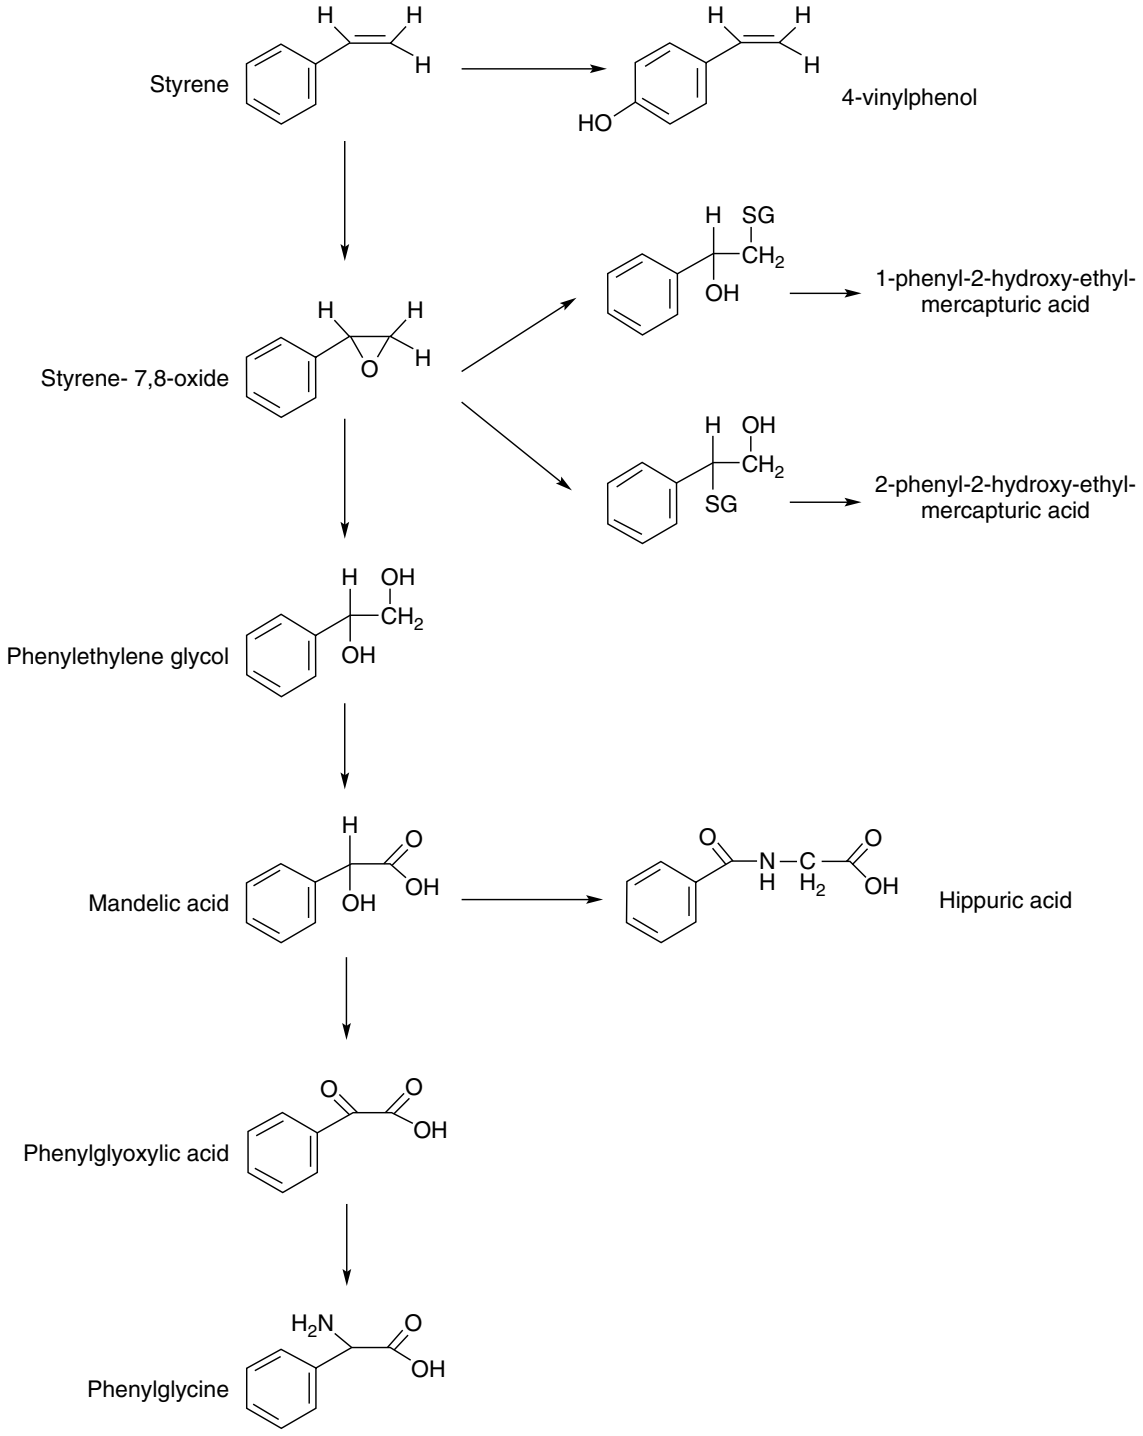

Figure 3 Part of the biotransformation pathway of styrene. This scheme shows the many options for selection of biomarkers. (Modified from Fustinoni *et al*., 2008.)

of the erythrocytes is 126 days in humans (Bishop and Surgenor, 1964), causing a linear decrease of the adduct after cessation of exposure with a half-life of 63 days in humans. This kinetic pattern was observed in studies following the adduct levels after withdrawal from smoking, although the levels of 4-aminobiphenyl (ABP) Hb adducts declined faster than expected (Maclure *et al*., 1990). The formation and decay of adducts to proteins free in solution, such as serum albumin (SA), follow first-order kinetics. For adducts to SA in humans this results in a half-life of 20 days (Bishop and Surgenor, 1964). Adducts to SA and Hb follow these kinetics as long as they are chemically stable. So far, a mechanism of enzymatic repair of adducts to SA and Hb has not

been reported. Some studies have shown the formation of adducts to proteins with a longer lifespan than SA and Hb, such as histones. So far these adducts have not been detected in humans *in vivo* (Scheepers *et al*., 2008).

5 DNA ADDUCTS AND DNA-REPAIR PRODUCTS

5.1 Addition Products

Similar to proteins, the DNA bases also contain nucleophilic targets for covalent binding of electrophilic intermediates (**Figure 5**). For a long time, sensitive detection of these products relied on isolation of DNA from peripheral lymphocytes. Some attempts to use other tissues for isolation of DNA adducts have been successful, such as exfoliated bladder epithelial cells that are excreted with urine (Talaska *et al*., 1996) and exfoliated epithelial cells that can be retrieved from swipes of buccal mucous (Romano *et al*., 1999). With ^{32}P-postlabelling it is possible to detect one adduct in 10^8 nucleotides. Identification of the adduct relies on coelution of the isolated adduct from human blood samples with laboratory-synthesized adduct standards, preferably using a liquid chromatography system for separation. Nowadays the sensitivity of mass spectrometry (MS)-based techniques is in the same range as for the ^{32}P-postlabelling method (Singh and Famer, 2006).

