Animal Welfare in the Toxicology Laboratory

Roy C. Myers and Bennett J. Varsho

CONTENTS

1 INTRODUCTION

Justification for proper care and humane treatment of animal models should be obvious. From a moral standpoint, it contradicts our sense of decency to cause pain and suffering in another species for no real benefit (see **Ethical, Legal, Social and Professional Issues in Toxicology**). Researchers must develop a measure of respect for laboratory animals and fully realize they feel pain and have basic needs for sustaining good health. Beyond moral issues, it must be remembered that animal welfare is crucial for good science. Animals experiencing pain, stress or poor health do not make good test subjects. One of the basic precepts of science is that a test group must contain a minimal number of variables other than those purposely introduced (such as a chemical dose for assessing biologic response). Subjects must be uniformly healthy and stress-free; otherwise, results are suspect and interpretations are difficult, if not impossible.

Animal researchers feel the mounting public scrutiny of their work from the media, the government and various animal advocacy groups. Laboratories are frequently targets of protests and other forms of negative publicity, with accusations of mistreatment or even torture. In some cases, animal rights activists break into laboratories to cause damage and/or to 'liberate' the research animals (see **Ethical Issues Related to Animal Welfare Considerations in the Toxicology Laboratory**). Obviously, all researchers must strive to avoid even a hint of animal abuse. A final reason to be concerned about animal welfare is direct and critical—it is the law. Most nations and international governing bodies clearly prohibit animal misuse. As will be seen in subsequent sections, there are specific requirements regarding the care, treatment, and disposition of laboratory animals. Failure to obey the laws can result in loss of licenses, rejection of studies and even fines or imprisonment. These all are powerful inducements for the proper use of animals.

2 BRIEF HISTORY OF ANIMAL WELFARE

Animal welfare and antivivisection activities were relatively common during the nineteenth century in the UK (Johns Hopkins Center for Alternatives to Animal Testing, 2008a). By 1876, the British government was pressured to pass the Animal Cruelty Act. In more recent times (1979), the Farm Animal Welfare Council

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

developed guidelines for animal use that became the 'Five Freedoms' (Wikipedia, 2008):

1. Freedom from thirst, hunger, and malnutrition
2. Freedom from discomfort due to environment
3. Freedom from pain, injury and disease
4. Freedom to express normal behaviour for the species
5. Freedom from fear and distress.

Political and social pressure to prohibit animal research also developed in the nineteenth century in the USA (Johns Hopkins Center for Alternatives to Animal Testing, 2008b). In 1866, the American Society for the Prevention of Cruelty to Animals was established. Numerous bills prohibiting animal research were considered by various legislatures between 1896 and 1900, but were all defeated. The advent of World War I and the growing enthusiasm for medical research tempered the opposition to animal use somewhat over the next several decades. However, a magazine story (Stan Wayman, Life Magazine, 1966) documented the poor living conditions for some dogs used in research. The US Congress, flooded with mail demanding controls on animal research, responded by passing new legislation (Laboratory Animal Welfare Act, 1966) which required that research animals receive humane care and treatment. Under this act, standards for care, treatment and transportation of animals became the responsibility of the US Department of Agriculture (USDA).

3 ANIMAL WELFARE LEGISLATION AND POLICY

Beginning with the Animal Welfare Act of 1966, several laws and regulations have been enacted in the USA to protect animals. Policies in other nations and international agreements are considered to be similar in content to the US policies. Examples are found in the *Guide to the Care and Use of Experimental Animals* published by the Canadian Council on Animal Care (CCAC; Canadian Council on Animal Care, 1993), guidelines produced by the Australian and New Zealand Council for the Care of Animals in Research and Teaching (ANZCCART; Australia and New Zealand Council for the Care of Animals in Research and Teaching, 2008), *Guidelines for Proper Conduct of Animal Experiments* published by the Science Council of Japan (2006), and so on. An effort to develop worldwide principles for laboratory animal use began in 1983, resulting in the *International Guiding Principles for Biomedical Research Involving Animals*, published in 1985 by the Council for International Organizations of Medical Sciences (CIOMS) (Association for Assessment and Accreditation of Laboratory Animal Care International, 1997a). The system in the UK is defined by the Animals (Scientific Procedures) Act of 1986. This law requires researchers to obtain a personal licence, a project licence and a certificate for the research facility. Whenever new research techniques are proposed, amended licences must be obtained (Association for Assessment and Accreditation of Laboratory Animal Care International, 1997b). Especially important in Europe is the European Directive 86/609 adopted by the Council of the European Communities (now the European Union) in 1986. This directive is fairly comparable to the US Animal Welfare Act (Association for Assessment and Accreditation of Laboratory Animal Care International, 1997c). More recently, the Council of Europe (separate from the European Union) published new guidelines for animal welfare, *Guidelines for Accommodation and Care of Animals* (Council of Europe, 2006), which are similar to those in the guide issued by the US National Research Council (discussed later in this chapter).

3.1 Animal Welfare Act

The Animal Welfare Act of 1966 (Public Law 89–544) has been amended several times and is administered by the US Department of Agriculture (1995). Within the USDA, the Animal and Plant Inspection Service (APHIS) enforces the Act (US Department of Agriculture, 1996). Recent amendments to the Act generally deal with issues not related directly to toxicology or they provide better definitions of animals to be excluded (US Department of Agriculture, 2008). The Act provides standards for animal husbandry, veterinary care, exercise (dogs) and psychological health (primates). Specifically excluded are rats and mice (by far the most commonly used research models), farm animals not specifically used for research and birds. To the extent possible, however, the conscientious investigator attempts to apply the principles of the Act to rodents during toxicological research. Researchers are required, under specified circumstances, to administer anaesthesia or analgesics to minimize distress. Unnecessary research or duplication of animal testing is prohibited. A very important aspect of the Act is the formation of an Institutional Animal Care and Use Committee (IACUC) at each facility to oversee animal use. The IACUC must include three or more members, one being a veterinarian, another being an individual not affiliated with the facility and others being from a variety of backgrounds, scientific and nonscientific (US Department of Agriculture, 1995). Study management personnel, such as study coordinators or study directors should be encouraged to serve on the IACUC to gain insight into animal welfare issues. It is often recommended that the 'outside' person be a nonscientist, possibly an ethicist or educator. The IACUC makes sure that the facility complies with the Act through

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat050
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

inspections (every six months), reviews of test protocols and formal reporting. One often-overlooked mandate of the Act is that researchers and facilities 'endeavour to build public confidence in animal research'. In other words, they should be open and truthful about the importance and practice of animal research.

In considerable detail, the Act specifies animal care conditions, promoting a healthy and stress-free atmosphere. These cover housing, ventilation, lighting, temperature, interior surface composition, caging, sanitation, pest control, feed and water, record keeping, veterinary care, training, handling and security. Specially trained APHIS inspectors (veterinarians or animal health technicians) are given full access to all areas where regulated animals are kept. Any deficiencies discovered by the inspectors are made known to laboratory management along with deadlines for correction. Failure to address the deficiencies adequately could result in suspension of the facility's animal licence or in legal action.

3.2 Health Research Extension Act

Passed in 1985 (P.L. 99–158) and implemented in 1986, the Health Research Extension Act has resulted in publication of the Public Health Service (PHS) Policy on Humane Care and Use of Laboratory Animals (Office for Protection from Research Risks, 1996). All facilities involved in PHS-sponsored projects must comply with this policy. Administration of the policy is the responsibility of the Office for Protection from Research Risks (OPRR) at the National Institutes of Health (NIH). Failure to comply results in a loss of NIH funding. In 2000, the OPRR Division of Animal Welfare was moved from OPRR, becoming the Office of Laboratory Animal Welfare (OLAW) within NIH.

Like the Animal Welfare Act, the Health Research Extension Act details the requirements for facility maintenance, employee training, handling techniques, veterinary care and record keeping associated with animal research. Highlighted are the IACUC, certification of the facility and compliance with the PHS *Guide for the Care and Use of Laboratory Animals* (National Research Council, 1996). The Guide, considered by most researchers as the definitive source for animal welfare instruction, will be described more fully later. Also emphasized is the appropriate use of analgesia and anaesthesia, together with methods of euthanasia consistent with those originally recommended by the American Veterinary Medical Association (AVMA) Panel on Euthanasia, 1993) and by the more recent AVMA Guidelines on Euthanasia (American Veterinary Medical Association, 2007). The PHS Policy is summarized by nine US Government Principles (driven by the Guide) which must be agreed to through submission of an 'assurance' of animal welfare prior to initiation of the study. The testing facility must be fully evaluated by an appropriate IACUC and/or accredited by the AAALAC International.

3.3 Good Laboratory Practices

With the adoption of the US Food and Drug Administration (FDA) Good Laboratory Practices (GLPs) regulations (US Food and Drug Administration, 1978; 1999), animal care and use considerations have become part of an overall plan for the conduct of scientifically sound studies. Basically, research under FDA standards must comply with the Animal Welfare Act and with animal treatment conditions recommended by the Guide. GLP requirements for detailed standard operating procedures (SOPs) and a quality assurance unit review also help ensure appropriate attention to animal welfare. Other agencies in the USA followed suite, with the passing of GLP regulations under the US EPA (Environmental Protection Agency) Toxic Substance Control Act (US Environmental Protection Agency, 1989a) and the US EPA Federal Insecticide, Fungicide and Rodenticide Act (US Environmental Protection Agency, 1989b). The US EPA revised animal-related GLPs in 1997 (US Environmental Protection Agency, 1997). Also providing guidance on basic animal welfare are several national or international GLPs such as those from the Organization for Economic Cooperation and Development (OECD; Organization for Economic Cooperation and Development, 1981; 1998).

3.4 Specific Testing Guidance

Study guidelines by the US EPA, FDA and OECD and many other agencies contain recommendations on the conduct of tests in a manner reflective of animal welfare. They especially promote euthanasia of distressed or moribund animals, limits of numbers of animals used, nonanimal screening and employment of available published data. As testing guidelines are updated, the emphasis on animal welfare issues typically increases.

4 ANIMAL WELFARE IN PRACTICE

It should be clear at this point that it is ethically and legally important to conduct animal research with as much attention to animal welfare as is practically possible. There are some very specific practices to achieve this, both from a standpoint of basic animal care and from the standpoint of humane research with animals. Responsibilities fall upon all personnel involved: institutional management, the investigator, technical staff and support staff (veterinary

to maintenance). All must be committed to the proper treatment of animals and to maintaining a suitable environment.

4.1 Animal Care

It would be impossible to discuss all principles of animal care in detail within this chapter. Instead, some basic concepts, as presented in the 'Guide' (National Research Council, 1996) and the Animal Welfare Act (US Department of Agriculture, 1995), are summarized below. An outline of the essential animal care considerations is given in **Figure 1**. Further information may be found in the *Guidelines for the Care and Use of Mammals in Neuroscience and Behavioural Research* (Institute for Laboratory Animal Research, 2003). It should be emphasized that all phases of animal care must be clearly detailed in facility SOPs with appropriate management review and approval.

4.1.1 General Animal Environment

In general, facilities used for animal research should provide for separation of animal rooms from those used for administrative purposes (offices, conference rooms, supply rooms, etc.). Moreover, when possible, animals should be housed in areas isolated from laboratories where tests are conducted. Such isolation permits

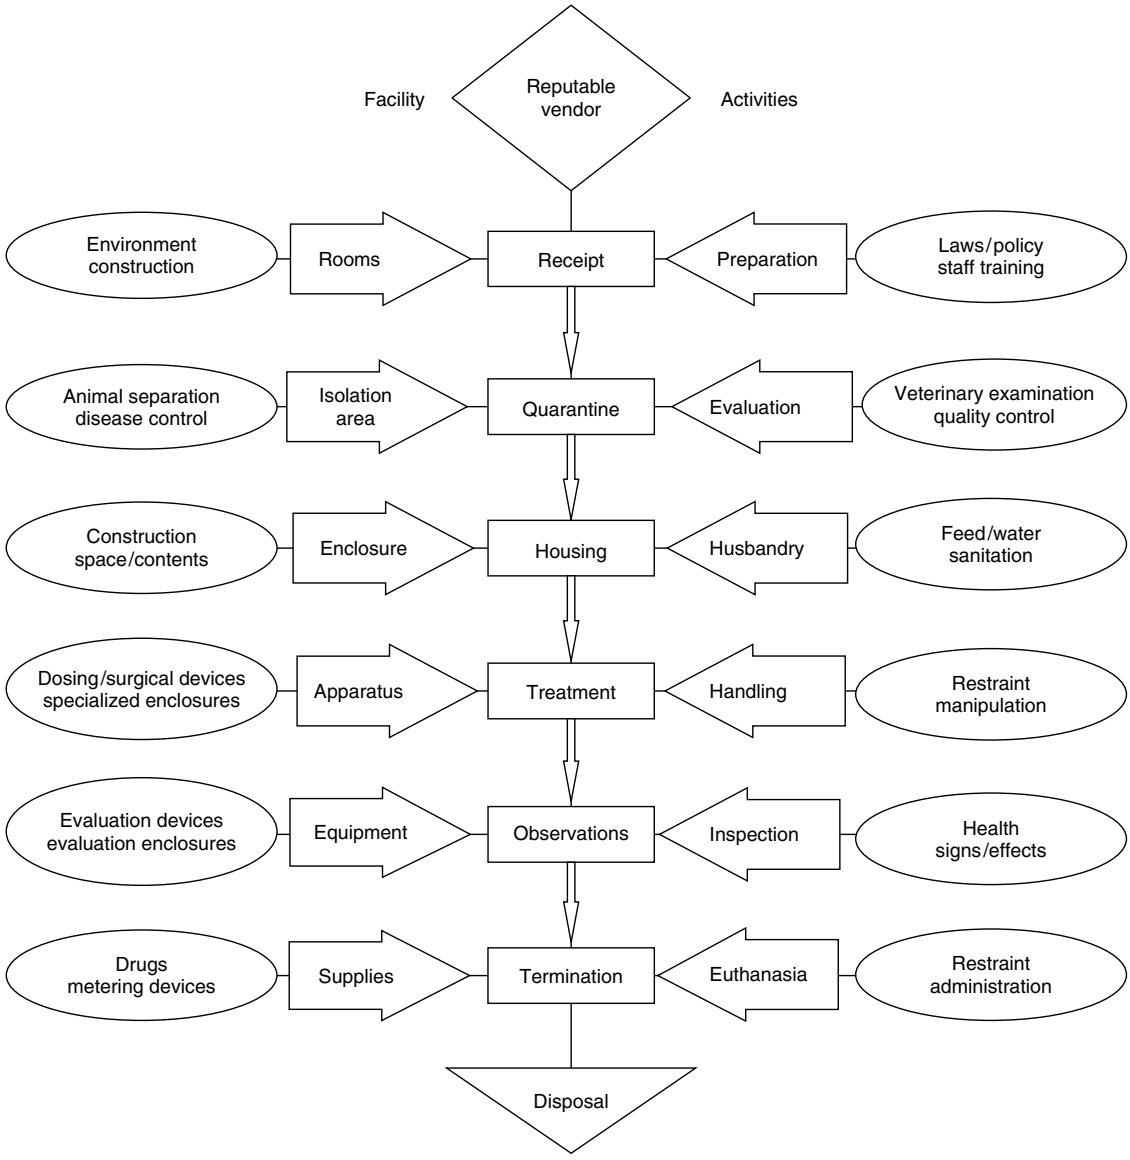

Figure 1 Essential considerations for animal care in the toxicology laboratory are shown diagrammatically. The central core includes the basic activities involving animals during their presence at the laboratory. Facility considerations and influencing factors are given on the left; animal care processes and influencing factors appear on the right.

minimal stress and confusion for the test animal. Surfaces within animal rooms should be resistant to moisture, vermin, cleansers and deterioration from frequent scrubbing. Porous surfaces and wooden surfaces, which allow collection of dirt and microorganisms, must be avoided. Exposed plumbing, ductwork and lighting fixtures must be minimized. Animals must be obtained from only reputable vendors or bred under carefully controlled conditions within the facility. Newly received animals should be quarantined until their health status can be fully determined.

There should be space dedicated to sanitation of caging and supplies, storage of feed and bedding, performance of specialized animal treatment (dosing, surgery, necropsy, etc.) and storage of scientific apparatus and supplies. Humidity in animal rooms should be relatively consistent and controllable within a range of 30–70%, while temperatures should be appropriate for the species housed and controllable within $\pm 1\,^{\circ}C$. Room lighting should be regulated by a timing device to provide a uniform diurnal cycle (typically 12 hours of light and 12 hours of darkness). Appropriate monitoring systems (recording devices and possibly alarms) should be used to ensure proper temperature, humidity and light cycles are maintained. There must be adequate air filtration to control the spread of dust and pathogens, and provisions must be made for temporary ventilation in the event of a mechanical failure. To avoid excess noise, rooms should be constructed of sound-limiting materials. Moreover, sounds generated by personnel and equipment should be kept to a minimum.

If animal surgeries are to be performed, there should be adequate isolation from sources of contamination. It is suggested that separate areas be provided for support materials and equipment, prepping, surgery and recovery. The recovery area should permit adequate observation of treated animals, as well as provide for the comfort of the animal (low lighting, reduced noise, special bedding, etc.).

4.1.2 Immediate Animal Environment

Adequate control of the immediate surroundings is crucial to animal research projects. Primary enclosures (cages, boxes, pens) must provide for basic needs such as feeding, maintenance of body temperature, moving, urination/defaecation, access to adequate airflow and resting. They must be constructed of materials with a smooth, impervious surface that resists rust and damage from frequent handling. Their design must permit animal observation, efficient changing of feed and water, and ease of cleaning and sanitation. Standard caging, especially for rodents and rabbits, typically is constructed of stainless steel with a mesh floor (although some researchers feel that a solid bottom with bedding is preferable). The wire mesh bottom permits animal waste to fall onto a collection tray underneath (**Figure 2**). A solid bottom (using plastics or vinyl-coated metal) may be more appropriate for larger animals. Some housing systems, for special types of research, involve closed boxes or cages with independent ventilation and air filtration systems. They also may have integral urine and faeces collection systems. Very large research models, such as sheep, goats, horses or cattle, may require barns, corrals or pastures. The basic needs for these animals will be similar to those of smaller research subjects, but with appropriate adjustments specific to each species.

Figure 2 A typical animal housing area is shown here. Note that the animal carriers are clean, well organized and well labelled. The cages are made of stainless steel with a mesh floor to allow waste to fall onto the collection trays (with special absorbent paper) underneath. 		>650 kg	>13.0 m^2	—	16–27
Horse	Single	Adult	13.0 m^2	—	16–27

[a]Recommendations for primary enclosure from the 'Guide' (National Research Council, 1996); larger animals may also require secondary enclosures for exercise, mating, or other activities.
[b]Typical preference for housing; group-housed animals are frequently single-housed according to study protocol.
[c]Space recommendation from the Animal Welfare Act (US Department of Agriculture, 1995).
[d]Recommended cage height for dogs is 6 inches above the head during normal standing position.
[e]Based primarily on the chicken.
[f]Height recommendation not specified; allowance should be made for typical postures.

Space recommendations are proportional to size, but are also based on expert judgement. These are detailed in the 'Guide' and summarized in **Table 1**. Attention must be given not only to floor area, but also to enclosure height. Volumes should be adjusted to account for special needs (mating animals, pregnant animals, nursing animals, etc.) and for addition of feed/water containers or other objects. Moreover, required volumes for singly housed animals may differ from each animal housed in a group. It is essential that temperature be maintained within species-specific limits (**Table 1**). Extreme temperatures (above 29 °C or below 4 °C) may cause clinical effects, including death. Relative humidity is not as critical, but for the sake of animal comfort and wellbeing, should be controlled to a range of 30–70%.

Animal enclosure ventilation provides a supply of breathing air, temperature control and removal of odours and contaminants. Under normal conditions, 10–15 air changes per hour are considered to be adequate. Special conditions, such as a large population density, presence of noxious gases, excessive heat generation by equipment or lighting, or potential air contamination with toxic materials, would require upward adjustment of airflow. If the primary enclosure system contains its own ventilation and filtration system, the room airflow could be adjusted downward if so desired.

Lighting in an animal area must be carefully controlled, because factors such as intensity, duration, wavelength and schedule can affect the physical and behavioural wellbeing of research subjects. Lighting should be diffuse throughout the housing area. The photoperiod should reflect each species' natural diurnal rhythm. For example, rodents are nocturnal and will feed mostly during darkness. They will maintain regular feeding patterns when lights are properly controlled. Moreover, rats are susceptible to phototoxic retinopathy; therefore, intensity should be maintained at 130–325 lux, according to the 'Guide'.

Many research animals are easily stressed by excess noise. They should be isolated from loud equipment, other animals (especially dogs, swine or nonhuman primates), or human activity that produces intense, persistent, frequent or high-frequency sounds. Technical staff should be discouraged from loud talk, excessive banging of equipment, playing of radios and excessive use of cell phones or pagers. Animals that typically rest during daylight hours may be severely disturbed by such activities.

Some species may require special features in their primary enclosures. For example, cats prefer a raised resting area within their cage. Other species (notably higher species such as nonhuman primates) require perches, tunnels, swings, toys or foraging devices. These permit natural behaviours that, in turn, enhance the animal's physical and psychological health. Animals such as dogs should have frequent access to runs or large pens where they can exercise. Many species (dogs, cats, primates) may benefit from frequent contact with humans. Consideration should also be given to an animal's natural social environment. For many species, individuals may communicate with other individuals through tactile, visual, auditory and olfactory contact. Therefore, whenever not otherwise required by the testing protocol, such animals should be housed in groups

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat050
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

or within a short distance of fellow members of the species. This may best be exemplified by the rat, which typically huddles with other rats during rest periods and tussles with its cage mates during active periods.

4.1.3 Animal Husbandry

All research subjects must be provided nutritious, uncontaminated feed specific for the test species. Supplies of feed should be chosen carefully with special attention to feed content, methods of storage, vermin control and notations of manufacture date and shelf life. Analytical reports should be available to the researcher, who should review them for nutritional content, as well as the presence of contaminants that may cause unwanted physiological responses. Feed must be stored in a dry, cool, clean area. It should be elevated from the floor using pallets, shelves or carts. Most feeds can be used for approximately six months after manufacture, although some special diets, such as those containing vitamin C supplements, may expire after just three months. Out-of-date feed should always be promptly discarded.

Feed containers should permit unimpeded access to their contents and should discourage contamination with animal waste. They must not be transferred between animals without being sanitized. In many instances feed should be restricted. For example, young rabbits received from a feed-restricted environment and placed into an *ad libitum* environment may initially overeat, develop diarrhoea and then stop feed intake. These animals become severely anorexic if not treated and may have to be euthanized. A useful practice is to restrict feed intake at first, gradually permitting *ad libitum* feeding. In some instances, intubation with fruit juice will stimulate normal feed patterns. Provision of a leafy vegetable (such as kale) may also help the rabbit regain its appetite. There have been several studies (quoted in the 'Guide') indicating that unrestricted feed consumption will lead to obesity, shortened life spans and increased disease (including cancer). These are undesirable conditions in long-term research projects. Some species thrive on a variety of diets and on special additions like fresh vegetables or grains.

Like feed, water supplied to animals must be palatable and uncontaminated. Water should be analysed by the facility or the supplier for contaminants, microbes and pH. Investigators should review reports from these analyses to ensure that the water is of sufficient quality. Water can be provided by individual bottles, pans or tubes, although automated systems may be preferable. For any system, the apparatus should be examined daily for proper operation and cleanliness. Automated systems should be flushed frequently, perhaps daily, and subjected to appropriate filtration and frequent sanitation. Some species may require training before they can learn to use the watering systems, usually by pressing the tips or levers to permit water flow and then holding the animal's mouth to the fluid. Care must be taken to avoid excess pressure in water systems for small animals such as mice. They may be unable to press the release devices and will quickly dehydrate as a result.

Choice of animal bedding can have a considerable effect on animal wellbeing. It should not have strong odours (for example, cedar chips can induce enzymatic and cytotologic changes) and should not produce excessive particulates. Bedding can consist of wood chips or other granular materials. Frequently, it is appropriate to place specially developed paperboard in trays under caging to collect waste (**Figure 2**). Such paperboard often minimizes odours and contains components that reduce microorganism growth. Like feed, bedding must be stored in a dry, clean area with elevation from the floor. The requirement for bedding change depends on the species, but typically varies from once a week to once a day. For rats and mice, at least, three changes a week is recommended.

Cleaning and sanitation of cages, racks and feeders should occur at least every two weeks for typical research animals. Devices such as solid-bottom cages and water containers should be sanitized every week. Primary enclosures should be treated with hot water (typically at 80 °C) and/or chemical disinfectants. Water and feed containers must be treated with hot water and detergents that kill microorganisms. All room surfaces must be cleaned and disinfected to prohibit disease. Special commercial solutions can be used to scrub floors and walls; they can also be used in room foggers. The effectiveness of sanitation should be monitored through analysis of wipe samples for the presence of bacteria.

Another method of controlling disease includes incineration of animal carcasses and waste. Recently, other methods for waste disposal have been developed, including use of a tissue digestor (containing potassium hydroxide, heat and pressure). Pesticides may be used to control vermin present outside the facility and in some areas inside. If chemical pest control is not practical or desirable, traps may be more appropriate for eliminating rodents.

4.1.4 Animal Identification

A discussion about animal identification might seem to be beyond the scope of this chapter, but there are considerations that have animal welfare implications. All research animals must be carefully tracked throughout the course of their presence at the research facility, from arrival to euthanasia and disposal. Failure to do this effectively could result in confusion in study data and possibly the need to repeat a portion (or all) of an animal research project (and excessive use of animals). Part of the tracking process involves the appropriate labelling of animal cages, pens, stalls or rooms with specific animal data (usually a unique assigned animal number or code, sex, possibly the source and strain of animal,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat050
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

study identification, treatment group, etc.). Labelling can be accomplished through use of printed cards, bar-coded stickers or some sort of electronic transponder.

According to the 'Guide', unique direct animal identification may include collars, bands, plates, tabs, coloured stains, ear notches or tags, tattoos, subcutaneous transponders and freeze brands. Toe-clipping (removal of certain toes according to a designated numbering code) for identification of small rodents is discouraged and only to be used whenever other methods are not feasible (and with approval of the facility IACUC). This method, if absolutely required, should be limited to altricial neonates and, along with other invasive procedures (ear notching, tattooing, subcutaneous implantations), must be done as painlessly and aseptically as possible. Veterinary guidance about proper technique and possible use of analgesics, anaesthetics or antiseptics should be considered.

4.1.5 Veterinary Care

A qualified veterinarian (certified and experienced in laboratory animal medicine) must be available on site or on call to provide oversight of animal care and handling. This includes direct or indirect responsibility for administration of veterinary drugs, euthanasia and surgical procedures. The veterinarian should ensure that laboratory animals are healthy as received (free of injury or disease) and that proper care is provided while the animal remains in the research facility. Any health status reports provided by the vendor or generated by the facility should be reviewed by the designated veterinarian to ensure that only healthy animals are used and to prevent unhealthy new arrivals from infecting the rest of the colony. This means that each new animal shipment must be separated from other animals on site.

The facility should have a programme by which a schedule of animal examinations is followed and periodic quality control is conducted. Typically, several animals from large shipments or a few animals chosen periodically from smaller shipments are subjected to necropsy, evaluation for clinical pathology, haematology, serology, clinical chemistry and possibly histopathology. These evaluations, to be completed under veterinary control, will help ensure that only disease-free animals are used in research projects. Otherwise, results could be confounded by the presence of disease or other anomalies. For example, certain rodent viruses can alter toxicological response from test substances, even though the animals may show no outward signs of disease. Any animals displaying infectious disease must be isolated from others, and preferably destroyed, before disease can spread. Any room contaminated by an infectious agent must be emptied and sanitized before reuse.

4.1.6 Technical Training

In typical research situations, substantial responsibility for the care of animals must belong to the animal technicians. As they tend to feeding, watering, cleaning and observation duties, these persons will normally have daily contact with the animals. In a sense, they comprise the first line of defence against illness, injury or excess distress from treatment. No research facility can afford to leave such efforts to poorly trained or otherwise ill-equipped individuals.

Ideally, animal technicians will have received some training in biology or animal science prior to employment. A number of colleges or community colleges offer degrees in these fields. Whether such formal training is received or not, they must be given on-the-job training with experienced technical staff, including direct involvement with staff veterinarians, before being permitted to work alone. Research facilities should have a programme in place to provide theoretical and practical instruction in animal care. There should be SOPs in place for reference, and progress in the training programme should be documented.

Probably the best insurance for adequate training of personnel is by formal certification. In Europe, guidelines for training courses in laboratory animal science have been developed by the Federation of European Laboratory Animal Science Associations (FELASA; Federation of European Laboratory Animal Science Associations, 2008), covering four categories of personnel—animal technicians, research technicians, scientists and specialists. Through a programme offered by the American Association for Laboratory Animal Science (AALAS), a nonprofit organization begun in 1950, technicians have the opportunity to become certified at three levels of achievement (American Association for Laboratory Animal Science, 2008). The beginning level of certification is for Assistant Laboratory Animal Technician (ALAT), followed by Laboratory Animal Technician (LAT) and Laboratory Animal Technologist (LATG). To determine qualification for certification at one of these levels, the candidate's education and experience are reviewed (up to five years of experience is required for a nondegreed LATG certification, for example). AALAS provides a number of training materials for each level. In some instances, formal training programmes are conducted (by local AALAS chapters, facility management, etc.) to help candidates through a preparatory course. The candidate must submit a formal application and fee to take the required certification examination. The examination can be taken throughout the year on a designated personal computer workstation or once a year at the AALAS National Meeting.

Difficulty and subject emphasis in the examination (and the training materials) reflect the level of certification involved. As the technician advances, less emphasis is placed on the basics of animal husbandry, health and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat050
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

welfare, while increasing attention to facility administration and management. Consistent emphasis is placed on general knowledge. The goal is to encourage technicians to become proficient in many phases of animal care, with achievement of appropriately higher certification levels as experience and education progress. AALAS members are also able to advance in their careers through attendance of local or national meetings, and through numerous educational resources that the association provides. AALAS also provides a programme for animal care management certification. A candidate must have 5–10 years of total work experience (depending on level of formal education), with at least three years of managerial experience. To achieve the Certified Manager Animal Resources (CMAR) status, he or she must complete three examinations by the Institute for Certified Professional Managers (ICPM) and one examination by AALAS. Recipients of CMAR designation must pay an annual recertification fee and must earn a specified number of continuing education credits.

As a final note about animal care certification, it is often desirable for nontechnical staff, such as study coordinators or study directors to complete one or more level of AALAS certification. It is a useful means of fully appreciating the needs of the animals and the function of technical staff. A bonus is that scientific decisions by researcher will more likely be reflective of humane animal use during study planning and conduct.

4.1.7 Laboratory Accreditation

Just as personnel should be certified for the proper use and care of animals, the research facility itself should be accredited. The organization that provides the standards of animal care excellence against which the facility can be measured is the Association for Assessment and Acreditation of Laboratory Animal Care (AAALAC) International (Association for Assessment and Accreditation of Laboratory Animal Care International, 1997d; 2008). The core of this organization was formed in 1950 by a group of Chicago veterinarians who established the Animal Care Panel. Over time, one of the key functions of this panel, through a number of publications and specialized committees, became the establishment of professional standards for laboratory animal care. These standards were used to develop an accreditation programme. In 1965, AAALAC was incorporated as a voluntary accreditation body with 14 medical and veterinary charter member organizations.

Today, over 750 institutions (companies, universities, hospitals, government agencies, research laboratories) have been accredited by AAALAC International including facilities in 30 countries. Over 180 consultants assist AAALAC International in evaluating animal care and use programmes, several of whom are international specialists. AAALAC International is administered by a board of trustees representing 68 member societies, several relating directly to medical or toxicology research (Society of Toxicology, American College of Toxicology and others). Interaction with the member societies ensures that AAALAC International remains responsive to the research community. Actual accreditation is conducted by a council of accreditation consisting of 45 animal medical experts, research scientists and other specialists.

Any private or public organization using animals for research, teaching or testing may apply to AAALAC International for accreditation. The application must describe the organization's animal care and use policies and responsibilities, animal environment, housing, management, veterinary medical care and the physical plant. AAALAC International assesses the institution's animal care and use programme by conducting a site visit. If the institution demonstrates excellence in animal welfare according to AAALAC International 'rules of accreditation' (including the principles presented in the 'Guide', EEC Directive 86/609 and individual national standards), full accreditation may be granted. Conditional or provisional accreditation may be awarded if correctable deficiencies are noted. Otherwise, accreditation is withheld. For accredited facilities, an annual report must be submitted detailing current animal facility status and any changes in animal care or use. Renewal visits are made every three years, after which continued full accreditation, conditional or deferred accreditation (short-term deficiencies noted, requiring correction) or probationary accreditation (serious deficiencies seen) is awarded. Serious and uncorrected flaws will result in revoked accreditation.

4.2 Humane Animal Research

Certainly, the proper care of animals is a crucial aspect of animal welfare in the toxicology laboratory. However, the other major aspect, the humane use of animals in research, is also crucial although somewhat more subject to interpretation. The actual research techniques, including restraint, treatment, manipulation, observation and euthanasia must be conducted with minimal discomfort. Yet the goals of the research project are to be accomplished as fully as possible. A number of organizations have published their policies on animal research, including the Society of Toxicology, the American College of Toxicology and many others. Basically, these policies state that there should not be unnecessary research, excessive numbers of animals in animal testing, or excessive pain or discomfort in animal research. Furthermore, all applicable regulations and policies regarding animal welfare must be followed. The conscientious researcher will make a serious commitment to these ends.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.2.1 Restraint of Animals

Many types of toxicological research require some sort of animal restraint, such as the use of straps, harnesses, boxes, boards, collars, wraps, leashes and others. Even manually holding an animal during transportation, treatment or observation could be considered a form of restraint. Ideally, any restraint would be for a short duration, but this is not always the case. Any type of mechanical or manual restraint must be conducted with the animal's comfort and wellbeing in mind. Any apparatus should be of appropriate design, size and materials to minimize discomfort or injury. The 'Guide' offers some basic guidelines, quoted below:

- Restraint devices are not to be considered normal methods of housing.
- Restraint devices should not be used simply as a convenience in handling or managing animals.
- The period of restraint should be the minimum required to accomplish the research objectives.
- Animals to be placed in restraint devices should be given training to adapt to the equipment and personnel.
- Provision should be made for observation of the animal at appropriate intervals, as determined by the IACUC.
- Veterinary care should be provided if lesions or illnesses associated with restraint are observed. The presence of lesions, illness, or severe behavioural change often necessitates temporary or permanent removal of the animal from restraint.

Large animals may be lead by a leash and lifted by the trunk. Handling of small animals requires a firm but careful grip (**Figure 3**). The specific technique depends on the species, and proper training is essential. Some animals may require grasping around the entire trunk; some may be grasped temporarily by a foot or limb; others may be picked up by the scruff of the neck; a few (especially the mouse) may be held briefly by the tail. The goal is to cause the least stress, while minimizing chance of injury (through biting or scratching) to the handler.

4.2.2 Animal Treatment/Dosing

It would be quite difficult to discuss, in detail, all the possible types of treatment employed during a toxicology project. Test substances may be administered by gavage (peroral intubation), feed inclusion, intravenous injection, dermal application, ocular application, inhalation, parenteral injection, intramuscular injection, subcutaneous injection, endotracheal intubation and others. Some projects require special techniques, such as surgery, implantation, introduction of probes or other invasive procedures. Each treatment presents a unique set of concerns for animal welfare. As discussed in other sections of the chapter, only adequately trained personnel should be permitted to perform the various treatments and subsequent observations. Moreover, all the concepts of proper animal use (minimum pain or distress, consultation with or conduct by veterinary staff, approval by the IACUC, appropriate use of anaesthetics or analgesics, minimal numbers of test subjects, observation for unacceptable distress, possible early termination of treatment) must be adhered to.

4.2.3 Animal Observation

Prior to and following treatment, all animals in a study must be carefully examined for any signs of illness and/or

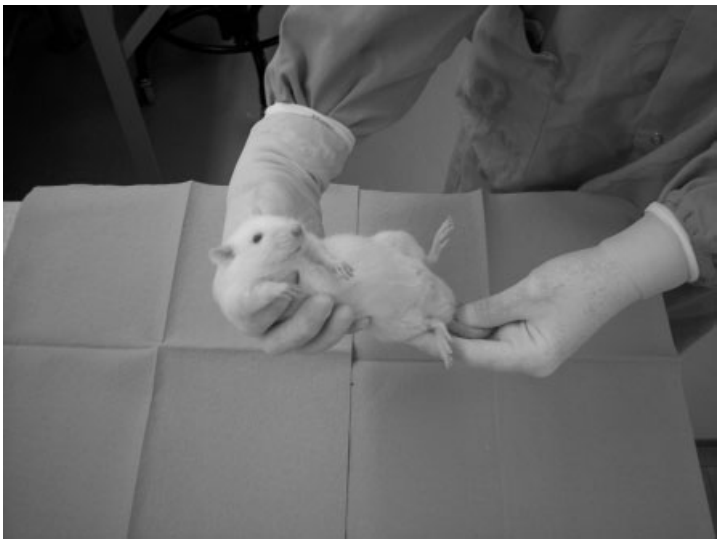

Figure 3 Physical examination of study animals is a crucial aspect of animal welfare and good science. Technical staff must be well trained in the handling and observation of test animals. (Photograph courtesy of Hilltop Lab Animals, Inc.)

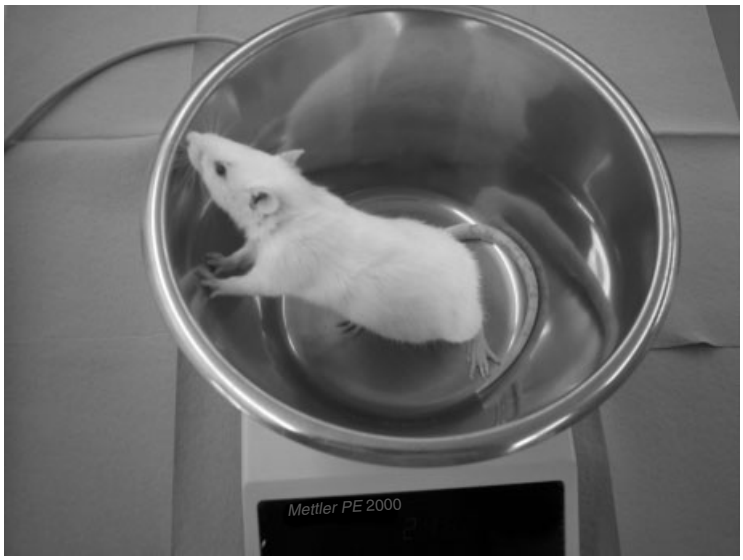

Figure 4 Weight is one of the basic measurements for monitoring the health of test animals. Those affected by illness, injury, or treatment/dosing may lose weight or fail to gain weight normally. The rat shown here appears to be healthy and curious about it surroundings as it is weighed. (Photograph courtesy of Hilltop Lab Animals, Inc.)

toxic effect. Typically, trained technical staff perform observations on a regular basis, but other study personnel (study coordinator, study director, veterinarian, other specialists) should also be involved in the examination process. Depending on the type of study and specific protocol, timing of observations will vary. The protocol and SOPs will detail the process of animal observation, which should include visual assessment, handling and perhaps a battery of simple determinations (such as righting reflex, blink response, startle response, toe pinch response and others). Animals should be examined for local irritation or lesions, changes to skin or fur, breathing difficulty, loss of locomotor ability, nervous system effect (tremors, convulsions, paralysis, coma), behavioural change, salivation, diarrhoea and so on (Myers and DePass, 1993).

For most studies, a critical assessment is body weight measurement (**Figure 4**). Weight loss is often the first indication that an animal is experiencing adverse effects from treatment. All observations must be carefully recorded and if effects are believed to be significant, supervisory or veterinary staff should be consulted. Many study protocols require additional assessment beyond simple physical examination, such as clinical chemistry (with urinalysis), haematology and (upon scheduled or unscheduled death) gross pathology and histopathology.

4.2.4 Surgery in Animals

Toxicologic studies requiring surgery present some unique concerns about animal welfare. According to the 'Guide' there are several categories of surgery. They can be considered to be major or minor, with further divisions of survival and nonsurvival surgeries. Major surgery penetrates and exposes a body cavity or results in significant impairment of physical or physiologic function. This type of procedure should only be performed once on any single animal, unless there is scientific justification (and IACUC approval). Cost savings alone do not justify multiple surgeries in one animal. In minor surgery, there is no exposure of a body cavity and little or no physical impairment is caused. In any case, the fate of the animal could be survival or euthanasia (or unplanned mortality). Basic requirements for any surgery are presurgical planning, involvement of qualified and well-trained personnel, suitable anaesthesia, good aseptic technique (sterile equipment, supplies, gloves, surgical site, etc.), use of proper facilities and equipment, and proper postoperative care. Of course, some of these factors may not be critical if the animal is scheduled for euthanasia immediately after the procedure. Surgery should be performed in an area separated from other animals to avoid excessive stress in them. While minor surgeries, or any surgeries on rodents, may not require a dedicated facility, major surgery on nonrodents should occur only in facilities (ideally, operating rooms) intended for that purpose.

After surgery, the animal should be placed in a clean, dry area where it can be observed for recovery from anaesthesia and for any signs of excessive distress. The investigator and veterinarian are responsible for determining whether unacceptable pain, unusual behaviour, respiratory distress or cardiovascular changes are present. Intervention, in the form of analgesics or even euthanasia, might be indicated. It should be noted that drugs such as sedatives, anxiolytics (drugs to reduce anxiety) and neuromuscular blocking agents are not analgesic or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

anaesthetic and so are not appropriate for use on their own. The staff veterinarian should provide guidance as to the timing of the animal's return to regular housing.

4.2.5 Euthanasia of Animals

The 'Guide' defines euthanasia as 'the act of killing animals by methods that induce rapid unconsciousness and death without pain or distress'. At some point, every test animal will either die on study or will be put to death. Euthanasia may be scheduled as part of the study protocol or may be the ultimate means to relieve an animal of pain or distress. Two major factors must be considered here. The first is the recognition of distress that is sufficiently severe to warrant euthanasia. The second is the determination of the most appropriate method of euthanasia. Neither of these considerations is trivial for the investigator.

Nearly all toxicology protocols recommend euthanasia of animals experiencing pain or suffering. Difficulty arises, however, in defining when distress is sufficiently severe to justify early termination. It might be worth noting that distress is not the same as stress (Institute for Laboratory Animal Research, 2008). Stress is a real or perceived disturbance of an animal's physiological or psychological wellbeing (such as relatively short-term pain, discomfort, physical injury, fear or anger from a dosing procedure or from a toxic effect). Distress is a negative state in which the animal is unable to adapt to one or more stressors, and thus cannot return to a normal state of wellbeing. Since the research animal cannot tell us how it feels, we must pay close attention to a number of visible signs. Recognition of pain and suffering is extensively discussed in the literature (Mroczek, 1992; Carstens and Moberg, 2000; Institute for Laboratory Animal Research, 2008). Broadly speaking, it can be manifested by any abnormal behaviour, unusual physical appearance or alteration of bodily function. More practically, only those signs indicative of prolonged, at least moderately severe, and possibly life-threatening abnormalities should trigger consideration of euthanasia. A number of these are listed in **Table 2**. By this reasoning, salivation or tremors may not indicate need for euthanasia; laboured breathing or convulsions may indicate that euthanasia is advisable.

In acute studies, one must be very careful in determining the need for early sacrifice. By their nature, signs up to and including death are frequently observed. Premature euthanasia will skew LD_{50} calculations, eliminate the evaluation of reversal of signs and confound determination of survivability. This is where technical experience becomes crucial. Technical and veterinary personnel familiar with the various signs and probable outcomes should be consulted for advice. Again, a balance between science and animal welfare is needed. Clearly, moribund (close to death) animals, those with lingering distress, or severe local effects (such as ocular damage) should always be euthanized.

In longer-term projects, the guidelines for euthanasia may be more flexible. Typically, the objectives are geared more towards subtle changes (such as altered tissue structure or function, weight effects, clinical chemistry or haematologic alterations, etc.). Animals showing substantial clinical signs or severe lesions, if suffering is clearly present, should be seriously considered for euthanasia, especially if the study is relatively long and sufficient numbers of animals remain available for evaluation. Animals with well-developed tumours should be euthanized, especially if they are part of a cancer study and they obviously represent a positive response. Any animal that is judged to be moribund, should be euthanized to end its distress and to make sure that appropriate necropsy and tissue study can be performed before autolysis occurs. Of course, animals showing signs of disease (particularly contagious disease) should be euthanized quickly to avoid distortion of study data and possible infection of other animals.

The methodology for euthanasia, carried out for either the relief of distress or for scheduled study termination, should be considered thoughtfully. It is not automatically a matter of injecting the animal with a lethal dose of sodium pentobarbital (although it may often be). In fact, depending on the species and circumstances of the study, some methods may seem rather exotic (such as microwave irradiation or decapitation). One of the best-known guidances for euthanasia is the *Report of the American Veterinary Medical Association (AVMA) Guidelines on Euthanasia* (American Veterinary Medical Association, 2007). This document details the elements of humane euthanasia, common (and uncommon) agents, species-specific methods and AVMA recommendations. According to the AVMA, euthanasia should be without pain or stress, preferably producing rapid unconsciousness, followed by cardiac or respiratory arrest and loss of brain function. Moreover, it is helpful (more for the researcher than the animal perhaps) if the method produces little animal movement immediately following the procedure. Personnel performing euthanasia must be appropriately trained and experienced so that the process itself (handling, restraint, euthanasia technique) is relatively painless and stress-free. The 'Guide' notes that euthanasia should be performed in a professional and compassionate manner and personnel should be able to clearly recognize the cessation of vital signs. It is recommended that euthanasia not take place in the presence of other animals, as possible, because they may become stressed by vocal or nonvocal (behaviour, odours) reactions of the euthanized animal.

Some examples of euthanasia procedures, and their advantages, are listed in **Table 3**. The AVMA has classified euthanasia agents into those producing hypoxia (usually due to depression of vital organs or processes), depression of vital nerve function and physical disruption

Table 2 Observable signs of severe pain or distress

Local effects[a]	
Skin corrosion	Severe erosion or ulceration penetrating most or all of dermis, large areas of severe necrosis
Ocular injury	Severe corneal opacity, corneal ulceration, purulent or bloody discharge, severe periocular necrosis
Extremity injury	Severe swelling, ulcerative lesions, apparent fractures, severe cutaneous erosion/sloughing, gangrenous appearance
Systemic effects[a]	
Nervous signs	Severe or persistent tremors, convulsions, narcosis, catalepsy
Locomotor/muscular signs	Hunched posture, ataxia, paralysis, prostration
Respiratory signs	Gasping or laboured breathing, very slow or rapid breathing, audible breathing (rales, wheezing)
Cardiovascular signs	Very slow or rapid heart rate, severe pallor, redness or cyanosis of extremities
Gastrointestinal signs	Persistent vomiting, severe diarrhoea, anorexia
Behavioural effects[b,c]	
Excessive vocalization[b]	Squealing, grunting, growling, whimpering, howling (especially during movement or handling)
Atypical actions[b]	Self-mutilation, stereotypic activity, restlessness, head shaking, apparent apathy to stimulants
Direct response to pain[b]	Licking, biting or scratching of affected area; unusual posture to relieve pressure on affected area (hunched or stretched appearance); excessive struggling or biting during handling; grimacing or baring teeth
Absence of actions[b]	Failure to groom, decreased socialization, poor reflexes, marked decrease in feed/water intake
Aggression[c]	Resistance to handling, biting, scratching, kicking, baring teeth, vocalization, attacking run, wrestling

Table 3 Methods of euthanasia in the toxicology laboratory[a]

Method	Species	Major advantages	Major limitations	AVMA recommendation
Barbiturate injection	Most	Rapid, safe, inexpensive	Requires training, restraint, drug control	Acceptable (preferred) method
Anaesthetic inhalation	Most	Rapid, multiple animals exposed	Initial irritation, hazardous to staff	Acceptable method for small species
Penetrating captive bolt	Large farm species	Rapid	Requires training, equipment, restraint	Acceptable method for large species
Carbon dioxide inhalation	Several small lab animals	Rapid, safe, inexpensive, multiple animals	Some species stressed or very tolerant, ineffective in immature rodents	Acceptable at high concentrations
Carbon monoxide inhalation	Most small	Rapid loss of consciousness	Hazardous to staff, difficult to detect	Acceptable method with appropriate generation (bottled gas only)
Microwave irradiation	Mice, rats	Rapid, safe, brain enzymes fixed	Specialized training, equipment, expensive	Acceptable method with appropriate equipment
Tricaine/benzocaine injection	Fish, amphibians	Rapid, safe	Expensive	Acceptable method
Cervical dislocation	Birds, small rodents/rabbits	Rapid, safe, inexpensive, no drug residue	Requires training, unpleasant for staff	Conditionally acceptable method when justified, some size limitations
Decapitation	Most small	Rapid, no drug residue	Requires training, some hazard, unpleasant	Conditionally acceptable method when justified
Gunshot	Large farm or wildlife species	Rapid, ease for certain species	Requires training, dangerous, unpleasant	Conditionally acceptable method when necessary
Electrocution	Foxes, sheep, swine, mink	Rapid, inexpensive, no drug residue	Requires special equipment, hazardous, unpleasant, severe contractions	Conditionally acceptable method in specialized instances
Pithing	Small amphibians	Rapid, no drug residue	Requires training, unpleasant, tissue damage	Conditionally acceptable method in specialized instances
Nitrogen/argon inhalation	Most small	Rapid, safe, readily available	Stressful in some species, must limit O_2, ineffective in immature rodents	Conditionally acceptable method in specialized instances
Exsanguination	Several	Safe, inexpensive	Very stressful	Unacceptable method without anaesthesia
Rapid freezing	Several small	Safe, inexpensive	Very stressful	Unacceptable method without anaesthesia
Air embolism injection	Several	Safe, inexpensive	Causes convulsions, other sign of distress	Unacceptable method without anaesthesia

Table 3 (*continued*)

Method	Species	Major advantages	Major limitations	AVMA recommendation
Drowning	Several	Safe, inexpensive	Very stressful, slow	Unacceptable method
Hypothermia	Rodent neonates	Possibly convenient	Stressful, slow	Unacceptable method
Strychnine dosing	Several	Possibly convenient	Causes convulsions, painful contractions	Unacceptable method
Chloroform injection	Several	Possibly convenient	Very hazardous to staff	Unacceptable method
Cyanide dosing	Several	Possibly convenient	Unpleasant, hazardous	Unacceptable method
Stunning (blow to head)	Several	Rapid, no drug residue	Unpleasant, sufficient force required	Unacceptable method without other lethal procedure (conditionally acceptable for pigs less than three weeks old)

[a]Summarized from the American Veterinary Medical Association (AVMA) Guidelines on Euthanasia (American Veterinary Medical Association, 2007).

of brain or vital nerve function (such as by cervical dislocation). In some instances, inhalant anaesthetics (such as ether, halothane, methoxyflurane) are preferred because of the rapid unconsciousness produced. These may be easily placed into a closed chamber to build up high vapour concentrations followed by introduction of the animal. Some species are more susceptible than others, and factors such as age or health status may affect reactions. A high concentration of carbon dioxide is useful for anaesthesia/euthanasia, especially for groups of small laboratory animals, except that times to death appear to be extended for neonatal rodents. Some inhalants may produce lung discolouration or other lesions and these agents should be avoided when pulmonary assessment is critical to a study.

Another major class of euthanasia agents consists of those typically injected intravenously (ear, tail, neck or limb veins) or, less commonly, intraperitoneally. Probably the most prevalent of these are the barbiturates, such as sodium pentobarbital. It produces rapid anaesthesia with minimal apparent distress when delivered in sufficient doses. For larger animals, chloral hydrate may be the preferable agent. Some available euthanasia solutions contain a barbiturate combined with local anaesthetics to make injection relatively painless.

The third method of euthanasia is by physical means such as cervical dislocation (by stretching and twisting the base of the skull from the first cervical vertebra), decapitation (by commercial guillotine), microwave irradiation (by equipment designed specifically for mice and rats) and exsanguination (by draining the blood from already unconscious animals). These procedures should be performed quickly and smoothly by experienced personnel. They typically are only used for specialized studies in which certain tissues or fluids must be preserved without drug contamination or degradation.

4.3 Improvements in Animal Research

The basis for making animal research more humane is found in the three Rs (Russell and Burch, 1959). These represent reduction, refinement and replacement—all important considerations while conducting animal testing. As the term suggests, reduction means limiting the numbers of animals to levels essential to meet the goals of the study. Refinement is improvement in test methods to reduce potential for pain and distress caused the test subjects. Replacement involves the use of alternative tests to substitute for whole-animal procedures. Salem and Katz (1998) have proposed a fourth R, responsibility. This introduces the commitment factor required for meeting the challenges of the first three Rs.

4.3.1 Reduction in Animal Numbers

Prior to modern concerns about animal use, many researchers paid little attention to the numbers of animals used in their research. The more animals tested, the more statistically meaningful the results became. Moreover, results could often be obtained more quickly if larger numbers of animals were tested at the start rather than awaiting preliminary findings and then planning studies accordingly. Today, the approach has become very different. Through improved planning, more patient study conduct and better data analysis, fewer animals

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat050
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

are needed for most research projects. Additionally (and very significantly), regulators around the world have decreased the numbers of animals required for several testing protocols.

Possibly one of the fields most significantly changed over the last two decades has been that of acute toxicity testing (see **Acute Toxicity**). Acute tests, by their nature, are more likely to result in distress and death as relatively high doses are administered by various routes (oral, cutaneous, intraperitoneal, intravenous, inhalation). In fact, for acute LD_{50} studies, the goal is determination of the dose that would be expected to kill half of the subject population. Animal rights activists find this test particularly objectionable. The classical method has been to dose several animals of each sex on each of several dose levels to give what was considered to be sufficient numbers for the LD_{50} calculation, such as was required by the probit analysis method (Bliss, 1935; Finney, 1971). The end result was typically a total of 50–100 animals for a single LD_{50} test to fulfil the requirement of obtaining several treatment levels with fractional mortality. Numerous evaluations have shown that acceptable LD_{50} values can be obtained with far fewer animals. For example, Weil *et al*. (1953) showed that for 24 compounds studied, the mean peroral LD_{50} in rats varied only from 4.76 to 4.64 $g\,kg^{-1}$ when the number of animals per dose level was decreased from 10 to 5. DePass *et al*. (1984) obtained comparable results with 11 compounds when numbers per level and numbers of dose levels were reduced.

The statistical method used to calculate the LD_{50} affects the number of animals required. Procedures like the moving average method (Thompson, 1947), approximate lethal dose method (Deichmann and LeBlanc, 1943) and up-and-down method (Bruce, 1985) require minimal numbers of test subjects. These methods have been summarized by DePass (1989), who reported that the conventional method (probit analysis) typically required roughly 50 animals (rats) per study; the moving average method required 10–20 animals; the approximate lethal dose method used about 5–10 animals and the up-and-down test required 6–8 rats. In the up-and-down method, a single rat is dosed at a time. Doses are increased or decreased to provide multiple lethal and nonlethal levels and permit calculation of an approximate LD_{50}. This method has been fully discussed and compared to other methodologies by Lipnick *et al*. (1995). According to the European Centre for the Validation of Alternative Methods (ECVAM; European Centre for the Validation of Alternative Methods, 2008a), the up-and-down method was adopted by the OECD as an alternative to the traditional LD_{50} test in 1998. The US EPA also listed this test as an acceptable substitute for the LD_{50} test in 1998 (US Environmental Protection Agency, 1998a). After further review by ECVAM in 2001, a revised up-and-down protocol was validated. The OECD now has adopted it as a replacement (rather than an alternative) for the LD_{50} test and discourages the use of the traditional LD_{50} test procedure (deleted from OECD guidelines in 2002).

Another significant issue in the LD_{50} test is whether both sexes require investigation. In the work of DePass *et al*. (1984), it was found that mean LD_{50}s (from 91 rat oral tests) were 2.47 $g\,kg^{-1}$ for males and 2.13 $g\,kg^{-1}$ for females. It has been the experience of several other researchers that females are somewhat more sensitive than males (although some have also disputed this), but that, overall, good correlation exists between the two sexes. Thus, several guidelines (US EPA, OECD) recommend using just one sex (the potentially more sensitive one) of animal for the LD_{50} determination (or estimate) and a few confirmatory animals of the opposite sex at critical dose levels.

Whichever method is used for an LD_{50} determination, it is most useful to do a preliminary test with one or two animals at different dose levels suspected to be near the LD_{50} (based on chemical structure and/or literature data). After a day or two, additional animals may be treated to begin to fill in levels. It may take a few more days of 'wait-and-see' before all required animals are dosed. This approach has been detailed by Myers and DePass (1993). If conducting the up-and-down test, one animal per level may be sufficient.

In cutaneous irritation tests, the classic protocol (Draize *et al*., 1944) requires that at least six rabbits receive a small dose (0.5 ml or 0.5 g) of sample on the clipped skin. A number of investigators have indicated that fewer animals are sufficient. Derelanko *et al*. (1993) analysed data from 224 studies, which provided skin irritation classifications based on six rabbits. The data were randomly reduced to include three, four and five rabbits per study and skin irritation was reclassified for each chemical tested. Agreements between classification with fewer animals and those with six animals ranged from 69 to 95% for negligible irritants, 76 to 85% for mild irritants and 90 to 100% for severe irritants. Absolute differences in dermal irritation indices (the numerical score to quantify degree of reaction, ranging from 0.0 to 8.0) among groups of three, four, five and six animals were small, with an average of no more than 0.3. The authors concluded that as few as three rabbits would normally be adequate. In fact, most recent guidelines (OECD, US EPA and others) have recommended no more than three in the skin test in recent years (Organization for Economic Cooperation and Development, 2002; US Environmental Protection Agency, 1998b). The recommended approach to skin irritation evaluation is to start with a single rabbit. If the irritation is severe (necrosis or ulceration noted) additional testing is unnecessary. More moderate reaction indicates the need for the full set of three animals. If results are equivocal, a few more rabbits may be dosed (up to six) to aid in the final interpretation.

Ocular irritation testing may be approached in a manner similar to that of the skin irritation procedures.

The researcher should remember, however, that the 'Draize Test' is probably one of the most controversial (to the public) of the short-term toxicity procedures. Every effort should be made to reduce animal use, while not compromising the data required. Previously, six eyes were usually required. However, three eyes are probably sufficient, although some protocols may require more, especially if the benefit of washing out the eye is a desired end point. A reasonable way to approach the eye test is first to review results of cutaneous testing if available. Severe skin irritants would be expected to cause substantial eye injury (of course, there are exceptions). This could be confirmed in a single eye test with a single animal if providing some ocular data is crucial. In any event, a single eye dose should be used as a preliminary guide to the need for further testing. Just as in the skin irritation test, if one eye is severely affected, dosing should be terminated. Otherwise, a total of three eyes should be dosed, or up to six eyes for equivocal findings. Both the OECD and the US EPA have adopted this approach.

The above approaches or variations of these may also be applied to other types of toxicological evaluations, including longer-term projects, such as chronic oral or inhalation studies, cancer studies or reproductive studies. The USDA has recommended a few general methods for animal reduction (Bennett, 1994), including animal sharing, improved statistical design, phylogenetic reduction and better quality animals. In animal sharing, certain study animals may be reused for procedural development, training, alternative route testing (e.g. screening for oral toxicity following cutaneous irritancy testing), tissue harvesting or routine physiologic/pathologic measurements. This should only take place when animals are not stressed from the original study and there is little chance that the goals of the secondary procedure will be compromised. Another method for sharing animals involves the use of common controls. A negative control, vehicle control or positive group used for one study may sometimes be shared with other studies if test parameters are equivalent. An example would be a series of dermal sensitization studies conducted in tandem, using a single set of naive, vehicle and positive control groups.

Statistical design for a toxicity study may be improved by maintaining state-of-the-art knowledge of applied statistics and by using the latest computer statistical packages (see **Statistics for Toxicology**). Inappropriate statistical design can result in failure to reach the study goals and, therefore, a necessary repetition of the project. Moreover, proper statistical analysis can permit the use of minimal numbers of animals (possibly fewer treatment groups or fewer animals per group). There must be sufficient numbers of animals to make a meaningful comparison among the treatment and control groups. No more subjects than statistically required should be used, as discussed by Erb (1990) and McCance (1989), among others. Phylogenetic reduction can be considered a type of reduction or replacement of animal use. It involves the use of the least advanced species that will permit attainment of the study objectives. An example might be increased use of rodents and fewer dogs or nonhuman primates in a dietary inclusion project. The end result could be fewer animals used overall and/or fewer animals from a phylogenetic higher order used.

The use of better quality animals is easily overlooked as a means of reducing animal numbers. However, there is considerable logic in the practice of purchasing the most healthy and genetically consistent animals possible. The loss of animals to disease or abnormality can necessitate repetition of toxicity studies. Otherwise, study findings may become indecipherable from inherent flaws in inferior animal populations.

It is also important that animal quality be confirmed as soon as shipments arrive, preferably by veterinary personnel. In conjunction with the use of better animals should be the practice of ordering fewer animals. Typically, a few extra animals are ordered to compensate for losses prior to or during the study. The investigator should always make a habit of ordering only enough to meet study needs, and insist that the vendor only deliver the quantity ordered.

4.3.2 Refinement of Animal Procedures

Methodologies in toxicology should continually be improved to provide for better science. Additionally, this process of *refinement* may frequently promote decreased pain and distress in the animal model. Some improvements may also decrease the numbers of test subjects required. There are several examples of refinement that apply to the acute toxicity procedures discussed previously.

In the acute toxicity tests, there should be a practical dose limit beyond which further treatment is unnecessary. Most agencies, such as the OECD and the US EPA have recommended this 'limit test' for a number of years. For example, acute peroral dosing with 2.0 or $5.0\,g\,kg^{-1}$ of test substance (depending on the agency involved) will generally be sufficient if all or most animals survive and no LD_{50} determination will be required. The premise is that larger doses (up to $16.0\,g\,kg^{-1}$ or even higher in some older studies) would be unlikely to be encountered by humans. There are exceptions, such as the need to evaluate potential cumulative doses or clearance of very large doses, but reasonable limits should be established just the same. The 'limit test' effectively reduces total animal numbers and decreases the numbers of animals experiencing distress, since sublethal doses are more frequently involved.

Many researchers have questioned the utility of using death as an end point in acute toxicology. It may be sufficient to determine only levels producing observable clinical signs. This is the approach of the 'fixed-dose

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

procedure' (van den Heuvel *et al*., 1990). Using a series of standardized dose levels, effect and no-effect levels are established. Materials are assigned toxicity classifications according to a specified scheme. In an international validation study, these classifications were found to correlate well to those assigned on the basis of full LD_{50} studies. Like the limit test, the fixed-dose procedure limits the degree of distress in animals, since lethality is avoided as much as possible. A variation of this method, which does include death as an end point, is the 'acute-toxic class method' (Schlede *et al*., 1994). It also uses a series of established dose levels to be given in a relatively complex pattern designed to efficiently determine lethal/nonlethal levels with few animals (usually three per group). After considerable review, the OECD and then the US EPA adopted both the fixed-dose procedure and the acute-toxic class method as acceptable alternatives to the traditional LD_{50} test. As of December 2001, the OECD has labelled these procedures as replacements for the LD_{50} test (European Centre for the Validation of Alternative Methods, 2008a).

As fewer animals are employed in a toxicology study, it becomes more desirable to gather all the data reasonably possible from those animals studied. Rather than simply observe for lethality and gross signs on an acute study, one could consider evaluation for subtle behavioural effects, tissue changes, haematological alterations and so on. This type of approach was recommended by Gad *et al*. (1984), and by Gad and Chengelis (1998; 1988). These authors proposed inclusion of interval necropsies to help identify target organs before tissues have time to recover from treatment. A few animals euthanized at three or four days (instead of the typical 14 days) could have selected tissues (kidneys, liver, spleen, lungs, brain, reproductive organs, stomach, intestine) removed, weighed and processed. Comparisons are made with tissues of animals terminated at 14 days. Additionally, Gad *et al*. recommended employment of a neurobehavioural screen designed to assess the peripheral and central nervous system. Benefits from such approaches, from an animal welfare standpoint, are decreased likelihood of additional testing to gather these data, better preparation for longer-term studies, and (perhaps) identification of subtle end points for other tests on similar materials.

A few relatively simple practices can substantially enhance the value of acute tests. One is routinely to test animal urine for occult blood (by Ames Hemastix® Reagent Strips), a potential early indication of kidney damage. Reagent strips are also available for measuring protein, glucose, nitrites, leucocytes and other urine parameters. These could prove useful in screening for acute toxic effects. Basic tests for righting reflex, grip strength, startle response and pupillary contraction give clues about neurologic damage. Suspected target tissues can be saved from selected animals at death or euthanasia for possible subsequent evaluation. Whenever study results indicate a potential organ effect, appropriate tissues are available for histologic assessment.

Skin and ocular irritancy tests can also be 'refined' to diminish stress in animals. Most regulatory agencies have already refined these procedures by eliminating the need for them when the pH is less than 2.0 or greater than 11.5, based on the assumption that strongly acidic or basic materials are severely irritating. However, this is not always a valid assumption, because irritation also depends on the characteristics (such as potential for buffering) of the chemical in question. In the skin test, lower dose amounts (0.05–0.1 ml instead of the usual 0.5 ml) might be administered for suspected severe irritants. Alternatively, diluted test substances may be applied. Of course, care must be taken to ensure the goals of the study and applicable regulations are fulfiled. Various transportation regulations, such as those of the US Department of Transportation (DOT; US Department of Transportation, 1991; 2000) or several international transportation agencies, have required evaluation for several contact periods, typically four hours (the standard contact time in most protocols), one hour and three minutes. Obviously, materials not severely irritating after four hours would not require the shorter contact periods. Materials suspected to be severely irritating should first be applied for one of the shorter time periods (preferably on a single animal) and results evaluated to determine whether longer contact periods are needed. Thus, a kind of range-finding study can be first conducted to establish irritant doses or contact times. This approach is also recommended by the US Environmental Protection Agency (1998b) and other agencies. If the specific test protocol permits, several doses may be applied simultaneously to a single animal set, with variations in dose amounts, contact times or even test substances. This process might be more appropriate for initial screens rather than definitive testing. A further refinement of the cutaneous irritation test could be the microscopic evaluation of dermal tissue. This will permit lesions not apparent grossly to be discovered, especially for low-dose or reduced-contact-period studies.

For ocular testing, one of the most effective methods to reduce stress is through low-volume doses. Instead of the typical dose of 0.1 ml, doses of 0.01 or 0.005 ml may be applied for potentially severe irritants (possibly in one or two animals). Additionally, treated eyes may be washed with lukewarm water at various times to limit the severity of response, as long as this does not interfere with the study goals (such as observation of healing time). Some of the most promising refinements in ocular testing have stemmed from improved techniques for assessing eye injury. These permit an increased likelihood of predicting ocular injury following doses that do not cause severe gross effects. Examples are measurements of intraocular pressure, examination by a slit-lamp biomicroscope, and corneal thickness measurements (Ballantyne, 1986; Myers *et al*., 1998). These and

other methods have been well correlated with traditional Draize scoring results and could become standard in the toxicology laboratory. A number of guidelines recommend use of a topical anaesthetic in eyes exhibiting severe injury, or even in conjunction with the initial treatment procedure. This may be acceptable wherever only the most basic ocular effects are to be evaluated (perhaps in comparative studies). However, topical analgesics or anaesthetics must be used with caution, as they may substantially affect corneal permeability, with ocular injury underestimated (Myers *et al*., 1998) or possibly overestimated. Thus, the investigator will be compelled to find a balance between scientific objectives and animal welfare. There are a number of reviews of eye testing available in the literature and on the Internet, including a fairly comprehensive one by Scheiwiller (2005).

The preceding considerations, while specific for acute toxicology, should also be applicable to toxicology in general. The USDA (Bennett, 1994) has generalized some of these approaches, and others, into four categories: decreased invasiveness, improved instrumentation, improved control of pain and improved control of techniques. The first two (decreased invasiveness and improved instrumentation) are somewhat related. Technologies such as magnetic resonance imaging, improved clinical chemistry/haematology analysers, video systems, computer-driven activity detectors and modern monitoring devices (using microelectronics, fibre optics and laser instrumentation) now may be used to collect data that formerly required considerable animal surgery, manipulation or restraint. The end result is that more data may be obtained with fewer animals and less invasiveness. Even simple procedures, such as the use of Hemastix®, may be considered a means of decreased invasiveness.

As for the improved control of pain, the use of tranquilizers, analgesics and anaesthetics should be considered when test animals are experiencing discomfort. Certainly, these are imperative during surgery, invasive blood collection (for example from the retro-orbital sinus) or invasive dose administration such as cannulation. Pain resulting after treatment, either the result of the procedure (such as surgery) or the result of a toxic response, should be relieved with the appropriate drug(s) if this does not conflict with the study objectives. An example might be application of an analgesic salve on sites of severe irritation following a repeated skin application study. In most instances, a qualified veterinarian should directly oversee administration of drugs controlling pain. The fourth USDA category for refinement, improved control of techniques, entails proficiency in the handling and restraint of animals. Animals must be handled in a gentle, consistent fashion. Both the handler and the animal should be properly trained. The test animal can be preconditioned to accept conventional or unconventional handling methods required by the study protocol. In this way, there will be minimal stress during the study.

4.3.3 Replacement of Animals

Much attention has been directed towards alternatives to animal research. While detailed discussion of these is beyond the scope of this chapter (see **Alternatives to In vivo Studies in Toxicology**), they will be considered in general terms as means to reduce animal numbers and distress. Alternative test systems may be employed as screens, supplements or even substitutes for whole-animal tests. They may permit rapid evaluation of multiple chemical substances for relative potential for toxicity or irritancy. They may also be used to predict reasonable starting doses for more definitive animal studies. Sometimes, alternative methods provide early indications of severe toxicity or irritancy so that methodologies can be appropriately adjusted (fewer animals, shorter exposure times, smaller doses, less invasive techniques, etc.) to minimize animal discomfort. Additionally, the alternative techniques may provide insight into the most appropriate species, route and other test conditions for a toxicity study.

Replacement methodologies may be divided into three general classifications: living systems, nonliving systems and computer simulations (Bennett, 1994). Living alternatives usually refer to *in vitro* models such as organ, tissue or cell cultures, invertebrate animals such as insects or simple marine species, and microorganisms such as bacteria or yeasts. In nonliving systems, chemicals or chemical matrices may be used to evaluate certain biologic reactions, such as enzymatic or immunological action. For example, there are commercially available artificial skin systems, which may or may not contain human or animal cellular components. These are used to evaluate potential for cutaneous penetration and/or irritation. Recent advances in computer and mathematic modelling have resulted in some promising methods of predicting acute toxicity, chronic toxicity, carcinogenicity, genotoxicity, reproductive toxicity and primary irritancy of chemical substances. Essentially, the computer models are based on structure–activity relationships (SARs), the assumption that similar chemical structures should produce similar biological effects. A few examples of the various types of alternatives are presented in **Table 4**. Extensive descriptions and reviews of alternatives to animal testing can be found in the literature, such as the book by Salem and Katz (1998), or online at the web sites of ECVAM, ICCVAM (Interagency Coordinating Committee on the Validation of Alternative Methods), CAAT and others.

It may be useful to look at some specific examples of alternative methodologies to see how they relate to animal welfare. A number of years ago, Kurt Enslein published his work on predictability of oral LD_{50}s using a computer-assisted SAR approach (Enslein, 1988). He compared computer-estimated LD_{50}s to those derived

Table 4 Examples of alternative methods used for replacement of animals in toxicological research

Test system	Alternative classification	Potential toxicity end point	Basis for procedure and measurement
Daphnia magna[a]	Living system	Lethality, endocrine disruption	Correlation of LC_{50}s to LC_{50}s of other species; evaluation of offspring sex ratio
Cultured mammalian hepatocytes[b]	Living system	Metabolic changes	Prediction of and disturbance in metabolic pathways from chemical doses
Neutral red dye uptake[c]	Living system	Metabolism, ocular injury, cytotoxicity, phototoxicity, lethality, others	Indication of cell injury by reduced dye uptake
Enucleated rabbit or chicken eye[d]	Living system	Corneal opacity	Evaluation of opacity, other morphologic changes in isolated eyes
Computerized structure/activity[e]	Computer simulation	Developmental toxicity, carcinogenicity	Prediction of effects based on computer input of chemical structure
Frog embryo teratogenesis assay[f]	Living system	Teratogenicity	Evaluation of microscopic morphology changes in frog embryos
Embryonic stem cell test[g]	Living system	Embryotoxicity, teratogenicity	Evaluation of inhibition of differentiation or growth of embryonic stem cells (mouse)
Rat skin transcutaneous electrical resistance assay[d]	Living system	Skin corrosion	Evaluation of electrical resistance change in explanted rat skin
EPISKIN™ and EpiDerm™ *in vitro* systems[d]	Living system	Skin corrosion	Evaluation of cell viability by mitochondrial activity
Spermatozoa swimming analysis[h]	Living system/computer simulation	Cellular motion effects	Mathematical analysis of changes in cellular movement or structure
Mutatox® bioluminescent bacterial test[i]	Living system	Genotoxicity	Assessment of light produced in presence of genotoxic agents
Cultured human or mouse neurons[j]	Living system	Neurotoxicity	Measurement of anticholinesterase activity
Corrositex® *in vitro* system[k]	Nonliving	Dermal corrosion	Assessment of lysis in biobarrier through determination of colour change

from animal studies for over 2000 chemicals and found that 50% of the LD_{50}s were equivalent within a factor of two and 95% of the LD_{50}s were within a factor of eight. With improvements in his programmes over the years and through the work of many others, this approach should be helpful in predicting relative toxicity for a number of actual or developmental molecules. At least in theory, numerous time-consuming and animal-intensive assays could be avoided and those chemicals with the best toxicity profiles would be pursued.

Ocular irritancy testing has been an area of intense alternative research, with considerable progress noted (Chu and Toft, 1993; Interagency Coordinating Committee on the Validation of Alternative Methods, 2008a). One promising commercial alternative (EpiOcular™, MatTek Corporation) contains normal, human-derived epidermal keratinocytes which have been cultured on a special medium to form a multilayered structure similar to the corneal epithelium. Following administration of the test substance, a series of biochemical procedures is conducted to measure relative potential for irritancy, cytotoxicity and permeability. EpiOcular™ or other alternatives could give useful preliminary indications of the intensity of ocular response. The investigator could then adjust the conditions for *in vivo* testing (sample volume, number of animals, timing of washing) to provide the maximum benefit with minimam animal distress. While these procedures continue to be evaluated, others have been validated as acceptable alternatives to animal testing (European Centre for the Validation of Alternative Methods, 2008a). One of the validated methods is another commercial product, Corrositex (In Vitro International)—an *in vitro* system which can be used to predict severity of dermal corrosion. It has been shown to correlate well with animal and human test results and has been accepted by several agencies, including the DOT, US EPA, OECD and others, as a replacement for animal testing.

One of the most animal-intensive studies is the chronic carcinogenesis assay. This costly, time-consuming work can be conducted on only selected test substances. An *in vitro* screen has been developed by Ames *et al.* (1975) to assess the genotoxicity/carcinogenicity potential of chemicals. The Ames Test utilizes mutated bacterial strains (*Salmonella typhimurium*) which are dependent on histidine for survival. These strains are sensitive to chemical carcinogens and react by reverting to histidine independence. Thus, colony growth in a histidine-free media indicates genetic mutation and the potential of carcinogenicity. Frequently, this assay is included in a battery of acute tests as a relatively fast and inexpensive cancer screen. Such a battery may be the only testing done for many of the new materials being developed. No animals are used in the Ames Test and subsequent long-term animal tests may or may not be indicated.

4.3.4 Responsibility for Animal Welfare

The 'fourth R', responsibility, applies to all who have an influence on how animals are treated. Each person, organization and agency must make a commitment to conduct or promote the most stress-free animal research possible. The technical animal staff must be fully trained and observant in animal care and handling. SOPs must be understood and followed. Communications must be open between technical and supervisory personnel regarding animal health and wellbeing. The facility management must be fully supportive of animal welfare and humane research. Even though pressures are high to keep costs low, finish projects rapidly, and maintain a high volume of data output, these goals should not overshadow good science and animal welfare issues. Efforts should be made to track any trends in poor treatment technique, dosing errors, accidental animal deaths or any hints of abuse. Senior staff should make sure that the facility, personnel, policy and work environment are sufficiently directed towards animal welfare. In the long term, this approach will project a respectable reputation for animal research. Along with this approach should be a commitment by those companies or organizations that sponsor animal research. They may have very special goals to reach from the research, but they must also be sensitive and supportive towards humane treatment of animals.

Since much research is guided by governmental or international agencies, it is most important that they keep current with validated animal research techniques. However, they should not yield to political or social pressures to eliminate needed animal testing. Instead, refinements or replacements of animal testing should be carefully integrated into research guidelines. Importantly, agencies should formalize accepted improvements in animal testing quickly to avoid delays or confusion in procedural development in the toxicology laboratory. There must be continual efforts for harmonization among agencies of one nation and among the nations of the world. Unfortunately, tests have been sometimes repeated because evaluation under the guidance of one agency may not fulfil the requirements of another agency or another country. This situation has now been undergoing rapid improvement through the efforts of the United Nations (UN) and the OECD (United Nations Economic Commission for Europe, 2008). Their efforts have resulted in the 'Globally Harmonized System of Classification and Labelling of Chemicals' (GHS). The first edition of GHS was approved in 2002, followed by revisions in 2004 and 2006 (published in 2007). Agencies, industries and countries around the world are reviewing the GHS requirements and deciding how to implement them. GHS is not a regulation and compliance is voluntary, but there will be considerable pressure for companies doing global business to adopt it.

DOI: 10.1002/9780470744307.gat050
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The most significant and most direct responsibility for animal welfare falls on the investigators (study directors, primary researchers, project managers). They must be thoughtful and knowledgeable in their approach to animal research issues. The welfare of animal subjects should become as much a part of study planning as are the scientific aspects. The investigator should first review the study goals and decide if sufficient work has been done previously. To do this, a review of available literature and historic data from the facility is helpful (see **Information Resources for Toxicology**). There are many sources of related literature on the Internet, including the AGRICultural OnLine Access of the USDA (AGRICOLA; AGRICultural OnLine Access, 2008) database containing millions of citations. If there is a precedence of similar testing, the new project should be aborted or at least altered to gain only the data still required. Some thought should be given to alternative methods, if they could provide adequate data. Throughout the process of protocol development, animal receipt, study conduct and study observations, animal welfare must be considered, like the approach shown in **Figure 5**.

If excessive suffering or pain is anticipated or apparent during a research project, procedures must be revised and/or animals euthanized. Sometimes, this decision is made at the expense of study data and, therefore, options must be considered carefully, with input from veterinary staff and the IACUC. Sponsoring organizations must be notified and the rationale provided. Moreover, animal welfare does not end with the termination of a toxicology project. Studies should be reviewed afterwards in light of potential improvement for animal welfare. Whenever possible, serious consideration should be given to publication of study findings so that other investigators will have access to them and avoid duplication of the work involved.

4.4 The Institutional Animal Care and Use Committee

As described briefly above, The Animal Welfare Act (US Department of Agriculture, 1995) requires the animal research facility to form an IACUC for oversight of animal-related issues, following the standards set forth by the 'Guide'. Additional information can be found in the *Institutional Animal Care and Use Committee Guidebook* published by the Office of Laboratory Welfare/Applied Research Ethics National Association (Office of Laboratory Animal Welfare/Applied Research Ethics National Association, 2002). Also, there is a web site dedicated to IACUC information at iacuc.org. An active, well-informed IACUC is one of the best guarantees that animal welfare policies are supported and followed. Although research facilities are sometimes criticized for self-policing (IACUC members are chosen by the management of the facility), there are numerous checks and outside (USDA, AAALAC) inspections that, along with practical considerations already noted, make most IACUCs effective. The required membership of an IACUC has been noted previously, and the total number of members depends on the size of the facility and the extent of its research. Beyond the mandated composition of the groups, it is desirable to include members from diverse backgrounds among scientific and nonscientific disciplines. Outside experts may also serve as consultants. There may be need for subcommittees to carry out the many functions of the IACUC.

As outlined in the 'Guide', the IACUC oversees and assesses the animal care programme and the use of animals on research. At least every six months, it inspects the facility (with emphasis in all animal housing, testing, sanitation and supply areas), reviews protocols (study and animal care) and carefully records all findings. A written report (containing meeting minutes, documents reviewed, areas inspected and items discussed) signed by most or all members, is issued to principal investigators and facility management detailing any deficiencies. Specifically, study protocols, and subsequent animal use and euthanasia, are evaluated on the following bases (the 'Guide'):

- Rationale of proposed animal use.
- Justification of the species used.
- Justification of the number of animals used.
- Availability of alternative methods.
- Adequacy of staff training and experience.
- Atypical housing or husbandry requirements.
- Consideration of sedation, analgesia and anaesthesia.
- Unnecessary duplication of testing.
- Use of repeated and/or major surgical techniques.
- Criteria for excessive pain or distress.
- Criteria and procedures for intervention (removal from study or euthanasia).
- Methods of euthanasia.
- Safety of working environment for personnel.

Standardized procedures (commonly used techniques), in addition to specialized research projects, must be considered by the IACUC. Standardized protocols should not require full review each time they are employed, but any revisions affecting animal use must be considered by the IACUC. All specialized protocols should each be reviewed by the IACUC. There should be a review/approval form for each project, which should be maintained as part of study records. These records should also be maintained in facility files, available for independent review, such as a USDA inspection. The IACUC report must reflect adherence to the Animal Welfare Act, with minor and major deviances noted. A major deficiency is one that threatens the health, wellbeing or safety of the animals.

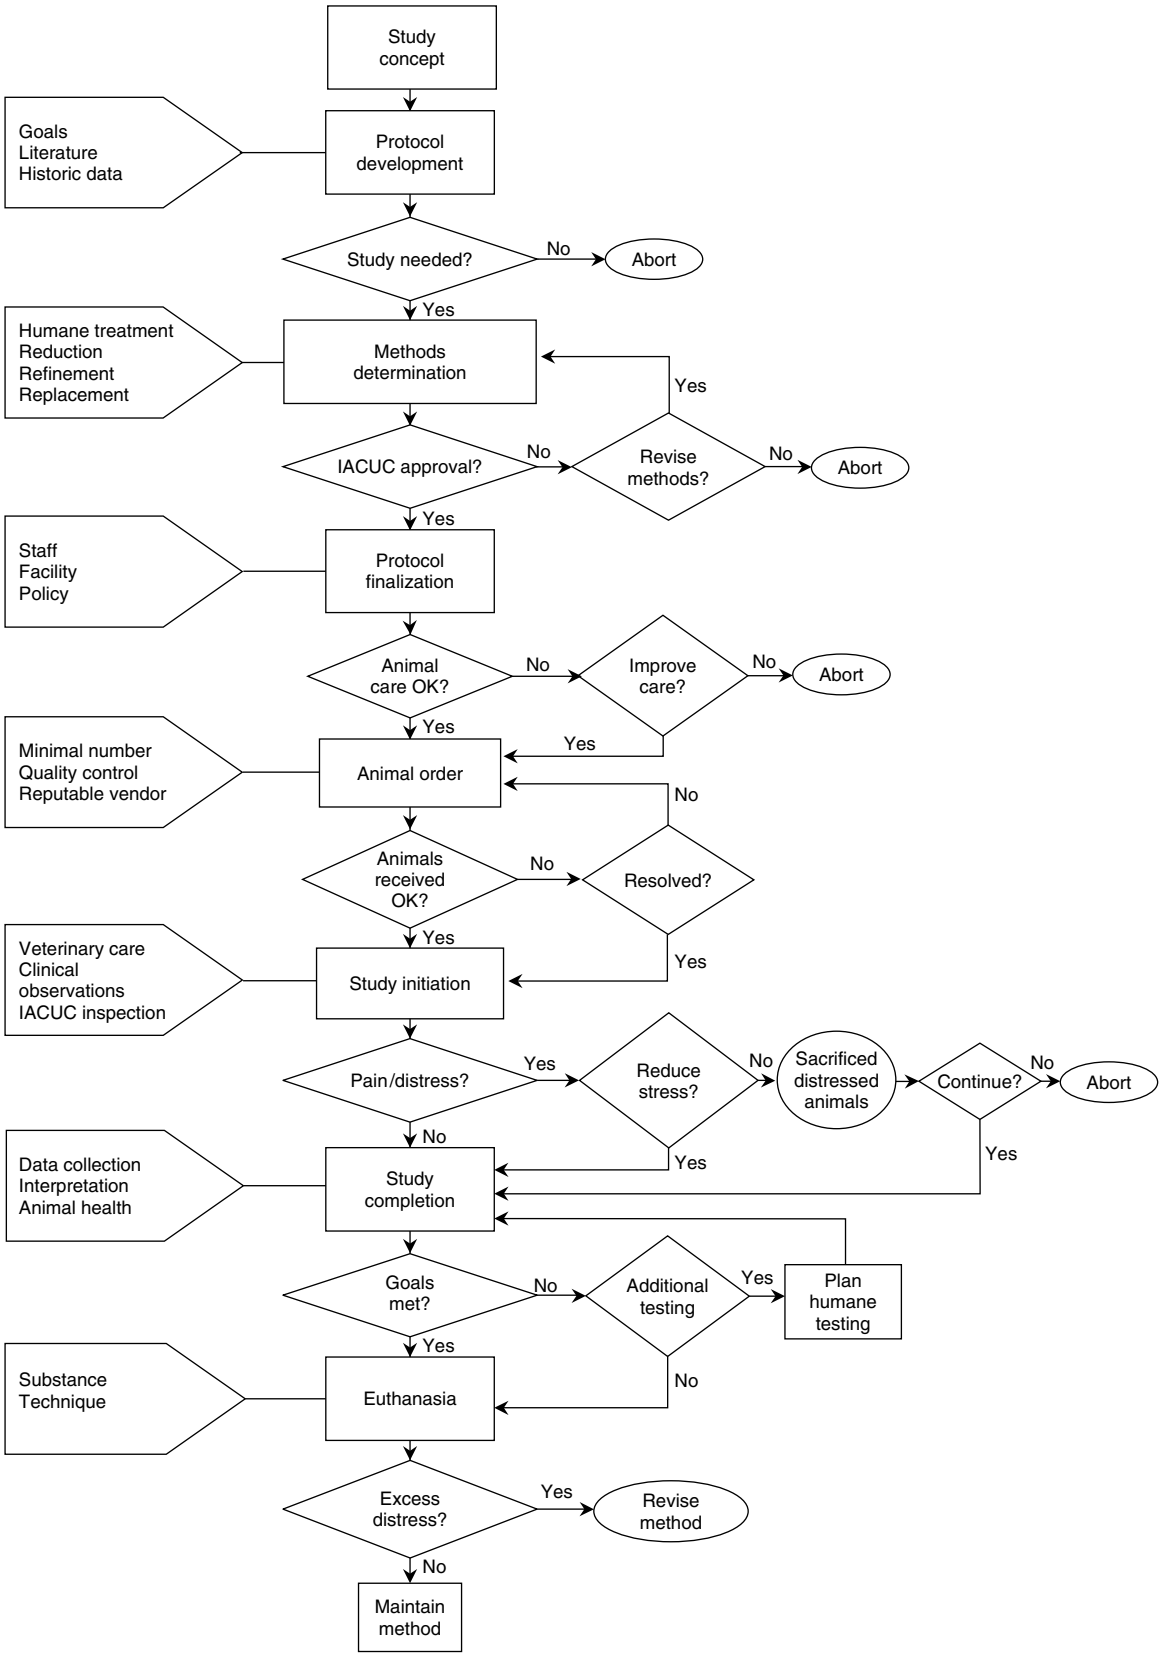

Figure 5 The schematic for humane treatment of animals in the toxicology laboratory shows the complexities of the decision processes. The central portion indicates the basic steps and decisions regarding animal use to be considered during a research project. Influencing factors appear on the left; options and secondary decisions are given on the right.

Identification of animal welfare deficiencies need not only originate from formal inspections, however. Any staff member should be encouraged to present concerns to the IACUC. Technical or nontechnical personnel, for example, should be free (without any negative consequences) to inform a direct supervisor or an IACUC member of any excessive pain/distress witnessed during the course of a toxicology project. Such information may be kept confidential, but careful documentation must be made. It then becomes the responsibility of site management and/or the IACUC to investigate and take appropriate corrective action as warranted. This process is discussed by Silverman (1994).

There must be a reasonable and specific plan, with an outlined schedule, for correction of significant deficiencies. Resolution of any major deviation should occur through a joint effort of the researcher, facility management officials of the area of concern (animal care supervisor, environmental or maintenance staff, purchasing agent, etc.), and veterinary staff, along with the IACUC. If major deficiencies are not resolved according to the plan and schedule, the remaining deficiencies 'shall be reported in writing by the IACUC, through the Institutional official, to APHIS and any Federal agency funding that activity' (The 'Act'). The IACUC will also withhold approval for the specific studies affected until concerns are resolved. Of course, conflicts may occur among staff, researchers, management and study sponsors. These will have to be resolved in light of the principles presented in the introduction—ethics, science, social pressures and legal requirements.

Secondary responsibilities of the IACUC are training staff members, providing information on animal use, interacting with other personnel (health and safety officers, managers, legal staff, etc.), developing a liaison with outside organizations promoting humane research and engaging in public education (Dell, 1994). Any complaints or charges of animal misuse made by the public or the media should be investigated by the IACUC. This should aid facility management in arriving at an appropriate response.

5 FUTURE DIRECTIONS

It is apparent that the issue of animal welfare has not lessened in importance over the last several years and will continue to be a major concern. Animal rights groups continually question the value and humaneness of animal research. They are well funded, highly visible, and often associated with the 'politically correct' among celebrities and government officials. The public and the media will certainly continue to question the need for animal research. In turn, government legislation will continue the attempts to ban or, at least, severely limit certain types of research. In 1992 the European Community's Council of Ministers voted to prohibit sales of cosmetics containing ingredients tested on animals after 1 January 1998 (Zurlo *et al*., 1993). This was done with the assumption that suitable alternatives would be available. After several delays in implementation, the current rule (European Directive 2003/15/EC) is that finished cosmetic products may not be tested in animals (American Veterinary Medical Association, 2003). Ingredients may not be tested in animals after March, 2009. Over the last several years, groups in the USA, such as the Soap and Detergent Association and the Cosmetic, Toiletry, and Fragrance Association have substantially reduced animal use in product safety testing, and have begun increased reliance on alternative methodologies.

Several US agencies such as the DOT, EPA and FDA have increasingly incorporated animal welfare concerns and alternative testing procedures into their guidelines. Recently, the US EPA announced that a 'Memorandum of Understanding' has been developed in collaboration with the NIH and the National Toxicology Programme (NTP) to use high-speed automated robots to screen chemicals for toxicity (US Environmental Protection Agency, 2008). The screening will use cells and isolated molecular targets instead of laboratory animals. Validation and implementation will take place over many years.

A number of research facilities continue to be proactive in developing alternatives to animal testing. One well-known facility in the USA is the Johns Hopkins Center for Alternatives to Animal Testing. It is funded by several major chemical and health product companies, food and cosmetic companies, animal welfare groups and Federal agencies. For the most part, such organizations recognize that whole-animal research will continue to be needed. Their goals are to more fully develop and validate *in vitro* tests, computer modelling, reduction in animal use and other alternative methods of toxicologic research (Johns Hopkins Center for Alternatives to Animal Testing, 2008c). They serve as information sources for alternative methods, with data on advantages and disadvantages. In 1997, the National Institute of Environmental Health Sciences (NIEHS) established the Interagency Coordinating Committee on the Validation of Alternative Methods (2008b). This group is composed of representatives from 15 Federal regulatory and research agencies involved with toxicologic research and information. ICCVAM, administered by the National Toxicology Program Interagency for Evaluation of Alternative Methods (NICEATM), promotes validation and acceptance of methods that reduce, refine or replace animal tests.

In Europe, the ECVAM spends millions of dollars on alternative research (Zurlo *et al*., 1993; European Centre for the Validation of Alternative Methods, 2008b). Numerous alternative methods have been validated by ECVAM and many more are under consideration. In the UK, FRAME (Fund for the Replacement of Animals in Medical Experiments) has been active for many years in

the development/validation of alternative methods. These and comparable organizations worldwide are expected to provide new directions and new options in toxicologic research over the years to come.

All individuals and organizations involved with animal research will be compelled to be increasingly vigilant in their approach to animal research, staying current with new legislation, new methodologies and changing public perceptions as they develop in the future. The basic need for animal research is not likely to disappear for many years. The approaches and attitudes towards animal welfare will need to evolve as new standards and technologies become available.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to Hilltop Lab Animals, Inc. (Scottdale, PA) and WIL Research Laboratories, LLC (Ashland, OH) for providing photographs relating to animal housing or use replacement.

Chemical and Biological Occupational Hazards in the Toxicology Laboratory

Bryan Ballantyne

CONTENTS

1 GENERAL CONSIDERATIONS

Many of the occupational hazards in the toxicology laboratory are common to those of laboratories specializing in other branches of science and technology. These cover a kaleidoscope of situations, including the handling of flammable and explosive materials, heating equipment, electrical devices, sharp instruments, glassware, lasers and radioactive isotopes. These general aspects of laboratory safety have been discussed in detail in various monographs (National Research Council, 1981; Fawcett, 1983; Armour, 1991).

Toxicology laboratories have specific biological and chemical hazards, and special precautionary measures, protective procedures and management protocols are required. There is exposure to a very wide range of substances, many at the research and development stage, whose human health hazards are unknown. Indeed the reason for conducting investigations on such chemicals is to determine various aspects of their toxicity and potential health hazards. Knowledge of the physicochemical properties of materials to be investigated, and of any relevant structure–biological activity relationships, should be considered in order to allow the most appropriate guidance on safe-handling practices. However, considerable caution is required, since many aspects of toxicity are not predictable. Some materials may have a relatively well-defined acute toxicological profile, but other special aspects of toxicity are being investigated in the laboratory, for example, long-term toxicity, genotoxicity, reproductive toxicity or metabolism and toxicokinetic studies. Because of the potential for repeated exposure to these substances in the laboratory, specific protective and precautionary measures may be necessary. Also, certain materials of high biological activity are used as positive controls; for example, in genotoxicity, developmental toxicity and sensitization studies. Clearly, for such materials the most stringent of storage and handling procedures are required. Additionally, there is a potential for exposure to chemicals used routinely in laboratory procedures, for example, in the histology laboratory. Since the toxicology and potential human health hazards of these latter materials are usually well documented, any necessary protective and precautionary procedures should be known.

Physical injury can occur during the handling of animals and from instruments such as scalpels, scissors

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat051
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and needles. Exposure to, and handling of, laboratory animals may cause physical injury, infections and irritant or allergic reactions. These aspects of toxicology laboratory practice, considered later (Sections 4 and 5), can be a significant cause of morbidity. Risk factors may be somewhat greater for certain groups of workers than for others; for example, animal cage cleaners are exposed to chemicals, mechanical equipment, high-pressure water and high temperatures.

2 ROUTES AND NATURE OF HAZARDOUS EXPOSURES

Exposure may occur by various routes and involve different toxicopathological processes. In general, containment of chemicals for acute studies can be accomplished more easily than for chronic studies because of the smaller number of animals used in acute studies, thus allowing the work to be conducted in exhaust hoods, which is not feasible with the larger number of animals used in repeated-exposure studies (Snellings, 1992).

During the dosing of animals there may be exposure to the test chemical. For example, whilst incorporating test material into feeds for peroral studies, a dust may be created during milling and mixing operations, and also during transfer of test diets. This could result in respiratory tract and cutaneous exposure. Test material applied to the skin of experimental animals may be disseminated by handling of animals, reclipping of hair, changing of bedding and sweeping animal room floors (Darlow *et al*., 1969). Exposure to vapour may occur during application of volatile test material to the skin. With exposure to airborne materials there may be a potential for fire or explosion. Some chemicals, such as pyrophorics, must be diluted with nitrogen before mixing with air. Exposure to test material may occur from leaking chambers or from the handling of animals just removed from a chamber, particularly if exposed to dust or aerosol. Chemical exposure may also occur from contaminated protective clothing. Although gloves may give protection against test chemicals, they may be a source of allergic reactions (see Section 3).

Some health hazards in the toxicology laboratory are known and well appreciated. These include irritant and allergic reactions to chemicals, animals and gloves. For certain potential adverse toxic effects the evidence may be conclusive, but in many other cases may be suggestive, but unproven. Thus, benzene is classified as an IARC (International Agency for Research in Cancer) Group 1 carcinogen with human evidence for leukaemia induction (Glass *et al*., 2003); however, other animal carcinogens are suspect (but unproven) as human carcinogens. There is limited evidence for an increased cancer incidence in laboratory workers (Nenzan, 1990; Summary, 1991) and for adverse developmental and reproductive effects (Heidam, 1984; Legge, 1986). Possible influences on reproductive performance and effects on the developing conceptus have been considered, but with variable findings. Thus, in some studies the risk of abortion or congenital malformation was not increased in laboratory workers (Baltzar *et al*., 1979; Olsen, 1983; Ayelsson *et al*., 1984; Heidam, 1984), but in others there have been indications of increased abortions (Strandberg *et al*., 1978; Lindbohm *et al*., 1984), or an increased risk of malformations (Meirik *et al*., 1979; Ericson *et al*., 1982; 1984) with specific or classes of substances. In a retrospective case-report study, Taskinen *et al*. (1994) found a possible association between exposure to toluene, xylene and formalin/formaldehyde during early pregnancy and an increased risk of abortion, but cautioned that the findings need careful interpretation because of frequent simultaneous chemical exposures. Wennborg *et al*. (2005) investigated major congenital and neural crest malformations in a cohort of Swedish university-employed women working in scientific laboratories; the entire cohort consisted of 2676 women from biomedical laboratories (exposed) and 1147 from other departments (unexposed). They found no significantly increased risk of congenital malformations in relation to laboratory work in general. However, an excess risk was found for organic solvents, especially benzene, for major congenital malformations and for neural crest malformations in offspring of women who had worked with benzene before the end of the second trimester of pregnancy. Thus, odds ratios (with confidence intervals, CI) for various groups were: laboratory work in general, 1.2 (CI = 0.7–2.0); solvent exposure before the third trimester, 1.8 (CI = 1.0–2.9) and neural crest malformations with benzene use, 5.3 (CI = 1.4–21.1). Benzene has previously been associated with reduced birth weight (Chen *et al*., 2000) and increased spontaneous abortion (Xu *et al*., 1998).

A relatively new area of investigation is that of nanotoxicology in support of health hazard evaluations of the technological uses of nanoparticles, in the length range of approximately 1–100 nm. Nanoparticles currently in use have been made from transition metals, silicon, carbon and metal oxides (zinc dioxide and titanium dioxide) (Dreher, 2004), and in may cases engineered nanoparticles exist as nanocrystals (Murray *et al*., 2000). A substantial proportion of inhaled nanoparticles are likely to deposit in the respiratory tract; ~30 to >90%, depending on breathing rate and particle size (Schulte, 2008). They readily reach the deep lung, and the alveolar region is the primary site of deposition for nanoparticles in the range 10–100 nm. There are indications that these materials may pose a hazard locally to the lung through oxidative stress, inflammation and tumourigenesis, and also cause systemic effects by redistribution to other organs following pulmonary deposition

(Donaldson *et al*., 2005; Donaldson *et al*., 2006). Translocation from lungs has been shown for brain liver, kidney and spleen (Elder *et al*., 2006; Geiser *et al*., 2005), and the rate depends on physicochemical properties of the nanoparticles, including size, chemical nature, shape and charge (Oberdörster *et al*., 2002; Kreyling *et al*., 2006). Occupational health precautions in the toxicology laboratory should be primarily preventive in nature, with appropriate health monitoring (Schulte *et al*., 2008). Currently many resources, particularly in the USA, Europe and Japan, are being devoted to the development of risk and safety evaluations of nanomaterials, environmental fate, human health effects, workplace and environmental monitoring and precautionary measures (Thomas *et al*., 2006a). A detailed review of nanotoxicology is given in **Nanotoxicology-The Toxicology of Nanomaterials**.

Whilst all chemicals should be characterized for potential adverse human health effects, and appropriate protective and precautionary measures be developed for their use and handling in the laboratory, certain groups of substances are clear candidates for this exercise. This includes volatile organic solvents because of the likelihood for exposure and their known local systemic toxicity.

3 LATEX ALLERGY

3.1 General Considerations

The rubber accelerator 2-mercaptobenzothiazole (MBT) has been reported to cause allergic contact dermatitis from gloves. It has been suggested that the thiol group is essential to MBT's covalent binding and/or haptenation to nucleophilic protein residues. Oxidation of MBT and its possible haptenation pathways in the pathogenesis of allergenicity were investigated by Chipinda *et al*. (2007). Oxidative transformation of MBT to the disulfide 2,2′-dithiobis(benzothiazole) (MBTS) was detected in glove matrix when hypochlorous acid, iodine and hydrogen peroxide were used as oxidants. Cysteine reduced MBTS to MBT with subsequent formation of the mixed disulfide 2-amino-3-(benzothiazol-2-yl disulfanyl) propionate. Spectrophotometry and mass spectrometry studies demonstrated the simultaneous reduction of MBTS and disulfide formation with Cys34 on bovine serum albumin, suggesting a potential route of protein haptenation through covalent binding between protein cysteinyl residues and the MBT/MBTS thiol moiety. The investigators concluded that the studies suggest that the critical functional group on MBT is thiol, and haptenation is via the formation of mixed disulfides between the thiol group MBT and a protein sulfydryl group. Allergens present in latex (Turjanmaa, 1987; Alenius *et al*., 1991), may result in the production of IgE antibodies and/or initiate T cell-mediated reactions following exposure (Frosch *et al*., 1986). As a consequence, reactions to latex glove materials that have been documented include urticaria, contact dermatitis, angio-oedema, conjunctivitis, rhinitis, bronchospasm, asthma and anaphylaxis (Seaton *et al*., 1986; Turjanmaa, 1987; Shama, 1991; Zotti *et al*., 1992; Warshaw, 1998; Toraason *et al*., 2000; Taylor and Erkek, 2004). Thus, the clinical syndromes that result from latex hypersensitivity may be variable, and include both type I- (IgE) and type IV-mediated responses. Overall, the prevalence of latex allergy may differ considerably for various exposure populations. For example, cited prevalences of latex allergy for healthcare workers in general in reliable series are 7.0% (Turjanmaa, 1987) and 12.1% (Liss *et al*., 1997). In one large detailed study of 741 nurses, the overall prevalence of latex sensitization, based on serum positive reactions for antilatex IgE, was 8.9% (Grzybowski *et al*., 1996). In another study, 21 out of 384 hospital nurses (5.5%) were positive for the presence of latex-specific IgE antibodies (Kaczmarck *et al*., 1996). It is recognized that atopy is a high-risk factor for the development of latex allergy (Kam *et al*., 1997; Liss *et al*., 1997).

3.2 Allergic Contact Dermatitis

Allergic contact dermatitis is a well documented type IV hypersensitivity reaction associated with latex exposure. Typical incidences are 7% in health care workers (Fisher, 1992) and 22% in dental workers (Katelaris *et al*., 1996). Contact urticaria, a type I reaction, may occur within 5–60 minutes after cutaneous exposure, and be clinically present as erythema, hives, pruritis and eczema. Rhinitis, conjunctivitis and periorbital oedema may also be present (Kam *et al*., 1997). For laboratory workers with established dermatitis, suspected of being caused by the gloves, patch testing with the glove rubber may be useful for diagnostic purposes. The possible contribution of glove powder to delayed onset cutaneous hypersensitivity may be assessed by patch testing with epichlorhydrin and preservatives, including isothiazolin-3-one (Heese *et al*., 1991). Localized urticaria may also be investigated by skin-prick tests. Radioallergosorbent tests (RASTs), enzyme-linked immunosorbent assays (ELISAs) and Western blot tests may be useful, but apparently have a low sensitivity in healthcare workers (Holzman, 1993; Slater, 1994). Filon and Radman (2006) found a significant relationship between latex glove allergy and positive skin test for latex with an odds ratio of 9.70 (95% CI 5.5–17.0). Suli *et al*. (2006) reported that skin-prick tests displayed the highest diagnostic efficiency, having higher sensitivity and specificity than specific IgE determination and use tests. They also noted that patch testing with rubber chemicals had a low sensitivity, but a good specificity; however, basophil histamine release and immunoblot showed low sensitivity and low specificity.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The investigators concluded that a combination of clinical history and skin-prick test should be used in order to diagnose latex allergy.

3.3 Respiratory Sensitization

Asthma occurs in a small population of those exposed to latex. Respiratory exposure to latex allergen is usually related to the use of powdered gloves, with allergens being transferred from gloves to powder, which may then become airborne as gloves are handled (Swanson *et al*., 1992). In one series in which airborne latex was measured in a healthcare institution, the latex aeroallergen concentrations ranged from 5–618 mg m^{-3} (Liss *et al*., 1997). Bronchial provocation testing has shown that airborne latex allergens produced a late asthmatic response. In one series, latency was 4–16 hour postexposure, and with a duration of 3–48 hours (Brugnami *et al*., 1994). The possible contribution of latex to occupational asthma requires, initially, confirmation of the presence of asthma by appropriate respiratory function tests, followed by challenge tests with monitoring of peak expiratory flow rate (PEFR) and forced expiratory volume in 1 s (FEV_1) (Marcos *et al*., 1991; Vandenplas *et al*., 1996). However, it should be borne in mind that provocation tests must be undertaken with considerable care and under skilled medical supervision, since severe systemic reactions, including anaphylaxis, may be induced (Pisati *et al*., 1994). Clearly, laboratory workers presenting with respiratory tract hypersensitivity reactions should also be investigated for the possible contribution of laboratory animal allergy (LAA). Hamilton and Adkinson (1998) in a multicenter study found that the Grear NAL (nonammoniated latex allergen preparation) skin test reagent at 100 μg ml^{-1} is a safe and effective method for confirmation of latex allergy.

With respect to pre-employment screening of laboratory animal workers, a complete history should be obtained, which should include factors that may indicate atopy. Special investigations should include respiratory function tests and, possibly, skin patch tests. For those with established allergic contact dermatitis, cotton liners and barrier creams may be effective, but the use of alternative forms of gloves is probably the best corrective measure. For those with established respiratory sensitization, a change in work conditions may be necessary.

4 LABORATORY ANIMAL ALLERGY

4.1 General and Background Considerations

LAA has been recognized for several decades as a health-related problem in those handling animals in various types of biological laboratories. Its high incidence and severity are such that a change of employment may be necessary. In the UK, LAA is a prescribed industrial disease under the Social Security Act of 1975. The prevalence of LAA in several surveys is shown in **Table 1**, where the range is 19.2–56.0%. It is therefore a factor of considerable occupational health concern in toxicology laboratories, particularly with respect to precautionary and protective measures. Lutsky (1987) surveyed 252 laboratory animal facilities in 21 nations, and concluded that LAA is a world-wide occupational disease. Other estimates of the range in incidence include 5–40% of research workers exposed to animals within the first year (Tfelt-Hansen *et al*., 2007). A high incidence, 59.5%, for LAA on skin-prick testing was recorded for veterinarians (Krakowiak *et al*., 2007). In addition to direct health consequences, those with LAA may be more susceptible to life-threatening anaphylaxis secondary to rodent bites (Teasdale and Davies, 1983; Hesford *et al*., 1995) or to minor injuries from needles used in animal procedures (Watt and McSharry, 1996).

The rat and mouse are most frequently cited as causes of LAA, but hamsters, guinea pigs, rabbits and cats

Table 1 Prevalence of laboratory animal allergy in different geographical locations, based on clinical effects, according to various surveys

Country	Group size	Incidence (%)	Reference
Japan	5641	23.1	Aoyama *et al*. (1992)
UK	138	44.0	Venables *et al*. (1988a)
UK	146	30.0	Slovak and Hill (1981)
UK	9	22.9	Beeson *et al*. (1983)
Sweden	101	32.0	Willers *et al*. (1992)
Sweden	146	41.0	Agrup *et al*. (1986)
Sweden	110	20.9	Weissenbach *et al*. (1988)
The Netherlands	99	19.2	Kruize *et al*. (1997)
Australia	228	56.0	Bryant *et al*. (1995)
Australia	121	32.0	Schumacher *et al*. (1981)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat051
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

have also been implicated (Sjostedt *et al*., 1995). Antigens responsible for LAA are usually associated with animal hair, dander and urinary protein. Two allergens have been identified in rat urine, saliva and pelt. Originally described were Rat n 1A, believed to be a prealbumin and Rd Rat n IB, an α_{2U}-globulin (Newman Taylor *et al*., 1977; Eggleston *et al*., 1989). Studies, confirming nucleotide and amino acid sequences, have shown that both allergens are variants of α_{2U}-globulin (Bush *et al*., 1998). In addition to the physiological proteinuria in rats, a raised excretion of urinary protein occurs in sexually mature male rats due to nephritis (Longbottom, 1984; Schumacher, 1987). Three mouse allergens have been identified (Sirayanian and Sandberg, 1979; Schumacher, 1980; Price and Longbottom, 1987). The major allergen, Mus m 1, previously referred to as Agl, is a prealbumin found in urine, hair follicles and dander. As a result of testosterone-dependent gene expression, the concentrations in urine and serum are four times greater in male than female rats. The second mouse allergen, Mus m 2, is a glycoprotein in hair follicles and dander, but not urine. The third mouse allergen is albumin (Price and Longbottom, 1987). Airborne mouse allergens appear to be present in direct relationship to the number of mice present, and the degree of work activity in animal rooms or laboratories (Twiggs *et al*., 1982). In guinea pigs, two allergens (Cau p I and Cau p II) have been proposed (Schou, 1993), which are probably concentrated in the fur, possibly explaining the higher allergenic potency in dander from guinea pigs compared with urine and saliva (Sjostedt *et al*., 1995). In the cat, the major allergen (Fed d 1) occurs principally in the pelt and sebaceous and mucous salivary glands, but not serum and urine (Anderson and Baer, 1981; Brown *et al*., 1984). Fed d 1 is produced in sebaceous glands and transferred to fur by licking. At least 12 cat proteins have been determined to be allergenic, but Fed d 1 is the major one (Charpin *et al*., 1991; Warner and Longbottom, 1991; Kleine-Tebbe *et al*., 1993; Bush *et al*., 1998). In the dog, the most important antigenic protein is Can f 1, a polypeptide present in hair, dander and saliva (Schou *et al*., 1991; Bush *et al*., 1998). In addition to the common causes of LLA, there are cases of allergy related to geographically specific causes; one potentially fatal example is occupational laboratory allergy to the African migratory grasshopper, *Locusta migratoria*. Lopata *et al*. (2005) evaluated scientists and technicians exposed these locusts in the laboratory. Six of 10 individuals experienced symptoms ranging from urticaria and rhinoconjunctivitis to asthma. Seven individuals demonstrated sensitivity on skin-prick testing, and five had specific IgE anybodies to *L. migratoria*. Novel antigens with molecular weights of ~700 kDa were identified in locust wings.

In general, animal aeroallergens are associated with relatively small particles, which can remain suspended in the air for long periods and have a respirable fraction. Airborne mouse allergen is in particles in the size range 3–18 μm (Price and Longbottom, 1990; Ohman *et al*., 1994). Rat allergens are in particles in the size range from <1 to >20 μm, with the majority being <7 μm in diameter (Platts-Mills *et al*., 1986; Corn *et al*., 1988).

4.2 Clinical Presentation

Commonly affected sites are the respiratory tract, eye and skin. Typical combinations of signs and symptoms for these sites are shown in **Figure 1** (Aoyama *et al*., 1992). Rhinitis and conjunctivitis are common (Agrup *et al*., 1986; Venables *et al*., 1988a; Aoyama *et al*., 1992; Seward, 2001; Ruoppi *et al*., 2004), as are cough, dyspnoea and wheezing. Rhinoconjunctivitis is usually the presenting symptom complex, with nasal congestion, rhinorrhoea, sneezing and itching eyes with excess lacrimation. In one study investigating the incidence of allergy in workers exposed to laboratory animals over a 12-year period in a pharmaceutical manufacturing facility, the most common symptoms were related to rhinitis rather than to asthma (Elliot *et al*., 2005a). It is in the more serious cases that asthma occurs, with reported incidences in the range 17–71% (Kruize *et al*., 1997; Hunskaar and Fosse, 1990). Urticaria and angio-oedema may be present. Slovak and Hill (1981) have described two distinguishable forms: regional LAA with classical rhinitis and negative skin-prick tests, and progressive LAA with rhinitis leading to asthma and positive skin-prick tests. It has been noted that the presence of symptoms of LAA are a major risk factor for the development of asthma. For example, Elliot *et al*. (2005b) studied 603 workers with 2527.4 person years over a 12.3 year period, and determined that the probabilities of experiencing asthma symptoms by the 11th year of follow-up were 0.367 for workers with allergy

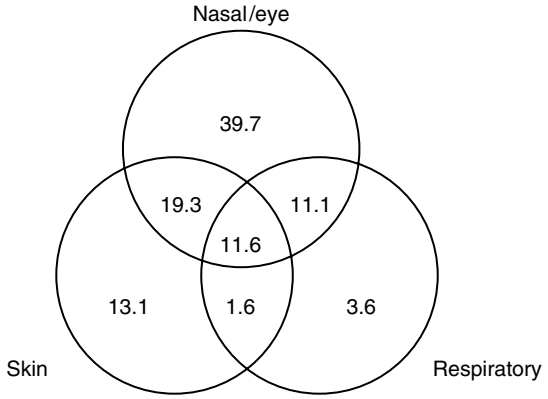

Figure 1 Combinations of symptoms in subjects with subjects with laboratory animal allergy in a survey by Aoyama *et al*. (1992). (Reproduced from Aoyama *et al*., 1992. © BMJ Group.)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat051
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

symptoms compared with 0.052 for those without allergy symptoms. The hazard ratio for asthma symptoms when comparing workers with and without allergy symptoms was 7.39 (95% CI, 3.29–16.60) after adjustment for sex and familial history of allergy. Female subjects developed asthma at a rate 3.4 times that for males.

Willers *et al*. (1992) found that those with LAA have a significant increase of trapped gas after pulmonary provocation with methacholine, and hence they associated LAA with small airway hyper-reactivity. However, pulmonary function testing does not reveal a decrement in forced vital capacity (FVC) or FEV_1 (Agrup *et al*., 1986; Willers *et al*., 1992). In a prospective study, Sjostedt *et al*. (1998) found increased methacholine responsiveness in FEV_1 at follow-up in skin-prick positive subjects. They suggest that airway responsiveness may start in the smaller airways and subsequently affect the larger airways. In the Aoyama *et al*. (1992) series, 70% of LAA subjects developed signs and symptoms within three years of exposure and 33% of these occurred within one year, particularly in those with respiratory symptoms. Agrup *et al*. (1986) found that first symptoms appeared within one year of the start of animal handling in 7 of 41 subjects: for the whole group the mean time to symptoms was 2.3 years (range one month to seven years). Kruize *et al*. (1997) reported a mean time of development of LAA symptoms of 109 months in nonatopics and 45 months in atopics. A longer latency of 0.5–12.0 years was described by Davies *et al*. (1983).

Family members of laboratory animal workers may be at risk of developing LAA due to spread of allergens outside the work facility. Thus, Krop *et al*. (2007) measured mouse and rat urinary proteins in samples of mattress dust and in extracts of hair-covering caps worn during work, and found that the levels of these allergens were significantly higher in mattress samples of laboratory animal workers than in controls. Hair-covering caps used in animal facilities had large amounts of rat and mouse urinary proteins, a finding that stresses the need for these to be used as part of industrial hygiene programmes to prevent spread of occupational allergens.

4.3 Predisposing Factors

4.3.1 Atopy

Predisposition of subjects (atopy) in most studies has been defined by a clinical history of allergy, positive skin-prick tests against nonlaboratory environmental allergens, and increased concentrations of serum IgE. Atopy has been frequently correlated with the development of LAA (Agrup *et al*., 1986; Kibby *et al*., 1989; Aoyama *et al*., 1992; Willers *et al*., 1992; Bryant *et al*., 1995; Fuortes *et al*., 1996; Ruoppi *et al*., 2004; Filon and Radman, 2006). However, not all cases are associated with atopy. For example, Gross (1980) found that prior allergies were more common in subjects with LAA (58%) in comparison with the general population (15%). Beeson *et al*. (1983) found the overall prevalence of atopy was 67% in LAA. The latency to onset of signs of LAA may be shorter in atopic than nonatopic subjects (Weissenbach *et al*., 1988; Kruize *et al*., 1997), and atopics may progress to a more severe form of the disease (Davies *et al*., 1983). Also, atopy may be strongly associated with the more severe manifestations of LAA, notably asthma (Cockroft *et al*., 1981; Slovak and Hill, 1987). In a study by Kruize *et al*. (1997), 13% of atopics with LAA had asthmatic symptoms compared with 6% nonatopics that had LAA.

4.3.2 Intensity of Exposure

The degree of exposure to allergens varies considerably and depends on, amongst other factors, stock density, tasks conducted, ventilation rates, cage design, bedding, air filtration and humidity. Although several studies have shown an association with the intensity of exposure expressed as concentration and/or duration of exposure (Cullinan *et al*., 1994; Elliot *et al*., 2005a; Kruize *et al*., 1997; Krakowiak *et al*., 2007), others suggest that intensity of exposure may not be a significant factor in LAA. However, analysis is complicated by the possibility of a self-selection bias. Thus, Venables *et al*. (1988b) found an inverse relationship between the prevalence of LAA, determined by symptoms and the duration of employment; they suggested that workers with LAA avoid exposure to animals. The available evidence indicates that environmental exposure is a strong determinant for the development of LAA, and that appropriate control measures may reduce morbidity (Bush *et al*., 1998). In the study by Kruize *et al*. (1997), intensity as expressed by time of exposure was a clear determinant; thus, an increased relative risk for developing LAA was found for nonatopics exposed for more than two hours per week, and an even higher relative risk for atopics with more than two hours exposure per week.

4.3.3 Cigarette Smoking

Several studies have not shown an association between cigarette smoking and susceptibility to LAA (Agrup *et al*., 1986; Willers *et al*., 1992; Fuortes *et al*., 1996; Kruize *et al*., 1997). However, Venables *et al*. (1988a) examined data from three cross-sectional surveys of 296 laboratory workers exposed to small animals and found evidence for an association between smoking and occupational asthma and skin weals to animal urine extracts. They suggested that smoking might be a risk factor for LAA.

4.4 Clinical Confirmation

Skin-prick tests are usually conducted with specific animal allergen extracts, but may not always be diagnostic. For example, Willers *et al*. (1992) noted a false positive incidence of 24% and a false negative incidence of 28%. Slovak and Hill (1987) found that 48% of those with LAA showed a positive skin reaction to allergens from the relevant species. They suggested that only those with a positive prick test develop progressive LAA (i.e. a strong correlation with asthma and a poor correlation with rhinitis only).

The RAST is used to measure specific IgE antibodies to preparations from urine protein extracts or superficial skin scrapes. Beeson *et al*. (1983) found that in subjects with LAA, 53% had positive skin-prick tests, and the RAST was also positive in 53%. Several groups (Vanto *et al*., 1982; Davies *et al*., 1983; Agrup *et al*., 1986; Venables *et al*., 1988a) have found that in those showing positive skin-prick tests, there was a good correlation with the results from RAST. Weissenbach *et al*. (1988) and Willers *et al*. (1992) consider that skin tests are more sensitive than RAST. Crossreactions between various species may occur (Agrup *et al*., 1986). Portengen *et al*. (2004) studied IgG4 in 529 laboratory animal workers, and found IgG4 titres were higher in atopic than nonatopic subjects, and increased with higher allergen exposures. Titres were highest in subjects who were sensitized and reported respiratory symptoms to rats compared with those who were not; 202 ± 5.7 GSD (geometric standard deviation) vs. 8.4 ± 18.3, respectively. IgG4 was a strong predictor of newly occurring sensitization and symptomatic rat allergy during follow-up in atopic and rat-sensitized subjects. The investigators consider that high anti-rat urinary allergen IgG4 is a strong predictor of prevalent and incident sensitization and symptomatic rat allergy in atopic and rat-sensitized subjects.

Studies by Adisesh *et al*. (1998) showed raised nitric oxide (NO) in exhaled air, increasing with symptom severity, suggesting this measurement might be a useful monitor in LAA. Hewitt *et al*. (2008) undertook serial measurements of NO in exhaled air in order to assess if the approach could detect exposure-related airway inflammation in 50 laboratory animal workers, of whom 11 had work-related symptoms and two of these has positive serology for LAA. Baseline NO was high (>150 ppb) in the two seropositive workers and increased progressively during a working week in one subject, confirming exposure-related airway inflammation. In seronegative subjects, mean NO concentrations were 19.8 ± 20.1 SD (standard deviation) ppb and 21.7 ± 20.8 ppb in the symptomatic and nonsymptomatic groups respectively, with no significant changes in expired air NO over time. The authors concluded that serial measurements of exhaled NO might provide complementary information in the assessment of possible occupational sensitization. Krakowiak *et al*. (2003) investigated the biochemical and nasal characteristics of nasal lavage fluid (NLF) and nasal resistance changes due to challenge with laboratory animal allergens in 25 patients with occupational asthma and rhinitis, in 22 patients with atopic asthma and rhinitis sensitized to house dust mite and in 15 healthy subjects. In patients with occupational allergy, nasal symptoms of varying severity developed directly after specific nasal challenge, and total symptom score immediately and 24 hours after challenge was significantly correlated with expiratory nasal resistance (ENR). The parentage of eosinophils and basophils in NLF increased significantly 5 and 24 hours after specific challenge and was correlated with ENR. The investigators did not find any significant increase in eosinophils, basophils and albumin in NLF, or changes in ENR, with nonoccupational asthma patients or in healthy subjects. The authors concluded that the changes in eosinophils, basophils and albumin in NLF reflect allergic inflammation, and are related to symptomatology and ENR in occupational allergy.

4.5 Workplace Management and Protective Measures

Lutsky *et al*. (1983) reviewed employer practices and concluded, at that time, there were no consistent or formal policies for addressing LAA. However, as discussed below, there have been marked improvements since then:

1. Pre-employment medical screens: these should include a history with particular, although not exclusive, reference to prior sensitization problems, personal habits, other occupational diseases and pulmonary and skin problems; respiratory function tests (including FVC, FEV_1 and PEFR); skin-prick testing; and measurement of serum IgE. However, pre-employment medical screens need to be interpreted with caution. Some atopics will not develop LAA, and a history of atopy may not be sufficient to exclude from employment. Thus, Botham *et al*. (1995) found that if atopy or pre-existing sensitization had been used as an exclusion criterion, this would have resulted in incorrect decisions for about one-third of their population. They believe that skin-prick tests and possibly RAST analysis should contribute to the pre-employment medical assessment. Also, they consider that atopics, and those already sensitized to laboratory animals, can be advised of their increased chances of developing LAA, but should not necessarily be excluded from employment. Greater consideration should be given to those

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat051
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

with a history of LAA, chronic skin disease, asthma or cardiovascular diseases, since these appear to make individuals more susceptible to induction and consequences of LAA than either a history of atopy or the presence of IgE antibodies alone. Important factors are a history of allergy to environmental antigens (especially domestic animals), strong reactions to skin-prick testing and high specific IgE to animal antigens. Fuortes *et al*. (1996) recommend that workers who are atopic or have respiratory symptoms should be placed in low-exposure situations.

2. Postplacement periodic medical evaluations: these are essential, and should include history, physical examination, respiratory function tests and possibly measurement of IgE as a potential indicator of the development of sensitization. In those developing LAA, the cause and possible progression of the disease should be carefully explained. With subjects who express a desire to continue working despite the development of symptoms, the prophylactic use of sodium cromoglycolate may provide some protection (Gross, 1980), but this should be regarded only as a temporary measure. In those with LAA, and particularly if asthma has developed, the only safe measure is one of job relocation where exposure to animal allergens does not occur.
3. Workplace management: this is the major way to control and/or prevent the development of LAA. The most important element is to reduce airborne allergen particles in workplaces and laboratories. For example, Gordon *et al*. (1992) demonstrated that rat urine aeroallergens can be significantly reduced by decreasing the stock density of rat housing areas and the use of filter cages or, when these cannot be employed, by replacing contact litter with noncontact absorbent litter. As noted previously, exposure concentrations of allergen vary considerably within the same facility, and between different facilities. Major determinants are stock density, tasks conducted, ventilation rates, cage design, bedding, air filtration and humidity. Clearly, attention should be directed at efficient extraction ventilation, handling procedures, personal protective equipment (including respiratory protective equipment), cage design and placement, the development of safe handling practices and worker education.

In the context of the number of laboratories using animals, there have been relatively few detailed measurements of aeroallergen exposure, but methods for measuring workplace aeroallergens have been described. These can be used, not only to determine the degree of exposure, but also to assess the effectiveness of engineering and other controls to reduce exposure. Gordon *et al*. (1997a) have described a method for measuring urinary protein in personal air samples for assessment of occupational exposure. They found high exposures in laboratory technicians having direct handling contact with animals. Hollander *et al*. (1997) described the measurement of rat and mouse urinary aeroallergens in airborne dust samples by the use of a sandwich enzyme immunoassay, having a detection limit of $0.075\,\mathrm{mg\ ml^{-1}}$. The highest levels of exposure were found during removal of contaminated bedding from cages. Nieuwenhuijsen *et al*. (1994), using a RAST procedure on specimens from personal air samples, found exposure concentrations to animal technicians over a work shift to be $32.4\,\mu\mathrm{g\ m^{-3}}$ (geometric mean). While handling rats the value was $68.0\,\mu\mathrm{g\ m^{-3}}$ and during cleaning out, $53.6\,\mu\mathrm{g\ m^{-3}}$. They also detected low concentrations of rat urinary aeroallergen close to, but outside, animal facilities.

Gordon *et al*. (1997b), who measured air samples for rat and mouse urinary aeroallergens by RAST inhibition, found that there was a sevenfold reduction in concentrations when mice were housed in ventilated cages operated at positive pressure, compared with conventional caging. There was a twofold reduction in personal exposures when soiled litter was removed by vacuum. Rat urinary aeroallergens associated with handling rats were reduced 25-fold when performed in a ventilated cabinet, compared with handling on an open bench. They concluded that a significant reduction in exposure to aeroallergens can be obtained by the use of ventilation systems for housing and handling, but the removal of soiled litter was less effectively reduced by vacuum procedures, and thus respiratory protective equipment may be desirable for this operation. A one-way airflow ventilation system drawing airborne allergens from the working area has been reported to reduce airborne particulates significantly (Yamauchi *et al*., 1989).

Fisher *et al*. (1998) described a comprehensive programme to reduce exposure to environmental allergens that resulted in the incidence of LAA being reduced from 10 to 0%. The programme included education and training: modification of work practices; engineering controls; the use of personal protective equipment including respiratory protection (generally dust-mist respirators); a medical surveillance programme for symptom assessment and RAST testing for animal allergies. The medical surveillance (including RAST), education and personal protective equipment instruction are performed annually and are mandatory for those working with laboratory animals. Engineering controls included filter-typed cages, high-efficiency particulate air-filtered room ventilation, increased room air exchanges and dust-free bedding. Reeb-Whitaker *et al*. (1999) found that for control of laboratory aeroallergen exposure, three strategies are the use of filter cage tops, operation of negatively pressurized

cages and the use of ventilated changing tables. Schweitzer *et al*. (2003) studied the influence of housing conditions on animal allergen exposure. They found that housing mice in ventilated cages operated under negative pressure and using ventilated change tables reduced ambient mouse allergen (Mus M 1) concentrations 10-fold compared with values when mice were housed in conventional caging and using conventional (nonventilated) changing tables. Housing mice in positively pressurized cages vs. conventional cages did not reduce ambient allergen values. They also noted that the percentage of animal workers reporting allergy symptoms correlated significantly with ambient allergen concentration. Thus, in rooms with the lowest allergen concentration (0.14 ± 0.30 ng m^{-3}) 12.9% workers reported allergy symptoms, but in rooms with the higher allergen concentrations (2.3 ± 00.4 ng m^{-3}) 45.9% of workers reported symptoms. These findings indicate that reduced exposure to laboratory animal allergens can improve the health status of animal care workers. The value of protective and precautionary measures is also demonstrated by the study of Botham *et al*. (1987) who found that the first-year incidence of LAA fell from 37% in subjects who started work with animals in 1980–1981 to 12% in those who started in 1984. This lower level of LAA was maintained in a subsequent study. The reduction coincided with the introduction of improved engineering controls and personal protective measures, including the use of educational programmes.

5 ZOONOSES

A concern about handling laboratory animals is the transmission from animals to the handler of viruses, bacteria or parasites through contact, a bite, or inhalation. Examples for large animals include Simean monkey virus B (Hull, 1973), tuberculosis from primates (Lennette, 1973) and Q fever from sheep (Lennette, 1973). Cat scratch disease is of presumed viral aetiology with the cat acting as a vector. There is regional lymphadenitis secondary to a primary cutaneous lesions; the disease is usually benign, with a good prognosis (Petersdorf, 1976). Rat bite fever may follow a bite from a rat, mouse or other rodent. The most common form, usually seen in laboratory workers, is caused by *Streptohaeillus meliniformis*, a Gram-negative bacillus found in the oropharynx of more than 50% of healthy rats. It presents as a febrile illness with myalgia, weakness and vomiting, followed by rashes and arthralgias (Sandle, 1983).

Eradication programmes have reduced the incidence of zoonotic disease. Most toxicology laboratories use only specific pathogen-free animals from suppliers with quality control programme. Details on the diagnosis, prevention and control of zoonoses are given by Acha and Szyfrei (1980).

6 SPECIFIC CONSIDERATIONS

In addition to the general physical and chemical hazards common to most laboratories of a toxicology facility, certain specialized areas may present particularly high-level concerns. In the pathology laboratory, personnel may be exposed to fixatives and solvents used in tissue preparation. For example, Kilburn *et al*. (1985) reported results of area sampling for formaldehyde, xylene and toluene in rooms where tissues and slides are processed, and determined the ranges to be: formaldehyde 0.2–1.9 ppm, xylene 3.2–102 ppm and toluene 8.9–12.6 ppm. They found that disturbances of memory, mood, equilibrium and sleep, which occurred simultaneously with headache and indigestion, were experienced more frequently in female histology technicians than in unexposed female clerical workers. Over a four year period, there was no evidence for cumulative effects (Kilburn and Warshaw, 1992). Formaldehyde has been shown to be carcinogenic in laboratory animals, but the currently available epidemiological information does not give convincing evidence that it is oncogenic in humans. Contact dermatitis from epoxy resin in immersion oil for microscopy has been described (Le Coz *et al*., 1999).

Several studies require positive control materials which are of high cytotoxicity, for example, in genotoxicity, carcinogenesis and reproductive toxicity investigations. Although most studies on exposure and effects of cytotoxic materials have been conducted on healthcare workers (see **Laboratory Recognition of Potential Xenobiotic Respiratory Sensitizers**), the results are relevant to toxicology laboratory situations. Some studies on the effects of occupational exposure to cytostatic drugs have shown increases in urine mutagenicity, peripheral blood lymphocyte cytogenetics and sister chromatid exchanges (Falck *et al*., 1979; Waksvik *et al*., 1981; Chrysostomou *et al*., 1986; Pohlova *et al*., 1986), but others have failed to demonstrate such effects (Gibson *et al*., 1984; Venitt *et al*., 1984). Differences are probably related to the degree of exposure and the protective measures used. In an animal toxicology study with cyclophosphamide, it was demonstrated that animal technicians could be exposed to the material (Sessink *et al*., 1993). Air filter samples showed <0.1–1.0 µg day^{-1}; surface wipes showed cyclophosphamide in adjacent rooms (<0.02–44 mg cm^{-2}); gloves were contaminated (2–99 µg per pair) and one of 87 urine samples from four animal technicians showed cyclophosphamide (0–7 µg). Several facilities have designed limited access facilities and specific safety programmes for genetic toxicology laboratories. Facilities include special considerations on room air flow and filtration, cupboard hoods, countertop

designs, sink placement, type of flooring, wall sealing, storage facilities and traffic flow (Inmon *et al*., 1985). Associated with these design features are considerations on protective clothing, safety responses, monitoring and training. The US Occupational Safety and Health Administration (OSHA) has published guidelines for handling antineoplastic drugs (OSHA, 1986). Many of the recommendations are applicable to the toxicology laboratory. Design features for high toxicity laboratories have been published by DiBerardinis *et al*. (1993).

7 PROTECTION, PRECAUTION AND MANAGEMENT

Several texts on the design of toxicology laboratories, safety measures and routine safe practices have been written (Fawcett, 1983; Armour, 1991). Only representative examples of some of the more important features will be considered here.

The facets of particular relevance to laboratory design include the provision of adequate general ventilation and of specific ventilation for particular operations (e.g. laminar flow cabinets for high-toxicity materials) and the use of extractor lines or scavenger systems to prevent localized exposure of laboratory personnel to vapours, gases or dusts. The design of ventilation, scavenger systems and fume cupboards should be such that air from the work area is not carried up in front of the facial area of personnel. Systems should be designed with sufficient flexibility to allow for future laboratory modifications. The design of inhalation units for safe working conditions has been considered elsewhere (McClellan *et al*., 1984). There should be sufficient storage space and shelving to avoid possible hazards from overcrowding of the bench. Separate appropriately illuminated, ventilated and temperature-regulated accessible storage is required in order that the quantities of test and working chemicals may be kept to a minimum in open laboratory conditions.

Protective clothing requires detailed consideration on an individual basis. However, because of the universal potential for breakage of glassware or splashing of chemicals, safety glasses should be worn routinely. Appropriate protective clothing is required when handling chemicals or animals, which may include laboratory coats, gowns and gloves. Contaminated laboratory coats should be discarded. Front-buttoned laboratory coats may not give the same degree of protection as the wraparound variety. Gloves should be chosen on the basis of known permeability characteristics. Although for widely used laboratory chemicals it is frequently known which is the most appropriate type of glove material, with unknown materials it may be appropriate to undertake permeability tests to ensure adequate protection. In some cases it may be necessary to wear two pairs of gloves to give extra protection. Smith and Grant (1988) found a six times lower puncture rate for the inner glove when two pairs of gloves were worn during surgery. In some situations, differing glove requirements may be necessary. For example, during animal restraining procedures one technician may require to wear more physically protective gloves (e.g. leather) whilst restraining an animal, whilst the experimenter may require thinner gloves for palpation or procedures such as intravenous injections. It should be remembered that latex gloves themselves might be a source of adverse effects as discussed above (Section 3). Also, severe urticaria has been documented following the use of glove powder (van der Meeren and van Erp, 1986). Respiratory protective devices should be made available for use when working with chemicals having an offensive smell, potent peripheral chemosensory irritant effect or high vapour toxicity, or they should be available ready for use in strategic positions in case of spills or vapour leakage. In most cases cartridge respirators are used, although full-face air-supplied devices are preferable. Respirators should not be used at the expense of carefully controlled ventilation, since they restrict vision and may have medical problems associated with their use (Ballantyne, 1981). The choice of respirator is critical; for example, Sakaguchi *et al*. (1989) studied the use of respiratory protective equipment in animal facilities to protect against animal allergens. They found that most respirators designed for removal of particulates did eliminate a significant proportion of room air allergens; however, one had an efficacy of only 65%. The use of respirators requires a management programme to cover the following (Ballantyne, 1981):

- Medical examination to eliminate those with medical conditions prohibiting or restricting their use
- Training programme for use and maintenance
- Routine inspection programmes
- Random audit programme.

Management, safety and training programmes should be in the form of carefully developed, readable and readily referenced protocols. For example, they should include factors such as the following. For all chemicals used, and all test materials, there should be a review of the known toxicity and occupational health problems in order that potential handling hazards can be determined and appropriate protective and precautionary measures undertaken. The Material Safety Data Sheet, if available, should help in this respect. Technical staff in training should handle materials and contaminated glassware, equipment and clothing under supervision. Safe methods should be developed for the legal disposal of hazardous materials without causing contamination of the environment (Pitt and Pitt, 1985). There should be strict laboratory regulations to prevent secondary routes of exposure, for example, smoking, eating and drinking should be prohibited in working laboratories.

Before being assigned to a laboratory position, persons should have a full pre-employment medical examination to assess their physical, haematological, biochemical and physiological functions as a basis for future reference. Also, this examination should be sufficiently detailed to allow the exclusion or restriction of those with predisposing factors to the development of laboratory-associated adverse health effects, for example, LAA, or those with existing medical conditions that could be exacerbated by exposure to chemical agents. Provision should be made for future periodic medical examinations with appropriate special investigations. Ideally these medical examinations should be conducted by a physician with experience in occupational medicine.

There should be adequate planning and facilities for the first-aid management of chemical and/or physical accidents. This should include the immediate access to rapid-release, high-volume showers and facilities for copiously washing the eye. A periodically maintained standard first-aid kit should be available and medical grade oxygen accessible; these should be placed in a readily available and conspicuously marked area. If specific antidotes are available for chemicals used in laboratory, these should also be readily available; for example, hydroxocobalamin for cyanides and atropine/oximes for anticholinesterases. A number of laboratory personnel, available on an on-call basis, should be specially trained in first-aid procedures. Additionally, the designated safety officer should be sufficiently familiar with chemicals in the laboratory and able to offer relevant information to a treating physician. A permanent and active safety committee is essential for the development of policies, their oversight, random audits and the success of safety programmes.

Information Resources for Toxicology

Philip Thomas Copestake

CONTENTS

1 INTRODUCTION

Our ability to access information, of all kinds, is now staggering. The Internet provides a window to an almost bewildering level of knowledge and detail on any chosen subject—much of it at little, or essentially no, cost—and available at our desks with just a few clicks at a computer. We have had to develop new skills in order to keep pace with these rapid advances in technology, not only in how we search for information, but also in assessing what we are looking at. We are often making judgements on the selection and value of information almost subconsciously, and at great speed, perhaps also under the pressure of work commitments and deadlines. Toxicology—like most scientific disciplines—has grown in parallel with the monumental changes that have taken place in recent decades in the ability to store, manage and disseminate information. It is essential that we have not only an appreciation of what information resources are available, but also an understanding of the processes by which they have been produced.

Information on toxicology is, of course, sought by a diverse array of people. They may be research scientists in industry or academia, seeking to understand the mechanisms by which materials are causing adverse effects, or occupational safety consultants advising on the risks to employees of a particular set of exposure conditions. They may be regulators, trying to establish guidance or legislation at a wider level to protect the general public from adverse health effects from the chemicals to which they may be exposed in their daily life. They even might be lawyers, entering the fray when something has gone seriously wrong. Poisons information centres will assist the medical profession with responding to acute emergencies. There is even the desire amongst the general public to seek information on the chemicals that have become an everyday part of their modern lives. It may be a highly specific question that is being addressed, or a more general requirement for data. The ultimate aim usually is to ascertain and understand the hazards that are inherent to a particular chemical or product, that can then be put alongside an associated level of exposure to determine the risks that those circumstances may present. If necessary, appropriate communication or management of those risks can then be attempted, whether it is on a local, national or international scale. Such an integral part of the world in which we live is toxicology, that it is inevitable that it can become subject to commercial and political influence. Toxicological information needs to be clear and widely available if we are to ensure chemical safety, minimize environmental damage and, on animal welfare grounds, reduce the level of unnecessary toxicity testing.

The aim of this chapter is not to attempt to provide a comprehensive list of resources that are available currently in the area of toxicology. Such compilations leave their author(s) open to criticism from those whose favoured tomes or preferred databases have been omitted, and can also quickly go out of date. Rather, an attempt is made to point readers in a valuable direction, provide some insight into the relative usefulness of the various forms in which information is made available, and offer advice on the factors that need to be acknowledged in order that they may be used effectively. Hopefully, it will provide a useful basis on which the various

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

available toxicological resources can be selected and used appropriately. Although key examples are given, these are by no means necessarily endorsements of these particular sources over others.

2 INFORMATION RESOURCES IN TOXICOLOGY—A BRIEF HISTORY

A particular problem with the science of toxicology is that information can be found amongst the resources of a diverse array of disciplines. The reasons for this are essentially to do with the way toxicology has evolved as a subject, and it is useful in this context to look first at how many of the information resources in toxicology have come to exist.

An independent scientific discipline is recognized by virtue of it having its own professional societies and specialist journals, textbooks and undergraduate courses. By these criteria, toxicology can be regarded as being a relatively young science in comparison with other medical disciplines. Although toxicology could perhaps be said to have matured late on in the twentieth century, its roots go back much further, intertwined with those of pharmacology and general medicine. In many respects, toxicology may even predate these older sciences, as man first became aware of the toxic effects of animal venoms and poisonous plants and utilized this knowledge for hunting and warfare. A historical overview of information resources in toxicology reflects, to a large degree, the growth of the science of toxicology itself; the development of many systems for information dissemination, from early texts to online databases and databanks, has been marked by landmarks in its history.

Early resources demonstrate the intimate association with medicine. The 'birth' of toxicological literature could probably be placed with the Ebers Papyrus of around 1500 BC. This ancient Egyptian text includes descriptions of the effects of a number of 'poisons', and outlines remedies for various diseases. Later, around 900 BC, Indian herbal medicine, in the form of Ayurvedism, provided the Vedic texts. Hippocrates, at around 400 BC, introduced rational medicine and described methods for controlling the absorption of toxic metals. Theophrastus (370–286 BC) described numerous poisonous plants, whilst Dioscorides (around AD 50) made an attempt to classify poisons. In 1198, the physician Maimonides wrote a volume entitled *Poisons and Their Antidotes.*

Most graduate toxicologists will know the name Paracelsus. It was in the sixteenth century that he wrote his treatise *Bergsucht,* which included, for essentially the first time, descriptions of the health effects associated with exposure to chemicals found in mining, including arsenic and mercury poisonings, and the asthmatic and gastrointestinal symptoms common to miners' disease. Paracelsus had a profound influence at that time, presenting many ideas which remain important concepts of toxicology today.

Developments in the Industrial Revolution gave rise to further information on occupational diseases associated with chemical exposure. Percival Pott recognized the role of xenobiotics in human disease and linked the occupation of chimney sweep with cancer of the scrotum in a publication of 1775. The Spanish physician Orfelia, often cited as the founder of modern toxicology, produced his *A General System of Toxicology* in 1817, perhaps the first comprehensive textbook in the field.

Although many topics of a toxicological nature would have appeared in the medical journals of the nineteenth and early twentieth centuries, it was not until 1930 that the first scientific journal devoted to toxicology emerged. Published in Berlin, this was *Sammlung von Vergiftungsfällen,* the precursor of the publication *Archives of Toxicology,* which continues today on behalf of the German Society for Experimental and Clinical Pharmacology and Toxicology. This journal was followed in 1938 by *Farmakologiia i Toksikologiia,* which was published in Moscow, and by *Acta Pharmacologica et Toxicologica* (now *Pharmacology and Toxicology*) in Copenhagen, in 1945. The growth of industry, particularly in the chemical and pharmaceutical sectors, following the Second World War was a major driving force for the increase in toxicological literature, and many organizations devoted to the science of toxicology have their origins in this period. The journal *Toxicology and Applied Pharmacology* began publication in 1959 and became the official organ of the Society of Toxicology, which was founded in 1961. It was joined by the journal *Fundamental and Applied Toxicology,* first published in 1981. The 1960s and 1970s saw the birth of what became known as the environmental movement—the push for more detailed information was coupled to this growing public awareness of, and concern about, the effects of chemicals on human health and the environment. The publication in 1962 of Rachel Carson's book *Silent Spring,* which highlighted the potential damage caused by the indiscriminate use of pesticides, was a jolt to public consciousness, and a major turning point in this aspect of the history of toxicology. There was greater regulatory control in response to such demands—companies increasingly became required to test their products and provide regulatory authorities with documented data to assure safety. Such requirements for information were paralleled through the latter half of the twentieth century by a steep growth in the number of journal titles available in toxicology. There was increased specialization in the toxicological sciences as they diversified, and this was reflected by the ever-growing number of specialist journals covering areas such as genetic toxicology and cancer, epidemiology, reproductive toxicology, contact dermatitis and ecotoxicology. We see such trends continue with more recent developments in areas such as nanotechnology

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and the consequent concern about the toxicology of nanoparticles, and genomics—the study of the effects of chemicals at the molecular level in the cell.

The enormous proliferation in information brings with it the problems of how to manage and track down relevant data. 'Secondary' indexes to the literature were developed to allow the search, identification and retrieval of information by specific subject headings. Major publications in the field included *Index Medicus* and *Excerpta Medica,* both of which covered the medical literature, *Biological Abstracts,* which took in the whole of the life sciences, and *Chemical Abstracts,* covering the entire field of chemistry. With the advent of computer technology in the latter half of the twentieth century, many of these resources became available in electronic form. Coupled with developments in telecommunications, large resources of information became readily accessible to researchers. Some regulations themselves involved the compilation of datasets in electronic form, establishing databanks of toxicological data made available in a standardized layout. Many of these resources continue to be important today. The fundamental collation and cataloguing of information, however, remains the same. What have changed are the availability and cost of information, and the speed at which it can be disseminated.

3 INITIAL GENERATION OF DATA—THE SCIENTIFIC COMMUNITY

Like most scientific information, toxicological data will begin life as the results from experimental research and observation. Early dissemination will take place on an informal level with immediate colleagues and peers. More formal presentation of results is likely to occur at professional seminars and meetings, and such gatherings frequently represent the first outside disclosure of new data, albeit usually to a closed audience. The early communication and discussion of data amongst scientists is an important aspect of the so-called 'scientific process' and the formation and possible rejection of ideas and hypotheses. Participation in such a process can be vital as a means of becoming aware of emerging toxicological knowledge, particularly to those working in the research environment or needing to respond to new detail that could impinge on how a particular chemical is viewed and controlled. The interdisciplinary nature of toxicology makes this human network and its organization critical to effective coordination and the spread of information. Often, toxicological topics also find their way into meetings covering broader subject areas such as food technology, cosmetology or other medical and life sciences.

The more tangible forms of information that result from such early processes may be the minutes or proceedings of meetings, conferences or seminars, news articles or company reports. Although much of this information can be highly valuable, by its very nature there is generally no systematic answer to tracking it down or being alerted to its existence. A weather eye on a multitude of relevant web sites is possibly one of the best strategies, together with participation in appropriate trade and research associations or scientific societies. Most will have web sites and perhaps e-mail or web-based alerting services to indicate when news or new content is available.

4 PRIMARY SOURCES—THE SCIENTIFIC LITERATURE

As is common with all science, the validity of toxicological findings is enhanced by formal publication. The vehicle for the primary publication of results of toxicological endeavour remains the scientific journal. It is generally through this respected part of the scientific process that experimental results are reported, then scrutinized, and perhaps re-evaluated by the wider scientific community.

Many scientific journals are, of course, commercial ventures by publishers seeking to fill a niche in the market of scientific literature, and they jostle for supremacy in their particular field through impact factors or citation statistics. The scientific reputation of a journal, however, can be a rather nebulous concept, and may have been built up over many years, perhaps as a result of it being the official publication of a distinguished association, society, or other scientific organization, or maybe through hard-won respect in the quality of the science being published. Every journal will have its own particular aims and scope. The editorial policy and list of those that sit on the editorial board may give some indication of its prestige.

Whilst many items, such as short communications or letters, may take the form of a narrative, most scientific papers appear in the well-established standard format, usually consisting of a Summary or Abstract, an Introduction—putting the study into context and providing an indication of why the investigation was carried out, the Methods—containing enough detail to allow the investigation, if necessary, to be repeated independently, Results—indicating in quantitative and/or qualitative terms what was actually recorded and observed, and a Conclusion—presenting a discussion of how these results could be interpreted, and lastly the appropriate bibliographic References to any documents cited in the paper.

Once a paper has been submitted to a journal, an initial decision will be made as to its suitability for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat052
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

publication—whether, for example, the paper fits in with the aims and scope of the journal, and represents a novel advancement in knowledge. An aspect of particular importance, and one on which the value of any journal is usually judged, is the so-called peer-review process. This mechanism involves the scrutiny of submitted papers by a number of independent referees who are chosen as experts in the particular field of interest. They will use their judgement as to whether the paper should be accepted for publication or make recommendations for amendment. The peer-review process is often regarded as the basis of scientific credibility and ensures that much science of poor quality never appears in the good scientific literature. The mechanism has worked well over the years, although it is by no means infallible. It is a system which is dependent to a large degree on the goodwill and professionalism of the referees, who generally give their time and skill free of charge.

One of the frequent problems with toxicological information is that much can languish unpublished as commercially sensitive reports. Companies are often understandably interested in protecting the huge investment that they may have made in terms of conducting laboratory studies. Although there will, of course, be obligations to ensure the safety of their products, and perhaps to inform relevant regulatory authorities if studies provide new insight into toxicology, there may not be tremendous desire to commit resources to putting the information into the open scientific literature.

For those that rely on ready access to the published literature, the cost of subscribing to scientific journals can be substantial. Specialist libraries have, over many years, faced stark choices and often difficult deliberations with the scientists that they serve over the merits or otherwise of subscribing to a particular journal. Many of the key publishers have responded to these difficulties, often for their own commercial survival as journal sales decrease, and the growing norm now is for individual articles to be bought. Tables of Contents that are made available as new journal issues are published can be scanned easily on the web, the abstracts perused, and those items of interest purchased as a download.

Another trend in scientific publication, and one being pushed hard in some quarters, is the development of the 'open access' journal. A significant number of journals, including several in the field of toxicology, are freely accessible as full text; the publishers rely on page or 'administration' charges to those submitting papers for publication, advertising, or charging for add-on alerting services, to cover their costs and make the publications viable on a profitable basis.

Currently, there are perhaps well over 100 journals devoted primarily to toxicology. As the science has developed, emerging subdisciplines have given rise to new titles. A very restricted core list for those interested primarily in hazard and risk assessment gives some indication of the range of titles now available:

American Journal of Epidemiology and Epidemiologic Reviews
Archives of Environmental Contamination and Toxicology
Archives of Toxicology
Basic and Clinical Pharmacology and Toxicology
Birth Defects Research Part B: Developmental and Reproductive Toxicology
Bulletin of Environmental Contamination and Toxicology
Cancer Causes and Control
Carcinogenesis
Chemical Research in Toxicology
Comparative Biochemistry and Physiology C—Toxicology and Pharmacology
Contact Dermatitis
Critical Reviews in Toxicology
Drug and Chemical Toxicology
Ecotoxicology and Environmental Safety
Environmental Health Perspectives
Environmental Toxicology and Pharmacology
Experimental and Toxicologic Pathology
Food and Chemical Toxicology
Fundamental and Applied Toxicology
Human and Experimental Toxicology
Inhalation Toxicology
International Journal of Toxicology
Journal of the American College of Toxicology
Journal of Applied Toxicology
Journal of Environmental Pathology, Toxicology and Oncology
Journal of Occupational and Environmental Medicine
Journal of Occupational Medicine and Toxicology
Journal of Pharmacological and Toxicological Methods
Journal of Toxicological Sciences
Journal of Toxicology and Environmental Health
Mutagenesis
Mutation Research
Neurotoxicology
Neurotoxicology and Teratology
Particle and Fibre Toxicology
Pharmacology and Toxicology
Regulatory Toxicology and Pharmacology
Reproductive Toxicology
Toxicological Sciences
Toxicology
Toxicology and Applied Pharmacology
Toxicology and Industrial Health
Toxicology In Vitro
Toxicology Letters
Veterinary and Human Toxicology

Other scientific journals also impinge vastly on the area of toxicology, most notably those dealing in medical, pharmacological or epidemiological research, and, with varying degrees of frequency, will publish useful data. More general, but highly prestigious, scientific periodicals such as *Nature* or *Science* also sometimes include reports which are of toxicological significance.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat052
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Keeping up to date with the scientific journal literature can be a daunting task. Current-awareness publications appear frequently, often weekly, or even daily. *Current Contents,* from Thomson Reuters (*http://thomsonreuters.com/products_services/scientific/Current_Contents*), is perhaps one of the better known of these services in the biomedical field, but other, often more specialized services, are available in both printed and electronic format, or as part of a service offered by the information unit of a trade association or scientific organization. Such 'selective dissemination of information' (SDI) can provide, on a regular, specified frequency, a focussed set of documents tailored to the specific requirements as outlined by the user.

Most scientific journals are now available in electronic format on the Internet, usually ahead of their printed version, and the web has also allowed for additional content such as data tables and perhaps lengthy comment or discussion to be included. Most of the key scientific journal publishers also have facilities on their web sites to search their full text journal content by keyword, date or author. The search capabilities vary in sophistication, with some only allowing fairly simple single keyword searching, whilst others have far more advanced search interfaces. These can be another useful way of keeping alerted to new publications of interest, as tailored searches can be saved, and any new content matching these search criteria e-mailed at specified intervals, perhaps daily, weekly or monthly. The searches can be across all of the journals published by the particular provider, or to a selected group of chosen subject journals. Such searches would, of course, need to be set up for each of the relevant publishers, a task that initially can be somewhat time-consuming.

5 STANDARD TEXTS, MONOGRAPHS AND EXPERT REVIEWS

Standard reference works compile and condense information into a form that can be seen to represent a culmination of the scientific process; they usually present a considered and generally widely accepted view in a particular area. They are often written, compiled or edited by distinguished experts in the field of interest. Many regularly used texts provide concise overviews or summary data on the toxicology of chemicals or chemical groups and can be useful for background or general material.

It is not within the scope of this chapter to commit to print a reading list of particular books recommended over others. New texts are constantly emerging and old favourites updated and reprinted; the usefulness of each will depend very much on the environment in which it is being used—the particular subject area of interest and the type and depth of information required. Some books have gained enviable reputations as essential texts to grace the shelves of any self-respecting toxicologist. What is important, however, is to acknowledge the limitations of some such material. One of the primary considerations is that of topicality. The gestation period and publication timetable of a large textbook are inevitably protracted. In a specialist area that is rapidly changing, the information may be somewhat out of date, perhaps by as much as two to three years, even as the text first appears on the bookshop shelves. Well-loved textbooks may remain on a library shelf for many years, and that same book, consulted 10 years after its initial publication, may present a very dated view from that currently prevailing. Although generally making use of experts, the task of writing or contributing to a book is usually essentially unpaid and thus the authors may not have been able to afford the time and resources to conduct a comprehensive and in-depth evaluation of all the information that might be available on a particular topic. Typographical errors are, unfortunately, not uncommon within published scientific works and the misplacement of a decimal point or the misprinting of a unit of measure, for instance, can have profound consequences to any dose–response analysis. Errors are sometimes even found to have been repeated in citations by other works. Consequently, it is always advisable, if the reference is available and resources permit, to check original data. This is not always an easy task, as, unfortunately, referencing within textbooks can be poor, and sometimes perhaps even nonexistent, making it at best difficult to trace and verify the cited data. Many texts are written with a very specific readership in mind and it is necessary to appreciate the context in which the book has been written, along with its published aims. Frequently, there is large overlap in the information provided by different texts so it is worth considering carefully the merits of purchasing any particular book.

Current details of textbooks that are available in toxicology are best sought from the catalogues, brochures and web sites of the major scientific publishers. Announcements of new books frequently appear in scientific journals and magazines and will inevitably be posted or e-mailed directly to those whose contact details lie within the publisher's marketing department. It is also worth taking note of published book reviews which may appear in trade-association journals, society information bulletins and in the more mainstream primary biomedical journals. Clearly, it is important to evaluate the suitability of any particular text to personal requirements. Cost will certainly be a consideration as many large textbooks (or even those smaller ones with a more specialist, and thus limited, audience) can be expensive. Many standard works are also now available electronically, making searching for particular topics easier.

Of particular use in the toxicological arena are monographs or reviews of data compiled and evaluated by

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat052
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

expert groups. Many sources of toxicological information emanate from national and international organizations. The nature of toxicology and its application are such that it has an extensive network of bodies that have some role in the generation, dissemination or use of toxicological information. Many of these will be governmental or quasigovernmental agencies, such as health, food or agriculture departments, or established research organizations. The industrial and consumer sectors will have their own interests represented by trade associations and consumer groups. On an international scale, organizations such as the World Health Organization (WHO), International Labour Organisation (ILO), the Organisation for Economic Co-operation and Development (OECD) and the European institutions of regulation will all have an input. Many well-established publications of this type can be of great value in providing a perhaps authoritative compilation of the data and particular view of toxicological significance:

WHO: The WHO and its various agencies publish a number of key reviews, some under joint sponsorship with the United Nations Environment Programme (UNEP) and the ILO in its collaborative International Programme on Chemical Safety (IPCS) (*www.who.int/ipcs/en/*). These include:

- *Environmental Health Criteria* (EHC) monographs (*www.inchem.org/pages/ehc.html*), and the more recent *Concise International Chemical Safety Assessment Documents* (CICADs) (*www.inchem.org/pages/cicads.html*), both of which provide comprehensive summaries of toxicological data on particular chemicals or groups of chemicals, together with details on the derivation of appropriate human and environmental guidance values for risk assessment.
- Evaluations published by the Joint FAO (Food and Agriculture Organization)/WHO Expert Committee on Food Additives (JECFA) (*www.inchem.org/pages/jecfa.html*) and those of the Joint FAO/WHO Meeting on Pesticide Residues (JMPR) (*www.inchem.org/pages/jmpr.html*), which assess data relating to food additives and contaminants.
- *Monographs on the Evaluation of the Carcinogenic Risk (of Chemicals) to Humans,* published by the International Agency for Research on Cancer (IARC) (*www.inchem.org/pages/iarc.html*), which provide summaries of the data pertinent to an assessment of carcinogenicity of chemicals to man, and present a consensus classification as to overall risk.
- *WHO Drinking-Water Guidelines* (*www.who.int/water_sanitation_health/dwq/guidelines/en/index.html*), *WHO Air Quality Guidelines* (*www.euro.who.int/air/activities/20050222_2*) and the *WHO Recommended Classification of Pesticides by Hazard and Guidelines to Classification* (*www.inchem.org/documents/pds/pdsother/class.pdf*).
- *Health and Safety Guides* (HSGs) (*www.inchem.org/pages/hsg.html*), which provide concise information in nontechnical language for use by decision-makers on risks from exposure to chemicals, with practical advice on medical and administrative issues.
- *Pesticide Data Sheets* (PDSs) (*www.inchem.org/pages/pds.html*), containing basic information for safe use of pesticides. Prepared in collaboration with the Food and Agriculture Organization (FAO), they give toxicological information on individual pesticides, with priority to those with wide use in public-health programmes and/or in agriculture.
- *Poisons Information Monographs* (PIMs) (*www.inchem.org/pages/pims.html*), which evaluate information on substances (chemicals, pharmaceuticals, poisonous plants, and poisonous and venomous animals) commonly involved in cases of poisoning. PIMs are designed as a concise, practical document to facilitate the work of poisons information specialists.

US Agency for Toxic Substances and Disease Registry (ATSDR): The ATSDR is an agency of the US Department of Health and Human Services and publishes a series of Toxicological Profiles (*www.atsdr.cdc.gov/toxpro2.html*), in depth reviews of substances found at hazardous waste sites.

US Environmental Protection Agency (EPA): The US EPA's Integrated Risk Information System (IRIS) (*http://cfpub.epa.gov/ncea/iris/index.cfm*) provides consensus information on human health effects from exposure to various chemicals found in the environment, and background to the development of oral and inhalation human health guidance values.

European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC): ECETOC (*www.ecetoc.org/*) Technical and Special Reports focus on the manufacture, processing, handling and use of chemicals.

OECD: The OECD-coordinated high production volume (HPV) programme (*http://cs3-hq.oecd.org/scripts/hpv/*) develops Screening Information Data Sets (SIDSs) and SIDS Initial Assessment Reports (SIARs).

National Industrial Chemical Notification and Assessment Scheme (NICNAS): The Australian NICNAS produces a number of Priority Existing Chemicals (PECs) Assessments (*www.nicnas.gov.au/Publications/CAR.asp*) on industrial chemicals.

By no means an exhaustive list, the above provides just a small selection of what is available. Many can be found for free over the Internet. The difficulty can be in determining quickly whether, for a particular chemical of interest, such an expert review is available. A trawl through the various expert group web sites is one—albeit

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat052
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

rather laborious—option. The date that any particular review was carried out is crucial, and it is important to appreciate that the data collation (search date) itself may have actually taken place some time before this. Unless it is clear what date the data search was undertaken (and the extent of that search), it is always a good idea to then search the literature from one or two years prior to the date of the review so ensuring that no additional key data have become available. Sadly, it is still rare for reviews to detail the search strategy that has been employed to identify relevant data—what databases were interrogated and when, and what keyword terms were used.

6 DATABASES

The meanings of many of the terms associated with the practice of information retrieval have been somewhat blurred as a consequence of modern technology; whilst the word 'database' today relates almost exclusively to any structured computer-held information, it was traditionally used as a term to describe any set of 'secondary' (or bibliographic) data compiled as an index to the primary scientific literature. Secondary publications such as *Index Medicus, Chemical Abstracts*, and *Biological Abstracts,* which were developed, as has been discussed, as tools to search the ever-expanding scientific literature, would therefore fall within this definition; they were essentially pointers to where the actual data—the primary journal articles—could be found.

Computerized, or 'online', databases were developed in the mid 1960s as a spin-off from the computer phototypesetting processes that were used in the production of these printed indexes; the bibliographic details to scientific papers were captured in machine-readable form which then allowed reformatting into suitable hard copy format, together with the creation of subject, author and cumulative indexes. With developments in computer and telecommunications technology during the 1960s and early 1970s it became possible for these machine-readable master tapes to be used directly for information retrieval. Large quantities of data could be searched and matched against any specified search word. Although at first the technology was cumbersome and slow by modern standards, and it was impossible to change the search strategy during the search, with improvements in the speed of electronic communications, *interactive* online searching quickly became a reality; the results of any search could be viewed as the search progressed and the strategy that had initially been employed to identify relevant information could be altered to provide, as necessary, a more focussed or expanded set of data. It was a revolution in the way information was held and disseminated and a huge advance in the mechanism by which literature searching was carried out.

We now take very much for granted the speed and ease of searching for information electronically, but it is worth pondering on what a tremendous improvement such systems made in locating relevant information. A search that would have taken many hours using traditional library resources could now be accomplished in a matter of minutes, and consequently at a fraction of the cost of a professional librarian's or information searcher's time.

Two large US corporations, Lockheed DIALOG and Systems Development Corporation (SDC), were the first to exploit the developments in computer technology for information retrieval. They were followed, in the mid 1970s, by European services such as ESA-IRS (European Space Agency—Information Retrieval Service), operated by the European Space Agency, and BLAISE (British Library Automated Information Service), an online system developed by the British Library in the UK.

Medicine was one of the first sciences to benefit from this new information technology. Medical Literature Analysis and Retrieval System (MEDLARS) became operational at the US National Library of Medicine (NLM) in 1964, followed by MEDLINE, the interactive online version of *Index Medicus,* in 1971.

MEDLINE continues to be one of the key biomedical bibliographic databases available, currently holding in excess of 15 million references to journal articles. Its stated subject scope is 'biomedicine and health', defined to encompass those areas of the life sciences, behavioural sciences, chemical sciences and bioengineering needed by health professionals and others engaged in research and clinical care. Increased coverage of the life sciences more generally began in 2000. Coverage is mostly from 1950 to the present, with some older material also now included. Approximately 5000 worldwide journal titles, published in around 40 different languages, are cited. MEDLINE is the primary component of PubMed (*www.ncbi.nlm.nih.gov/sites/entrez*), a service provided by the NLM's National Center for Biotechnology Information (NCBI) (*www.ncbi.nlm.nih.gov/*), and is accessible through their web site or via a number of commercial online database providers as discussed below.

As has been discussed, the period of computerization during the second half of the twentieth century was one in which toxicology as a science was coming into its own, with the consequent huge expansion in its information base. There was developing concern amongst researchers in the field about the dispersion of toxicological information over a diverse array of published scientific literature. The Toxicology Information Program was established at the NLM in 1967 in an attempt to address this, and one of its early achievements was the development in 1972 of TOXLINE. TOXLINE was set up in the hope of providing a 'one-stop shop' for searching the toxicological literature. At the time there was no unified bibliography of toxicological information available, as there was, for example, with medicine

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat052
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in the form of *Index Medicus.* The solution was to combine various subsets specifically relating to toxicology from a number of different electronic secondary data sources. Thus, sections from *Index Medicus* and *Chemical Abstracts* that were relevant to toxicology were included, together with others such as from *Pesticides Abstracts,* and the *International Pharmaceutical Abstracts* (IPA). More specialist collections of bibliographic information were also included, such as the files of the Environmental Mutagen Information Center (EMIC) and the Environmental Teratology Information Center (ETIC).

Currently, TOXLINE (*http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?TOXLINE*) comprises the following:

Standard biomedical/toxicology journal literature: *PubMed/MEDLINE*
Special journal and other research literature: *Developmental and Reproductive Toxicology (DART)*
International Labour Office (CIS — Centre international d'information de sécurité et de santé au travail (International Occupational Safety and Health Information Centre))
Technical reports and research projects: *Federal Research in Progress (FEDRIP)*
Toxic Substances Control Act Test Submissions (TSCATS)
Toxicology Document and Data Depository (NTIS — National Technical Information Service (US Department of Commerce))
Toxicology Research Projects (CRISP— Computer Retrieval of Information on Scientific Projects (US National Institutes of Health))
Archival collection (no longer being updated): *Aneuploidy (ANEUPL)*
Environmental Mutagen Information Center File (EMIC)
Environmental Teratology Information Center File (ETIC)
Epidemiology Information System (EPIDEM)
Hazardous Materials Technical Center (HMTC)
Health Aspects of Pesticides Abstract Bulletin (HAPAB)
International Pharmaceutical Abstracts (IPA)
NIOSHTIC ((US) National Institute for Occupational Safety and Health (NIOSH) Technical Information Center)
Pesticides Abstracts (PESTABs)
Poisonous Plants Bibliography (PPBIB)
Swedish National Chemicals Inspectorate (RISKLINE)
Toxicological Aspects of Environmental Health (BIOSIS)

Despite this heterogeneous array of subsets which go to make up the full files, the user of TOXLINE is presented with an interface which suggests a single, apparently homogeneous, system covering toxicology.