In contrast to protein adducts, most DNA structure modifications are not stable, due to the activity of enzymatic repair (base and nucleotide excision repair, O^6-alkylguanine-DNA alkyltransferase, glycosylases, etc.). This means that some adducts may disappear after several hours to a few days. However, some bulky adducts, such as those formed by polycyclic aromatic hydrocarbons (PAHs) may be more stable. These adducts have been successfully used to characterize both occupational (Van Schooten *et al*., 1995; Binkova *et al*., 1998; Hemminki *et al*., 1997) and environmental exposures (Hemminki *et al*., 1990; Perera *et al*., 2005) to PAHs. These DNA-adduct levels also correlate well with tobacco smoking (Phillips *et al*., 1988; Talaska *et al*., 1991).

Phosphotriester adducts also appear more persistent because there are no known enzymatic repair systems in eukaryotic cells, and the development of methods for this type of adduct could yield interesting novel biomarkers for long-term exposure (Scheepers, 2008).

5.2 Products of DNA Repair

After repair, N-7-guanine and N-3-adenine adducts are excreted in urine, which offers an opportunity to use these enzymatic repair products as biomarkers of short-term exposure. Adducts of ethylene oxide to N-7-guanine have been chemically characterized by LC-ESI-MS/MS (liquid chromatography-electrospray ionization tandem mass spectrometry) (Marsden *et al*., 2007). Such repair products have also been used to characterize exposure to aflatoxin B1 (Ross *et al*., 1996; Qian *et al*., 1994). If determined in urine these products do not provide information on the tissue where the adduct was formed.

5.3 Other Approaches

Reactive oxygen species can be formed during inflammatory processes resulting from exposure to

[b]Nitroamine-4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone.
Based on Törnqvist *et al*. (2002).

fine particles. Some reactive intermediates of chemical exposures may also be involved in redox cycling or auto-oxidation, generating reactive oxygen species. Especially when transient metals are also present, reactive hydroxyl radicals can be formed. Such events can cause oxidative damage to DNA that is normally effectively repaired by nucleoside and base-excision repair enzymes, but a residue of repair products may be excreted. These repair products can be used as biomarkers for oxidative damage. Of several repair products 8-hydroxydeoxyguanine (8-OHdG) has been most used as a biomarker. This approach is valuable to assess general exposure to oxidants, but cannot be used to study the contribution of specific agents (Battershill *et al*., 2008).

Chromosome aberrations, sister chromatid exchanges (SCEs) and micronuclei can be related to cancer, but they are not specific to a particular chemical exposure. Also, the determination of urinary mutagenic activity in the *Salmonella typhimurium* assay (Bos and Jongeneelen, 1988) is nonspecific to the causal agents and therefore not suitable in most studies of exposure assessment.

6 GUIDELINES FOR HUMAN BIOLOGICAL MONITORING OF EXPOSURE TO CARCINOGENIC SUBSTANCES

6.1 Study Design

6.1.1 Research Question

Human biological monitoring can be used for scientific research, routine monitoring or to find answers to *ad hoc* questions.

Scientific research can be done to validate a biomarker in a volunteer study, that is, a study of kinetics of excretion of a biomarker, or a field validation to assess the suitability of a biomarker for the purpose of exposure characterization. Once validated, biomarkers can be used as quantitative exposure parameters in epidemiological studies.

Well-validated biomarkers can be used in long-term monitoring programmes to reveal trends in exposure that can help to support policy-makers. Examples of such programmes are NHANES (2008) and GerES (2008) (see list of references for web addresses of these projects).

Biological monitoring can be used to reconstruct exposure after chemical incidents in industry or any incidents that are marked by unintended release of chemicals into the environment. Biomarkers of exposure can also be used to evaluate the effectiveness of remedial actions in a workplace, such as a change in work procedures or introduction of personal protective equipment.

6.1.2 Study Population

The study population may be selected at random from the general population. In occupational settings the subjects who are at risk are often clearly identifiable by their job title. For some study aims it may be useful to compare two groups that are different with respect to one or more determinants of exposure, or that may be different in health status. Before selecting study subjects, a list of inclusion and exclusion criteria should be drafted.

6.2 Design

6.2.1 Follow-up Study

Sequential observations can be a good way to find out about work-related sources of exposure. In the setting of occupational exposure a pre-exposure or background value may be obtained on the morning before the start of the first shift of a workweek (preshift spot sample) and subsequent samples may be collected on the same day or on subsequent days during a working week, including a postshift sample at the end of the workweek. Using this design, a great number of individuals can be followed parallel in time. This strategy can be extended by including reference subjects. The reference subjects should have characteristics very similar to the subjects from the index group (age, social economic status, gender, smoking status), but with a suspected lower exposure. In practice, persons with mild, but specific, health complaints may be compared with persons that did not report any of these symptoms, to study the possible role of chemical exposure.

An intervention study is often used to evaluate a change in time. This can be a change in the determinants of emissions of toxic substances or a change in the determinants of exposure. In an intervention study, the initial situation (before the change) is compared to a new situation, using well-standardized methods. To rule out a temporal covariate, it is recommended to use a crossover design. Two possible designs for intervention studies are illustrated in **Figure 6**.

6.2.2 Confounders and Effect-modifiers

Besides the exposure to a carcinogenic substance, several host factors may have an influence on the biomarker level in an individual (**Table 2**). Some dietary factors may have a direct influence as sources of (co)exposure. For other factors it is possible to adapt the study design. For example, the results in smokers and nonsmokers can be analysed in separate groups. However, if factors are less frequent or the influence on biomarkers is not well understood, it is recommended to reduce their influence by standardization.

6.2.3 Questionnaires

The characteristics of study subjects can be registered in a questionnaire. Information about gender, age and biometry of the subjects, as well as some questions

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat176
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

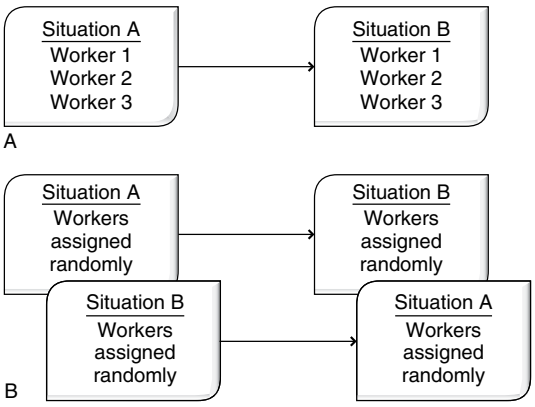

Figure 6 Study design to evaluate a transition from situation A to situation B. All workers can be followed at the same time (a). In order to rule out the influence of a temporal covariant (e.g. season or workday in the week) or the effect of sequence (e.g. a learning effect), the population can be randomly divided in subgroups (b). Each worker is assigned to one of the groups at random. Half of the population is followed in the transition from situation A to B, whereas the other half is followed in a transition from B to A.

about physical exercise, diet and alcoholic beverages, and use of medication is obtained using standardized questions. Sometimes outliers in biomarker levels can be explained using the information from the questionnaire.