In terms of breadth of scope and size, TOXLINE remains the premier online bibliographic database in the field of toxicology. The number of citations it holds now runs into several millions. Thousands of journal titles are cited at least once, although a more limited core set of journals, running into the hundreds, provides the bulk of the records.

Toxicology and medicine are, of course, subjects where other general or more specialized online computer databases may provide useful information, and a search in TOXLINE alone may not be considered adequate. The wider scope of MEDLINE may result in additional hits, and databases such as EMBASE (*www.embase.com/*), the online version of *Excerpta Medica*, or BIOSIS Previews (*www.thomsonreuters.com/products_services/scientific/BIOSIS_Previews*), which includes the indexing service *Biological Abstracts*, are certainly worth considering for a general and comprehensive trawl for toxicological information. EMBASE, from the publisher Elsevier BV, is a comprehensive pharmacological and biomedical database renowned for extensive indexing of drug information. Currently, it contains more than 18 million records primarily dating from 1974 to present, including a MEDLINE subset, and covering the literature from more than 7000 journal titles. BIOSIS Previews is produced by Thomson Reuters and includes *Biological Abstracts* records, now from 1926, together with additional material from the review literature, books, meeting abstracts and patents. Again, more than 18 million records are included from 5000 source titles. Coverage is to virtually every life sciences discipline, including traditional biology (botany, ecology, zoology), together with the interdisciplinary subjects of biomedicine (including toxicology), biochemistry and biotechnology.

There is much overlap between databases in the information they select and index and it is certainly worth considering carefully whether a particular database will cover the area of interest comprehensively, but not be so broad as to generate a large amount of unwanted information. Specialized and more selective databases may be more appropriate for a search in a particular subject category. The scope of literature selection may also be an important factor in database choice. Whilst many bibliographic databases are fairly strong on conventionally published scientific information, they do not cope as well with the less structured literature such as meeting or conference reports, pronouncements from expert groups, dissertations and theses, or even press releases from government departments or agencies, all of which may be useful to the toxicologist. The TRACE database (*www.bibra-information.co.uk/trace.html*), developed by **bibra**—toxicology advice & consulting, is an important example of a more specialized bibliographic database, designed primarily to identify key data for hazard and risk assessment, and covering the scientific journal literature as well as much of this other valuable material.

Web-based interfaces provide easy access to most of the databases discussed here. TOXLINE and MEDLINE are available free via the NLM's TOXNET Toxicology

Data Network (*http://toxnet.nlm.nih.gov/*) or the NLM home page (*www.nlm.nih.gov/*). They also form part of the services available through commercial database providers such as STN (*www.stn-international.de/*), ProQuest (Dialog, DataStar) (*www.dialog.com/sources/subject/*), and Wolters Kluwer (Ovid) (*www.ovid.com/*). These host services can provide vastly more-complex search capabilities and customized interfaces, and also allow tailored alerting services to be set up using specified delivery formats such as text, HTML, XML and RSS (Really Simple Syndication) web feed. Whilst such services come at a cost—generally with up-front registration fees and charges for content—they can clearly be of value in terms of time saved.

Searches for information can be constructed and refined in most online databases by combining search terms using the Boolean operators AND, OR and NOT. The inclusion of the operator AND will retrieve articles which are common to both sets, whilst OR will add the two sets together. For example, a search can be narrowed by indicating that documents that contain the search word CANCER must also contain the word MAN (i.e. CANCER AND MAN), whilst it could be broadened by specifying that the document should contain any of the words CANCER OR CARCINOGENICITY OR TUMOUR, as well as (AND) MAN OR HUMAN OR WORKER. The logical operator NOT will eliminate documents that contain the specified search term, for instance CANCER NOT STOMACH would retrieve any records that contain the search word CANCER, but not any that also contain the word STOMACH. It should be used with care, since documents that do contain useful information may be unintentionally eliminated; if the topic of interest is cancer of the colon, a paper which discusses both colon and stomach cancer would have been eliminated using the above strategy.

In addition to the use of Boolean logic, other search techniques involve the use of relational operators allowing a user to specify, for example, that two search words must appear adjacent to each other (STOMACH next to CANCER, for instance), or within a specified number of words from one another (say CANCER within four words of STOMACH, to retrieve both STOMACH CANCER and CANCER OF THE STOMACH). It may be possible also to require that words appear in a specified order, or within the same sentence or paragraph. The search may be limited to words appearing in the title only, or to just the keywords that have been added to the record by the databases indexers. Truncation of terms is another possibility, such that MUTA-, for instance, could be used as a search term to include papers containing any of the words MUTATION, MUTANT, MUTAGEN, MUTAGENIC, MUTAGENICITY, and so on. Search statements can often be complex and may need careful and expert construction, but once developed can often be saved for future use, with perhaps a different chemical or date range.

The key to effective searching and identification of relevant information lies not only with a suitable search strategy, but also with how the documents within any database are indexed. Each record in a bibliographic database represents one scientific paper, journal article or document. The record generally has standard elements or fields which may include the Authors, Title, Publication Type and Reference, Language of the Paper, Year of Publication, Country of Publication, Organization(s) for which the authors work, Keywords or Descriptors, and perhaps the Abstract. Each of these fields may be used as an entry point for searching or to limit the search using such methods as mentioned above. The Title, Keywords and Abstracts are most frequently used as the basis for searching, although full text searching is also now possible.

TOXLINE, as is common with many systems, is essentially 'free text'; that is, there is no fully controlled vocabulary applied across all of the subfiles for the purposes of indexing and searching. In order to search comprehensively on a particular subject, it is therefore necessary to consider including as many synonyms for each search term as possible. The computer will then look for any documents in the database where this word appears, in the title, abstract or keyword fields.

More valuable for information retrieval is the use of a restricted and structured thesaurus of index terms such, for example, that the word MAN would be used as a keyword to the exclusion of any others, even if these others, such as HUMAN, WORKER or CHILD, and so on, were the only ones to appear in the text in relation to a paper that includes human data. In this instance, a search restricted to the keywords field on 'MAN' would retrieve *all* relevant papers; searching with a list of synonyms is not needed. A controlled vocabulary such as this is well developed, for instance, with the MEDLINE, EMBASE and BIOSIS Previews databases. The MEDLINE indexers have at their disposal a large hierarchical tree structure of terms, known as Medical Subject Heading (MeSH) terms. The indexers select the most appropriate of these descriptors to represent the subjects covered by a particular paper. The tree structure allows for broad and narrow concepts to be described. Whilst the most specific term available is applied in each case, 'explosion' of a broader term on searching would retrieve this and related documents. The search word ASTHMA would miss any articles indexed under ASTHMA IN CHILDREN, unless the term ASTHMA was exploded in the search. The MeSH thesaurus is continually evolving, with new terms added frequently, as the sciences that it describes grow and develop. Often the terms applied can be given added weight by the indexers as major or minor concepts in the article. This again allows refinement of searches if large sets are initially being retrieved.

The selection of keywords and, in particular, the use of structured vocabularies requires particular knowledge and experience by both the database indexers themselves and by those wishing to search. Expert indexing is crucial to the effectiveness of a database and, unfortunately, on occasion is clearly lacking. Inappropriate or inadequate indexing of a particular paper will severely decrease the likelihood of it being retrieved during a specific search, or may lead to it appearing as a false drop. Similarly, errors during the entering of a paper's details, perhaps of a simple typographical nature, can result in an item failing to be retrieved.

Chemical names can present particular difficulties when searching for data, and thus are a major problem for those seeking information pertinent to toxicological hazard and risk assessment. Chemical nomenclature can be complex and all synonyms and permutations may have to be included in a comprehensive free text search, necessitating perhaps a high degree of chemical knowledge. Searching precisely on a parent compound without retrieving large numbers of papers on derivatives which include the parent name can also be a huge problem, as can searching for information on a generic class of substances, which would depend on a high degree of detailed chemical indexing, including generic details. Such comprehensive indexing is, unfortunately, lacking in many databases. The inclusion of Chemical Abstracts Service (CAS) Registry numbers in database records can eliminate many of the problems associated with chemical indexing. CAS Registry numbers are unique numbers for specific chemicals, assigned by the CAS. Unfortunately, comprehensive and accurate inclusion of CAS Registry numbers across the biomedical databases is, again, rather limited.

Although such considerations are, sadly, often given little thought today by those who use databases, the indexing policies and the expertise of the database indexing, together with the initial selection criteria for documents which should appear as records, clearly are vitally important aspects of database construction and the consequent use to which they can be put. The value of any bibliographic database must be judged by its ability to identify all relevant data sources.

Two criteria are important in assessing performance. The first of these is the ability of any search to 'recall' information, which is defined as the number of relevant citations retrieved out of the total number of relevant citations in the database being searched, and can also be viewed as the 'sensitivity' of the search. The second criterion is 'specificity' (or 'precision'), which measures the ability of the search to discriminate between relevant and nonrelevant citations and is the proportion of those records identified which prove, on final analysis, to be of relevance. Large, broad-scope databases can perform very poorly on the basis of these criteria. The varied requirements of the different types of user—the basic research community, applied researchers, those charged with evaluating hazard and risk, and so on—are accommodated at the expense of specificity, while the use of nonspecialist selection and indexing reduces both specificity and recall. It is not unusual when searching for toxicological data on a particular well-researched chemical to retrieve a hit list running into several hundreds or even thousands. The ideal is for a database to be subject specific, retrieving only information of relevance, which is easy to search, and comprehensive for that subject. In toxicological hazard and risk assessment, the loss of information may undermine an opinion on safety in use.

7 DATABANKS

Under its precise definition, a 'databank' provides factual information in the form of numeric data or textual statements. In contrast, as described above, a *database* acts as an index—providing the bibliographic location of where that factual information can be found. The electronic availability of many of the compilations of data we have discussed from, for example, expert groups, could be said to place them firmly into this category. A number of additional key compilations of structured toxicological data are useful—and frequently used—and therefore mentioned here.

Some of the issues in relation to the indexing and searching of databases discussed above would also apply to computer-based databanks. What makes the latter different is that the factual nature of their content presupposes some degree of value addition. The criteria for the selection and evaluation of the data become more crucial, and the nature and purpose of the databank should be considered carefully. An example of a commonly used databank in toxicology is the Registry of Toxic Effects of Chemical Substances (RTECS) (*www.cdc.gov/niosh/rtecs/*), produced by the US National Institute for Occupational Safety and Health (NIOSH) in response to the US occupational safety and health regulations. It contains useful information on an enormous number of chemicals, although the data are limited in nature, and certainly are not intended to provide a complete assessment of hazard or risk.

The Hazardous Substances Data Bank (HSDB) (*http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?HSDB*) is another favoured and well resourced US databank, supported by the NLM. It contains extensive data including toxicity, safety and handling, emergency response, environmental fate, and exposure potential information on a large number of potentially hazardous chemicals. Information is selected for inclusion by a scientific review panel, the initial aim of which was to establish a databank of 'evaluated' data. The result has been a predilection for qualitative statements on hazard rather than quantitative insights on dose–response, essential to any evaluation of hazard and risk.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat052
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Additional useful resources include others produced by the NLM:

Chemical Carcinogenesis Research Information System (CCRIS) (*http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?CCRIS*): This is a scientifically evaluated and fully referenced databank developed and maintained by the US National Cancer Institute (NCI). It contains over 9000 chemical records with carcinogenicity, mutagenicity, tumour promotion and tumour inhibition test results. Data are derived from studies cited in primary journals, current awareness tools, NCI reports and other special sources, with the test results reviewed by experts in carcinogenesis and mutagenesis.

GENE-TOX (*http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?GENETOX*): Created by the US EPA, GENE-TOX contains genetic toxicology (mutagenicity) test data resulting from expert review of the open scientific literature. Data on more than 3000 chemicals are included.

International Toxicity Estimates for Risk (ITER) (*http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?iter*): Compiled by Toxicology Excellence for Risk Assessment (TERA), ITER contains over 650 chemical records with key data in support of human health risk assessments. ITER provides a comparison of international risk assessment information from the ATSDR, Health Canada, the Netherlands National Institute of Public Health and the Environment (RIVM), US EPA, IARC and other independent parties whose risk values have undergone peer review.

Regulatory drives also result in important compilations of toxicological data. Renewed efforts within Europe under the Registration, Evaluation, Authorisation and restriction of CHemicals (REACH) regulation (*http://echa.europa.eu/*), for example, aim to make publicly available large amounts of toxicological data on the thousands of chemicals on the market within the European Union (EU). The level of detail that will have to be supplied by manufacturers or importers will be determined by the overall tonnage and will use the structured International Uniform Chemicals Information Database (IUCLID) format. It will be a huge and costly undertaking for industry, but the resulting databank should prove a valuable resource of up-to-date toxicological information.

8 THE INTERNET—WORLD WIDE WEB

We now take the Internet, and particularly the World Wide Web, for granted; it has become for most of us a key daily interface with the outside world. It acts as the portal to many of the resources that have been described in this chapter—the primary scientific journals, many of the expert review publications, access to the various databases and databanks. It also provides access via general search engines such as Google (*www.google.com/*), Yahoo! (*http://yahoo.com/*) or AltaVista (*www.altavista.com/*) to an unimaginably huge repository of information from all manner of organizations, companies, individuals, pressure groups and others from around the world. A general search for toxicological data can be useful, using chemical names, CAS Registry number or other chemical identifier. The crucial thing here is to validate what is being viewed—essentially anybody can post information on the Internet and it is easy to disguise spurious information as being legitimate.

9 ACCESSING THE RESOURCES

As we have seen, there are now many entry points to the various toxicological resources available—be it direct to a particular provider's web site, via the compilation of several sources into a search portal, or through a commercial host provider; the bewilderment from choice seems to be a modern phenomenon. There is always a continuing desire to collate information into user-friendly interfaces, and several are worthy of note in the field of toxicology.

The NLM is, as is clear, a big player in toxicological resources. Its freely available TOXNET Toxicology Data Network (*http://toxnet.nlm.nih.gov/*) brings together the key resources it provides in this area, including the TOXLINE, HSDB, CCRIS, GENE-TOX, IRIS and ITER databases/banks, amongst others. Even more advanced is its ChemID*plus* web-based search system (*http://chem.sis.nlm.nih.gov/chemidplus/chemidheavy.jsp*) that provides access to structure and nomenclature files used for the identification of chemical substances cited in the NLM databases, including those from TOXNET. ChemID*plus* provides structure searching and direct links to many biomedical resources, both within NLM and on the Internet. The system contains over 380 000 chemical records, of which around 270 000 include chemical structures. It is searchable by name, synonyms, CAS Registry numbers, molecular formula, chemical structure and/or biological or chemical properties.

The INCHEM interface (*www.inchem.org/*) is the IPCS portal to the various documents and expert reviews with which it is involved, including IARC Monographs, EHC documents, CICADs, JECFA and JMPR monographs and evaluations, and SIDS/SIARs for HPV chemicals.

Other players have also done their utmost to make our lives easier—the OECD's eChemPortal (*http://webnet3.oecd.org/echemportal/*) provides access to a range of databanks, including those of the IPCS (INCHEM), SIDS, and the European Commission (the European Chemical Substances Information

System—ESIS (*http://ecb.jrc.ec.europa.eu/esis/*)). It is this clever packaging and repackaging of resources that is likely to remain a feature of our lives as toxicologists for many years to come.

10 CONCLUSION—QUALITY AND QUANTITY

With the huge growth in information and the diversification of media and speed by which it is distributed, it is easy to lose sight of issues of quality. The proliferation of new sources not only brings tremendous advantages in terms of accessibility and speed, but also introduces new problems, in particular those of accuracy and verification. More is not necessarily better, and it is particularly important these days to consider how the information is being produced and compiled, and by whom. Unfortunately, the tremendous increase in toxicological data in recent times has not been matched by better quality control or analysis. Information is frequently misapplied or misunderstood. Expert selection and evaluation are something that comes at a price, and the adage 'you get what you pay for' is an important one in the area of toxicological information. It is no easy task to assimilate a focussed set of quality information from a diverse set of scientific disciplines, and particular expertise is required to add significant value to that information such that it becomes meaningful within the context in which it is being sought.

Another difficulty is presented by the nature of the science. Toxicology is often described as an 'art' as well as a science. The large subjective component in the interpretation of toxicological data can lead to conflicting views among experts in the field. Many of these areas are controversial and are thus open to political factors. Toxicology impinges on so much of our daily lives that it perhaps suffers from this more than many other sciences. The issue of independence can thus be an important factor.

It is difficult to predict what future moves will be made in information resources for toxicology. What is certain, however, is that the electronic revolution will continue to make a big impact. Predictions of the imminent demise of traditional methods such as the hard copy publication of primary journals have not yet been realized, however. The printed textbook and journal article are still popular media. The most important changes in information resources for toxicology are likely to be those prompted by the increasing specialization within the science and, of growing necessity, those of information quality control and analysis.

There has always been a move towards trying to provide data sources that can be readily accessible to the end (perhaps nonexpert) user. The danger is that the layman may not appreciate the issues of selectivity, validation and evaluation, and the intricacies of chemical searching that are crucial to the effective and appropriate use of toxicological information. The hope is that the future will see a growing understanding of the benefit of quality, value-added resources over poor-value quantity.

Toxicities Associated with Parenteral Nutrition

Judy L. Aschner and Heather M. Furlong

CONTENTS

1 INTRODUCTION

Parenteral drug and nutritional therapies are mainstays of modern medicine. Parenteral nutrition contains both the macronutrient building blocks and the micronutrients required for optimal human nutrition. Prior to the development of modern parenteral nutrition formulations in the late 1960s, patients with short-bowel syndrome and functional gastrointestinal diseases died of malnutrition. Today, more than 40 000 patients in the United States are permanently dependent on parenteral nutrition to survive (Mullady and O'Keefe, 2006). Many tens of thousands more are sustained for finite periods of time with complex nutritional therapy via the intravenous route. Despite the unquestionable value of parenteral nutrition for patients with structural or functional intestinal diseases, life-threatening complications related to the presence of unintended chemical and microbial contaminants are well recognized. In addition to these iatrogenic and often preventable toxicities, insufficient knowledge of the optimal dosing and ratios of parenteral nutrition additives may pose risks to human health. In the case of both contaminants and supplements added in potentially toxic quantities, infants and children represent a particularly vulnerable population. This chapter will review the potential toxicities associated with both unintended contaminants in parenteral nutrition, including microbes, phthalates, bisphenol-A (BPA), particulates, lipid-peroxidation products and aluminium, as well as intentional supplementation with potentially toxic substances, including trace metals, amino-acid mixtures and lipid emulsions (**Table 1**). Special attention will be paid to parenteral nutrition-associated liver disease (PNALD), which remains an unpredictable, poorly understood and potentially life-threatening complication of prolonged exposure to parenteral nutrition.

2 CONTAMINANTS IN PARENTERAL SOLUTIONS

Parenteral nutrition, while life-saving, carries the potential for serious risks to human health related to the presence of unintended contaminants. Parenteral contaminants that can affect patient safety include microbes, phthalates, BPA, particulates, lipid peroxidation products and aluminium (**Table 1**). The toxicities associated with these contaminants are discussed in detail below.

2.1 Microbial Contamination

Blood-stream infections are associated with significant morbidities and mortality. Microbial contamination of intravenous solutions has been uncovered during investigation of some hospital outbreaks of septicaemia. The

products most likely to be the source of parenteral microbial contamination are blood products, including red blood cells and clotting-factor concentrates, heparin–sodium chloride solutions and components of parenteral nutrition, particularly lipids (Vonberg and Gastmeier, 2007). The most common patient-care settings are haematological–oncological departments and intensive care units. The neonatal intensive care unit is a unique high-risk environment, where prolonged use of parenteral nutrition and high utilization of blood products are coupled with a relatively immunocompromised patient population.

In a review by Vonberg and Gastmeier (2007), accidental microbial contamination of parenteral nutrition was associated with a high mortality. The ability of parenteral nutrition to support the growth of organisms is dependent on the nutritional composition of the solution. Increased parenteral caloric intake, particularly the administration of large concentrations of intravenous lipids, increases the risk for bloodstream infections in patients receiving parenteral nutrition (Vonberg and Gastmeier, 2007). Mortality rates as high as 22–50% have been reported in patients receiving contaminated lipid-containing intravenous products, such as total parenteral nutrition (TPN) or propofol. This is significantly higher than the associated mortality rate of under 10% in patients who received contaminated parenteral solutions that did not contain lipids (Vonberg and Gastmeier, 2007). Lipid emulsion has been shown to support pathogens at 25 °C (Jarvis and Highsmith, 1984).

The spectrum of pathogens involved in hospital-acquired outbreaks depends on the type of contaminated product administered. The pathogens most commonly associated with contaminated blood products include bacteria, such as *Yersinia enterocolitica* and *Serratia* spp., and viruses, such as hepatitis A, hepatitis C and parvovirus B19. Contamination of blood products with human immunodeficiency virus (HIV) is rare in the current era of universal screening. The most likely microbial contaminants in parenteral nutrition are *Staphylococcus epidermidis*, *Staphylococcus aureus*, *Staphylococcus saprophyticus*, *Enterobacter cloacae*, *Klebsiella oxytoa*, *Serratia marcescens*, *Acinetobacter calcoaceticus*, *Stenotrophomonas maltophilia*, *Pseudomonas aeruginosa*, *Burkholderia cepacia*, *Flavobacterium* spp. and *Candida albicans*. These organisms have been implicated in >95% of cases of blood-stream infections associated with contaminated parenteral nutrition (Habsah *et al*., 2005). *Candida parapsilosis* has also been detected in batches of parenteral nutrition products after routine monitoring using randomly amplified polymorphic DNA (RAPD) (Marais *et al*., 2004). Outbreaks of *Enterobacter* spp. septicaemias have been described in neonatal intensive care units in Brazil caused by microbial contamination of TPN solutions (Campos *et al*., 2007; Tresoldi *et al*., 2000). In Malaysia, a neonatal intensive care unit outbreak of *Pantoea* spp. sepsis in eight patients was attributed to the administration of contaminated parenteral nutrition. Seven of the eight infected neonates died (Habsah *et al*., 2005). Systemic infections and central venous catheter colonization with the lipophilic yeast, *Malassezia furfur*, has also been described in neonatal intensive care unit patients receiving lipid emulsions as part of their TPN (Aschner *et al*., 1987).

Guidelines have been established by the American Society of Health-System Pharmacists (2000) for the preparation of parenteral nutrition admixtures. Sterility and quality-assurance measures to avoid extrinsic contamination and to ensure accurate delivery of parenteral nutrition additives must be in place if an automated compounding device is used for preparation of parenteral nutrition (Kochevar *et al*., 2007). Contamination can occur through a variety of mechanisms including: (i) the use of contaminated components during manufacturing, (ii) inadequate or inappropriate aseptic technique for solution preparation, (iii) failure to sterilize the solution, (iv) contamination of the lipid emulsion or the dextrose solution, (v) contamination of the solution during storage, (vi) administration problems and (vii) an ascending method of infection (Tresoldi *et al*., 2000). The mortality and morbidities associated with microbial contamination of parenteral nutrition solutions are preventable. Standardized procedures, continuous quality-improvement initiatives and on-going surveillance should eliminate this source of iatrogenic morbidity.

The use of multidose drug vials deserves special mention. Numerous preventable infections and unnecessary deaths have been traced to the practice in hospitals of using drug vials intended for single use for multiple patients in an attempt at cost containment (Vonberg and Gastmeier, 2007). The Centers for Disease Control and Prevention in the United States and most manufacturers

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat053
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

warn against this practice. Furthermore, the cost effectiveness of using manufacturer-intended multidose vials has been called into question (Sheth *et al*., 1983).

2.2 Phthalates

Polyvinyl chloride (PVC)-based medical devices contain 20–40% (by weight) di-(2-ethylhexyl) phthalate (DEHP) (Kavlock *et al*., 2006). DEHP is the only plasticizer or phthalate approved by the United States Food and Drug Administration (FDA) for medical devices (Calafat *et al*., 2004). DEHP provides PVC with its desired properties of flexibility, strength, usability at a range of temperatures, ability to withstand sterilization, resistance to kinking, optical clarity, weldablity, barrier capability and centrifugability (Kavlock *et al*., 2006). PVC-containing devices include blood bags, tubing for intravenous (iv) therapy, ventilator tubing, extra corporeal membrane oxygenation (ECMO) circuits, enteral and parenteral nutrition containers, and oxygen and suction equipment (Pak *et al*., 2007). DEHP is not bound to PVC and is released from these devices. The rate at which it is released is dependent on the temperature at which the device is stored and used, the storage time, the flow rate through the tubing, the percentage of DEHP in the PVC and the presence of lipids in the solution stored in the device (Calafat *et al*., 2004). DEHP is lipophilic in nature and will dissolve in solutions containing lipids such as parenteral nutrition, lipid emulsions, plasma, platelets and blood. Extraction of DEHP from PVC devices is increased when comparing parenteral nutrition containing lipids to formulations of parenteral nutrition with no added lipids (Pak *et al*., 2007).

In experimental animals, DEHP has been shown to produce a wide range of adverse effects, including liver toxicity and testicular atrophy. The ability of DEHP to produce adverse effects in humans is controversial and has been an active topic of debate in scientific and regulatory circles. The FDA Center for Devices and Radiological Health (CDRH) performed a safety assessment to determine the tolerable intake (TI) values for DEHP and develop an index of safety or risk in patients exposed to DEHP (*http://www.fda.gov/cdrh/ost/dehp-pvc.pdf* , accessed 8 April 2009). A TI value is defined as the dose of a compound that is not expected to result in adverse effects following exposure for a defined period. Based on the results of the safety assessment, CDRH concluded that the amount of DEHP released from PVC bags used to store and administer crystalloid fluids or intravenous drugs poses little to no risk to patients. The possibility of risk of potentially toxic DEHP exposure in patients receiving TPN with lipids is age-dependent. While the dose of DEHP received by adult patients receiving TPN admixtures is estimated to be less than the TI, the dose of DEHP received by neonates undergoing TPN supplementation is uncertain, with at least some, but not all, studies suggesting that neonates can receive very high doses of DEHP. Calafat *et al*. (2004) reported premature infants who received iv therapy for more than two weeks had urinary levels of mono-(2-ethylhexyl) phthalate (MEHP) that were approximately 26 times higher than that compared to the median for children aged 6–11 years who experienced only common environmental exposures to DEHP (Calafat *et al*., 2004). Exposure to DEHP from sources besides for TPN commonly utilized in neonatal patients requiring intensive care raises the overall level of concern about increased risk of DEHP-mediated adverse effects in critically ill neonates. One such source is transfusion of blood products. Relatively high doses of DEHP can be received by patients who are transfused with large volumes of blood and blood products over a short period. Thus, neonates undergoing exchange transfusion or ECMO, as well as trauma or surgical patients of any age requiring massive blood transfusions, might be at risk.

DEHP is hydrolysed rapidly to MEHP, which is then oxidized through a multistep pathway to other metabolites including mono-(2-ethyl-5-hydroxyhexyl) phthalate (mEHHP) and mono-(2-ethyl-5-oxohexyl) phthalate (mEOHP). mEHHP and mEOHP are excreted in the urine and faeces either as the free form or as conjugates. Exposure to DEHP can be assessed by monitoring urinary levels of MEHP, mEHHP and mEOHP. MEHP can also be formed exogenously by lipase enzymes in stored plasma or blood or by hydrolysis in stored and heated iv fluid, resulting in conversion of released DEHP in stored blood, plasma or iv fluids to MEHP before reaching the patient. Exposure to MEHP is important since this compound is thought to be more toxic than DEHP.

2.2.1 Special Considerations in Children

Children may be more susceptible than adults to the toxic effects of DEHP. Several studies show that testicular toxicity occurs in prepubertal rats at lower oral doses than is required to produce this effect in sexually mature rats (Gray *et al*., 1977; Sjoberg *et al*., 1985b; Dostal *et al*., 1988). However, this age-related effect in testicular toxicity was not seen following intravenous administration of DEHP to rats (Sjoberg *et al*., 1985a). Various physiological factors and metabolic differences between children and adults may result in increased sensitivity of children to DEHP. Compared to adults, children (especially neonates) have a reduced glucuronidation capacity. Approximately 60% of DEHP is excreted in humans as the glucuronide conjugate (Albro *et al*., 1982). Reduced glucuronidation capacity could result in delayed excretion of DEHP. Bilirubin is excreted as a glucuronide conjugate. The DEHP metabolite, MEHP, also undergoes glucuronidation and has been shown to interfere with bilirubin conjugation (Sjoberg *et al*., 1991), posing

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat053
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

a particular hazard to neonates who are at risk of kernicterus.

Lipase enzymes in the gastrointestinal tract convert DEHP to the toxic metabolite, MEHP. Infants have high gastric lipase activity to aid in the digestion of fats in milk (Hamosh, 1996; Lee *et al*., 1993), raising the possibility that infants convert DEHP to MEHP more efficiently than do older children or adults. An increased permeability of the blood–testis barrier in children as compared to adults could result in increased exposure of the testes to DEHP or MEHP (Furuya *et al*., 1978). DEHP may exert toxic effects on the testes through depletion of zinc or Vitamin E. Both zinc and Vitamin E deficiencies are common in preterm infants and DEHP could exacerbate zinc and Vitamin E deficiency from other causes in preterm infants (Obladen *et al*., 1998; Chan *et al*., 1999).

Children typically receive a larger dose of DEHP than adults do when the dose is expressed on a $mg\,kg^{-1}$ basis. Further, medical procedures that are almost exclusively performed in children, such as ECMO and double-volume exchange transfusion, can result in potentially large DEHP exposures. Critically ill infants spend weeks to months in the neonatal intensive care unit exposed to multiple medical devices, many of which are made of plastic and contain PVC (Calafat *et al*., 2004). It has been speculated that the well-known effects of DEHP on hepatic enzyme activity contribute to the unexplained hepatobiliary dysfunction in neonates requiring TPN (Loff *et al*., 2000).

In 2000, the first expert panel of the National Toxicology Program's (NTP) Center for the Evaluation of the Risks to Human Reproduction (CERHR) suggested that the DEHP intake for infants who are critically ill may be 2–3 orders of magnitude higher than the general population. The benefits of the medical interventions were recognized to outweigh the risks, but the panel expressed concerns that DEHP in male infants and toddlers may adversely affect the development of their reproductive tract (Calafat *et al*., 2004; Kavlock *et al*., 2006). In 2003, concerns were also raised by the American Academy of Pediatrics and the FDA, based on animal data documenting DEHP to be toxic to the male reproductive tract at doses nearing those resulting from intensive medical procedures in humans (Calafat *et al*., 2004; Shea, 2003). Further research on the effects of DEHP and safe alternatives to DEHP are needed.

2.3 Bisphenol-A

BPA is used in the production of polycarbonate plastics and epoxy resins, which have many applications, including as components of certain medical products and their packaging. On 14 April 2008, the NTP released a draft brief that raised concerns that exposure to BPA could be linked to developmental problems of the endocrine system in infants and young children. NTP released a final report on BPA on 3 September 2008. Following the release of the NTP report, public concern focussed on exposure to BPA from plastic baby bottles and the linings of baby-food containers. However, exposure from parenteral sources represents an unknown risk. There are many FDA-regulated products that are known to contain BPA including medical devices and biological products such as blood products, vaccines and drugs. Unfortunately, information on the presence and levels of BPA for products with direct patient contact is largely unknown. Important areas for future study include the rate and extent of BPA release from devices and biologics, the conditions that affect the release and leaching of BPA, estimates of patient exposure to BPA from parenteral exposures, possible alternatives to BPA in medical devices, and studies that evaluate the toxicity or justify the safety of BPA in these products Department of Health and Human Services, Food and Drug Administration (2008).

2.4 Particulates and Precipitates

Safe administration of parenteral nutrition depends upon knowledge of the stability and compatibility of its various components. Both the stability and compatibility of parenteral nutrition solutions are affected by factors such as the infusion container, administration set, filter and reactive, but necessary, additives (Driscoll, 2003). The simple act of opening multiple commercial injectables that compose a parenteral admixture begins the degradation of these individual components. Complex reactions begin to occur when they are combined into a single container. The responsibility rests on the pharmacist to assign an expiration date that is based on the best available information to ensure degradation does not proceed to a point where infusion is clinically dangerous (Driscoll, 2003).

2.4.1 Problems with Instability

Instability of parenteral nutrition admixtures and breakdown of nutritional components over time may lead to formulation failure or disruption (Mirtallo *et al*., 2004; Driscoll, 2005). Certain amino acids, intravenous fat emulsions (IVFE) and vitamins are subject to instability (Mirtallo *et al*., 2004).

Vitamins are susceptible to physicochemical instability in parenteral nutrition formulations. Several vitamins are known to degrade over time and in the presence of oxygen. Very few have a clinically significant impact in the acute-care setting. However, when the patient is dependent on long-term TPN and body reserves are low, the impact can be significant. The best example of this is the degradation and absorption of vitamin

A into the plastic matrix of the infusion container, following preparation of TPN in weekly batches. In a case report, a home TPN patient developed night blindness within six months. The patient was treated with a large intramuscular dose of vitamin A and symptoms resolved. Following a relapse, daily dosing of vitamins was provided and the problem resolved (Mirtallo *et al*., 2004).

Ascorbic acid, or vitamin C, when added in batch fashion, is degraded and results in the formation of large particulates. Degradation is avoided by adding such vitamins just prior to infusion (Mirtallo *et al*., 2004). Protection from light may also reduce degradation; it has been shown that vitamin C degrades with phototherapy (Smith *et al*., 1988).

Another potential toxicity associated with vitamin C administration is the formation of oxalate particulates. Oxalate ($C_2H_2O_4$) is a relatively strong dicarboxylic acid with a molecular weight of 90.04 Da. Oxalate is derived directly from ascorbic acid, glyoxalate, glycolate and glycoaldehyde. Glycine, hydroxyproline, ethanolamine, hydroxypyruvate and xylulose can also serve as indirect precursors of oxalate formation (Rockwell *et al*., 1998). Oxalate particulates have been described in parenteral nutrition solutions and have been associated with catheter occlusions (Das, 1986), and nephocalcinosis (Rockwell *et al*., 1998) in neonatal patients receiving parenteral nutrition. TPN solutions contain the oxalate precursors ascorbate and glycine. Glycine is present in all commercial amino-acid solutions. Ascorbic acid is a component of the intravenous multivitamin formula for parenteral nutrition (M.V.I. Pediatric; Armour Pharmaceutical, Kanakee, IL, USA). Increased urinary oxalate excretion has been reported in infants receiving TPN (Campfield and Braden, 1989). Degradation of parenteral ascorbate has been reported to cause elevated serum oxalate concentration and systemic oxalosis in adults with renal insufficiency (Balcke *et al*., 1984; Swartz *et al*., 1984) and in patients receiving long-term TPN (Buchman *et al*., 1995).

Trace metals, particularly copper, iron and zinc, potentiate ascorbate degradation to oxalate (Kassem *et al*., 1969). In contrast, ascorbate is protected by the presence of amino acids, especially cysteine. Unfortunately, routine amino-acid solutions typically used in TPN contain relatively little cysteine. Thus, in part to protect neonates from the metabolic load associated with oxalogenesis, supplemental cysteine beyond that provided by amino-acid solutions is recommended for infants receiving TPN.

2.4.2 Problems with Incompatibility

Incompatibility generally involves the coexistence of two or more electrolytes in solution that leads to precipitation of an insoluble product (Driscoll, 2005). The most dangerous risk of incompatibility in parenteral nutrition formulation is the development of macroprecipitates exceeding 5 μm. These macroprecipitates may subsequently pass into the central circulation causing vascular accidents. Two forms of precipitates can appear in a prepared formulation—solid and liquid (Mirtallo *et al*., 2004).

2.4.2.1 Solid Precipitates

Solid precipitates develop when incompatible combinations of salts are added to a parenteral nutrition formulation (Mirtallo *et al*., 2004). Perhaps one of the most lethal consequences of mishandling TPN is the formation of rigid, crystalline precipitates. This can be the result of: (i) poor compounding techniques, (ii) inadequate knowledge of the admixture components and (iii) assignment of inappropriately long expiration dates (Driscoll, 2003).

Calcium salts are very reactive and form insoluble products with numerous additives (Mirtallo *et al*., 2004). Most notorious is the precipitation of insoluble dibasic calcium phosphate formed as a result of either poor compounding technique or inadequate knowledge of admixture components or patient condition (Driscoll, 2003). Dibasic calcium phosphate precipitates have resulted in embolic deaths. This can be avoided through a variety of measures, which include the choice of calcium gluconate as the preferred form of calcium in multicomponent parenteral nutrition formulations. Order of compounding is important to avoid formation of insoluble precipitates—generally phosphate is added first and calcium is added closer to the end to benefit from the larger volume of solution (Mirtallo *et al*., 2004). The methods for determining calcium-phosphate precipitation vary widely and rely on unaided and aided visual detection using high-intensity lamps against a contrasting background or Tyndall beam, turbidimetric analysis, polarized light microscopy and, to a limited extent, the actual counting and sizing of particulate growth over time using light obscuration. The United States Pharmacopeia, the British Pharmacopoeia and the European Pharmacopoeia state that for the determination of particulate matter in aqueous injectables, the measurement can be made to meet pharmacopeia specifications using light obscuration (the reference method) or a microscopic particle count test (Driscoll, 2005).

There are alternative parenteral salts that may reduce the risk of calcium-phosphate precipitates. Organic phosphates such as glucose-1-phosphate, fructose-1,6-diphosphate and glycerol phosphate have been shown to be compatible with organic calcium. Glycerol phosphate is the most commonly used; the organic phosphates are not readily available or approved worldwide (Driscoll, 2005).

Bicarbonate salts present risks for precipitation as they react with calcium to form an insoluble precipitate, calcium carbonate. Therefore, bicarbonate salts should not be added to TPN solutions. If an alkalinizing salt is needed, sodium acetate or potassium acetate should be

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat053
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

used. Acetate salts are frequent components in neonatal TPN.

Ascorbic acid in supraphysiologic doses to achieve an antioxidant effect is highly unstable. It readily degrades in the presence of oxygen to form oxalic acid. Oxalic acid is highly reactive with calcium and will form an insoluble precipitate, calcium oxalate. For this reason, ascorbic acid should be administered as a separate infusion (Mirtallo *et al*., 2004).

2.4.2.2 Liquid Precipitates

Phase separation with the liberation of free oil will result in liquid precipitation (Mirtallo *et al*., 2004). All IVFE are thermodynamically unstable and have short shelf lives (24 months). Instability of IVFE is manifested by an increasing population of large fat globules greater than 5 μm, a process known as coalescence (Driscoll, 2003). The major concern about destabilization of IVFE and formation of large fat globules is that lipid droplets greater than 5 μm can occlude the microvasculature (pulmonary capillaries) and cause embolic syndrome and death (Driscoll, 2005). Evidence in rats and guinea pigs has demonstrated tissue damage associated with unstable IVFE compared to stable IVFE (Driscoll, 2003). Egg lecithin is the primary emulsifier used in IVFE as a stabilizer and imparts a negative charge to the lipid droplets. The addition of cations (sodium, potassium, calcium, magnesium) impedes stabilization by neutralizing the droplet surface charge (Driscoll, 2005). The physicochemical limitation of the IVFE is clearly outlined by the manufacturer. The pharmacist should use this brand-specific information and not extrapolate to other products (Mirtallo *et al*., 2004). Appropriate methods for analysis of the stability of IVFE have been debated. The United States Pharmacopeia has proposed the light obscuration method with a pharmacopeia limit defined as the volume-weighted percentage of fat greater than 5 μm, or less than 0.05%, irrespective of the final lipid concentration (Driscoll, 2005).

Total nutrient admixtures containing fat emulsion, as well as other components of parenteral nutrition, such as carbohydrates, amino acids, vitamins, minerals and trace elements in a single container have been formulated for neonates and infants. However, given the limited amount of published stability information available, the practice guidelines from the American Society for Parenteral and Enteral Nutrition (ASPEN) recommend the use of 2-in-1 formulations with separate administration of IVFE for neonates and children (Mirtallo *et al*., 2004).

2.5 Lipid Peroxidation Products

Lipids are the primary source of energy for infants and young children and thus are an essential component of paediatric parenteral nutrition. Prior to the introduction of parenteral lipid emulsions in TPN in the 1960s, essential-fatty-acid deficiency was commonplace. Current lipid emulsions provide an important energy source, essential fatty acids and, in some countries, required lipid-soluble vitamins. However, concern has been raised about the potential toxic effects of lipid-peroxidation products, which can pose a particular hazard to premature infants with low antioxidant defences. Lipid emulsions for parenteral use can be peroxidized during storage; these peroxidation products can induce cell damage, at least *in vitro* (Pitkanen, 1992). Lipid peroxidation can also occur *in vivo* in adult and neonatal patients receiving parenteral lipid emulsions. Fat emulsions have been linked to increased oxygen-derived free-radical activity in infants (Hasanoglu *et al*., 2005). Lipid emulsions contain various amounts of polyunsaturated fatty acids (PUFAs), which can serve as substrates for the formation of lipid hydroperoxides by free radicals. Factors that increase lipid peroxidation include ambient light, phototherapy for hyperbilirubinaemia, contamination by air and presence of trace elements (Laborie *et al*., 2000).

As PUFA are essential components of biological membranes, their peroxidation *in vivo* may cause cellular damage. Lipid peroxidation has been implicated in the development of common complications of prematurity, such as bronchopulmonary dysplasia, necrotizing enterocolitis and retinopathy of prematurity, although a causal relationship between these neonatal morbidities and peroxidation of parenteral lipid emulsions has not been proven (Krohn and Koletzko, 2006). Studies showing that *in vitro* lipid peroxidation is inversely related to the α-tocopherol/PUFA ratio of the fat emulsion suggest that additional vitamin E may be beneficial (Pitkanen, 1992; Pironi *et al*., 2003). L-Carnitine was also shown to be effective in inhibiting lipid peroxidation of a linoleic acid emulsion (Gulcin, 2006). However, L-carnitine has not been shown to improve lipid tolerance, ketogenesis or weight gain in neonates receiving TPN (Cairns and Stalker, 2000). This study did not address the impact of carnitine supplementation on disease parameters related to oxidative stress in premature infants.

As noted above, exposure of TPN to ambient light generates organic peroxides (Neuzil *et al*., 1995; Silvers *et al*., 2001) and hydrogen peroxide (Laborie *et al*., 1998; Khashu *et al*., 2008). Furthermore, photosensitized riboflavin present in parenteral multivitamin preparations catalyses electron transfer between electron donors such as vitamin C, amino acids or lipids and dissolved oxygen, producing hydrogen peroxide (Laborie *et al*., 1998; Khashu *et al*., 2008). Light exposure also induces a loss of antioxidant vitamins in TPN (Chessex *et al*., 2007). Shielding TPN from light represents an approach to protect the solution from the generation of peroxides and by-products of lipid peroxidation (Laborie *et al*., 1999; 2000). It has been hypothesized that these reactive species may play an important role

in the pathogenesis of various neonatal conditions, including bronchopulmonary dysplasia. Khashu *et al*. (2008) examined whether generation of oxidants in light-exposed TPN impacts lipid metabolism and impairs glucose uptake in preterm neonates. They reported slightly higher blood glucose and significantly higher triglyceride levels in preterm infants receiving light-exposed TPN, compared to a comparable group receiving light-protected TPN (Khashu *et al*., 2008). These same investigators reported that photoprotection of TPN solutions facilitated advancement of minimal enteral nutrition (Khashu *et al*., 2006) and, most provocatively, was associated with a 30% relative reduction in the incidence of death or bronchopulmonary dysplasia (Chessex *et al*., 2007). These results should be examined in a large, randomized, controlled trial. If replicated, the simple and inexpensive intervention of shielding TPN from light could have a major impact on the medical outcomes and healthcare costs associated with neonatal intensive care.

2.6 Aluminium

Aluminium is the third most abundant component of the earth's crust. It is a nonessential toxic metal with no known physiologic role. The gastrointestinal tract provides a protective barrier against the absorption of aluminium when consumed orally, with only 1% absorbed systemically. However, when delivered parenterally the gastrointestinal barrier is bypassed and aluminium is deposited in bone, liver, spleen, kidney, brain and other tissues. Aluminium contamination of parenteral nutrition and associated aluminium toxicity has been recognized since the 1980s (Gura and Puder, 2006; Advenier *et al*., 2003). Aluminium toxicity has been implicated in vitamin D-resistant osteomalacia, dementia and fracturing bone disease in dialysis patients and TPN-associated cholestasis in neonates. With a half-life of up to seven years, aluminium will remain in the body for an extended period of time (Gura and Puder, 2006).

Much of the raw material used to manufacture solutions used for intravenous nutritional support of hospitalized patients is contaminated with aluminium (Klein, 2005). Pharmaceutical manufacturers have only recently obtained the technology necessary to detect aluminium contamination of their products. Aluminium contamination in parenteral nutrition can be found in a variety of parenteral nutrition components (Gura and Puder, 2006). Casein hydrolysate, a common protein source in parenteral nutrition in the 1980s, was highly contaminated with aluminium. Since then, there has been a substitution of crystalline amino acids and a reduction of the aluminium burden (Klein *et al*., 1991; Vargas *et al*., 1988). Other additives, such as multivitamins, trace elements, calcium and phosphate salts, contain measurable amounts of aluminium (Gura and Puder, 2006) ranging from a concentration of $3–3439\,\mu g\,l^{-1}$ (Klein *et al*., 1991).

In July 2004, the United States FDA mandated that manufacturers measure aluminium content of parenteral nutrition products and disclose this information on the label (Klein, 2005). This regulation regarding aluminium content labelling applies only to products that are routinely used in the preparation of parenteral nutrition. Large-volume parenterals (dextrose solutions, sterile water for infusion, fat emulsions and crystalline amino acids) are required to limit their aluminium content to less than $25\,\mu g\,l^{-1}$ (Gura and Puder, 2006). The rationale for this recommendation originates from a 1986 report that demonstrated that teens and adults on long-term TPN receiving $25–30\,\mu g\,l^{-1}$ aluminium had no significant aluminium accumulation in bone, serum or urine (Heyman *et al*., 1986). This does not, however, take into consideration the aluminium contribution from small-volume parenterals, which can be significant (Klein *et al*., 1991). No upper limit for aluminium has been established for small-volume parenterals, such as trace elements, salts and multivitamins. These products are among those most highly contaminated with aluminium. Regulation simply requires that the aluminium content be labelled at the time of expiration. When the product contains less than $25\,\mu g\,l^{-1}$, it is sufficient to state 'contains no more than $25\,\mu g\,l^{-1}$ aluminium'. Those small-volume parenterals that exceed $25\,\mu g\,l^{-1}$ must list the maximum amount at expiration for each batch product (Gura and Puder, 2006). Although these regulations have been instituted with the goal of limiting exposure to less than $4–5\,\mu g\,kg^{-1}\,day^{-1}$, which is the maximum amount deemed 'safe' by the FDA, pharmacists are not required to notate the total aluminium content on the labels of patient parenteral nutrition containers (Gura and Puder, 2006).

Manufacturers of these solutions are required to provide the FDA with the validated method they are using to measure aluminium content, samples of their results and assurance that the method conforms to 'Good Manufacturing Practices' specified by the FDA (Klein, 2005). A statement must be added in the warning section of the package insert that states 'levels of aluminium greater than $4–5\,\mu g\,kg^{-1}\,day^{-1}$ accumulate at levels associated with central nervous system (CNS) and bone toxicity' (Driscoll and Driscoll, 2005). In other countries, limitations are different; the British Pharmacopoeia requires only that calcium chloride salts meet specific aluminium content limits (Gura and Puder, 2006).

Many factors affect the extent of aluminium contamination in the parenteral admixture (Gura and Puder, 2006; Klein *et al*., 1991). The source of raw materials may account for batch-to-batch variability of the same product manufactured by the same company. Glass and rubber

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat053
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

contain more aluminium than plastic and play an important role with regards to container design. As aluminium may leach from glass containers, the quality of the glass is an important variable. The type of product contained is important, as calcium and phosphate salts have high affinity for aluminium and increase leaching from glass containers. Aluminium also leaches from glass according to the stability constant of the amino acids for aluminium with cysteine, cystine, aspartic acid and glutamic acid having the highest affinity. Heat sterilization enhances the leaching of aluminium from glass and rubber stoppers. The longer a product is on the shelf, the more potential there is for leaching of aluminium into the solution (Gura and Puder, 2006). Thus, aluminium contamination is unpredictable and highly variable (Klein *et al*., 1991).

Options for decreasing aluminium contamination include substituting potassium phosphate with sodium phosphate. More importantly, a change to sodium phosphate in plastic vials would decrease the leaching of aluminium from the glass containers. Another alternative is the use of calcium chloride in place of calcium gluconate, which is highly contaminated. However, this would predispose premature infants to hyperchloraemia and the associated metabolic acidosis. Koo *et al*. (1986b) have recommended using a 1:1 ratio of calcium gluconate and calcium chloride with sodium and potassium acetate instead of sodium and potassium chloride (Koo *et al*., 1986b). Finally calcium acetate is a consideration as it has minimal contamination, but it is less soluble and there are minimal data regarding compatibility (Gura and Puder, 2006).

2.6.1 Special Considerations in Infants and Children

There have been concerns about aluminium toxicity in infants and children receiving parenteral nutrition since the 1980s. Parenteral nutrition solutions are the main source of aluminium exposure in neonates, contributing as much as 88.7% of total aluminium intake among neonates in intensive care nurseries (Moreno *et al*., 1994). The major route of aluminium elimination is renal. Preterm kidneys have limited ability to excrete aluminium (Koo *et al*., 1986a). Compared with adults, preterm infants excrete only 23% of an intravenous aluminium load. Marked aluminium accumulation in bone, urine and plasma has been demonstrated in infants after only three weeks of TPN (Sedman *et al*., 1985). Long-term moderate aluminium exposure causes osteomalacia with alterations in bone formation and mineralization, parathyroid hormone secretion and urinary calcium excretion. Acute intoxication causes an encephalopathy. The risk of aluminium toxicity is dependent on the length of exposure and on renal function, although toxic levels have been observed in patients with normal renal function on long-term TPN.

Aluminium toxicity has been implicated in the pathogenesis of PNALD and cholestasis. Hepatic aluminium concentrations in children on TPN were noted to be 5–17 times normal (Klein *et al*., 1984). Furthermore, aluminium loading in piglets and rats causes hepatic accumulation and damage (Klein *et al*., 1984; 1987; 1988; 1989).

There are strong data supporting the adverse effects of aluminium on bone mineral content, metabolic bone disease and bone growth. TPN containing high concentrations of aluminium is associated with reduced serum 1,25 hydroxy-vitamin D (1,25(OH)2D) levels in serum in children (Klein *et al*., 1985). In adults on long-term TPN containing high aluminium concentrations, bone disease is manifest by long-bone pain and pain in weight-bearing joints, decreased bone-formation rate and patchy osteomalacia. Children develop evidence of radiographic rickets and bone fractures (Klein *et al*., 1982). In one study, bone formation varied inversely with both plasma aluminium and bone-surface aluminium, suggesting that aluminium acquired during TPN can reduce bone formation and lead to patchy osteomalacia (Vargas *et al*., 1988).

Aluminium can be toxic to the CNS of both preterm and term newborns. High brain-tissue levels of Al have been identified at autopsy (Popinska *et al*., 1999). In one highly concerning randomized, controlled trial comparing infants fed aluminium-depleted TPN to those on standard TPN, infants receiving standard TPN had significantly lower mental developmental indices, with an adjusted loss of one point per day of TPN (Bishop *et al*., 1997). This finding, reported in 1997, requires replication. If reproducible, stricter limitations on aluminium content in parenteral formulations for neonates should be mandated or techniques for aluminium depletion should be incorporated into routine parenteral nutrition administration practices.

Questions remain as to 'safe' levels of aluminium in intravenous solutions for various patient populations. The FDA defined the maximum safely tolerated amount as $5\,\mu g\,kg^{-1}\,day^{-1}$, noting that amounts in excess may cause CNS or bone toxicity. It is concerning that aluminium intake from parenteral nutrition solutions in neonates has been reported to be as high as $6.6–16.7\,\mu g\,kg^{-1}\,day^{-1}$ (Moreno *et al*., 1994; Popinska *et al*., 1999). ASPEN defined aluminium intakes as safe when they are $<2\,\mu g\,kg^{-1}\,day^{-1}$; a dose that does not result in accumulation in tissues and fluids. ASPEN defined unsafe aluminium content as $2–15\,\mu g\,kg^{-1}\,day^{-1}$, as this is an amount that results in tissue loading, but no documented toxicity. Toxic levels are defined as $60\,\mu g\,kg^{-1}\,day^{-1}$, which is a dose that results in tissue accumulation and symptoms of toxicity (Klein *et al*., 1991). For term and preterm infants, a 'safe' dose has not been established. However, based on the literature, it appears that neonates are being exposed to greater aluminium loads than are known to be safe for adolescents and adults. In the absence of

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

reliable label information and to prevent iatrogenic toxicity, the aluminium content of parenteral nutrition should be assessed regularly. Aluminium contamination of TPN additives is an under-recognized danger to TPN patients, with infants on prolonged TPN at greatest risk.

3 POTENTIALLY TOXIC COMPONENTS IN PARENTERAL NUTRITION

In addition to toxicity associated with the presence of inadvertent contaminants in parenteral nutrition, risks may be associated with intended components, such as amino-acid mixtures and lipid emulsions. Deliberate supplementation of parenteral nutrition with essential trace metals may also pose risks when present in high concentrations or when the underlying health status of the patient alters the metabolism or requirements of these trace elements.

3.1 Amino Acids

The goals of parenteral nutrition amino-acid preparations are to provide essential amino acids of sufficient quantity and appropriate composition to support normal growth and a normal plasma amino-acid profile. The earliest parenteral amino-acid preparations were protein hydrolysates, with fixed amino-acid compositions. Complications from infusions of these early protein hydrolysates included hyperammonaemia, acid–base disorders and allergic reactions, particularly in paediatric and neonatal patients (Storm and Helms, 2007).

The 1970s ushered in the pharmaceutical-grade crystalline amino-acid formulations which were based on adult amino-acid requirements. When these adult parenteral crystalline amino-acid formulations were administered to infants, new complications related to the amino-acid composition of these adult formulations occurred. Manufacturers had ignored the growing body of literature suggesting that paediatric parenteral amino-acid requirements were different to adult amino-acid requirements. For example, it was already known that phenylalanine hydroxylase activity was absent or low in infants and young children, making tyrosine a conditionally essential amino-acid in paediatric populations (Raiha, 1973). Likewise, cystathionase is not fully functional in neonates and infants, making cysteine and taurine essential amino-acids (Sturman *et al*., 1970). Winters *et al*. (1977) documented the abnormal plasma amino-acid profile of infants receiving any parenteral amino-acid formulation that had been developed based on the amino-acid requirements of adults. The abnormal profiles included low levels of branched-chain amino acids, abnormally low plasma levels of cystine and high normal to elevated levels of methionine. Plasma levels of phenylalanine were in the low normal range, but plasma tyrosine levels were consistently below normal. The total glutamine and glutamic acid composition was also found to be below the requirements needed in childhood (Winters *et al*., 1977). The conclusion was that creation of paediatric-specific amino-acid formulations was needed.

The ultimate result was the introduction of F-14 or TrophAmine in July 1984. TrophAmine was the culmination of many phases of formulation development, normal volunteer testing, plasma amino-acid profile determination and reformulation to engineer the first successful paediatric amino-acid formulation (Storm and Helms, 2007). Compared with adult formulations, TrophAmine contained increased essential amino-acid content, increased branched-chain amino-acid content, a broader nonessential amino-acid content which included aspartic acid, glutamic acid and taurine, with modifications in the level of almost every amino acid compared with that in adult amino-acid formulations. Also, the pH of the amino-acid formulation was lowered to 5.5 to enhance calcium and phosphate solubility (Storm and Helms, 2007). Further enhancements included the addition of *N*-acetyl-L-tyrosine (NAT) and L-cysteine-HCl. NAT, a soluble and stable source of tyrosine, resulted in normal or near-normal plasma tyrosine levels in paediatric patients. L-Cysteine-HCl both enhanced plasma cystine levels and further lowered the pH, thus improving calcium and phosphate solubility, which is important in achieving the increased calcium and phosphate requirements of infants and children receiving parenteral nutrition. Use of this paediatric formulation in term infants achieved normalization of all plasma amino acids at an intake of $2.4\,g\,kg^{-1}\,day^{-1}$, with the exception of tyrosine, and a positive nitrogen balance. The new paediatric amino-acid formulations also improved growth and nitrogen balance and resulted in more normal amino-acid profiles in premature infants compared with the traditional adult formulations (Helms *et al*., 1987).

The newly approved paediatric amino-acid formulations, TrophAmine (McGraw, Bethlehem, PA) in 1984 and Aminosyn PF (Abbott, Abbott Park, IL) in 1985 represented a significant advancement in the delivery of paediatric parenteral nutrition. However, as is often the case in paediatric medicine, a one-size-fits-all approach is rarely optimal. Scrutiny of these formulations in low-birth-weight premature infants revealed plasma phenylalanine levels that were more than two standard deviations above normal and poorer utilization of cysteine and NAT as tyrosine (Heird *et al*., 1988; Adamkin *et al*., 1991). Future improvements are needed in formulations for preterm infants to address their higher tyrosine requirements and poor retention of NAT.

The problem of PNALD and the identification of the inciting ingredient(s) contributing to this persistent problem in neonatal medicine have yet to be resolved. In

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat053

its most severe form, it can lead to hepatic failure and death or the need for liver transplant. The incidence of TPN-induced hepatic steatosis and cholestasis is clearly higher in the paediatric than in the adult population. It is correlated directly with the degree of prematurity and duration of parenteral nutrition, and inversely with the amount of enteral feedings tolerated. Compared with adults, young children conjugate more of their bile-acid pool with taurine instead of glycine. Therefore, higher concentrations of taurine have been incorporated into paediatric amino-acid formulations (Storm and Helms, 2007). A number of observational and retrospective studies suggested that use of the newer paediatric amino-acid formulations resulted in a relatively low rate of TPN-associated cholestasis that was most dependent on the length of TPN exposure, rather than the commercial product used (Beck, 1990; Storm and Helms, 2007; Forchielli *et al*., 1995), although at least one retrospective comparison study favoured TrophAmine over Aminosyn PF (Wright *et al*., 2003). An examination of the aetiology of hepatic failure among young children on liver transplant lists suggests that despite the introduction of paediatric-specific amino-acid formulations, PNALD remains a significant problem. Unfortunately, the role of amino-acid formulations vs. other TPN components, such as lipids and aluminium contamination, remains unresolved.

3.2 Lipid Emulsions

Most commercial fat emulsions used in TPN are composed of soybean oil or a combination of soybean oil and safflower oil in which long-chain triacylglycerols have been partially replaced with medium-chain triacylglycerols (MCTs) (Chen and Yeh, 2003). Lipids are necessary in parenteral nutrition-dependent patients due to their high caloric value and essential fatty-acid content. However, they too have been implicated in PNALD (Alwayn *et al*., 2005; Gura *et al*., 2008; Diamond *et al*., 2008). Soybean oils contain phytosterols, which are thought to have a deleterious effect on biliary secretion. Soybean oil-based ω-6-fatty-acid emulsions are not cleared in the same manner as enteral chylomicrons, which may lead to accumulation of lipids in the hepatic Kupffer cells, impairment of liver function and steatotic liver injury. Thus, the development of hepatic steatosis results from an imbalance in the rates of entry, synthesis or clearance of fat from the liver (Day and James, 1998). Standard lipid emulsions may also enhance the production of proinflammatory cytokines, because they are a relatively rich source of ω-6-fatty acids, which are the precursors to arachidonic acid (Mayer *et al*., 2003c; Fernandes, 1994).

The metabolism of lipids depends on their route of administration. Enteral lipid micelles are absorbed by the enterocyte, packaged into chylomicrons and released into the portal venous system for uptake in the liver. The emulsified particles of commercially available lipid emulsions mimic the size and structure of chylomicrons, but differ in their content. Artificial lipid particles, which primarily contain essential fatty acids and ω-6-triglycerides, are devoid of cholesterol or protein. These ω-6-fatty-acid-containing emulsions are dependent on lipoprotein lipase, apolipoprotein E and low-density lipoprotein receptors for clearance, and they release less essential fatty acids than do chylomicrons. These factors are thought by some to contribute to the steatohepatitis associated with the intravenous administration of the lipid emulsions most commonly used today (Allardyce, 1982; Colomb *et al*., 2000; Alwayn *et al*., 2005).

Until very recently, fish-oil emulsions for use in parenteral nutrition were not commercially available. In the United States, in 2008, they are considered experimental and require human-subjects review by institutional review boards. Fish oils are rich sources of ω-3-fatty acids, especially eicosapentaenoic acid (EPA; C20:5) and docosahexaenoic acid (DHA; C22:6). Numerous studies have demonstrated the hypotriglyceridemic, antiatherogenic and antihypertensive effects of oral dietary fish oils (Harris, 1989; Nestel, 1990; Knapp and FitzGerald, 1989; von Schacky, 1987). In contrast, the use of fish oil in human parenteral nutrition has not been well studied.

The mechanism of clearance of ω-3-fatty-acid-containing lipid emulsions is incompletely understood. In humans, the ω-3-fatty acids have been shown to accelerate the clearance of chylomicron triglycerides (Park and Harris, 2003). In animal models, ω-3-fatty-acid solutions have been shown to decrease lipogenesis and prevent or attenuate parenteral nutrition-induced hepatosteatosis in rats and guinea pigs (Van Aerde *et al*., 1999; Yeh *et al*., 1997). They also decrease interleukin 6 and other proinflammatory cytokine levels *in vitro* and *in vivo* (Mayer *et al*., 2002; 2003c; Rallidis *et al*., 2003) and displace arachidonic acid from tissue fatty-acid pools and inhibit the arachidonic-acid pathway of inflammation (Chen *et al*., 1992; Simopoulos, 2002). In 2005, Alwayn *et al*. investigated the role of ω-6-and ω-3-fatty acid emulsions in a murine model of nutritionally induced liver damage. They showed that mice exclusively fed a fat-free, high-dextrose liquid diet developed hepatic steatosis and essential-fatty-acid deficiency. Supplementation with ω-3-fatty acids by either the intravenous or enteral routes prevented dietary-induced hepatic steatosis. In contrast, supplementation with a conventional ω-6-lipid emulsion worsened hepatic steatosis (Alwayn *et al*., 2005). These data suggest that the content or the ratio of ω-6-:ω-3-fatty acids delivered intravenously is aetiologic in hepatic steatosis. It has been shown that a high polyunsaturated ω-6-:ω-3-long-chain fatty acid ratio is associated with nonalcoholic fatty-liver

disease and may favour lipid synthesis over oxidation and secretion (Araya *et al*., 2004). The standard soybean-based lipid emulsion contains 15 times higher polyunsaturated ω-6-:ω-3-fatty-acid ratio compared with the ω-3-fish-oil-based fatty-acid emulsion and 11 times higher than the normal diet (Alwayn *et al*., 2005).

Despite experimental evidence that ω-3-fatty acids may be beneficial in preventing or reversing hepatic injury, the mechanisms for the salutary effects are poorly understood. Chen *et al*. (1996) described the effects that various fatty acid compositions had on rats that received TPN. They demonstrated a lower hepatic fat content in rats that received TPN containing lipid emulsions that were high in ω-3-fatty acids compared with those given TPN with fat emulsions derived from olive or safflower oils (Chen *et al*., 1996). Proposed mechanisms include stimulation of both peroxisomal and mitochondrial β-oxidation of fatty acids, thereby decreasing the availability of nonesterified fatty acids as substrates for triacylglycerol synthesis and secretion (Chen and Yeh, 2003; Burdge *et al*., 2003; Neschen *et al*., 2002; Willumsen *et al*., 1993). ω-3-fatty acids have also been shown to inhibit *de novo* lipogenesis in rat livers by reducing the activity of acetyl CoA carboxylase (Neschen *et al*., 2002). Other potentially protective properties of ω-3-fatty acids include their propensity to lower the activity of superoxide dismutase and glutathione peroxidase (Yeh *et al*., 1997), their limited ability to be esterified to glycerol (Rustan *et al*., 1988; Nossen *et al*., 1986) and their ability to reduce the synthesis of arachidonic acid (Chen *et al*., 1992; Alwayn *et al*., 2005).

Despite these promising human and animal studies, fish-oil-based lipid emulsions are not commonly used in medicine and have only recently become commercially available. Omegaven™ is a fat emulsion comprised of ω-3-fatty acids from fish oil produced by Fresenius Kabi AG (Bad Homburg, Germany). It is not approved for use in the United States. This or a similar ω-3-based lipid product has been used in Europe and Asia in adult trauma and surgical patients (Morlion *et al*., 1996; Grimm *et al*., 2006; Wichmann *et al*., 2007), adults with sepsis and systemic inflammatory response syndrome (SIRS) (Mayer *et al*., 2003a; 2003b), patients with inflammatory bowel disease (Grimminger *et al*., 1993a) and adults with psoriasis (Grimminger *et al*., 1993b; Mayser *et al*., 1998), atopic dematitis (Mayser *et al*., 2002) and rheumatoid arthritis (Proudman *et al*., 2008).

Paediatric experience with Omegaven™ is limited. It has been hypothesized that use of Omegaven™ in infants and young children with TPN-induced liver disease could potentially reverse or prevent the cholestasis and development of hepatic failure (Diamond *et al*., 2008; Gura *et al*., 2008). The published evidence is limited to a case report of two patients from Boston, both with severe end-stage liver disease who demonstrated reversal of PNALD, and in one case removal from the transplant list, following a switch from ω-6-fatty-acid-based lipid solution to Omegaven® (Gura *et al*., 2006). This was followed by a recently published case series from Boston of 18 patients treated with Omegaven™, all of whom demonstrated resolution of their PNALD (Gura *et al*., 2008). Clearly there is a need for well-designed prospective studies to determine the optimal approach to parenteral nutrition comparing ω-3-fatty-acid lipid emulsions, alone or in combination with ω-6-fatty-acid emulsions, to the standard ω-6 solution. Such a trial will not only answers questions as to the efficacy of ω-3-fatty-acid lipids, but also affords an opportunity for optimal safety assessment (Diamond *et al*., 2008).

3.3 Trace Metals

Until 30 years ago, trace elements were thought to be of little significance in human nutrition. It is now recognized that many factors can render individuals and population groups susceptible to disease resulting from trace element deficiencies or excess. However, there is insufficient knowledge about the nutritional requirements, causes and effects of micronutrient deficiencies and toxicities.

All nutrients have an optimal range of intake, with either deficiency or excess being potentially harmful. Clinical deficiencies have been described for six of the elements: iron, iodine, zinc, copper, chromium and selenium. The trace metals that are typically added to PN solutions include zinc, copper, chromium, manganese and selenium. Most often these trace metals are added as a cocktail containing fixed ratios of zinc, copper, chromium and manganese, with selenium often added separately. The goals for trace metal supplementation in parenteral nutrition should include prevention of trace-metal deficiencies and avoidance of toxicity from excess intake. Although trace-metal deficiencies have been commonly reported in patients dependent on prolonged parenteral nutrition, this chapter will focus on trace-metal toxicities associated with inadvertent excess concentrations of, or adverse reactions to, parenterally delivered trace metals.

3.3.1 Iron

Anaphylactic reactions have been reported following administration of iv iron dextran (Kumpf, 2003). Although the occurrence risk is low, the reaction can be severe. Therefore, a test dose is recommended prior to infusion of therapeutic iron dextran. Routine addition of iron to parenteral nutrition solutions is not recommended. Intravenous iron may worsen infection risk. Moreover, iron should not to be used in lipid-containing solutions because trivalent cations (Fe^{3+}) can destabilize lipid emulsions. Iron dextran has, on occasion, been added to lipid-free parenteral nutrition solutions, but iron overload is a risk, requiring periodic

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

monitoring. An alternative to iron dextran is iron citrate, which does not carry the same risk of adverse reactions.

3.3.2 Chromium

Chromium is an essential trace metal important in glucose tolerance and lipid metabolism (Leung and Galbraith, 1995). Chromium deficiency during prolonged TPN is well documented. It causes hyperglycaemia and glycosuria, impaired growth and negative nitrogen balance. The current recommendation for chromium supplementation to TPN is $0.2\,\mu g\,kg^{-1}\,day^{-1}$ for paediatrics patients and $10–15\,\mu g\,day^{-1}$ for adults. This amount may exceed that required for sufficiency in neonates. Oral chromium is poorly absorbed; breast fed infants receive only $0.05\,\mu g\,kg^{-1}\,day^{-1}$. Chromium is excreted primarily via the urine. Therefore, reduction in dosage may be required in the face of renal dysfunction.

Chromium is a known contaminant of crystalline amino-acid solutions and chromium as a contaminant may provide amounts in excess of recommendations. Elevated chromium is associated with mutagenesis and carcinogenesis. The long-term use of multiple trace-element products at recommended doses has also been associated with excessive serum concentrations of chromium. Chromium was found in high concentrations in up to 94% of 382 patients on short-term TPN (Leung and Galbraith, 1995) with approximately 50% having serum levels greater than 10-fold of normal. The source of excess chromium was found to be the amino-acid solution. Elevated chromium levels have been reported in TPN patients in Germany, the United Kingdom and the United States (Leung, 1995). Chromium excess has also been reported in children receiving TPN contaminated with chromium from amino acid and phosphate additives (Moukarzel *et al*., 1992; Bougle *et al*., 1993). It has been suggested that chromium supplements may not be needed in routine TPN administration. Further study is required to determine the effects of high concentrations of chromium during prolonged parenteral nutrition.

3.3.3 Copper

Copper is an essential constituent of many enzymes, including the important antioxidant enzyme, Cu-Zn superoxide dismutase and cytochrome oxidase, the terminal oxidase in the electron transport chain. Normal copper levels and homeostasis are essential for normal growth and development, as demonstrated by the inborn errors of copper metabolism: Wilson's disease and Menkes disease. In Menkes disease, mutations in the ATP_7A gene results in generalized copper deficiency, neurological dysfunction and connective tissue disease. In Wilson's disease, mutations in the ATP_7B gene cause copper accumulation in the liver and copper overload. Wilson's disease has facilitated the recognition of copper as a highly toxic trace metal with significant oxidizing potential (Houwen, 2008).

Copper deficiency in patients receiving unsupplemented TPN is well documented and can cause neutropenia and anaemia unresponsive to iron therapy (Leung and Galbraith, 1995). In infants, copper deficiency also causes osteoporosis and delayed bone growth. Copper toxicity is rare, but can be seen in infants on parenteral nutrition who also have liver disease, as 80% of copper is eliminated via biliary excretion. Excess copper intake is thought to contribute to liver cirrhosis. Current TPN recommendations call for $20\,\mu g\,kg^{-1}\,day^{-1}$ for preterm and term infants with normal biliary excretion and 0.5–1.5 mg daily in adults. Higher amounts may be needed in patients with excess gastrointestinal losses. Copper should be withheld when hepatic cholestasis is present.

3.3.4 Manganese

Manganese is an essential metal required for normal growth, development and cellular homeostasis. However, exposure to high manganese concentrations can result in manganese deposition in the brain and an irreversible psychological and neurological syndrome known as manganism. Manganism, which clinically resembles Parkinson's disease, is associated with destructive symmetric lesions in the globus pallidus, substantia nigra, subthalamic nucleus and, to a lesser extent, in the caudate and putamen.

In adults, the concentration of manganese in the diet is known to influence the amount of manganese absorbed from the gastrointestinal tract and the amount eliminated in the bile. When dietary manganese levels are high, adaptive changes reduce gastrointestinal absorption of manganese, enhance manganese liver metabolism and increase biliary excretion of manganese (Britton and Cotzias, 1966; Davis *et al*., 1993; Dorman *et al*., 2001; Finley and Davis, 1999; Mahoney and Small, 1968; Malecki *et al*., 1996). Thus, despite large fluctuations in oral manganese intake, brain and other tissue manganese levels remain relatively constant. No formal recommended dietary allowance for manganese has been established, but the US National Research Council has established an estimated safe and adequate dietary intake (ESADDI) of $2–5\,mg\,day^{-1}$ for adults (Greger, 1998).

The earliest introduction of long-term parenteral nutrition for patients with intestinal failure was accompanied by morbidities due to inadequate replacement of micronutrients. Although evidence for the essentiality of manganese in humans is limited, guidelines for its inclusion in parenteral nutrition supplements were developed by the American Medical Association (1979) and the American Academy of Pediatrics, Committee on Nutrition (1985). However, it is important to note that there have been no reported cases of manganese deficiency in long-term parenteral-nutrition patients (Dickerson, 2001). Rather, recognition has been growing of hypermanganesemia and its associated complications in

patients receiving long-term parenteral nutrition. Patients with cholestatic liver disease are at particularly high risk for hypermanganesaemia because more than 90% of manganese is excreted through the bile (Malecki *et al*., 1996; Agency for Toxic Substances and Disease Registry (ATSDR), 2000).

The published literature cites a broad, 200-fold range for the recommended adult daily parenteral dose of manganese, from a low of 0.18–0.91 μmol (10–50 μg) to a high of 40 μmol (2.2 mg) (Aschner and Aschner, 2005). The ASPEN Task Force for the Revision of Safe Practices for Parenteral Nutrition recommends the addition of 60–100 μg daily manganese supplements to adult parenteral nutrition formulations (Mirtallo *et al*., 2004). In 1985, The American Academy of Paediatrics Committee on Nutrition recommended a manganese intake of 2–10 $\mu g\,kg^{-1}\,day^{-1}$ for exclusively parenterally fed preterm infants (1985). This became the standard of care throughout the USA and Europe, and has influenced the composition of currently available commercial multiple trace-element products. In 2003, the recommendations for manganese supplementation in parenteral nutrition for paediatric and neonatal patients were revised. The Pediatric Nutrition Handbook—5th edition recommends 1 $\mu g\,kg^{-1}\,day^{-1}$ American Academy of Pediatrics (2003). The 2004 ASPEN Special Report also recommends 1 $\mu g\,kg^{-1}\,day^{-1}$ for preterm neonates <3 kg and for term neonates 3–10 kg. However, this recommendation, like the 1985 recommendation, is not evidence-based.

It is believed that parenteral exposure poses a risk for manganese toxicity, since the bioavailability of manganese in parenteral fluids is near 100% (Dobson *et al*., 2004) and parenteral administration bypasses the normal regulatory mechanisms of the gastrointestinal track. Furthermore, many components of parenteral nutrition are contaminated with manganese, particularly KPO_4 (280 $\mu g\,l^{-1}$) and $MgSO_4$ (225 $\mu g\,l^{-1}$) (Kurkus *et al*., 1984; Hambidge *et al*., 1989; Wilson *et al*., 1992). Wilson *et al*. (1992) reported that the manganese content of parenteral nutrition solutions in the absence of trace element supplementation was 7.3 $\mu g\,l^{-1}$ (range 5.6–8.9 $\mu g\,l^{-1}$). Hambidge *et al*. (1989) recommended that manganese supplements be omitted from the parenteral nutrition solutions when there is evidence of cholestasis, concluding that the amount of manganese present as contaminant in intravenous solutions appears to provide adequate manganese in these patients.

Manganese intoxication has been reported in association with parenteral nutrition solutions providing ≥0.1 mg manganese per day, ~1.5–2.0 $\mu g\,kg^{-1}\,day^{-1}$ for an average adult (Ono *et al*., 1995; Nagatomo *et al*., 1999; Bertinet *et al*., 2000; Takagi *et al*., 2002). As with other forms of manganese poisoning, these patients developed elevated serum manganese levels and had symmetrical high-intensity T1-weighted magnetic resonance (MR) signals in the globus pallidus consistent with manganese accumulation at this site. Some patients demonstrated characteristic psychiatric symptoms and clinical signs of manganese-induced parkinsonism-like syndrome. Withdrawal of the manganese supplement from the parenteral nutrition significantly decreased manganese levels in both the blood and brain (Bertinet *et al*., 2000).

Data in children are more limited than in adults. Fell *et al*. (1996) reported 11 children on prolonged parenteral nutrition with hypermanganesaemia and cholestasis. In a child with a movement disorder, T1-weighted MR showed bilateral symmetrically increased signal intensity in the globus pallidus and subthalamic nuclei. Similar changes were seen in five other children, one with hypermanganesaemia and cholestasis, and four on long-term parenteral nutrition without liver disease, but with elevated manganese blood levels (Fell *et al*., 1996).

As a paramagnetic trace element, manganese can be detected by magnetic resonance imaging (MRI). Manganese deposition appears as a hyperintense signal (i.e. a shortened T1) in the basal ganglia, specifically the globus pallidus on T1- (short TE/short TR) but not T2- (long TE/long TR) weighted MRI. Other metals, such as copper and iron, do not manifest this appearance. There are numerous case reports in the literature of increased T1-weighted signal intensities in older children and adults exposed to prolonged parenteral nutrition (Mirowitz *et al*., 1991; Mirowitz and Westrich, 1992; Ejima *et al*., 1992; Dietemann *et al*., 1998; Mizoguchi *et al*., 2001). When blood manganese levels were measured in these patients, hyperintense T1-weighted signals in the basal ganglia were associated with elevated manganese levels. Discontinuation of manganese supplementation was associated with improvement in clinical symptoms and MRI findings.

It is standard clinical practice to supplement adult and pediatric patients receiving parenteral nutrition with a multiple trace-element solution containing a fixed ratio of zinc, copper, chromium and manganese. Sometimes selenium is added to this trace-element cocktail. The use of trace-element solutions with fixed ratios of multiple components limits flexibility that may be needed to regulate manganese intake (or that of other trace elements) under various clinical conditions, such as cholestatic liver disease.

There are growing concerns about potentially toxic manganese levels in neonates who require prolonged parenteral nutrition. Standard clinical practice in the United States includes the daily addition of the trace-metal supplement, Multitrace®-4 Neonatal (American Regent, Inc.), which contains 25 $\mu g\,ml^{-1}$ of manganese. This supplement is most often added at a dose of 0.2 $ml\,kg^{-1}$ or 0.2 $ml\ dl^{-1}$ of parenteral nutrition solution. For the infant receiving 150 $\mu g\,kg^{-1}\,day^{-1}$ of PN, this will provide an additional 5.0–7.5 $\mu g\,kg^{-1}\,day^{-1}$ of manganese. This amount is far in excess of the amount of manganese absorbed

DOI: 10.1002/9780470744307.gat053
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

by healthy infants on a diet of human milk. There are additional considerations that raise concern about manganese toxicity in the parenterally fed neonate. Not only is the absorptive control of the intestine bypassed in infants receiving manganese-supplemented parenteral nutrition, but the excretion of manganese is likely to be poor, as parenterally fed infants pass little or no stool and frequently develop overt evidence of hepatic dysfunction and cholestasis. The immature and more permeable blood–brain barrier of neonates confers a further risk of manganese-induced CNS toxicity during a critical stage of brain development. There have been sporadic cases in which children with excessive exposure to manganese have developed overt signs of neurotoxicity (Cawte, 1985; Fell *et al*., 1996; Woolf *et al*., 2002). Rodent studies suggest that neonatal animals, when compared to adult animals, are at an increased risk for manganese-induced neurotoxicity, based on their propensity to achieve higher brain manganese levels and altered brain dopamine concentrations following similar oral exposures (Chandra and Shukla, 1978; Kontur and Fechter, 1988; Pappas *et al*., 1997; Dorman *et al*., 2000). In monkeys and rats, a correlation exists between the severity of CNS symptoms and manganese brain concentrations, with both the rate and extent of manganese transport into the CNS influencing the clinical outcome (Suzuki *et al*., 1975; Roels *et al*., 1997). Tran *et al*. (2002) demonstrated that high dietary manganese intake in neonatal rats resulted in developmental deficits (Tran *et al*., 2002).

A reciprocal relationship between iron status and manganese uptake has been established. In the plasma, both metals are bound to albumin and transferrin, and both compete for the same carrier transport systems on endothelial cells (Mena *et al*., 1974; Aschner and Aschner, 1990; Aschner and Aschner, 1991; Erikson *et al*., 2002). Transport of manganese and iron to extrahepatic tissues, including the brain, occurs via transferrin-mediated endocytosis and via the divalent metal transporter 1 (DMT-1) (Chua and Morgan, 1997; Malecki *et al*., 1999; Erikson *et al*., 2002; Garcia *et al*., 2006). In the presence of low iron, both DMT-1 and transferrin receptors (TfRs) are up-regulated to maximize the body's ability to sequester iron; this also results in increased manganese transport. The converse is also true; in the presence of high levels of iron, DMT-1 and TfR levels are decreased, resulting in decreased manganese transport (Erikson *et al*., 1997; 2002; Andrews, 1999; Roth and Garrick, 2003). *In vivo, iv* ferric-hydroxide–dextran complex inhibits the net uptake of manganese across the blood–brain barrier and high iron-containing diets likewise reduce the concentration of manganese in the CNS (Diez-Ewald *et al*., 1968; Aschner and Aschner, 1990). Conversely, iron deficiency results in more manganese uptake into the brain, both in adults (Mena *et al*., 1974; Aschner and Aschner, 1990; Erikson *et al*., 2002; 2004) and in neonates (Garcia *et al*., 2006).

Worldwide, iron deficiency is the most prevalent nutritional deficiency, affecting over two billion people; infants are one of the most vulnerable populations. Iron stores in sick newborns are low. Iron-deficiency anaemia in this population is exacerbated by the lack of a safe preparation for parenteral iron supplementation, and by frequent phlebotomy losses. This problem is particularly acute in the premature infant as iron stores mainly accumulate in the foetus in the third trimester (Rao and Georgieff, 2002). Since iron and manganese use similar transport systems, it has been hypothesized that anaemic populations are more susceptible to manganese intoxication, even when exposed to low or normal levels of manganese. A significant gap in our knowledge exists with respect to the interaction between iron deficiency and manganese neurotoxicity. Specifically, the role of iron status in the distribution patterns and accumulation of manganese in the CNS in infants is unknown.

Unfortunately, published prospective studies or randomized, controlled trials of manganese supplementation in parenterally fed adults and children are entirely lacking. Given the anecdotal evidence of excessive blood and tissue levels of manganese in patients requiring prolonged TPN, such prospective studies are sorely needed. Target populations for such investigations include adults with hepatic disease, patients of any age with iron deficiency and neonates on prolonged TPN. Based on current knowledge of trace element homeostasis in health and disease, it seems likely that an individualized approach to trace-metal supplementation in parenteral nutrition patients is required. As noted by the 2004 ASPEN Special Report, 'The ratios of trace elements in commercially available paediatric multiple trace element products result in excessive intake of manganese if recommended doses of zinc are given. It is clear that micronutrient requirements for children receiving parenteral is a fertile area for research and an area in which further commercial product development is required' (Mirtallo *et al*., 2004). There is a need to better define the safe and effective dose of parenteral manganese and to identify practical methods for assessing tissue stores in patients requiring long-term parenteral nutrition (Dickerson, 2001; Erikson *et al*., 2007).