Table 3 contains examples of some coexposures that could interfere with the primary exposure of interest. In the case of collection of repeated spot urine samples, breath samples or blood samples, some questionnaires have to be completed (repeatedly) at each moment of sample collection.

6.3 Ethics Issues

In this section some general guidelines are given regarding ethics issues that need consideration during the processes of preparation and performance of human biological monitoring studies. Information will be provided for the study protocol that is needed in order to obtain approval from the ethics committee that is responsible for the evaluation of scientific studies involving human subjects.

6.3.1 Informed Consent

An information and consent procedure is normally used in biomedical research to inform human subjects about the purpose of the study, their role in the study and their rights (e.g. the possibility to discontinue their participation and their own and external access to personal data). This procedure should be in line with the Declaration of Helsinki (World Medical Association, 2000).

Table 2 Factors that may influence the observed level of a biomarker

Factor	Influence	Remedy
Circadian rhythm	Temporal variation in composition of body fluids	Standardize times of sample collection
Body fat	Influence on toxicokinetics	Register body mass index or a more specific measure of body fat
Meal	Influence on blood lipid content	Collect samples before rather than after a meal
Smoking	Direct influence on levels of several biomarkers (sometimes indirect by induction of metabolic activity)	Study influence of smoking in a separate group and standardize for this effect. Register the amount smoked per day
Alcohol	Inhibition or induction of metabolic activity	Register the number of alcoholic beverages per day
Medication	Inhibition or induction of metabolic activity	Register use of prescribed and nonprescribed medication
Diet	Direct influence on levels of several biomarkers	Register use of certain food components, standardize by asking volunteers to refrain from consumption of certain specific food components
Food supplements	Direct influence on levels of several biomarkers	Register the use of certain specific food supplements like creatine monohydrate
Physical exercise	Influence on toxico-kinetics	Register level of physical exercise and evaluate impact by physiologically based pharmacokinetic (PBPK) model

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat176
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 3 Possible sources of coexposure in the general population

Chemical marker	Source
Antineoplastic agents	Treatment with these agents
(Total) arsenic	Consumption of seafood
Chlorinated hydrocarbons	Evaporation from recently dry cleaned clothes
Nickel/chromium	Orthopaedic or dental implants
PAH	Treatment of psoriasis or eczema with coal-tar ointment or use of coal-tar containing shampoo; consumption of broiled, fried, smoked and barbecued meat and fish
Phthalates	Leaching from plastics
Platinum	Exhaust fumes from gasoline-powered vehicles with platinum-containing three-way catalysts

6.3.2 Sample Coding

Coding is a measure to ensure confidential handling of information, protecting the individual and enabling blinded analysis. It should be specified by whom, where and how the samples are coded, how the code forms are kept in an archive and what links between code and study outcome exist (Knudsen, 2004; 2005). Persons who have access to the code list must be identified. It should also be clear for how long the code lists will be kept and who is responsible for their destruction.

6.3.3 Protection of Privacy of Study Subjects

During the study, the privacy of the study subjects should be respected. Normally, the information identifying a person will be kept in the medical file by the physician directly responsible for the medical health of the study subjects (occupational physician or general physician). Also databases containing the results from questionnaires should be made anonymous. If explicitly requested individual study subjects will be granted access to their individual study results.

6.3.4 Obtaining Ethics Approval

To obtain ethics approval a request should be submitted to a national, regional or local review committee recognized by the (health) authorities. The purpose of the study and the study protocol should be outlined. The study protocol includes the method of recruitment of study subjects, inclusion/exclusion criteria of study subjects, description of activities that may lead to exposure to specific carcinogenic substances studied, study design, specification of the analytes, future use of samples and protection of privacy of the study subjects. Usually all information and documents that will be provided to the study subjects should also be reviewed by the ethics committee.

6.4 Communication

6.4.1 Introduction to the Study

Depending on the purpose of the study and the size of the study population, a study can be introduced personally by a physician or during a meeting by oral presentation. It is useful to supply written information to the study subjects in any case. The most important points that should be addressed are presented in **Table 4**.

6.4.2 Obtaining Informed Consent and Enrollment

The purpose of informed consent is to make sure that persons participate in a study purely on a voluntary basis. Participants should not feel obliged to take part based on (material or immaterial) obligation to the investigator. Also, they should be informed of all details concerning the study and their participation, and be convinced that no information is withheld from them. They should have the opportunity to ask questions and let additional information influence their decision to take part. The informed consent form states that even after taking the decision to participate and signing the form, the participants may decide to discontinue participation without the obligation to explain to the investigator about it.

6.5 Collection, Transport and Storage

In this section the collection, transport and storage of blood, urine and exhaled air samples will be discussed in general terms. More specific information can be found in biological applications datasheets that have been made available on the internet for specific carcinogenic substances (BIOMONECS, 2006).

6.5.1 Blood

Blood can be collected from the forearm by vena puncture. If only 5–10 µl of blood is required, a skin prick with a sterile lancet to collect blood from a vein in the finger of the study subject may suffice. For metals, special tubes with low metal content are needed. If plasma and blood cells are to be used, an anticoagulant should be

Table 4 Issues to be included in information provided to the study population

Subject	Contents
Purpose	The purpose of the study should be clearly stated.
Parameters	The parameters that will be investigated should be specified and the relationship of these parameters with the goal of the study should be clarified.
Role of participants	The role of the participants should be made clear, specifying in detail when and how samples will be collected, how and when questionnaires will be completed and what other requests are made to the participants. It should be made clear that participation is on a voluntary basis.
Privacy	Clarify how the privacy of the participants will be protected during and after the study. Will the data collection be anonymous and who will keep the biological samples and the data, and for what period of time? Also restrictions and procedures for future use of biological samples or data (by third parties) should be described.
Recruitment	The procedure for recruitment of participants should be explained (e.g. the use of inclusion/exclusion criteria) and the informed consent procedure should be explained.
Results	The moment and the way of presenting the study outcome to the participants should be made clear. It is important to inform the participants of any plans to disseminate the information to health authorities or to the scientific community or by uploading the data into a specific computer database.
Compensation	It should be made clear to what extent participants will be compensated for efforts and expenses.
Financial support	It should be stated how the study is financially supported and which parties are involved.
Contact	Names and contact information of the study coordinator(s).

added. If using an anticoagulant the tubes should be thoroughly mixed directly after blood collection.