Peroral Toxicity

William J. Brock

CONTENTS

1 INTRODUCTION

Every day humans are exposed to a multitude of chemicals. Humans are impacted by those exposures, either adversely or beneficially or even without a health outcome. Oral exposure represents the principle route of exposure to substances for humans. Each day we consume foods that contain a plethora of chemicals deemed to be safe. However, there are many reports in the scientific literature and in the lay press that suggest that exposure to some substances, including microorganisms, represents a potential for adverse health outcomes. In 2007, there were reports in the lay press about an increase in lead exposure to children from toys manufactured in China, and even our pets were at risk for kidney toxicity and subsequent lethality from a contaminant in pet foods being imported into the United States. Exposure to pharmaceuticals has led to an increased risk of cardiovascular effects, liver toxicity and other toxicities that had not been revealed in either preclinical studies or controlled clinical studies. The occurrence of toxicity has led to product withdrawals and in some cases litigation. Hence, assessing the potential for adverse health effects in humans, an understanding of the similarities in absorption and the physiology of systemic distribution and metabolism of these agents in animals is of prime importance. Changes in regional blood flow to the gastrointestinal tract, the presence of food and nutrients, as well as disease states will all have some influence on the degree of absorption and the biological fate of the agent. Therefore, a great deal of time and energy has been devoted to furthering our knowledge relative to *in vitro* and *in vivo* models used in toxicological assessment of environmental and therapeutic agents.

In this chapter, we will examine the role of oral exposures in the potential for systemic toxicity, mechanisms involved in absorption from the gastrointestinal tract and local toxicity associated with oral administration.

2 CELLULAR ENVIRONMENT OF THE GASTROINTESTINAL TRACT

The gastrointestinal tract is a tube open to the environment with absorption occurring along the entire length.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat054
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The extent of absorption is dependent on a variety of factors, as described below, but the epithelial lining, regional blood flow along the 'tube' and the local environment within the lumen will influence absorption. Epithelium lines the entire gastrointestinal tract, although specialized cells will be present in certain regions of the gastrointestinal tract. The structure of the epithelial cell with its highly developed involutions leads to a greater surface area for absorption.

The cellular lining of the buccal cavity and oesophagus provides opportunities for the absorption of potentially toxic compounds. The circulatory drainage of the buccal cavity, the mouth and the tongue is to the jugular vein and hence xenobiotics directly enter the general systemic circulation thereby bypassing the hepatic-portal loop. Indeed, absorption from the buccal cavity has long been recognized as a way to achieve high therapeutic levels quickly, and has been an advantageous route for administration of nitrites for treatment of cardiovascular disorders, for example, angina. In addition, a number of investigators have examined buccal absorption of insulin as a means of treatment for diabetes (Oh and Ritschel, 1990; Hoffman and Ziv, 1997; Chetty and Chien, 1998). However, this route has not yet proven to be completely efficacious, but continues to be the subject of research for a variety of drugs and over-the-counter (OTC) preparations, for example, steroids, anti-inflammatory agents, and so on.

The oesophagus serves as the pipeline for delivery of substances to the stomach. The cellular structure of the oesophagus is composed of a stratified squamous epithelial lining with varying degrees of keratinization dependent on the diet of the animal species. Rodents and primates (omnivores) will have a greater degree of cellular keratin compared with rabbits that are principally herbivores. The muscular layer of the oesophagus is composed of striated muscle or a combination of striated and smooth muscle. Animals with more striated muscle partially explains why certain species do not vomit, for example, the rat, in contrast to animals that regularly vomit (dog and guinea pig) because of the greater amount of smooth muscle.

The stomach of an animal represents arguably the most important structure when considering oral administration of substances. The cellular structures and functions of the stomach, local pH and bacterial environments, as well the presence or absence of food will have dramatic effects on local toxicity, as well absorption of nutrients and a wide variety of xenobiotics. In the rodent species, for example, the nonglandular stratified squamous epithelium is adjacent to a cardiac (fundic) portion of the stomach. The two areas of the stomach are separated by a limiting ridge. The nonglandular portion serves for food storage. The cardiac portion of the stomach is proximal to the oesophagus. Acid secretion is stimulated by histamine (H_2 receptors) and by acetylcholine (M_3 muscarinic receptors). The H_2 receptors increase intracellular cyclic adenosine monophosphate (cAMP), and the muscarinic receptors and the gastrin receptors exert their effects by increasing intracellular free calcium. Gastrin also acts by stimulating the secretion of histamine from enterochromaffin-like cells (ECL cells). Vesicle- and granule-containing cells are the predominant endocrine cell types in the acid-secreting portion of the stomach.

The cellular make-up of the fundic portion of the stomach is comprised of numerous specialized cells. Parietal and chief cells function to secrete pepsinogen and hydrochloric acid and serves to create the acidic environment of the stomach. Mucoid cells, as the name implies, secrete mucous into the lumen of the stomach and help preserves the cellular integrity of the stomach from the corrosive action of hydrochloric acid. Also present in the stomach are enteroendocrine cells that serve to secrete various endocrine substances including histamine, serotonin, gastrin and other inflammatory mediators. In general, these cellular structures also appear within the cardiac portion of the stomach. Sato (2007) recently described tuft cells, also known as brush cells, as a widespread cell type found in the digestive tract. The most characteristic morphological features of these cells are their long and blunt microvilli. Although the function of tuft cells is not yet completely known, these cells seem to possess the cellular and molecular basis for chemoreception. Interestingly, these cells also have been characterized in the gallbladder and respiratory tract of various species.

The intestinal tract makes up the longest structure of the gastrointestinal tract and serves primarily for the absorption and secretion of nutrients. A comparison of the length of the intestine of rat and human certainly shows the human intestine to be longer. However, the length of the intestine relative to the entire length of the gastrointestinal tract reveals that the rat and human are similar, that is, the intestine makes up about 81–83% of the gastrointestinal tract (**Table 1**). Furthermore, it is this section of the gastrointestinal tract that functions in the metabolism of endogenous and exogenous compounds, either from cellular enzyme systems of the intestinal tract or from bacterial action on compounds. Morphological aspects of the intestinal tract result in an increase in the functional capacity of the small intestine, including its length, villi and microvilli. These latter characteristics will influence the mucosal surface area, thereby resulting in changes in transit time of a compound through the gastrointestinal tract. Transit time through the intestinal tract usually occurs within a few hours compared to a much longer duration within the stomach and colon.

An osmotic gradient of ion and water transport occurs, with differences in functional capacity occurring between the duodenum and the jejunum. In the duodenum passive movement of sodium and water is from the lumen into systemic circulation. In contrast, fluid and sodium movement of fluid and ions occurs from systemic circulation

Table 1 Absolute and relative length of small intestine in humans and animals[a]

Species	Region	Absolute length (cm)	Relative length (%)
Human	Small intestine	680	81[b]
	Duodenum	25	4[c]
	Jejunum	260	38
	Ileum	395	58
Rat	Small intestine	125	83
	Duodenum	9.5–10	8
	Jejunum	90–135	90
	Ileum	2.5–35	2
Pig	Small intestine	182	78
Dog	Small intestine	414	85
Rabbit	Small intestine	356	61

[a]Modified from DeSesso and Jacobson (2001), Kararli (1995).
[b]Value is relative to the entire length of gastrointestinal tract.
[c]Value is relative to region of the gastrointestinal tract, for example, small intestine.

into the lumen of the jejunum. Net secretion occurs in the ileum and jejunum of guinea pigs, the ileum of rabbits and the proximal portion of the jejunum in neonatal swine. The jejunum absorbs sodium, chloride and bicarbonate against an electrochemical gradient, but this decreases with animal age. Bile salts are primarily absorbed from the ileum.

The cells lining the mucosa of the small intestine are composed of simple columnar epithelium on the villi and cuboidal epithelium in the crypts. Intestinal cells secrete fluids and electrolytes, but these secretions are then reabsorbed by intestinal villus cells. Enterocytes absorb simple carbohydrates and amino acids and then actively transport them into systemic circulation. Transport of electrolytes across epithelial cells occurs by multiple mechanisms, including passive ionic diffusion and energy-dependent active transport.

Goblet cells are present throughout the intestine, with the numbers of cells increasing through the distal end of the intestine. Paneth cells containing lysozymes also are present in the intestinal tract and are found in monkeys, mice, rats, hamsters and guinea pigs, but not in dogs or swine. Paneth cells secrete mercury and other heavy metals into the intestinal lumen and become necrotic in chronic, for example, methyl mercury, intoxication of primates. Phagocytic M cells are located on the epithelium overlying the lymphoid tissues and serve to transfer antigen material from the intestinal lumen to the immune system. In addition, M cells engulf pathogenic microbes and foreign particulates.

The circulatory pattern of the gastrointestinal tract is an important consideration when extrapolating toxicological data obtained from oral toxicity studies to other routes of exposure, as well as assessing the risks associated with oral administration of xenobiotics. Arterial blood is supplied by a number of arteries, but it is the venous circulation that becomes important for toxicology, particularly for 'first-pass' hepatic metabolism. All portal vein blood empties into the sinusoids of the liver. Hence, all material absorbed from the lower portion of the oesophagus to the proximal end of the rectum are cleared to the liver prior to entering the general systemic circulation. Substances metabolized by the liver can potentially reappear in the gastrointestinal tract (enteroheptic circulation) leading again to absorption, further metabolism and even bioactivation by metabolic enzymes present in the gastrointestinal tract (see **Toxicokinetics of Xenobiotic and Metabolite Distribution and Excretion**).

3 MECHANISMS OF ABSORPTION OF XENOBIOTICS

The gastrointestinal system should be viewed as a long tube that is open to the outside environment, with absorption occurring across the entire length of the gastrointestinal tract. The cellular make-up of this system has been described above, but because of this cellular environment the surface area available for absorption of xenobiotics is quite large. Absorption can occur by a several processes, and these are the same processes as for absorption of nutrients. Furthermore, absorption of xenobiotics is dependent on the molecular size of the compound and the microenvironment of the gastrointestinal lumen, as well as the lipophilicity of the agent, that is, the greater the lipid solubility of the agent the greater potential for absorption. Absorption of xenobiotics and nutrients from the gastrointestinal tract occurs primarily by passive diffusion or active transport. Other means of absorption, however, include filtration, facilitated transport, pinocytosis, and so on.

Although the cellular structures are important in absorption of substances, for example, nutrients, these

Table 2 pH of contents in different regions of the gastrointestinal tract[a]

Species	Stomach		Small intestine			Colon
	Anterior	Posterior	Duodenum	Ileum	Jejunum	
Human	1.5–3.5		5–7	6–7	7	5.5–7
Monkey	4.8	2.8	5.6	5.8	6.0	5.1
Dog	5.5	3.4	6.2	6.2	6.6	6.5
Pig	4.3	2.2	6.0	6.2	6.9	6.8
Rabbit	1.9	1.9	6.0	6.8	7.5	7.2
Rat	5.0	3.3	6.5	6.7	6.8	6.6
Guinea pig	4.5	4.1	7.6	7.7	8.1	6.7
Mouse	4.5	3.1	—	—	—	—

[a]Modified from Kararli (1995).

structures also serve as barriers to impede the potential absorption of molecules, thereby serving to protect the host. In simple diffusion, molecules cross the membranes of the epithelial cells, but first must partition from the gastrointestinal fluid adjacent to the membrane, termed the unstirred water environment, and then cross the mucus layer coating the membrane before crossing the lipid membrane into the cell. The molecule must pass through the cytoplasm and then through the basement membrane and the capillary or lymphatic wall membranes. The lipid membrane favours absorption of hydrophobic species, thereby accounting for the greater absorption rate of un-ionized species, although absorption of ionized forms of a molecule may be absorbed to a limited degree most likely due to the microenvironment at the cellular interface. The process of diffusion is related to the concentration gradient across the membrane. The fluid content of the gastrointestinal tract, innervations of the tissues and blood flow to the tissues will influence the rate of absorption.

The intestine can absorb vast quantities of fluid from the intestinal lumen to maintain normal homeostasis. Greater than 98% of consumed fluid is absorbed. The balance between absorptive and secretory processes is a highly regulated process. Disruption of these integrated processes can result in disease states or conditions that can result in excessive fluid secretion. Under certain conditions, the secretory function can exceed the absorptive function leading to diarrhoea and loss of fluid. An extreme example has been noted in cholera patients where fluid loss can be up to 20 l per day (Montrose *et al*., 2003). In the stomach, about 2500 ml of gastric juice is secreted daily, and contains a variety of substances, for example, ions, gastric enzymes, and so on. The hydrochloric acid secreted by the gastric tissue kills ingested bacteria, provides the necessary pH for pepsin to start protein digestion and stimulates bile flow. The mucosal cells of the stomach secrete HCO_3^- to maintain a pH gradient of pH 1–2 at the luminal side to pH 6–7 at the surface of the epithelial cells. The pH within the gastrointestinal tract will also depend on the type of food consumed, and there will be a difference in the pH of the lumen depending on whether the measurements were made on an empty stomach, for example, or the measurement is taken of the contents (**Table 2**).

Implicit in the foregoing discussion is the absorption of substances in the 'normal' homeostatic state. Disruption of normal gastrointestinal homeostasis potentially will affect the absorptive environment of the gastrointestinal tract for drugs and nutrients. Indeed, under some circumstances, disease states of the gastrointestinal tract can affect viability and survival. Anand *et al*. (2007) described a disease state of preterm infants, necrotizing enterocolitis, which results in multiple organ failure and death principally related to the degeneration of the gastrointestinal tract thereby leading to gastrointestinal pathogens invading the body, termed bacterial translocation. Although somewhat of an extreme example, a disease state, whether chronic (Crohn's disease) or acute (the 24-hour gastrointestinal 'bug') will have an effect on absorption. Indeed, in the latter case antiemetics are given, for example as a suppository to help relieve symptoms.

3.1 Passive Diffusion

Permeation of xenobiotics across biological membranes occurs primarily by diffusion with absorption into systemic circulation dependent on the concentration gradients across the gastrointestinal epithelium. Small molecules of molecular weight less than 600 are readily absorbed across the epithelia through aqueous pores within the membrane, whereas larger molecules are absorbed across the gastrointestinal epithelium based primarily on the physiochemical properties of the agent, for example, hydrophobicity. The degree of gastrointestinal absorption tends to increase with an increase in hydrophobicity.

Estimation of absorption has historically been associated with an assessment of the octanol–water partition coefficient, log P, and is the log of the equilibrium ratio,

Benzoic acid	1.90
Trichloroethylene	2.61
1,4-Dichlorobenzene	3.40
Phenanthrene	4.50
Vitamin A	5.68
Dichlorodiphenyltrichloroethane (DDT)	6.20

K_{ow}, of the solute concentrations in the two phases:

$$K_{ow} = \frac{[\text{solute}]_{oct}}{[\text{solute}]_{w}} \quad (1)$$

High positive values of log *P* indicate very lipid soluble compounds that can readily traverse biological membranes (**Table 3**).

Absorption across biological membranes is also based on the ionization of the molecule as many compounds are organic acids or bases. The ionized form of the molecule will be more water soluble and less likely to be absorbed, although some absorption will occur through aqueous pores. In contrast, the unionized form of the molecule will have greater absorption with the limit of that absorption, being based on molecular size and lipid solubility, as noted above. The degree of ionization is dependent on the pK_a and pH of the solution according to the Henderson–Hasselbalch equation. This basic principle of ionization that we learned in introductory chemistry was that the pK_a is the ratio of the concentration of the un-ionized form of the molecule to the concentration of the ionized form of the molecule:

$$\text{For acids} : pK_a - \text{pH} = \log\frac{[\text{unionized}]}{[\text{ionized}]} \quad (2)$$

$$\text{For bases} : pK_a - \text{pH} = \log\frac{[\text{ionized}]}{[\text{unionized}]} \quad (3)$$

As the acidic pH of the stomach is encountered, organic acids would be largely unionized and readily available for absorption. For example, benzoic acid (pK_a 4) is about 50% ionized at stomach pH. As the compound moves into the small intestines, the local pH increases to about 7, so that the molecule becomes largely ionized. For organic bases, the opposite occurs. At low pH, an organic base is largely ionized, with very little of the compound available for absorption, whereas within the intestines, the degree of ionization declines and absorption potential increases.

3.2 Active Transport

Although a majority of xenobiotics will be absorbed across the gastrointestinal epithelium by simple diffusion, a number of compounds, including many nutrients, are absorbed via active transport mechanisms. Active transport is the movement of a molecule across a membrane that is driven by energy in the form of expenditure of adenosine triphosphate (ATP) and against a concentration gradient. In addition, specific transport proteins are often found that facilitate transport so that even large molecules can be moved across the membrane. Therefore, active transport results in greater concentrations of compounds within the cell. Indeed, active transport of compounds into the cell becomes particularly important when structurally related toxicants, such as 5-fluorouracil, compete for the transporter proteins. This competition can be used for therapeutic benefits.

In the last decade or more, a great deal of research has been reported on various protein transporters. Intestinal transporters can be classified as either influx or efflux (Hurst *et al*., 2007; Kunta and Sinko, 2004). The influx transporters are expressed throughout the intestine, although there are regional differences in levels of expression. Examples of different transporters with some examples of substrates are shown in **Table 4**. The reader is referred to the excellent review of transporters by Bleasby *et al*. (2006) who demonstrated, using *in silico* preparations, variations in species of the transporters as well as tissue distribution. In addition, the publication by Wagner *et al*. (2001) provides a thorough review of transporters, substrates and effects of foods and other factors on drug absorption and elimination. Although a complete description of all intestinal transporters is beyond the scope of this chapter, numerous intestinal transporters have been described in the literature each with its own specificity for nutrients and xenobiotics. Clearly, inhibition of these transport mechanisms or competitive inhibition with xenobiotics can potentially lead to toxicity that will be expressed in various tissues. In some pharmaceutical applications, knowledge of these transport mechanisms may lead to therapies, including treatment for obesity.

The multidrug resistant protein (MDR) was one of the first family of protein efflux transporters identified. This transporter was found to transport chemotherapeutic agents out of gastrointestinal cells, as well as cells of other organs. Other gastrointestinal transporters that have been identified include nucleotide transporter (NT), divalent-metal ion transporter (DMT) and peptide transporter (PEPT). Absorption of xenobiotics may be

Table 4 Examples of gastrointestinal influx and efflux transporters

Transporter	Regional expression	Substrates	References
Influx Transporters			
Di/tripeptides (PEPT1)	Small intestine	Angiotensin converting enzyme inhibitors; β-lactam; penicillins	Friend (2004), Katsura and Inui (2003), Oh *et al*. (2002)
Organic anion-transporting polypeptides (OATP1A2; OATP1B1; OATP1B3)	Small intestine (apical membrane of villi enterocytes)	Fexofenadine; taurocholic acid; oestradiol 17-β-glucuronide; pravastatin	Glaeser *et al*. (2007), Katsura and Inui (2003)
Fatty acid translocase (FAT; CD36)	Proximal small intestine (apical membrane of villi enterocytes)	Long-chain fatty acids; cholesterol	Nassir *et al*. (2007), Baillie *et al*. (1996), Poirier *et al*. (1996)
Concentrative nucleoside transporters (N1, N2, N3)	Intestine with maximal transport in jejunum	Pyrimidine and purines	Pastor-Anglada *et al*. (2007)
Sodium-dependent bile salt transporter, ASBT (SLC10A2)	Ileum	Bile acids	Groen *et al*. (2007)
Efflux Transporters			
P-glycoprotein (P-gp)	Stomach, jejunum, ileum, colon	Anticancer drugs; digoxin; glucuronide conjugated drugs; ketoconazole	Yokooji *et al*. (2007), Thiebaut *et al*. (1987), Bleasby *et al*. (2006), Canaparo *et al*. (2007)
Breast cancer resistance protein (BCRP)	Intestine	Topotecan; glucuronide conjugated drugs	Wagner *et al*. (2001), Suzuki and Sugiyama (2000)
Multidrug resistance-associated protein (MRP)	Duodenum, colon	Anticancer drugs; digoxin; phase II conjugated drugs	Cao *et al*. (2006), Doherty and Charman (2002), Wagner *et al*. (2001)

increased from what would be predicted based solely on physiochemical properties, for example, K_{ow}, if the substance is a potential substrate for the influx transporters. Efflux transporters, in contrast, are able to function as an absorption barrier.

The jejunum of the human is a region of the intestinal tract with the highest levels of protein carriers and surface area (Lennernas, 2007). Human jejunal permeability (P_{eff}) is a useful determinant for approximating the fraction of oral dose absorption. As reviewed by Lennernas (2007), intestinal P_{eff} are often based on multiple parallel transport processes. Site-specific jejunal P_{eff}, however, do not reflect the permeability along the entire intestinal tract, but are useful for approximating the fraction oral dose absorbed. A jejunal P_{eff} value of $>1.5 \times 10^{-4}$ cm s^{-1} suggests that a substance will be completely absorbed no matter which transport mechanism is utilized. Moreover, jejunal P_{eff} determined for drugs transported mainly by active carriers may be predictive of the fraction absorbed.

Nassir *et al*. (2007) characterized the regional absorption of fatty acids and cholesterol in enterocytes isolated from transgenic and wild-type species. They reported on the transporter CD36, a membrane protein that is expressed in the intestine on the luminal surface of enterocytes. CD36 null ($CD36^{-/-}$) mice exhibit impaired chylomicron secretion, but no significant changes in lipid absorption. In addition these authors reported CD36 levels decreased from the proximal (duodenal) to distal (ileum) regions of the intestine. Moreover, enterocytes isolated from the small intestines of CD36 knockout mice, when compared with wild-type counterparts, exhibited reduced uptake of fatty acid and cholesterol in the proximal end of the intestine. These authors concluded that proximal intestinal absorption of dietary fatty acid and cholesterol is based on CD36 expression, whereas absorption of these nutrients is independent of CD36 expression.

Like that of fatty acids, an ileal transport protein has been described by Groen *et al*. (2007) and others (Kanda *et al*., 1996; Grober *et al*., 1999), and these authors have suggested that inhibition of this transport protein may contribute to reduced bile acid absorption potentially leading to reduced bile flow. The intestinal bile

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat054
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

acid-binding protein (I-BABP) is a cytosolic protein that binds bile acids with a high affinity with its expression restricted to the ileum where it is involved in the enteroheptic circulation of bile acids. Groen *et al*. (2007) further showed that in wild-type and Atp8b1$^{G308V/G308V}$ mice (mouse model of cholestasis), intestinal taurocholate absorption was mediated by the ileal bile salt transporter ASBT (sodium-dependent bile acid salt transporter). However, no difference in the ileal protein expression of ASBT was noted between these two strains, suggesting that increased plasma taurocholate is not related to increased intestinal bile salt absorption.

Cellular efflux pumps such as P-glycoprotein (P-gp) serve as possible defence mechanisms and also influence the bioavailability and disposition of xenobiotics (Zhang and Benet, 2001). P-gp is a plasma membrane-bound drug efflux protein found primarily in drug eliminating organs and presumably functions as a detoxifying transporter because it actively extrudes xenobiotics from the body (Ambudkar *et al*., 1999). In the small intestine, P-gp has been localized to the apical membrane of the intestinal epithelial cells (Thiebaut *et al*., 1987), consistent with a role in efflux of compounds into the intestinal lumen. Pharmacokinetic studies of paclitaxel, digoxin and cyclosporine A in knockout mice have revealed the importance of intestinal P-gp in limiting the oral bioavailability of these drugs (Schinkel *et al*., 1995; Sparreboom *et al*., 1997).

In humans, intestinal P-gp contributes to the variability in the pharmacokinetic properties of cyclosporine A (Lown *et al*., 1997) and tacrolimus (Hashida *et al*., 2001; Fukatsu *et al*., 2001) of organ transplant patients. There also is evidence that these systems can be up-regulated by environmental xenobiotics. Lecoeur *et al*. (2006) analysed the ability of diazinon to act as an efflux modulator in human Caco-2 cells and concluded that following repeated oral exposure, diazinon increased P-gp expression and activity. This suggests the involvement of P-gp in the transfer of diazinon that may have potential consequences for xenobiotic interactions.

Absorption from the colon has a clear benefit in certain disease cases, and has long been recognized as means to avoid first-pass liver metabolism. The degree of absorption depends on many factors, and this route has proven useful for many therapeutic agents. Calcagno *et al*. (2006) compared the gene expression of the Caco-2 cell line to normal colon to determine if this cell line would be predictive of colonic absorption. These investigators found that the gene expression pattern of the cell line closely patterned the transporter profile of normal colon, but was distinctly different from tumour samples. Hence, colonic drug absorption will parallel normal colon. However, as noted previously, caution needs to be exercised when attempting to predict absorption in various disease states, for example, colon cancer.

3.3 Filtration

Passage of small solutes can occur with movement of water through pores and tight epithelial junctions within the gastrointestinal tract. Transport of molecules with molecular weights less than 200 would be carried through by the hydrostatic forces of water—'solvent drag' (Blanchard, 1975). Although filtration is more common in the kidney, it can occur to a limited extent in the gastrointestinal tract, for example, calcium absorption.

3.3.1 Facilitated Diffusion

Facilitated diffusion is a carrier-mediated process of absorption similar to active transport. However, absorption does not occur against a concentration gradient, thereby distinguishing this process from active transport. Furthermore, facilitated diffusion does not require the expenditure of cellular energy and is not subject to inhibition by cell poisons.

The transport of glucose into the cell occurs with the Na^+-K^+ pump, which generates an Na^+ gradient across the cell membrane. The glucose-Na^+ symport protein uses this Na^+ gradient to transport glucose into the cell. In the gastrointestinal tract, cells take in glucose and Na^+ from the intestine and transport them through the cell into the blood stream by the Na^+-glucose transporter, glucose permease (a glucose-facilitated diffusion protein) and Na^+-K^+ pumps. A similar mechanism for glucose transport occurs in the central nervous system.

Morgan *et al*. (2007) proposed a jejunal facilitated transport mechanism of glucose absorption. In this model, the authors proposed that intestinal absorption occurs by the sodium-dependent glucose cotransporter, SGLT1, which causes insertion and activation of a high-affinity facilitated-transport glucose transporter (GLUT2). These authors showed that perfusion of calcium-depleted rat jejunum with glucose and the calcium-channel blockers nifedipine and verapamil, reduced GLUT2, but not SGLT1, suggesting that dietary sufficiency may mediate a significant pathway of glucose-stimulated calcium uptake and that luminal supply of calcium is necessary for GLUT2-mediated glucose absorption.

3.4 Pinocytosis

Cells have the ability to transport macromolecules (proteins, polysaccharides, polynucleotides) to their interior through endocytosis, a broad term that includes phagocytosis and pinocytosis. Phagocytosis is the process of enveloping a particle by modifying its membrane to form a phagosome around the particle. Phagosomes are then pulled by cytoskeleton motion of the cytosol into one or more lysozymes for digestion of the particles.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat054
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

In contrast, pinocytosis transports liquid substances into the cell. Pockets occur in a given area of the cell membrane, capturing the liquid and forming vesicles that are then pulled by cytoskeleton motion into the cytoplasm. Pinocytosis may be selective or nonselective. Selective pinocytosis occurs in two stages. The liquid substance adheres initially to membrane receptors and then the substance is transferred to vesicles that leave the membrane surface and transport their contents into the cytoplasm. In nonselective pinocytosis, the vesicles envelop all the solutes present in the extracellular fluid.

Absorption of nutrient biomolecules occurs via this route and the disposition of particles, for example cadmium and ferretin are absorbed via this mechanism. Uptake of proteins via pinocytosis has been observed in neonatal rats, guinea pigs and rabbits (Leece and Broughton, 1973). Interestingly, immune complexes responsible for food allergies may be absorbed into systemic circulation by pinocytosis (Walker and Bloch, 1983; Sasser and Jarboe, 1980; LeFevre and Joel, 1977).

4 FACTORS AFFECTING GASTROINTESTINAL ABSORPTION

Normal physiological functioning of the gastrointestinal tract, for example food intake and bodily responses to food intake, can affect the systemic absorption of xenobiotics as well as nutrients. In addition, absorption into the systemic circulation from the gastrointestinal tract is affected by metabolism of the agent by intestinal microflora or metabolic enzymes present in the gastrointestinal epithelium. In addition to physiological effects, the chemical nature of substances administered will affect intestinal transport into systemic circulation, but also may affect the normal functioning of the gastrointestinal tract, for example, transit time.

Alternative routes of drug administration continue to be an area of intense research. However, the oral route remains the preferred route of drug administration. During the process of drug discovery, oral bioavailability is often a prerequisite when considering a candidate drug for further development with poor bioavailability often resulting in the rejection of a potential drug candidate and leading to higher product costs for drug development of alternative drugs, formulations and salt forms. Since each new candidate drug is expected to offer unique physicochemical characteristics, the study of its absorption and bioavailability marks a critical step in the development of a new drug.

4.1 Chemical Factors

Most pharmaceutical preparations are marketed as racemic mixtures, although the stereoselective preparations have become important in recent years as drug manufacturers have explored the use of stereochemistry in extending patent protection, for example with fluoroquinolone antibiotics and omeprazole, as well as examining differences in pharmaceutical activity. This 'chiral switching' has resulted in a number of drugs becoming available as both a single enantiomer and a racemic mixture. There are two principles in chiral drug development—*de novo* development of a single enantiomer or a switch from an existing racemic drug to one of its isomers in a pure form. Single enantiomer drugs are a rapidly growing proportion of new drugs, with about 20% of new drugs coming to the pharmaceutical market about 10 years ago, compared to almost 75% of the pharmaceuticals being single enantiomer drugs within the last few years (Agranat *et al*., 2002). 'Chiral switches' exploit single enantiomers of racemic mixtures and have become important in drug development portfolios. In recent years, comparability of biologics has emerged as an important area of development, with small differences in structure resulting in similar, or at times, significant differences in pharmaceutical activity and bioavailability.

Stereoisomers often have very similar physicochemical properties, so it is difficult to distinguish between them in achiral environments. As noted, however, in the body these stereoisomers can have very different effects. Drug absorption processes are likely to be stereospecific when mediated by carrier molecules. Passive diffusion is not, however, governed by such a specific mechanism. The importance of stereochemical aspects in considering the bioavailability of drug molecules has been well emphasized by Jamali *et al*. (1989) and Jamali (1992). Brocks *et al*. (1991) showed that following an oral dose of the racemic anti-inflammatory drug etodolac, the blood vs. time area under the curve (AUC) for the active *S*-etodolac was about 10-fold lower in plasma and synovial fluid than the inactive *R*-enantiomer. Although it is unclear why the differences existed, the authors postulated it may be due to stereoselective metabolism. In a subsequent study, these authors showed that the lower AUC in rat plasma of *S*-etodolac, compared to the *R* enantiomer, was related to a greater distribution to tissues, owing to a lesser degree of binding to plasma proteins and to a higher rate of glucuronidation (Brocks and Jamali, 1991).

In a similar example, propranolol enantiomers are stereoselective when high doses of the racemic drug are given by oral administration (Marier *et al*., 1998). At low oral doses, the kinetics of the propranolol enantiomers are identical, but at much higher doses the kinetics of the enantiomers are stereoselective, that is, the AUC for *S*-propranolol is greater than the AUC for *R*-propranolol. Propranolol enantiomer plasma-protein binding is not stereoselective. *In vitro* incubation of the individual enantiomers showed that the intestinal intrinsic clearance of *R*-propranolol is greater than that of *S*-propranolol. Tracy

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(1995) has reviewed a number of drugs that show stereoselectivity on pharmacokinetic and pharmacodynamic properties.

As described by Sabnis (1999), chemical complexes of interest in the pharmaceutical industry can be divided into three categories based on the energy of attraction between the components of the complexes: (i) covalently linked complexes, (ii) ionic complexes and (iii) inclusion complexes. Within the gastrointestinal tract, there will be minimal changes to a molecular complex held together by covalent bonds, although the metabolic capability of microorganisms within the cellular constituents of the gastrointestinal tract can readily metabolize substances (see below). Prodrugs can take advantage of the metabolic competency of the gastrointestinal tract as these xenobiotics are prepared by chemical modification of the drug by the addition of a labile moiety to improve the solubility, absorption or uptake by the target organ (Hussain *et al*., 1987; Lai *et al*., 1987; Hansen *et al*., 1992; Lokind and Lorenzen, 1996). Ionic complexes are held together by weak forces such that these substances will be generally labile and, therefore, susceptible to configurational changes in the structure. These interactions, referred to as 'soft' or 'dynamic', occur rapidly and can readily be reversed (Tsuchida, 1991).

Inclusion compounds, which form the third category of complexes, result more from the general architecture of the compound. In these cases, the constituents of the complex are 'trapped' in the open structure of another molecule to yield a stable arrangement. Examples of this would include cyclodextrins, as these compounds trap lipophilic drugs to form a complex having a comparatively more hydrophilic character (Albers and Muller, 1995). Cholestyramine also serves an example, as this compound can trap bile acids (Zhu *et al*., 1992).

As described above, pH and partition coefficients will have a great influence on systemic absorption of substances from the gastrointestinal tract. The importance of ionization in drug absorption is based on the observation that the nonionized form of the drug has a greater K_{ow} than the ionized form, which becomes of prime importance in determining the degree of membrane penetration (Navia and Chaturvedi, 1996; Sabnis, 1999). Therefore, the partition coefficient and its bioavailability are influenced by the structural changes brought about by the substitution of different chemical groups. Since an alteration in the chemical structure may affect the pharmacological activity, formation changes or examination of a prodrug are means to improve the bioavailability.

Lui *et al*. (1986) examined differences in stomach pH between humans and dogs, as the dog is often used to examine absorption pharmaceutics. In this investigation, pH was continuously recorded through the use of Heidelberg capsules that transmit data through a radio frequency transmitter. Gastric pH was significantly higher in dogs, compared to humans (**Table 5**). The authors suggested that the differences between dogs and humans were related to differences in gastric secretion and pancreatic bicarbonate secretion, with gastric secretion being lower in dogs and pancreatic secretion being higher in humans. Hence, it would be expected that dogs would have a greater gastric and intestinal pH. The implications of this difference could be that xenobiotic absorption may differ. However, the time–pH profiles for dogs and humans tend to be similar, such that absorption of compounds would not significantly differ. Clearly, where the pK_a of poorly soluble drugs falls within the range pH 5–8, there may be discrepancies between absorption in dogs and humans. The purest specimens of parietal cell secretion that have been obtained contain approximately 0.17 N HCl, with a pH as low as 0.87 (Montrose *et al*., 2003). The pH of the cytoplasm of the parietal cells, like that of other cells, is 7.0–7.2.

Table 5 Regional gastrointestinal pH values[a]

Region	Human	Dog	Rat
Stomach (lumen)	2.5	2.8	3.2–3.8
Duodenum	5–7.8	5–7.6	7.5
Jejunum	5–7	6.2–7.3	6.5–6.8
Ileum	7	6.6–7.9	7.1
Colon	7.5	6.5	6.5–6.6

[a]Adapted from Sutton (2004), Martinez *et al*. (2002), Davies and Morris (1993).

As previously discussed, the stomach contains cells responsible for acid secretion. The acidic stomach aids in the digestion of foods, as well as the absorption of xenobiotics and nutrients. Gastrin secretion is activated by the presence of food, whereas gastrin secretion is reduced during fasting because of the low pH of the stomach environment. Species differences in stomach pH exist, although the differences are not widely variable. As seen in **Table 5**, the difference in stomach pH between dogs and humans is not significant. Sutton (2004) showed some differences between dogs, rats and humans with respect to regional gastrointestinal pH.

4.2 Physiological Factors

A major factor that can affect absorption of xenobiotics and, hence, influence toxicity is transit time of substances through the gastrointestinal tract. When foods and other substances enter the intestinal tract, peristaltic action is triggered by distension of the wall in the intestine. The movement of substances from the stomach through the intestine to the rectum for elimination can take several days, although in normal circumstances this occurs within about 24 hours. Although the origin of these coordinated contractions is not well understood, they appear to be dependent on a combination of

[a]Adapted from Martinez *et al*. (2002).

internal rhythmic contractions and neural, paracrine and humoral factors. The presence of food increases motility through the gastrointestinal tract due to signals propagated throughout the enteric nervous system from the walls of the stomach. In addition, the presence of fats in the duodenum appears to trigger another mass peristaltic reflex. Protein-rich food leaves more slowly, and emptying is slowest after a meal containing fat. The rate of emptying also depends on the osmotic pressure of the material entering the duodenum. Since fats are particularly effective in inhibiting gastric emptying, some people drink milk, cream, or even olive oil before a cocktail party. The fat delays intestinal transport from the stomach where its absorption is slower. Hence alcohol enters the small intestine more slowly so that a sudden rise of the blood alcohol to a high level and consequent embarrassing intoxication are avoided. Fraser (1997) suggested that alcohol interacts with drugs and foods delaying their absorption and gastric emptying time. Therefore, it remains somewhat uncertain whether foods affect alcohol transit time or alcohol affects food transit time. Interspecies differences in fluid retention and solid material as a measure of transit time are shown in **Table 6**.

Measuring transit time has become, in certain cases, part of the safety pharmacology study programme for new pharmaceutical compounds. The description of the methods is very limited in the International Conference on Harmonisation (ICH) Guidance (ICH, 2000). However, in this study design, a 15% activated charcoal suspension is administered orally to fasted rats about 30 minutes after the oral dose of test article. The rats are subsequently euthanized, about 60 minutes after receiving the charcoal administration, and the intestines removed. The distance travelled by the charcoal as a fraction of the length of the intestine is measured, providing an indication of whether the test article had an effect on transit time relative to controls. Atropine and morphine, substances known to affect transit time, are usually included as a positive control substance. Harrison *et al*. (2004) suggested that this study design, which is most common, should be supplemented with the use of isolated cell systems, ligated segments of the intestine, and so on.

Another factor related to intestinal transit time is the relative length of the intestinal tract (see **Table 1**). Clearly, as the length increases, so too will the residence time. The intestinal tract of the dog is relatively short and simple compared to, for example, ruminant animals. Intestinal transit appears to be quite different, in a variety of ways, from movement through the stomach. The time taken by the material to reach the ileocaecal valve, once emptied from the stomach, is relatively consistent. Apparently, transit through the small intestine is less dependent on the size or state of the matter, and the presence of food does not influence the intestinal transit (Davis *et al*., 1986). Therefore, it is during intestinal transit that the maximum opportunity exists for drug absorption for most dosage forms.

The residence time for a dose taken on an empty stomach depends on the time of dosing relative to the occurrence of the 'housekeeper wave', the peristaltic action that moves contents from the stomach into the pylorus (Gleysteen *et al*., 1985). Langguth *et al*. (1994) studied the influence of various fasting-state gastrointestinal parameters on the variability in absorption of cimetidine in dogs. These authors found that gastric emptying increased the variability of cimetidine concentration in blood, affecting the pharmacokinetic profile of the drug. Lipka *et al*. (1995) reported similar results for celiprolol. Sababi and Bengtsson (2001) used an *in situ* model of intestinal motility using two animal anaesthetics that result in different intestinal motility patterns, that is, Rapinovet (propofol) displayed a migrating motor complex with Inactin (thiobutabarbital) showing more of a fed-like motility response. These authors found an increase in plasma of 3-methyl-glucose when the animals were anaesthetized with Inactin compared to the other anaesthetic.

Gastauer *et al*. (1979) reported on a sex-related difference in the bioavailability in dogs of different oral dosage forms of digoxin, with the drug more rapidly eliminated in female dogs. Gender-related differences in metabolism are well known. It is not clear from this publication what role metabolism within the gastrointestinal tract played in this difference.

Adusumalli *et al*. (1992; 1993) evaluated age and sex of the animal as possible factors that affect the bioavailability of dosage forms. In their studies, no sex-related differences in the pharmacokinetics of azelastine were observed. When comparing age-related differences, however, they observed a higher maximum systemic concentration of the drug (C_{max}) and a lower volume of distribution at steady state in young dogs (four to six weeks old), although the bioavailability was not affected. In contrast, when these investigators examined the pharmacokinetics of felbamate, they did see age-related differences in the bioavailability (Adusumalli *et al*., 1992). Gender- and age-related differences in intestinal metabolism and absorption of substances have been reported for ethanol (Thomasson, 1995). Jones (2003), however, suggested that there are insufficient data to conclude a gender difference, but that the lower volume of distribution in women explains sex-related

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

differences. In women, nickel absorption has been shown to be less than men (Nielsen *et al*., 1999).

More recently, Duan *et al*. (2006) reported that ageing enhanced cholesterol absorption by suppressing expression of the jejunal and ileal sterol ATP-binding cassette efflux transporters and up-regulating expression of the duodenal and jejunal sterol influx transporter, Npc1l1. In addition, these authors found that oestradiol treatment increased cholesterol absorption through intestinal up-regulation of these transporters. Doyle-McCullough *et al*. (2007) examined the intestinal uptake *in situ* of latex microparticles as a function of species, age and gender. These authors found that some parameters, species and gender, did not affect the extent of microparticle uptake, but that uptake varied with age, with uptake being significantly greater in young adult males (seven weeks) than in younger (three weeks) and older (17 and 52 weeks) age groups of animals. A lack of a gender effect on intestinal uptake also has been shown for naproxen and pilocarpine (Fagerholm *et al*., 2005; Omori *et al*., 2004). However, Bai *et al*. (2005) reported that men have a greater malabsorption of nutrients in coeliac disease, despite this disease being more common in women. Overall, therefore, gender differences have been observed with certain xenobiotics, but not with others, suggesting that generalities in gender differences related to intestinal transport or metabolism cannot be conclusively identified.

A number of investigators have examined jejunal and ileal absorption of compounds, as these segments of the gastrointestinal tract represent those areas where the greatest absorption occurs for pharmaceutical agents. Studies with Caco-2 cells, everted intestinal sacs and other membrane systems have been used to examine the active transport of xenobiotics (Berggren *et al*., 2004). In these studies by these investigators and others, the *in vitro* models were predictive of jejunal and ileal absorption of compounds such as digoxin, verapamil, bile acids, and so on. (Amelsberg *et al*., 1996; Johnson *et al*., 2003; Berggren *et al*., 2004). In a review by Bohlen (1998), the role of intestinal blood flow and other physiological factors, and cellular mechanism had an influence on intestinal absorption. Such a conclusion was similarly reached by Winne (1980) nearly 30 years ago.

4.3 Food Interactions

Food has long been recognized as a factor that influences the absorption of drugs, chemicals and other nutrients. Indeed, in routine acute oral toxicity testing of substances, fasting of animals is often utilized, as suggested by regulatory guidance. As alluded to throughout this chapter, foods can modify the absorption of substances, including other food substances, by changing dissolution, solubility and enhancing binding to food-containing materials, as well as changing gastric residence time, altering blood flow, and so on. In an extensive review of the subject, Singh (1999) classified drugs into categories of 'Decreased', 'Delayed', 'Accelerated', 'Increased' and 'Unaffected' in terms of the effects of foods on gastrointestinal absorption (**Table 7**).

The classification was based on an alteration of the maximum blood concentration ($C_{\max}$) and the area under the blood concentration and time curve (AUC) of the pharmaceutical. For 'Decreased' and 'Delayed' absorption, the author indicates that the extent of absorption is not affected, but the time course of absorption is changed. Whether such a change is due to a direct interaction of the food with the pharmaceutical or whether there is a delay in gastric emptying time from the stomach to the intestine appears to largely depend on the pharmaceutical. In contrast, drugs that show 'Accelerated' or 'Increased' absorption appear to be those with poor solubility. Furthermore, the altered absorption results from a greater gastric residence time allowing for an increased dissolution in the presence of, for example, bile acids. Overall, however, a majority of the drugs that Singh (1999) examined were 'Unaffected' by the coadministration of foods, with only a few drugs showing 'Accelerated' absorption in the presence of foods. Weber and Ehrlein (1998) also showed that gastric emptying time affects intestinal absorption. In their studies, carbohydrates were absorbed at a higher rate compared to fats and proteins, although there continued to be a large absorptive reserve within the intestine. Numerous authors have examined the role of foods and beverages on the absorption of drugs and nutrients, with the outcome of the research showing a great deal of disparity between the drugs and the food substances (Lee *et al*., 1997; Fraser, 1997; Kinoshita *et al*., 1996; Watkins *et al*., 1992).

The influence of foods on absorption has been recognized for many years. Dahan and Altman (2004), Palumbo *et al*. (2005) and numerous other authors (Lilja *et al*., 2004; Paine *et al*., 2004; 2005) have shown that grapefruit juice coadministered with drugs will alter the pharmacokinetics of some drugs due to an inhibition of cytochrome P450 3A4 in the small intestine. Wagner *et al*. (2001) showed that grapefruit juice resulted in about a twofold increase in the $C_{\max}$ of talinolol. The active ingredients in grapefruit juice, flavanols, appear to affect various gastric transporters for drugs and other substances with the multidrug transporter P-gp being the more characterized transporter (Wagner *et al*., 2001; Glaeser *et al*., 2007; de Castro *et al*., 2007). Edwards *et al*. (1996) also identified 6′,7′-dihydroxybergamottin, a furancoumarin in grapefruit juice, as a potent inhibitor of cytochrome P450 3A4 that also may be responsible for the altered pharmacokinetics of certain drugs.

Probably the most common example of food influencing the toxicity of a substance is with ethanol. Ethanol is completely absorbed from the gastrointestinal tract, with about 20% of an ingested dose being absorbed from

the stomach and the balance in the duodenum (Jones, 2003). Absorption of ethanol is significantly delayed when taken concurrently with a diet high in lipid content. Moreover, when the lipid diet is administered directly into the duodenum, ethanol absorption is delayed for several hours. The absorption of ethanol in the presence of food may occur because of binding to food particles, increase in local metabolism of ethanol or increased presystemic metabolism through the hepatic first-pass effect. What has clearly been demonstrated, however, is that ethanol ingestion on an empty stomach leads to a greater blood-alcohol concentration.

There is an abundance of literature on the effects of foods and dietary supplements on the bioavailability of drugs and chemicals. An online search using PubMed (*www.ncbi.nlm.nih.gov*) with the topic of foods and food-drug interactions returned well over 1000 references. In the previous edition of this book, Tyler (2000) described how the acute oral toxicity of various glycol ethers was modified in the fasted and fed state of rats and mice. In general, the toxicity (as measured by the LD_{50}) was greater in the fasted animal, a finding that is consistent with much of the literature for a lengthy list of substances. Hence, the impact of foods on the absorption of xenobiotics is clearly established. However, there are circumstances where the presence of food can have a negative or opposite effect, that is, decrease the absorption of substances. A classic example would be the binding of some antibiotics and other drugs, for example, tetracycline, mercaptopurine, levofloxacin, to the components of milk (Matsumoto *et al*., 2001; Jung *et al*., 1997; Amsden *et al*., 2003; de Lemos *et al*., 2007). The negative effect of food on absorption can be related to a number of mechanisms including chelation, adsorption of the drug to food, acid instability within the gastrointestinal tract, enzymatic hydrolysis of peptides, increased viscosity and, as described above, altered motility.

4.4 Xenobiotic Interactions

In addition to the influence of foods on gastrointestinal absorption of substances, a large number of publications are available on the effects of interactions between xenobiotics on absorption. Xenobiotic interactions may affect absorption by virtue of one substance altering the local environment within the gastrointestinal tract, affecting the metabolic competency of cellular enzymes, binding the other, altering motility, and so on.

Larsson *et al*. (1983) showed that omeprazole, picoprazole and cimetidine possess gastric antisecretory properties that may alter the bioavailability of a concurrently administered drug. Choi *et al*. (2004) demonstrated that coadministration of flavone enhanced the pharmacokinetics of paclitaxel, prolonging the half-life and increasing the AUC. The authors suggested that the alteration in the pharmacokinetics of paclitaxel was related to the inhibition of cytochrome P450 and the P-gp efflux pump. Similarly, Zhang *et al*. (2003) had previously suggested that Tween 80, a commonly used solvent for drug delivery, inhibits P-gp, resulting in an increased absorption of digoxin administered to rats.

Alterations in gastrointestinal absorption by inhibition of transporters or alteration of the metabolism of substances are clearly recognized as one means of enhancing or inhibiting absorption. However, other factors will be of importance, and include binding the substances to gastrointestinal contents, for example, as

described above for foods, or through chelation. *In vitro* studies by Tanaka *et al*. (1993), demonstrated that levofloxacin and other quinolones will bind to different aluminium salts, resulting in lower bioavailability. Similarly, Deppermann and Lode (1993) showed a significant decrease in bioavailability by aluminium-based antacids on ciprofloxacin, ofloxacin, norfloxacin and lomefloxacin. Mechanistically, the authors suggested that the absorption of quinolones by aluminium hydroxide reprecipitation may be responsible for the reduced bioavailability. Similarly, absorption of inorganic ions, for example iron, is disrupted by the presence of other cations, for example copper. Iturri and Nuñez (1998) found that cadmium and copper, manganese or lead, but not mercury, inhibited the uptake of iron in perfused mouse duodenal preparations. Furthermore, the inhibition by copper and cadmium was dependent on the iron redox state, since neither cation inhibited Fe^{3+} uptake. The authors proposed that Fe^{2+} and Fe^{3+} are transported from the gastrointestinal tract by different mechanisms, or that Fe^{3+} is reduced in enterocytes to Fe^{2+} and the subsequent absorption is not inhibited by either cadmium or copper.

The mucosal layer of the gastrointestinal tract serves to protect the intestinal epithelium from the acidic environment of the stomach, as well as protecting the cellular environment from mechanical and other chemical forces of digestion. Nonsteroidal anti-inflammatory drugs (NSAIDs), for example aspirin, have long been recognized as causing an ulcerogenic effect in the stomach. Indeed, the search for new NSAIDs has focussed not only on the potential for these compounds to affect the inflammatory process, but also on being less ulcerogenic to the stomach. The newer generation COX2 inhibitors have shown some success. Regardless, ulcer formation of the gastrointestinal tract will certainly change the bioavailability of drugs much in the same way as disease states alter absorption.

4.5 Microbial Influences

There has been long recognition that gastrointestinal microflora play a major role in the metabolism of xenobiotics in the gastrointestinal tract (Goel *et al*., 2005; Smith *et al*., 2005). Turner *et al*. (2003) demonstrated that human gut microflora influence the metabolism of isoflavones, thereby altering the bioavailability of this class of compounds. Clearly, local interactions at the cellular level between bacteria and food constituents may have dramatic influence on the metabolism of xenobiotics, thereby influencing the absorption and hence toxicity.

Bacteria are present throughout the length of the gastrointestinal tract although there is a significant bacterial concentration in the large intestine. Few bacteria are present in the gut at birth, but a rapid colonization occurs shortly after. It has been estimated that the average adult has 1014 different intestinal flora. The stomach has the least amount of microflora ($<10^3$CFU ml^{-1}), primarily because the low pH destroys many organisms. In contrast, almost the entire digestion process can be attributed to the large number ($>10^{14}$ CFU ml^{-1}) of anaerobic bacteria present in the large intestine (Patel, 2005). Normal gastrointestinal bacteria produce antibacterial chemicals (called bacteriocins) as a result of their metabolism. This by-product can generate a local antibiotic effect that hinders the reproduction of invading flora. Secretions in the large intestine consist primarily of alkaline mucus that protects the epithelium and neutralizes acids produced by bacterial metabolism.

5 GASTROINTESTINAL METABOLISM

Historically, the metabolism of xenobiotics has been classified as either a Phase 1 or a Phase 2 reaction. Although such terminology is somewhat outdated, this classification remains convenient for the purposes of description of the mechanisms of metabolism. Phase 1 reactions result primarily in the oxidation of parent compounds, but also involve reduction reactions. Cytochrome P450 reactions often result in an increased polarity of the parent molecule and generally precede conjugation reactions (Phase 2 metabolism). These enzyme systems are responsible for the metabolism of xenobiotics, but are also responsible for the metabolism of nutrients and endogenous compounds. Over the last 20 years, different isoforms of cytochrome P450 have been characterized for their metabolic specificity. For example, cytochrome P450 3A4 is the major isoform that metabolizes most drugs, whereas halogenated hydrocarbons are generally substrates for cytochrome P450 2E1. Parkinson (2001) has described the different isoforms of cytochrome P450 with regard to substrate specificity, and inhibitors and inducers of these enzyme systems. The liver contains the highest concentration of metabolic enzymes, and the enzymes are located within the endoplasmic reticulum. In the gastrointestinal tract, heterogeneity of the enzyme concentrations can be found, with a decrease in levels of activity from the upper to the lower intestinal tract (Martinez *et al*., 2002).

Distribution studies by Chhabra and Fouts (1976) revealed that enzyme activity declines from the proximal end of the intestine to the distal-colonic end of the intestine. These authors examined aniline hydroxylase, aminopyrine *N*-demethylase and aryl hydrocarbon hydroxylase in intestinal microsomes and found these enzymes along the entire length of small intestine. Maximal activity was present in the proximal intestine. Mizuma *et al*. (1997) examined the intestinal transport and metabolism of kyotorphin (KTP) in rat everted

small intestine. These authors found that KTP on the mucosal side was metabolized within 60 minutes. No metabolism was detected on the serosal side of the intestine. In intestinal homogenates, KTP was metabolized and was decreased by peptidase inhibitors, bestatin, *o*-phenanthrolin and tryptophan hydroxamate.

In perfusion studies of the rat small intestine, regional differences in intestinal metabolism and elimination of cimetidine were observed (Piyapolrungroj *et al*., 2000). The metabolite cimetidine *S*-oxide was formed to a greater extent in the jejunum compared with the ileum, and the occurrence of the metabolite was a function of the pH-dependent intracellular uptake. Perfusion studies with inhibitors of cimetidine mucosal transport and inhibitors of microsomal *S*-oxidation provide an inhibition profile suggesting that jejunal cimetidine permeability decreases with increasing intracellular cimetidine concentration.

Inhibitors and inducers of cytochrome P450 enzymes have been extensively examined. Chhabra and Eastin (1984) presented data from their laboratory demonstrating induction of intestinal metabolism in various species. In their study (**Table 8**), the authors found that intestinal cytochrome P450 activity was refractory to induction by phenobarbital or 3-methylcholantrene, although it is well known that hepatic cytochrome P450 isozymes are well induced by either substance (Parkinson, 2001).

As discussed above, dietary components have an influence on the absorption of xenobiotics. Similarly, diet will influence the metabolism of xenobiotics, and the literature is full of examples (see Domeneghini *et al*., 2006; Ramesh *et al*., 2004).

6 BIOPHARMACEUTIC CLASSIFICATION SYSTEM AND HUMAN DRUG ABSORPTION

In 1995 Amidon *et al*. (1995) devised a biopharmaceutics classification system (BCS) to classify drugs based on their aqueous solubility and intestinal permeability. The authors suggested that dissolution rate had a minimal impact on bioavailability of highly soluble and highly permeable (BCS Class 1) drugs when the dissolution of a drug is sufficiently rapid (Kaus *et al*., 1999). As a result, various regulatory agencies, including the Food and Drug Administration (FDA) now allow bioequivalence waivers of formulations of BCS Class 1 drugs to be demonstrated by *in vitro* dissolution (often called a biowaiver). Definitive BCS classification is done when a potential Class 1 candidate enters human testing, with classification according to methods outlined in the FDA guidance (Food and Drug Administration (FDA), 2000; **Table 9**). For instance, solubility is determined at pH 1.2, 7.5 and at a pH approximating the pK_a (pK_a − 1, pK_a and pK_a + 1) of the agent.

Kasim *et al*. (2004) undertook an analysis of approximately 260 oral immediate-release drugs, and compared the BCS classification of these drugs based on the partition coefficient (log *P* or *C*log*P*) or dose number.[a] For a majority of the drugs examined, BCS classification was the same. About 67% of the drugs were classified as 'high solubility' drugs.

For classification of drugs, preference is often given to data developed from clinical or preclinical studies with a preference given to data developed from renal excretion data in human studies, or a human mass balance study with radiolabelled material. Human absolute bioavailability studies and preclinical permeability studies using rat intestinal perfusion or Caco-2 cells also are considered for classification. For immediate-release dosage forms, a product is considered to be a rapidly dissolved substance when not less than 85% of the labelled amount of the substance dissolves within 30 minutes in acidic media (0.1 N HCl or simulated gastric media), pH 4.5 media and pH 6.8 media, or simulated intestinal fluid without enzymes. Recently, Benet *et al*. (2008) recommended the extent of drug metabolism (≥90%) as an alternate method in defining Class 1 marketed drugs suitable for a waiver of *in vivo* studies of bioequivalence.

Class 1 substances are those that are well absorbed and where the rate-limiting step for absorption is dissolution of the agent. For immediate-release dosage forms, that is, those formulations that dissolve very quickly, gastric emptying time becomes rate limiting for absorption. Amidon *et al*. (1995) proposed that the dissolution profile should be determined over time and for at least 85% dissolution at several different pH values. This proposal has been incorporated into the FDA guidance FDA 2000. For Class 3 drugs, absorption is limiting, and drugs of this class show a large variation in permeability. Monographs for several pharmaceuticals have been published in the open literature with an eye towards obtaining a biowaiver from conducting *in vitro* or *in vivo* bioequivalence and bioavailability studies (Yu *et al*., 2002; Blume and Schug, 1999; Kortejarvi *et al*., 2005). Without the waiver, pharmaceutical companies would be mandated

Table 9 Biopharmaceutical classification system[a]

Biopharmaceutical classification	Description	Examples
Class 1	High solubility—high permeability	Chlorpheniramine, cloxacillin
Class 2	Low solubility—high permeability	Clofazimine, gibenclamide
Class 3	High solubility—low permeability	Hydralazine, methotrexate
Class 4	Low solubility—low permeability	Theophylline, trimethoprim

[a]Adopted from Food and Drug Administration (FDA) (2000) and Amidon *et al*. (1995).

to undertake *in vivo* bioavailability and bioequivalence testing for newly formulated generic drugs or reformulation of existing patented drugs. Such testing could have considerable cost ramifications. Class 4 drugs represent those drugs that would be difficult to formulate for oral dosage forms.

In vivo differences in the rate and extent of absorption of a drug of two equivalent solid oral products may be due to differences in drug dissolution. When the *in vivo* dissolution of a solid oral dosage form is rapid in relation to gastric emptying time, the drug has high permeability and the rate and extent of drug absorption is unlikely to be dependent on dissolution and/or gastrointestinal transit time. Under such circumstances, the FDA suggests that a demonstration of *in vivo* bioavailability or bioequivalence may not be necessary for drug products containing Class 1 drug substances. The BCS approach outlined by the FDA may be used to justify a biowaiver for highly soluble and highly permeable drug substances, Class 1 agents, for an immediate-release, solid oral dosage form.

A drug substance is considered highly soluble when the highest dose strength is soluble in 250 ml or less of aqueous media over the pH range 1–7.5. The permeability class boundary is based on the fraction of dose absorbed in humans and on the rate of mass transfer across human intestinal membrane. A drug substance is considered to be highly permeable when the extent of absorption in humans is determined to be 90% or more of an administered dose based on a mass balance determination or in comparison to an intravenous reference dose. A drug substance is considered rapidly dissolving if 85% or greater of the labelled amount of the drug substance dissolves within 30 minutes. Lennernas (1998) examined several methods used to predict human intestinal permeability. The author suggested a good correlation exists between the measured human effective permeability values and the extent of absorption of drugs in clinical pharmacokinetic studies. Estimations of the absorption half-lives from the measured effective intestinal permeability (P_{eff}) agree very well with the time to maximal amount of the dose absorbed. Human *in vivo* permeability can be predicted using preclinical permeability models, such as *in situ* perfusion of rat jejunum, the Caco-2 model and excised intestinal segments.

Prediction of passively transported compounds can be accurately predicted, although those agents that are absorbed by carrier-mediated transport mechanisms need to be evaluated with a special degree of caution (Lennernas, 1997; 1998). Clearly, added research is needed to further characterize the influence of active transport mechanisms, for example, multidrug-resistance transporters and intestinal metabolism, for example, Cytochrome P450 3A4, on drug bioavailability that is observed with anticancer agents (Schellens *et al*., 2000).

7 ORAL ADMINISTRATION OF XENOBIOTICS: PRACTICAL CONSIDERATIONS

Guidance standards for toxicological protocols have been published by the OECD and the EPA. For oral toxicity assessments, the guidance protocols are available for acute oral toxicity, 28- and 90-day toxicity and long-term chronic and oncogenicity studies. In the guidances, the rat and mouse are indicated as preferred rodent species with the dog specified as the preferred nonrodent species.

Generally, the oral administration of xenobiotics to experimental animals will be by bolus gavage or continuous administration. The first case, the most common means of administration, most often utilizes rodents, although dogs, rabbits, minipigs, nonhuman primates and variety of other animals are used, with each presenting their own advantages and disadvantages. By gavage, a stainless steel or flexible tube is used to deliver the xenobiotic. For rodents, the tube usually deposits the substance within the oesophagus, but with the force of depression of the syringe, the material is forced into the stomach. For larger species, a flexible tube is used that can deliver the material directly into the stomach with a wash of the tube included, using water or the vehicle. In addition, capsules or tablets can be delivered into the stomach for larger species, for example dogs, rabbits, monkeys, although with skilled technical ability tablets can be administered to rats. The dog is very prone to emesis following administration of substances in liquid formulations. Therefore, the use of capsules or tablets may potentially overcome this problem. Recently, the minipig has gained favour as an alternative nonrodent

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat054
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

species in safety assessments, as it is less prone to emesis (Svendsen, 2006; Dincer *et al*., 2006; Kano *et al*., 2005).

Alternatively, studies are carried out in which the test material is incorporated into the diet or drinking water. When included with the feed or water, measurements of food and water consumption becomes necessary in order to calculate a dose rate. In addition, a homogeneous distribution of the test material within the feed is necessary and could include suspending the test material in corn oil or other vehicles to ensure distribution. Including the test article in drinking water poses additional issues in study conduct. Spillage of diet and water can potentially lead to inaccurate determination of dosage. Furthermore, for water administration, ensuring homogenous distribution of substances can be problematic if the compound is not completely soluble. Incorporating test chemicals into diet or water also may result in an unacceptable taste for the animal such that there is reduced consumption. In these cases, it is often advisable to undertake a short-term study to test for the palatability of the compound prior to undertaking longer-term studies.

Although dispersion of substances in water is not usually a problem with soluble test materials, stability of a compound in water can be problematic. Hence, determining the stability of the waster solution prior to study initiation becomes mandatory. The instability of a water solution of a compound was evident in a chronic drinking water study with vinyl acetate, in which the compound was formulated on a weekly basis (Lijensky and Reuber, 1983). In a subsequent chronic study, the water solutions were prepared daily to compensate for the rate of hydrolysis of the compound (Bogdanffy *et al*., 1994). In addition to instability, volatile materials may evaporate from the water. Often, however, volatile liquids are formulated in another solvent, for example corn oil, and then suspended in water. Although not an ideal means of compound delivery, fluorocarbons were incorporated into vehicles, for example, corn oil, for administration many years ago (Longstaff *et al*., 1984).

With gavage administration, animals can be treated fairly rapidly and automated systems have been adapted from equipment designed for cutaneous application. Administration of dosing solution or suspensions can be labour intensive and represents a major cost factor in toxicology studies. In a typical subchronic study with a control and three dose groups, the number of rats often included is about 80–100 animals that may need to be treated for as long as 90 days. As the duration of the study increases, the numbers of rats included in these studies increases such that for a two year carcinogenicity study, upwards of 400–600 animals may be used. Well-trained technicians, however, can gavage a specific animal quickly, and the skilled technician often can gavage a few animals within a minute or so. This can also be a disadvantage. With the administration of compounds that are somewhat viscous, for example corn oil solutions and suspensions, there is a greater chance of gavage errors, whether through perforation of the oesophagus, directly discharging the compound into the trachea or through aspiration. In a recent experience by this author, a rather viscous dosing solution appeared to adhere to the gavage needle and as the needle was withdrawn the compound was aspirated into the lung by the rat. This led to an increase in mortality across the dosing groups. Having the technicians delay for a few seconds before withdrawing the dosing needle prevented further mortalities.

When conducting studies by gavage, the dosing vehicle selected to solubilize or suspend the test article is critical to ensure absorption of the compound without the vehicle having an effect on absorption or, most importantly, that the vehicle does not exert toxicity (Gad *et al*., 2006). Generally, aqueous solutions of the test article are preferred. However, other solvents are used in preclinical studies and include a rather lengthy list of neat materials and combinations of materials. The formulation must be suitable for the intended route of administration, maintain the stability of the active ingredient and preferably maximize the systemic bioavailability of the drug. Occasionally, the vehicle is specified by the sponsor of a study, but more frequently the laboratory conducting the studies has experience with different vehicles and can provide advice. Because the process of vehicle selection has been mostly one of custom or personal choice, there are many vehicles which have seen use in preclinical formulation. Gad *et al*. (2006) provided various characteristics that make vehicle selection preferable. Although the intent of their paper was to review vehicles for different routes of administration, it is important to note that many of the cited characteristics are useful for oral administration, for example maintain stability, minimize dose volumes, and so on.

As alluded to previously in this chapter, a dosing vehicle can alter the bioavailability of a compound. A classic example of this was reported many years ago by Kim *et al*. (1990). These authors found that a single dose of carbon tetrachloride at l0 or 25 mg kg^{-1} in corn oil caused less severe hepatic injury than when given at the same dosages undiluted or as an aqueous emulsion to rats. In contrast to this report, however, the hepatotoxicity of chloroform was enhanced when administered in corn oil (Bull *et al*., 1986). Koporec *et al*. (1995) subsequently showed that carbon tetrachloride hepatotoxicity was not influenced by the vehicle. In their study, rats orally administered carbon tetrachloride at doses of 0, 25 or 100 mg kg^{-1} by gavage in either corn oil or a 1% Emulphor aqueous emulsion for 13 weeks. These authors found that corn oil did not significantly alter the subchronic hepatotoxicity of carbon tetrachloride compared to the aqueous emulsion. Clearly, discrepancies in experimental outcomes for similar compounds further complicate the choice of a vehicle for compound administration.

Other vehicles have become more often used, and include carboxymethyl cellulose (CMC), polyethylene glycols (PEGs), dextrans, and so on (see Gad *et al*., 2006). In selecting these other vehicles, caution needs to be exercised to ensure toxicity to the animal does not occur or have an affect on intestinal metabolism. Mountfield *et al*. (2000) reported the effects of various commonly used formulation ingredients on cytochrome P450 3A inhibition using dog, monkey and human microsomes. Although these authors did not observe changes in cytochrome P450 3A with most formulation ingredients, greater inhibition of cytochrome P450 3A activity was observed with amphiphilic ingredients, for example, Tween 80 and oleic acid. Yoo *et al*. (1999) showed that bioavailability following sublingual administration of clomipramine was enhanced hydroxypropyl-β-cyclodextrin compared with saline administration.

Toxicity produced by the vehicle also needs to be considered. For example, it is well known that Tween 80 may cause anaphylactic reactions in dogs, with intravenous administration (Varma *et al*., 1985; Eschalier *et al*., 1988). In addition, Tween 80 has been shown to have an electrophysiological effect in anaesthetized dogs (Torres-Arraut *et al*., 1984), as does Cremophor EL (Lorenz *et al*., 1977). Dogs are susceptible to emesis such that oral administration of substances that cause gastrointestinal irritation may evoke an emetic response. Hence, the use of vehicles in the dog that may be mucosal irritants, for example, Tween 80, might result in emesis, thereby affecting the bioavailability of the drug. Dose selection of the vehicle, therefore, becomes an important consideration in the design of the study. The maximum dose volume used in toxicity studies should not exceed 20 ml kg^{-1} as a single dose. Indeed, it is often best to minimize the dose volume to 10 ml kg^{-1} or less unless divided doses are considered. Many of the vehicles used in toxicology studies have been used for many years and have been found to be acceptable to ensure limited effects on experimental animals and have limited effects on the stability of the test material. Clearly, many of these factors should be determined prior to undertaking a study.

8 SUMMARY

From the above discussion, it is clear that numerous factors will affect the passage of drugs and chemicals through the gastrointestinal tract into systemic circulation. These factors involve anatomical features, species differences, physiological features and biochemical features, including intestinal metabolism and effects on transporters. With regard to assessing the potential risk of chemicals, these features will need to be considered, as there will be differences between experimental animals and humans.

The cellular environment of the gastrointestinal tract and the molecular mechanisms of absorption will have a major influence on the bioavailability of xenobiotics. As noted, the pH of the local cell environment will affect the ionization status of the compound, whereas a drug may inhibit cellular transporters of other substances, for example, nutrients, thereby having an affect on the nutritional status of the animal. Moreover, there has been demonstrated evidence that some substances will affect the metabolic status of the gastrointestinal tract. Cytochrome P450 3A is the more common form of cytochrome isoforms found in the intestine, but there are numerous examples beyond those described in this chapter that can inhibit, or induce, metabolism, much in the same way that hepatic metabolism is affected by chemicals. In addition, the bacterial content of the gastrointestinal tract can affect the absorption of substances, primarily by bacterial metabolism. The fasting status of the animal also will affect absorption, and is probably one of the more important considerations in the design of a toxicology study. It has been clearly shown that absorption occurs more readily in the fasted animal, and that toxicity may be enhanced, since there is a greater surface area of the gastrointestinal tract available for absorption. Finally, chemical interactions will potentially modify absorption through binding of the compound or changing the local cellular environment.

From a practical perspective, oral administration of compounds is the most common method for compound administration in toxicology studies. In oral toxicity studies, one will need to consider the drug formulation and the potential effects of the vehicle on the stability, as well as the potential toxicity, of the vehicle. For the most part, a majority of the vehicles being used currently in laboratories have a long history of use, such that toxicity of the vehicle does not become too much of a concern, but the principle of toxicology, the dose makes the poison, is always a consideration.

Cutaneous Toxicology

Jim E. Riviere and Nancy A. Monteiro-Riviere

CONTENTS

1 INTRODUCTION

Skin is one of the largest organs of the body and therefore dictates that particular attention should be paid to it when considering systemic toxicoses. However, the skin is also a primary interface between the body and the environment, making it particularly relevant to assess dermal toxicity after occupational or environmental exposure to chemicals. The skin is often a primary exposure route for cosmetics and is the preferred route of administration for topically applied drugs targeted either locally for dermatological applications or transdermally for systemic therapy. Toxicity to this organ is manifested by alteration to one of its biological functions including loss of barrier function, damage to dermal collagen or vascular structures, hair loss, damage to adnexial structures such as sweat and sebaceous glands, carcinogenic transformation of epidermal cells or activation of the resident immune system. The unique exposure of skin to the environment also makes this organ susceptible to direct interaction with ultraviolet (UV) radiation that may result in sunburn, phototoxicity or cancer.

Absorption and toxicity are inextricably linked in evaluating the potential for a chemical or drug to cause dermal toxicity. A *barrier* is defined as something that obstructs or impedes. For most applications in dermatotoxicology, this obstruction refers to the impediment of chemical movement across or into the skin. This barrier can be viewed as restricting diffusion, but also could be viewed as impeding absorption of intact drug through metabolism in the skin. Topically applied chemicals may either *penetrate* the skin to have a local effect and/or be *absorbed* across the skin and result in systemic absorption and distribution throughout the body. It is important to keep these terms separate since both are important parameters with different experimental end points.

Any review of skin toxicology must divide the discussion into three sections; percutaneous absorption or penetration, toxicological effects and the *in vivo* or *in vitro* model system used to evaluate these. This chapter will focus on introducing the reader to the succinct elements of the structure and function of skin that are relevant to understanding dermal toxicity. More advanced texts should be consulted for further discussion in this area (Riviere, 2006; Wilhelm *et al*., 2007; Roberts and Walters, 2008).

2 STRUCTURE AND FUNCTION OF SKIN

The skin is the largest organ of the body, with the integument accounting for some 20% of body weight in most species. Skin has the function of protecting the internal organs of the body from extremes in temperature fluctuations, allergens, pollutants, toxic chemicals and organisms such as bacteria, fungi, parasites and viruses found ubiquitously in the environment. The skin of humans and most animals is actually quite similar morphologically across species. Perforating the skin are several types of appendages (depending on the species), including hair follicles, sebaceous and sweat glands, spines, quills, scales, spurs, horns, claws, nails and hooves. The specific and comparative anatomy of

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

skin and hair has been reviewed extensively elsewhere (Montagna, 1967; Monteiro-Riviere, 2006).

On the histological level, the skin can be divided into two very distinct regions: the epidermis and the dermis. The epidermis consists of stratified squamous keratinized epithelium that undergoes a programmed proliferation and differentiation that will eventually result in the formation of the major barrier to chemical penetration: the stratum corneum. Two primary cell types exist in the epidermis: keratinocytes and nonkeratinocytes (melanocytes, Langerhans cells and Merkel cells).

Five distinct layers of keratinocytes can be present in the epidermis, as shown in **Figure 1**. Starting from the deepest layer, they are the stratum basale (basal layer), stratum spinosum, stratum granulosum, stratum lucidum and the stratum corneum. Each cell layer originates from the stratum basale layer, a single layer of cuboidal or columnar cells that rest on the basement membrane. These cells are attached to the basement membrane by hemidesmosomes, and to each other and to the cells of the stratum spinosum by desmosomes. The stratum basale cells continuously divide, with some remaining as basal cells and others moving upward and maturing by changing their intracellular content and biochemical pathways through the process called keratinization. It is this viable and dividing epidermal cell layer that is the target for chemical transformation into cancerous cells.

The next more superficial layer, the stratum spinosum, is composed of irregularly shaped polyhedral cells that make up much of the bulk thickness of the epidermis. The next layer composes the stratum granulosum consisting of several layers of cells that begin to flatten horizontally. Of primary interest within these cells are the membrane-bound organelles, the lamellar granules, which contain polar phospholipids including glycosphingolipids and free steroids, as well as numerous hydrolytic enzymes. Nonmembrane-bound electron-dense keratohyalin granules are also present. These consist of profilaggrin, a precursor protein of filaggrin and play a role in keratinization and barrier function. As lamellar granules accumulate within these cells they will release their products via exocytosis into the intercellular spaces between the stratum granulosum and stratum corneum layers of the epidermis, eventually forming the extracellular lipid matrix of the stratum corneum that participates in the penetration barrier of the stratum corneum. As these epidermal cells continue their migration upwards, they may form the stratum lucidum, a translucent line of cells found only in areas of very exceptionally thick skin such as the plantar and palmar surfaces (foot pads) (Monteiro-Riviere, 1991; 2006).

The stratum corneum is the outermost superficial epidermal layer and is the most important when considering drug or chemical absorption after topical exposure, since it is the primary barrier to percutaneous absorption. In addition to the barrier function for xenobiotics trying to enter the body from the environment, the stratum corneum also provides a barrier to insensible water loss, an evolutionary adaptation that allows terrestrial animals to exist in a nonaquatic environment. Most cosmetics are targeted to improve this function. It is this function that is assessed when transepidermal water loss (TEWL) is

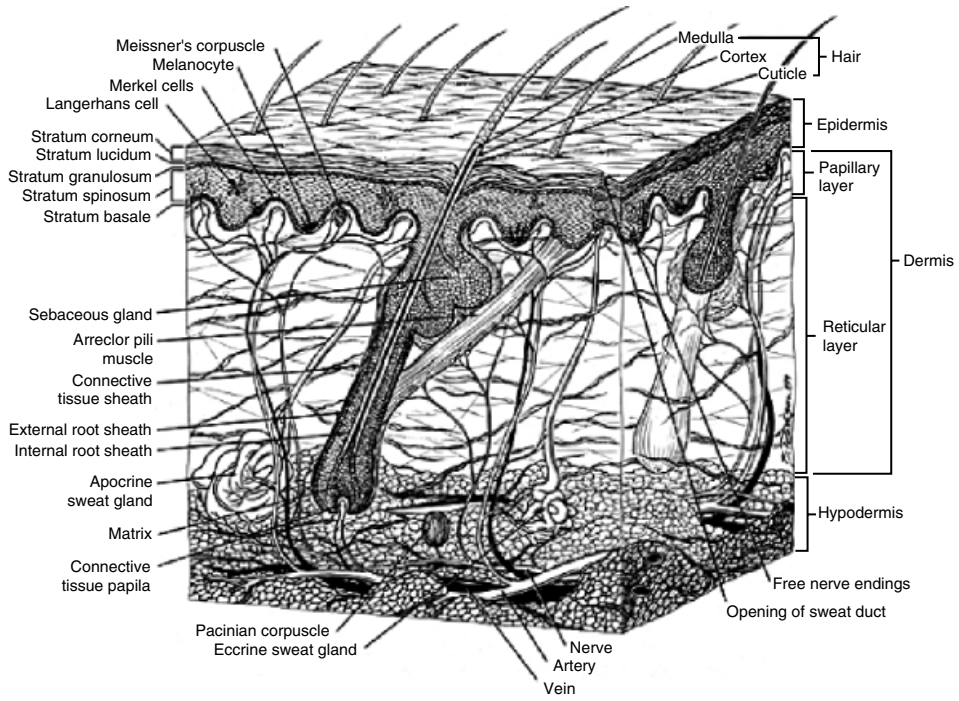

Figure 1 Structure of skin.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

measured as a biomarker of barrier function in cutaneous toxicology studies.

The stratum corneum consists of several dead layers of cells, organized into vertical columns in a tightly packed geometrical configuration, the thickness of which varies depending on location (Monteiro-Riviere, 1991). Each corneocyte is embedded in the lipid matrix produced by the lamellar granules. These cells are bathed in the lipid matrix, forming the so-called 'brick and mortar structure' (Elias, 1983) where the dead corneocytes represent the 'bricks' and the intercellular lipids represent the 'mortar'. There is a consensus that chemicals are absorbed through skin via this intercellular pathway, with partitioning into and diffusion through the lipid predictive of compound absorption. These intercellular lipids consist of a mix primarily of sterols, other neutral lipids and ceramides. These dead cells are also surrounded by a thick plasma membrane with a submembranous layer of involucrin, also produced earlier in development. Although highly water retarding, the dead, keratinized cells are highly water absorbent (hydrophilic), a property that keeps the skin supple and soft as they absorb water on its way to being evaporated from the surface. With intracellular and intercellular barriers firmly in place, the stratum corneum has the ability to constrain the passage of unwanted chemicals and toxins from the environment. A natural oil covering the skin, the sebum, appears to maintain the water-holding capacity of the epidermis, but has no appreciable role in retarding the penetration of xenobiotics. This is especially prevalent in some species including sheep.

In addition to the keratinocytes, epidermal nonkeratinocytes are present throughout the epidermis and do not participate in the formation of keratin. They include the melanocytes, Merkel cells (tactile epithelioid cells) and the Langerhans cells (intradermal macrophages).

Melanocytes are dendritic cells located in the basal layer of the epidermis and hold pigment-containing ovoid cytoplasmic granules referred to as melanosomes. These cells impart colour to the skin by transferring melanosomes to neighbouring keratinocytes. Merkel cells are located in the basal region of the epidermis and are thought to function as slow-adapting mechanoreceptors for touch. Langerhans cells are dendritic cells and are located in the stratum spinosum but may also be present in dermal lymph vessels, lymph nodes and dermis. The Langerhans cells' primary function is to detect antigens penetrating the stratum corneum layer and then migrate out of the epidermis once activated and present the antigens to lymphocytes in regional lymph nodes. They are often considered the initial receptors for cutaneous immune responses. It should be stressed that an antigen need only penetrate the skin to elicit a dermatological immune response. Systemic absorption is not necessary. The epidermis is not perfused by vascular capillaries and thus obtains nutrients by diffusion from the underlying dermis. The basal cells of the epidermis sit on the epidermal–dermal junction (EDJ) which may be a target for vesicating agents such as sulphur mustard or lewisite.

The dermis is composed of connective tissue consisting of collagen, elastic and reticular fibres dispersed in an amorphous ground substance and can be divided into two rather poorly demarcated areas. The superficial papillary layer consists of loose connective tissue that connects the epidermis (stratum basale/basal lamina) to the deeper reticular layer of the dermis. The reticular layer consists of dense irregular connective tissue connected to the hypodermis, which is composed mostly of superficial fascia or fat. Dispersed throughout both layers of the dermis is a network of arterial and venous blood vessels and connecting capillaries needed to nourish the cells of the dermis and epidermis via diffusion, as well as take part in the final stages of the percutaneous absorption of compounds. Lymph vessels, nerves, apocrine and eccrine sweat glands, sebaceous glands, Pacinian (pressure receptor), Meissner's (touch receptor), and Ruffini (mechanical receptor) corpuscles, hair follicles and smooth muscles (arrector pili) are some of the other major structures found in the dermis. Cutaneous blood flow rates may be one of the factors affecting the passive percutaneous absorption of chemicals.

Figure 2 shows photomicrographs illustrating the appearance of skin in humans and pigs.

There are interesting aspects of skin biochemistry that may impact dermal toxicity. The skin, specifically the

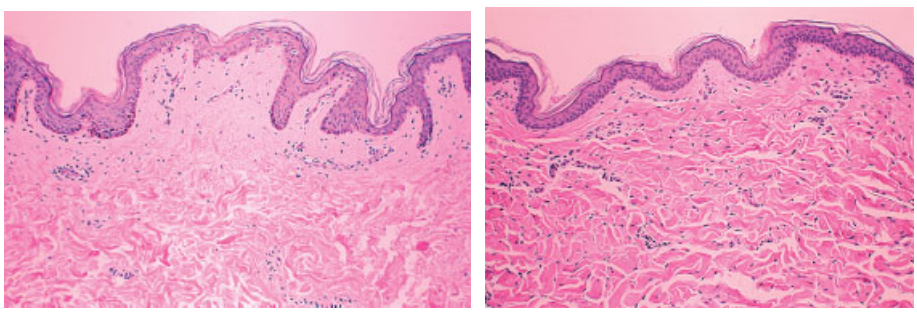

Figure 2 Photomicrograph of human (A) and porcine (B) skin.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat055
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

epidermis, is mostly an anaerobic organ. The absence of capillaries directly feeding oxygen to the epidermal cells makes the epidermal cells relatively oxygen poor in the normal state when compared to other tissues with a more direct blood supply. Due to this low oxygen tension, the epidermis produces 70–80% of its total energy requirements (adenosine triphosphate) through the anaerobic metabolic pathway (glycolysis), with lactic acid being the end product of glucose utilization. The epidermal cells, the most active of which are those in the single bottom layer of the stratum basale, are the primary cells involved in this energy production, with the lactic acid end product passively diffusing into the dermis and then into the blood vasculature, eventually being recycled by the liver back into glucose. Although the glycolytic pathway produces most of the energy requirements of the epidermis, other energy pathways (tricarboxylic acid cycle and pentose phosphate shunt) are also utilized to lesser degrees in some phases of epidermal growth (Freinkel, 1983).

The stratum corneum is the primary line of defence to prevent percutaneous absorption of drugs. However, any drug passing through the stratum corneum may face a metabolic, rather than a physical, diffusional barrier. The skin has a remarkable ability to metabolize xenobiotics. These metabolic reactions consist mainly of oxidation, reduction, hydrolysis, and the phase I and II conjugation reactions. Some of these reactions are major pathways for the metabolism of topical steroids as well as other drugs. Numerous studies have demonstrated the metabolic capabilities of skin when topically exposed to caffeine, testosterone, butylated hydroxytoluene, salicylic acid, norepinephrine, benzo(a)pyrene and benzoyl peroxide—to name only a few—in many species of laboratory animals, as well as in human skin. The cytochrome P450 enzyme system, most commonly associated with the liver, is present and is inducible in skin (depending on the compound that was applied topically) (Riviere and Chang, 1992; Mukhtar, 1992; Bashir and Maibach, 2005). These studies all suggest that the skin has formidable metabolic functions in addition to the traditional barrier functions. For many compounds, such as benzo(a)pyrene, this could result in metabolic activation to toxic moieties or active molecules after topical prodrug administration.

In addition to these metabolic activities, skin also has a marked ability to synthesize lipid, which is used to construct the extracellular epidermal barrier. Epidermal cells manufacture a variety of neutral lipids, ceramides, glycosylceramides, gangliosides, sterol esters, fatty acids, alkanes and phospholipids, which are largely found in the extracellular barrier of the stratum corneum. Some of these lipids tend to be site-specific, with phospholipids and sterols residing mostly in the basal cell layers and some sterols and neutral lipids occupying the upper regions of the epidermis, mainly the stratum corneum. It is now accepted that this complex intercellular lipid matrix provides the primary barrier to drug penetration. The effects on percutaneous absorption by the intercellular lipid structure has been discussed in greater detail elsewhere (Wertz, 1992; Potts and Francoeur, 1992; Elias and Feingold, 1992; Monteiro-Riviere *et al*., 2001b). The primary protein product of the skin is keratin, which is the main intracellular component of the stratum corneum layer. In tandem with extracellular lipid, keratin forms the major component of the epidermal barrier. Keratin primarily consists of cysteine, serine, glutamic acid, arginine, aspartic acid and glycine amino acid residues. Of significance within the keratin molecule structure is the intrachain cysteine disulfide bridging that further strengthens the overall keratin macrostructure. Keratin is the major protein foundation of hair (Monteiro-Riviere, 1991; 2006).

3 PERCUTANEOUS ABSORPTION

For a topically applied chemical that is not a direct corrosive agent (see discussion below), penetration and/or absorption through the epidermal barrier are required for a dermatotoxic response to be expressed. The major end points for assessing a chemical's ability to be absorbed through skin are either to determine its permeability constant or estimate the rate and extent of absorption after topical dosing from a specific concentration and formulation, including the chemical of interest. In this latter vein, dosing conditions can also be designed to mimic occupational or environmental exposure scenarios in response to the needs of specific regulatory issues. These approaches are fully developed and discussed elsewhere (Cleek and Bunge, 1993; Bunge and Cleek, 1995; Riviere, 2006).

The movement of chemicals across the stratum corneum barrier into the epidermis occurs primarily by passive diffusion driven by the thermodynamic force arising from the greater applied concentration of the drug on the surface of the skin compared to that in the skin and/or blood. This is best quantitated using Fick's law of diffusion that states that the steady state of drug flux across a membrane can be expressed as:

$$Flux(J) = \frac{DP}{h}(Concentration\ Gradient \times (Applied\ Surface\ Area \quad (1)$$

D is the diffusion coefficient or diffusivity of the drug in the intercellular lipids of the stratum corneum, P is the partition coefficient for the drug between the stratum corneum and the dosing medium on the skin surface and h is the skin thickness or actual path-length through which the drug diffuses across the diffusion barrier.

Because of the aforementioned 'brick and mortar' structure of the stratum corneum, the diffusion path length is tortuous and much greater than the actual

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

thickness. The driving force for this thermodynamic process is the concentration gradient that exists between the applied dose and the dermal perfusate or blood.

The compound's permeability coefficient Kp is defined as DP/h. Kinetically, this is a first-order rate constant that forms the basis for the absorption rate constant (Ka) used in pharmacokinetic models describing chemical percutaneous absorption and transdermal drug delivery. Dermal absorptive flux should always be expressed in terms of the surface area of the dosing site, making the two important properties of dosage after topical exposure the concentration of drug applied, as well as the surface area of application. Finally, Fick's law expresses the steady-state flux of drug that occurs when this rate becomes constant. In skin diffusion studies, this occurs after the passage of a *lag time* that is a function of the drug 'loading' the stratum corneum and dermis, diffusivity and thickness of the skin. Lag time can be calculated as $(h^2)/6D$. For molecules with small diffusivities, initial absorption rates may be very low. If steady state is not achieved, Fick's second law of diffusion may be employed, although data requirements and experimental design are much more complex.

The diffusivity of a chemical is a function of the molecular weight, molecular size, molecular interactions with skin constituents (e.g. hydrogen bonding, hydrophobic interactions, etc.), the drug's solubility in the membrane milieu and the degree of ionization. These properties form the basis of the quantitative structure activity relationship (QSAR) equations presented below. Large molecular weight drugs (approximately greater than 500 Da, e.g. proteins) have extremely low diffusivities, thus effectively preventing them from being absorbed across the skin barrier and result in significant systemic fluxes. When diffusivity is very low, an exceedingly long lag-time could occur, due to its increased dependency on this parameter. Note that this rule of thumb applies relative to the ability to generate significant transdermal fluxes for pharmacological activities, and not necessarily absorption of small quantities of chemicals that could exert a local effect. However, from the perspective of cutaneous toxicology, very small quantities of chemical may still penetrate into the skin and elicit a toxicologic response, especially when the mechanism of such toxicity is not dose related (e.g. allergic response, carcinogenicity). For compounds that are partially ionized, diffusivity is significantly decreased, suggesting that only the nonionized fraction of a weak acid or base is available for diffusion across the stratum corneum. This is a function of the pH of the dosing medium as well as the pH of the skin.

The penetrating drug must have some propensity to partition into the intercellular lipids of the stratum corneum for diffusion to occur. The partition coefficient determines the ability of the drug to gain access to the diffusion pathway and is usually determined in experimental systems by measuring octanol/water or lipid/water partitioning. The higher the ratio, the greater is the lipophilicity. It is generally accepted that the optimal log octanol/water partition coefficient for a drug to penetrate the stratum corneum is approximately two. In other words, the drug is partitioned in the lipid phase approximately 100-fold. For hydrophilic drugs with low partition coefficients, prodrugs could be formulated (e.g. by esterification) which increases the drug's permeability across the stratum corneum. The lipophilic moiety (e.g. ester) is then cleaved in the epidermis, dermis or even plasma and the active parent drug is then distributed throughout the systemic circulation. If the partition coefficient is too great, the drug may have a tendency to sequester in the stratum corneum and not enter the more aqueous dermis, thereby decreasing systemic delivery. If it does penetrate into the dermis, the high lipid partition coefficient may favour formation of a dermal depot.

It must be noted, that the drug must also have partitioning properties that are favourable for entering into solution in the aqueous plasma, or be able to bind to plasma proteins for systemic absorption to occur. Finally and most importantly for many pharmaceutical and risk assessment issues, the tendency to partition is counterbalanced by solubility in the dosing vehicle. For a compound to be absorbed, it must have sufficient solubility to be in solution while still possessing sufficient lipid solubility to partition into the stratum corneum lipids. Optimization of these two independent properties may be required to obtain significant dermal absorption.

There are other factors that also are important in assessing absorption. After the lag time has passed, chemical flux across skin is at steady state. It is this value that should be used to calculate Kp. In an infinite-dose experiment where the amount absorbed is minimal compared to that applied, a plot of cumulative flux will easily allow precise measurement of flux. However, in a finite-dose experiment, where a significant fraction of the dose actually gets absorbed, the flux after the lag time has passed will ultimately decrease as the chemical is depleted from the dosing solution. The slope of the initial portion of this flux profile is thus usually termed *pseudo-steady state*. At steady state, the flux (J) can be presented as $J = Kp \cdot$ concentration.

Experimental data can also be reported as maximum flux ($J_{\max}$) and the time to this flux ($T_{\max}$). This term is often used as the parameter to quantify the absorption properties for toxicological end points since there are no assumptions inherent to its determination. $J_{\max}$ for a specific chemical can be determined from a saturated solution of the compound and will give an estimate of the worst-case dermal exposure for a chemical. However, if a supersaturated solution is applied, $J_{\max}$ may be even greater, its value being a function of thermodynamic activity in the dosing vehicle countered by the extent of interaction between the vehicle and the skin. Depending on the circumstances and the nature of the chemical

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and vehicle involved, $K\mathrm{p}$ or $J_{\max}$ may be the optimal parameters to characterize exposure.

A great deal of research has been focussed on relating the physical chemical properties of the penetrant to its permeability through skin (Moss *et al*., 2002); an area coined quantitative structure permeability relationships (QSPeR). The first such relationship widely used to assess chemical absorption was that of Potts and Guy (1992):

$$\mathrm{Log}K\mathrm{p} = 0.71\log PC_{\mathrm{octanol/water}} - 0.0061MW - 6.3(R^2 = 0.67) \quad (2)$$

where MW is the molecular weight.

This equation was subsequently modified (Potts and Guy, 1995) to relate $K\mathrm{p}$ to molecular properties of the penetrants as:

$$\mathrm{Log}K\mathrm{p} = 0.0256MV - 1.72\sum\alpha - 3.93\sum\beta - 4.85(R^2 = 0.94) \quad (3)$$

where MV is molecular volume, $\sum\alpha$ is the hydrogen-bond donor acidity and $\sum\beta$ is the hydrogen-bond acceptor basicity.

The most promising approach is to generalize this approach using linear free-energy relationships (LFERs) to relate permeability to the physical properties of the penetrant under defined experimental conditions (dose, membrane selection, vehicle). Geinoz *et al*., (2004) should be consulted for a critical review of most such QSPeR models applied to dermal absorption. Abraham's LFER model is representative of the dermal QSPeR approaches presently available (Abraham *et al*., 1999). This model was selected since it is broadly accepted by the scientific community as being descriptive of the key molecular/physiochemical parameters relevant to solute absorption across skin. This basic model can be written as:

$$\log K\mathrm{p} = c + a\sum\alpha + b\sum\beta + s\pi + rR_2 + vV_x \quad (4)$$

where π is the dipolarity/polarizability, R_2 represents the excess molar refractivity, V_x is the McGowan volume and the other parameters are as described earlier. The variables c, a, b, s, r and v are strength coefficients coupling the molecular descriptors to skin permeability in the specific experimental system studied.

All of these approaches have modelled permeability in single aqueous vehicle systems. Formulations and solvents have long been know to alter a chemical penetrant's solubility and partition coefficient into the stratum corneum, the two factors which determine dermal absorption. For a lipid-soluble drug, a lipid base formulation would tend to decrease absorption by retaining the applied drug at the skin surface. In contrast, an aqueous base would promote absorption solely by this partitioning phenomenon, which would favour drug movement out of the formulation into the more favourable lipid environment of the stratum corneum. The actual solubility of the compound in the vehicle further modifies this relationship. The reverse scenario would be operative for a hydrophilic drug.

Our laboratory has focussed significant research on the effects of chemical mixtures on dermal absorption of penetrant compounds (Riviere and Brooks, 2005; 2007). In order to quantitate mixture effects, we have been exploring using an additional term, referred to as the mixture factor (MF), to modify a QSPeR equation to better predict absorption from mixtures:

$$\log K\mathrm{p} = c + m\mathrm{MF} + a\sum\alpha + b\sum\beta + s\pi + rR_2 + vV_x \quad (5)$$

The nature of the MF is determined by examining the residual plot (actual—predicted log $K\mathrm{p}$) generated from the base LFER equation based on molecular descriptors of the permeants, against a function of the physical chemical properties of the mixture/solvents in which they were dosed. The selection of an appropriate MF is based on its correlation to the residuals of the normal QSPeR model. Importantly, the MF seems to improve prediction of permeability and absorption across different LFER models (e.g. Potts and Guy as well as Abraham approaches).

4 DERMAL TOXICITY

If a cytotoxic chemical is capable of dermal penetration, it may have a high probability of causing toxicity to the skin. The clearest approach to assessing chemical-induced damage to skin is to assess what abnormalities occur when the specific anatomical structures discussed above are perturbed after exposure to topical compounds.

4.1 Direct and Contact Irritants

A large number of cutaneous irritants specifically damage the barrier properties of skin, which results in an irritation response. These include organic solvents, which extract the intercellular lipid and perturb the skin's barrier, as assessed by increasing TEWL. Some chemicals destroy or digest the stratum corneum and underlying epidermis with a mode of action classified as corrosive. Such compounds cause chemical burns and include strong acids, alkalis and phenolics. They directly attack the epidermal barrier and chemically destroy the underlying viable cell layers. The best treatment in these cases is to dilute and remove the offending agents by flushing

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat055

with water. Time is of importance since even with immediate treatment with specific decontaminants after experimental phenol exposure, phenol was observed to still penetrate skin (Monteiro-Riviere *et al*., 2001a). The exception is CaO (quicklime), which violently reacts with water and generates heat, resulting in further thermal damage, and metallic (e.g. tin, titanium) tetrachloride compounds, which hydrolyse to hydrochloric acid on exposure to water causing further skin damage. These types of reactions are easy to assess using *in vitro* models such as the Corrositex® system, which detects macromolecular damage by acids and bases to a collagen matrix resulting in a chemical colour change in an associated detector system.

Direct irritation may be defined as an adverse effect of compounds directly applied topically to the skin not involving prior sensitization and thus initiation by an immune mechanism. Epidermal cells may be directly affected resulting in the initiation of a series of sequelae leading to irritation. Several types of adverse effects and chemical interactions may be manifested when a compound is placed upon the skin surface. Irritation is usually assessed by a local inflammatory response characterized by erythema (redness) and/or oedema (swelling). Other responses may be present that do not elicit inflammation, such as an increase in thickness. Irritant reactions may be classified by many characteristics, including acute, cumulative, traumatic and pustular, however two classifications are generally studied by toxicologists. Acute irritation is a local response of the skin usually caused by a single agent that induces a reversible inflammatory response. Cumulative irritation occurs after repeated exposures to the same compound and is the most common type of irritant dermatitis seen. The mechanisms of irritation are thus very complex and are still being characterized, since they involve interaction of inflammatory cytokines, with subsequent involvement of the immune system.

If a penetrating compound is capable of interacting with the immune system, the manifestations seen will be dependent upon the type of immunologic response elicited (e.g. cellular versus humoral, acute hypersensitivity, etc.). This response is termed contact dermatitis. Immune cells localized within skin (e.g. Langerhans cells, lymphocytes, mast cells) may modulate the reaction or the keratinocytes themselves may initiate the response. In fact, keratinocytes were once thought to produce only keratin and mucopolysaccharides, but recent studies have shown that they can produce growth factors, chemotactic factors and adhesion molecules. Keratinocytes may act as the key immunocyte in the pathophysiology of allergic contact and irritant contact dermatitis. Direct irritation of keratinocytes by toxic chemicals may also initiate this cytokine cascade without involvement of the immune system, blurring the distinction between direct and indirect cutaneous irritants (Nickoloff, 1993; Nettis *et al*., 2002). Damage in irritant contact dermatitis is a function of the duration of contact, strength of the irritant (penetrability and inherent potency) and frequency of contact.

It must be stressed that the primary mechanism by which most chemicals cause dermal irritation (e.g. organic solvents, corrosives) is through impairment of the stratum corneum barrier properties discussed earlier, reflected by an increase in TEWL. If the stratum corneum barrier is perturbed, a feedback response may be initiated, whereby regeneration of the barrier occurs. This reaction is mediated by cytokines (especially tumour necrosis factor (TNF)-α) originating locally within the epidermis. However, additional responses to these inflammatory mediators may in themselves launch an irritation response mediated by the keratinocytes. Some workers also believe that this disruption of barrier function is the initiating event resulting in atopic dermatitis, suggesting that therapies aimed at restoring barrier function are more important than those targeted at down-regulating the immune response.

Regardless of the initiating mechanism (direct irritation, immunologically mediated contact dermatitis), the sequelae to many irritants are the same, being primarily erythema and oedema. Testing strategies used to assess both types of dermatotoxicologic insults will be presented below.

4.1.1 Phototoxicity

Unlike other internal organs, the skin has the potential to be constantly exposed to sunlight. This often results in adverse effects. UV radiation encompasses short-wave UVC (200–290 nm), mid-wave UVB (290–320 nm) and long-wave UVA (320–400 nm). With the recently identified increase in UVB exposure in certain geographical regions apparently secondary to ozone depletion, this topic is becoming increasingly important. Although the ozone layer surrounding the earth filters out all UVC radiation, enough UVB and UVA reach the earth's surface to pose chronic and acute health hazards. The most common adverse effects from this exposure include sunburn and skin cancer, mostly be attributed to UVB exposure. Sunburn, the excessive cutaneous exposure to UVB radiation, is the most frequent and familiar phototoxic reaction. Phototoxicity is a nonimmunological UV-induced response. The effects on skin are similar to a typical sunburn characterized by erythema, oedema, vesication, increased skin temperature and pruritis followed by hyperpigmentation. Irradiated skin injury is histologically characterized by the presence of sunburn cells in the stratum basale layer of the epidermis. These cells are dyskeratotic with a bright eosinophilic cytoplasm and a pyknotic nucleus in H&E stained tissue. Ultrastructurally, they possess cytoplasmic vacuoles, and condensed filament masses mixed with remnants of other cytoplasmic organelles (Monteiro-Riviere *et al*., 1994). Exposure to UV light may also induce carcinogenicity in all skin

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat055
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cell types, including basal and squamous cell carcinomas as well as the more invasive and lethal malignant melanoma.

In addition to the direct effects of UV light on skin described above, some chemicals may be photoactivated to toxic intermediates that then cause skin toxicity. Exogenous phototoxic chemicals can be found in therapeutic, cosmetic, industrial or agricultural formulations, with tetracycline antibiotics being the classic example. Phototoxicity may also be secondary to endogenous substances resulting from abnormal products of intermediates of haeme biosynthesis such as porphyrins, caused by an inherited or acquired enzymatic defect. Several types of phototoxic events may occur, classified based on whether they are oxygen dependent or not. When a reaction involves oxygen, the molecules can absorb photons and transfer the energy to oxygen molecules, thereby generating singlet oxygen, superoxide anions and hydroxyl radicals that cause damage to the skin. This occurs when protoprophyrins are UV irradiated. A photochemical reaction involves absorbance of photons by the chemical resulting in an excited state that will react with the target molecules to form photoproducts. A good example of this type of reaction is 8-methoxypsoralen (xanthotoxin), which reacts with specific sites on DNA by forming covalent bonds between the pyrimidine base and the furocoumarin. This phototoxic reaction may be restricted to areas of skin exposed to UV light, an attribute that has been employed with therapeutic advantage to treat accessible skin tumours and psoriasis. With other compounds like chlorpromazine and protriptyline, the molecules absorb photons to form stable photoproducts which then induce cutaneous toxicity (Marzulli and Maibach, 1996; Moulton-Levy and Maibach, 2008).

4.1.2 Vesication

Another mode of chemical-induced damage to the skin is vesication where agents cause blisters, which are separations of the epidermal and dermal layers of the skin. There are two histological classes of blisters that reflect different mechanisms of vesication. Intraepidermal blisters are formed due to the loss of intercellular attachment caused by cytotoxicity or cell death, while defects in the basement membrane components contribute to the blisters that occur within the EDJ. The chemical warfare agent sulphur mustard (bis-2-chloroethyl sulphide; HD) is the prototypical chemical that has been used to define this type of toxicity. HD is a bifunctional alkylating agent that is highly reactive with many biological macromolecules, especially those containing nucleophilic groups such as DNA and proteins. HD is known for its severe cutaneous damage and systemic toxicity.

The HD-induced dermal lesion is characterized by vesication and slow wound healing (Papirmeister *et al*., 1991). Our laboratory has shown that the epidermal–dermal separation associated with vesication occurs in the upper lamina lucida of the basement membrane after HD-induced dermal injury in the isolated perfused porcine skin flap (IPPSF) (Monteiro-Riviere and Inman, 1995). It was once thought that alkylation of DNA with subsequent DNA crosslinks or breaks were the primary and initial event responsible for HD cutaneous toxicity (Papirmeister *et al*., 1991). This lead to the hypothesis that DNA alkylation, metabolic disruption and proteolytic activity had occurred. Studies in our laboratory have shown that gross blisters and microvesicles, with separation occurring at the upper lamina lucida of the basement membrane, were present at 5 hours after HD exposure (Zhang *et al*., 1995a; Monteiro-Riviere and Inman, 1995). This suggests that a basement membrane component is the target of HD alkylation. Vesication is also accompanied by inflammation, necrosis and apoptosis (Zhang *et al*., 1995b; Monteiro-Riviere and Inman, 1997).

5 MODELS FOR EVALUATION OF ABSORPTION AND TOXICITY

The focus of dermal absorption studies is to predict chemical behaviour in humans. Studies are often conducted directly on humans for many drugs and cosmetics, however, for screening of unknown molecules or severe toxicants, or to serve the needs of traditional toxicology testing for chemicals with suspected toxicity, surrogate animal species must be used. The selection of an appropriate species to study dermal absorption is largely based on the use of the data that will be generated. These objectives include assessing penetration or absorption and systemic exposure after topical application, dermal sensitivity testing, carcinogenesis and potential for direct toxicity to skin. Anatomical factors that play a role in selection of a model species include diseases, skin thickness, hair follicle density, blood flow and regional species differences (Bronaugh *et al*., 1982; Monteiro-Riviere *et al*., 1990; Monteiro-Riviere, 1991; 2006; 2008).

5.1 Absorption and Penetration

A large amount of literature compares dermal absorption of a wide variety of chemicals in humans and multiple animal species (Feldmann and Maibach, 1974; Maibach and Feldmann, 1974; Bronaugh *et al*., 1982; Scott *et al*., 1991; Wester *et al*., 1998; Riviere, 2006). To compile such data, factors such as applied dose, surface area, use of occlusive dressings, and vehicle or formulation should

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat055
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be controlled. Since rodents are the primary laboratory animal used to assess safety of numerous drugs and chemicals, their use in dermal absorption studies is required for making route-to-route extrapolations. Mice and rats are also employed for carcinogenicity 'skin-painting' studies. In general, rodents (mice, rats) are more permeable to chemicals than humans, making them suitable for defining worst-case absorption scenarios for toxicological end points. Rabbits and guinea pigs have been utilized in dermal immunology protocols assessing issues such as contact dermatitis and skin sensitization. Rabbits have also been used to assess dermal absorption, but in many studies they have showed an increase in absorption with many compounds compared to humans.

Animal species with minimal hair or fur should be used when the goal of the study is to predict the rate and extent of chemical absorption in humans. As hair follicle density increases to the level seen in furred rats ($\approx 300\,cm^{-2}$) or mice ($\approx 650\,cm^{-2}$), the interfollicular skin becomes thinner, thereby increasing absorption. In contrast, hair follicle density in humans is only $11\,cm^{-12}$, which is the same as pigs. Hairless rodents usually lack hairs, but actually have a lower hair follicle density ($\approx 75\,cm^{-2}$), the term hairless being applied to their lack of hair shafts and not follicles (Bronaugh *et al*., 1982). Apes are often selected due to their evolutionary closeness to humans, however regions of the body with minimal hair (ventral abdomen) must be used.

The domestic pig is widely touted as an appropriate animal model (Feldmann and Maibach, 1974; Maibach and Feldmann, 1974; Scott *et al*., 1991; Wester *et al*., 1998). In addition to similarities in hair follicle density, number of epidermal cell layers, skin thickness and cutaneous blood flow, the biochemistry and biophysics of the stratum corneum lipids are comparable to humans. Since body mass/surface area ratios are also like humans, extrapolations of systemic exposure are facilitated. In whatever species employed, one should be cognizant of the fact that regional differences in skin anatomy exist making the crucial animal descriptor both species and body site. In addition, when pig skin obtained from an abattoir is employed, one must be sure to harvest skin before scalding occurs in the carcass decontamination process.

Once an appropriate species is selected, the decision must be made between using intact animals *in vivo* versus numerous *in vitro* approaches. The 'gold-standard' for absorption studies are *in vivo*, however the extent of variability inherent to this work often precludes intact animals being used for detailed probing of the mechanisms involved. Additionally, *in vivo* approaches are expensive, require special facilities, and are not accepted by some regulatory authorities for cosmetic screening. These approaches are extensively reviewed elsewhere (Riviere, 2006).

5.1.1 In Vivo Approaches

The classic technique used to assess absorption of any compound exposed to the body is by measuring the amount excreted into urine and faeces compared to that excreted after intravenous administration of an equivalent dose. The ratio of the total amount excreted after dermal to intravenous dosing is termed the *bioavailability*, referred to as F. This parameter can be calculated by collecting the plasma concentrations and comparing the ratio of their areas under the concentration-time profile (AUC). The reason F has to be determined relative to a parenteral route such as intravenous is that differences in metabolism between chemicals may change the rate and or extent of excretion or the percentage of a drug present in the central plasma compartment. Once the fraction of the dose eliminated in urine or faeces is known, then only the excreta needs to be collected to get future estimates of absorption. An extension of this is used when urine is monitored for assessing systemic exposure. If creatinine concentrations are also collected (marker of urine production), and drug mass normalized by it, then monitoring of only chemical concentrations and creatinine is sufficient to make estimates of relative systemic exposure or absorption after different topical chemical treatments.

All of these approaches require timed samples and careful analysis. Experiments should only be ended when the majority of the compound has been eliminated (e.g. approximately 80%). For dermal applications with very slow rates of absorption, the length of the study required to insure complete systemic distribution and elimination can be lengthy. Truncating studies earlier may lead to erroneous conclusions. When conducting such studies, care must be taken to insure the dose completely covers the marked exposure area and that this surface area is measured.

Additional approaches have recently been developed which attempt to assess *in vivo* absorption by monitoring the drug absorption process from the perspective of concentrations in stratum corneum tape strips (Rougier *et al*., 1985; Nylander-French, 2000). This approach, termed *dermatopharmacokinetics*, analyzes the amount of drug in skin at the application site by sequentially removing and analyzing the drug on the surface (nonabsorbed drug) by gentle washing and swabbing. Various approaches are then employed to model the diffusion gradient reflected in the stratum corneum depth profiles. These techniques must first be calibrated to normal human absorption end points before reliable predictions can be made.

5.1.2 In Vitro Approaches

A primary technique used to study dermal absorption in both humans and animals is to mount skin samples into a diffusion cell and measure chemical flux into a perfusate bathing the dermal side of the skin sample. Specific

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat055
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

protocols have been established relative to membrane preparation and perfusate composition (Bronaugh and Stewart, 1984; Bronaugh and Stewart, 1985). Skin may be either full-thickness, heat-separated epidermal membranes or dermatomed skin (skin sliced into discs of predetermined thickness). If haired animal skin is employed, the skin section must be sufficiently thick to avoid cutting off the base of the hair follicles in the dermis. Skin is then clamped between two chambers, one of which contains a vehicle from which the absorbed chemical will be sampled. *Static* diffusion cells sample this chamber and replace with new perfusate at each time point. *Flow-through* cells use a pump to pass perfusate through the receptor chamber and collect flux by repeatedly collecting the perfusate.

In some systems, the skin disc is first fully hydrated and allowed to equilibrate with media before dosing. Receptor fluid is usually saline for pharmaceutical drug studies or a media containing albumin or a surfactant/solvent for studies of organic chemicals where some degree of lipid solubility in the receptor fluid is required. Perfusate should be heated to 32 or 37 °C according to experimental guidelines. If the chemical is dissolved in water and dosed in the donor chamber at a dose that far exceeds the amount absorbed, this experimental condition is termed an *infinite dose* experiment. In contrast, if the dose is applied at typical exposure situations and exposed to ambient air or covered (occluded), the experiment is termed *finite dose*. In this case, relative humidity of the dosing environment may be important.

The skin source is an important consideration. In human studies, skin may either be obtained fresh from reconstructive surgical procedures, or dead from cadaver sources. In the latter case, skin is often frozen and then thawed before use. In these cases, a membrane integrity test is conducted using ^{3}H water absorption to screen skin discs for lack of barrier integrity. Fresh skin should be used to insure an intact barrier and healthy tissue, a factor extremely important for metabolism studies and to minimize hydration from the ^{3}H integrity studies. These skin samples are often perfused with oxygenated media to maintain metabolic functions. Artificial skin grown using air–liquid interface cultures are also available, although the permeability through such systems is presently much greater than that of normal human skin. Many artificial 3D model systems only contain keratinocytes and do not contain all of the other cell types or appendages that are present in skin. When only the stratum corneum is to be studied, some workers have used shed snake skin as a model to assess the absorption properties and have reported results comparable to humans.

In vitro models are the predominant approach used to assess dermal absorption today. They are the sole method used to calculate absorption parameters, such as permeability discussed above. Numerous protocols have been proposed for specific purposes, such as assessing absorption of lipophilic pesticides versus transdermal delivery of more hydrophilic drugs. Differences between such protocols often relate to surface decontamination methods (swabs, wash, etc.), perfusate composition (addition of vehicle to enhance solubility of penetrant) and length of experiment. If penetration is to be assessed, chemical concentrations in the remaining skin disc after surface drug removal must be measured. Finally, specific types of experimental designs must be used to provide data for specific mathematical modelling approaches, considerations that often dictate specific approaches.

5.2 Toxicity

There are several types of irritancy testing protocols that are performed in order to comply with federal and international safety regulations. The most common test, developed in 1944, is the Draize test to measure acute primary irritation (Draize *et al*., 1944). The test compound is applied in an occluded fashion to a clipped area of abraded and intact skin of at least six albino rabbits, and evaluated at 24 hours, when the patches are removed. The exposed areas are re-evaluated at 24 and 72 hours and scored according to **Table 1**, which depicts scores for erythema and oedema ranging from one to four depending on the severity of the irritation. Many modifications have been made to this scoring system over the years and most cosmetic and pharmaceutical companies have their own modified Draize test. Since these tests are conducted in an occluded fashion, irritancy is potentiated due to hydration reducing the skin barrier and promoting penetration. The Draize test may be modified to assess sensitization and contact dermatitis by pre-exposing animals to a sensitizing dose of the study chemical or a general sensitizer such as dinitrophenol (DNP) and then rechallenging the animals at a later date to illicit the immune-mediated response.

More sensitive markers of *in vivo* irritancy than gross examination have been developed. Many studies have correlated Draize scores with noninvasive biophysical estimates of erythema, the hallmark of skin irritation. Erythema may be assessed using a myriad of different colour-measuring instruments that attempt to objectively quantitate, on a continuous scale, the subjective categorical assessment inherent to human scoring systems. These systems are based on reflectance principles and operate by irradiating skin with specific light wavelengths and measuring the colour of the reflected light. These systems can also detect toxin reactions that alter the melanization process and produce altered skin pigmentation. Erythema, which results from increased blood flow, may be directly assessed using noninvasive laser Doppler velocimetry, which measures dermal blood flow. As mentioned in the absorption section above, a sensitive indicator of loss of barrier function associated with dermal irritation is TEWL.

Table 1 Draize skin reaction assessment scores

Erythema	Score	Skin reaction
	0	No significant change
	1	Very slight (barely perceptible)
	2	Well defined; pale red
	3	Moderate to severe; definite red; area well defined
	4	Severe; beet or crimson red
Oedema	**Score**	**Skin reaction**
	0	No significant change
	1	Very slight (barely perceptible)
	2	Slight; edges show definite raising
	3	Moderate; edges raised 1 mm
	4	Severe; raised more than 1 mm and extending beyond area of exposure

Phototoxicity: In vitro 3T3 neutral red uptake
- OECD 432 adopted April 2004

A great deal of research has been conducted to develop humane alternatives to the Draize test using principles of modern *in vitro* science. A number of test systems have been approved by the Organization for Economic Cooperation and Development (OECD) and are listed in **Table 2**. Additional systems employ a skin organ culture approach that attempts to provide the stratum corneum barrier and viable epidermal cells, which can react to penetrated compounds. Since these are essentially organ culture systems, the cell viability may be assessed by sampling the bathing culture medium. Neutral red (3-amino-7-dimethyl amino-2-methylphenazine hydrochloride) can be used to probe lysosome integrity while thiazol blue (3-4,5-dimethylthiazol-2,5-diphenyltetrazolium bromide; MTT) is a mitochondrial enzyme substrate that can assess if these organelles are metabolically viable. Leakage enzymes such as lactate dehydrogenase (LDH) can be assayed to detect cell membrane damage. Reactive products (cytokines, prostaglandins) produced by keratinocytes may be detected in the culture medium. Recent work in our laboratory assessing the potential cutaneous toxicity of manufactured nanomaterials has demonstrated that these systems, fully validated for chemical toxicity assessment, may not be optimal for nanomaterials due to their interaction with dye production (binding, catalysis) or cell imaging (Monteiro-Riviere and Inman, 2006; Monteiro-Riviere *et al*., 2009).

5.3 Absorption/Toxicity Models

The optimal *in vitro* cutaneous model should possess viable cells and structures similar to intact skin, as well as a functional vasculature. Such a model would allow topical chemical absorption to be assessed simultaneously with direct toxicity. Our laboratory has developed the IPPSF, an *ex vivo* perfused skin preparation precisely for this purpose (Bowman *et al*., 1991; Riviere *et al*., 1986; Monteiro-Riviere, 1990; Riviere and Monteiro-Riviere, 1991). An anatomically intact alternative animal model, the IPPSF possesses a viable epidermis and an accessible and functional microcirculation. It is experimentally much closer to *in vivo* than excised skin and is thus a more appropriate *in vitro* model for assessing percutaneous absorption. The IPPSF model has been shown to be predictive of *in vivo* human absorption (Wester *et al*., 1998). This model was also used to study UV phototoxicity (Monteiro-Riviere *et al*., 1994). In addition to morphologically assessing the dose-dependent formation of sunburn cells, decreased

glucose utilization was observed, accompanied by increased vascular resistance and cell proliferation decreased by assaying proliferating cell nuclear antigen (PCNA). Levels of prostaglandin E_2 in the perfusate from UVB exposed skin flaps also increased in a dose-dependent manner, reflecting the cutaneous irritation response. This study demonstrated the utility of this model, since the morphological, biochemical and physiological changes could be experimentally monitored and evaluated in the same preparation.

6 CONCLUSION

There is continued and renewed interest in assessing dermal absorption and toxicity of topically applied drugs and chemicals, since skin is a common route of exposure for occupational and cosmetic entities, as well as dermatological and transdermal drug preparations. Penetration is inextricably linked to dermal toxicity, since most toxicants, no matter how potent, must first penetrate the protective stratum corneum barrier to reach cellular target sites (e.g. Langerhans cells or other epidermal cells). Testing approaches that ignore this barrier function may overestimate the potential for dermal toxicity. Another unique aspect of dermal toxicology is that for most types of topical irritants, once initiated, the cutaneous response characterized by erythema and oedema are similar and fairly independent of initiating mechanism. A major challenge to most research protocols is to move towards *in vitro* platforms that are predictive of *in vivo* responses. This challenge will continue to drive dermatotoxicology for the foreseeable future.

Inhalation Toxicity

Geoff H. Pigott

CONTENTS

1 INTRODUCTION

Of the three main portals of entry into the body, inhalation, ingestion and dermal penetration, the first two are quantitatively dominant. The main portal of entry for bulk materials is via ingestion and the digestive tract is adapted to facilitate this, in particular, for the entry of nutrients. To achieve sufficiently rapid exchange, the epithelium lining the gut is folded with an extensive network of microvilli so the total area available for absorption is very large. In the case of inhalation, the main function of the lung is to facilitate the entry of oxygen and dispose of surplus carbon dioxide. This also requires a large surface area for efficient function and the total gas exchange area of the lung is about half that available for absorption via the gastrointestinal tract. By comparison with these structures the skin area exposed to external influences is small and better adapted to protect the organism from the environment.

Extraneous materials, both gaseous and particulate, may be entrained in the inspired air and thus have the capacity to enter the circulation by inhalation exposure. The physiological adaptations that facilitate gas exchange will clearly also maximize absorption of other external agents which might penetrate to the alveolar spaces. Chemicals absorbed in this way are readily dispersed in the blood. Unlike ingested materials, these do not automatically pass through the liver before entering into the general circulation. Thus, the potential for metabolic detoxification may be significantly reduced for chemicals absorbed by inhalation, and this can lead to different dose–response relationships for inhaled compounds when compared with oral exposures, although there are fewer differences in the character of response expressed.

Oral exposure is relatively simple to execute, and dosimetry easy to measure with acceptable accuracy, and this is often the primary route by which the toxicity of xenobiotics is assessed. Thus in many cases, a primary aim of the inhalation toxicologist may be to define whether inhaled material will significantly influence the character of the response and/or lead to very different dose–response relationships compared with oral exposures. In some instances, for example, gaseous pollutants, the lung may be the primary route of entry, but for others, such as liquid or solid aerosols, oral exposure may be quantitatively significant even when the exposure is via the air.

Nevertheless, inhalation exposures are significant, both for their potential systemic effects and, often more importantly, for the local response in the lung itself. Assessment of these responses, especially establishing quantitative dose relationships is challenging, both technically

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and intellectually. Much human disease is transmitted via the air and the mechanisms by which the various responses are induced are at best only poorly understood and often not at all at the molecular level. Elucidation of the mechanisms and kinetics involved is a major challenge.

This text outlines the major features of lung structure and physiology as a backdrop to the range of potential effects that can be induced. The various responses to toxicants, both gaseous and particulate are described, together with the major factors that determine tissue dose. Finally the model systems developed to assess inhalation toxicity are outlined.

2 BASIC STRUCTURE AND FUNCTION OF THE LUNG

2.1 Lung Anatomy

The primary purpose of the lung is gas exchange of oxygen from ambient air with carbon dioxide produced by respiration. The physical exchange between air and circulating blood is achieved by diffusion and thus may be approximated by applying the equations of Fick's laws. These determine that the main requirements for rapid equilibration will be a short path for gas exchange, that is, the capillaries carrying the blood must be only a short distance from the external air, and a large surface area to accommodate the necessary volume exchange for the organism. The total surface area required is a function of body size, although not directly proportional. The structures evolved to achieve this are more complex than this limited function might suggest. Respiratory exchange is vulnerable to many factors. Water loss is perhaps the most difficult to control. Incoming air may be dry, the diffusive surface needs to be moist to facilitate both solution of the gas and its rapid diffusion. Unless this process is controlled, the resultant loss of water would be rapidly fatal to most land-dwelling organisms. A second feature is the potential for infection. A moist warm area, plentifully supplied with nutrients via blood, provides perfect conditions for culturing microorganisms, including pathogens. In higher organisms these problems have been resolved by two different structures: those present in mammals and those in birds. Most important, for the purposes of toxicology, is the mammalian system (**Figure 1**). All such structures consist of a system of nasal turbinates which warm and condition incoming air and remove any larger particles that may be suspended in it. Air is then conducted via the trachea into a series of branching tubes. The branches may be symmetric or asymmetric, but their purpose is to distribute air flow into a series of balloon-like sacs, the alveoli, in which the process of gas exchange takes place. From the trachea down, the organ is encased in a sealed cavity in the chest which may be expanded and contracted by muscular activity, thereby pumping air in or out. For many of the smaller mammalian species, nose breathing is obligatory, although in others, for example primates, dogs, there is also the option of inhaling and exhaling via the mouth (oronasal breathers)

This basic structure consists of several different types of cell. The greater part of the internal nasal passage is covered by respiratory epithelium. Embedded within this are mucus-producing goblet cells, ciliated cells, cuboidal cells and basal cells, together with other specialized structures, in particular the olfactory epithelium occupies part of this structure. This latter epithelium consists of sensory cells with densely packed nerve endings, together with the sustentacular (supporting) cells. Responses of this structure are beyond the remit of this chapter. The larger conducting airways are lined with a pseudo-stratified epithelium containing ciliated cells and secretory cells. The most important of the latter are the mucus cells that produce a high molecular weight glycoprotein, the basic component of respiratory tract mucus, and the serous cells, which produce a more

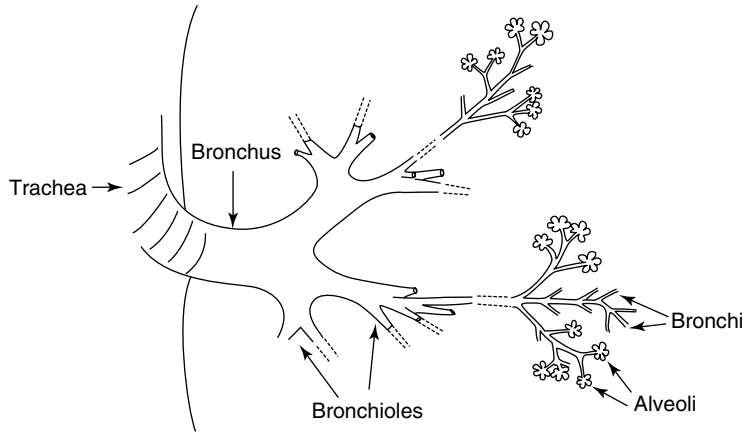

Figure 1 Basic structure of the mammalian lung.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat056
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

fluid matrix in which the mucus partially dissolves. This system provides a sticky surface which can trap particles, including bacteria and other microorganisms present in the incoming air, in the surface layer, with a more mobile layer beneath. Flagellae on the surface of the ciliated cells beat in a regular fashion such that the mucus is cleared towards the larynx, where it is eventually either swallowed or expectorated. This is an important primary defence mechanism for lungs; material deposited on the 'mucociliary escalator' may be cleared from the lung within an hour or so. Inhibition of the system may therefore have significant influence on lung dosimetry and factors that cause such inhibition can enhance the toxicity of other pollutants by effectively increasing the received dose. The conducting airways also contain connective tissue within the walls, which imparts stiffness so that they remain patent under reduced pressure, and smooth muscle, which can contract and constrict the airways in response to various adverse stimuli.

Respiratory bronchioles (about 2 mm diameter in man) are the transition zone between the purely conducting airways and the area of gas exchange. These are lined with a cuboidal ciliated epithelium and also the nonciliated Clara cells. The Clara cells have several roles including secretion of components of pulmonary surfactant. They also have metabolic capability for xenobiotics via a P450-type enzyme system, are considered the major sites for metabolism of mucus that has strayed beyond the ciliated airways and are the progenitor cells for the ciliated bronchiolar epithelium.

Beyond the respiratory bronchioles are alveolar ducts and finally alveoli. This region is marked by a transition to a different epithelial type, consisting of Type I and Type II epithelial cells. Type I cells are flattened and have a very large surface area. These are the locus for gas exchange. Type II epithelial cells produce lung surfactant and may also divide to replace damaged Type I cells. In most species they are slightly more numerous than the Type I cells, although they occupy much less of the lung surface area, being more cuboidal. The alveolar spaces contain specialized macrophages (alveolar macrophages). These are derived from similar stem cells to macrophages found elsewhere in the lymphatic systems and reside in the interstitium before entering the alveolar spaces. However, in their terminally differentiated form they are distinct from the circulating macrophages.

The above describes primarily the 'air side' of the lung. On the 'body side' there is a branching structure of blood vessels ending in a capillary bed which closely lines the interior of the alveolar spaces. The whole is supported by a structure consisting primarily of connective tissue and cartilage and contained within an airtight sac (the visceral pleura) consisting primarily of mesothelial cells. The lung is contained within the thoracic cavity, a bony cage formed by the ribs, which also contains an airtight lining (the parietal pleura) consisting of mesothelial cells. The base of the cavity is sealed by a muscular membrane (the diaphragm) which can expand and contract, together with the ribcage, to vary the air space within the chest cavity. This creates the bellows effect which is responsible for the process of breathing.

The lung lymphatics are mainly situated around the bronchial vascular channels that drain to the hilar lymph nodes. In addition, there is a fine system of lymphatic vessels on the pleural surface, which drain into the pleural space and ultimately through the diaphragm and into the peritoneal cavity.

This picture is simplified in this text in order to emphasize the main structures involved and to direct the reader towards the functional areas that may be affected by various toxicants. More details on the anatomical structure of the lung and of the cellular types present may be found in standard anatomical texts. A detailed understanding of the cell types involved may be important in the assessment of mode of action of individual toxicants, but, as with many aspects of toxicology, it is more important in the first instance to consider the basic principles.

The second anatomical structure which has evolved for gas exchange is exemplified by the lung in birds. This is sometimes described as a 'bottle brush' lung and consists of a series of air sacs leading into branching airways, which then recombine to give a 'flow through' structure rather than the 'in and out' structure seen in most mammalian systems. In some respects this provides more efficient gas exchange, but at the expense of being more prone to external influences and infection. This is arguably the price which much be paid for the greater efficiency per unit weight and hence facilitation of flight. More information on these structures can be found, for example Duncker, 1971; Duncker, 2004; Powell, 2000, but they will not be considered further in this text.

2.2 The Physiology of Gas Exchange

The movement of air into and out of the lungs follows a bellows-type action. The chest is expanded so that the rib cage moves upwards and outwards while the diaphragm is moved downwards. This increase in volume of the thoracic cavity allows the lung to expand passively in response to the partial vacuum created. Air flows through the nasal passages and/or the oral cavity via the trachea and the branching tube systems towards the alveoli. After the process of gas exchange this process is reversed, with the rib cage contracting, the diaphragm moving upwards and the consequent reduction in volume of the thoracic cavity driving the air from the lung back into the atmosphere. The process typically involves expansion of the lung from a minimum of approximately 1.2 l to a value of approximately 5.5 l in the typical 60 kg adult. These values are known as the residual volume (RV) and total lung capacity (TLC) respectively and show a relationship to body size in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat056
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

all mammalian species. The maximum difference which can be achieved between these values is termed the forced vital capacity (FVC). Normal respiration involves a lesser change in lung capacity, which may be as small as 500 ml for a person at rest. This change is termed the tidal volume (TV), which increases markedly in response to stress and/or exercise. In oronasal breathers increases in TV are likely to coincide with an increase in the frequency of mouth breathing, rather then nose breathing. This has significance, especially for the intake of particulates and aerosols; these are discussed later. Measurements of the various capacities of the lung can provide important indices of injury. These measurements are well developed in humans, where a series of normal physiological values has been established over a long period of time. These depend mainly on age and sex, but have also been developed for specific populations.

The volume change associated with a unit of pressure change across the lung is defined as compliance. Measurements of compliance show that the values obtained during expiration (lung deflation) differ from those achieved during inspiration (lung inflation). This hysteresis illustrates the contribution of pulmonary surfactant in maintaining the structure and integrity of the lungs. A brief consideration of the nature of the alveoli, that is, small air-filled sacs bound with an aqueous fluid, leads to the conclusion that other things being equal, once deflated they should be extremely difficult to reinflate, due to the effects of surface tension. The gas pressure (P) needed to keep equilibrium between the collapsing force of surface tension (T) and the expanding force of gas pressure in an alveolus of radius (r) is expressed in the equation:

$$P = \frac{2T}{r} \text{(Laplace's rule)} \qquad (1)$$

indicating that once collapse commences, this is an accelerating force. The surfactant produced by Type II pneumocytes is highly surface active and consists predominantly of phospholipids, mainly phosphatidyl choline. Other phospholipid components include phosphatidyl glycerol and phosphatidyl inositol. Surfactant also contains about 10% protein and 10% neutral lipids, including cholesterol. All components have been shown to be important for the overall function (Goerke, 1998). This surfactant not only reduces the overall surface tension within the lung, but has the unusual property of further decreasing the surface tension as it is compressed. Thus, as alveoli deflate, the surface tension decreases, so that at the end of expiration the value approaches zero. This makes the lungs relatively easy to reinflate. Conversely, as inflation continues the surface tension increases, imposing an effective limit on the size to which individual alveoli can expand. Surfactant also plays an important role in entrapment of particles that may be deposited in the alveolar spaces. Abnormalities in pulmonary surfactant, whether induced or congenital, may be important contributors to pulmonary disease (Devendra and Spragg, 2002).

Gas exchange across the alveolar membrane is primarily passive. Oxygen diffuses inwards and combines with the iron contained in haemoglobin in the red corpuscles. The diffusion path is sufficiently short for this process to be completely saturated well within the half second or so that the red corpuscles spend adjacent to the alveoli. At the same time carbon dioxide is released from the blood and diffuses across the membrane into the alveoli. This is enhanced by the presence of the enzyme carbonic anhydrase in the red blood cells, which dissociates the bicarbonate formed when carbon dioxide is collected from the tissues. Each inspiration does not result in a complete change of air in the alveolar spaces; although there is mixing of the inspired air, the flow rate becomes very low beyond the terminal bronchiole. As a result alveolar air contains about 5.5% carbon dioxide and diffusion from the blood results in equilibrium with this value, (a feature that is well recognized in tissue culture).

2.3 Defence Mechanisms in the Lung

These can be divided into two categories, mechanical and biological. Together they are effective in reducing exposure of the more sensitive areas of the lung to many toxicants, especially those in particulate form.

2.3.1 Mechanical Defence Mechanisms

The mechanical defence mechanisms reflect the structure of the respiratory tract. These are effective against particulate (liquid or solid) contaminants in air and provide a defence against invading microorganisms. The primary air intake through the nares will include entrained particles. However, in general, the initial airflow is upwards and this creates a vertical elutriation effect which eliminates the largest particles. It is generally agreed that particles much larger than about 50 μm will not enter the respiratory tract, at least during nose breathing. In obligate nose breathers, such as small rodents (and other underground dwelling animals), the nasal turbinates are convoluted. Thus, in addition to warming and humidifying incoming air, they create a turbulent flow, which causes the impaction of much of the particulate burden onto the mucus-lined cellular surface. Air flow over the larynx creates further turbulence and further deposition so that as air enters the trachea only relatively small particles (less than about 10 μm) remain entrained in the air flow.

For oronasal breathers, the nasal turbulence may be bypassed and larger particulates remain entrained in the airflow at the larynx. Nevertheless, the turbulence created

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat056

at this point is sufficient to remove most of the larger particles such that air entering the trachea is substantially depleted of particles $>15\,\mu m$. Thus, although the pattern of deposition in the oronasal region will vary between obligate nose and mouth breathers, air entering the trachea is depleted of large particles in both groups.

In the trachea and bronchi further deposition mechanisms operate. As outlined above, the major deposition route for larger particles is inertial impaction, which is enhanced by turbulent airflow. This mechanism continues to influence deposition within the ciliated airways although it becomes progressively less important as the larger particles are deposited. In a system of branching tubes, with a consequent division of the airflow into substreams, inertial deposition of particles on the carina is inevitable, and there is substantial evidence for such deposition in both humans and experimental animals. The mucus coating of the conducting airways ensures that, once deposited, by whatever mechanism, particles remain trapped in this surface and are subsequently cleared and not resuspended. However, some exposures lead to inhibition of the clearance mechanism and in these cases carinal deposits may be significant in the development of lung disease, including the development of bronchial carcinoma in cigarette smokers.

Gravitational settlement becomes increasingly significant as a route for particle deposition as the diameter of the bronchioles decreases. This is readily modelled in principle as the particles essentially follow Stoke's Law. (Quantitative aspects of deposition are addressed in Section (4.3.3).) The tortuous route for airflow means that the absolute importance of this deposition mechanism varies within lung lobes and possibly between them, but settlement becomes the dominant process for particle removal in all the bronchiolar regions. At this point, diffusion is relatively unimportant, although it becomes increasingly so as airway size diminishes further. By the time the incoming air has penetrated to the respiratory bronchiole, where the mucus coating of the conducting airways is no longer present, most particles $>2.5\,\mu m$ have been removed. Particle deposition in the respiratory bronchioles and alveolar areas depends primarily on diffusion. Although gravitational settlement still plays a part, the remaining particles are sufficiently small for Brownian motion to be a significant factor in maintaining their suspension. Particles above about $0.5\,\mu m$ diameter may be substantially deposited in the alveolar region, although the very smallest particles (less than $0.1\,\mu m$) may remain in suspension for sufficient time to allow a proportion to be exhaled.

All of the above assumes that the particles involved are insoluble. Particle solubility or even wettability will influence behaviour within the respiratory tract and hence the ability of the organism to remove them from the air. At one extreme, hygroscopic particles will increase in diameter as they penetrate the respiratory tract. This leads to the possibility of devising particles with properties that maximize their deposition in specific regions of the tract. This property is exploited for therapeutic purposes in a limited number of cases.

2.3.2 Physiological Defence Mechanisms

A primary defence mechanism is the ability of the major airways to constrict. Smooth muscle in the bronchial walls contracts in response to various stimuli, effectively restricting airway size and thus the TV. In the short term this reduces exposure to contaminated atmospheres, but may rapidly become an impediment when the restricted airflow becomes physiologically limiting. Chronic contraction of this musculature is associated with asthma.

The contribution of the mucus layer in the branching airways has already been mentioned. This is an important feature for the removal of deposited materials within the conducting airways. Pulmonary surfactant plays a similar role in the nonciliated airways, but in this instance excess surfactant is removed by alveolar macrophages. In addition to clearing excess or damaged surfactant, these mobile phagocytes will engulf any particulate material found within the alveoli/terminal bronchioles. In common with other macrophages, phagocytosis results in particles being confined in secondary lysosomes, where they may be digested or dissolved by a combination of enzyme attack and low pH. The latter may be especially important for mineral particles. The pH range of the secondary lysosome is variously quoted in the range 4–5.5, but these values have limited applicability. In effect, hydrogen ions may be secreted directly through the lysosome membrane onto the contained particle, with limited water present. This is a probable mechanism for the aggressive dissolution of particles seen in the secondary lysosome, a process that is more effective than the nominal pH value would indicate.

Particles refractory to digestion may suffer various fates. Some particles, especially crystalline silica may disrupt the membrane in the secondary lysosome. This may be important in various disease processes. Particles nontoxic to the lysosome membrane may be maintained for longer periods. The fate of particle-laden macrophages depends to a degree on the materials ingested, but many may re-enter the interstitial space and the lymphatic circulation and significant burdens of particulate contaminants may subsequently be found in local drainage lymph nodes. Alternatively, in cases of heavy contamination, some macrophages accumulate in groups of adjacent alveoli. This concentration may be sufficient to fill the relevant alveolar spaces to the point where gas exchange is significantly inhibited. At this point, various pathological reactions may occur, including the formation of giant cells and the induction of a 'foreign body' reaction. This latter usually results in the collected macrophages, with their burdens of contaminant particles, being sequestered within a fibrous

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

capsule, where they may remain for very long periods. Finally, some alveolar macrophages migrate to the ciliated airways, where they are entrained in the mucociliary escalator and eventually find their way to the pharynx, where they are subsequently ingested, or occasionally expectorated.

3 RESPONSES OF THE LUNG TO TOXIC INSULT

In addition to systemic effects following absorption into the lung, there are several local reactions that can be induced and which may have more or less of an effect on lung function. These range from primary irritation, which can result in a temporary and reversible, but occasionally very severe, reduction in the exchange capacity of the lung, to longer-term effects involving permanent damage, reduction of exchange capacity and in some cases to lung cancer. Further responses may be mediated by the immune system and can lead to permanent disability via airway constriction in an asthmatic-type response. These latter reactions, which can occur in response to gases, liquids or particulates are addressed in **Risk Assessment of Chemicals** (respiratory sensitization). The local reactions have a relatively limited range of outcomes, primarily manifest as reduced lung function, but there is a range of underlying mechanisms. These mechanisms relate to the intrinsic properties of the toxicants concerned, in particular their physical state (gases, liquid aerosols and particles), as well as their mode of action. Thus it is convenient to consider each of these physical states separately when attempting to model and predict the effect on the respiratory system. However, in adopting this broad classification for pollutants it is necessary to remember that in a significant number of cases the states will overlap, for example, liquid aerosols will be in equilibrium with vapour,[a] low melting point solids may change from dusts to liquid aerosols as they warm in the lung.

3.1 Toxicity of Gases

These are the simplest form to consider, at least in terms of entry into the lung, as they will mix completely with incoming air. Concentration is usually expressed in terms of partial volume (v/v) usually as parts per million (ppm), but for some of the more common and nontoxic gases this can be expressed as a percentage. Defence against such toxicants is limited to restriction of air intake overall.

For gases, the lung is the most important and usually the only portal of entry. Their subsequent fate depends on the nature of the gas. Small and relatively inert molecules may have no specific effect and enter and leave with the air stream, though their presence in sufficient quantities may dilute the oxygen content of the air to the extent where asphyxiation occurs. More commonly, hydrocarbon and other lipid-soluble gases may dissolve in the alveolar membranes and reduce gas exchange by that route. Once in the alveolar spaces, gases will be absorbed by diffusion and can exert systemic affects. This property is widely exploited in the use of anaesthetic gases, (for example see Franks, 2006). As mentioned previously, this portal of entry bypasses the metabolizing systems present in the liver and thus may modify dose–response relationships in comparison with oral exposures. Though there is metabolic capacity in the lung (mainly in the Clara cells found in the terminal bronchioles), this is less extensive than the liver and it is possible for gaseous pollutants, in particular, to bypass these specialized cells. Once absorbed, gaseous pollutants can, in theory, exert effects throughout the body, although in practice these are most commonly seen in the blood. Specific examples include carbon monoxide poisoning and hydrogen sulfide poisoning. Both of these are attributed to the combination of the inhaled gas with haemoglobin, with consequential effects on oxidative processes for energy production.

A common feature of gases that are known to provoke systemic effects is their lack of water solubility. The more soluble gases are generally associated with a localized response. These include the acid halides, sulphur oxides and nitrogen dioxide, all of which will dissolve in the fluids lining the lung surface. The most common response is irritation of the lung. The form which this takes depends on how far the gas has penetrated into the lung before dissolution and hence on its solubility. The most soluble gases induce an acute sensory irritation, characterized by an irritant or burning sensation in the upper respiratory tract throat and chest; the eyes may also be irritated by similar mechanisms. There is a reflex decrease in breathing rate and there may be bronchial constriction. The onset is very rapid and severity tends to be concentration dependant. The immediate effect is to reduce the intake of contaminated air and thus limit exposure. The effects are usually sufficiently severe to induce exposed individuals to escape from the situation in order to alleviate them. This is the principle of the irritant gases used in riot control. Generally, minor exposures of this nature have no long-term consequences. However, prolonged exposures and/or higher concentrations may result in severe respiratory distress caused by lung irritation and inflammation. Chronic exposures result in a degree of resistance to initial irritant effects, but may also lead to a range of longer-term deleterious consequences, including emphysema, bronchitis and in some cases squamous metaplasia of epithelia. All of these are a consequence of cellular damage and in the case of 'pure' acid gases, are likely to be consequent on the concentration dissolving in the surface liquid being sufficient to overcome the buffering capacity of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat056
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

natural fluids, with consequent loss of homeostasis for the underlying epithelia. There may be a similar response to alkaline gases (of which ammonia is the only common example), although high pH tends to be more directly damaging to tissue than low pH, so that effects are more severe.

For gases that can penetrate deeper into the lung, either by dint of concentration or lower rate of dissolution, the effects can be more severe. Where dissolution occurs in alveolar spaces, a severe lung oedema may result, which in extreme cases can be fatal. This is an acute phase of lung injury where fluid can seep into the alveolar spaces, presumably as a consequence of damage to the Type I epithelial cells and/or a loss of integrity in the junctions between them. The result is an accumulation of a serous fluid in the alveolar space, which severely limits the diffusive exchange of oxygen and carbon dioxide, even in the absence of frank structural damage. With continued exposure, this condition may become rapidly progressive and ultimately fatal. However, if exposure is discontinued, in many cases the condition will resolve completely, with no obvious residual injury. Chronic lower-level exposures to such agents can result in lasting tissue damage, with various consequences which will be discussed later. Tissue damage in the alveolar area may be more extensive and more difficult to repair than that in the upper airways. Thus, the longer-term consequences of exposure to these gases, which include sulphur trioxide and nitrogen dioxide, tend to be much more severe.

In the case of several pollutant gases, additional mechanisms contribute to the overall effect. Examples include chlorine and bromine. Although both of these gases are sensory irritants, this is not a reflection of their intrinsic properties, but rather of their ability to react with water to produce both the acid halide and the relevant hypohalide. This latter is sufficiently reactive to produce oxidative damage in the underlying tissue. It is probable that the oxidative damage caused by exposure to agents such as hypochlorites (and other oxidizing agents, such as ozone), is mediated through superoxide/free radicals and is evident when these are present at sufficient concentrations to overwhelm local defence mechanisms. It is likely that the lung is particularly susceptible. Most tissues are exposed to oxygen only in combined form. Even under these conditions, formation of superoxides and free radicals can be a mechanism of cellular injury, although most cells are equipped with adequate mechanisms to detoxify these radicals as they are formed. Uniquely, the lung is exposed to molecular oxygen and its primary function is to capture this and convert it to its combined form with haemoglobin. Thus, within the pulmonary tissues, cellular defence systems must be sufficiently sensitive to capture and detoxify free radicals and superoxides, but not sufficiently active to react directly with molecular oxygen. This is a difficult equilibrium to maintain and prolonged exposure of the normal lung to enhanced oxygen levels will result in long-term damage.

As with the sensory irritants, the less soluble or less reactive gases may penetrate deeper into the lung where there is a larger surface area exposed and where the consequences of such exposures may be more severe, as the surface cells are not protected by a mucus layer.

3.2 Toxicity of Liquid Aerosols

There are two main features that distinguish exposures to liquid aerosols from those to gases. The first is the relative dose that may be achieved. Particles have an inherently higher molecular density than gases, so that the rate of transfer to the lung from a liquid (or solid) aerosol can be much higher than that from gases. Secondly, they behave as particulates and thus aerosol size is a major determinant of the site of action (see below). In the case of liquid aerosols, the range of response is not dissimilar to that from gases. Sensory irritation is an important response and because of the higher quantities of material delivered to the epithelium by particle deposition this can be especially severe. In most circumstances this will limit exposure. The nature of the aerosol will also determine its ability to penetrate into the alveolar spaces. Those aerosols that are hygroscopic are less likely to penetrate more deeply, as their particle size will increase due to the humidity in the lung. However, nonhygroscopic and particularly hydrophobic liquid aerosols of sufficiently small size can be deposited efficiently in the alveolar spaces and the dose delivered may be substantial. This high dose to the lung can result in significant potential for local injury. In particular, aerosols which penetrate to the alveolar spaces may produce severe pulmonary oedema.

3.3 Particulate Aerosols

There is an especially wide range of potential responses to these exposures. There are several reasons for this. As with liquid aerosols, regional deposition is strongly dependant on particle size. However, once deposited, especially in the alveolar region, where residence times are long, the range of response observed depends strongly on particle properties. Those particles which are soluble can exert either a local or systemic effect as a result of the properties of the inhaled material. As with liquid aerosols, the relative quantity delivered can be substantially in excess of that achieved by gaseous inhalation and the effects more severe. This is well exemplified by the response known as metal fume fever. This acute response to inhalation of very finely divided aerosols (individual particle sizes of the order of 1 μm or less)

has historically been encountered in metal-working and welding. Although it is most commonly associated with copper, magnesium and more especially zinc, inhaled as the oxides, it has also been less frequently encountered following exposure to fumes from a range of metals. Symptoms include chills and fever, nausea and occasionally vomiting, fatigue, weakness and aching of the head and body. Lung capacity may also be reduced. The symptoms have been likened to malaria or influenza leading to misdiagnosis (Kurzbaum *et al*., 2007). However, the condition is transient and recovery is complete after a day or so. No fatalities have been recorded. This disease is now extremely rare, as modern industrial hygiene practices preclude exposures of sufficient intensity to induce the response. The mechanism is believed to be a result of metal–protein complexes being released into the bloodstream, inducing a response akin to a foreign protein, although this is not true immunity.

Larger and less readily soluble particles may induce a different spectrum of response. This may include fibrosis, emphysema and lung cancer.

A fibrotic response is most commonly seen after exposure to siliceous minerals (especially crystalline silica). It is probably associated with toxicity to alveolar macrophages, which attempt to clear the particles deposited in the alveolar space. As previously indicated, even benign dusts, when present in sufficient quantity, can induce limited local collagen production, to sequester the material from the surrounding tissue. This 'foreign body response' can be regarded as a minimal reaction to what is effectively an overloading of the clearance mechanism. In fibrosis this effect is amplified and may progress for a long period, even in the absence of continued exposure. It is most likely that the relevant particles prove toxic to macrophages following phagocytosis. The macrophages then release cytokines which cause the ingress of fibroblasts and the induction of collagen synthesis in order to repair localized damage and to sequester the toxic particles. However, the particles remain active and further macrophages may attempt clearance and thus amplify the process. The exact mechanism(s) involved remain to be elucidated, but cytokine production and fibroblast recruitment is an important contributor and suggest possibilities for treatment (Thannickal *et al*., 2004; Kuwano *et al*., 2001). In the case of crystalline silica, the process produces a nodular fibrosis, which can be scattered through the lung. In extreme cases individual nodules can become the size of a hen's egg. The presence of these nodules reduces lung compliance and may eventually result in respiratory insufficiency. The associated inflammatory response may also be important. Silica and similar minerals are regarded as lung carcinogens, although they are not mutagenic, at least in the classical sense. Fenton-type[b] actions at the particle surface can give rise to peroxides at least *in vitro* (Castranova *et al*., 2004), but these reactions seem to be of lesser importance *in vivo* and are considered unlikely candidates for mutagenic activity. The tumours may be secondary to the fibrosis seen: inflammatory reactions at the site of fibrosis lead to cellular proliferation that could act as a carcinogenic promoter.

Particles may also induce lung tumours by other means. Examples include various metals, especially the transition metals nickel and chromium. The exact mechanism for these tumours has not been elucidated, but plausible theories include the catalysis of oxidative damage or direct interaction with the DNA–histone complex resulting in changed gene expression.

Although many of the occupational diseases of mining and quarrying, and associated industries can be traced to the presence of quantities of crystalline silica in the materials handled, this is not always the case. It is evident that the inhalation of even inert particles in sufficient quantity can result in respiratory insufficiency. It is well established in experimental animals that there comes a point where the clearance mechanisms in the lung are overwhelmed. In these circumstances, there is a continued and progressive build-up of inhaled material within alveolar spaces which eventually, by dint of the quantity involved, results in reduced efficiency of gas exchange within the lung. This process is known as lung overload and is generally associated with exposure to very high dust concentrations. Consequences in experimental animals include the induction of a chronic inflammatory response, which leads to epithelial hypertrophy, metaplasia and ultimately to lung tumours (Hext, 1994). There is limited evidence for similar responses in humans in the past, mainly in coal miners, but the reaction does not include the tumours seen in rats (Levy, 1995). The condition is rare in modern working conditions.

The other major change seen in response to alveolar damage is emphysema. In this condition the alveolar walls are destroyed, leading to large air spaces within the lung parenchyma. This apparently increases lung compliance, but reduces the efficiency of gas exchange by effectively decreasing the area available. The main cause of emphysema is considered to be cigarette smoking, but exposure to other pollutants can produce a similar response. As with fibrosis, it is believed that this process is mediated by macrophages, but in this instance liberation of digestive enzymes, in particular, elastase is considered the proximal cause. Emphysema is associated with severe or recurrent inflammation and it is believed that the participating leukocytes are responsible for the release of proteolytic enzymes. One of the main defences against uncontrolled digestion by proteolytic enzymes, including elastase, is the protein α-1 antiprotease. It was once believed that a concomitant deficiency of this protein in the circulation was necessary for the induction of emphysema. However, it is now evident that proteases other than elastase are important in the aetiology and that the previous theory was an oversimplification. Current theories on the molecular mechanisms

of emphysema have been reviewed by Morris and Sheppard (2006) and Wright and Churg (2007).

The inhalation of particulates may also induce disparate responses dependant on particle size. At one extreme, irritant particles such as caustic soda may cause localized damage to the upper respiratory tract and larynx as a consequence of their alkalinity. This may be particularly important in the case of larger particles that are entrained during mouth breathing. The size of the particles can give rise to a sufficient local concentration of alkali to be damaging. This is speculative, but may be a rare example of reversal of the convention that larger particles are of lesser importance in the induction of responses in the respiratory tract. At the other extreme, nanoparticles may be especially efficient at delivering systemic doses of chemical via the inhalation route. These particles are sufficiently small to penetrate the alveolar epithelium, presumably mainly through gap junctions. This aspect of toxicology is addressed in **Nanotoxicology-The Toxicology of Nanomaterials**.

In the case of poorly soluble particles, material entrained on the mucociliary escalator may contribute to systemic exposure by the oral route. These particles are cleared relatively rapidly (within an hour or so in man) to the larynx where they are then swallowed. In some circumstances this may be a significant route of exposure although this is mainly at the high concentrations used with exposures to experimental animals, rather than for human exposures, which are generally at very much lower levels.

3.3.1 Fibres

These represent a special case of particulates. Readily soluble fibrous minerals and other materials behave in most respects in a manner identical to more compact particles. However, durable, and perhaps semidurable, fibres have specific effects which are not seen following oral exposure, even at very high levels.

The internationally accepted definition of a fibre is a particle with a length/diameter ratio $>3:1$. To further differentiate these from acicular particles, which occur in many minerals, a minimum length of 5 µm is generally specified. The aerodynamic behaviour of fibres is dominated by their diameter (d). Falling speed is proportional to d^2 and directly proportional to the density, with the length making only a minor contribution. This may be rationalized by the observation that fibres will align in any air flow so that they are parallel to the direction of travel, as this represents the minimum air resistance. The physiological consequence is that relatively long fibres penetrate deeply into the lung. Fibres over 100 µm length have been reported in alveolar spaces although these are relatively rare. Nevertheless, fibres 20–40 µm long penetrate with reasonable frequency.

The literature on the effects of fibres is dominated by the observed responses to asbestos. This is understandable given the history of this group of substances, but not always illuminating when attempting to quantify dose–response relationships. There are more than 140 silicate minerals that qualify for the term asbestos, but only five of these have been studied in any detail or have any commercial importance. The most commonly mined and used asbestos was chrysotile (white asbestos), which is a serpentine mineral of similar chemical composition to talc. This is chemically and biologically distinct from the amphibole asbestos minerals, of which crocidolite (blue asbestos), amosite (brown asbestos), anthophyllite and actinolite have been exploited commercially, especially the first two. Another amphibole (tremolite) is frequently encountered as a contaminant of both chrysotile asbestos and talc, especially in the large North American ore body, which has been a prominent source of both these minerals. Although there are significant differences in both chemistry and in physical properties between these minerals (and especially between chrysotile and the amphiboles), they have been processed in the same facilities and by similar techniques, such that, aside from the initial mining and milling, pure exposures are rare. Thus, although there is ample experimental evidence for differentiating between the effects of these minerals, the practical response has been to classify and control them as a group. Although this solution has resulted in effective control of exposures, it can be argued that it has hindered understanding of fibre toxicology, (especially carcinogenesis) and has possibly resulted in over-regulation of some uses of these minerals.

During the early phase of asbestos exploitation, from approximately 1900 to 1930, little attention was paid to workplace hygiene and workers were often exposed to massive levels of airborne fibres. Exposure to all types of asbestos can cause a progressive fibrosis of the lung. This is differentiated from that caused by silica in that, probably due to penetration of fibre into the interstitium, the accumulation of fibrous tissue is reticulated rather than nodular. Asbestosis can thus be differentiated from silicosis by X-ray and fibrosis produced in response to asbestos is often described as 'honeycomb lung'. *In extremis*, this fibrosis can be rapidly fatal and the incidence of death in asbestos-processing operations provoked regulations (in 1930 in the UK) to control the dust levels in the workplace. At about the same time, the link between lung cancer and asbestos exposure was first made, although this was only firmly established much later, when the synergy with cigarette smoking was also discovered. These discoveries led to further tightening of the rules relating to exposure levels in the workplace. The occurrence of mesothelioma (a rare tumour of the pleura or peritoneum) in populations exposed to amphibole asbestos, was first reported in Wagner *et al*. (1960); this is now seen as a major problem from exposure to asbestos (and by extension possibly to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat056
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

fibrous minerals in general). The tumour has a very long latent period (maybe more than 40 years). This latter feature contributes significantly to problems of control, since there is a very long interval before the efficacy (or otherwise) of exposure reduction is established.

Once the range of effects of asbestos was understood, the extent (if any) to which these extended to other fibrous particulates, whether natural or man-made, was an obvious concern. The discovery of high local incidence of mesothelioma in villages in Turkey, where there was significant exposure to the natural zeolite mineral erionite (Baris *et al*., 1978), reinforced this concern. However, the extent to which this property extends to other fibres remains controversial. The relevant evidence is summarized below.

Asbestosis is established as being caused by even short asbestos fibres, indeed these may be more potent. It is almost certainly related to the surface chemistry of the fibres concerned and does not differ in mechanistic terms from fibrosis produced by particulates. In this respect, control presents no special challenge and there are short-term assays (including inhalation assays) that are good predictors of fibrosis, at least in the progressive form.

The above is true for reactions in the lung parenchyma. Asbestos has also been observed to cause a fibrotic thickening of the pleura, both parietal and visceral. This reflects the ability of very fine fibres to penetrate the junctions between Type 1 cells and enter the lymphatic circulation. Where, as with asbestos, this effect is progressive and pleural thickening severe, the response may be significant, although this generally is seen only at levels of exposure where pulmonary fibrosis is also evident. More problematic are the relatively fine pleural plaques which are seen after some low exposures to asbestos and may also be seen after exposure to some other mineral fibres, notably refractory ceramic fibres (Lockey *et al*., 1996). In the latter case the plaques may be considered to be no more severe than a foreign body response. The location of these lesions suggests that they are precursors to, or a site of initiation of mesothelioma, especially when they are severely fibrotic, as seen following heavy asbestos exposure. Epidemiological evidence does not show an association with refractory ceramic fibre exposure and mesothelioma, so that the plaques seen in these workers may serve mainly as an index of exposure rather than a potential focus for disease. Nevertheless, given the particularly long latent period of this tumour and the relatively recent development of the man-made mineral fibres (MMMF) industry, at least in respect of the tonnages currently handled, this interpretation cannot be considered conclusive.

In the case of lung cancer, epidemiology suggests that fibre length is an important contributory factor. No mechanism has been directly established and it should be noted that incidence in experimental animals, although high, tends to be at different locations from that seen in man. Human lung cancer following asbestos exposure is frequently bronchogenic. In animals it is almost exclusively peripheral. The additional association with cigarette smoking in man may give a clue to the reasons for this difference. Deposition of dusts and fibres on the bronchial carina is well known. At this point, interaction with inhaled cigarette smoke, a mixture of fine particulate and gaseous contaminants, is both possible and likely. Absorption of some of this mixture by deposited asbestos fibres may serve as a delivery mechanism. The well-established inhibition of mucociliary clearance in heavy smokers may further enhance the received dose. Alternatively the fibre itself, due to its irritant properties, may promote clonal expansion of cells previously initiated by the carcinogens in cigarette smoke.

Despite many attempts, there is currently no model of the induction of lung cancer in rodents by cigarette smoke and hence no rodent model of tobacco-related lung cancer. Thus, it is possible that the aetiology of tumours in animals could differ from that in humans. There is definitive epidemiological evidence that, at least in man, exposure to asbestos and cigarette smoking interact in the induction of lung cancers (though not mesothelioma), such that this can approach a multiplicative relationship. Evidence from animal studies must be viewed with some caution in view of the inability to duplicate the effect. In this context, it is not possible to determine whether the effect might extend to other fibres. However, there is now a consensus that this response does not occur without at least minimal lung fibrosis, so that control of this response will also control lung cancer incidence.

Mesothelioma is perhaps the most interesting of the responses. This tumour arises from the epithelial cells lining the pleural and peritoneal cavities. It is thus evident that either fibres exert their effect remotely or that they must penetrate through at least one layer of interstitial cells before reaching their target. The latter is the most probable route and the consequent incidence of pleural plaques has already been mentioned. Asbestos fibres may be found throughout the lymphatic circulation and in particular in the fluid draining from the pleural space. This fluid passes into the peritoneal cavity, which is the second (after the pleurae) most common primary site for mesothelioma.

It is generally agreed that in order to induce mesothelioma, fibres must be long, thin and durable. However, all three properties have been challenged and a closer definition of these terms continues to prove difficult. The long and thin components are relatively easy to explain qualitatively. In order to reach the target tissues, the fibres must be respirable. This, for mineral fibres, puts an effective diameter limit at 3 μm, although significant deposition in numerical terms is not seen until about 2 μm diameter, with peak deposition being in the region of 0.5–1 μm diameter. This is reflected in the epidemiology where there are well-documented differences in human disease associated with exposures from different sources

of nominally the same mineral. These were related to fibre diameter (Timbrell, 1972) based on a study of the relative sizes of asbestos fibres from various sources.

Animal models confirm the importance of dimension. Wagner *et al*. (1973) demonstrated that a high incidence of mesothelioma could be induced in animals by intrapleural injection and that this could be related loosely to fibre size, with submicron diameter fibres being the most active. Similar experiments in the USA by Stanton's group (Stanton and Wrench, 1972; Stanton *et al*., 1977; 1981) examined mineral fibres with a wide range of compositions and sizes, and also concluded that there was a clear correlation between diameter and proportion of dosed animals with mesothelioma. The Stanton group classified fibres only into broad categories, but were able to conclude that the probability of mesothelioma was greatest for fibres of less than 1.5 μm diameter and greater than 8 μm in length. The findings have been widely accepted, in particular as showing that 8 μm is the critical length above which fibres could cause mesothelioma, although this is a simplistic overinterpretation of Stanton's results. More recent experiments have shown that 8 μm is an underestimate and 20 μm is now considered the most likely discriminating length. This has at least a potential mechanistic justification, as alveolar macrophages can fully incorporate fibres up to approximately 16 μm length into a secondary lysosome. Fibres longer than 16 μm may thus have at least a proportion of their length 'free' in the alveolar space, at least until additional macrophage(s) engulf the remainder and form a giant cell. It is also clear that penetration into the interstitium, or the pleural space, is an important step in tumour induction. Partially for this reason, but also because of experimental determinations with a range of fibres, it has been suggested that for the development of mesothelioma, fibre diameter must be less than 0.5 μm. These thin fibres may be translocated readily from their site of deposition via the lymphatic system to the pleural surfaces and elsewhere.

The definition of durability is also unresolved. As mesothelioma is induced in relatively low yield in inhalation studies, even at enhanced exposure rates, most evidence on durability has been derived from injection experiments, which are used as a surrogate for inhalation, although these generally measure mainly dissolution and are thus of less value for fibres that fragment. Durability can be considered to act by means of dose limitation. Continuing exposure to fibres that dissolve or fragment to the point where they are more readily cleared, will result in a lesser cumulative dose than similar exposures to more durable fibres. There is now significant evidence (Hodgson and Darnton, 2000) that there is a level of exposure to asbestos that will not result in disease and this has been equated with a total lung burden of about 10^6 fibres g^{-1}. Thus fibres that are sufficiently fragile to keep the lung burden below this value would not be expected to be toxic. Various values for dissolution/clearance half-life have been proposed in order to exonerate specific fibre types, but none has been rigorously calibrated by reference to primary inhalation exposures. Thus, although the importance of durability is recognized, the property remains difficult to quantify.

Chrysotile asbestos falls into the category considered less durable, since this mineral consists effectively of bundles of fibrils which can fragment over a relatively short period. The fibrils are readily dispersed and can be detected in the circulation and in urine. These fibrils are approximately 20 nm diameter and <1 μm long. They are not associated with any of the manifestations of asbestos-related disease. This observation is in agreement with the epidemiological observations of a relatively low incidence of mesothelioma following exposures to 'pure' chrysotile. Thus, Churg *et al*. (1993) argued that no more than 50 mesotheliomata worldwide could have been caused by exposure to chrysotile and it was possible that these cases were not asbestos related, but were the result of a 'spontaneous' mesothelioma rate of 1 per million deaths. However, all conclusions on the carcinogenicity of chrysotile are complicated by the frequent contamination of this mineral with fibres of the amphibole tremolite. There is evidence that mesothelioma cases in chrysotile workers are associated with an increased burden of long tremolite fibres compared to exposed, but tumour-free controls. However, experimental studies in animals can induce mesothelioma with apparently pure chrysotile, provided the fibres are sufficiently long. This distinction remains controversial, but is unlikely to be resolved, since all forms of asbestos are now subject to significant restrictions worldwide and most investigative work is now directed elsewhere.

The nonasbestos fibre that has been shown unequivocally to induce mesothelioma in man is the durable zeolite mineral, erionite (Wagner *et al*., 1985). This is at least as potent as asbestos in animal experiments and in many cases more so. Whether this tumour might be induced by other fibres, in particular MMMF, remains controversial. Some fibres, particularly the crystalline whiskers (mainly produced in relatively small quantities, often for research) can induce mesothelioma in high yield in animals. There has been insufficient exposure to constitute a human risk and as a matter of prudence exposures to these fibres are carefully controlled. In the case of the fibres produced in greater bulk, mainly for insulation, such as glass wools, rock wool and slag wools, there is no epidemiological association with mesothelioma. This statement must be tempered by the knowledge that 'pure' exposures to these fibres are relatively rare. Those whose exposures are sufficiently historic to establish a true estimate of risk are likely also to have been exposed to asbestos, since the fibre was used in similar circumstances. More recent exposures have been controlled to levels where even if there were a potential risk, significant incidence of the tumour would be unlikely.

Another property of fibres, especially man-made fibres, is their potential to cause irritation. This is seen mainly as irritation of the skin and mucus membranes, but can also affect the upper respiratory tract, larynx and eyes. The properties which influence this property are stiffness and diameter. It has long been established that fibre diameters $>5\,\mu m$ are generally necessary to induce significant skin irritation (Heisel and Hunt, 1968), probably reflecting the fact that this is principally a mechanical effect (inducing limited localized histamine release). Fibres of this size may be impacted on the larynx during mouth breathing and this can lead to a dry cough and discomfort. It is believed not to have long-term consequences, but in practical terms, as the discomfort is immediate and directly attributable to exposure, it may provoke more adverse reaction from workers than the longer-term health risks associated with finer fibres. It is possibly this immediate reaction to certain MMMF, notably the glass wool extensively used in domestic insulation, that raises public concern over the possible long-term effects of these materials.

4 ASSESSMENT OF INHALATION RESPONSES

One of the most useful sources of information for inhalation toxicity is studies with human volunteers. The advantages are that the target species is directly assessed and the use of carefully controlled atmospheres gives reliable information on dosimetry. The disadvantages include: for ethical reasons only healthy volunteers are used, (generally males); exposure concentrations are relatively low and for practical purposes, the studies are of relatively short duration. Examples include the assessment of sensory irritation responses, especially in the upper respiratory tract, to gases which have been previously characterized in other systems; this has been reviewed by Doty *et al*. (2004).

Although human exposures give the most useful information they are clearly unsuitable as a primary screen. Other models have therefore been devised for this purpose.

4.1 Properties Required of a Model for Inhalation Exposures

An acceptable model for the assessment of inhalation toxicity will:

- Show an identical response to humans for a full range of toxicants to be tested.
- Show a similar dose relationship to humans for the lesions observed.
- Have identical size-selective properties to the human respiratory tract.
- Allow accurate quantification of both the atmosphere and the dose received.
- Induce long-term responses within a considerably shorter timescale than that required for humans.

There are no model systems that fully meet all of these requirements. As with many aspects of toxicology, mammalian systems tend to react in a similar manner and this is as true for the lung as it is for other organs. The use of a short-lived species allows even complex responses, such as lung fibrosis and lung cancer, to be modelled within a relatively short time compared to the human lifespan, although these experiments may take one to two years. The size-selective properties of the human lung are difficult to model exactly: small animal species have smaller respiratory tracts and the limit values for respirable and inhalable fractions are lower than those for humans. This difference is enhanced further when the model species is an obligate nose-breather. Dose quantification is possible in most of the model systems employed; establishing the received dose in humans is more problematic.

Inhalation exposures are the most technically challenging of the models used in toxicology, at least in terms of equipment required and range of expertise needed to conduct a satisfactory experiment.

The most common animal model for the inhalation toxicologist to study is the rat, although the dog, mouse, hamster and guinea pig have also found significant use. Studies with primates are rare, but not unknown.