If isolated red or white blood cells are needed, it is recommended that the cells be precipitated by centrifuge and the cells rinsed with a sterile solution of 0.9% sodium chloride within eight hours of collection. Alternatively, lysis may be required to terminate any biochemical activity in the blood cells prior to storage. Isolated cell fractions and plasma may be stored at $-20\,^{\circ}C$ to $+4\,^{\circ}C$, depending on the stability of specific analytes. For blood cells to be used in biological assays, the addition of freezing medium with stabilizer and freezing at $-80\,^{\circ}C$ is common.

6.5.2 Urine

With a spot urine sample an aliquot of urine is collected from one void, for example, a preshift and postshift sample in workers. A sample collected just after awakening is a well-defined concentrated preshift sample.

For postshift urine collection, the study subjects should take off any contaminated (work) clothes and wash their hands before collecting a urine sample to avoid contamination of the urine sample or the urine container.

For 24 hour urine, all urine should be collected. As an alternative, the study subject can be asked to collect a part of each void (e.g. midstream), but in that case the total volume of each void should also be registered. Collection of 24 hour samples is not recommended, unless the study subjects are well instructed and collection of such samples is needed because of the study purpose. This may be required after an accidental high exposure or in a study where volunteers are exposed under controlled conditions, for example, to study excretion kinetics.

Prelabelled polypropylene and polyethylene bottles can be used with a wide opening that can be sealed with a screw cap. When analysing metals it is generally recommended to rinse the urine container with a 3% nitric acid solution prior to use. Urine bottles should be filled to a maximum of three-quarters of the container volume when storing at temperatures below $0\,^{\circ}C$.

In spot urine samples, adjustment for the sample density is recommended. The most common correction is by determination of the urinary creatinine content. A normal creatinine level is around $1\,g\,l^{-1}$. Values as low as $0.05\,g\,l^{-1}$ or higher than $2.5\,g\,l^{-1}$ should be treated as an outlier. In that case the creatinine level is not reliable and may be indicative of an error during sample collection or abnormal kidney function.

On-site treatment of the samples is only needed to protect the analyte or the integrity of the sample. Micro-organisms may appear in urine samples due to contamination from the ambient environment or due to an infection of the bladder or urethra. Samples may be stored at $-18\,^{\circ}C$. If the samples are stored at $4\,^{\circ}C$ for not much longer than 24 hours no preservation is needed. Organic preservatives, such as natrium azide or citric acid may interfere with the analytical procedure and therefore it is useful to verify any interference with the analysis in advance. Inorganic preservatives that may be used are acid solutions (analytical grade solutions of hydrochloric acid, nitric acid or sulfuric acid) until a pH of approx. 2 is reached. Use of a 6 M solution of hydrochloric acid is

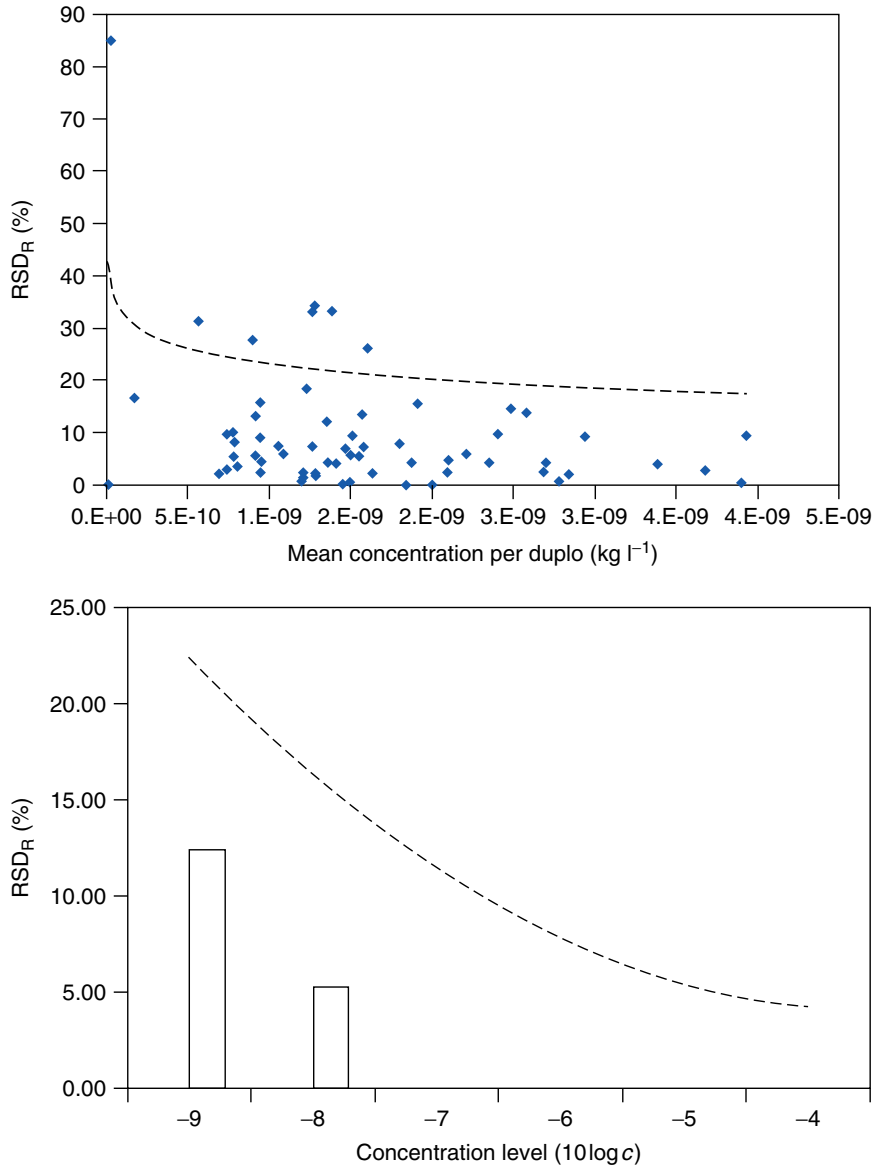

Figure 7 RSD_R in relation to concentration of nickel (μg l^{-1}) in background samples. The dotted line represents the RSD_R required according to IUPAC (1990) in both panels. The raw data are presented in the upper panel. For seven samples the RSD_R exceeds the required value. The lower panel shows that the aggregated data fulfill the IUPAC requirement.

effective as a preservative for storage at 4 °C. A warning text should be printed on the label if a preservative is added to the urine bottle in advance.

After storage at 4 °C or lower, a precipitate may appear, consisting of salts and sometimes protein sediment that could capture some of the analyte inside. It is recommended to gradually warm up the sample to 37 °C in a water bath, and homogenize the sample thoroughly before analysing.