Historically, rats were often exposed in whole-body chambers, with the atmosphere distributed throughout. This system has now been almost totally superseded by a head-only or, more commonly, snout-only exposure system. In such systems, the rats (or other small rodents) are confined in tubes, usually of transparent plastic, from which their snout protrudes at a tapered end. Some form of restraint is applied at the rear, with the tail usually free (**Figure 2**) to facilitate thermoregulation in the test animal. Rodents in particular readily acclimatize to such devices, especially if exposures are performed in full illumination, when they will normally be at rest. Animals to be exposed are placed, via suitable ports, such that their noses protrude into the test atmosphere, which in some cases is delivered specifically to the breathing zone of each animal. The test atmosphere is maintained at a slight positive pressure compared to the restraining tubes so that there is no dilution from air flow past the test animal. The whole apparatus is generally enclosed in a ventilated space so that the test atmosphere, including any leaks, may be disposed of in a safe manner. Duration of exposure varies, but is usually in the region of 4–6 hours for acute and subacute exposures and either five or seven days per week. This system offers several advantages over whole-body

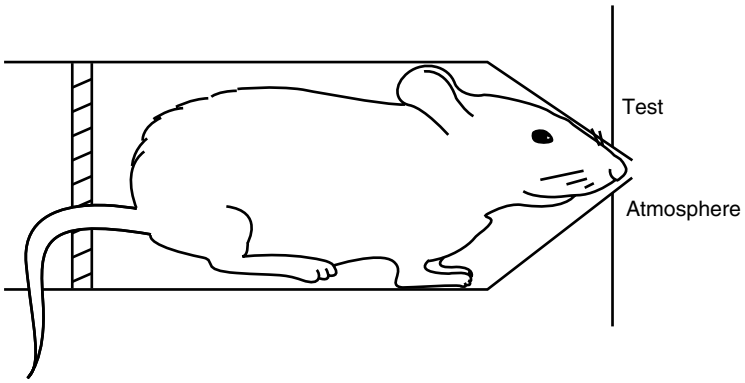

Figure 2 Restraining tube for nose-only exposure of small rodents.

exposures. First, the contamination of fur is minimal. This is especially important with liquid and solid aerosols where, with a whole body chamber, oral exposure (via deposition on the fur with subsequent grooming), may significantly exceed exposure to the lung. This may make interpretation of response especially difficult. Secondly, the system is easy to control. The smaller volume in which the test atmosphere must be generated leads to shorter path length between the generator and the final exhaust, thus minimizing the possibility of atmosphere deterioration in the process. The system is also economical with test compound. The restraining tubes may be adapted to act as a whole-body plethysmograph so that the respiration rate, TV and lung compliance of the individual animals can be measured in real time. For all these reasons whole-body chambers are generally used only for chronic exposures, especially when these are designed to be continuous; such experiments are rarely conducted.

Selection of equipment for atmosphere generation must take account of the properties of the compound. The simplest system is for gases, where adjustment of the relative flow rates of test gas and dilution air will give the desired atmospheric concentration. However, it is important to ensure that within the system, there is a chamber that achieves turbulent mixing to avoid stratification of the test atmosphere. This is especially important where the test involves heavy vapours. In circumstances where very high concentrations of low reactive gases are to be tested, it may be necessary to supplement the test atmosphere with oxygen, in order to maintain more or less normal levels. In general, it is advisable to restrict dilution to maintain minimum oxygen content of 19% of the total atmosphere, in order to avoid changes which may be spuriously attributed to the compound. In the case of volatile liquids, generation is normally achieved by bubbling air through a reservoir of the material. The reservoir may or may not be heated, dependant on the volatility of the compound concerned. The saturated vapour may then be diluted in air to give suitable concentration(s). Where heat is applied, the possibility of condensation aerosols cannot be ruled out and, if a pure gaseous exposure is desired, then the atmosphere may need to be passed through a suitable cyclone to remove particulates prior to entering the test chamber.

Liquids of low volatility are generally tested as aerosols. These are almost universally generated with a nebulizer, using the Venturi effect to produce sufficiently small droplets to be respirable for the species concerned. For more difficult liquids, simple nebulizers may be replaced by more complex versions, such as the ring nebulizer. Nevertheless, for very high-viscosity liquids, it may be necessary to dilute the test article with a suitable inert solvent, in order to generate a respirable atmosphere. Where this is done it is important to consider the nature of the aerosol to which the test animal may be exposed. Exposure to an aqueous solution is generally as acceptable as exposure to the neat material. However, if an organic solvent is used (acetone and alcohol are the most common, but others might be considered) then it is necessary either to ensure a sufficient path length for the solvent to substantially evaporate from the aerosol droplets prior to exposure, or to make an assessment of the potential effects of such solvent on the likely reaction in the test animal. The latter may be difficult. Typically particle size for aerosols is measured in the breathing zone. If the particle consists of a significant proportion of solvent then this may continue to evaporate after the aerosol is inhaled, resulting in a progressive size reduction as the particle penetrates the respiratory tract. Thus, respirability may be significantly under-estimated by the measurement in the breathing zone. In addition, if the particle penetrates to the alveolus, the presence of residual solvent may influence the behaviour once deposited. For example, it may accelerate the dispersal of the aerosol into lung surfactant.

Fortunately most of the changes induced are likely to enhance rather than reduce the apparent toxicity of the test aerosol, such that this system can be regarded as failsafe. However, where it is adopted it is important that the experiment include a solvent control, where test animals are exposed to the maximum concentration of solvent that could be achieved by any of the test groups. This provides some indication of the potential for solvent

effects, but, as the pure solvent will evaporate more rapidly than the test solution, does not remove the need for expert judgement of the contribution of the solvent to any reaction seen.

In the case of particulates, there is a wide range of generation systems available. Most depend on similar principles. Possibly the simplest system is the air ejector, although its use is restricted to free-flowing powders. This makes use of the Venturi effect in a similar manner to the generation of liquid aerosols, except that in this case powder is entrained into the system rather than a liquid. Typically, the test powder will be delivered from a reservoir into a groove in a rotating table, with the intake for the air ejector positioned above the groove. Adjustment of air flow and rotation speed can be used to regulate the ultimate atmospheric concentration. Many test substances are not sufficiently free flowing to be generated in this simple system: even a few aggregates may block the system. Other devices that overcome this sensitivity rely on mechanical lofting of material, usually from a compacted plug of dust. One of the most frequently used is the Wright's dust feed, where a rotating blade scrapes dust continuously from a plug of compacted material in a reservoir. Air blown over the blade entrains the dust into the test atmosphere. A common variant replaces the blade with a rotating brush. In each case the dust plug is advanced by a suitable mechanism and adjustment of the rate of advance and the airflow determines atmospheric concentration.

Fibre generation uses similar equipment, although compromises are necessary. Severe mechanical attrition may fragment test fibres so that the ultimate atmosphere is not representative of the material selected for test. A number of designs for generators aim to reduce this mechanical attrition. These include the Timbrell generator (converted from a coffee grinder) where a rapidly rotating paddle scrapes fibres from the end of a plug (which is advanced in a similar manner to that in the Wrights dust feed) and thus entrains them into the airflow. A variant involves a rotating brush, where the stiffness of the bristles can be adjusted such that fibre comminution is avoided. As with all such systems it is important to establish the extent (if any) to which the generation system influences fibre size, but in any case characterization of test atmospheres is of paramount importance in these experiments, if the observed responses are to be correctly interpreted.

4.2 Measurement of Test Atmospheres

It is important to establish both the characteristics and stability of test atmospheres in order to achieve an accurate estimate of dose. This involves measurement at frequent intervals. For achieved concentration, this measurement should be made at least once per hour during exposure, preferably more frequently for shorter-term experiments, so that adjustments can be made to maintain the specified concentration.

This is readily achieved for gaseous mixtures, where direct measurements from a side stream or directly from the breathing zone via a gas-tight syringe are a matter of routine.

4.2.1 Assessment of Aerosols

While the defence mechanisms leading to the removal of particulates from the air stream before it reaches the alveolar region is relatively simple to describe in qualitative terms, measuring and modelling deposition is more challenging. This is nevertheless important because exposures to particulate atmospheres of pollutants of synthetic or natural origin involve a range of particle sizes and the size spectrum can have substantial influence on the reaction induced. Definition and measurement of the size range that will enter the respiratory tract (the inhalable fraction) is an important aspect of atmosphere characterization. Dust or aerosol particles larger than this, although presenting visual hazards and possibly an ingestion hazard to oronasal breathers, will have no effect on the lung itself. Similarly, particles which penetrate beyond the conducting airways to the alveolar regions are less readily cleared and have the potential for longer-term residence which may result in substantial effects. In addition, the thin alveolar epithelium (to maximize gas exchange) is less well protected than the mucus covered epithelia of the upper respiratory tract. This combination of factors means that material which can penetrate to the alveolar area (the respirable fraction) receives most attention from the toxicologist. Thus, definition of these fractions and their measurement is of major significance in the assessment of occupational and environmental exposures and for characterizing test atmospheres.

Total atmospheric concentration is readily measured by gravimetric sampling of nonvolatile aerosols and suitable capture and assay methods, such as absorption tubes, are available for other substances. However, particle size distribution is of special importance and this must be established (and confirmed periodically) for each test atmosphere. For any given generation system, particle size distribution tends to be more stable than total concentration, so measurement once or twice during each exposure period is usually sufficient to establish the characteristics. Once stability has been established (usually in proving trials before the test species is introduced) measurements should be made at least once per exposure period and preferably more frequently.

Various mechanical devices can be used to assess particle size distribution in aerosols. All depend on impaction or elutriation.[c] The horizontal elutriator is the simplest in principle. In this device size-selective properties are conferred by parallel plates or a cyclone. The

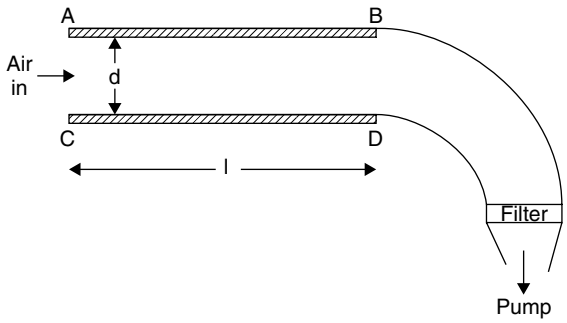

Figure 3 The principle of the horizontal elutriator.

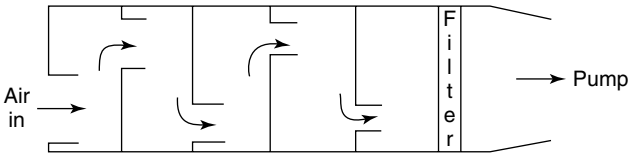

Figure 4 The principle of the cascade impactor. Air is drawn through at a constant rate so that velocity increases at each stage as aperture size decreases.

parallel-plate device illustrates the principles involved. Parallel plates AB and CD with length *L* are a fixed distance *d* apart. Airflow is introduced into one end of the device and a collector is connected to the other end (**Figure 3**). In such devices, airflow is essentially laminar so that ignoring the (relatively small) effect of the reduced airflow at the surface of the plate, the cut-off size of the elutriator is defined by the maximum size of a particle that entering at point 'A' in the airflow falls at such a speed that it just emerges at point 'D' into the collector. Particles larger than this will deposit within the elutriator, particles smaller will penetrate to a greater or lesser extent. This device illustrates the contribution of the probability function in the assessment of deposition potential, and in actual deposition in the lung. Essentially, all particles entering at point 'C' will deposit rather than emerge. Particles entering at positions intermediate between 'A' and 'C' have a probability of collection that is proportional to the square of their aerodynamic equivalent diameter (AED) and the exact point at which they enter. Such devices can be calibrated with aerosols of known size and density and can produce reliable and reproducible results from very diverse atmospheres. Although simple in concept, commercial devices may be complex. Replacing gravimetric assessment with laser systems can give instant readouts rather than time-weighted averages.

It is obvious that this device models only gravitational settlement and diffusion. These are the most important deposition mechanisms in the lower respiratory tract and therefore the device will give a reasonable (upper) estimate of the fraction which might penetrate, for example, to the alveolar spaces. Definition of the respirable fraction is the most common use for these devices. It is equally obvious that the fixed cut-off is determined by the construction of the device and therefore is not readily varied, except to the degree that airflow can be manipulated across the device without introducing turbulence. Thus, although the device will give a reasonably accurate assessment of the respirable fraction, or some other selected cut-off, it gives no further information on particle size distribution. Thus definition of exposure to different species (each having specific lung aerodynamics) is difficult if these are the only measurements available.

The cascade impactor makes use of the inertial properties of particles and can give significant information on particle size distribution within a given atmosphere. The principle is also simple to describe. The system maintains a fixed airflow into the device which consists of a series of plates or stages (**Figure 4**). At each stage, airflow is further restricted so that velocity increases. Each stage is also arranged so that airflow is off-set from the previous stage. Particles above a specified size, defined by the velocity of the airflow, have sufficient inertia to impact on the relevant plate, so that consecutive stages collect ever smaller particles. The devices have four or more stages usually followed by collection of the very finest material on a filter. Devices of this type are relatively versatile. The size of particle collected on each plate can be varied, dependent on the overall airflow, although the proportional size relationship between the plates is fixed by the design of the device. At the end of the sampling period the plates are weighed (or the test substance washed off and analysed) to determine the relative fraction deposited in each plate. These impactors may also be calibrated by standard reference materials.

These systems still find wide use and are reliable, but have the disadvantage of giving only retrospective results. Devices using lasers and applying the Tyndall effect can give real-time measurement of particle size distributions. Such devices are currently beyond the resources of many laboratories, although they offer clear benefits for dose assessment.

4.3 Other Models

4.3.1 Animal Models

Currently, there is no reliable alternative to an inhalation study in the whole animal to assess the full range of potential responses to unknown materials. Various alternatives may allow assessment of specified responses if suitably calibrated. For example, sensory irritation has been successfully modelled in mice as a predictive screen (Alarie, 1981) and results from this have been used extensively for setting air quality standards. This

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat056
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

system has been refined over time, but the basic principles remain. The main strength of such systems is the focussed response, but this is also the main disadvantage when a wider assessment is required.

Various attempts have been made to develop systems that overcome the complexities of generating reliable and reproducible test atmospheres. These include administration to experimental animals by nonphysiological routes. Two routes predominate, intratracheal injection and intracavity injections.

Intratracheal injections are used to assess the primary response of the lung to a bolus of material, usually in saline suspension. It is typically used to investigate the toxicology of particulates, although it is probably more useful for investigation of liquids. Problems arise when either the amount injected is excessive and/or particle sizes are not representative of material that would naturally deposit in the alveolar spaces. Injection volumes are relatively large (typically 0.1–0.5 ml for a rat) to ensure that the material is washed down to the lower respiratory tract, rather than lodging in the trachea, where it could be readily cleared. In practice, much of the material reaches the alveolar spaces, but if the quantity injected exceeds about 0.1 mg (in the rat) it may accumulate in localized foci which are refractory to the normal clearance mechanisms. While this technique may give basic information about the fundamental response to injected particles, the reactions seen may not be a true representation of that which would occur during inhalation exposure. In particular, accumulations of a dust in the alveolar spaces tend to dissolve much more slowly than the same amount of material deposited by inhalation. This may result in a more prolonged and/or qualitatively different response to that normally seen. Nevertheless, when correctly calibrated and used comparatively this system can provide useful information. Use in isolation, especially when larger quantities are injected, gives results that are frequently misleading.

Intracavity injections include injections into the pleural space and into the peritoneal cavity. Both primarily expose mesothelial cells and therefore potentially assess the capacity for mesothelioma induction. Intrapleural injection and implantation has been outlined in Section (3.3.1) and was used calibrate the carcinogenic potential of a range of fibres. Based on these results, deductions concerning the importance of different size ranges were derived. Both techniques have been criticized, in that they used a constant mass of fibre. Thus, the numbers of fibres applied depend on particle size.

The technique of intraperitoneal injection was first developed in the 1930s in the USA, where injection of a fixed mass into the peritoneal cavity of guinea pigs was used to assess the fibrogenic potential of dusts. These studies were of three to six months duration. As the response is not markedly quicker than that seen in the lung following inhalation, the more physiological route is generally preferred. More recently Pott (1992) used intraperitoneal injection in rats to assess the carcinogenic potential of mineral fibres; these injections used constant fibre number. This technique appeared to maximize the potential for fibres to produce tumours. The technique is open to several criticisms. The numbers of fibres injected are beyond the range which might physiologically penetrate to the peritoneal space. The exact dimensions of the latter have not been determined, but clearly since 'natural' deposition is via the lung, nonrespirable fibres would not be present, although they are not excluded from injected material. The effects of the inclusion of these fibres, which may provoke an irritant response in the cavity, have not been established. Administration of a constant number of fibres may involve injection of very large masses of sample, if the fibres involved are mainly coarse. In the extreme, the quantities involved may be lethal and the injected mass may be controlled for this purpose. The combination of these factors is likely to lead to 'false positive' results.

Injection techniques may overcome one problem associated with inhalation exposures. When the rat is used as a model the respirable limit for fibres is below than that in humans. The respirable limit for mineral fibres in rats is normally considered to be about 1.5–2 μm diameter (equivalent to about 5 μm AED) with peak deposition below 1 μm physical diameter (2.5 μm AED). Corresponding values for humans are approximately 3 μm physical diameter as the respirable limit, with maximal deposition at about 1 μm. Thus, the rat model does not fully assess the potential effects of those fibres that lie between 2 and 3 μm diameter. Injection overcomes this restriction as the fibres injected may be of any selected size. Nevertheless, dosimetry considerations indicate that the fraction within the 2–3 μm size range that is deposited in the human alveoli will be small and injection may overestimate responses. One difficulty with these models, as with other surrogates, is well illustrated by reference to estimation of the potential for mesothelioma induction. The range of fibres known to induce mesothelioma in humans, and thus calibrate the system, is limited. Thus the test system is optimized to give a strong response to these materials. However a 'positive' result in the test is usually defined by a lesser response. Thus, the true significance of 'positive' results in such assays is debatable, although these systems are almost certainly oversensitive by comparison with the epidemiological results.

4.3.2 In Vitro Tests

There are various *in vitro* tests, which allow assessment of particular responses and/or the elucidation of mechanisms. These systems, which include lung slices and cultured cell lines, can be very sensitive and the tissue dose received accurately quantified. The main disadvantage is the narrow focus of response. A further problem with such systems is that the properties assessed are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat056
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

seldom the subject of routine evaluations of significant numbers of 'new' materials. In these cases the system may require recalibration on each occasion that it is used and confidence in the result may be limited. In practice, such techniques are valuable when developed to support specific research projects, especially those elucidating mechanism, but at present have limited application as a more routine screen.

4.3.3 In Silico Assessments

Current use of computer simulations is confined mainly to the assessment of deposition of aerosols in the respiratory tract.

As stated earlier, calculation of the proportional deposition of particles of different sizes in various areas of the lung is difficult because of the complex nature of airflows within it. Nevertheless, deposition curves for the human lung were developed many years ago, and find extensive use in the interpretation of measurements in the workplace air and for environmental air pollution. These curves are based on measurements of deposited particles *post mortem* and are refined from time to time. Perhaps the best known is that developed by the American Conference of Government Industrial Hygienists (ACGIH, 2001).

Although it is possible (at least in theory) to define a level in the respiratory tract below which a particle of a specific size will not penetrate, due to its physical properties, it must be recognized that the forces of impaction, gravitational deposition and diffusion act on particles at all levels of the respiratory tract, although their importance varies with region and development of models to assess this is complex.

One of the most important concepts for such modelling is the recognition that particles in air behave in accordance with Stoke's Law, that is, falling rate in still air may be described by the equation:

$$V = \frac{g \cdot d^2(\rho_{\text{particle}} - \rho_{\text{air}})}{18\mu} \qquad (2)$$

where V = falling speed of particle; g = acceleration due to gravity; d = particle diameter; ρ_{particle} = density of particle; ρ_{air} = density of air and μ = viscosity of air.

This equation is valid for spherical particles. It may be seen that there are two components of importance, the first being the particle diameter, the second the particle density. This means that the equation is generally directly applicable to liquid aerosols where the particles are more or less spherical and the density reflects that of the bulk liquid. For particulate aerosols, this equation is less directly useful, in that the particles may have a variety of shapes and densities. The use of the AED concept to overcome this problem has already been described and it is extensively applied in model development.

Diffusion may be modelled using Fick's law, and extension of the models to include interception, though more difficult, can be encompassed by the equations developed to describe the cascade impactor. More difficulty is encountered when attempting to fit these equations with airflows within the lung. Nevertheless these may be approximated by the use of physical models including whole lung casts prepared from cadavers (Martonen *et al*., 2000). Thus all the basic elements to construct models are available.

As computing power has become more accessible, sophisticated models have been developed and there are several algorithms for deposition that are reasonably successful at predicting the behaviour of specific particles, for example Heyder *et al*. (1986). Although all are to some extent empirical, the algorithms have been developed to the point where models of aerosol deposition in the human lung that allow for the effects of nose or mouth breathing are available (Esmen *et al*., 2002). Results from these simulations emphasize the importance of aerosol size distribution in determining received dose to the deep lung, and thus demonstrate the limitations of relatively simplistic measurements of respirable fraction for exposure assessment. Similar calculations have been made for deposition of fibres ranging from relatively simple algorithms (Burke and Esmen, 1978) to more advanced models (Dai and Yu, 1998). Nevertheless all of the above are to a greater or lesser extent empirical in that they rely on deposition measurements in animals and humans for initial calibration and algorithm development.

The problem of calibration of these models by comparison with the living lung is not trivial. This has been attempted in a number of ways. For human deposition arguably the most accurate is the measurement of particles within the alveolar spaces *post mortem*. This should give a reasonable estimate of the maximum size particle that can penetrate to this region. It can be argued that diseased states will increase or decrease this size by virtue of dilating or narrowing the airways, but the effect is likely to be small. The probability function illustrated with reference to the horizontal elutriator above (and elaborated by Esmen *et al*., 2002) shows that in practice a precise definition of the upper limit is not critical as the deposition curve is asymptotic. This is especially true when particle number is the determinant factor in any response. Nevertheless reasonable accuracy is needed when computing received mass dose since the contribution of these larger particles will be disproportionate to their number.

These direct measurements have been supplemented by other assays such as spheres of known size tagged with radiolabel, but for ethical reasons these studies have been relatively less numerous and generally confined to healthy volunteers. Similar measurements in experimental animals are probably more representative and these have also extended to deposition modelling of sized fibres (Morgan *et al*., 1980), but their relationship to the deposition in the human lung is uncertain. This is well illustrated by the size-selective properties of the rat

lung. For many years this was assumed to be similar to that for humans, but the (substantial) difference is now well established. This may also extend to clearance rates (Snipes *et al*., 1989), another factor of critical importance for assessment of long-term dose to the lung. Further data development for calibration remains a major constraint on model development.

Accurate predictions of deposition are an important component for risk assessment, but may also help to resolve questions of mechanism. For soluble particulates, particle size will determine both deposition site and dissolution rate, as the latter must depend on exposed surface area. Thus the difference in respirable size between rat and human lungs may have profound effects on the ability to model response, especially for soluble materials, as the weight of material in the 4–7 μm AED fraction (approximately the difference between human respirable and rat respirable aerosols) can be substantial and perhaps lead to an underestimation of response if uncorrected. Conversely, if physical size is important (as may be the case with fibres), then these differences can *in extremis* invalidate model systems completely. Attempts to enhance exposures in animal models may increase or even introduce the property to be assessed, while size-dependent toxicity of fibres in the 4–7 μm AED range cannot be assessed fully in rodent models. Other observations also emphasize the need for careful size measurement of airborne particulates. Epidemiological studies have shown that response to airborne pollution can be correlated with the PM_{10} and the $PM_{2.5}$ fractions (see **Air Pollution**) and these correspond with peak human deposition values for inhalable and respirable dust respectively. The relative difficulty in recreating responses in animal models may be at least in part, a reflection of the relative dose received for a given atmospheric concentration. Accurate predictions of deposition rates in model species compared to man will allow this aspect of uncertainty to be reduced or eliminated.

5 DOSIMETRY

Historically, a primary aim of toxicology, including inhalation toxicology, has been hazard identification. Measurements of received dose and the kinetic aspects of distribution and elimination have largely concentrated on pharmacological agents, although basic information on absorption, distribution, metabolism and excretion (ADME) may be collected for some chemicals (see **Toxicokinetics of Xenobiotic and Metabolite Distribution and Excretion**; **Toxicokinetics**). It is less common to collect ADME data for other than oral exposures except by indirect means. As a consequence, assumptions are often made concerning received dose from inhalation exposures in order to conduct risk assessments. These tend to be oversimplified, but fail-safe. As a result, many risk assessments may be unduly cautious. While this ensures safety, it may be wasteful of resource if controls are more stringent than necessary to achieve the desired level of protection. Improved understanding of dosimetry, especially by the inhalation route, is a primary means by which risk assessments can be improved.

For inhalation exposures an initial assumption is that dosimetry follows Haber's law. This can be expressed in the simple form (Witschi, 1999):

$$C \times t = K \tag{3}$$

where C is the concentration of a toxicant required to produce a specified response; t is a measure of time and K is a constant representing a particular effect induced.

This postulates equivalence of short intense exposures with lower, but more prolonged, administration (the basis of most toxicology models). Thus, experimentally a one hour acute exposure can be roughly related to a four hour exposure by simple proportionality. Although this law has been extensively employed in risk assessments (Gaylor, 2000), it has long been recognized as oversimplification except under limited conditions. This is most evident at the extremes. There must always be a finite time before any effect is expressed, irrespective of the intensity of the dose. Similarly, at very low doses the effect will either never be expressed or perhaps (theoretically) expressed only in a period that exceeds the lifetime of the exposed species. Nevertheless, the rule generally holds within limits, especially for gases. The interpretive problem is the definition of the limits of applicability. Extension to longer-term exposures is much less certain, but it has frequently been adopted, even for aerosols. In particular, for comparative assessment of responses, in both experimental exposures and epidemiological studies, the 'cumulative dose' is often used. This may conventionally be expressed in units of exposure and time, for example, as mg m^{-3} h, and is a simple product of the average concentration and the duration of exposure. While the relationship is reasonably secure within relatively narrow exposure bands (e.g. to allow for small fluctuations in daily exposure rates in a long-term experiment), as exposures become more diverse so the uncertainty must increase. There are multiple reasons for this uncertainty, but the major influence is that of the various clearance mechanisms operating within the lung. Clearance is seldom negligible, especially at low concentrations, although higher concentrations of pollutants may well inhibit the process. Thus diversity of a computed cumulative dose and the real lung burden increases with time, often to the extent where true comparison becomes impossible. This is seen experimentally, where the lung burden will generally reach an equilibrium level after a relatively short period (<100 days), at least in rats. At very high concentrations, deposition rate exceeds the clearance capacity, leading to a continuing increase in lung burden. This 'lung overload' is well documented

and known to produce responses that are atypical of less intense exposure (see Section 3.3).

Miller *et al*. (2000) attempted to allow for at least some of the above deficiencies by proposing a power law formula that recognizes Haber's law as being a special case in the more general relationship:

$$(C - C_0)^{\alpha} \times t^{\beta} = K \quad (4)$$

where C = concentration in air; C_0 = a threshold concentration below which no effect is expected; K = constant representing effect and α and β are constants that reflect clearance.

The utility of the equation in specific circumstances depends on the ability to determine α and β with appropriate precision. Currently this is not possible without extensive experimental data. Even if these data were to be available, extrapolation to man may alter the values of one or both constants. Nevertheless, this equation suggests that cumulative doses might be estimated by relatively simple relationships; the challenge is to determine how these can be employed generically to avoid the need for extensive experimentation on individual chemicals.

Even less well understood are the relative effects of lower cumulative doses, in particular the response to a short, but intense exposure, as opposed to low-level, but prolonged intake. For the purpose of setting hygiene and environmental quality standards, these are often equated, with epidemiological results from industrial exposures extrapolated to environmental exposures at much lower, but more constant levels. It should be noted that even when occupational exposures are reasonably well documented, these consist of relatively few measurements by comparison to the rigour with which atmospheres are assessed experimentally, and can seldom be related to 'true' exposure of specified individuals. Several simple observations can show how individual exposures can vary quite widely, so categorizing exposure into, for example, low, medium and high bands and assigning nominal exposure limits to these may provide a helpful indication of likely exposures but is subject to high uncertainty. Subsequent extrapolation of these bands to environmental exposure leads to even greater uncertainty, which is reflected in the wide confidence limits that are often calculated for such exposures. It is common practice to adopt, for example, a 95% lower confidence limit for an acceptable exposure. This is then often further reduced by the application of a 'correction' or 'assessment' factor to reflect the fact that the measured exposures spanned only a fraction of the working day and involved healthy adults only. Resultant environmental quality standards can be very low. These values can be difficult to achieve and significant resource may be expended in order to reduce exposures to levels that are deemed acceptable. One of the major challenges for the inhalation toxicologist is therefore to refine these indices of exposure to give a more accurate assessment of dosimetry. The aim of this exercise will be to improve ability to compare dissimilar exposures and thus to ensure that, where necessary, resources are applied cost effectively to ensure public safety.

6 FURTHER DEVELOPMENTS

Current systems for experimental inhalation exposure have been refined to the point where major developments are unlikely. Although the rat has limitations as a model species for man, the large database that has been developed over many years in this species mitigates against the adoption of alternatives and those which have been proposed, such as the hamster, have different limitations. Thus it is unlikely that there will be any major change in the assessment screens used for new (or existing) chemicals, although limited experimentation with larger species may be needed to model deposition kinetics for particles that are respirable in man, but not in rats.

A major concern with the current database is the lack of quantitative information, especially for human exposures, that can be used in risk assessments. Development of more usable exposure data will depend on experimental results. Only in carefully controlled settings is it possible to elucidate the fine details of all aspects of human exposures. However, basic research in this area should allow the development of more accurate predictive models that can then be more widely used. Such models would have profound effects on the risk assessment process, as it should be possible to estimate the range of exposures in the population rather than relying on additional (arbitrary) factors to allow for the variations between individuals and diurnal fluctuations.

Specific mechanisms for lung injury have proved difficult to elucidate. Emphysema and fibrosis are major causes of disability worldwide. Despite many years of experimentation, the molecular basis of the development of these conditions is still not fully understood. Recent developments in cellular signalling and gene expression may help to establish the precise pathways involved and this in turn may provide a more secure basis for intervention.

Cancers of the lung remain a major problem. It is likely that current developments will increase understanding of the aetiology of cancer in general and that these developments will be as relevant to the lung as they are to other sites. However, the specific issue with mesothelioma may provide a further challenge and also an opportunity to elucidate at least part of the mechanism for cancer induction. Efforts to explain the genesis of this tumour by surface properties of 'active' fibres have shown that this is not the answer—or at best only part of the answer—and there remains a strong association

with fibre size. The combination of physical attributes and association with a single cell class suggests that a specific mechanism may be involved. This may be more accessible to the investigator than the more widespread effects of less specific carcinogens.

Overall it is expected that inhalation toxicology will continue to develop from the model development and descriptive phase into a fuller understanding of mechanism. This is likely to be facilitated by the development of specific model systems, probably *in vitro,* to allow cellular responses to be isolated and investigated.

NOTES

[a.] The term vapour is used in various contexts and may thus be regarded as inexact. In this text it is used to mean the gaseous phase of a substance that is liquid at the temperature in question.

[b.] In Fenton's reaction iron cycles between the Fe(II) and Fe(III) oxidation states. The oxidation step produces a highly reactive hydroxyl radical (·OH) that attacks organic molecules. A silica surface potentiates the reaction.

[c.] The dictionary definition of this term is separation of particles by an upward air flow. In practice many such devices, including that described here, use a horizontal air flow.

Mixed Routes of Exposure

John J. Clary

CONTENTS

1 INTRODUCTION

Mixed routes of exposure to chemicals are very common in environmental settings (air, water, soil, food) and occupational settings that may also include environmental exposure to the same chemicals. While many human exposures are by multiple exposure routes, one route usually predominates. There may be a tendency to think of the predominant route as the only route of major concern. For example, in an occupational setting inhalation exposure may be the primary concern. This leads to the establishment of acceptable workplace, exposure levels, that is, threshold limit values (TLVs) and permitted exposure levels (PELs) by the American Conference of Governmental Industrial Hygienists (ACGIH) and Occupational Safety and Health Administration (OSHA), respectively. Airborne material, especially vapours, can result in pulmonary, as well as oral and dermal exposure in the workplace. In some cases a skin notation is added to a TLV or PEL due to a concern for potential irritation to skin, mucous membranes and eye from the chemical in question. Concern about assessing total exposure is addressed by the ACGIH TLV Committee, in some cases, where adequate data exist by the use of biological monitoring and the establishment of a biological exposure index (BEI). This involves measuring a chemical or its metabolite in biological specimens (blood, urine, hair, etc). Biological monitoring may not always feasible due to problems in sampling, etc.). Adequate data must exist to use this approach. Analytical data may be more difficult to collect, but it is clear that this is the best method to assess total exposure in the workplace.

Environmental exposures are often from several routes of exposure. A toxic material may be in the air, on food and/or in drinking water. Dermal exposure is possible if water is used for bathing. If the toxic material is volatile and found in the water, the heating of the water could also result in pulmonary exposure. Although one route of exposure is the major one, the other routes may be a factor in determining both total exposure and metabolite production.

Many regulatory agencies and industries rely on risk assessment in making risk management decisions. Risk assessments usually examine several routes of exposure, independently for each route of potential exposure, and then the different routes of exposures are added together to define the total exposure and risk. While this approach has limitations, total exposure data usually do not exist in human or animal experiments used in the risk assessment. Many times very conservative default assumptions are used.

Differences in absorption rate and metabolic breakdown by different routes of exposure may result in changes in the metabolite blood level in key tissue affecting toxicity. The ultimate toxic agent may be formed as a result of metabolism by the liver. Portal

circulation following oral exposure will result in the production of metabolites more rapidly than systemic circulation (pulmonary). Distribution to the target organ is also a factor to consider. In addition, species difference in absorption and metabolism may further complicate the issue.

The route of exposure(s) is a factor both in the design of toxicity studies and in the evaluation of a chemical's effect in humans. When testing a chemical for toxicity in animals, the route of primary concern should be the route of exposure(s) during human use. Various factors have to be incorporated into experimental design. If pulmonary exposure is the primary concern, then an inhalation study should be conducted. A whole-body exposure study has been used in evaluating many chemicals, but a nose-only exposure might give a better indication of just the effect of pulmonary exposure. Aerosol, vapours or dust exposure in a whole-body inhalation will result in test material being deposited on the fur of experimental animals. Dermal and oral exposure (as a result of grooming) may result in a significant exposure under these conditions.

If the oral route is the primary route of concern, then the questions of incorporating the test material in drinking water or feed (for foods) or using a gavage technique (drugs) should depend on the most likely human exposure. If the material is a pesticide, in addition to inhalation and dermal workplace exposure, oral exposure, on or in food, is also possible.

The length of exposure period, short time, such as intravenous (instantaneous) or oral (bolus), compared with longer exposures such as in drinking water, inhalation exposure over a six hour period per day or continuous dermal exposure, may also be important for the response if multiple routes of exposure are of concern. A workplace exposure could result in both inhalation and dermal exposure. Dermal exposure would most likely continue until the exposed individual changed clothes and washed the affected areas. Absorption and metabolism most likely will proceed at different rates, and this possibly could affect the course and nature of the toxic response.

This chapter will discuss the question of multiple exposure routes in both experimental animals and humans. Multiple routes of exposure could have a significant effect on the toxic response in animal experimentation and in human experience.

2 MIXED EXPOSURE IN ANIMALS

2.1 Inhalation

2.1.1 Nose Only vs. Whole Body

Nose-only inhalation exposure is selected over whole-body exposure many times because of cost or availability of test material, or other concerns such as contamination of the chamber by radio-labelled material. Whole-body exposure is usually less labour intensive and therefore may be less costly to conduct. Handling of the animals in a nose-only study requires more labour and the exposure is more likely to be stressful than a whole-body exposure. In a nose-only exposure, the test agent is much less likely to be found on the fur or skin. Dermal and oral exposures are minimized under these conditions. Grooming in whole-body exposure studies could result in significant ingestion of test materials, especially dusts, mist or aerosol by experimental animals or their offspring in multigeneration studies. This is demonstrated in an inhalation study of rats exposed for six hours by the whole-body route to radioactive 4,4-methylene diphenyl diisocyanate (MDI). Radioactivity was found in all tissues. The highest dose of radioactivity was found in the respiratory and gastrointestinal tract suggesting that grooming after exposure was a major source of exposure (Gadhill *et al*., 2005).

Oral exposure also results from vapour or particle exposure as a result of being trapped or dissolved in the mucus fluid in the respiratory tract and being removed by the mucociliary escalator and then swallowed.

There have been a few studies that have compared nose-only with whole-body exposure in terms of response. Several studies are listed below that illustrate the difference in response.

In an inhalation study in mice comparing water aerosol exposure with nose-only or whole-body inhalation, a small increase in maternal toxicity, foetal malformations and variations were observed in the nose-only exposed mice, suggesting that stress of the exposure method was a factor (Tyl *et al*., 1994).

In a rat inhalation study of respirable chromium, rats were housed in conventional cages (whole-body exposure) or fibre-glass tubes that allowed exposure to the nose-only (Langard and Nordhagen, 1980). The whole-body exposed rats excreted 8.4 times more faecal and 5.5 times more urinary chromium than the rats in the nose-only exposure. This suggests that significant additional exposure is primarily by the oral route (grooming).

In an acute inhalation study in rats exposed to chloropicrin, responses to nose-only and whole-body exposure were compared. The LC_{50} values were 14.4 ppm whole-body vs 6.6 ppm nose-only. The higher LC_{50} in the whole-body animal could be a result of the rats trying to avoid the vapour by huddling together and placing their noses in their fur or their cage-mates' fur as a filter. In the whole-body exposure the response (irritation and/or damage to respiratory tract) was biphasic. The first phase lasted about three days and the second phase was observed 6–14 days after exposure. In the nose-only animals, effects were observed in the first three days only. The response seen on days 6–14 only in the whole-body

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat057
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

exposure could be a result on grooming of material from fur (Yoshida *et al*., 1991).

In a mouse study of aerosol exposure to two viruses, *Klebsiella pneumoniae* (KB) and Venezuelan equine encephalitis (VEE) virus, the viral concentration reached a maximum tissue level 23–36 hours earlier in the nose-only vs. the whole-body exposure. Higher levels of KB were found in tissues with nose-only exposure. KB was found in the cerebellum at 73 hours only in the nose-only exposed mice, but the resulting toxic response was similar by either route of exposure (Stephenson *et al*., 1988).

An argument for whole-body inhalation exposure in animal experiments, in addition to cost, may be that this type of inhalation exposure results in some dermal exposure, more like the normal exposure scenario in humans for workplace chemicals. It is common for occupationally exposed workers to receive both inhalation and dermal exposure to airborne chemicals during the normal workday, if adequate protective measures are lacking.

2.2 Oral

In early nutrition experiments to establish nutrient requirements for trace elements and vitamins, the problem of ingestion of the faeces by the rat was an experimental detail that had to be considered to prevent underestimating the requirement. Ingestion of faeces could still be a source of continuous oral exposure if the test agent or its metabolites (given by inhalation, or the dermal or oral routes) is excreted in the faeces. The resulting total exposure might be higher and the duration of exposure might be a factor in the production of toxic effects, no matter what the route of exposure used.

The effect of the duration of the exposure can be a factor in the response. This was demonstrated when a one week gavage dosing was compared with administration of the same concentration of test chemical in the drinking water for one week (La *et al*., 1996). Formation of DNA adducts and cell proliferation was measured. The gavage dosing resulted in two to four times the adduct formation and up to three times the cell proliferation, demonstrating the effect of a bolus dose vs. continuous dosing also by the oral route.

2.3 Dermal

In dermal studies, exposure by the oral route is possible through grooming. This may be prevented by the use of a collar, the placement of the test material on the animal and individual housing. If the test agent is volatile and care is not taken to prevent volatilization, inhalation exposure is possible.

2.4 Group vs. Individual Housing

Group housing vs. individual housing may be a factor in multiple routes of exposure. Inhalation exposure to irritating material may cause rats to huddle together and use the fur of other rats in the group as a filter and thereby reduce inhalation exposure. Individual housing may be useful in preventing or reducing exposure from coprophagy, grooming or off-gassings from fur of test materials.

2.5 Multiple Routes of Exposure

Toxicity studies, in general, normally use a single route of exposure. This makes the calculation of dose and the interpretation of results easier. Very few studies make an attempt to determine, calculate or estimate the effect of exposure from all routes simultaneously on the toxic response. This is understandable, as the contribution by exposure from other routes is most likely very small in comparison with the main route of exposure.

In a 1983 study, an attempt was made to study the effects of total exposure to shale (inhalation, ingestion and dermal) in hairless mice (Bernfeld and Hornberger, 1983). The exposures were carried out by mixing the test material (shale) with the bedding for 68 weeks of the study. Five groups of 200 hairless female mice were used: one group on conventional bedding material (dried and ground corncob as a negative control group), one group on processed shale (termed 100% processed shale), one group on a 1:1 mixture of processed shale and conventional bedding material (termed 50% processed shale), one group on a 1:9 mixture of processed shale and conventional bedding material (termed 10% processed shale) and one group on natural shale (termed 100% natural shale). Half of the animals in each group (100 mice) received about 25 µg of lanolin per mouse per week, over approximately 1 in^2 area of the lower back to simulate possible synergistic effects of ointments or skin lotions applied simultaneously with the shale. The other half received five weekly portions of 0.1 ml of acetone, as a negative control group to the lanolin treatment. The particle size distribution of processed shale ranged from particles of 0.1 µm diameter to a mesh size of 60 or more. About 2% of the weight of the shale consisted of particles of 1 µm or less, about 23% of 10 µm or less and about 36% of 44 µm or less. This suggests that up to approximately 20% of the shale was respirable.

A dose-related coat of black powder was observed during the experimental period covering the surface area of the skin of the hairless mice. In addition, visual evidence at necropsy supported an observation that dose-related amounts of shale had been ingested and inhaled as estimated by lung, trachea and larynx colour.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat057
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Histopathological evaluation of all sites of abnormal gross appearance and selected sections of skin, large and small intestines, caecum, lungs, trachea and larynx of all animals revealed no deleterious effects due to the exposure of the mice to processed or natural shale. The only major pathological findings were a significant number of lymphomas in all groups, including the controls. The prevalence of lymphoma was unrelated to the bedding materials and a high incidence was found in historical controls.

This study is an example of an investigation of potentially chronic and carcinogenic effects evaluated simultaneously as a result of dermal, ingestion and dust inhalation exposure in a single study.

This study would be criticized today because of Good Laboratory Practice issues and the use of an unacceptable protocol from a regulatory point of view, but it is still a rational attempt to evaluate the combined toxic effects of three routes of exposure simultaneously. It might be considered today as an interesting screening study. The same approach could be used for screening pigments or other coloured nonvolatile materials.

In another rat study with a combined chronic exposure to chloroform, exposures were by inhalation only (six hours per day five day per week for 104 weeks), oral only (1000 ppm for 104 weeks) and both routes at the same time (104 weeks). It was concluded that the combined exposure enhanced carcinogenicity and chronic toxicity in the kidneys was greater than the additive rate (Nagano *et al*., 2006).

3 HUMANS

Exposure of humans (occupationally or from environmental sources) is usually mixed, from both the route point of view and perhaps the agents involved. In a single day we are all exposed to environmental airborne chemicals from many ambient sources, low-level contaminants in food and dermal exposure to other chemicals in material we handle. Occupational exposure can also be significant in chemical production and use.

3.1 Occupational Exposure

Occupationally exposed workers can have dermal, inhalation and possible oral exposure when working with many chemicals. The evaluation of agricultural workers exposed to pesticides is a good example of mixed exposure from the inhalation, dermal and oral routes. Inhalation and dermal exposure would be expected during normal use. Interestingly, it appears at least in some cases dermal exposure appears to be the major route of exposure in occupationally exposed pesticide workers. This suggests biological monitoring may be a more accurate predictor of exposure than airborne levels (He, 1993). Oral exposure could result from vapour or particles being trapped or dissolved in the mucus fluid in the respiratory tract and being removed by the mucociliary escalator and then swallowed. Ingestion of food from pesticide-treated crops may contain a pesticide residue, or a low level of pesticide may be found in the drinking water.

Dermal exposure to chemicals can result in significant inputs to the total dose in many workplace situations. Dermal exposure may increase in relative importance when airborne occupational exposures are reduced. Dermal exposure normally occurs by one of three pathways: (i) immersion (direct contact with a liquid or solid chemical substance); (ii) deposition of aerosol or vapour and uptake through the skin or (iii) surface contact (transfer from contaminated surfaces such as clothes).

Even the eye may be an important route of exposure for some chemicals such as nerve agents. Airborne nerve agents, in addition to pulmonary exposure, have been reported to penetrate the conjunctiva rapidly and stimulate muscarine receptors. Individuals exposed to nerve gas (such as the sarin released in the Tokyo subway) experience lacrimation and rapid miosis. Miosis is not normally seen or is delayed following dermal exposure to sarin (Holstege *et al*., 1997).

The most common method for measuring exposure in occupationally exposed workers is the air level of the chemical in question. The occupational exposure limits most commonly used are the TLV and PEL, which are normally based on air levels. Biological monitoring, where possible, is recommended as the most precise means of estimating the total absorbed dose of a chemical or pesticide by multiple routes. Dermal exposure is difficult to measure routinely, but estimates can be derived for the measurement of dermal exposure. Personal air sampling is the preferred method for the measurement of inhalation exposure, including measurement of the respirable fraction and/or any vapour component of a chemical.

The potential for significant dermal exposure should not be ignored. In an exposure assessment in pharmaceutical workers exposed to fentanyl during production, air and hand wipe samples were collected and all showed exposure. A significant correlation between hand exposure and urinary excretion was observed. Inhalation exposure results appeared to correlate with the dermal values, suggesting that dermal exposure is the primary route of exposure to fentanyl in production workers (Van Nimmen *et al*., 2006). This suggests that routine air monitoring would be a less accurate measure of exposure than dermal exposure. The best measure of total exposure appears to be urinary levels (biological monitoring)

Airborne exposure monitoring conducted simultaneously with biological monitoring is useful in determining

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the sources of exposure. If biological monitoring indicates a much greater exposure than predicted by just airborne exposure, then dermal exposure or even dietary exposure may be a significant source of exposure, as demonstrated above.

3.2 Environmental Exposure

Inhalation, dermal and oral exposure are all potential routes of exposure in the environment. Environmental exposures are often mixed. The sources of the exposure are more varied than those found in the workplace. Inhalation exposure can come from factory emissions, incineration, spills of volatile chemicals, volatilization from bodies of water and automobile exhaust, to name only a few. Dermal exposure can come from the air, water, soil and direct contact. Oral exposure can come from food, soil and water. All these exposures may be occurring at the same time and contributing to the total exposure of the individual.

An example of these multiple routes of exposure is a study concerned with the risks to humans and wildlife posed by dioxin-contaminated soil (Paustenbach, 1989). Exposure was by dermal contact (soil), inhalation (dust) and ingestion (soil by children and food and water by adults). Environmental exposure to plants, fish, birds, wildlife and grazing livestock can result in contamination of food, in addition to potential toxic effects to these environmental species. Other factors that influenced the exposure were absorption by the various routes, bioaccumulation (soil-wildlife, fish food chain, soil sampling, residential vs. industrial sites), uptake by plants, run-off, biological half-life, leaching into groundwater, weather and others.

3.3 Other Exposures

Multiple routes of exposure may occur from other sources, such as cosmetics, food and drugs. The use of cosmetics results in primary dermal exposure, but oral exposure may also take place from lipstick. Other cosmetic ingredients may be added to food or be present as a natural component (e.g. lactic acid). Both dermal and oral exposure will occur. Several routes may be used to administer a drug. The rate of absorption of drugs may be a key factor in determining the route(s) selected by a physician. Ideally, the correct concentration of a drug or active ingredient at the target site is desired. Differences in absorption, distribution and metabolism considerations could lead to multiple routes of administration (exposure) in some cases.

3.4 Biological Markers of Exposure

Biological monitoring can use human data and animal experimentation data. It gives the best picture of total exposure from all routes. Biological monitoring may be used as an identification of total exposure, a marker of a toxic effect, or a marker of susceptibility to a toxic agent. The biological marker can be the chemical itself or a metabolite. It can be measured in human blood, urine, hair, fingernails or other biological fluids or samples. Depending on the nature of the biological marker, either short-or long-term exposure may be estimated. Currently the ACGIH TLV Committee has set acceptable BEI values based on biological monitoring for approximately 50 chemicals found in the workplace (American Conference Governmental Industrial Hygienists (ACGIH), 2007). These values are established by determining the level of the biological marker in individuals exposed just to inhalation exposure of the chemical of concern. The use of biological markers allows total exposure from all routes to be compared with inhalation-only exposure.

Blood lead is a good example of biological monitoring, measuring total exposure from inhalation and ingestion in a workplace situation. Inorganic blood lead has been used as background for occupational exposure limits for lead (Skerfving, 1993). A two-compartment model is used to describe lead metabolism. There is a rapid compartment (reflecting soft tissues), with a lead half-time of about one month, and a slow lead half-time (reflecting the bone lead pool), with a half-time of approximately a decade. There are significant interindividual variations in lead metabolism. The whole-blood lead level is useful for biological monitoring for recent absorption. The relationship between exposure and blood lead concentration is curvilinear, with a decreasing impact of rising exposure. Blood lead level may be affected by the slow release of lead from the bone lead pool. The average blood lead level in individuals exposed only to 'background' lead exposure varies considerably. Blood lead levels in workers are roughly related to air lead levels in the workplace. These air levels may underestimate exposure, as they do not take into account additional exposure from other routes such as food, drink and tobacco. Total exposure can be estimated by biological monitoring.

Biomarkers based on metabolites have also been used. For example, benzene exposure results in muconic acid in urine, resulting from the ring opening of a benzene metabolite. 5-Phenylcysteine resulting from the addition of benzene oxide to a cysteine sulfydryl group in albumin and in haemoglobin is another biomarker for benzene exposure (Bechtold and Henderson, 1993).

Biological monitoring can be used as an estimate of the absorbed dose of a chemical, especially if animal and human metabolism and pharmacokinetic data are available. An example of this approach is a study of atrazine applicators (Lucas *et al*., 1993). Enzyme-linked

immunosorbent assays (ELISAs) were used to detect atrazine and its metabolites in the urine. The primary urinary metabolite was the mercapturic acid conjugate of atrazine. This study demonstrated a correlation between cumulative dermal and inhalation exposure and total atrazine equivalents excreted over a 10 day period.

Most biomarkers are correlated with air concentrations. Once this correlation has been established it can be used to determine the different sources of exposure and the amount that each route of exposure contributes to the total exposure. Air concentrations and biological monitoring have been used to evaluate the exposure of occupationally exposed factory workers to the solvent methylene chloride (Ghittori *et al*., 1993). The air concentrations were determined by personal passive dosimeters. The biological monitoring of workers was performed by determining the concentration of carbon monoxide in alveolar air and methylene chloride in urine. A correlation between the methylene chloride concentration in air and the carbon monoxide concentration in alveolar air was found when workers who smoked were removed from the analysis. Smokers who worked with methylene chloride had elevated carbon monoxide levels compared with nonsmoking workers, thus demonstrating the impact of smoking as another source of exposure that elevates carbon monoxide levels. In this case, a significant linear correlation was found between the air concentration of methylene chloride in the breathing zone and the methylene chloride concentration in urine.

4 RISK ASSESSMENT

Risk assessment is widely used to make risk management decisions. All potential sources of exposure are considered in risk assessment. Exposure results in potential inhalation, dermal and oral exposure if the chemical of concern is airborne and respirable. In addition to direct inhalation and dermal exposure, airborne fallout can enter the water supply and be deposited on growing food crops, resulting in additional dermal and oral exposure. Leachate from landfill or contamination of surface water from surface run-off or airborne deposition can result in contamination of the water used for drinking and personal hygiene.

USEPA has developed a relative source contribution (RSC) policy for chemical exposure from drinking water comparing oral with the contribution from other sources. However RSC is based more on professional judgement that actual data (Howd *et al*., 2004).

In most cases, risk assessment is based on data from each source that come from different experiments and possibly different species. Physiologically based pharmacokinetic (PBPK) modelling is used to integrate all exposures and other factors such as absorption, distribution, metabolism and elimination by the different routes and also species differences (Medinsky and Klaassen, 1996). PBPK modelling can be used to examine toxicity resulting from separate exposure routes and the influence of the time separating two routes of chemical exposure. PBPK modelling provides a basis for extrapolation across species, routes and doses and is a useful tool for risk assessment.

In an assessment of bis-(pentabromophenyl) ether in a worker exposed population, the major routes of exposure were inhalation of dust and skin exposure. Consumer exposure was considered negligible by all routes. Oral was considered the main environmental exposure. In an occupationally exposed worker the contribution of environmental oral exposure was considered insignificant to the total exposure in workers (Anonymous, 2004). This assessment is a good example of demonstrating that the major route of exposure varies with the population at risk.

Risk assessment as practiced has built-in conservative default assumptions, such as water consumption, absorption by various routes and animal to human extrapolation. The resulting risk assessment is most likely predicting a risk greater than the real risk because of the conservative approach used. This in itself is acceptable, but determining the actual risk would require that a realistic exposure scenario is established and that the effect on the total toxic response is determined. Any synergistic or inhibiting effects of one route vs. another should also be determined.

Many of these exposure estimates are derived from modelling. For example, a modelling approach has been used to demonstrate the effects of gasoline-contaminated drinking water (Shehata, 1985). The model estimated ambient and indoor air quality from volatilization from drinking water. Oral and dermal burdens were estimated using benzene, toluene and xylene as surrogates for gasoline. Exposure to vapours during showering in the confined area of a bathroom was estimated to be possibly high enough to cause acute mucous irritation. While this type of information is useful for risk assessment, it is based on exposure modelling of several routes of exposure and not actual data. The use of risk assessment is widespread and these types of exposure estimates from multiple-route exposure can be a source of concern. Exposure assessments can have a large impact on the risk assessment process. More sound experimental data in both animal and humans are needed to evaluate how good these estimates really are.

A simple two-compartment PK model has been the standard for studies describing the kinetics of radiolabelled tracers, such as manganese. In an attempt to describe exposure by both inhalation and oral routes of exposure at the same time, a unified model from the simple two-compartment PK model failed to work. The model was revised for route of exposure differences in availability, and proved to describe distinguishable pools of manganese, one in the gastrointestinal (GI)

tract-derived portal blood and the other in venous/arterial blood. The authors concluded that route-dependent differences in handling of absorbed manganese are a necessary component in PBPK modelling (Clewell *et al*., 2004).

Another example of modelling is illustrated by an assessment of total exposure from trichloroethane (TCA)-contaminated water during showering (Byard, 1989). Exposure from three sources and two routes was estimated (inhalation dermal water and dermal vapour). It is interesting that in this assessment, the predicted exposures during showering by the inhalation and dermal water routes were similar. The exposure to the skin by dermal vapour exposure was estimated to be 1% of the inhalation or dermal water dose.

Biological monitoring is a good way to validate PBPK modelling. Biological monitoring should be encouraged if practical, especially when the experimental data used for PBPK modelling are limited (absorption, distribution, metabolism and elimination) and from different species.

5 SUMMARY

While risk management decisions are based on risk assessments that estimate total exposure from all sources, the design of toxicological experiments in animals is usually route specific. A comparison of acute lethal doses by different routes points out how the difference in the route of exposure can affect the toxic response. There are very few cases where experiments in animals were designed to assess total exposure from several routes. Multiple routes of exposure are found, however, in many of the human responses to toxic agents. Thought should be given to conducting mixed-exposure studies in animals to evaluate how predictive the PBPK and risk-assessment modelling are in estimating the actual response.

Neurotoxicology

Frode Fonnum

CONTENTS

1 CELL TYPES IN THE NERVOUS SYSTEM

The brain contains several different types of neurons, glial cells and epithelial cells. A substance is considered neurotoxic when it causes a pathological effect on the function of the nervous system. A neuron consists of cell body with a nucleus, dendrites, axons and nerve terminals. **Figure 1** shows a schematic drawing of a nerve cell and illustrates how different toxic substances may interact with different parts of the neuron. Dendrites, cell bodies, axons and terminals of the neuron may be targeted by different toxic substances. All protein synthesis in the neurons takes place in the cell body. The dendrites and the cell bodies are covered with receptors and receive incoming signals in the form of chemical transmitters from other neurons. Excessive excitation of

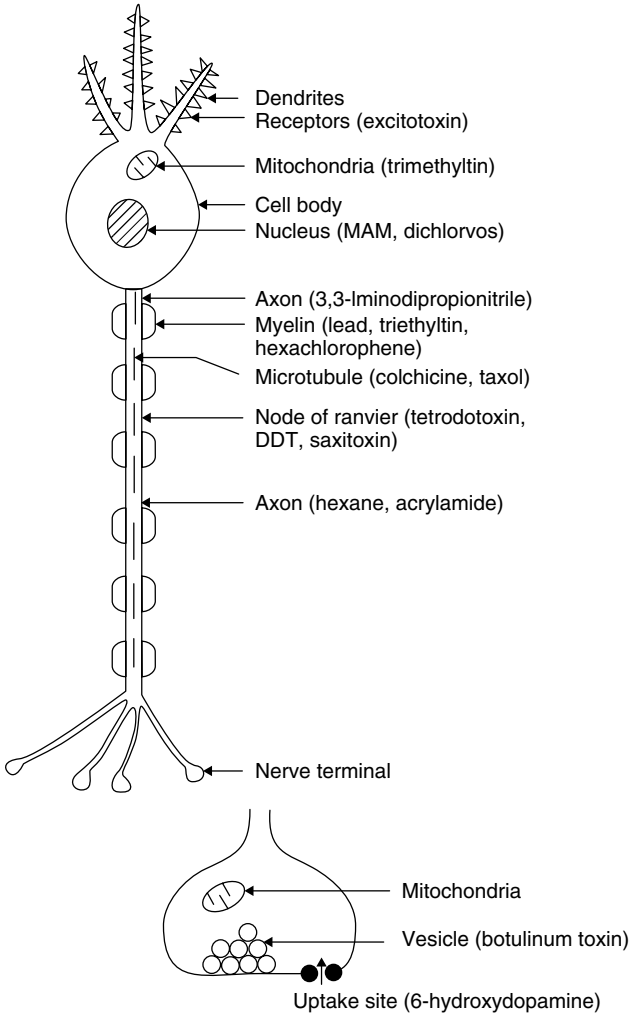

Figure 1 Schematic drawing of a nerve cell with dendrites, cell body, nucleus, axon and terminals, giving examples of toxic compounds which target different parts of the cell. Excitotoxins target receptors on dendrites and cell bodies. Methylazoxymethanol (MAM) and dichlorvos react with DNA and its repair system. 3,3-Dipropionitrile causes proximal axonopathy, whereas hexane and acrylamide cause distal axonopathy. Tellurium and lead cause myelinopathy. 6-Hydroxydopamine is an example of a compound which targets the terminal through its plasma membrane uptake, whereas botulinum toxin targets proteins in the synaptic vesicles.

receptors may cause neuron degeneration by a phenomenon called excitotoxicity. Degeneration of neurons is accompanied by gliosis, that is, the proliferation of astroglial cells. The transmitter signal received by the cell is then transferred electrically down the axon. The axon is usually thinner than the dendrites and may extend from several micrometres up to a metre. The axons contain cytoskeletal proteins, such as neurofilaments and microtubules that are involved in the transport of proteins from the cell body to the nerve terminals. Proteins are also transported retrogradely, that is, from the terminal to the cell body. The transport involves the proteins kinesin and dynein which act as a microtubule-associated adenosine triphosphatase (ATPase). Membrane-bound proteins are transported at a rate of 400 mm per day in the anterograde direction by kinesin, whereas similar proteins are carried in the retrograde direction by means of dynein. The transport of mitochondria occurs with an intermediate rate of 50 mm per day. Soluble proteins and the cytoskeletal proteins move with a slow rate of 1–4 mm per day (Barry *et al*., 2007). The axons are usually surrounded by an insulating layer consisting of myelin cells that are named oligodendroglia in the central nervous system (CNS) and Schwann cells in the peripheral nervous system (PNS). Several toxic compounds are specifically directed to the myelin cells. Myelin has a complex multilamellar structure. Compounds affecting energy metabolism and membrane stabilization may cause intramyelinic oedema, a pathological condition often seen in myelinopathy. Other compounds may lead to a selective loss of myelin called demyelination. In the peripheral nervous system remyelination may occur after a toxic insult, whereas in the central nervous system this is rare. The insulation of axons by myelin increases the impulse transport down the axon (Blakemore, 1984). The surface of the nerve cells contains ion channels, and they are highly localized in the nodes of Ranvier. Several toxins have been found to affect ion channels.

The axon branches out and ends in small enlargements called the nerve terminals. A simple neuron usually has several thousand terminals. The terminals contain synaptic vesicles filled with neurotransmitters and the vesicles release the transmitter by exocytosis. The neurotransmitters are amino acids (glutamate, γ-aminobutyric acid (GABA) and glycine), amines (catecholamines and serotonin), acetylcholine, adenosine derivatives or different peptides. The terminals have high affinity uptake mechanisms for many transmitters. Uptake of false transmitters or inhibition of the transport mechanisms, which will prolong transmitter action, may have fatal consequences.

The glial cells are the myelin-forming cells, astrocytes and microglia. The astrocytes have a large cell body from which a number of processes radiate. The processes sometimes end in thickenings called end feet which surround the capillaries in the CNS. The astroglial cells contain active uptake mechanisms for many neurotransmitters and interact strongly with the neurons metabolically. The astrocytes take up GABA and glutamate from the extracellular space after their release from the nerve terminals and transport glutamine, lactate and some other amino acids back to the neuron. The astrocytes play an important part in the replenishment of the tricarboxylic acid (TCA) cycle of the neurons (Fonnum and Hassel, 1996).

Microglia cells are widely distributed and are extremely sensitive to neuronal damage. It was established early on that they proliferate after axotomy. Now it is recognized that they become activated and undergo a series of morphological and phenotypic changes within minutes after a toxic insult. The phenotypic changes involve new types of antigen such as major histocompatibility complexes not normally encountered on resting cells. These antigens are normally expressed in the immune system (Streit *et al*., 1989). Activation of microglia may result in transformation into macrophages that phagocytize necrotic neuronal debris (Streit and Kreutzberg, 1988).

2 THE BLOOD–BRAIN BARRIER (BBB)

The blood–brain barrier (BBB) establishes an essential barrier between the brain and the blood circulation, and protects the brain from many polar toxic substances. The BBB consists of nonfenestrated endothelial cells surrounding the brain's microvessels (Rees and Karnovsky, 1967). The nonfenestrated cells are linked by tight junctions, whereas in the rest of the body the endothelial cells are spaced apart and allow substances, including proteins, to penetrate (**Figure 2**). The endothelial cells in the BBB also have low pinocytotic activity. The endothelial cells around the capillaries are surrounded by the end feet of the astrocytes, but it is uncertain to what extent the astrocytes contribute to the BBB. Transport through the BBB is limited to nonpolar substances and to several nutrients for which there are a specific uptake systems. There are uptake systems for hexoses, monocarboxylic acids, neutral, acidic and basic amino acids, nucleosides and purine bases (Miller *et al*., 1985). Many toxic substances can enter the brain with the aid of these uptake systems.

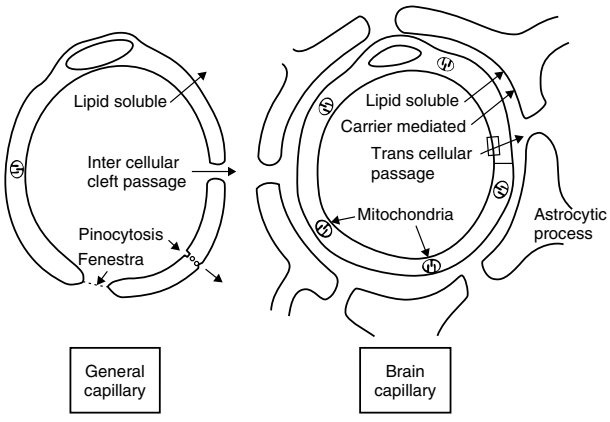

Figure 2 A capillary vessel normally found in the body and a capillary vessel in the BBB. In the brain capillary, the epithelial cell is nonfenestrated and is linked by a tight junction. Outside the epithelial cells are the end feet of astrocytes. Toxic compounds can only enter the brain if they are lipophilic or if a transport system is available.

In humans, the BBB is established at birth, whereas in rats it is on postnatal day 10. There are some areas in the brain that have a weaker BBB, namely the choroid plexus and the circum ventricular organs (median eminence, subfornical organ, area postrema and neurohypophysis). These regions have endothelial cells of the fenestrated type, but they maintain the tight junctions between the cells.

The peripheral nerves are also protected from many toxic substances. The peripheral nerves are protected from the extracellular fluid by the epineurum which consists of connective tissue. The endoneural capillary system also has some similarities with the endothelial cells of the BBB, but the barrier is less efficient. In the brain the cerebrospinal fluid (CSF) acts as a sink for toxic agents, but in the peripheral nervous system this sink is lacking. Some parts of the peripheral nervous system are less well protected. The perineurium is neither present in the nerve terminal branches nor in the myoneural junctions. These are therefore easily attacked by tetanus and botulinum toxins. The peripheral ganglia are covered by an efficient perineurium barrier, but the ganglionic cells do not have an efficient barrier. The sensory and autonomous ganglia are therefore readily exposed to neurotoxins such as lead and mercury (Olsson, 1990).

3 TOXIC AGENTS ACTING ON NEURON CELL BODIES AND DENDRITES

The toxic mechanism leading to degeneration of neurons is complex and can be regarded as an interplay between several mechanisms. This chapter shows that there is a close connection between excitotoxicity, oxidative stress formation, mitochondrial damage, removal of damaged protein and DNA repair. It is often not possible to say which is the most important factor.

3.1 Excitotoxins

Excitotoxins are a group of neurotoxic substances that excite somatic and dendritic receptors in such a way that the neurons may die (**Table 1**). All excitotoxins are, in principle, agonists of the glutamate receptors in the brain and are structurally related to glutamate. There is a good correlation between their excitatory potency and neurotoxicity (Olney, 1969). There are three classes of glutamate receptors linked to an ion channel, namely the α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA), *N*-methyl-D-aspartic acid (NMDA) and kainate receptors. The receptor most often

Table 1 Excitotoxins

Endogenous toxins	Exogenous toxins
L-Glutamate	Kainate
L-Aspartate	*N*-Methylamino-L-alanine
L-Homocysteate	Ibotenate
L-Cysteine sulfinate	Domoate
L-Cysteine sulfonate	*β*-*N*-Oxatylamino-L-alanine
Glutamate	L-Alosine

linked to neurotoxicity is the NMDA receptor, which has an ion channel for calcium and sodium (Hollmann and Heineman, 1994).

Kainate has been used as an antihelminic agent and is extracted from seaweed. It has been used as a medicine in low doses for children and this explains why they did not observe a toxic effect (Olney, 1981). Kainate does not cross the BBB and has to be injected to enter the brain. Kainate injected into the neostriatum was used to produce the first model for Huntington's disease (Coyle and Schwarcz, 1976). Ibotenate is found in *Amariata* mushrooms. Domoate is produced by algae (*Nitzchia pungens*) and was believed to be responsible for cognitive deficits and death after mussel poisoning in Canada (Stewart *et al*., 1990). *β*-*N*-oxalylamino-L-alanine (L-BOAA) and *β*-*N*-methylamino-L-alanine (BMAA) are two plant-derived excitatory amino acids. Zeevalk and Nicklas (1989) found that L-BOAA and L-BMAA cause exitotoxic damage in chick retina, BOAA through a non-NMDA receptor and BMAA through the NMDA receptor. L-BOAA has been found in the bean *Lathyrus sativas* and is believed to be the toxic agent causing lathyrism, a well-known disease in certain parts of India and also in the Mediterranean basin. Lathyrism is characterized by specific paraparesis which can occur after consumption of the bean. The toxic agent should normally be removed from the bean by a special treatment before the bean is consumed (Ravindranath, 2002). BMAA is another excitatory amino acid present in cycad flour derived from sago palm seeds (*cycas cincinalis*). It has been suggested that it is responsible for 'Guam disease' where the patients obtain Alzheimer's disease, Parkinson's disease and amyotrophic lateral sclerosis (ALS) together (Spencer *et al*., 1987). Today this is considered less likely, since BMAA is not active enough. Wilson *et al*. (2002) showed that neurological lesions were induced in mice fed cycad flour even when the amounts of methylazoxymethanol (MAM), BOAA and BMAA had been reduced to very low or undetectable levels. They concluded that an as yet undiscovered toxin must be responsible for the neurodegenerative disease in Guam. Khabazian *et al*. (2002) have isolated and characterized other putative neurotoxins in cycad flour. The most toxic fractions of the washed cycad flour contained several sterol glucosides, of which *β*-sitosterol glucoside (BSSG) occurred in the largest amounts, between 21 and 155 mg kg^{-1} washed cycad flour. BSSG was shown to be neutrally active, evoking a rapid depolarizing field potential and causing cell loss. BSSG also evoked a significant release of labelled glutamate, an effect that could be attenuated by AP5 (2-amino-5-phosphonopentanoate, an NMDA antagonist). As no or only low amounts of cycasin or MAM were present in the cycad flour, the authors concluded that the molecule responsible for the cycad-induced neurodegeneration was BSSG, which activates neuronal cells via glutamate release leading to NMDA receptor activation, culminating in cell death.

The mitochondria are also involved in excitotoxicity. Novelli *et al*. (1988) showed that reduction of ATP synthesis, by KCN or the omission of glucose, increased the toxicity of glutamate. Several other mitochondrial inhibitors, such as 3-nitropropionate or malonate, inhibitors of succinic dehydrogenase, or aminooxyacetate, an inhibitor of aspartate aminotransferase were linked to excitotoxicity. Glutamate antagonists ameliorated the effect of the mitochondrial inhibitors and showed that there was a link between mitochondrial enzyme inhibitors and excitotoxicity (McDonald and Schoepp, 1993; Greene and Greenamyre, 1995).

Excitotoxicity is not a single event, but is a result of a cascade of events (Fonnum and Lock, 2004). This cascade, which involves receptor activation, an increase in intracellular calcium and a generation of reactive oxygen species (ROS), is illustrated in **Figure 3**. It may be initiated by a high concentration of extracellular glutamate caused by inhibition of glutamate uptake, or by excessive release of glutamate. Alternatively, it starts with exposure to an extracellular excitatory compound. In all cases this leads to the activation of one of the glutamate receptors, either the AMPA or the kainate receptor. Activation of the AMPA receptor is accompanied by the entry of sodium ions and depolarization of the membrane. The NMDA receptor is normally blocked by Mg^{2+} in the ion channel. On depolarization of the membrane, Mg^{2+} is released from the NMDA ion channel and this allows the permeation of calcium through the ion channel into the neuron (Choi, 1988). A high intracellular concentration of calcium has severe consequences. It may be sequestered into the mitochondria and induce depolarization of the mitochondrial inner membrane. Such depolarization may increase the release of ROS, which are produced by the electron-transport chain (Schinder *et al*., 1996). Such reactive oxygen radicals can also be formed by calcium activation from xanthine oxidase, nitric oxide synthetase or arachidonate in the nerve terminal (Fonnum and Lock, 2004). The oxygen radicals may attack proteins, lipids and DNA, and be the final step in the excitotoxic events. The high intracellular calcium can also activate membrane-destructive enzymes such as calpain, endonucleases and phospholipase A. In some cases the excitotoxic effect occurs via

DOI: 10.1002/9780470744307.gat058
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

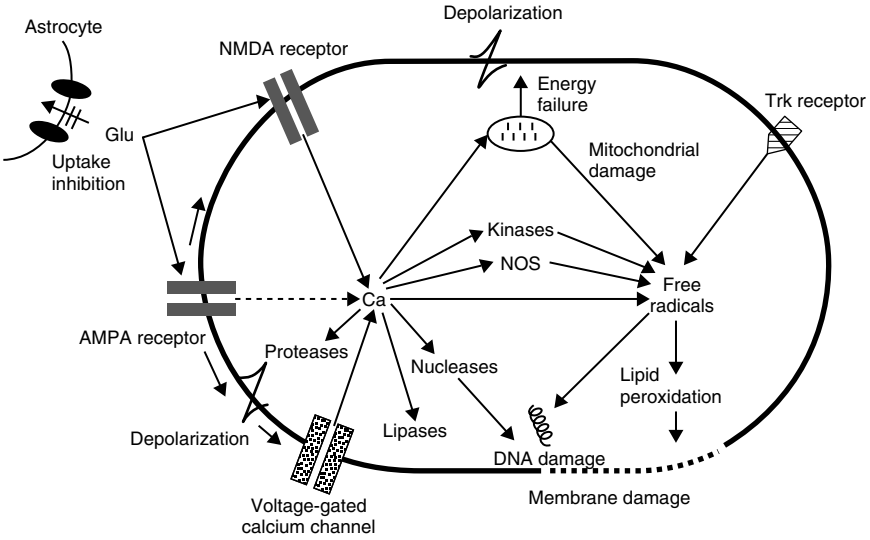

Figure 3 The cascade of reactions during excitotoxicity. Excitotoxins activate the glutamate receptors and depolarize the neurons. Calcium enters the neuron through the ion channel of the NMDA receptor and through voltage-activated calcium channels. The high intracellular calcium leads to the formation of reactive oxygen species either through the electron-transport chain of the mitochondria, by xanthine oxidase or nitric oxide synthetase. Free radicals lead to protein damage, DNA damage and peroxidation of membranes. Calcium also activates protease, lipase and DNAase. (Figure is taken from (Fonnum and Lock, 2004) by permission of Journal of Neurochemistry.)

the kainate receptor and in this case ROS also play an important role.

Some of the excitotoxins are also believed to play an important role in the development of several neurodegenerative disorders. One of the difficulties in explaining the action of several excitotoxins, such as domoate and L-BOAA, is the fact that they pass poorly through the BBB. The BBB has certain weak sites and it can also be weakened by different mechanisms, including infections. In experimental studies on young animals before the establishment of the BBB, glutamate, aspartate, homocysteate and other excitatory amino acids may produce brain damage through an excitotoxic mechanism (Olney, 1969; Karlsen and Fonnum, 1976). Olney *et al*. (1990) claimed that the toxic effect of cysteine was substantially increased in the presence of bicarbonate. Alternatively, the toxic mechanism of cysteine could be a special case of excitotoxicity, where cysteine will exchange with intracellular glutamate or lower the redox potential of the NMDA receptor to a more sensitive mode (Mathisen *et al*., 1996).

When evaluating the importance of excitotoxicity in neurodegenerative disorders, one should bear in mind that many of these disorders probably originate through different mechanistic steps. There is strong evidence from the high extracellular level of excitatory amino acids that excitotoxicity plays a role in the development of brain damage due to both focal and global ischaemia, and hypoglycaemia (Ikonomidou and Turski, 1995). Head trauma like concussion (Pugilist brain), high cerebral pressure and acute subdural haematoma also cause high extracellular levels of glutamate in human brain (Engelsen *et al*., 1985) and the primary damage is ameliorated by glutamate antagonists (Lipton, 1993). The neurological effects of HIV also involve the glutamate receptor (Raber *et al*., 1996). The toxic mechanism in development of amyotrophic lateral sclerosis may include both a high extracellular level of glutamate due to a loss of glutamate transport (Rothstein *et al*., 1996) and increased ROS due to mutations in Cu/Zn superoxide dismutase (Bowling *et al*., 1993). Excitotoxicity is also involved in the development of neurological degenerative diseases such as Huntington's and Parkinson's diseases.

4 BRAIN DAMAGE BY OXIDATIVE STRESS

The three most important free radicals in the brain are superoxide ($\bullet O_2^-$), nitric oxide ($\bullet$NO) and the hydroxyl ($\bullet$OH). Together with peroxynitrite and hydrogen peroxide they are called reactive oxygen species and play an important role in oxidative stress in the brain. The brain is regarded as particularly sensitive to oxidative stress for several reasons (Halliwell, 2007). Firstly, the brain, which is 1–2% of the body weight, utilizes about 20% of the oxygen being taken up in the body. About 1–5% of this oxygen is lost from the electrochemical chain in the mitochondria as superoxide (Fridovich, 1978). Several brain regions such as the basal ganglia (substantia nigra, globus pallidus, putamen

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat058
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and nucleus caudatus), red nucleus and cerebellar nuclei have a high content of protein-bound iron, for example in transferrin and haemoglobin (Beard *et al*., 1993). A small amunt of iron can be released by the action of superoxide on iron-binding proteins and participate in the formation of the active hydroxyl radical. Also, injured neurons can release their intracellular iron into the surrounding tissue. The brain contains enzymes such as monoamine oxidase (MAO), producing high concentrations of H_2O_2, which, in the presence of metal ions, can produce the active OH radical. The brain also contains neurotransmitters, such as dopamine, which are auto-oxidative. The brain is also sensitive to ROS because of its high content of unsaturated fatty acids in membranes. These acids are rapidly peroxidated (Halliwell, 2007).

The brain also has only a modest antioxidant defence. Enzymes such as catalase are hardly present in the brain and superoxide dismutases are only present at 10–20% of levels in the liver. The most important antioxidant in the brain seems to be glutathione (GSH) peroxidase, which is a selenium-dependent enzyme (LeBel and Bondy, 1991). Selenium deficiency leads to toxic effects in the brain. Further, the peroxiredoxin system, with a low K_m, is important, since it may reduce oxidative stress at a low concentration (Rhee *et al*., 2005). The low-molecular-weight antioxidants, ascorbate, GSH and vitamin E, are naturally occurring in the brain. Ascorbate is present in a high concentration (mM) and there is a specific uptake system for ascorbate in the brain and in the neuron (Qiu *et al*., 2007). The highest level of GSH (mM concentration) is found in the astrocytes and they transport cysteine into the brain for GSH synthesis (Dringen and Hirrlinger, 2003). Vitamin E is found in micromolar concentrations and has several different functions in the brain. The level of vitamin E in brain is strongly regulated and it takes at least six months to modify the level. Vitamin E deficiencies give neurological symptoms (Muller and Goss-Sampson, 1990).

Superoxide radicals are obtained from the electron chain or are formed from hydrogen peroxide by superoxide dismutase. The superoxide radical has only limited reactivity. Its main importance is to participate in the formation of the very active hydroxyl radical and peroxynitrite. Hydrogen peroxide is also a poor oxidizing agent, but it penetrates cell membranes easily. Superoxide and hydrogen peroxide can react in the presence of iron or copper ions to give the hydroxyl radical via the Haber–Weiss reaction:

$$\bullet O_2^- + H_2O_2 \rightarrow \bullet OH + OH^- + O_2 \qquad (1)$$

In the cells hydrogen peroxide yields hydroxyl radicals by reaction with metal ions through the Fenton reaction:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + \bullet OH + OH^- \qquad (2)$$

In fact, the damage to cells does not occur from the reactivity of superoxide or hydrogen peroxide, but rather from the hydroxyl radical. In this context it is obviously important that iron or copper ions are available.

•NO is synthesized by various forms of nitric oxide synthetase that catalyse the conversion of arginine to citrulline and •NO (Bredt and Snyder, 1994). Neurons produce •NO by means of a calcium-activated enzyme, often linked to the NMDA receptor, whereas glial cells synthesize •NO in a calcium-independent manner. The latter enzyme is induced by pathological conditions (Bolaños and Almeida, 2006). •NO itself is not a very strong oxidizing agent, but together with superoxide radicals it will produce the toxic peroxynitrite (Beckman *et al*., 1990). The mechanism of •NO neurotoxicity is not yet fully understood. Peroxynitrite will interfere with a key enzyme in the TCA cycle and cause energy deficiency. Mitochondrial complexes II–III and IV seem at present to be the main target for peroxynitrite (Almeida *et al*., 1998).

The hydroxyl radical is very reactive and will react with DNA, membrane lipids and carbohydrates. In DNA it will react with deoxyribose, oxidize purine and pyrimidine bases and cause strand breakage. In membranes it will react particularly with the polyunsaturated fatty acids. It will form lipid radicals, which will react with oxygen to form peroxyl radicals and this can start a cascade of reactions (Halliwell, 2007).

Oxidative stress is involved in brain damage often caused by excitotoxic mechanisms. Examples are the toxic mechanism of methylmercury (Sarafian and Verity, 1991), 3-nitropropionate (Dawson *et al*., 1995), 2-chloropropionate (Sturgess *et al*., 2000), polychlorinated biphenyls (PCBs) and brominated flame retardants (BFRs) (Mariussen and Fonnum, 2006), 1-methyl-4-phenyl-1,2,3,5-tetrahydropyridine (MPTP), X-rays, toluene and glucocorticoid treatment (LeBel and Bondy, 1991). Oxidative stress is probably also involved in Alzheimer's, Parkinson's and Huntington's diseases, Friedrich's ataxia and amyotrophic lateral sclerosis (Butterfield, 2006; Kwong *et al*., 2007). Oxidative stress can be attenuated by enzymes and antioxidants. Spin traps such as α-phenyl-*N*-*t*-butylnitrone is a widely used agent to trap radicals *in vitro* (Carney *et al*., 1991). In cell-culture experiments and in animal models, the oxidative stress can be modified by antioxidants like *Ginkgo biloba*, but it is rare to find good evidence of antioxidants in human brain disease (Halliwell, 2007). In principle, iron chelating agents should be very effective in preventing oxidative damage. So far, desferol has shown great potency in cardiac disease, but it passes the BBB only with difficulty (Gassen and Youdim, 1997).

4.1 Effects on DNA

Neurons, which are postmitotic cells, depend on an active DNA repair mechanisms in order to survive. This is consistent with the fact that extensive neurodegeneration is found in people with the rare autosomal recessive photosensitive disorders xeroderma pigmentosum and Cockayne's syndrome, which are associated with a defect in nucleotide excision repair (Kohji *et al*., 1998; Rapin *et al*., 2000). It is also interesting that permeabilized neurons exposed to a methylating agent (*N*-methyl-*N*′-nitro-*N*-nitrosoguanidine; MNNG) and glutamate, increase the number of single-strand breaks by two- to fivefold and double-strand breaks of DNA by two- to sixfold (Rao, 2007). DNA repair mechanisms play an important role in preventing oxidative stress damage. 8-Oxo-7,8-dihydro-2′-deoxyguanosine (oxo8dG) is one of the most common adducts formed as a result of the action of ROS on DNA. This adduct is repaired by an active mechanism of base excision repair (BER) also involving specific *N*-glycosylases, DNA polymerases and DNA ligases. Oxo8dG is removed from DNA by a bifunctional glycolyase/AP lyase enzyme, termed 8-oxoguanine glycosylase 1 (OGG1) (Liu *et al*., 1996). Oxo8dG is the result of several toxic compounds and found in a series of neurological diseases. A less successful repair of this and other oxidative lesions in DNA will have severe consequences.

DNA damage to mammalian cells, including cerebellar granule cells, initiates transient phosphorylation cascades, which modify the activities of proteins regulating both apoptosis and repair. In these cases the production of DNA damage or inhibition of repair commits the damaged neurons to apoptosis (Sastry and Rao, 2000). In the following, the role of DNA damage in the selective toxicity of foreign compounds to granule cells in the cerebellum is shown as an example.

4.1.1 Methylazoxymethanol (MAM)

MAM is an alkylating agent which may be metabolized to diazomethane and subsequently methylates nucleotide bases. It has been extensively been used as a scientific tool and is found as one of the constituents of cycasine from Guam. A single administration of MAM to a pregnant rat during foetal development induces a permanent atrophy of the brain structures formed at that time. Treatment of rats at gestational day 15 has the most dramatic effect since this is associated with the most rapid growth in the brain (Johnston *et al*., 1981). Postnatal treatment with MAM affects the cerebellar granular cells. The repair enzyme for methylated bases is O^6-methylguanine-DNA methyltransferase, which is less active in the brain than in other organs.

4.1.2 Trichlorfon and Dichlorvos

Trichlorfon is an organophosphonate widely used in the treatment of ecto- and endoparasites, and in the aquaculture industry to control salmon lice. In human medicine it is used against the trematode *Schistosoma haematobium*. Trichlorfon is spontaneously converted to dichlorvos, which is responsible for its anticholinesterase action. It was early discovered that when sows were treated late in gestation with trichlorfon, the piglets showed severe locomotion disturbances, including ataxia (Berge *et al*., 1987). The toxic effect has been reproduced in guinea pigs, but not in rats. When pregnant sows or guinea pigs were exposed to trichlorfon or dichlorvos, the cerebellum, medulla and hypothalamus were the brain structures most heavily affected. Histological examination showed degeneration of dividing cerebellar granular cells (Mehl *et al*., 2007). The lesion was neither due to anticholinesterase activity nor to an effect on neuropathic esterase, since other inhibitors of these enzymes do not produce such effects. It was suggested that dichlorvos and probably trichlorphon alkylates DNA and inhibits the DNA repair enzyme O^6-methylguanine-DNA methyltransferase (Mehl *et al*., 1994).

5 AXONOPATHY

Axonopathy is used to describe a lesion in which the primary site is the axon itself. During axonopathy the axon and the nerve terminals degenerate, often together with the myelin surrounding the axon, whereas the cell body is left intact. This is caused by an insufficient amount of proteins transported to the axons and the terminals, and therefore impaired function and eventually neuropathy will follow. Also the retrograde transport, which sends information from the terminals to the cell body, is probably essential for the cell function. The different forms of transport seem to be dependent on the proper functioning of microtubules and neurofilaments. There is a large number of compounds which can cause axonopathy, including acrylamide, carbon disulfide, chlordecane, colchicine, disulfiram, hexane, 3,3-iminodipropionitrile, organophosphate insecticides, taxol and vincristine (Spencer and Schaumberg, 1980).

6 DISTAL AXONOPATHY

6.1 Hexane Metabolites

Hexane has been used as a solvent in the leather and graphic industries. It was recognized early that daily exposure to this solvent could be accompanied

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat058
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

by sensorimotor distal axonopathy. Histologically, the distal part of the axon shows massive swellings of the neurofilament, often proximal to the nodes of Ranvier. This results in marked distortions of the axons including retraction of the myelin.

The toxic mechanism of hexane has been investigated using a large number of hexane metabolites. The mechanism involves the oxidation of hexane to 2-hexanol, 2-hexanone and finally to 2,5-hexandione, which is the toxic agent (Krasavage *et al*., 1980). Particularly important was the finding that 2,5-hexanedione forms crosslinks with amino groups of the amino acid lysine and thereby forms a pyrrole (Graham *et al*., 1991). 3,3-Dimethyl-2,5-hexanedione, 2,3-hexandione and 2,4-hexandione cannot form pyrroles with lysine for steric reasons and are consequently not toxic. In contrast, 3,4-dimethyl-2,5-hexanedione, which forms a pyrrole rapidly, is toxic. 3-Acetyl-2,5-hexanedione, which also forms a pyrrole readily, but does not allow the pyrrole group to oxidize, is not neurotoxic. Thus pyrrole formation is not enough to produce the neurofilamentous swelling observed during hexane exposure. Pyrrole oxidation, followed by nucleophilic attack and neurofilament crosslinkage, seems to be necessary for the development of axonopathy (St. Clair *et al*., 1988). In both humans and experimental animals, the loss of sensory impulses begins distally and then, on continuous exposure, progresses proximally.

6.2 Carbon Disulfide

Carbon disulfide has been used in the rubber and viscose rayon industry. Exposure to high concentrations of carbon disulfide causes effects both on the nervous system and on the cardiovascular system. The pathology of the axon caused by carbon disulfide exposure is identical to that caused by hexane. The sequence of events begins with the initial reaction between carbon disulfide and lysine residues on proteins to form a dithiocarbamate (Lam and DeStefano, 1986). The dithiocarbamate protein adduct subsequently undergoes decomposition to isothiocyanate adducts. The isothiocyanate–protein adduct can crosslink to other proteins (Amarnath *et al*., 1991).

6.3 Acrylamide

Acrylamide is used as a precursor for polyacrylamide, which is found in building material as well as laboratory equipment. The toxic agent is acrylamide itself, whereas polyacrylamide is apparently nontoxic. The axonopathy induced by acrylamide begins with distal degeneration of the axon and then progresses proximally if the exposure continues. The axonopathy is characterized by multifocal paranodal swellings of distal parts of the axons, both in the peripheral and the central nervous system. The swellings contain neurofilaments, fragments of smooth endoplasmatic reticulum and degenerating mitochondria. In the peripheral nervous system, the tibial, plantar and sural nerves are most often affected. Acrylamide axonopathy is reversible with time, but full recovery depends on the severity of the intoxication (Smith and Oehme, 1991). In the CNS, acrylamide causes the loss of Purkinje cells and of nerve cell volume in the cerebral cortex (Cavanagh, 1982). The potential of acrylamide to cause developmental neurotoxicity has been tested in rats and the conclusion is that the offspring are not affected at lower doses than the mother. The mechanism of action is controversial and at least three different explanations have been offered. LoPachin (2005) and coworkers suggest that the lesions arise in the nerve terminal. Based on longitudinal silver stain they have shown progressive degeneration of nerve terminals in all CNS regions and in the Purkinje cells after acrylamide exposure. They therefore conclude that the axon degeneration is secondary to the degeneration of the nerve terminal. On the other hand, Sickles *et al*. (2002) suggest that the toxic effect is linked to fast anterograde and retrograde transport. They found that vesicle transport, as a measure of fast transport, is inhibited in animals exposed to acrylamide. They therefore proposed that acrylamide reacts with the motor of the fast axonal flow, namely the protein kinesin. Due to the wide reactivity of acrylamide, they did not exclude that other proteins involved in axonal transport are also affected. Sabri and Spencer (2002) agreed with the suggestion that fast axonal flow is affected, but maintain that energy perturbation is involved. This is based on their early finding that glyceraldehyde dehydrogenase is inhibited by acrylamide.

6.4 Organophosphorus Compounds

The toxic organophosphorus compounds which cause axonopathy after exposure are triorthocresylphosphate (TOCP), which is used in machine oil, and a series of earlier used insecticides. The degeneration of axons does not occur immediately after exposure, but is usually delayed by 7–10 days. The effect can only readily be seen in hens and humans. Major outbreaks of axonopathy occurred during prohibition in the USA when a popular drink (Ginger Jake) was contaminated with TOCP. Another outbreak was in Morocco when olive oil for consumption was contaminated with TOCP. Altogether 40 000 human cases of paralysis have occurred after exposure to organophosphorus compounds such as TOCP and several different herbicides or cotton defoliants (Johnson, 1982). TOCP is metabolized to 2-(*o*-cresyl)-4,4-1,2,3-benzodioxaphosphorin-2-oxide, which will phosphorylate an esterase called neuropathy

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat058
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

target esterase (NTE). It was earlier established that the enzyme possessed phenyl valerate esterase activity in the presence of paraoxon and was inhibited by mipafox (Johnson, 1982). For a toxic effect to appear *in vivo*, more than 70% of NTE must be inhibited and the inhibited NTE must further be dealkylated (i.e. loss of an alkyl group). The enzyme has now been purified and the mechanism revealed (Johnson and Glynn, 1995). NTE reacts with those organophosphates that cause paralysis with swelling and degeneration of distal parts of long nerves in the legs and spinal cord. Cloning of NTE complementary DNA allowed the generation of constitutive and brain-specific NTE-null mice; the former die by midgestation, whereas the latter may display age-dependent neurodegeneration. NTE is not required by dividing cells, but is needed for survival of postmitotic cells such as placental secondary giant cells and brain neurons. NTE is localized to the cytoplasmic face of the endoplasmic reticulum (ER) and catalyses the deacylation of ER-membrane phosphatidylcholine to soluble products: glycerophosphocholine and fatty acids. Phosphatidylcholine is the major phospholipid of eukaryotic cell membranes. When NTE is inhibited by organophosphorus agents it probably disrupts membrane phospholipid homeostasis and ER functions. This will affect axonal transport and glial–axonal interaction. The distal parts of long axons will be particularly vulnerable to loss of these support functions (Glynn, 2006).

The identification of NTE has allowed the relationship between the enzyme and the delayed neuropathy to be studied with series of organophosphorus compounds (Johnson, 1982). The best inhibitors of NTE are alkyloctylphosphorofluoridates and dialkylphosphorofluoridates. The best inhibitors are alkyl phosphates with alkyl groups 12–14 carbon atoms (Wu and Casida, 1995). When one of these compounds, ethyl octylphosphorofluoridate, was administered to mice, which are insensitive to delayed neuropathy, the animals developed ataxia, paralysis and died within one to three days.

7 PROXIMAL AXONOPATHY

3,3′-Iminodipropionitrile is a neurotoxic nitrile affecting both the peripheral and central nervous system and produces a proximal axonopathy (Griffin and Price, 1980; Llorens *et al*., 1993). This axonopathy is characterized by neurofilament-filled swellings of the proximal part of the axon. This damages the transport of neurofilaments, but not the axonal transport of actin and tubulin (Griffin *et al*., 1983). 3,3-Iminodipropionitrile is also responsible for the 'waltzing syndrome' which manifests itself as choreiform and circling movements. This has been assumed to be due to impaired function of and damage to the vestibular hair cells (Llorens *et al*., 1993). Another compound, which in high concentrations also leads to a block of neurofilament transport proximally, is 3,4-dimethyl-2,5-hexanedione. As already discussed, this hexanedione rapidly forms a pyrrole and also allows oxidation of the pyrrole. It has been suggested that the position of the filamentous swelling along the axon reflects the rate of the reaction (Anthony *et al*., 1983). Hexanedione will therefore block filaments at the proximal part of the axon. At lower concentrations it leads to more distal axonopathy.

7.1 Cytoskeletal-Active Compounds

The microtubules that are present in the axons play an important part in axonal transport. Both vincristine and colchicine, which bind to tubulin and inhibit the formation of microtubules, have been found to cause peripheral neuropathy. Taxol, which also leads to axonopathy, stabilizes the polymerized form of tubules and prevents the dissociation of microtubules into subunits. It is interesting that both the inhibition of formation and the dissociation of microtubules cause axonopathy (Hanson and Edström, 1978). All three compounds are in use clinically and have caused neuropathy in humans.

When colchicine and later other microtubule poisons, such as the *Vinca* alkaloids were given intracerebroventricular, they specifically caused degeneration of the hippocampal granule cells (Goldschmidt and Steward, 1980; 1989). Such administration of colchicine produces cognitive impairment due to the degeneration of hippocampal neurons. Intracerebroventricular colchicine injection resulted in free-radical generation characterized by alterations in oxidative stress markers with a significant increase in malondialdehyde (MDA) and nitrite levels and depletion of reduced GSH activity in the rat brains (Veerendra Kumar and Gupta, 2002). When colchicine was stereotactically injected into the brain, it destroyed several different cholinergic neurons (Fonnum and Contestabile, 1984).

8 MYELINOPATHIES

Loss of myelin is accompanied by slower conduction in the axons and also in aberrant conduction of impulses between adjacent processes (Rasminsky, 1980). The effect of toxic compounds either result in segmental demyelination or in intramyelinic oedema (**Table 2**). Demyelination is often accompanied by axonopathy.

8.1 Hexachlorophene

Hexachlorophene was used to treat newborn infants to avoid staphylococcal infections (Mulick, 1973). The compound penetrated the skin and resulted in

Table 2 Compounds causing myelinopathy

Agent	Effects
Diphtheria toxin	Segmented demyelination
Hexachlorophene	Intramyelinic oedema CNS and PNS
Tellurium	Demyelination
Triethyltin	Intramyelinic oedema CNS
Lead	Intramyelinic oedema PNS

intramyelinic oedema. Hexachlorophene has experimentally been shown to bind tightly to cell membranes and destroy ion gradients across membranes. It also uncouples mitochondrial activity and reduces the production of ATP. Both effects could be responsible for development of the oedema (Towfighi, 1980). The high pressure from the intramyelinic oedema may injure the axon and lead to axonal degeneration.

8.2 Lead

Man has been exposed to lead, through lead moulding, soldering and through lead pipes, for centuries. In some areas the consumption of lead pigments in paint caused lead poisoning in children. In this connection there have been many reports showing a correlation between increased brain lead level and decreased school performance (Needleman and Gatsonis, 1990). In experimental animals, lead exposure leads to demyelination. In humans the picture is less clear. Children seem to be more susceptible to lead encephalopathy than adults. In children lead exposure can result in severe brain oedema, probably due to damage to the endothelial cells (Johnston and Goldstein, 1998). Children exposed to lead are, however, often exposed to other environmental toxins.

In humans demyelination is less well developed, but axonopathy is often found. One often finds, however, decreased conductance in peripheral axons, which indicate demyelination. The effect of lead exposure is predominantly localized to the motor axons (Chang, 1990).

8.3 Triethyltin

In 1950s a number of severe cases of triethyltin poisoning occurred after exposure to Stalinon, a preparation used for treatment of acne. Triethyltin is readily absorbed through the skin, and the compound caused intramyelinic oedema in the CNS and consequently a rapid increased intracranial pressure (Krigman and Silverman, 1984; Chang, 1990). In experimental animals, there was first weakness of the hind legs followed by paralysis and later tremor and convulsions. Of the alkyltins, only triethyltin produces an effect on myelin.

8.4 Diphtheria Toxin

Diptheria toxin comes from the bacteria *Corynebacterium diphtheriae*, which is transported via the blood to the PNS where it passes into the parenchyma. It inhibits the synthesis of the proteolipid of myelin and the synthesis of the basic protein of the Schwann cell, and thus causes segmented demyelination both in man and in experimental animals. The lesion appears to be most extensive in spinal nerves and dorsal root ganglia (McDonald and Kocen, 1984).

9 ION-CHANNEL NEUROTOXINS

Ion-channel neurotoxins are widely distributed in nature and offer important protection for prey. The ion-channel toxins generally target voltage-activated channels. In this review we will focus on a few important toxins acting on the voltage-activated sodium channel, although toxins acting on potassium channels and calcium channels are also found. The sodium channel is highly selective for small univalent cations ($Na^+ = Li^+ > K^+ > Rb^+ > Cs^+$) and has relatively small functional diversification, compared to other ion channels. Nevertheless, small differences have been noted. The voltage-activated sodium channel is a tetrameric protein (230 kDa) with an ion pore, a selectivity filter and two gates. One of the gates is closed at the resting membrane potential and opens rapidly during depolarization (m-gate). The other is open at the resting potential and closes slowly during depolarization (h-gate). The combined action of these gates allow for the generation of rapid 'spikes', the so-called action potentials.

There are five different binding sites for sodium-channel toxins (**Figure 4**). Tetrodotoxin, which is isolated from the ovaries and liver of the puffer fish (*Tetraodan*), is one of the most toxic low-molecular-weight compounds known. Saxitoxin is produced by several dinoflagellates, and may also be found in shellfish. Tetrodotoxin and saxitoxin block the ion transport by direct blockage of the ion port outside the so-called selectivity filter. Another class of toxins includes batrachotoxin, dichlorodiphenyltrichloroethane (DDT), pyrethroids, veratridine, aconitine and grayanotoxin. They are hydrophobic and facilitate opening of the m-gate and stabilize the h-gate in the open position thereby preventing or slowing down repolarization of excitable cells. Batrachotoxin is derived from the skin of a south or central American frog and is the most selective and potent toxin of sodium channels. Aconitine

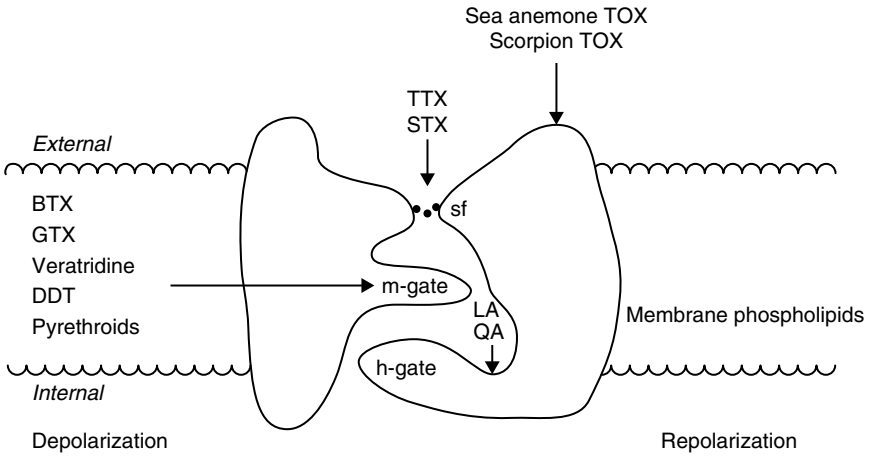

Figure 4 The sodium ion channel with its selectively filter and h- and m-gates. The binding sites for tetrodotoxin (TTX), saxitoxin (STX), scorpion and sea anemone toxins (TOX), batrachotoxin (BTX) and LA (local anaesthetic) are shown. GTX: grayanotoxin; DDT: dichlorodiphenyltrichloroethane; QA: quaternary ammonium salts; sf: selectivity filter.

is a plant alkaloid and grayanotoxin, which is composed of a group of three diterpenoids, is also obtained from plants.

DDT and pyrethroids are important pesticides which act on the sodium channel. Pyrethroids were originally extracted from the flowers of *Chrysanthemum*, but a large number are now synthesized. The pyrethroids are usually separated in two groups based on their chemical structure. Group 1 pyrethroids include the conventional compounds without a cyanogroup, and Group 2 include several compounds which contain a cyanogroup. DDT and pyrethroids of Group 1 will cause repetitive firing of the neuron, whereas pyrethroids of Group 2 do not cause repetitive firing. Instead, Group 2 pyrethroids cause gradual depolarization of the membrane and thereby block impulse conduction (Narahashi *et al*., 1994; 2007).

The third group of toxins is derived from some African scorpions and sea anemones. Their lethal action derives mainly from secretion of neurotransmitters which cause arrhythmia in the heart and repetitive firing and depolarization in nerves. The toxins from scorpions and sea anemones have different chemical structures, but seem to bind to the same site outside the sodium channel. The binding of these toxins is voltage dependent (Catterall, 1995).

10 TOXINS ACTING ON THE NERVE TERMINAL

10.1 Clostridium Neurotoxins

Tetanus toxin and botulinum toxins A, B, C, D, E, F and G are proteins produced by the bacterium *Clostridium basili*. All the toxins recognize a receptor on the motor endplate or the preterminal axon, and are taken up by receptor-mediated endocytosis. The tetanus toxin acts on the inhibitory neurons in the spinal cord, whereas the botulinum toxins target the cholinergic endplates. They all have a similar chemical structure and all block the release of neurotransmitters. The toxins consist of two peptides which are linked together by an S–S bridge. The heavy peptide chain recognizes the cell to be attacked. The botulinum toxins are split after being taken up into the terminal (Simpson, 1990). The the isoforms A, B and C enter neurons by binding to the synaptic vesicle protein SV2 (Dong *et al*., 2006). Membrane translocation of the toxin triggered by acidification of the vesicular lumen is followed by structural rearrangement of the toxin. The light peptide chain has a zinc-dependent endoprotease activity and is released into the cytoplasm. The proteolytic activity is directed against specific proteins involved in transmitter release. Botulinum toxins A and E cleave SNAP-25 (soluble NSF attachment protein), B, D, F and G cleave VAMP (vesicle-associated membrane protein) and C cleaves syntaxin. These peptides are part of the SNARE complex, which is essential for vesicle fusion to presynaptic membranes and transmitter release. The effect of botulinum toxins can last for a long period—up to 30 days. Botulinum toxins do not lead to neuronal cell death. When the toxins are removed and *de novo* synthesis has occurred the cells regenerate their function (Rossetto and Montecucco, 2008).

The tetanus toxin is transported retrogradely to the cell bodies in the spinal cord, where it crosses the synaptic cleft and can be taken up into inhibitory nerves by a similar mechanism as described for the botulinum toxin. In the inhibitory terminals it inhibits transmitter release by cleavage of VAMP. As a result, inhibitory feedback regulation is lost, leading to overexcitation of the neuron and muscle cramps (Turton *et al*., 2002).

10.2 α-Latrotoxin

Black widow spider venom potentiates release of neurotransmitters from nerve terminals. The active component is a protein called α-latrotoxin. It depletes the terminal of small, clear synaptic vesicles, but does not alter the content of dense core vesicles. α-Latrotoxin probably binds with high affinity to neurexin 1-α, a specific protein in the nerve terminals (Ushkaryov *et al*., 2008).

10.3 Convulsants

Several convulsants in the CNS act on the GABA synapse, either as inhibitors of GABA synthesis and release, or by blocking the chloride channel of the GABA receptor. GABA is synthesized by the pyridoxal phosphate-dependent enzyme glutamate decarboxylase. Compounds which bind to pyridoxal phosphate such as isoniazid, semicarbazide and thiosemicarbazide, or compounds which inhibit glutamate decarboxylase directly, such as allylglycine and 3-mercaptopropionate, decrease GABA and cause convulsions (Abe and Matsuda, 1979).

Several other convulsants interact with the $GABA_A$ receptor. This receptor complex has three distinct binding sites: the GABA binding site, the benzodiazepine binding site and the picrotoxin binding site (**Figure 5**). Compounds which react with the GABA receptor are anxiolytic and convulsant β-carbolines, barbiturates, some anaesthetics, such as alfoxalone, and some anthelmintics and insecticides, such as avermectin and lindane. The binding of GABA to the receptor opens the ion channel and thereby increases the chloride conductance; the binding of benzodiazepine increases the probability of the opening of the chloride channel, whereas the binding of picrotoxin blocks the opening of the channel. The sedative barbiturates work by prolonging the opening time of the chloride channel. Other convulsants, such as the bicyclophosphate esters, penicillin G, and various important insecticides like aldrin, lindane, endosulfan, dieldrin and avermectin, bind at or close to the picrotoxin site and modify the opening of the chloride channel (Sieghart, 1992; Vergnes *et al*., 2000). Bicuculline, a GABA antagonist, is also a convulsant. β-Carbolines are a group of compounds which bind at or close to the benzodiazepine site. Unlike the benzodiazepines they are, however, convulsants and are inverse agonists of benzodiazepines (Lumis and Martin, 1992).

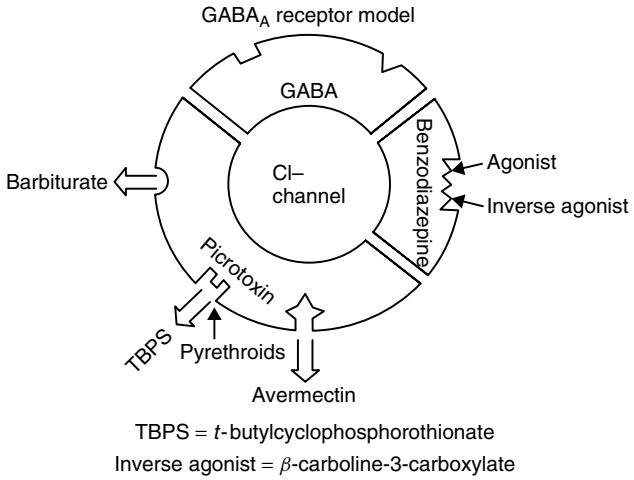

Figure 5 $GABA_a$ receptors have three main sites that interact with each other. They are the GABA site, the bezoxydiazepine site and the picrotoxin site. Substances modify the chloride channel of the GABA receptor by interacting with these three main sites.

11 CHEMICAL LESIONS OF SPECIFIC NEURONS

A series of specific compounds which can selectively destroy groups of neurons, have been developed. Several of these are used mainly for research purposes and they do not pass the BBB, but must be injected intracerebrally. Stereotactic injections of ibotenate, quinolinate and kainate have been used to obtain destruction of cell bodies, while sparing axons passing the sites. Subcutaneous administration of glutamate has been used to destroy specific cell groups before the BBB is fully established (Karlsen and Fonnum, 1976).

During ageing, there is a loss of catecholaminergic neurons resulting from their auto-oxidation. In extreme cases this results in Parkinson's disease. The metabolism of catecholamine involves monoamine oxidase, yielding H_2O_2 as a by-product. H_2O_2 will either give a superoxide radical from a dismutase reaction or a hydroxyl radical by the Fenton reaction. Both radicals are important for cell destruction, as discussed previously.

6-Hydroxydopamine is an analogue of dopamine which is readily taken up into catecholaminergic terminals. When administrated systemically it will be taken up and subsequently undergoes auto-oxidation in sympathetic neurons. The result is therefore a selective destruction of the sympathetic innervation (Malmfors and Sachs, 1968). 6-Hydroxydopamine does not penetrate the BBB, but when administrated stereotactically, it will destroy catecholaminergic cells in the substantia nigra.

Another compound which selectively destroys catecholaminergic structures is MPTP. MPTP was synthesized as a by-product from the production of the illegal opiate analogue meperidine. Within hours to days after consumption it results in parkinsonian-like symptoms (Davis *et al*., 1979). MPTP is uncharged and therefore passes readily through the BBB and is taken up into

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat058
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

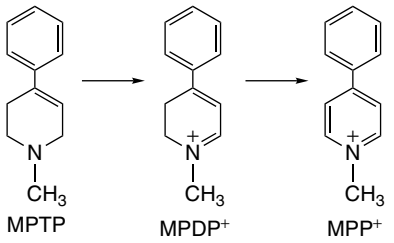

Figure 6 MPTP is taken up across the BBB and then diffuses into astrocytes. In astrocytes it is oxidized by monoamine oxidase B to the methyl phenyldihydropyridinium ion ($MPDP^+$) and finally to the methyl phenylpyridinium ion (MPP^+). This is taken up into dopaminergic cells and inhibits the mitochondrial activity.

astrocytes, where it is converted by monoamine oxidase B to the methyl phenyldihydropyridinium ion ($MPDP^+$) and further to the methyl phenylpyridinium ion (MPP^+) (**Figure 6**). The toxic effect of MPTP is to a large extent blocked by the monoamine oxidase B inhibitor deprenyl. MPP^+ is released from the astrocytes into the extracellular space before a toxic concentration is reached within the glial cells (Wu *et al*., 1992). It is then taken up into the dopaminergic cells by the same uptake mechanism as for dopamine (Javitch *et al*., 1995). The toxic MPP^+ is therefore accumulated and trapped within these cells, and makes them a target for its toxic action. It has also been shown that MPP^+ can be formed from MPTP, catalysed by iron. MPP^+ inhibits oxidative phosphorylation and kills the cells. MPTP is an example of a compound that is much more toxic to monkeys and man than to rodents (Nagatsu and Sawada, 2006). The findings of the toxic effects of MPTP and 6-hydroxydopamine have opened up the possibility that environmental toxins may play a role in development of Parkinson's disease.

5,6-Dihydroxytryptamine and its 5,7-isomer are taken up into serotonergic cells by the transport system for serotonin. Since there are few serotonergic structures peripherally, they are usually administrated stereotactically into the brain, and act in a manner similar to that of 6-hydroxydopamine (Bjørklund *et al*., 1974).

Reports from northern China indicate that 3-nitropropionic acid (3-NPA) is also likely to be responsible for the development of putaminal necrosis, with delayed dystonia in children, after ingestion of mildewed sugar cane. The compound inhibits succinic dehydrogenase, activates palpain and causes massive oxidative stress. The effect is degeneration in the striatum and the compound is suggested as a model for Huntington's chorea. The effect in the striatum cannot fully be explained by inhibition of succinic dehydrogenase because the enzyme is equally inhibited in other brain regions. It is therefore believed that the neurotransmitter activities in the striatum make this a more vulnerable part of the brain (Brouillet *et al*., 2005).

AF64A (ethylcholine mustard aziridinium ion) is a choline analogue, and this has been used specifically to destroy cholinergic cells. This selectivity of this compound is a result of selective uptake into cholinergic cells and its subsequent reaction with the protein synthesis system (Fisher and Hanin, 1986). The specificity of the compound, however, has been criticized (Villani *et al*., 1986).

Intraperitonal injection of 3-acetylpyridine has been found to cause selective degeneration in the inferior olive nucleus and hypoglossus nucleus (Desclin and Escubi, 1974). The specificity is believed to depend on the specific uptake into certain cell types of acetylpyridine, which acts as an antimetabolite. More detailed studies have shown loss of cells in other brain structures, particularly the hippocampal region (Balaban, 1985).

Trimethyltin (TMT) has been used as a stabilizer of plastic and as a pesticide. After systemic administration it gives relatively specific lesions to the pyramidal cells in the hippocampal region (Naalsund *et al*., 1985). TMT has been suggested to act as a mitochondrial uncoupler blocking mitochondrial ATPase. This will lead to oxidative stress. Recently, a peptide, termed stannin, has been specifically localized to TMT-sensitive cells, and blocking stanin synthesis in primary neuronal cultures with an antisense directed against stannin messenger RNA has been reported to protect neurons from TMT toxicity (Toggas *et al*., 1993). It therefore seems possible that the binding of TMT to stannin initiates the toxic reaction. In addition, tumour necrosis factor and other compounds seem to be involved in the toxic mechanism (Reese *et al*., 2005).

12 ENVIRONMENTAL TOXINS

12.1 Polychlorinated Biphenyls

PCBs are a group containing 209 different congeners. The compounds were, until 1977, used in electrical insulation, fire prevention and as additives to paints and building material, but have since been forbidden in most countries. PCBs are stable and lipophilic compounds, and therefore they are biomagnified in the food chain. Top predators such as polar bears, seals and seagulls contain high concentration of PCBs. The highest level of PCBs in brain was found in dead polar seagulls from Svalbard and ranged from 0.9–29.5 mg kg^{-1} brain wet weight (Gabrielsen *et al*., 1995). The neurotoxicological significance of PCBs is well documented after several incidents of accidental exposure. In 1968, more than 1000 people in the Kyushu province in Japan were exposed to cooking oil containing several different chlorinated aromatic chemicals, including PCBs. Symptoms were neurological abnormalities. About 10 years later, a similar incident took place in Taiwan. Some

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat058
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of the children in the exposed groups had problems in neurological development and speech (Mariussen and Fonnum, 2006). In the United States there have been two studies of children in Michigan and in North Carolina, respectively, where they found a correlation between the PCB level and poor performance in behavioural tests (Jacobson and Jacobson, 1996). This indicated that exposure to PCB mixtures during development affects neurological development and impairs cognitive function. Developmental neurotoxicity of PCBs has been confirmed in several laboratory animal species, including the nonhuman primates. In young animals there is an effect on learning and memory, in adult animals there is an effect on motor behaviour (for a review see Kodavanti and Tilson, 1997; Mariussen and Fonnum, 2006).

During the last 20 years there has been an attempt to understand the cellular bases of PCB-induced behavioural and neurological effects in animal models. PCBs are divided into two groups based on their ortho substitution. PCBs that have no ortho substitution will have a planar configuration and a high affinity for an aryl hydrocarbon (Ah) receptor, like other planar polychlorinated compounds, including 2, 3, 7, 8-tetrachlorodibenzodioxin (TCDD). Other PCB congeners with ortho-substituted congeners are nonplanar and have no access to the Ah receptor. These congeners, which dominate in PCB mixtures, are regarded as neurotoxic. The mechanisms behind the neurotoxic effects are not well understood, but ortho-substituted PCB congeners have been reported to act on different parameters of importance for brain function (Mariussen and Fonnum, 2006).

Repeated exposures to PCB doses appear to affect brain dopamine levels, both during development and in adults (Seegal, 1996). Low concentrations of ortho-substituted congeners have been reported to inhibit uptake of neurotransmitters, particularly dopamine, into synaptosomes and synaptic vesicles (Mariussen *et al*., 1999; Mariussen and Fonnum, 2001). Bemis and Seegal (2004) exposed rat-brain synaptomes to PCBs and conclude that the reduction of dopamine in synaptosomes was primarily due to inhibition of the vesicular uptake. This has been confirmed by *in vivo* studies. Seegal *et al*. (2002) showed by microdialysis that extracellular PCBs increased dopamine for the first three days after giving PCBs, as an indication of dopamine synaptosome-transporter inhibition. It decreased thereafter, as evidence of vesicular-transport inhibition. Caudle *et al*. (2006) found a reduction in both the dopamine synaptosome transporter and vesicular transporter after giving rats 7.5 and 15 $mg\,kg^{-1}\,day^{-1}$ of PCBs for 30 days. PCBs are weaker inhibitors of glutamate and GABA transport into synaptosomes (Mariussen and Fonnum, 2001), although an effect of higher molecular weight PCBs cannot be excluded. It has been suggested that the cholinergic receptors could be involved to explain the cognitive and hypoactive behaviour (Eriksson *et al*., 2001). The effects found were small and it should be kept in mind that in the striatum there is an interplay between dopaminergic and cholinergic structures.

Several studies have shown that the ortho-PCBs can induce both apoptotic and necrotic cell death of several neuronal populations, such as cerebellar granule cells, hippocampal cells and mesencephalic cells *in vitro* (Kodavanti *et al*., 1994; Mariussen *et al*., 2002; Lee and Opanashuk, 2004). Mariussen *et al*. (2002) further showed that the cell death could be related to the formation of oxidative stress. Both parameters were reduced by Vitamin E, MK801 (an NMDA receptor blocker), the AMPA receptor agonist NBQX (2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo[f]quinoxaline-2,3-dione), and NAME (*N*-ω-nitro-L-arginine methyl ester, a nitric oxide synthase inhibitor). Lee and Opanashuk (2004) also showed that dopaminergic cells were more susceptible to PCBs than nondopaminergic cells and that protection were offered by antioxidants. The PCB congeners also interfere with the signal transduction system in neuronal cells, namely the production of 1,4,5-inositol trisphosphate and the subsequent mobilization of intracellular calcium. Increased activity of protein kinase C is also reported (Kodavanti *et al*., 1994).

Thyroid hormones and retinol are important regulators during the development of the nervous system. PCBs have been reported to bind competitively to the transport protein for these compounds, and PCBs consequently lower the plasma level of thyroid hormone and retinol. PCBs have also been reported to block the thyroid hormone receptor. Such effects may have severe consequences for the development of the foetus (Ulbrich and Stahlmann, 2004).

12.2 Brominated Flame Retardants (BFRs)

There are several groups of flame retardants (FBRs), but three groups dominate with regard to production volume, namely tetrabromo bisphenyl A (TBBA), polybrominated diphenyl ether (PBDE) and hexabromocyclododecane (HBCD). The total annual production of the three reaches about 200 000 tonnes per year. BFRs are found in textiles, furniture, clothing and electronic equipment. Humans are mostly exposed to BFRs through house dust and food consumption. TBBA is bound chemically to the material, whereas PBDE and HBCD are added to the material. This means that, in principle, TBBA is less readily released into the environment. TBBA is also less lipophilic and probably less important as a neurotoxic agent. From a toxicological point of view PBDE is the most important. PBDEs are structurally similar to PCBs and they consist of 209 congeners. They

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat058
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

are provided as mixtures named tetraBDE, pentaBDE, hexaBDE and decaBDE after the number of bromo constituents. When males rats were given tetraBDE ($10.5\,mg\,kg^{-1}$), pentaPBE (0.8 and $12.5\,mg\,kg^{-1}$) and hexaPBE (0.45 and $9\,mg\,kg^{-1}$) on days 3, 10 and 19, and were tested after two and four months, they showed permanent aberrations in spontaneous behaviour (Viberg *et al*., 2003; 2004). Rats receiving pentaBDE and hexaBDE also showed affected learning and memory functions when tested in the Morris water maze (Eriksson *et al*., 2001; Viberg *et al*., 2003). They registered a 20% decrease in nicotinic binding sites in the hippocampus in their experiments.

There are several similarities displayed by the FBRs and the PCBs. Mariussen and Fonnum (2003) showed that pentaBDE, HBCD and TBBA inhibited the uptake of dopamine into both synaptic vesicles and into the synaptosomes at low (μM) concentrations similar to findings for PCBs. TBBA also inhibited the transport of other neurotransmitters, such as glutamate and GABA. The three groups, TBBA, HBCD and pentaBDE also induced cell death in cerebellar granule cells at similar concentrations to PCBs. Again, as shown for PCBs, vitamin E and MK 801 protected against cell death indicating intrasynaptosomal increase of calcium and oxidative stress (Reistad and Mariussen, 2005; Reistad *et al*., 2006; 2007). Others also showed that pentaBDE was cytotoxic (Madia *et al*., 2004). Further, pentaBDE and the PCB mixture Arochlor 1254 released arachidonic acid and thereby activated phospholipase A2 (PLA2) from cerebellar granule cells. They also induced protein kinase C (PKC) translocation and disrupted calcium homeostasis in the microsomes (Kodavanti and Ward, 2005; Kodavanti and Derr-Yellin, 2002).

13 MERCURY

Mercury exists in several different forms, such as metallic mercury, HgCl, $HgCl_2$ and methylmercury. The lipophilic methylmercury has been the toxic agent in poisonings in Japan and Iraq. In 1971, in Iraq, 500 people died and 5000 were severely injured after eating seed grain dusted with methylmercury fungicide. The wheat was not intended for eating, but for planting. In some areas the wheat arrived too late and during a famine the seed grain was therefore used for human consumption. Several weeks after consumption, the first symptoms, which were loss of sensation in the skin and blurred vision, appeared. Later severe symptoms such as blindness, deafness, loss of coordination and death occurred. The use of this fungicide is now forbidden. In Minamata in Japan industrial effluent containing mercury was released into the bay and converted by micro-organisms to methylmercury. The methylmercury in the sediment was transferred, via smaller organisms, to fish, which were consumed by the inhabitants (Cranmer *et al*., 1996).

In daily life, humans are most commonly exposed to methylmercury by consumption of contaminated fish and other foodstuffs. There have been three large investigations, in the Seychelles (van Wijngarden *et al*., 2006), New Zealand (Crump *et al*., 1998) and the Faroe islands (Debes *et al*., 2006), concerning the possible side effects to children in populations having a high proportion of fish in their diet. It was found that the benchmark value of methylmercury during pregnancy was 10–12 ppm in maternal hair in these investigations of children (van Wijngarden *et al*., 2006). But other forms of exposure, such as occupational and dental material, should also be kept in mind. Mercury vapour taken up through the lung can combine with cysteine in the blood and be transported over the BBB. The intraoral concentration of mercury is correlated to the number of tooth fillings; mercury is continuously released from tooth fillings.

In general, it can be said that mercury compounds have a wide range of effects, both in the nervous system and in other organs, particularly the kidney. In the brain, methylmercury particularly injures the neurons of the visual cortex and the small granular cells of the cerebellar cortex (Shiraki, 1979). In the cerebellum, larger neurons, such as the Purkinje cells, seem to tolerate methylmercury better than the smaller neurons. In the methylmercury particularly affects the dorsal root ganglion cells (Schiønning *et al*., 1998).

The molecular mechanism of the toxicity of methylmercury is not known. It reacts with protein SH groups and leads to a production of ROS in nervous tissue (Sarafian and Verity, 1991). At an early stage, it has an effect on protein synthesis, either by inhibiting the transport of amino acids across the BBB or by a direct effect on the ribosomes.

14 LESIONS IN ASTROCYTES

The astrocytes play an important role in regulating extracellular fluid, and in the synthesis and metabolism of neurotransmitters. These cells have the ability to take up potassium ions and also buffer the pH of the extracellular fluid. Further, the cells have the ability to take up, glutamate and to a lesser extent GABA, from the extracellular space and convert these compounds to glutamine. The astrocytes, in contrast to neurons, contain pyruvate carboxylase, which is important for the replenishment of the TCA cycle, and glutamine synthetase which converts glutamate to glutamine. Glutamine can be transported back to the neuron and used for replenishment of the TCA cycle (Fonnum and Hassel, 1996).

Fluoroacetate and its toxic metabolite fluorocitrate have received considerable attention as specific inhibitors of glial metabolism and they have been used in several studies to characterize the importance of glial cells (Fonnum *et al*., 1997). Fluoroacetate is the toxic ingredient of the poisonous plant *Dichapetalum* (Peters,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat058
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1963). Fluoroacetate is an example of a nontoxic substance which is converted to a toxic metabolite, fluorocitrate, *in vivo*. The selective gliotoxic action of these two substances is due to the fact that they are preferentially taken up into glial cells only. Further, in the case of fluoroacetate, it is converted by acetyl thiokinase to fluoroacetyl CoA and further to fluorocitrate. Currently, sodium fluoroacetate is licensed in the USA for use against coyotes, which prey on sheep and goats, and in Australia and New Zealand to kill unwanted introduced species.

Fluoroacetate crosses the BBB. It is, however, not brain specific, since it is also toxic to the heart and kidney. Fluorocitrate does not cross the BBB, and has to be injected intracerebrally. The toxic action of fluorocitrate is due to its reversible inhibition of the TCA enzyme aconitase. Ultrastructural investigation shows that four hours after intracerebral injection of fluorocitrate, the astrocytic cytoplasm looks empty, and there is a loss of glycogen. The endoplasmatic reticulum is swollen and fragmented, and the mitochondria look swollen. Biochemically, there is a large loss of glutamine and GSH, and smaller changes in glutamate, aspartate and GABA. The synthesis of glutamine from acetate is completely inhibited (Paulsen *et al*., 1987).

The accumulation of citrate during inhibition of aconitase is believed to be an important part of the toxic mechanism *in vivo*. Citrate will chelate calcium and Bosakowski and Levin (1986) showed a strong negative correlation between the calcium concentration in serum and the toxic effect of fluorotoxins. Calcium administration increased the survival time of rats poisoned with fluoroacetate.

Since fluoroacetate is only useful close to lethal doses, intracerebral injection of fluorocitrate is mainly used in inhibition of glial metabolism. Fluorocitrate and fluoroacetate have both been used in *in vitro* studies of cell culture or brain slices, but fluoroacetate has to be used in 100-fold higher concentrations. Both compounds have also been used in microdialyses (Fonnum *et al*., 1997). As a method for evaluating the glia specificity of the inhibitors, the glial metabolism can be restored with glial-specific substrates, such as isocitrate or 2-oxoglutarate (Fonnum *et al*., 1997).

Methionine sulfoximine is an excellent inhibitor of glutamine synthetase and treatment with this compound is followed first by a decrease in the level of glutamine and later by a decrease in glutamate in the brain. There will also be an increase of ammonia in the brain that will produce pathology in the astrocytes. Animals exposed to high concentrations of methionine sulfoximine develop seizures after a few hours, whereas low doses give pathological-looking astrocytes (van den Berg and van den Velden, 1970). The related buthionine-l-sulfoximine more specifically inhibits GSH formation.

Another compound with a potential as a gliatoxin is D,L-aminoadapic acid. Pedersen and Karlsen (1979) showed that intravitreal injection was accompanied by specific degeneration of Müller cells in the retina. Subsequent work has shown that L-aminoadipic acid is a selective gliatoxin in the brain. The primary mechanism seems to be that aminoadipic acid is a selective substrate of the cystine-glutamate antiporter in glia cells (Pow, 2001). Whether the subsequent effect is due to an effect on protein synthesis (Nishimura *et al*., 2000) or whether it is due to a reduction in GSH (Reichelt *et al*., 1997) is an open question.

Whereas there are several neurotoxic substances, there are only few gliotoxic substances. To some extent it seems that astrocytes can survive for a long time with no or minimal metabolism. Astrocytes also have a more powerful glycolytic activity and a high amount of ATP can be supplied in the absence of the TCA cycle. Further, astrocytes have a higher level of the antioxidant GSH and can therefore resist attack by free radicals to a much larger extent than neurons.

15 CONCLUSION

The effect of toxic compounds on the CNS is often difficult to evaluate due to the complex function of the brain and the specificity of different brain areas. We can therefore expect to find evidence of CNS effects from several toxic compounds in the future. The development stage seems particularly vulnerable.

Both excitotoxicity and free-radical formation may be common toxic mechanisms for a wide variety of toxic substances. Also, an evaluation of the importance of neurotoxic substances and genes in the development of neurological degenerative diseases should be an important research topic for the future.

A group of toxic compounds not dealt with in this review are the acetylcholinesterase inhibitors. They are dealt with under the chapters on pesticides (**Toxicology of Pesticides**) and warfare gases (**Toxicology of Chemical Warfare Agents**).

The Role of Behavioural Toxicity in Risk Assessment

Bernard Weiss

CONTENTS

1 INTRODUCTION

Over 30 years ago, the United States Congress set into motion the Toxic Substances Control Act (TSCA). It denoted the beginning of a new era in environmental regulation. It called for evaluating the safety of chemicals before commercial production. To the astonishment of many, it acknowledged behaviour as a valid index of environmental health on the same scale as cancer and reproductive disorders. It was included in a workshop held in 1974 to prepare for TSCA by illustrating the variety of methods to be used for such evaluations (Weiss *et al*., 1975).

Behavioural toxicology at that time represented a concept and perspective just emerging in toxicology. Pharmacologists had begun to recognize it in the late 1960s, due to its coupling with behavioural pharmacology, as an independent subject matter (Weiss and Laties, 1969). The first meeting entirely devoted to the discipline had taken place in Rochester in 1972 (Weiss and Laties, 1975). Following TSCA, signed into law in 1976, the discipline, which had hardly passed through infancy at the time, took an accelerated path to maturity.

One source to which we must grant credit is the USSR, whose scientists insisted that functional measures, particularly of central nervous system (CNS) status, provided a much more sensitive and valid criterion of toxicity than pathology, the dominant criterion in the West. Although Soviet dogma and perceived political advantage granted functional measures superior status in the hierarchy of standards, veneration of Pavlovian doctrine also exerted a marked influence. US scientists, comparing generally stricter Soviet with more lenient US exposure standards for many substances, were compelled to ask whether the differences arose from the measures used to determine toxicity.

Behaviour as a criterion of toxicity is now firmly embedded in the toxicological sciences and in regulatory

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat059
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

directives as well. Most large manufacturers of chemicals and pharmaceuticals now include some form of functional neurotoxicity assessment, largely behavioural, in screening new compounds. The basis for what is considered a 'level of concern' for blood lead, in the US Environmental Protection Agency's (USEPA) phrasing, is how children perform on psychological tests. Debates over 'safe' levels of methylmercury in fish are also based on psychological test performance.

Occupational settings provided another ecological niche in which behavioural toxicology could thrive. The committees that stipulate threshold limit values (TLVs) for workers had long relied on behavioural criteria of excessive exposure, as in their definition of the short-term exposure limit (STEL): 'The maximum concentration to which workers can be exposed for a period of up to 15 minutes continuously without suffering from . . . narcosis of sufficient degree to increase accident proneness, impair self-rescue or materially reduce work efficiency . . . '.

Therapeutic drugs provide still another terrain open to exploration by behavioural questions. One compelling example is cancer chemotherapy. Although oncologists have always been aware of the neurotoxic potential of chemotherapeutic agents, they confronted them in the form of severe reactions such as seizures, disorientation and overt peripheral neuropathies. During the past decade, however, they have learned that patients may suffer much more subtle forms of toxicity, such as cognitive impairment, which patients describe as 'chemobrain', and which have been documented by neuropsychological tests (Weiss, 2008).

The content of this chapter is guided by three aims. First, it seeks to familiarize readers from other disciplines with the terminology and tenets of behavioural toxicology. These tenets channel the way methods are developed and applied; methods cannot be applied in isolation without appreciating the principles supporting their use. A second aim is to discuss the methods themselves, the kinds of information they are designed to yield and the objectives that govern their application. Automated techniques will be featured, whenever possible, because of the unique demands of behavioural testing in the regulatory and risk assessment arenas. Observational techniques are valuable as pointers to functional deficits, but are rarely definitive and are much more difficult to reproduce from one laboratory to another. The third aim is to provide examples from current research in behavioural toxicology to amplify the way in which methods are applied. Laboratory animal testing will be the primary context for these descriptions, although some of the methods, especially those designed for sensory and motor assays, are applicable to or have been derived from human testing.

1.1 Principles and Definitions

Behavioural toxicology rests on a simple but significant premise: in essence, to fully determine how a chemical affects an organism, it is crucial to evaluate how the whole organism functions when exposed to that chemical. Many other approaches occupy special niches and yield important information, of course. *In vitro* systems, such as cell cultures, may provide helpful mechanistic data. Neurochemical research yields information about changes in the chemical milieu of the brain, such as neurotransmitter activity. Morphological assays convey critical information about the structural integrity of the brain. Neurophysiological observations offer insights about the electrical activity that reflects the locus and timing of nervous system events. Advances in imaging technology, such as magnetic resonance imaging (MRI) and positron emission tomography (PET) scans, furnish an even more unique window on the brain's universe. All of these sources of information, however, are designed ultimately to extract answers to one fundamental question: what are the processes and structures that govern the organism's behaviour? For toxicology, the question is transformed: is the organism's ability to function at risk?

The ancillary premise of behavioural toxicology is that the myriad functions that collectively define behaviour can be isolated for study. This principle does not assert that one particular function can be severed from all other functions. It simply means that it can be observed selectively by appropriate investigative techniques, much like a muscle group selectively subjected to stress by someone lifting weights; the muscle group is not detached from the rest of the body. Memory, for example, cannot be isolated from the ability to perform a motor response when reacting to a stimulus, but the form of the response can be specified so that it is minimally confounded with memory function. The degree of isolation depends on the experimenter's aims. Some tests, often designated as apical, call upon many functions at once. Others, such as some sensory tests, are designed as narrow probes of a single function. Narrow or broad, however, behavioural tests are aimed at the total organism and its governing systems. Tests of colour vision span a complex pathway from the eye to the brain and involve multiple sites in the brain itself.

The chapter is organized around different classes of techniques. Although the sequence proceeds approximately from simpler to more complex methods, the progression is not wholly monotonic. Sensory function testing, for example, may embody both relatively simple and relatively complex techniques. The sequence of topics is guided mainly by how an investigator might proceed in asking increasingly deeper and more detailed questions of a chemical. Rarely, however, will one measure or end-point suffice to illuminate fully the nature of a toxic effect on behaviour. Behaviour is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat059
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

simply too abundant a source of functions, questions and methods. This chapter provides a survey of the leading methods, some of their findings and descriptions of others that seem to offer noteworthy potential for toxicological questions.

2 REFLEXIVE AND NATURALISTIC TECHNIQUES

Questions about a chemical's neurobehavioural toxicity may be provoked for many reasons. Chemicals already established in use sometimes spur questions because of new regulations, new exposure information, accidents and other situations calling for additional information. In these circumstances, the questions tend to be directed towards specific effects. For new chemicals, information has to be gathered more broadly because of the diverse functions that might be affected. Simple screening tests are typically applied in the early phases of an assessment, and tend to rely on easily observable or measured end points. Many of these fall into the category of reflexive and naturalistic behaviours not requiring extended training or advanced instrumentation. Naturalistic is often used as a synonym for spontaneous, or to denote behaviours not explicitly defined by an experimental procedure. All behaviours are naturalistic, however, to the extent that they fall within the capabilities of the organism under study.

2.1 Functional Observation Batteries

A common element in many arrays of preliminary screening tests is a functional observation battery (FOB), now a standard procedure in most testing protocols, and based primarily on reflexive behaviours. Their role is not new; pharmacologists, testing a new chemical, would typically administer it to rats or mice to observe whatever overt effects it would produce. Such observations would also parallel determination of the LD_{50}, currently out of fashion. FOBs in essence represent a more systematic and more focused scheme for conducting a clinical examination and have been adopted internationally. **Table 1** lists some of the measures typically included in current rodent test batteries.

Table 1 Typical measures examined in functional observation batteries

- Home-cage and handling
- Posture
- Ease of handling
- Piloerection
- Vocalizations
- Open field
- Time to first step
- Urination, defaecation
- Gait
- Bizarre behaviour
- Rearing behaviour
- Reflex and physiological
- Approach response
- Touch response
- Finger snap response
- Righting reflex
- Grip strength
- Catalepsy
- Forelimb grip strength

The limitations of FOBs are not always appreciated. The prime developer of the FOB battery at the USEPA (Moser *et al*., 1995) cautions users against inflated expectations from such procedures. First, their role in the assessment process is to gauge the potential of a chemical to produce neurotoxicity and to suggest which more specific tests, such as those aimed at cognitive function, might be undertaken. They are not designed to identify underlying mechanisms. Second, they are not intended to provide the basis for setting exposure standards, even though, for some chemicals, their sensitivity may achieve parity with more advanced procedures. FOB data can also be used to model dose–response functions (Zhu *et al*., 2005), but like other methods that depend upon observer judgements, FOB observers need to be trained to employ scoring criteria consistently because observational methods are notoriously subject to observer drift in how the nominal criteria are interpreted. In addition, at sites where FOBs are conducted, concordance between observers must be monitored to ensure that all base their scoring on the same criteria. Furthermore, observers should be kept unaware of the identity of the chemical under test; covert bias of which the observer is unaware can easily contaminate a study. Because of the training required, and because the observers themselves need to be observed, FOBs tend to be labour intensive.

A comprehensive neurological examination is even more daunting, and is not suitable for screening or simple hazard identification. The numerous facets of such an examination are described by O'Donoghue (1996) and include many more specific assessments than included in the typical FOB. Such an expanded FOB is designed for other purposes such as securing information needed to identify the locus of damage.

2.2 Naturalistic Behaviours

Animal behaviour observed in a natural or quasinatural setting is the domain of the discipline of ethology. Instead of attempting to isolate specific forms or expressions of behaviour in the laboratory, ethologists undertake to study behaviour in the context of an animal's total

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat059
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

environment as it appears in nature. Ethology has played a minor role in behavioural toxicology because it requires major investments of observer time and often presents interpretive puzzles in the form of what specific circumstances and events control specific behaviours. Laboratory investigators can select aspects of the behaviours that animals show in natural settings and transfer them to a laboratory setting.

Psychobiologists have studied laboratory analogues of naturalistic behaviours from many vantage points. Such behaviours have undergone an expansion of interest with the emergence of endocrine disruption as an element of neurobehavioural risk assessment. It has promoted the contrivance and use of techniques that might reflect disorders of endocrine function attributable to environmental chemicals. Sexually dimorphic end points are especially responsive to interference with gonadal hormone dysfunction, particularly when exposure occurs during early development, a stage at which the brain undergoes sexual differentiation (Weiss, 2002). Virtually all drugs and chemicals produce sexually dimorphic effects, so that even preliminary screening should be alert to sex differences in response.

2.2.1 Reproductive Behaviours

The major role accorded gonadal hormones in discussions of endocrine disruptors highlights sexual behaviour as a prime end point. Male rat sexual behaviour is of particular interest because of the striking array of chemicals labelled as 'environmental oestrogens'. In the standard assessment of copulatory function, observers record measures such as intromission latency following the introduction of a receptive female into the male's space. Although this is the standard technique, and useful, it suffers from its lack of concordance with the natural ethological setting in which the female has a wide range of opportunities to set the pace of copulation. It measures only male copulatory behaviour in a situation with a restrained female.

Abnormalities such as undescended testes, which can occur following gestational exposure to phthalates and other antiandrogenic chemicals, can cloud the relation between the motivational states underlying reproductive behaviours and endocrine function. To preclude such confounding, investigators can assay sexual motivation rather than the mechanics of copulation. The partner preference paradigm offers such an assay. The partner preference test is based on studies demonstrating that olfactory stimuli govern the appropriate selection of sexual partners in rats, mice, ferrets and other mammalian species. Normal males spend more time near oestrous females, and normal females spend more time near sexually active males. Furthermore, hormonal status plays a critical role in partner preference in both male and female rats (Harding and McGinnis, 2003; Clark *et al*., 2004).

Preference testing can be conducted with a set of three attached enclosures. The test animal is placed in the central enclosure, giving it the opportunity to see and smell the two stimulus animals without contacting them directly. For testing males, one side enclosure will contain a male. The other will contain an ovariectomized stimulus female brought into oestrus by injecting 10 µg per rat of oestradiol benzoate 48 hours and 1.0 µg per rat progesterone 1 hour before testing. Choice is measured by proximity to one or the other side of the central enclosure over a period such as 10 minutes. Gonadectomized males prefer the odour of sexually active males rather than that of receptive females (Xiao *et al*., 2004).

2.2.2 Play Behaviours

'Rough-and-tumble' play, and play fighting in particular, is sexually differentiated. In juveniles from many mammalian species, including humans, males engage in it more frequently than females (e.g. Hines, 2003 and Vreugdenhil *et al*., 2002a,b, in humans; Pellis, 2002 in rats) and the sex differences are determined by perinatal exposure to gonadal hormones (Hotchkiss *et al*., 2002). Males castrated at birth exhibit frequencies of play fighting similar to those seen in their female littermates. Females treated perinatally with androgens exhibit frequencies similar to those of males. In rats, play fighting begins to appear at about 18 days of age and peaks between 30 and 40 days of age. Its frequency wanes subsequently, but does not disappear entirely, and also undergoes changes in form.

Smith *et al*. (1997) describe an established protocol. After weaning at postnatal day (PND) 21, same-sex paired littermates are maintained in regular housing. Before the assigned day, for example, PND 34, each pair is habituated to the test enclosure (50×50 cm in area) for 15 minutes a day for three successive days (e.g. PND 30–33). Each rat is then socially isolated for 24 hours in a standard cage; social isolation increases the frequency of play fighting substantially. On the test day, the two members of each pair are placed in the test chamber and video recorded for 10 minutes with illumination provided by red LED lighting. Play fighting is scored in accordance with the categories below (Pellis and Pellis, 1997; Smith *et al*., 1997):

Nape contact: One animal brings the tip of its snout into contact with or within 1 cm of its partner's body.
Pouncing: One animal lunges towards its partner with forepaws extended.
Pinning: One animal is astride its partner, who is supine, with its forepaws on the partner's ventral surface.
Wrestling: The two animals rolling and tumbling over one another.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Chasing: One animal rapidly pursues the other.
Boxing: The two animals stand erect on their hind legs with forelegs raised.

Hotchkiss *et al*. (2003) and Colbert *et al*. (2005) found that the antiandrogenic fungicide, vinclozolin, altered play behaviour in male rats exposed during early development.

2.2.3 Aggression

Aggressive behaviours are displayed by most animals, including common laboratory species (Scott, 1972). A standard method for eliciting attack behaviour in rodents is to introduce an intruder male into another male's home cage, and record the following behaviours on the part of the resident (Miczek *et al*., 1984): (i) attack: leaping towards the intruder; (ii) threat posture: arched back posture; (iii) tooth chattering and (iv) boxing posture: standing on hind legs with forelegs extended; and, on the part of the intruder, escape and defensive behaviours, primarily adoption of a supine posture.

Kawai *et al*. (2003) measured aggressive behaviour in male mice exposed prenatally to the plasticizer bisphenol A, which is an oestrogenic compound currently found in most humans because of its widespread use in many products. They used the resident intruder protocol as their criterion. At eight weeks of age, the treated mice exhibited considerably more aggressive behaviours than their controls. In interpreting such results, it should be recalled that masculinization of the brain results from a process by which testosterone, released by male foetus testicular tissue, is converted by brain aromatase (CYP 19) to oestradiol (Weiss, 2002).

2.2.4 Maternal Behaviour

The early environment of both rodents and humans is governed by the mother's behaviour. In rodents, subtleties in maternal behaviour, such as the amount of licking and grooming behaviours engaged in by rodent dams largely determine how robustly offspring respond to stress when they mature (Cameron *et al*., 2005). Such outcomes are expressed through the hypothalamic–pituitary–adrenal axis. Moreover, licking and grooming behaviours are transmitted to the female offspring, apparently epigenetically, so that daughters behave like their mothers. Maternal stress alters dam behaviour, which may account for how it changes the response of offspring to lead exposure (Cory-Slechta *et al*., 2008).

For those reasons, chemical exposures *in utero* that modify maternal behaviour in the female offspring are important end points to measure in assessing neurobehavioural toxicity. Palanza *et al*. (2002) provide one example. They administered bisphenol A (BPA) to pregnant rats, then studied the maternal behaviour of the female offspring. Dams exposed to BPA prenatally spent less time nursing their pups and more time out of the nest compared with control females. The F2 females were not tested for their own maternal proclivities, but the report by Cameron *et al*. (2005) suggests that they, in turn, would also show reductions in duration of maternal behaviours.

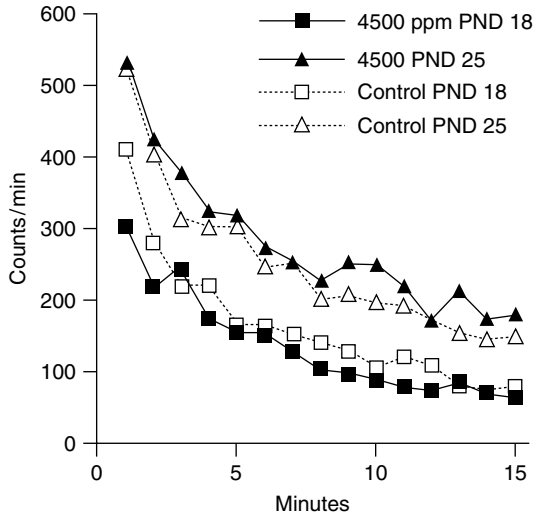

Figure 1 Time course of habituation in motor activity, in control rats and in rats exposed to methanol vapour (4500 ppm) or air from gestational day (GD) 6 to PND 21. The rats were placed in a circular runway where movements were recorded by a ring of photocells. Statistical analysis established a significant interaction between methanol exposure and postnatal day ($p < 0.01$). (Reproduced from Stern *et al*., 1997. © Elsevier.)

2.3 Motor Activity

Motor activity is used extensively in evaluating neurotoxicity. It is considered 'apical' (Geyer and Reiter, 1985) in that it is the joint outcome of several functional capacities. The overall level of motor activity shows a biphasic pattern over time in the normally developing rat, with increases up to about four weeks of age, followed by a decline to a more steady-state level. Typically, female rodents are more active than males before attaining sexual maturity (e.g. Elliott and Grunberg, 2005).

Exemplifying the usual developmental pattern, prenatal and neonatal exposure to methanol vapour depressed activity on PND 18 and elevated it, compared to controls, on PND 25 (Stern *et al*., 1997). Like other investigators, Stern *et al*. (1997) recorded a gradual decline in activity over the 15 minute test period used in their experiment (**Figure 1**). This habituation phenomenon, which represents a form of learning, is a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

useful and easy measure to implement, that ought not to be neglected. Rate of adaptation to the environment provides information independent of absolute number of counts.

As with FOBs, activity measures are designed only to reveal potential neurotoxicity, not to indicate possible mechanisms. Devices in common use include photocell arrays that can measure both horizontal and vertical (rearing) movements, and motion detectors based on disturbed ultrasonic fields or capacitance changes (see **Figure 2**). Typical enclosures consist of running wheels and unencumbered spaces (open field) equipped with photocells to identify exploratory activity. Some laboratories have devised means for measuring activity in the home cage, which allow them to collect data over the full 24 hour period. Despite differences in design, responses to chemicals in different devices are relatively congruent and replicable across laboratories (Crofton *et al*., 1991).

A newly developed device expands the possibilities afforded by recordings of locomotor activity (McKerchar *et al*., 2006). The instrument, a force-plate actometer, uses a stiff, low-mass horizontal plate coupled to four supporting force transducers positioned at the corners of the plate. Movements of the subject are sensed by the transducers, whose signals are processed by computer to yield measurements of locomotor activity in different areas of the field, rotation around the centre and whole-body tremor. Spatial resolution is less than 1 mm, and temporal resolution is 0.02 seconds. A similar device is described by Zumwalt *et al*. (2006). One advantage of such a device is that it can also measure features such as whole-body tremor, as shown in **Figure 3**.

The predominant questions aroused by activity data arise from their lack of specificity. Especially, what does it mean to measure a decrease in activity? Couldn't any chemical, at a sufficient dose, produce enough debility to curtail spontaneous activity? The answer is obvious, but hardly precludes the usefulness of motor activity as one component of an ensemble of tests. A single measure, in isolation, is not sufficient to render a decision. Increases in spontaneous activity are usually more informative than decreases because they indicate a nervous system site of action.

Activity measures need not be confined to presumed neurotoxicants. One of the flaws attributed to such measures is that they may be responsive to other kinds of variables, such as illness lacking a neurogenic aetiology. This feature may prove an advantage for certain questions. Activity measures proved edifying in demonstrating some of the indirect effects of ozone exposure. Ozone is primarily a deep-lung irritant, not a neurotoxicant, but it can evoke subjective complaints at low levels, especially in conjunction with exercise, and depress athletic performance. In controlled experiments with humans, some subjects cease exercising, due to symptoms such as painful breathing. Most animal experiments with ozone, however, feature lung pathology or pathophysiology rather than discomfort. Tepper *et al*. (1982) adopted, instead, a behavioural perspective framed by the human studies. They measured wheel running in rats exposed concurrently to different concentrations of ozone ranging from 0.03 ppm (control) to 1.0 ppm. Running wheels are standard tools for measuring locomotor activity and are used widely in psychobiology for tracking circadian and ultradian rhythms. Even at the lowest tested concentration of ozone, 0.125 ppm, the 1 hour standard specified by the USEPA, activity fell significantly. These findings are consistent with observations that indicate correlations of reduced respiratory function (forced expiratory volume in 1 second; FEV_1) in children with ambient oxidant concentrations. In a subsequent study, Tepper and Weiss (1986) attached a brake to the running wheel that the subjects could release for 10 second periods by pressing a lever on a fixed-ratio schedule. In this situation, ambient ozone at 0.08 ppm reduced the reward potency

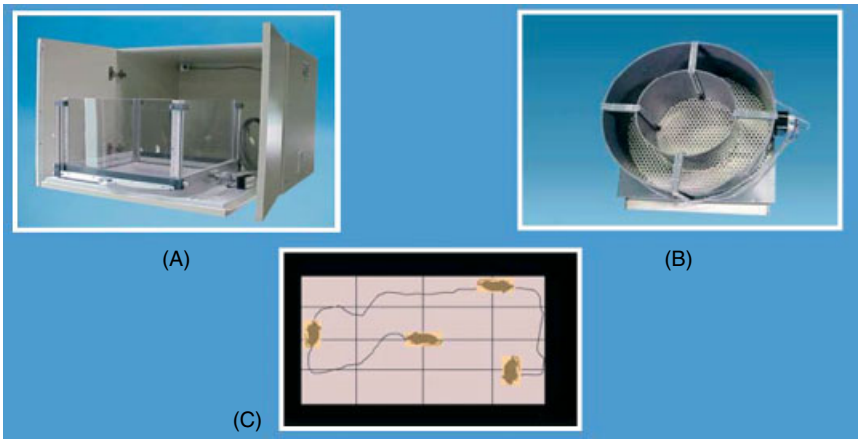

Figure 2 Examples of systems used for the study of locomotor activity. (A) Chamber with a photocell array above the floor; activity is measured as number of photocell beam interruptions. (B) Photocells arranged in a ring configuration. (C) Schematic of an open field; an observer records every crossing of a line.

of wheel running as reflected by lower lever-pressing rates, indicating that ozone reduced the motivation to run.

Cyclical variations in several different behaviours can prove more informative. One form of cyclical motor activity pertinent to neurotoxicology is that coordinated with the oestrus cycle. Normal female rats housed in running wheels show peaks in activity during proestrus. Disturbances of normal oestrus cyclicity by chemicals may provide clues both to toxicity and its mechanisms. Weekly administration of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) to female Sprague–Dawley rats beginning prenatally led to a loss of normal oestrus cyclicity and hastened reproductive senescence (Franczak *et al*., 2006), a result attributed to its endocrine disruptor properties.

The reward properties of wheel running were studied by Markowski *et al*. (2001), who adopted another approach. They studied the reward properties of wheel running, much like Tepper and Weiss (1986), in female rats exposed prenatally to low doses of TCDD on gestational day 18. Because TCDD disturbs oestrus cyclicity, it was hypothesized that the motivation of females to run would change. In this arrangement, shown in **Figure 4**, the subjects had to press a lever on a fixed-ratio schedule to release the brake for 15 second periods. **Figure 5** reveals that TCDD reduced the motivation to run, as measured by lever-pressing to release the break. As plotted by a benchmark dose model, the largest effect occurred at 60 ng kg^{-1}, yielding the kind of U-shaped dose–response function common in endocrine disruption research (**Figure 6**).

3 SIMPLE, SPECIFIC, FUNCTIONAL TESTS

3.1 Motor Function and Coordination

At some phase of the evaluation process, investigators may need to probe further into possible functional deficits than permitted by the methods described above. For explicit assessments of motor function, such as might be required for evaluating potential organophosphorous-induced delayed neuropathy, FOBs may not be adequate for quantitative grading. Two useful techniques for such a situation are foot splay measurements and rotarod performance.

Foot splay is the simpler of the two and requires no instrumentation. The hind feet of a rat or mouse are inked with a food dye. It is then dropped from a specified height (such as 30 cm for rats and 15 cm for mice) after the experimenter has gripped it firmly by the loose skin at the shoulders. The distance between the marks made by the feet is a measure of hindlimb splay resulting from neuropathy induced by the compound under study. Several consecutive trials are typically used to calculate a mean.

Weiss *et al*. (2005) administered methylmercury to pregnant mice and, in some groups, continued to administer methylmercury to the offspring until 26 months of age. Hind-limb splay proved a sensitive measure of methylmercury neurotoxicity, even in those offspring exposed only prenatally, but also showed interactions with ageing. Norreel *et al*. (2001) found it useful in

surveying motor deficits in a mouse model of a neurological disease. In rats, LoPachin *et al*. (2002) found splay measures sensitive to agents producing peripheral axonopathies.

Upper body strength typically diminishes with age, and is also sensitive to a variety of neurotoxicants. One method used to assess it is to determine the subject's ability to grasp a horizontal wire with its forepaws and to remain suspended. In their study of rat ageing, Shukitt-Hale *et al*. (1998) observed a steady decline in the latency to fall (i.e. hang time). At six months of age, the rats could hang on for a mean of 20 seconds. At 22 months of age, that duration decreased to about seven seconds.

Rotarod techniques place the animal on a grooved, rotating rod to which it clings to avoid a fall. At low rates of revolution, unimpaired animals have no difficulty remaining on the rod. As rates increase, animals can no longer cling for extended periods of time. The rod is typically divided into sections so that several animals can be tested at once and number of revolutions is counted automatically. By using individual counters beneath each animal's position that cease incrementing when it falls, a score can be assigned to each subject. One common effect of methylmercury exposure is impaired coordination. Sakamoto *et al*. (2004) administered methylmercury to neonatal rats, presumably a vulnerable period, and observed dose-related deficits in rotarod performance that were correlated with the severity of neural damage.

3.2 Sensory Function

Reflex, that is, involuntary behaviours such as those included in FOBs, predominate in the assessment of sensory function because they are relatively simple and inexpensive. They do not require extended training, as do the operant procedures discussed later. Neither do they provide the vital quantitative information required for extrapolation to the covert varieties of dysfunction that threaten humans. The acoustic startle response (ASR), and its transformation into reflex modification procedures, demonstrates how it is possible to convert a reflex into a readily quantifiable functional criterion.

The ASR is frequently used as a measure of sensory-motor reactivity. It describes the neuromuscular reaction to a brief loud sound. The central nervous system mechanisms underlying the ASR have been delineated by investigations extending over more than two decades. In the typical procedure used with rodents, a subject is restrained in an enclosure in which the response to the evoking stimulus is measured by an accelerometer or strain gauge attached to the enclosure platform. The output of the transducer, following stimulus delivery, is processed to yield measures of integrated response amplitude and latency and amplitude of the multiple peaks and troughs characteristic of this kind of signal.

Localized brainstem and midbrain circuitry mediate the response although the behavioural output can be conditioned, probably via processing by higher-level brain regions such as the amygdala and/or cortex (Davis *et al*., 1997). If the startle-eliciting stimulus is preceded by a weaker 'prepulse' acoustic stimulus, the response amplitude will be reduced. By administering a range of prepulse intensities across different tone frequencies, and measuring the amplitude of the response correlated with each prepulse frequency and intensity, an auditory sensory threshold can be established. Threshold differences observed at specific frequencies are frequently the result of neurotoxicant-induced damage to sensory processing mechanisms. In contrast, a reduced response amplitude noted across the entire prepulse range is often the outcome of motor system impairment.

Goldey and Crofton (1998) used this procedure to examine damage to the auditory system inflicted by developmental exposure to polychlorinated biphenyls (PCBs) in the form of Aroclor A1254. They found that the resulting hypothyroxinemia and hearing loss induced by exposure could be attenuated by the administration of thyroxin.

Reflex procedures are less adaptable for visual function, somatosensory function and even advanced auditory function because the complex nature of the relevant stimuli, such as visual patterns or speech, precludes their use as modulators for reflex modification. The complexity of the stimuli engenders a need for correspondingly complex behavioural assessments, especially when the pivotal questions about toxicity hinge on emerging, covert effects.

3.2.1 Visual Function

Vision is the sensory system of greatest concern in human toxicology because of its dominant role in our behaviour. With improved understanding of how the system works, scientists whose interests span both toxicology and visual science have been able to ask questions directly applicable to humans. Among the environmental neurotoxicants associated with damage to the visual system, methylmercury engenders many concerns. At high exposure levels, due to the damage it inflicts on areas in the brain subserving visual function, it severely impairs vision. Human poisonings in adults, as in the catastrophe in Minamata, Japan, and primate experiments (e.g. Evans *et al*., 1977) reveal damage in the visual cortex and associated functional impairment. Because of the extreme

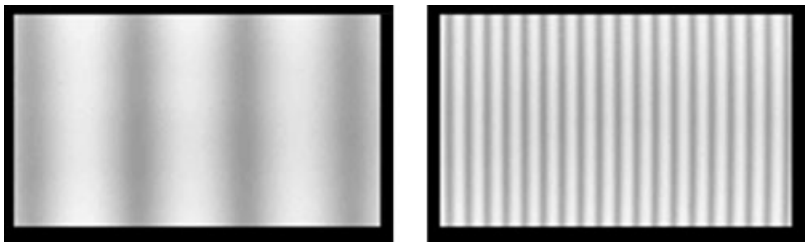

Figure 7 Oscilloscope display showing two spatial frequencies used in contrast sensitivity testing. (A) Low spatial frequency. (B) High spatial frequency.

sensitivity of the foetal brain to methylmercury, which underlies current exposure guidelines in fish, Burbacher *et al*. (2005) undertook to study nonhuman primates exposed only through maternal ingestion during gestation.

They presented stimuli consisting of alternating black and white sinusoidal gratings that varied in spatial frequency and contrast. The subjects, restrained in primate chairs, faced two oscilloscopes on which the stimuli were presented. One oscilloscope was blank; the other presented a sinusoidal grating of specified spatial frequency and contrast (see **Figure 7** for examples). The subject had access to two response buttons. If it pressed the button corresponding to the grating, it received an apple juice reward. By varying spatial frequency and contrast, the experiments were able to construct contrast sensitivity functions. The exposed monkeys exhibited a significant loss of contrast sensitivity, particularly for the higher spatial frequencies. Because exposure had occurred 11–14 years earlier, these results indicated that permanent damage to the visual system had occurred early in development.

Rats and mice are not visual animals. Despite their more primitive visual capacities, however, they are capable of complex visual discriminations and even of rudimentary colour discrimination. The mouse retina contains both rods and cones, although the latter account for only 3% of the total receptor population. Jacobs *et al*. (2004) designed an arrangement for assessing colour vision in mice that can serve as a model for testing rodent visual capacity. They presented subjects with a three-alternative forced-choice discrimination task. Test stimuli were projected on to three circular test panels. If the mouse chose the correct panel, it received a liquid reward from feeder tubes mounted above each panel. With this system, the experimenters could measure a variety of functions, including spectral discriminations. By this means, they determined that these discriminations were connected to two classes of cones with different peak sensitivities at two different wavelengths. A similar procedure has been used with rats (Jacobs *et al*., 2001).

3.2.2 Somatosensory Function

Cutaneous or somatosensory discriminations are important for neurotoxicology because, for mechanoreceptors especially, they require intact peripheral nerves and receptors, while peripheral neuropathies are induced by members of many classes of chemicals: organophosphorus pesticides, heavy metals, solvents and cancer chemotherapy drugs. Sensitivity to vibration is a recognized measure of somatosensory function. Maurissen *et al*. (1983) administered acrylamide to six monkeys trained to press a key when they detected vibration applied to a fingertip (**Figure 8**). Correct detections were reinforced with fruit juice delivered through a tube. On catch trials, when no stimulus was applied, juice was delivered if the monkey refrained from responding. Over a period of many weeks the monkeys were given 10 mg kg^{-1} each weekday until signs of overt toxicity, such as body-weight loss, began to appear. Vibratory thresholds rose during this time and remained elevated for many weeks after the other signs of toxicity had faded.

This study exemplifies several important features of sensory testing. First, the magnitude of the stimulus, produced by an electronically controlled and monitored rod, was specified as displacement amplitude, the appropriate measure. Many publications on altered vibration sensitivity induced by chemicals use a tuning fork, which offers no prospect of measuring amplitude, or simply report the voltage setting of one of the popular electronic instruments, which conveys no useful information. Second, the psychophysical procedure itself was constructed to yield unbiased threshold measures because of the introduction of catch trials. Third, the vibrator itself had to be calibrated to a resolution of fractions of a micrometer because of the high sensitivity of cutaneous sensation. Simple devices are useless for setting human exposure standards because they cannot detect incipient dysfunction.

Precise instrumentation is clearly crucial in securing precise estimates of somatosensory function. Additional examples of the level of instrumentation required can be found in Bensmaia *et al*. (2005) and Tommerdahl *et al*. (2005). Equally important, but frequently slighted, is the psychophysical procedure that determines the pattern and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat059
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

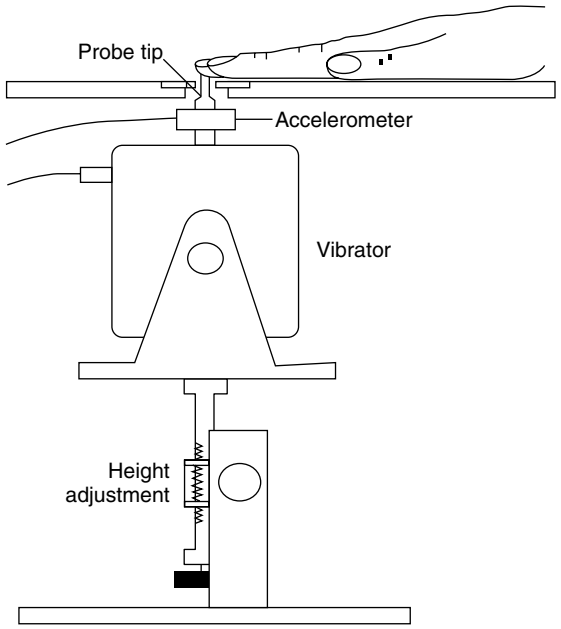

Figure 8 Apparatus used for testing sensitivity to vibration in humans and nonhuman primates. An electronically-driven vibrator under computer control determines both amplitude and frequency.

sequence of stimulus presentation, the appropriate physical dimensions of the stimulus and the form of the subject response. Commercial producers of equipment habitually seem oblivious to these requirements, but even laboratory investigators, much too often, choose unsuitable experimental models. Maurissen (1985) noted that many reports purporting to measure vibration sensitivity provided flawed descriptions of the stimuli. Rather than measuring or noting the amplitude of stimulus displacement, the appropriate measure, they report irrelevant, meaningless or improper values such as a voltage setting. In addition, many alleged measures of sensory function fail to use the appropriate psychophysical testing procedures. Maurissen (1985) divides psychophysical methods into four categories:

- Method of limits
  - Ascending and descending series of stimulus intensities from above and below thresholds, respectively
- Method of constant stimuli
  - Equally spaced stimulus values presented in random sequence
- Method of adjustment
  - Observer varies stimulus intensity to exceed and dip below detection limits
- Adaptive methods
  - Stimulus intensity rises with failure of detection and falls with correct detection.

He divides response requirements into three categories:

- Forced-choice procedures
  - Subject must choose among alternatives
- Yes–no procedures
  - Subject responds if stimulus is detected, refrains if it is not
- Rating procedures
  - Subject reports likelihood of presence or absence using rating scale.

Because rodents are the species of choice in most laboratory experiments, methods suitable for their evaluation warrant consideration. Xerri *et al*. (2005) designed a situation requiring rats to discriminate a pattern of roughness on the floor of an operant chamber. Under one condition, the chamber contained a heterogeneous floorboard covered with a combination of squares of high or low roughness arranged in a checkerboard pattern. Under the other condition, it contained a homogeneous floorboard covered with low roughness squares. Each condition was associated with either the left or right lever mounted on the chamber wall, and the rat received a food pellet reward for a correct choice.

Many experiments have assessed tactile discriminations in rodents by relying on their exquisitely sensitive vibrissae, an advantageous sensing device for nocturnal species. Mehta *et al*. (2007) designed an apparatus consisting of a tube into which the rat inserted part of its head. Its task was to discriminate the position of a rod lowered into either the rostral or caudal vibrissae field, and to make the appropriate lever choice. Other experimenters have used mazes whose walls are coded by roughness, or have applied vibratory stimuli to the whiskers.

4 COGNITIVE FUNCTION

4.1 Simple Cognitive Tests

Perhaps the most vexing questions about neurotoxicity are directed towards functions such as learning and complex performance. Human behaviour is largely acquired behaviour and often emitted in response to circumstances that require discriminating judgements and decisions. The data that come from FOBs, motor activity and reflex measures offer little guidance about the possibility of impaired cognitive function. Learned behaviours are usually included in screening batteries for that reason. There are many varieties, but the one used most often today is the water maze, followed by other maze techniques.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat059
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Mazes were a staple of experimental psychology for many years, and some psychologists and other neuroscientists still rely upon them as behavioural assays. For toxicity testing, they represent a considerable investment that is often unacknowledged: the cost of technician time. When a full-time technician is assigned to test animals, usually one at a time, the cumulative cost far exceeds outlays for the kind of automated equipment devoted to schedule-controlled operant behaviour, discussed later. Repeated handling of the animals is a confounding factor often ignored as well, although handling acts in complex ways on arousal and stress mechanisms.

One of the most widely used techniques to assay cognitive function in rodents is known as the Morris water maze. It was devised to study spatial learning. The apparatus is simplicity itself: a tub of water into which the animal is placed. The animal can escape from this aversive situation by climbing onto a submerged platform. Because the water is rendered opaque by dissolving dried milk powder in it, the subject must learn to rely on the surrounding visual cues to learn the location of the platform. Most investigators now use automated visual tracking to record the patterns of movement in the tub during the acquisition process. It is especially attractive to investigators with limited research budgets because of its simplicity, so that human labour can be substituted for automated equipment, although technology is now available to record the subject's path as it searches for and learns the location of the platform.