6.5.3 Exhaled Air

End-exhaled air is recommended as a well-defined fraction that can easily be collected in the field. For collecting an end-exhaled sample, a breath sampler can be used (**Figure 2**). The study subject should be instructed to take the sample after a standardized period of time following the end of exposure. The sample should be collected in a clean environment. Breath sampler and solid sorbent tubes may be reused after cleaning. When cleaning, instructions from the supplier of these materials should be followed and materials should be tested before use, to avoid carryover of organic analytes from one sample to another. Storage of breath samples in the gas phase is not recommended because analytes may be lost due to leakage of the breath-sample container, adsorption of the analyte onto the sample container and/or by chemical reactions of the analytes with other components in the breath sample. It is recommended to transfer the organic substances from the breath sampler to a solid sorbent

Table 5 Background values of nonsmoking adults

Substance	Biomarker	N	0.95 percentile	
			$\mu g\,l^{-1}$[a]	$\mu g\,g^{-1}$ creatinine[a]
Aniline	Aniline in urine	60[ee]	22.1	23.8
Arsenic	Arsenic in urine	64	20.4	23.0
Benzene	Benzene in end-exhaled air	65	$8\,ng\,l^{-1}$	—
	S-Phenyl-mercapturic acid in urine	64	7.3	6.5
	t,*t*-Muconic acid in urine	64	0.32	0.33
Butylbenzylphthalate (BBP)	MBP[b] in urine	64	116	146
	MBzP[c] in urine	64	29.7	28.0
Cadmium	Cadmium in urine	64	0.36	0.39
Chloroform	Chloroform in end-exhaled air	60[ee]	$0.1\,ng\,l^{-1}$	—
Chromium	Chromium in urine	64	0.39	0.42
Diethylhexylphthalate (DEHP)	5-oxo-MEHP[d] in urine	64	82.6	72.3
	MEHP[d] in urine	64	25.1	26.3
	5-Hydroxy-MEHP[d] in urine	64	99.6	109
	5-Carboxy-MEHP[d] in urine	64	142	152
Nickel	Nickel in urine	64	3.3	3.3
Platinum	Platinum in urine	60[ee]	$30\,ng\,l^{-1}$	$35\,ng\,g^{-1}$
Polycyclic aromatic hydrocarbons	1-Hydroxypyrene in urine	64	0.20	0.17
Tetrachloroethylene	Tetrachloro-ethylene in end-exhaled air	54[ee]	$0.2\,ng\,l^{-1}$	—
o-Toluidine	*o*-Toluidine in urine	60[ee]	0.50	0.62
Trichloroethylene	Trichloro-ethylene in end-exhaled air	54[ee]	$0.1\,ng\,l^{-1}$	—

[a]Unless otherwise indicated.
[b]MBP = mono-*n*-butyl.
[c]MBzP = mono-benzyl phthalate.
[d]MEHP = mono-(2-ethylhexyl) phthalate.
[e]No subjects from United Kingdom.

within a few hours of sample collection. Once the organic analytes are transferred to a solid sorbent, the sample can be stored at room temperature in a clean environment for a prolonged period of time. It is recommended to seal the sorbent tubes in a gas-tight plastic bag to avoid contamination during transportation and storage.

6.6 Chemical Analysis

6.6.1 Performance Characteristics

The most important characteristics are precision and sensitivity. Precision is expressed in reproducibility and repeatability. Reproducibility is usually expressed as a relative standard deviation (RSD). The criterion for acceptable reproducibility can be taken from a consensus publication from IUPAC (Pocklington, 1990) as the between-laboratory reproducibility relative standard deviation (RSD_R) that can be calculated from $2^{(1-0.5\log c)}$ where c is the concentration expressed as a decimal fraction (**Figure 7**). The within-laboratory method performance, expressed as the repeatability relative standard deviation (RSD_r) is about one-half to two-thirds of the RSD_R (Pocklington, 1990).

The sensitivity of a method is determined by the limit of detection (LOD) and quantification limit of quantification (LOQ). The LOD is defined as the lowest amount of analyte in a sample which can be detected, but not quantified. The lowest amount of analyte in a sample which can be quantitatively determined with specified precision and accuracy under certain experimental conditions is called the limit of quantification.

6.6.2 External Quality Assurance

The quality of the analysis should be evaluated using reference standards. For biomarkers only few certified

reference materials are available from the Community Bureau of Reference (BCR) in Brussels. Round robins are useful for intercomparison of lab performance using matrix-mixed standards for different biological materials.

6.7 Interpretation of Results

6.7.1 Background Values

Some studies provide background values for biomarkers in the general population, such as for metals by Brune *et al*. (2003). In 2006, background values were established as part of a EU project (**Table 5**). For this campaign, samples were collected in 2003 and 2004 in Belgium, Denmark, Germany, Sweden, the Netherlands and the United Kingdom in male and female (1:1), mostly white-collar workers, 18–65 of age. All subjects were nonsmokers or smokers who stopped smoking more than six months prior to sample collection.

6.7.2 Biological Limit Values

The EU has a system of biological limit values (BLVs), although not many BLVs have been published so far. The ACGIH has a system of biological exposure indices (BEIs) that is updated each year (ACGIH, 2008). In addition BAT values established by Deutsche Forschungsgemeinschaft (2008) can also be used.

6.8 Dissemination of Results

It is preferred to collaborate with a physician, who is authorized to keep the study outcome and the key to the person code list (two-way verification of person identity). In this way it is possible for the physician to disclose the data to an individual subject if needed. This may be done if the outcome is unexpected and may be indicative of a risk to the health of the subject.

ACKNOWLEDGEMENTS

Most of the content of this chapter is based on the results of the project Biological Monitoring of Exposure to Carcinogenic Substances (BIOMONECS) that was supported by the European Union (contract no. QLK4-CT-2002-71801). The author is indebted to Dr. L.E. Knudsen and dr. M. Törnqvist for valuable discussion and comments.

Cardiac Toxicity of Anthracyclines

Richard D. Olson and Barry J. Cusack

CONTENTS

1 INTRODUCTION

The first doxorubicin with broad-spectrum activity used in the treatment of cancer was doxorubicin (DOX) (adriamycin). It was isolated by Federico Arcamone and coworkers in 1968 from microbes (*Streptomyces peucetius var.caesius*) in the soil near the Adriatic Sea, hence the name adriamycin. DOX has been used in treatment of breast cancers, acute lymphoblastic leukaemias, sarcomas and small-cell carcinoma of the lung. Its efficacy has made DOX one of the most important chemotherapeutic agents to increase childhood cancer survival.

Anthracyclines, including DOX, daunorubicin (DNR) and epirubicin, have troublesome side effects that decrease their clinical utility and prevent their use in some clinical settings. Anthracyclines produce mucousitis, nausea, myelosuppression and alopecia. These side effects are acute and reversible, although neutropenia is frequently the dose-limiting side effect in clinical practice. However, this class of antineoplastic agents is most known for an irreversible, chronic cardiotoxicity that limits the total, cumulative dose. It may be fatal.

Anthracyclines can elicit an early (acute) and delayed (chronic) cardiotoxicity (Bristow *et al*., 1978; Buzdar *et al*., 1985). The acute cardiotoxicity can manifest with electrocardiogram (ECG) changes including ST-T changes, widening of the QRS complex and decreases in voltage. Dysrhythmias, pericarditis, myocarditis and reversible decreases in cardiac contractility have been reported clinically. These acute changes are usually not considered a major clinical problem (Bristow *et al*., 1978), although some researchers suspect that both the acute and chronic injury may summate yielding the overall clinical picture of anthracycline cardiotoxicity. The chronic cardiotoxicity can be fatal (Buzdar *et al*., 1985) and has necessitated lowering the recommended total cumulative dose, especially in combination with other antineoplastic drugs, such as herceptin and taxanes in treatment of breast cancers (Dresdale *et al*., 1983; von Hoff *et al*., 1979; Watts, 1991). Cardiotoxicity of anthracyclines is identified

by echocardiography or radionuclide angiography, but the most sensitive technique is myocardial biopsy.

2 MODELLING ANTHRACYCLINE CARDIOTOXICITY: TARGETS OF INJURY

2.1 Acute *In Vitro* Cardiotoxicity

Acute and chronic animal models of anthracycline cardiotoxicity have yielded important insights into how anthracyclines injure the heart. Perhaps the earliest model of anthracycline cardiotoxicity was the isolated contracting cardiac muscle fibre or tissue. These included isolated contracting atria and ventricular muscle preparations studied *in vitro*. As a result of these studies, we now know the subcellular targets and anthracycline structures responsible for anthracycline cardiotoxicity in this model.

The hallmark of DOX cardiotoxicity in the isolated rabbit atria is a selective decrease in contractility of the first contraction following a rest interval, compared to contractility of repetitive contractions at a steady-state contraction rate of 1 Hz (Shadle *et al*., 2000; Burke *et al*., 2002). The first contraction following the rest interval is normally enhanced because of an increase in sarcoplasmic reticulum (SR) activator calcium (Ca^{2+}) during the rest interval. Thus, interventions or drugs that selectively impair SR Ca^{2+} function, such as caffeine, selectively impair enhanced contractility of the rested contraction compared to contractility of the repetitive contractions at steady state, which is less dependent on SR Ca^{2+} stores (Bers, 1985; Bose *et al*., 1988; Bouchard *et al*., 1989; Bouchard and Bose, 1989). DOX and DNR, like caffeine and ryanodine, selectively impair postrested contractions, suggesting that anthracyclines cause cardiotoxicity in this model by impairment of SR function (Shadle *et al*., 2000; Burke *et al*., 2002).

Anthracyclines, like caffeine, also impair the force–frequency relationship of cardiac muscle. For example, in rabbit atria or papillary muscle preparations, the increase in contractility that occurs at higher rates of stimulation is selectively decreased compared to contractility at slower rates of contraction (steady state). The enhanced contractility that occurs at higher rates of contraction (treppe) results, in part, from increased SR Ca^{2+} stores (Shadle *et al*., 2000; Burke *et al*., 2002).

Further evidence for the idea that anthracyclines target SR comes from comparative studies with neonatal rabbit atrial preparations (Burke *et al*., 2002). Neonatal rabbit atria have immature and relatively nonfunctional SR, and activator Ca^{2+} comes primarily from transsarcolemmal Ca^{2+} sites (Burke *et al*., 2002; Klitzner and Freidman, 1989). Thus, agents that selectively impair SR function should have attenuated effects on contractility. Indeed, caffeine and anthracyclines elicit dramatically reduced impairment of contractile function in the neonatal-rabbit isolated atrial preparation (Burke *et al*., 2002).

In isolated SR preparations from dog heart, caffeine and anthracyclines have very similar effects on Ca^{2+} release (Shadle *et al*., 2000; Olson *et al*., 2000). Both caffeine and anthracyclines cause Ca^{2+} release from Ca^{2+}-loaded SR preparations, an effect blocked by ruthenium red, indicating that anthracycline- and caffeine-induced Ca^{2+} release is mediated through the Ca^{2+} release channel. These effects by anthracyclines on SR are not free-radical mediated, but require the quinone moiety since they occur rapidly and free radicals are not detected in the isolated SR preparation (Shadle *et al*., 2000; Olson *et al*., 2000). Replacement of the quinone with an imino (DNR vs. 5-imino DNR) abolishes the anthracycline impairment of cardiac function and SR Ca^{2+} release (Shadle *et al*., 2000; Olson *et al*., 2000).

In summary, in the isolated cardiac and SR preparations *in vitro*, anthracyclines cause toxicity by targeting the SR and impairing cardiac Ca^{2+} metabolism through a mechanism requiring the quinone moiety, but probably independent of redox cycling and free-radical generation.

2.2 Chronic Cardiotoxicity

Is the SR a target in the more clinically relevant chronic model of anthracycline cardiotoxicity? At the onset of chronic cardiotoxicity, cardiac SR begins to swell and vacuoles appear, suggesting dysfunction in activator Ca^{2+} sequestration, storage or release, and chronic DOX cardiotoxicity leads to impairment of cardiac Ca^{2+} transients (Olson and Mushlin, 1990; Singal *et al*., 1987; **Figure 1**). The decrease in Ca^{2+} transients appears to result, at least in part, from loss of SR activity. (Dodd *et al*. 1993) found that the density of the cardiac SR Ca^{2+} release channel was reduced by 50% in a chronic rabbit model of DOX cardiotoxicity, suggesting that the SR might be an important target in DOX-induced disruption of cardiac Ca^{2+} homeostasis. Arai *et al*. (1998) demonstrated that chronic DOX administration in rabbits down-regulated the gene expression of cardiac SR Ca^{2+} release channel and SR Ca^{2+} pump, phospholamban and messenger RNA. Both SR Ca^{2+} release channel density and messenger RNA (mRNA) concentration significantly regress with left-ventricular fractional shortening (FS) assessed by M-mode echocardiography to predict the degree of cardiac dysfunction (**Figure 2**). These data suggest that SR is an important subcellular target in chronic DOX cardiotoxicity.

How might chronic anthracycline administration lead to a decrease in protein concentrations of SR Ca^{2+} release

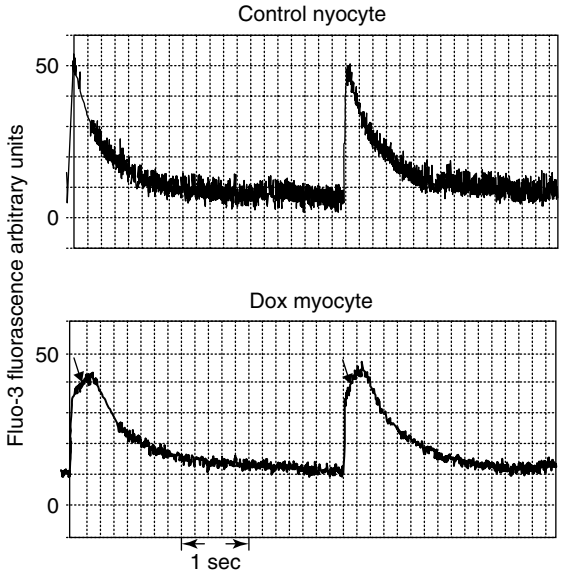

Figure 1 Examples of fluo-3 calcium transients elicited by electrical stimulation (0.25 Hz, 37 °C) in isolated adult ventricular myocytes obtained from a pair-fed control (top tracing) and from a chronic doxorubicin-treated rabbit (bottom tracing). The control myocytes show a typical very rapid upstroke of $[Ca^{2+}]_i$ to a peak with a subsequent decline. In this example, there is some high-frequency tape recorder noise superimposed on the calcium transient. The bottom tracing shows an abnormal calcium transient contour, which we found typical of doxorubicin-treated male rabbit myocytes. The initial upstroke is somewhat slower than in the control myocytes, and is followed by a very distinctive and unusual secondary slowing in the upstroke of the calcium transient (see arrow) which results in a significant delay in the time to peak of the calcium transient. (In collaboration with Dr. William H. Barry, University of Utah, SLC, Utah.)

channels and associated proteins? Although the answer to this question is currently unknown, one possibility relates to decreases in thyroid hormone in the chronic model of DOX cardiotoxicity.

Triiodothyronine (T3), the active cellular form of thyroid hormone (thyroxine, T4), is a powerful effector of Ca^{2+}-handling proteins and contractile function of the heart. Circulating T4, released from the thyroid gland in response to thyroid stimulating hormone (TSH), is converted into T3 primarily by iodothyronine 5′monodeiodinase in the circulation and liver. In the myocyte, T3 binds to nuclear T3 receptors and the complex then binds to thyroid hormone response elements on genes to regulate transcription. The SR Ca^{2+} pump (SERCA2) gene contains thyroid-hormone-receptor-responsive elements and both the SR Ca^{2+} pump and Ca^{2+} release channel are under the regulatory influence of T3 (Jiang *et al*., 2000; Muller *et al*., 1997; Rohrer and Dillman, 1988; Pennock *et al*., 2000). Indeed, thyroid hormone modulates the abundance of SR Ca^{2+}-release-channel receptors and the degree of [^{3}H]-ryanodine binding to the Ca^{2+}-release-channel receptors (B_{max}) in a rabbit model (Jiang *et al*., 2000).

Cardiotoxic doses of DOX in the chronic rabbit model caused nearly an 80% reduction in free triiodothyronine (fT3) up to three months after cessation of DOX administration (**Figure 3**). This was not due to caloric restriction from anorexia, since age-matched pair-fed control rabbits had normal fT3 levels (**Figure 3**). The data from these studies suggest that the role of T3 in mediating changes in SR proteins in the chronic model of DOX cardiotoxicity needs further evaluation.

In summary, it appears that the SR is a target of injury in both the acute and chronic animal model of anthracycline cardiotoxicity. Other sites, including mitochondria, have also been suggested to be injured, perhaps leading to apoptosis and myocyte dropout that occurs in anthracycline cardiotoxicity.

3 RISK FACTORS FOR ANTHRACYCLINE CARDIOTOXICITY

3.1 Anthracycline/Herceptin Drug Interaction

The HER2 (ErbB2) proto-oncogene encodes a 185 kDa transmembrane tyrosine kinase that is a member of the epidermal-growth-factor family and has important effects on cell growth, differentiation and cell survival (Slamon *et al*., 2001; Seidman *et al*., 2001; 2002; Ewer *et al*., 1999; Feldman *et al*., 2000). HER2 appears to have

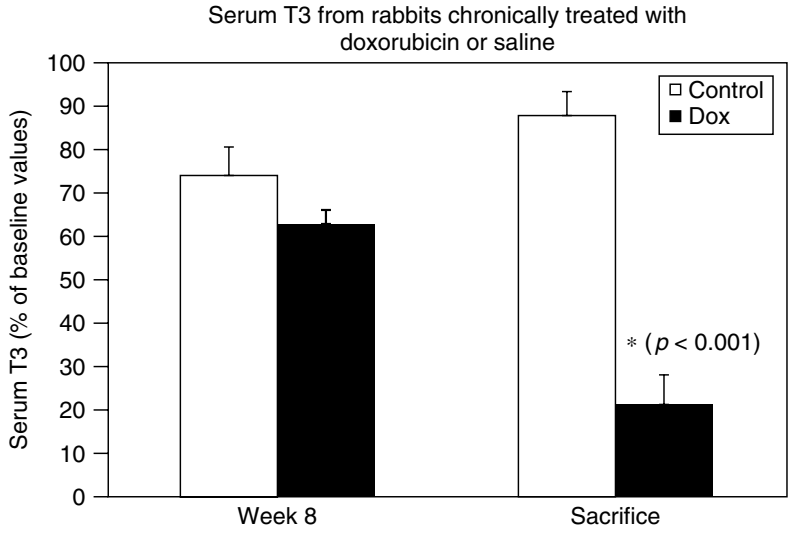

Figure 3 Serum concentrations of free triiodothyronine (T3). The T3 values were obtained eight weeks after beginning DOX or saline injections and at sacrifice, and expressed as a percentage of pretreatment baseline values. Values are mean ± SEM. *$p < 0.001$ vs. control.

an important role in the adult heart. Ozcelik *et al*. (2002) conditionally mutated HER2 in cardiomyocytes of mice. Most of the mutated mice reached adulthood, but developed a severe dilated cardiomyopathy. Crone *et al*. (2002) also developed a conditional knockout HER2 mouse model in which the protein expression was inhibited by 70% compared to control mice. At three months of age, there was no difference in body weight or heart rate between the wild-type and left ventricular end diastolic diameter. However, echocardiographic analysis of hearts from the mutated mice showed decreased FS and enlarged end diastolic dimensions (left ventricular end diastolic diametersLVEDDs) compared to the wild-type ($FS = 38 \pm 3\%$ vs. $19 \pm 2\%$; $LVEDD = 3.7 \pm 0.1$ mm vs. 4.6 ± 0.2 mm). Hearts from the conditional knockout mice also had increased apoptosis and overexpression of the anti-apoptotic gene *Bcl-xL* partially protected the increase in LVEDD and decrease in FS, suggesting that apoptosis may be important in development of heart failure. These studies have led to the speculation that HER2 may mediate cell survival by blocking apoptosis and cell-death injury. Impairment of these pathways may create a susceptibility for increased anthracycline-induced cardiotoxicity (Chien, 2000; 1999).

Approximately 45 000 women will die of breast cancer in the US this year (Slamon *et al*., 2001). Of women with breast cancer, 25–30% overexpress HER2 (Slamon *et al*., 2001; Seidman *et al*., 2001; 2002; Ewer *et al*., 1999; Feldman *et al*., 2000). Higher levels of HER2 is associated with a worse prognosis, which prompted researchers to target the HER2 protein in women with breast cancer (Slamon *et al*., 2001; Seidman *et al*., 2001; 2002; Ewer *et al*., 1999; Feldman *et al*., 2000). Thus, a humanized monoclonal antibody to the protein was developed (herceptin, traz) and when used in combination with other forms of chemotherapy, increased median time to disease progression from 4.6 months (chemotherapy alone) to 7.4 months and a lower death rate at one year (22% vs. 33%; $p = 0.008$) (Slamon *et al*., 2001). Cardiac toxicity was the most severe side effect, which occurred in 27% of women treated with traz, an anthracycline and cyclophosphamide and 13% treated with traz and paclitaxel (cardiac toxicity occurred in 8 and 1% of patients that received only the anthracycline and paclitaxel treatment arm, respectively (Slamon *et al*., 2001). Retrospective review of other studies (Seidman *et al*., 2002) confirmed that the risk of cardiac dysfunction was highest when anthracyclines were used in combination with traz and has led to the reduced clinical use of anthracyclines with traz in treatment of metastatic breast cancer overexpressing HER2. This is unfortunate because anthracyclines and traz yield the best therapeutic benefit (Slamon *et al*., 2001).

3.2 Gender-Related Risk for Cardiotoxicity

Recent data reveals that anthracycline cardiotoxicity is more pronounced in female than male cancer patients. Females have a 300% greater risk of DOX cardiotoxicity than males, which increases to 500% if females are postpubescent, suggesting a contribution by sex hormones (Lipshultz *et al*., 1995; Sibler *et al*., 1993). These recent clinical findings suggest that DOX cardiotoxicity is a significant women's health issue and has

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat177
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

mandated reducing the cumulative dose of DOX to 360 mg m^{-2}, when used with taxanes or eliminating altogether the combined use of DOX with herceptin (Seidman *et al*., 2002; Gianni *et al*., 1995; Dombernowsky *et al*., 1996). Unfortunately, these recommendations are at the expense of reduced effectiveness in treating breast cancer.

The mechanism of this gender-related difference in risk for developing DOX cardiotoxicity remains enigmatic. One explanation for the gender-related differences in cardiotoxicity may relate to differences in cardiac and plasma pharmacokinetics of anthracyclines. Females had half the average plasma clearance of DOX than males, which might lead to higher cardiac levels of DOX and intracardiac conversion to the cardiotoxic metabolite, doxorubicinol (DOXOL) (Paz-Ares *et al*., 1995; Wasan and Kwong; 1997).

What might contribute to gender differences? Gender differences in risk for DOX cardiotoxicity suggest that sex hormones might contribute. Oestrogens alter gene expression of many enzymes. For example, oestrogen causes an increased expression of cardiac nitric oxide synthase (NOS; endothelial, eNOS and neuronal, nNOS) (Weiner *et al*., 1994; Andersen and Stender, 2000; Hayashi *et al*., 1997; Chen *et al*., 2003; Nuedling *et al*., 1999; Fraser *et al*., 2000; Wang and Abdel-Rahman, 2002; Xu *et al*., 1999). In addition, oestrogens cause the inactive form of eNOS to dissociate from a scaffolding caveolae protein in sarcolemma (a scaffolding caveolae protein in sarcolemma), yielding the active form. Recent studies demonstrate that DOX is a substrate for all three isoforms of NOS (nNOS, eNOS and inducible, iNOS) (Garner *et al*., 1999). DOX binds to the reductive domain of NOSs and undergoes a semiquinone redox cycling to generate superoxide anions and other free radicals. This interaction of DOX with eNOS has been demonstrated to cause cytotoxicity, including impairment of iron metabolism, apoptosis and lipid peroxidation, and has been suggested to mediate DOX cardiotoxicity (Kalivendi *et al*., 2001; Vasquez-Vivar *et al*., 1999; Duquaine *et al*., 2003). Since cardiac levels of eNOS and nNOS are expressed at higher levels in females than males, DOX might cause a selective gender-related increase in cardiac oxidative damage and free-radical injury contributing to the gender differences in DOX cardiotoxicity.

3.3 Age as a Risk Factor

Old age is a major risk factor for cardiotoxicity (Marchandise *et al*., 1989; Palmeri *et al*., 1986; Rabinovitch *et al*., 1989; von Hoff *et al*., 1979). Palmeri and coworkers studied patients with normal resting left ventricular ejection fractions (LVEFs) and noted that age is a significant predictor of final LVEF after completion of DOX therapy (Palmeri *et al*., 1986). Rabinovitch and colleagues also found that age was a significant predictor of LVEF during DOX therapy (Rabinovitch *et al*., 1989). The high risk of cardiotoxicity is not due to an altered incidence of coronary heart disease in older cancer patients (von Hoff *et al*., 1979). Early peak concentrations of DOX are increased with age (Robert and Hoerni, 1983), likely due to a highly significant decline in distribution clearance [CL(d)] with increasing age ($p < 0.0005$) (Li and Gwilt, 2003). This may contribute to the enhanced risk of cardiotoxicity with age, given that previous studies have indicated that peak plasma anthracycline concentrations are more important than total area under the curve (AUC) as predictors of cardiotoxicity (Bielack *et al*., 1989). There is no information on the effect of age on DNR kinetics in man.

What biochemical pathways may predispose to age-dependent anthracycline cardiotoxicity? The activity of rat heart antioxidant enzymes, superoxide dismutase and cytosolic Cu–Zn superoxide dismutase (SOD) declines with age (Ji *et al*., 1991). Myocardial a product of lipid peroxidation, increases with age in homogenates and mitochondria (Ji *et al*., 1991; Sawada and Carlson, 1987). Mitochondria and homogenate from senescent heart generates more O^{2-} and H_2O_2 (Ji *et al*., 1991; Sawada and Carlson, 1987). Lipid peroxidation is increased in Fischer 344 rat heart with age (Phaneuf and Leeuwenburgh, 2002). In addition, activity of aconitase, which is also a major target of superoxide and peroxynitrite disruption of the [4Fe–4S] cluster, declines with age in the heart muscle. Thus, the aged heart may be 'primed' for damage from free-radical insult from agents such as anthracyclines.

4 ANTHRACYCLINE PHARMACOKINETICS

The original anthracycline agents, DOX and DNR, have a similar structure (**Figure 4**), with a planar tetracyclic anthraquinone ring linked by a glycosidic bond to the amino sugar, daunorubicinol. DOX and DNR are extensively metabolized, undergoing reduction of the carbonyl group to respective alcohol metabolites DOXOL and daunorubicinol (DNROL). Carbonyl reduction is catalysed by ubiquitous cytosolic carbonyl reductases (Lovless *et al*., 1978). The other major metabolic pathway involves reductive cleavage of the daunosamine sugar moiety to yield anthracycline aglycones, that are without antitumour activity (Lovless *et al*., 1978). Concentrations of DOX and DNR in tissues are much higher than in plasma. Following cellular uptake, at least in whole-heart perfusion models, the greatest concentration of anthracycline is in the nucleus and mitochondria. There is considerable conversion of parent compounds to DOXOL