Many neuroscientists find the apparent simplicity of the technique appealing, but only if they have failed to consider its defects. One glaring problem is its sensitivity to water temperature, especially in the form of temperature–chemical interactions (Rauch *et al*., 1989; Sandi *et al*., 1997). It is a particularly questionable technique for questions that may involve stress. Engelmann *et al*. (2006) conducted an extensive study in rats of the response of various stress indicators to water maze testing. Microdialysis measures taken with an indwelling catheter were seen to reflect a significantly increased release of arginine vasopressin within the periventricular nucleus and to elevate plasma adrenocorticotropic hormone (ACTH) and corticosterone. These findings duplicate those observed when rats are subjected to a forced swimming procedure, which is explicitly designed to stress the animals and to study the phenomenon of learned helplessness (Bowers *et al*., 2008).

The radial arm maze was designed to provide another measure of spatial learning and discrimination. It takes the form of a central zone from which multiple runways, typically eight in number, extend in a radial pattern like the spokes of a wheel (**Figure 9**). Usually, the end of each runway is baited with a food pellet, but experimenters may choose to bait less than the maximum number. The subjects learn to return to the central zone and then proceed to investigate other spokes. Eventually, they develop the strategy of following a reliable sequence of spokes so that they do not miss a baited arm. The number of trials required to learn to retrieve all the pellets without error is the most frequent measure of performance. Radial arm mazes are used in many areas of neuroscience; one notable application is in studies of ageing, where they have provided criteria for investigating the source of performance deficits associated with advanced age.

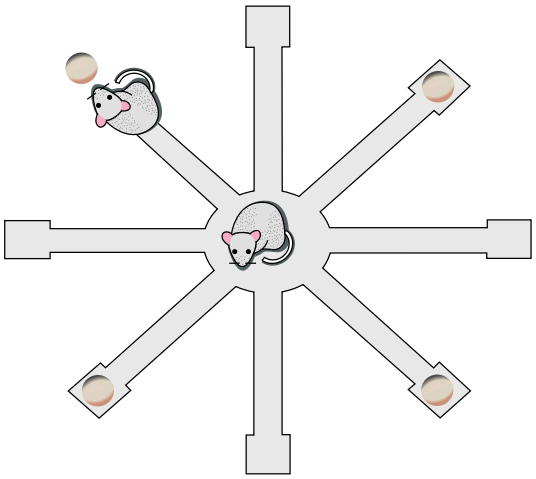

Figure 9 Schematic of a radial maze. A trial begins with the subject placed on the central platform. The arms are baited with food, and performance measures are based on the sequences of arm choices employed by the subject to secure the food.

Radial maze performance proved sensitive to developmental exposure to A1254 in a study by Roegge *et al*. (2000). They administered it to pregnant and lactating female rats from GD 6 to weaning at PND 21. Both male and female offspring were tested on a 12 arm radial maze when they reached adulthood, but only eight of the 12 arms were baited with food pellets to enhance task difficulty. The PCB-exposed males made significantly more working and reference memory errors than control males, but the exposed females performed as well as control females. Such sexually dimorphic effects are common.

5 ADVANCED BEHAVIOURAL ASSESSMENTS

5.1 Operant Techniques

The test procedures described above would generally be applied during the earlier phases of a programme to evaluate the neurotoxicity of a chemical. They serve more to identify its potential for neurotoxicity, rather than to yield information about the more advanced functions critical for human performance. In our accustomed environments, we make decisions based on analyses of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat059
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

intricate data, we make subtle distinctions among stimuli, we combine motor and cognitive functions in acts such as typing manuscripts and driving, and we alter our behaviour in accord with a long history of experience. The likelihood of a neurotoxicant contaminating our environment at a level high enough to produce an overt, simple defect is far less than the chance of such a chemical insinuating itself at low levels into that environment and inducing undetected and covert functional disorders. Identifying an agent as potentially neurotoxic is only the first, and largely minor, step in the risk-assessment process. Determining the full consequences of environmental levels to which the population might be or is exposed is a far more abstruse and demanding art. Simply buffering no-observed adverse effect levels (NOAELs) derived from simpler assays with large uncertainty factors is not always a feasible solution. Even now, with lead no longer contaminating gasoline, many individuals continue to be exposed from dust deposited in earlier years, and from residential dust from paint. The question now posed is how much to invest in cleaning up the remaining lead contamination, which invokes the question of how much it needs to be reduced to eliminate, in particular, its undesirable effects on brain development. Those questions continue to make lead's neurotoxicity an important research question whose central theme is derived from its effects on complex performances such as those assayed by psychological tests (Gilbert and Weiss, 2006). The clearest effects in animal models are those documented by schedule-controlled operant behaviour (Cory-Slechta, 2001).

Organisms interacting with their environment, the crux of behaviour, exemplify a dynamic system. Those incapable of adjusting to the demands of this continuous transaction fail to survive. Many techniques attempt to capture a slice in time of this capacity, like the water maze, or claim one specific functional aspect as their territory. Schedule-controlled operant behaviour targets the fluid rather than static relationship between an organism's behaviour and its environmental consequences.

Operant behaviour refers to learned or acquired behaviour that is controlled by its consequences. It describes most of the repertoire of human behaviour. Some of the other techniques, such as maze performance, also study learned behaviour and have long histories in behaviour science. These techniques primarily offer an index of the acquisition phase of learned responses, which can also be conceived of as a transition behaviour, but they provide snapshots of learning. In many experiments, this transition phase confounds the specific response to be learned, such as locating the hidden platform in the water maze, with the subject's adjustment to a novel environment. Schedule-controlled operant behaviour can provide a clearer and more detailed view of the acquisition process by building on what experimenters call steady-state performance

Figure 10 A standard chamber for the study of schedule-controlled operant behaviour. In this chamber, provision has been made for three response levers, three banks of lights and a pellet feeder; pellets are visible in the food magazine under the centre lever. Auditory signals can also be presented.

(Weiss, 1970). The latter term, in fact, describes quasi-stable performance because absolute stability is never attained; the inherent variability of our responses means that our transactions with the environment are continuously in flux. A simple example: the skill of automobile driving is tested constantly as the conditions of traffic and weather change. The fixation of many investigators on a single score, such as that derived from a maze, neglects this essential property of behaviour. Schedule-controlled operant behaviour captures its fluctuating essence.

The term, schedule-controlled, refers to the way in which experimenters define the relationship between a specified response by the organism and the effects of that response. A typical operant chamber is shown in **Figure 10**. A prototypical situation is one in which a rat, by depressing one of the levers mounted on the front panel, can trigger the release of a small food pellet. The food pellet is termed a reinforcer and the process is termed reinforcement. The rat's responses produce food delivery according to the contingencies, or schedule, programmed by the experimenter.

The USEPA regards behavioural assessments based on operant schedules as both definitive and sensitive measures of complex cognitive function. In listing the criteria by which solvent neurotoxicity was to be determined, it noted that, 'Solvents may have neurotoxic effects on memory, learning and performance which can be permanent. These effects are less well understood . . . The schedule-controlled operant behaviour test has . . . typically been required as a second tier test . . . it

is proposed as a first-tier test . . . because of EPA's desire to obtain data on the effects of solvents on learning, memory, and performance'.

Schedule contingencies come in many varieties. Some are based primarily on time. Interval schedules specify relationships between elapsed time and the availability of reinforcement. A fixed-interval schedule might specify that the first response five minutes since the last reinforcement will produce the next reinforcement (FI 5). Another way to construct a schedule based on elapsed time is to specify the interval between successive responses; a differential reinforcement of low rate schedule might require a minimum of 20 seconds between responses (DRL 20) for reinforcement. Response number, in the form of ratio schedules, is another widely used performance criterion. A fixed-ratio schedule might require 100 responses (FR 100) for reinforcement delivery.

The primary virtue of schedule-controlled operant behaviour is its flexibility. It can be used to study rate of responding during steady-state behaviour, or the acquisition of new behaviour against a background of stable behaviour, or the ability to distinguish related visual stimuli, or the speed of responding to a stimulus, or the accuracy and other characteristics of motor control.

One of the most useful features of operant behaviour is that animal subjects can train themselves. Experimenters typically begin with a rat, say, which is maintained at 85% of its free-feeding body weight. At this weight, rats will respond consistently for food pellets provided that they do not earn enough food during a session to become sated. One advantage of this regimen is that leaner rats remain healthier than rats allowed to feed freely, making it more feasible to conduct extended chronic studies. Once a rat has reached the targeted body weight, it can be trained in an experimental chamber where food pellets are occasionally released into a receptacle mounted on the wall. Rats quickly learn to associate food pellet delivery with the receptacle and the sounds accompanying pellet release by the food magazine. Because rats tend assiduously to explore their surroundings, a lever mounted on a wall near the pellet receptacle will almost inevitably be depressed. If a press is programmed to deliver a pellet, it is almost certain that it will soon be pressed again. Those animals who are not adventurous enough to explore the lever can be encouraged to do so by placing some food on it or (as we have done) smearing it with peanut butter. In a short time, the rat is pressing the lever repeatedly. We take advantage of overnight sessions, when the chambers usually lie unused, for this kind of training because it requires no experimenter intervention. After one or several sessions on this continuous reinforcement schedule (FR 1), the rat is ready to be introduced to more complex contingencies.

Different experimental approaches have been employed to address questions about how to use operant procedures as indices of behavioural toxicity. One approach focusses on the initial, transition-state performances that occur in response to changes in experimental conditions (Weiss, 1970). Transition-state performances are of particular interest because they demonstrate the capability of the subject to learn, or adapt or adjust to a changing environment. Those behavioural adjustments may indicate an adverse effect not seen under final steady-state conditions when compensatory factors have had an opportunity to emerge. A transition-state procedure can also be viewed as a dynamic 'challenge', which imposes burdens on the subject and thereby reveals deficits or vulnerabilities not detected under steady-state conditions. Other investigators have demonstrated the sensitivity of transition states in studies of prenatal or early development effects of ethanol (Gentry and Middaugh, 1988), methylmercury (Newland *et al*., 1994; 2004), mercury vapour (Newland *et al*., 1996) and lead (Newland *et al*., 1994). In addition to our interest in transition-state performance as an index of learning, and its demonstrated sensitivity to environmental changes, including chemical exposures, we find it appealing for the practical reason that, under many conditions, less time may be required to examine transition-state than steady-state performances.

In a study of the effects of prenatal TCDD (Hojo *et al*., 2002) on operant performance, food-reinforced, fixed-ratio lever pressing was used under a procedure in which the fixed-ratio criterion is maintained for only a few sessions before being shifted to a new value. The procedure is similar to one used by Gentry and Middaugh (1988) to study the effects of prenatal ethanol exposure and by Paletz *et al*. (2006) to study the effects of prenatal methylmercury exposure and diet. As shown in **Figure 11**, transitional performances showed marked sex differences; male offspring showed reduced responding while female offspring exhibited elevated response rates. In general, as the ratio requirement increased, the dose differences followed suit.

These results illustrate experimental approaches that are especially useful for neurotoxicology. They demonstrate that transitions from one schedule value to another can be a potent index of functional capacity. These data testify to the practicality of operant performance in developmental studies. The discipline of behavioural pharmacology, whose methods correspond closely with those of behavioural toxicology, most typically relies upon the stability of schedule performance to study several doses in the same organism to plot dose–effect functions. Behavioural teratology is unable to take advantage of repeated-measures designs and so finds it burdensome to train animals to asymptotic performance. Focussing on early transition phases requires no prolonged training. At the same time, if investigators so choose, the animals have already been equipped with a foundation of training enabling them to be tested with more complex and demanding schedules.

5.1.1 Complex Schedules

All schedules depend upon intact short-term memory for optimal performance, but the relation can be made more explicit. Rice and Karpinski (1988) measured the ability of lead-treated and control monkeys to remember the location of a previous response. The monkeys faced a panel with two levers. On such a delayed spatial alternation task, they are required to alternate responses between the two levers to secure reinforcement. Delays of varying durations between successive response opportunities can be programmed to measure short-term spatial memory function. Monkeys dosed with lead during infancy, after infancy, or continuously from birth, with doses that generated steady-state blood lead levels of 11 or 13 $\mu g\ dl^{-1}$, showed impaired performance compared to controls. Both initial learning, and subsequent performance at the longer delay values, faltered because of indiscriminate and preservative responding, a consistent finding in the lead literature.

A delayed spatial orientation arrangement for mice and rats is shown in **Figure 12**. Markowski *et al*. (2002) used such an arrangement to study the effects of TCDD on working memory. Offspring were exposed to a single maternal dose of 0.0, 0.06, 0.18 or 0.54 $\mu g\ kg^{-1}$ by mouth (po) of TCDD on gestation day 15. A random series of delay intervals (0.01, 3, 6, 9, 12 or 24 s) was tested during each session, with the expected outcome that more incorrect choices were made at the longer delays. For both male and female offspring, the dose of 0.18 $\mu g\ kg^{-1}$ produced the worst performance.

5.1.2 Assessment of Complex Motor Function

The elementary procedures used to screen for neurotoxic potential rely heavily on motor deficits as indices of

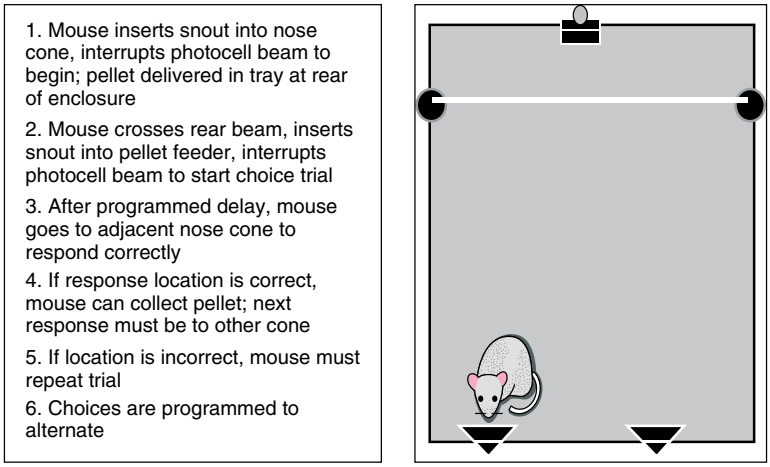

Figure 12 Schematic showing protocol for testing effects of delays on spatial alternation performance.

dysfunction. Coarse, blatant disturbances of motor function are only the first phase of an adequate assessment. On many occasions, the central question is not the potential for neurotoxicity, which typically has been identified much earlier, but whether prevailing environmental exposure levels may be responsible for covert impairment. Furthermore, such questions frequently apply to fine motor control as a component of more complex tasks, such as driving. Responding to such questions in the animal laboratory requires extensive training of subjects and the proper selection of criteria. For human testing, although extensive training may not be necessary, precision instrumentation is still as vital.

The basic physical properties that define movement comprise time or duration, displacement (either linear or angular) and mass. From these basic units, the following combinations, among others, can be derived (Newland, 1988): linear velocity, angular velocity, acceleration and force. The simple measures of motor function included in screening batteries are not conveyed in terms of such properties, but, instead, report data such as number of photocell interruptions (locomotor activity) or the length of time a rat can remain on a rotating rod. Most operant performance measures are given as response rates derived from switch closures. A rich variety of information about motor function, however, can be secured from situations ordinarily yielding relatively gross data. All that is required is a small investment in proper instrumentation.

Nonhuman primates are especially suited for questions about complex motor function. Newland and Weiss (1991) trained squirrel monkeys (*S. sciurea*) to grasp a rod attached to a sensitive angular position transducer and to maintain it in a prescribed angular band for eight seconds. During that time, the position of the rod was sampled at a high rate and stored to allow for spectral analysis. Ethanol at doses ranging from 0.25 to 1.0 g kg^{-1} po reduced tremor power significantly, most markedly at the dominant frequency band of about 7–10 Hz. These data support the claims by elderly individuals with essential tremor that modest consumption of alcohol reduces their tremor.

Many environmental neurotoxicants induce such effects. Among them are virtually all classes of insecticides, several heavy metals and volatile organic solvents. Newland (1988) noted that abnormal tremor could serve as an apical test for motor system dysfunction because it can be induced by impairment in many parts of the central nervous system devoted to movement. An investigator pursuing such measures should be aware of the precautions required to secure and process such data. Physiological tremor is composed of many contributing frequencies of varying amplitudes, so that the analysis of its electrical analogue is aimed at dissecting the signal into its components. The distribution of variance over frequency, the power spectrum, defines the composition of the tremor. Such process is radically different from observing tremor clinically; neurologists are capable of detecting grossly deviant tremor, but such observations are incapable of providing the information needed to set exposure standards or to detect incipient dysfunction.

One of the earliest signs of manganese intoxication is abnormal fatigue. Miners who have suffered excessive exposure to the ore complain of extreme tiredness. Because primates are the only nonhuman species in which the signs of manganese neurotoxicity correspond to those seen in humans, Newland and Weiss (1992) constructed a device requiring monkey subjects to respond, for fruit juice reinforcement, with a response similar to rowing. The monkeys pushed with their feet and pulled with their arms against a spring whose resistance approximated their body weight. On the FR component of a multiple fixed-ratio fixed-interval schedule, manganese chloride administered intravenously (iv) on several occasions over a period of several months reduced response rates, shifted the distribution of inter-response times to longer intervals, and increased the number of incomplete responses.

Effort is a variable too often neglected, rather than exploited, in behavioural testing. Zarcone *et al*. (2007) trained mice to press on a disk behind a wall of an operant chamber, as shown in **Figure 13**. If the force exerted exceeded a prescribed criterion, such as 8 g, for a prescribed duration, the mouse earned 0.05 ml of sweetened condensed milk delivered via an electromechanical dipper. The mice displayed remarkable precision in performance, exerting just enough force to exceed the criterion.

The experiments described above comprise no more than a minute sample of possibilities. The technology afforded by the experimental analysis of behaviour permits behaviour to be moulded to answer whatever questions experimenters devise. Complex motor responses, amenable to detailed, precise analyses such

as those exemplified by the mathematical tools applied to tremor, can be elicited even in the rat. The correlation may not be perfect, but it generally holds that the order of complexity in response topography and its analysis is correlated with its usefulness for extrapolation to humans.

6 HUMAN TESTING

6.1 Adults

Most of what is known about neurotoxic chemicals was driven by observations in humans. Almost all of the literature in neurotoxicology, in fact, remains based on substances identified through their adverse effects on humans. Few, if any of the screening procedures described earlier in the chapter have successfully prevented the marketing of agents or classes of agents that had been planned for introduction into environments presenting the possibility for human exposure. The marked success stories of neurotoxicology, exemplified by lead, are successes because they revealed neurobehavioural effects at exposure levels previously believed to be safe, and because they unearthed unanticipated facets of neurotoxicity. Lead's neurotoxicity, recognized for over two millennia, had not been questioned, only its potency. Similarly, organophosphorus insecticides are universally recognized as powerful nerve poisons; neurobehavioural testing, however, disclosed their ability to impair function in the absence of overt clinical toxicity or long after the disappearance of overt signs. Much of neurotoxicological research is still aimed at the identification of potential neurotoxicants, but the primary issues confronting risk assessment derive from another question: how much is safe? Human behavioural testing is still the ultimate arbiter.

Many of the earliest attempts to assess neurotoxicity in humans adopted procedures that had been developed for clinical neuropsychological testing. Such procedures often proved poorly designed for research in neurotoxicology because they evolved as diagnostic instruments, not as tools with which to screen populations or for experimental investigations. They typically were used to provide a functional profile of a patient, often one who had suffered brain damage. They had not been contrived to determine, for example, whether workers exposed to pesticides differed from controls on various psychological dimensions, or to yield a dose–response function for acute exposures relating concentration to performance. Nevertheless, lacking more appropriate tools, they were invoked to respond to some pressing questions about exposed populations. The pioneering reports from the Finnish Institute of Occupational Health (Hanninen, 1988) relied heavily on clinical instruments. Neurotoxicology also borrowed techniques from the experimental psychology laboratory. Such techniques lacked the standardization and norms provided by most clinical tests, but offered the virtue of greater specificity, flexibility and a scientific basis.

Moreover, the time taken for evaluation may be limited, especially in the workplace, so that a compact but comprehensive test battery is more suitable than the typical, largely paper and pencil tests administered by clinical neuropsychologists. Responses on paper and pencil tasks also have to be scored and transcribed, leading to transcription errors and rescoring.

Faced with the need to assess specified populations exposed to defined hazards, or to evaluate particular stressors experimentally, neurotoxicology turned to the development and adoption of computerized testing. It made the mechanics of testing more efficient; it offered considerably more uniformity in how test stimuli were presented; it made it possible to test several subjects simultaneously; it could use testers who did not require advanced clinical training; it could automate scoring and analysis; it allowed remote testing (as in an exposure chamber) and it proved adaptable for translation of procedures used in the animal laboratory. Perhaps most important of all, it moved human testing from clinical diagnosis to the realm of performance.

Performance tests differ from conventional clinical tests in several respects (Wetherell, 1996). Tests devised for clinical applications aim to differentiate between individuals. Performance tests are designed to differentiate among stressors such as drugs, toxic chemicals and conditions such as sleep deprivation. Clinical tests should be relatively insensitive to environmental perturbations because they should serve to identify stable traits in the individual, but performance tests are expressly designed to reflect such perturbations. Finally, clinical tests generally are meant to be given only once; in contrast, performance tests should be capable of repeated administration. Practice effects can be minimized with alternate forms.

Slikker *et al*. (2000) offer a comprehensive discussion of the properties and usefulness of computerized test batteries and how they reflect and extend traditional approaches. Several current batteries have been used widely enough, and are well-enough established, to be considered as appropriate instruments for neurotoxicology. The Cambridge Neuropsychological Test Automated Battery (CANTAB) (Fray and Robbins, 1996) consists of a suite of computerized tests, now numbering 22, that embrace a variety of cognitive functions: visual memory, executive function, working memory, semantic and verbal memory, attention, decision-making and response control (designed to assess behaviours such as impulsivity). Most of the tests are explicitly designed to be independent of language and culture. Alternate forms are available for repeated testing. The CANTAB has been used extensively in patients with Alzheimer's and Parkinson's diseases (Blackwell *et al*., 2004). The

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

BARS (Behavioural Assessment and Research System) battery is specifically designed for the detection of neurotoxicity in populations with limited education or literacy (Rohlman *et al*., 2003). It too can be used for repeated assessments.

One of the newer features of computer-based testing is the incorporation of instructional materials. Particularly because of the variety of populations that undergo assessment for neurobehavioural function, including those unfamiliar with testing procedures and that are often illiterate, more effective means for communicating test instructions have been sought by investigators. The computer itself is a tool that can be adapted for such a purpose. Anger *et al*. (1996), in response to such a need, use computer graphics for the BARS battery to teach subjects how to perform the tests before the test items themselves are presented. The technique relies on a sequence of approximations to the final performance, much like the technique, called shaping, used to train animals on schedule-controlled operant behaviour.

6.2 Children

New initiatives, such as the formation of an office devoted to child health at the USEPA, and heightened public and legislative awareness of the special vulnerabilities of children to toxic agents, have promoted the design of test batteries specifically targeted to developmental neurotoxicity. These differ from the more established, traditional tests that have helped propel behavioural teratology into its current prominence. Intelligence tests such as the Stanford–Binet and the Wechsler Intelligence Scale for Children (WISC) occupied critical roles in demonstrating the threats posed to brain development by lead and PCBs. The Bayley Scales of Infant Development, suitable for earlier ages, also enjoyed wide use in such contexts. The virtue of such instruments lies in the detailed amount of information available about their reliability, about the population used for standardization and in the extensive literature describing their application to an enormous diversity of problems.

These and other traditional tests, by themselves, cannot serve all the purposes of investigations undertaken to discriminate between populations that differ in exposure sources and levels. Test scores are meant primarily to yield information about the child and its unique traits rather than about the population to which the child belongs. They also provide information mostly about cognitive function rather than a more complete assessment of all functions.

In an attempt to construct a more comprehensive battery, Davidson *et al*. (2006) recruited graduates of the University of Rochester Neonatal Intensive Care Unit (NICU) and compared their performance to controls on a broad array of measures. The NICU population is known to be at risk for both major and mild anomalies in perception, motor functioning, learning, memory and cognition. They were chosen for study as a surrogate population for those at risk due to exposure to elevated levels of neurotoxic chemicals. The study aimed to evaluate the capacity of these tests and tasks to predict such potential deficits.

The test battery included the following measures:

- Audiometry and tympanometry
- Auditory processing
  - Pitch pattern sequence test (auditory information processing)
  - Auditory continuous performance test (cognitive)
  - Dichotic digits test-double pairs (auditory information processing)
- Electrophysiological tests
  - Cognitive event related potentials (cognitive)
  - Auditory evoked potentials (auditory information processing)
  - Otoacoustic emissions (auditory information processing)
- Experimental tasks (neuropsychological)
  - CANTAB (cognitive, auditory and visual information processing)
  - Multiple fixed-interval schedule self-control (cognitive)
- Experimental tasks (sensory and motor)
  - Fine motor control
  - Scotopic visual form discrimination (somatosensory)
  - Visual spatial contrast sensitivity (somatosensory)
  - Monitoring and vigilance (complex perceptual motor).

In total, the battery yielded 63 measures. A battery this comprehensive would not necessarily be suitable for every investigation. It was devised to include most of the end points from which investigators would choose in studies of specific exposures, thereby providing guidance for such choices. A special aim of the work was to provide data on sensitivity and specificity.

Over one-third of the 63 measures proved capable of detecting prediagnosed lower IQ, the presence of a learning disability (LD) or a neonatal risk profile with at least 70% sensitivity and specificity. Sensitivity and specificity were obtained from curves estimating receiver operating characteristics (ROC). A variety of covariates were included in the statistical analysis, such as gender, age, hearing status or familiarity with computers. Tests were also eliminated from the battery if they were affected by too many covariates. Further studies are planned to confirm the capability of the battery to detect subtle changes associated with neurotoxic exposures.

The CANTAB has also been used successfully in children with various behavioural disorders (Rhodes *et al*., 2006; Goldberg *et al*., 2005). It was also used

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat059

successfully in defining specific behavioural and cognitive deficits produced by lead exposure in four- to five-year-old children in Rochester (Canfield *et al*., 2004) and to study the effects of lead on executive function in children with a particular dopamine receptor polymorphism (Froehlich *et al*., 2007).

Testing of infants, both human and animal, for cognitive function presents unique problems simply because of their limited physical repertoire. A useful guide to the kinds of tests that offer cross-species comparisons was provided by Sharbaugh *et al*. (2003). It is a useful demonstration of the possibilities offered by approaches that rely on fundamental behavioural principles for experimental design.

7 RISK ASSESSMENT ISSUES

Toxicology is an applied science. It is supported as a research enterprise because it yields information about threats to human health. Its contributions to basic science, which are substantial, are gratifying bonuses. Behavioural testing is only one of the biological measures, however, relied on to establish health risks. From that vantage point, it can be appreciated that research should seek the most direct extrapolation to humans. The methods described in this chapter can be divided roughly into two categories. One set of methods is most suitable for determining if an agent is a potential neurobehavioural toxicant. Screening tools, such as FOBs, enjoy widespread adoption because they serve this role in helping to determine if a new chemical might pose unjustified health hazards. They are primarily instruments for hazard identification.

The other set of methods is used in a different way. If screening is classified as a first-tier effort, methods such as schedule-controlled operant behaviour are classified as second-tier approaches. That is, they amplify and extend the first-tier information and may provide more specific indices of toxicity. Such a classification system copes only obliquely with the situation that still prevails: first, almost all the neurotoxicants we know about have been identified as a result of human exposures rather than from simple preliminary screens; second, rigorous probing with behavioural measures almost invariably discloses impaired function at exposure levels lower than previously believed to present health risks. The main lesson from such a history might be that preliminary screening is most efficiently carried out by employing complex, advanced behavioural assays at the beginning of an assessment programme rather than assigning them to a secondary role. Whatever the strategy chosen, however, as this chapter demonstrates, the supply of behavioural test procedures is virtually limitless and can be moulded to virtually any need.

Behavioural toxicology in the year 2009 can boast of impressive progress during the past four decades. Clever and productive investigators transformed it from a science originally at the margins of traditional toxicology to a science that now exercises leadership in policy disciplines such as risk assessment. An inevitable by-product of success, however, is the enlargement of expectations. Some of it we compulsive malcontents have imposed on ourselves. Some of it is due to an expansion of opportunities. And some is due to newer kinds of questions asked of us. The past is an imperfect, but illuminating guide to the next stages of this evolution.

Peripheral Chemosensory Irritation: Fundamentals, Investigation and Applied Considerations

Bryan Ballantyne

CONTENTS

1 INTRODUCTION AND BACKGROUND

The major causes of adverse effects from occupational and general environmental exposure to xenobiotic chemicals, and the investigation of such effects, relate to toxicological processes. However, certain induced, but reversible, pharmacological and physiological effects may result in discomfort, distraction or inattention in an affected person(s). Included in such transient effects are, as examples, nauseating odours and the induction of narcosis, either of which may lead to uncomfortable working conditions, a feeling of ill health and be distracting, and hence a factors contributing to physical accidents. For these reasons both effects have been used as a basis to quantitatively assign exposure limits for certain chemicals in the occupational environment (Amoore and Hautala, 1983; ACGIH, 2007). A further common source of discomfort and distraction in the workplace and general environment is that of peripheral chemosensory irritation (PCSI), in which there is an interaction between a substance having PCSI properties and sensory receptors in exposed body surfaces (skin and mucosae), resulting in local discomfort or pain at the site of contact, together with certain related local and systemic reflexes. This chapter reviews the nature, causation and clinical manifestations of the PCSI effect, factors influencing the response, approaches to animal and human investigations, quantitation, physiological significance and practical implications and applications.

2 THE NATURE AND GENERAL FEATURES OF PERIPHERAL CHEMOSENSORY IRRITATION

The words irritant and irritancy are often used somewhat loosely in many toxicological texts, and may not be specified or defined with respect to whether the words are being applied to pathological or pharmacological processes. With acute pathological processes irritancy should be used to imply a local vascular and cellular inflammatory reaction (primary irritation), and in pharmacological processes it should indicate a generally reversible functional interaction between the causative molecule and peripheral nerve sensory receptors (Ballantyne, 1983).

PCSI is a pharmacological process in which causative molecules interact with sensory nerve receptors in skin or mucosae and produce a local sensation (discomfort, itching, burning or pain) together with induced related local and some systemic (autonomic) reflexes. PCSI effects subside after removal of the stimulus and do not result in any long-term adverse sequelae. Thus, the major characteristics associated with a PCSI event are that the causative material acts locally (in exposed surfaces) by stimulation of peripheral nerve sensory receptors, which results in transient local sensations with locally mediated and some systemic (autonomic) reflexes, and not per se in any longer-term sequelae (Ballantyne, 2006). Although the pharmacological and pathological processes of irritancy should be clearly mechanistically and functionally differentiated, it should be noted that many substances capable of causing a pharmacological PCSI effect may, but usually at higher applied concentrations, also result in an inflammatory response. In this respect a PCSI effect may give a biological warning of exposure to a potentially harmful substance. Early in the history of investigations into the mechanistic causation of PCSI effects, it was considered that they were attributable to a 'common chemical sense' that was independent of touch, temperature and pain (Parker, 1912). However, it was subsequently shown that PCSI effects are mediated by several types of receptors, most of which also respond to noxious, thermal and/or mechanical stimuli (Green, 2000). This concept that PCSI effects are principally mediated by chemically sensitive neural elements of pain and temperature, that is, a process of PCSI, replaced the idea of a common chemical sense. The word 'chemesthesis' was introduced to stress that chemosensory irritation is a multimodal sense (Green *et al*., 1990). Sites generating a PCSI effect are discussed in Section 3.

A characteristic feature of the PCSI response from many PCSI molecules is the development of a progressive decrease in the sensory irritant response with sequential applications of the causative material, a phenomenon referred to as tachyphylaxis (or tolerance). Also, crosstachyphylaxis between chemically different PCSI materials may occur with some, but not all, materials. When crosstachyphylaxis occurs it is possible that this may be the result of a similar mode of action of the responsible materials and stimulation of the same peripheral sensory nerve receptor (Foster and Ramage, 1981). For example, Chang and Barrow (1986) used a depression of respiratory rate (DRR) model (see Section 8.2.5) in the rat to investigate crosstolerance between formaldehyde and chlorine. They demonstrated formaldehyde pretreatment induced a significant crosstolerance to the PCSI effects of chlorine, as shown by a shift-to-the-right of the concentration–response curves. Also, Babiuk *et al*. (1985) demonstrated that pre-exposure of rats to formaldehyde vapour caused crosstolerance with acetaldehyde, as evidenced by the concentration causing a DRR by 50% (RD_{50}) being increased three to five times, and similarly with acrolein with which the RD_{50} increased five times by formaldehyde pre-exposure. However, PCSI crosstolerance was not seen with propionaldehyde, buytyraldehyde, crotonaldehyde, cyclohexanecarboxal-

dehyde, cyclohex-3-ene-1-carboxaldehyde and benzaldehyde, confirming that crosstolerance is not a generalized phenomenon. Tolerance and crosstolerance are clearly of practical relevance because repeated exposure to a specific PCSI material, or pre-exposure to another PCSI, may result in a reduced sensory warning on subsequent exposures, and hence a correspondingly lesser degree of protection. Although the mechanism of production of tolerance is not totally understood, it has been proposed that in some cases a chemically induced histopathological change in the nasal epithelium may result in tolerance and crosstolerance. Tolerance has been reviewed in detail by Bos *et al*. (1992).

3 SITES GENERATING A PERIPHERAL CHEMOSENSORY IRRITANT RESPONSE

From a practical viewpoint, the principal surface sites at which a PCSI effect can be experienced are the mucosal surfaces of the eye and respiratory tract, and the skin. At all these sites local sensations and related local reflexes are produced. Additionally, systemic reflexes develop, which include transient increased systolic blood pressure (SBP) and diastolic blood pressure (DBP) and bradycardia; these are common to all sites of contact, but often of variable severity, depending on the potency of the local effects.

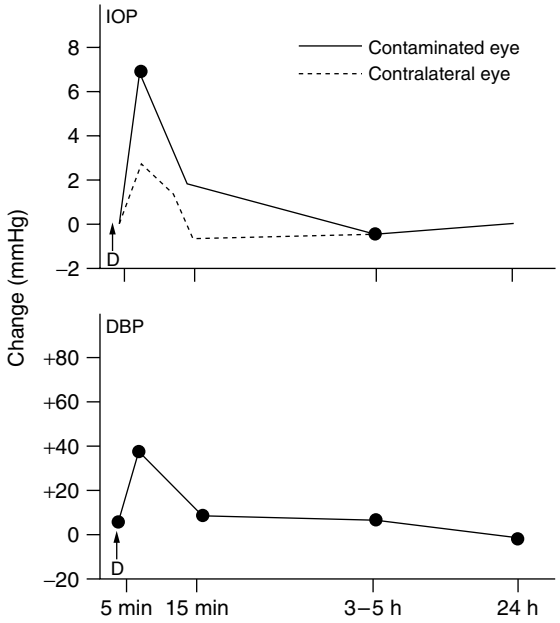

Figure 1 Effects of potent peripheral chemosensory irritation of the human eye on intraocular pressure (IOP) and diastolic blood pressure (DBP). At D, one eye of the volunteer had 0.05% dibenz[b.f]-1,4-oxazepene (CR) dissolved in polyethylene glycol 300 applied to the cornea of one eye. There was a transient increase of IOP in the contaminated eye and, to a lesser extent, in the contralateral eye (A). Also, (B) there was a transient increase in DBP. (Reproduced with permission from Ballantyne *et al*., 1977. © Elsevier.)

3.1 Eye

Following local contamination of the eye with a PCSI material there develops (depending on the concentration of PCSI applied) local itching, discomfort or pain, accompanied by excess lacrimation and blepharospasm as local reflexes. These effects produce transient variable degrees of visual impairment, and result in a warning of exposure to an irritant substance. Also, systemic autonomic reflexes may occur, including increased SBP and DBP with bradycardia. Also, there may be a transient increase in intraocular pressure (IOP). Following cessation of PCSI stimulation, the sensory, local and autonomic reflexes diminish; for example, effects on IOP and DBP are shown in **Figure 1**.

The transient increase in IOP (**Figure 1**) is most likely to occur following splash contamination of the eye with a PCSI material in solution (Ballantyne *et al*., 1976; 1977a; Ballantyne, 1983), but has also been demonstrated following exposure of the eye to a PCSI in the vapour phase (Ballantyne *et al*., 1976; 1977a). There appears to be an association between the magnitude and the duration of the increase in IOP and the inflammatory potential of the causative PCSI material, as evidenced by conjunctival hyperaemia. Changes in local blood flow, mostly congestion in the episcleral venous plexus, may be causal factors. However, following contamination of an eye with a PCSI material, there is an increase in IOP both in the contaminated eye and, to a lesser degree, in the contralateral eye (**Figure 1**). This indicates the possible existence of a systemic, as well as a local, cause of the increase in IOP (Ballantyne *et al*., 1977a). Thus, in addition to local changes in blood flow, the following may be factors in the production of PCSI-induced transient ocular hypertension; (i) squeezing of the eyeballs during blepharospasm; (ii) reflex contraction of the extraocular muscles and (iii) increase in central venous pressure resulting from the pain and stress of potent sensory irritation (PSI) (Collins *et al*., 1967; Miller, 1967; Rengstorff, 1975; Ballantyne, 1977a). The transient increase in IOP that occurs with a noninjurious concentration of PCSI substance is unlikely to be detrimental to ocular function, except possibly for susceptible individuals in whom there may be precipitation or exacerbation of glaucoma (Ballantyne *et al*., 1973a; 1973b; Rengstorff, 1975).

3.2 Respiratory Tract

Effects are experienced in human subjects inhaling PCSI materials as discomfort or pain in the nasal mucosa, oronasal pharynx, larynx, trachea and bronchi, with associated local reflexes of coughing, sneezing, rhinorrhoea, increased respiratory tract secretions, changes in breathing rate and decreased tidal volume (TV). The clinical presentation varies somewhat based on the chemistry of the PCSI material, its solubility and the principal sites of receptor activation (**Table 1**). A characteristic of respiratory tract chemosensory responses to PCSI substances is that they stimulate afferent cholinergic nerves in the nasal mucosa leading to reductions in breathing rate and TV (Cauna *et al*., 1969; James and Daly, 1969; Ulrich *et al*., 1972). Various sensory receptors are present in the lower respiratory tract (Crofton and Douglas, 1981; Widdicombe, 1981). With respect to sensitivity to inhaled chemosensory irritant materials, the most important of these appear to be J receptors and airway irritant receptors (Kristiansen *et al*., 1986; 1988; Nielsen and Vinggaard, 1988). Stimulation of J receptors results in apnoea, rapid shallow breathing and systemic hypertension with bradycardia. Stimulation of airways irritant receptors causes hyperpnoea and bronchoconstriction (Douglas, 1981). The overall effect of stimulation of lower respiratory tract receptors is, in most species, an increase in breathing rate and TV (**Table 1**). However, with most PCSI substances effects are produced at lower concentrations by trigeminal nerve stimulation than occurs with lower respiratory tract receptor stimulation. Therefore, with a biologically effective PCSI challenge by respiratory route exposure, the trigeminal reflex will usually predominate. These respiratory regional differences in chemoreceptor sensitivity form the basis for the tRD_{50}, concerned with assessing the margin of warning provided by the PCSI response for respiratory tract injury (see Section 8.2.5).

3.3 Skin

An itching or burning sensation follows contamination of the skin with a PCSI material, and is often accompanied by a local erythema.

Table 1 Effects produced by peripheral chemosensory irritant materials on respiratory tract chemoirritant receptors

Location	Effect
Nasal mucosa	Decreased breathing rate Decreased tidal volume
Lung	Increased breathing rate[a] Decreased tidal volume Bronchospasm

[a]A few species have decreased breathing rate (e.g. mouse).

3.4 Other Sites

Contamination of the oral cavity with a PCSI material can result in a stinging or burning sensation on the tongue or palate, accompanied by increased salivation.

4 MOLECULE–SENSORY-RECEPTOR INTERACTIONS AS THE MECHANISTIC BASIS FOR PERIPHERAL CHEMOSENSORY IRRITATION

Several investigators believe that molecules capable of producing a PCSI response interact nonspecifically with sensory nerve receptors and, as noted in Section 2, the expression 'common chemical sense' was originally used to differentiate PCSI function from other chemically induced sensations, such as taste and smell (Keele, 1962). Molecules producing PCSI effects have widely varying chemical structures and, in general, there are no morphologically identifiable specific receptors for the PCSI response. In skin, however, PCSI molecules demonstrate some selectivity in that they excite polymodal nociceptive receptors and warm thermoreceptors (Foster and Ramage, 1981), but the sensitivity of these receptors is divorced from their mechano- and thermoreceptive functions (Green and Tregear, 1964). The most distinct and marked PCSI effects result from stimulation of corneal and nasal mucosal sensory receptors, and in these tissues it is considered that a direct interaction occurs between PCSI molecules and trigeminal nerve chemoreceptors that are on C-fibres and possibly Aδ-fibres (Nielsen, 1991; Nielsen *et al*., 1996). The potent PCSI material capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) is capable of binding with receptors on both C- and Aδ-fibres and desensitizing them to other PCSI molecules; this desensitization may be sustained (Bevan and Szolesanyi, 1990; Holzer, 1991; Thurauf *et al*., 1991). Hence, pretreatment with capsaicin can be used as a method to recognize PCSI effects generated from capsaicin-sensitive nerves and it is used as a pharmacological tool to investigate sensory irritant effects (Ballantyne, 2006). For example, Hansen and Nielsen (1994a) studied the sensory irritant effects of *n*-propanol and ethylbenzene in mice after pretreatment with capsaicin and found that intranasal preapplication with capsaicin decreased the sensory irritant response to these materials. They also showed that pretreatment with indomethacin had no effect on the PCSI response, indicating that there was a direct receptor interaction rather than an indirect effect from tissue damage. Other aspects of desensitization have led to suggestions concerning differential receptor binding. Thus, Hansen *et al*. (1992), using a reflexly induced decrease in breathing rate in mice as an index of PCSI, found that methyl ethyl

ketone at low vapour concentrations caused a desensitization of the response, but little desensitization was seen at higher concentrations. In contrast, *n*-propanol desensitized the receptor at all concentrations. However, pre-exposure of mice to *n*-propanol did not influence the response to methyl ethyl ketone. The authors concluded that the results indicated that the two ketones bind to different receptor sites, which have different properties.

Molecules with a variety of differing chemical structures are capable of causing PCSI effects (Nielsen, 1991); for example, molecules having a C=C and carbonyl grouping, in particular in the presence of a halogen, have sensory irritant properties (Dixon and Needham, 1946). With a material having known PCSI effects, the introduction of certain groupings into the molecule may alter its sensory irritant potential, the magnitude of which depends on the specific grouping introduced. For example, based on RD_{50} measurements, compared with the sensory irritant styrene, the chloro-derivative, 3-chlorostyrene, is 2.6 times more potent and β-nitrostyrene is 364 times more potent (Alarie, 1973). Some homologous series of chemicals may show a clear relationship between molecular weight (MW) and PCSI potential. Thus, for a series of C_3–C_7 *n*-alkylamines Nielsen and Vinggaard (1988) noted that PCSI potential increased, as reflected by decreasing values for the nasal exposure, as the chain length increased. Also, **Table 2** indicates that for a series of *N*-(3′-hydroxy-4-methoxyphenyl)-2-chloroamides (**Figure 2**), the PCSI potential, as determined by a guinea pig blepharospasm (GPB) test increased (became more potent) as the C chain length increased (**Table 2**, **Figure 3**). Less clear relationships have been have been shown for other series; for example, differences exist within a monoalkylamine series by RD_{50} measurements (**Table 3**). The primary saturated aliphatic monoamines in this series show a decrease in RD_{50} value (i.e. increased potency) by nasal exposure (nRD_{50}) as the MW increases (**Figure 4**). Thus, for this series, whose nRD_{50} values ranged from 17 to 157 ppm, analysis by linear regression showed a significant ($p = 0.01$) correlation between nRD_{50} and MW (**Figure 4A** $r = -0.79$). If *t*-octylamine is omitted from the analysis, because this compound does not fall into the generally decreasing nRD_{50} series (**Table 3**), then the association between MW is stronger (**Figure 4B**; $r = -0.9874$, $p = 0.0006$). In contrast, the secondary saturated aliphatic monoamines do not show a statistical relationship between nRD_{50} and MW ($r = 0.4262$, $p = 0.47$). The unsaturated aliphatic amines, allylamine and diallylamine, were the most potent PCSI materials in the series, with respective nRD_{50} values of 9 and 4 ppm. This agrees with measured nRD_{50} values for other allyl compounds, including allyl acetate (2.9 ppm), allyl glycidyl ether (5.7 ppm), allyl alcohol (3.9 ppm) and allyl ether (5 ppm) (Gagnaire *et al*., 1987; Nielsen *et al*., 1984). However, with many homologous series, MW has little influence on PCSI potential, as shown in **Table 4** for GPB studies with a series of *N*-phenyl-2-chloroamides. Over the range of MWs tested, the PCSI effects were similar.

Experimental studies have suggested that PCSI molecules interact with membrane-associated binding sites, and that binding affinity is a major factor in determining the potency of the PSI response (Green *et al*., 1979). In certain cases these effects may be associated with –SH or $–NH_2$ groups of membrane proteins or enzymes, and/or the amide nitrogen of a peptide bond (Alarie, 1973; Dixon and Needham, 1946; Douglas, 1981; Schauenstein *et al*., 1977; Silver *et al*., 1967). However, different mechanisms probably operate for different chemical groupings. For example, the PCSI potential of saturated aliphatic aldehydes decreases with their hydration constant, which may determine their degree of crosslinking with receptor proteins. In contrast, unsaturated aliphatic aldehydes such as acrolein and crotonaldehyde do not hydrate to any degree, but they undergo addition reactions with –SH, $–NH_2$ and other groups (Schauenstein *et al*., 1977; Steinhagen and Barrow, 1984). For higher MW, less reactive aldehydes, the sensory irritant effects may be due to a physiological mechanism involving thermodynamic and solubility properties of the molecule in a lipid bilayer containing receptor proteins (Luo *et al*., 1983; Nielsen and Alarie, 1982). It was shown by Gagnaire *et al*. (1993) that

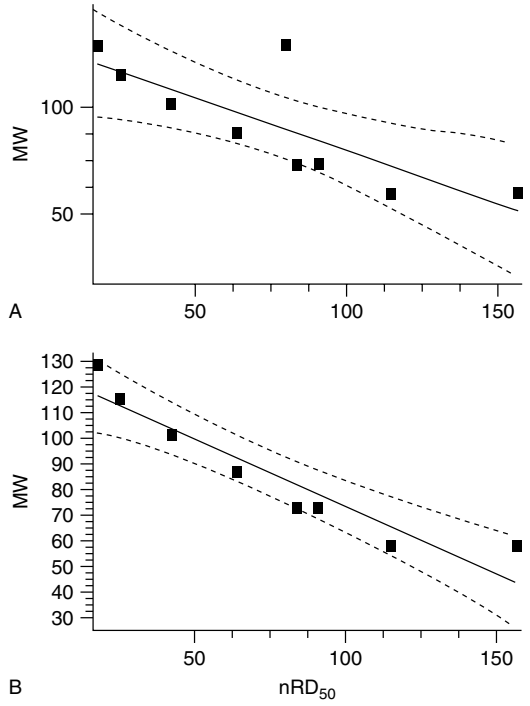

Figure 4 Linear regression analysis for assessment of the correlation between nRD_{50} in mice and molecular weight (MW) for the primary aliphatic monoamines listed in **Table 2**. (A) Analysis for all nine primary amines shown in **Table 2**; $r = -0.79$, $p = 0.01$. (B) Analysis for primary amines excluding *t*-octylamine; $r = -0.9874$, $p = 0.0006$.

RD_{50} values for aliphatic amines were related to their octanol–water partition coefficients (P_{ow}), with a linear relationship between lipophilicity and sensory irritation. For the series of monoamines shown in **Table 3**, the primary saturated aliphatic compounds show a strong association between PCSI potential (as RD_{50}) and log P_{ow} (**Figure 5A**; $r = -0.9524$, $p = 0.0003$), indicating a linear relationship between lipophilicity and PCSI potency. However, this does not extend to the secondary saturated aliphatic monoamines (**Figure 5B**; $r = 0.3945$, $p = 0.51$). Cometto-Muñiz and Cain (1995) studied a homologous series of aliphatic alcohols, ketones and alkylbenzenes, and found that thresholds for eye irritant decreased with increasing C chain length, implicating lipophilicity in the irritancy potential. Dudek *et al.* (1992) compared the Swiss–Webster mouse RD_{50} value for toluene (4900 ppm) with those for various halogenated derivatives of toluene, which were found to be significantly more irritant (range 4.3–27 ppm). They believed that their findings were compatible with the interaction of these PCSI molecules with a receptor protein in a lipid bilayer. The trends in RD_{50} values were related to the development of a partial positive charge on the toluene α-carbon–halogen bond by the positioning of a ring chlorine, and the bond dissociation energies of the α-carbon–halogen bond for the halogenated isomers of benzyl halide. Quantitative structure–activity relationship (QSAR) considerations have suggested the importance of hydrogen bonding in relation to the activation of PCSI receptors by nonreactive volatile organic molecules (Abraham *et al.*, 1990; Nielsen, 1991). The effect of hydrogen bonding on upper respiratory tract irritation, assessed in detail by QSAR, demonstrated that the process involved nonreactive irritants as hydrogen bond acids; that is, the receptor site is a hydrogen bond base. However, the range of nonreactive irritants was not large, with most hydrogen bond acid compounds being simple alcohols. To further investigate this area, Nielsen *et al.* (1996) studied the following three compounds with differing hydrogen bond acidities; methyl hexafluoroisopropyl ether, trifluoroethanol and hexafloropropan-2-ol. The respective RD_{50} values determined in CF-1 mice were $\geq$160 000, 110 400–23 300 and 165 ppm. QSAR showed that methyl hexafluoroisopropyl ether and trifluoroethanol behaved as predicted nonreactive sensory irritants, whereas hexafluropropan-2-ol was

much more potent than predicted, which could result from a coupled reaction involving both strong hydrogen bonding and weak Brønsted activity. Kasanen *et al.* (1998) have studied stereospecificity in detail.

5 THE FUNCTIONAL BIOLOGICAL AND PHYSIOLOGICAL SIGNIFICANCE OF PERIPHERAL CHEMOSENSORY IRRITANCY

There are several inter-related aspects of the functional biological aspects of the PCSI response in normal biological circumstances, as discussed below.

5.1 Biological Warning and Protection Functions

The local sensations produced in the PSI response give a warning that such materials, which may produce tissue injury at higher concentrations, are present in the immediate environment. The sensations produced cause the affected individual to seek an uncontaminated area. The local reflexes resulting from sensory irritation are important from the viewpoint of protective mechanisms that limit further exposure. For example, with ocular sensory irritation the resultant excess lacrimation removes material from the corneal and conjunctival surfaces, and blepharospasm restricts further access of material to the eye. Sensory irritation of the respiratory tract results in decreased breathing rate, decreased TV and cough, all of which limit inhalation of the irritant material. However, certain potent PSI materials may inhibit the phagocytic capacity of pulmonary macrophages (Hogg *et al.*, 1983). Because many materials causing a PCSI effect may also produce tissue injury (inflammation) at higher exposure concentrations, a determination of the exposure conditions leading to a PCSI response can be an important factor in determining, or quantifying, what are suitable safe occupational or environmental exposure limits (Ballantyne, 1983). For materials that produce a PCSI response, the eye irritation threshold is usually above odour thresholds. For example, Cometto-Muñiz and Cain (1995) studied a homologous series of aliphatic alcohols, ketones and alkylbenzenes, and found that the ratio of eye irritation thresholds to odour thresholds varied from 15 with 2-propanone to 2 695 for propyl benzene, This indicates that with a known PCSI material, the odour may increase the warning margin of exposure to the material.

Whilst the biological importance of a PSI response is clear, it is also obvious that the absence of such a response with a material capable of causing tissue injury can be a potential hazardous situation. Such an absence of a warning on contact can be conducive to local injury. Examples of materials that may injure due to the absence of sensory warning on contact include dimethyl sulfate and methyl bromide (Grant and Schuman, 1995). In these circumstances it may be required to add a material with PSI properties; for example, addition of chloropicrin to ethyl bromide used for fumigation purposes.

5.2 Harassment and Incapacitation

Both the sensory effects (discomfort and pain) and the local reflex effects may be distracting and harassing, and thus produce variable degrees of incapacitation. For example, blepharospasm and excess lacrimation result in an impairment of vision. This may be detrimental to efficient working, and also may predispose the affected individual to accidents. Therefore, PCSI is an important consideration in relation to safe working conditions.

5.3 Effect on Pulmonary Defence Mechanisms

The effect of PCSI materials on the pulmonary defence mechanisms is variable. For example, sulphur dioxide and formaldehyde at low concentrations may stimulate phagocytosis (Katz and Laskin, 1976), whereas other PCSI materials may inhibit the phagocytic capacity of pulmonary macrophages. A dose-related inhibition of the normal phagocytic response of the pulmonary alveolar macrophage has been shown with cigarette smoke (Green and Carolin, 1967) and marijuana smoke (Cutting *et al*., 1974). In a study of the effect of dibenz[b.f]-1,4-oxazepine (CR) and 10 of its derivatives on the phagocytosis of rabbit pulmonary alveolar macrophages towards *Staphylococcus epidermis*, it was found that CR was the most potent inhibitor, and the 1- and 2-chloro-derivatives were the least potent (Hogg *et al*., 1983). Whereas inhibition of phagocytosis was dose dependent, the degree of inhibition was not correlated with either the nature or the position of the substituent groups on the CR molecule. Also, no discernable relationship existed between the inhibition of phagocytosis and the sensory irritancy of the compounds tested.

6 FACTORS INFLUENCING THE PERIPHERAL CHEMOSENSORY IRRITANCY RESPONSE

Numerous endogenous and exogenous factors may influence the concentration or dosage required to induce a PCSI response, its subjective severity, and its latency and duration. Some of the more important of these factors are discussed below.

6.1 Concentration

PCSI effects are not produced until a certain concentration of the causative substance [the threshold concentration (TC)] is attained. At suprathreshold concentrations, the exposure concentration is a determinant of the following.

- The proportion of the exposed population that respond; the higher the concentration, the larger the proportion of the population that are affected. On a linear basis, in general there is a typical biological sigmoid curve (with proportionate values) or Gaussian curve (with absolute data). This is illustrated in **Figure 6**.

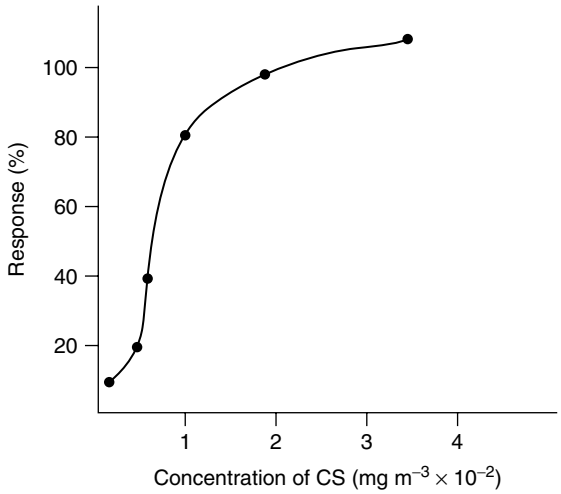

Figure 6 Sigmoid concentration–response curve of the threshold PCSI response for sensation induced in the human eye by an aerosol of 2-chlorobenzylidene malononitrile (CS). The % response is the proportion of the population responding for each concentration tested. By probit analysis, the concentration causing a 50% response in the population studied (TC_{50} with 95 confidence limits) is 4.0 (2.3–6.6) × 10^{-3} mg m^{-3}. (Ballantyne, 1999).

- The latency to onset of PCSI effects; the higher the concentration, the shorter the time to onset of effects (**Figure 7**).
- The duration of the sensory irritant effect, particularly after a brief (pulsed) exposure. The higher the concentration, in general the longer is the persistence of the PCSI effect (**Figure 7**).
- The subjective experience of the response. For example, the higher the concentration of PCSI material applied to the eye, the more marked is the induced blepharospasm (e.g. intermittent to sustained) and the more severe is the induced pain.

Although concentration is an overall determinant of sensory irritant response, molecular size and shape is most likely an integral component of this determinant. For example, Cometto-Muñiz *et al*. (2006; 2007) studied 'cut-off' effects for the detection of ocular irritation for vapours of homologous *n*-alkylbenzenes, 2-ketones, aldehydes and carboxylic acids, the results of which indicated that cutoffs rest on limitations related to the dimensions of the molecules rather than limitations related to their vapour concentration. For example, the stimulus molecule could exceed the size that permits it to fit into the receptor pocket of a receptive protein.

6.2 Particle Size

For PSI materials in particulate form, size may be an important determinant of both the severity and the site of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

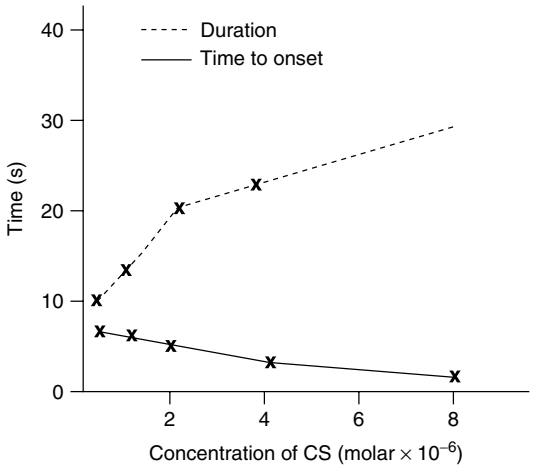

Figure 7 Effect of the concentration of 2-chlorobenzylidene malononitrile (CS) on the latency to onset (solid line) and duration (interrupted line) of discomfort in the human eye. As the concentration of CS in solution applied to the eye increases, latency decreases and the duration of the induced effect increases (Data after Ballantyne and Swanston, 1973a.)

the response. For example, small particles of respiratory dimensions rapidly produce both ocular and respiratory PSI effects, whereas larger particles produce predominantly ocular irritation with prolonged recovery. This was shown by Owens and Punte (1963) using particles of *o*-chlorobenzylidene malononitrile having respective sizes of 1 and 60 μm mass median aerodynamic diameter (MMAD).

6.3 Motivation and Distraction

Both increased motivation and distractions can raise the threshold for the induction of PCSI effects, and enhance tolerance for suprathreshold sensory irritancy. For example, in the workplace the concentration at which sensory discomfort becomes apparent with a particular material may be significantly higher than that causing threshold effects with the same material tested under carefully controlled laboratory conditions. It thus follows that the quantitative values obtained for sensory irritant effects in carefully controlled experimental situations probably represent the most sensitive index for those effects, and thus represent the most reliable and safest estimates on which to base occupational exposure guidelines (OEGs).

6.4 Tolerance

Subjects may develop tolerance to a PSI material if exposure is gradual and at low concentration; the individual adapts by a decrease in the apparent feeling of discomfort and harassing effects (Beswick *et al*., 1972). The development of tolerance is clearly of importance in the workplace, since an adaptation to a warning of potentially harmful chemicals may lead to a decrease in safe working conditions, particularly if there is not strict adherence to carefully derived occupational exposure limits (OELs).

6.5 Personality

There are significant personal and psychological factors in tolerance to pain, and a similar variability exists between individuals with respect to the discomfort produced by PCSI materials. Thus, under a given set of circumstances some will tolerate the discomfort more readily than others. This also is a factor to be considered when assessing the variability to sensory irritants in the workplace.

6.6 Personal Habits and State of Health

Smoking, medication and certain diseases may affect susceptibility to PCSI materials. For example, in a study of worker sensitivity to sodium borate dust, Woskie *et al*. (1998) found that those who smoked, used nasal sprays, or who had allergies or colds were more sensitive to sensory irritant effects, and Dunn *et al*. (1982) showed that smokers were less sensitive to nasal CO_2 irritation.

6.7 Temperature and Humidity

It has been demonstrated that increased environmental temperature and humidity may decrease endurance to peripheral sensory irritation (Punte *et al*., 1963).

6.8 Vehicle

With sensory irritants in solution the vehicle used to dissolve or suspend the active PCSI substance may modify its irritant potential. Surface-active vehicles, for example, can facilitate penetration and enhance the PCSI response, as shown by a lowering of the concentration necessary to induce both threshold and incapacitating effects.

7 QUANTITATION AND INTERPRETATION OF PERIPHERAL SENSORY IRRITANT OBSERVATIONS

As noted above (Section 6.1), there is usually a clear positive relationship between exposure concentration for a PCSI material and the proportion of the exposed population responding, and this is sigmoid or Gaussian in form (**Figure 6**). This indicates that whilst the majority of the exposed population respond over a well-defined region about the median, a small proportion (at the left-hand side of the curve) is hyper-reactive to peripheral sensory irritant stimulation and a small proportion (to the right) is hyporeactive. For ease of presentation and calculations the concentration–response data are usually converted to a linear configuration by a log-probit plot. It is conventional to calculate a 50% response level, with 95% confidence limits (CLs), in order to allow statistical comparison of the relative potency of the PCSI response under defined conditions. This comparison should also include a determination of the slope on the concentration–response regression line, in order to obtain the best possible estimate of comparative sensory irritant potency. A variety of values, discussed below, are calculated to allow the sensory irritant response to be quantified.

For effects that can be objectively evaluated it is common to refer to the effective concentration (EC); that is, the exposure concentration that produces the specific effect under consideration. When sufficient data exists it is common to calculate the sensory irritant potency as the EC_{50}; that is, the concentration, calculated from the exposure concentration–response data, which causes a specific irritant response to occur in 50% of the exposed population under the particular conditions of the observations. Examples of effects that may be quantified and expressed as an EC_{50} include depression of breathing rate, blepharospasm and subjectively assessed discomfort (e.g. pain). Certain defined effects may be referred to by specific expressions; for example, a 50% depression in breathing rate is usually referred to as the RD_{50}. For the subjective evaluations in humans, such as the degree of discomfort, it is also possible to determine and cite 50% response levels; for example, thethreshold concentration 50% (TC_{50}) and, above TCs, if the degree of discomfort is severe, the incapacitating (intolerable) concentration 50% (IC_{50}) can be obtained. In some situations it may be useful to calculate different levels of incapacitation; for example, IC_{10} or IC_{90}.

As with proportion of the population responding to various exposure concentrations of a PCSI challenge, there is also variability between individuals in the latency to effect and duration of effect. Therefore a complete description of a PCSI response requires information on the exposure concentration, proportionate response, latency and duration of response. **Figure 8A** shows the relationship between the exposure concentration

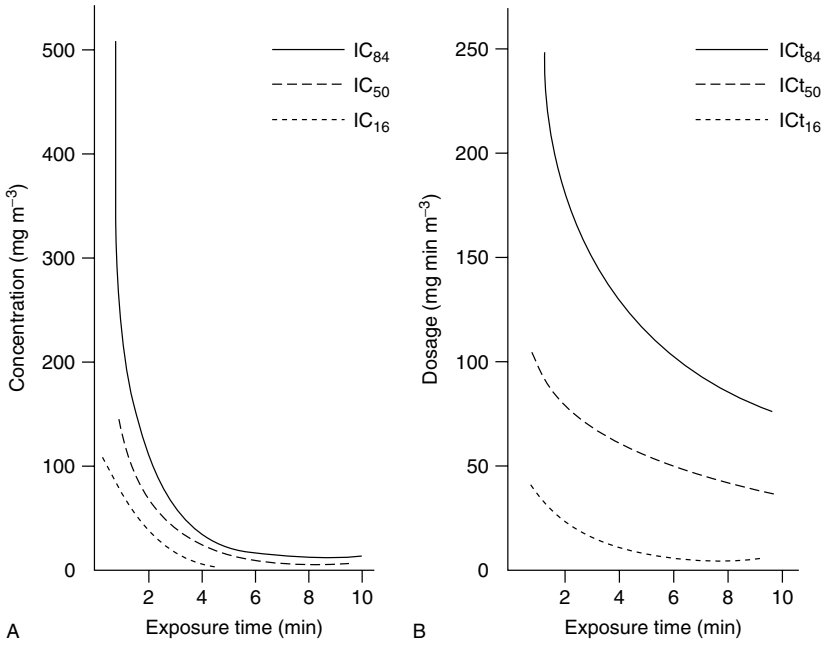

Figure 8 Graphical representation showing the relationship between the atmospheric concentration of 1-chloroactephenone (CN) and the exposure time (A) and the exposure dosage (Ct) of CN and time (B) required to produce defined levels of incapacitation. The incapacitating concentrations (IC) and incapacitating doses (ICt) are plotted as a function of time required to cause intolerable effects in 16, 50 and 84% of the population studied. (Data after McNamara *et al.*, 1968.)

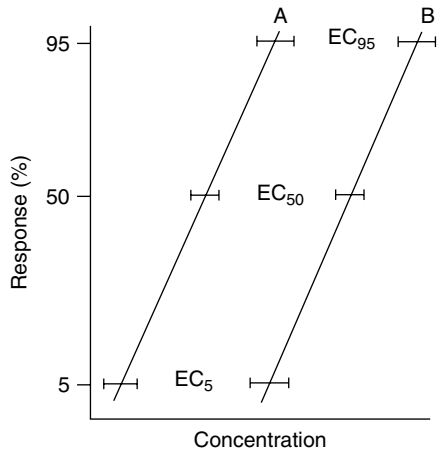

Figure 9 Comparison of two PCSI materials (A and B) having significantly different EC_{50} values, but similar slopes of the concentration–response regression lines. In view of the parallel nature of the two regression lines, the EC_5 and EC_{95} values are also significantly different for materials A and B. Thus, A and B are biologically significantly different from each other, with respect to PCSI potency, over a wide concentration range.

and exposure time to produce different degrees of incapacitation in a particular group of human subjects. It can be seen that for any given exposure concentration, the proportion of the population responding increases with exposure time, reflecting variable latency within the group. Also, and a further indication of variability, within limits a given degree of incapacitation can be produced by various reciprocally related exposure times and exposure concentrations. The reciprocal relationship between exposure time and concentration to produce a given degree of incapacitation also has implications for the exposure dosage (Ct) received. **Figure 8B** shows that for any given level of incapacitation the exposure dosages are greater for the high concentration–short exposure duration conditions than for the lower concentration–more prolonged conditions. Thus, whilst increasing the exposure concentration shortens latency to response, it also results in a greater exposure dosage to produce a given equipotent incapacitating effect.

Ideally, data derived from the use of animal models should indicate the range of concentrations over which PCSI effects may be expected to occur in humans. However, as discussed later, most animal models are less sensitive than the human to PSI materials. In general, animal models will detect those materials having a potential to produce PCSI effects in humans, but normally do not rank different materials in their order of potency for the human. Also, they do not accurately predict the concentration range over which effects may be anticipated in humans.

In comparing the relative potency of different PCSI materials, it is important not only to compare the EC_{50} and 95% CL, but also to examine the slope of the regression line. For example, if two different PCSI materials have significant EC_{50} values and the slopes of the regression lines on the dose–response lines are similar, then it may be concluded that the materials are not significant, with respect to PCSI potency, over a wide exposure concentration range (**Figure 9**). In contrast, even with materials of closely comparable EC_{50} values, if the slopes are different this may have important practical relevance with respect to proportionate population response. This is illustrated in **Figure 10** for two materials having the same EC_{50} values, but differing slopes. Due to the differing slopes, the values of the EC for the two materials differ significantly from each other at both high response (e.g. EC_{95}) and low response (e.g. EC_5) levels. It follows that for the material having the steeper slope, once the TC is exceeded then only a small incremental increase in exposure concentration is required to cause an effect in the majority of the population. Thus, in such situations in the workplace it may be necessary to add a wider concentration margin below the relatively narrow concentration range required to convert a threshold to an incapacitating effect. In contrast, with the material having the shallower slope the concentration range necessary to convert a small response rate to a large response rate will be much greater. However, in these circumstances it may be

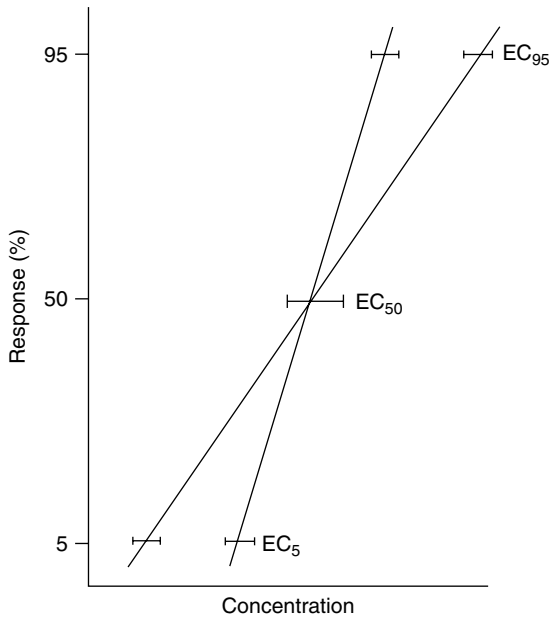

Figure 10 Comparison of two PCSI materials having the same EC_{50} value, but differing slopes on the concentration–response regression lines. This results in the respective EC_5 and EC_{95} values being significantly different from each other. This has implications with respect to hyper-reactive individuals in the group with the shallow slope, and safety margins for the group with the steeper slope (see text; Section 7).

necessary to consider the measures necessary to protect the small proportion (EC_5) that is hypersensitive.

When differences in slopes are present in a comparative evaluation, there are two major implications. First, the relative potency of two materials may not be the same at different levels of response. Second, it may not be statistically valid to calculate a potency ratio. However, in such circumstances it may be useful to calculate the comparative potencies (CPs) at different levels of irritancy. This is defined as follows (Ballantyne, 1977):

$$CP_x = [A] \text{ causing } (x) \text{ response}/[B] \text{ causing } (x) \text{ response}$$

where [A] and [B] are concentrations of PCSI materials A and B, and (x) is a specific response rate.

For individual specific materials, it is often useful to compare their threshold and ICs; for example, IC_{50}/TC_{50}. This effectiveness ratio (ER) can be used to indicate if the threshold value gives an adequate warning of potentially incapacitating exposure; the greater the value of the ratio, the more effective is the warning of the threshold effect. The value can also be used to show how many times the TC has to be increased to result in an incapacitating effect. **Table 5** gives an example of values for the CP of *o*-chlorobenzylidene malononitrile (CS) and dibenz(b.f)-1,4-oxazepine (CR), and the ERs for the individual materials. It can be seen that as the concentration increases, the comparative potency of CR is greater than that for CS; thus the aerosol concentration of CS required to attain a TC_{50} is twice that for CR, for an IC_{50} is 5.1 times and for an IC_{75} response is 9.1 times. Also, there is a wide margin between the TC_{50} and IC_{50} for CS and CR, indicating a significant PCSI warning at the TC_{50}. However, the increase in concentration required to convert threshold to incapacitating effects is greater with CS (900×) than with CR (350×), indicating the latter to have a greater PCSI potency. A similar situation applies with the IC_{75}, but the proportionate increases required are even greater with CS.

8 METHODOLOGIES FOR ASSESSING SENSORY IRRITANT POTENTIAL

Nonanimal methods for determining the potential of substances to produce PCSI effects have included QSAR considerations and chemical models. Biological approaches include the use of *in vitro* and *in vivo* models, and the controlled exposure of human volunteer subjects. Some of these approaches with their relative advantages and disadvantages are considered below.

8.1 Chemical Models

Some correlations have been made between PCSI potential and certain physicochemical characteristics, although this has been only for a limited series of materials, and comparisons between irritant and nonirritant materials are sparse. In an effort to predict what materials are likely to have PCSI properties, various artificial membranes have been devised to simulate biological membranes. These have included monolayers and bilayers of lecithin, with monitoring of phase transitions to measure interaction with a PCSI. Approaches used to investigate transitions have included differential scanning calorimetry, electron spin resonance and X-ray diffraction. In general, the use of such chemical membrane simulants has not been a reliable predictor for PCSI effects.

8.2 Animal Biological Models

There are several biological models, both *in vivo* and *in vitro* and of varying degrees of sophistication and sensitivity, which have been used to qualitatively or quantitatively assess the PSI potential of various classes of chemicals. These include the following.

Table 5 Comparative potencies (CP) and effectiveness ratios (ERs) for aerosols of 2-chlorobenzylidene malononitrile (CS) and dibenz(b.f)-1,4-oxazepine (CR) by respiratory exposure of male human volunteer subjects[a]

Material	Degree of irritancy (mg/m^3)[b]			ER	
	TC_{50}	IC_{50}	IC_{75}	IC_{50}/TC_{50}	IC_{75}/TC_{50}
CS	4.0×10^{-3}	3.6	10.0	900	2500
CR	2.0×10^{-3}	0.7	1.1	350	550
CP	2.0	5.1	9.1	—	—

8.2.1 Isolated Intestinal Segment

This is a nonspecific method based on the use of segments of small intestine, which are suspended in an incubating bath in such a manner that permits contraction of the segment to be mechanically measured. The PSI is added to the bath at varying concentrations, and a record kept of those concentrations causing contraction of the intestinal segment.

8.2.2 Frog Flexor Reflex (FFR)

This approach, also nonspecific, involves a determination of the minimum concentration of irritant that causes withdrawal of the hind limb of decerebrate frogs from test solutions of PCSI materials added to an incubating bath. The method involves the sequential immersion of the hind-limb preparation in increasing concentrations of PCSI substance in solution. After each immersion, the limb is washed with saline and after a period of 5 minutes the limb is immersed in the next solution. The time (T) between immersion of the hind limb and its reflex withdrawal from the solution is noted. The log-molar concentration of PCSI is plotted against T and the curve extrapolated to infinite time by the use of a template of a standard curve, in order to permit the minimum irritant concentration (T_m) to be determined. The mean minimum irritant concentration from six frog preparations ($\check{T}_m$) is used for comparison between different materials. The method is essentially *in vitro*, simple, economic, easy to conduct and has been used by some as a reliable screening test for detection of materials having a PCSI potential (Ballantyne, 1999; Feniak, 1966). However, with some materials the frog flexor reflex (FFR) test will show poor reproducibility and tachyphylaxis may develop. Although the FFR test is relatively insensitive compared with other methods, such as the *in vivo* GPB and mouse depression of respiration (RD_{50}) tests (**Table 6**), the procedure correlates well ($r = 0.99$) with the GPB test (**Table 7**), but is less well correlated with the mouse RD_{50} ($r = 0.76$) (**Table 8**).

of afferent nerve activity has been used with the following neurophysiological preparations.

8.2.3.1 Ciliary Nerve

Ciliary nerve recording following corneal stimulation is frequently undertaken using an excised cat eye mounted on a warm chamber, with the cornea exposed and the attached long ciliary nerve laid over recording electrodes (Green and Tregear, 1964). Test sensory discharge can be induced by light tactile stimuli or cooling the surface. The respective thresholds are 0.1–1.0 g and 5–20 °C (Green and Tregear, 1964).

8.2.3.2 Nasopalatine, Ethmoidal and Sphenoidal Nerves

Nasopalatine, ethmoidal and sphenoidal recording following nasal mucosal stimulation has been carried out with success in the rat (Cooper, 1970; Kulle and Cooper, 1975). For example, Tsubone and Kawahi (1991) used the ethmoidal nerve to record afferent impulses during exposure of the rat to various irritant gases. They found that formaldehyde and acrolein stimulate nasal mucosal sensory endings at about 1.0 ppm, with acetaldehyde producing a significantly lesser degree of stimulation. The concentrations producing a 50% increase in nerve activity were 1.8 ppm for formaldehyde, 1.2 ppm for acrolein and 908 ppm for acetaldehyde.

8.2.3.3 Laryngeal Nerve

Laryngeal nerve recording has been conducted following PCSI stimulation of the laryngeal mucosa. It is usual to conduct the study in anaesthetized and tracheotomized rats, with action potentials recorded from the recurrent laryngeal nerve. Unlike the corneal (ciliary nerve) preparation, the laryngeal model is more complex and slowly adapting (Dirnhuber *et al*., 1965).

8.2.3.4 Cutaneous Nerves

For cutaneous application of a PCSI material, a convenient model is by topical application to the hind-limb, with recording of afferent action potentials from the saphenous nerve (Foster and Ramage, 1981).

8.2.4 Blepharospasm Test

The induction of blepharospasm in conscious animals in response to topical application of a PCSI substance to the cornea, or from exposure to atmospherically dispersed material, is a frequently used approach to assess the PCSI potential on the cornea. It is a simple and reliable *in vivo* method, which can also be performed in most species, including human subjects. For solutions, the test involves sequentially applying increasing concentrations to the surface of the cornea and noting the proportion of the test population that develop blepharospasm following the initial blink reflex. In this way, the response rate can be calculated and an EC_{50} for blepharospasm calculated. If the test substance is in solution, or has to be diluted, it is important that an inert be used. For materials dispersed in the atmosphere a similar observation is employed to sequential increasing concentrations of the test substance.

There is species variation in the sensitivity of the blepharospasm test for the same substances applied to the eye (**Table 9**). In general the guinea pig is the most suitable test species because of cost, size and sensitivity to PSI materials. It is reproducible, free from tachyphylaxis, and differentiates PCSI molecules having close similar structures. However, it does not correlate well with the depression of breathing rate test in the mouse ($r = 0.68$; **Table 10**).

In addition to detecting chemicals having PCSI potential, the GPB test has found use in various drug applications. For example, it has been successfully used as a screen for the development of comfortable ophthalmic drug preparations. In studies by Bar-Ilan (1997), results from a GPB test were compared with the number of human subjects who noted pain or discomfort with various concentrations (2.5–17.5%) of sulfacetamide. The dose–response curves for the guinea pigs and humans were essentially identical, with a threshold at 5% sulfacetamide and a linear increase up to a maximum at 12.5–15.0%. The good relationship between the GPB test and the human nociceptive response with sulfacetamide indicated the usefulness of the procedure for predicting the degree of ocular discomfort in humans.

[c]Effective concentration 50%.
Correlation coefficient (r) = 0.60 (p = 0.06).

8.2.5 Depression of Breathing Rate

Inhalation of PSI materials by laboratory animals results in a decrease in breathing rate, which is reflexly induced by stimulation of trigeminal sensory receptors in the nasal mucosa. The decrease in breathing rate is due to a pause in the expiratory phase of the breathing cycle, resulting in a characteristic notching pattern (**Figure 11**). The approach basically involves head-only exposure of animals to various concentrations of test material, and recording the breathing rate by means of a plethysmograph. Using a minimum of four animals, the mean proportionate decrease in breathing rate for a given concentration is calculated. Up to a limiting value, there is usually a relation between the increase in concentration (C) of the test substance inhaled and the resultant decrease (D) in breathing rate (**Figure 12**). Since C and C/R are linearly related, a least squares regression between the two can be undertaken and the concentration causing a 50% depression in the breathing rate (RD_{50}) calculated. To ensure that the most sensitive response is obtained, preliminary studies are necessary to determine if the exposure time is long enough to obtain the maximum decrease in breathing rate at the exposure concentrations. This can vary with different chemicals. For example, with glutaraldehyde vapour

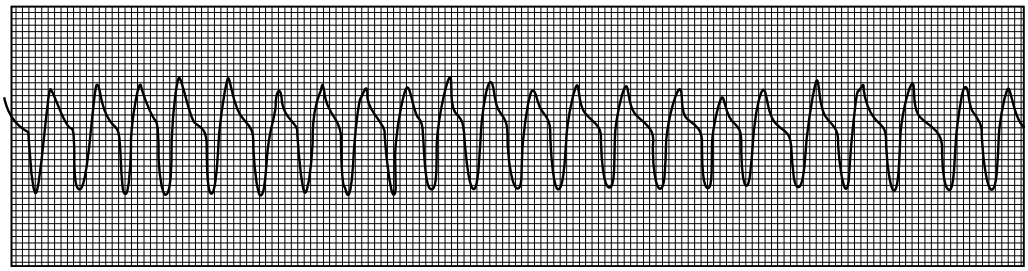

Figure 11 Effect of exposure to glutaraldehyde vapour on the breathing cycle of the mouse. The respiratory cycle shows a prolongation of the expiratory phase that produces a characteristic notching.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat060
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

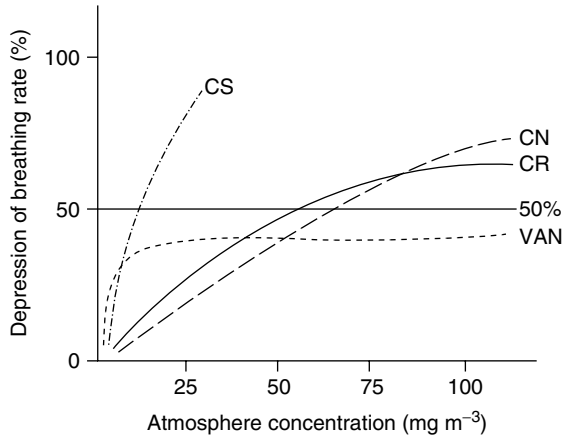

Figure 12 Relationship between depression of breathing rate in the conscious mouse and the airborne concentration of several PCSI substances: CS = 2-chlororbenzylidene malononitrile; CN = 1-chloroacetophenone: CR = diben[b.f]-1,4-oxazepine: VAN = *N*-nonanoylvanillylamide. (Data after Ballantyne *et al*., 1977.)

a plateau for decrease in breathing rate was obtained within 5–10 minutes (**Figure 13**), and with methyl isocyanate within 10–15 minutes (Ferguson *et al*., 1986). If the exposure time is not sufficiently long (i.e. a plateau is not reached), then a misleadingly high value may be obtained; for example, with 1,6-hexamethylene di-isocyanate the 10 minute RD_{50} was 0.96 ppm and the 120 minute RD_{50} was 0.22 ppm; for toluene the 10 minute RD_{50} was 0.81 ppm and the 120 minute value was 0.25 ppm (Sangha *et al*., 1981).

Species variations in sensitivity occur, with the mouse being the usual animal used for testing. It has also been shown that strain variations also occur. A factor of 10 has been demonstrated between the least sensitive and the most sensitive strains of mice (Alarie *et al*., 1980). Swiss–Webster mice are most frequently used species, although no significant differences in sensitivity have been shown between Swiss–Webster and B6C3F_1 mice (Steinhagen and Barrow, 1984). The rat is not an appropriate species (Babiuk *et al*., 1985). In order to permit head-only exposure of the test species, and to simultaneously record the breathing movements, it is necessary to use a whole body plethysmograph with a neck restraint made of rubber. Studies involving multiple exposures have suggested that this method could result in pituitary gland lesions (Kaempfe and Dudek, 1994). Subsequent detailed studies with ND-4 Swiss–Webster mice given single sham and test material (dust) exposures did show pituitary lesions with both the sham (7/7) and test material (52/80) groups (Werley *et al*., 1996). Histology revealed pituitary gland haemorrhages. The authors concluded that the lesion is produced by increased pressure in the blood supply to the pituitary gland, but believe that the lesion (as an artefact of methodology) should have little effect on the usefulness of the procedure as a screening test. Details of the RD_{50} investigation have been published elsewhere (Ballantyne *et al*., 1977b), and comprehensive lists of measured RD_{50} values have been published (Alarie, 1981a; 1981b; Bos *et al*., 1992; Schaper, 1993).

For any substance there is a difference in the concentration causing a typical PCSI response by stimulation

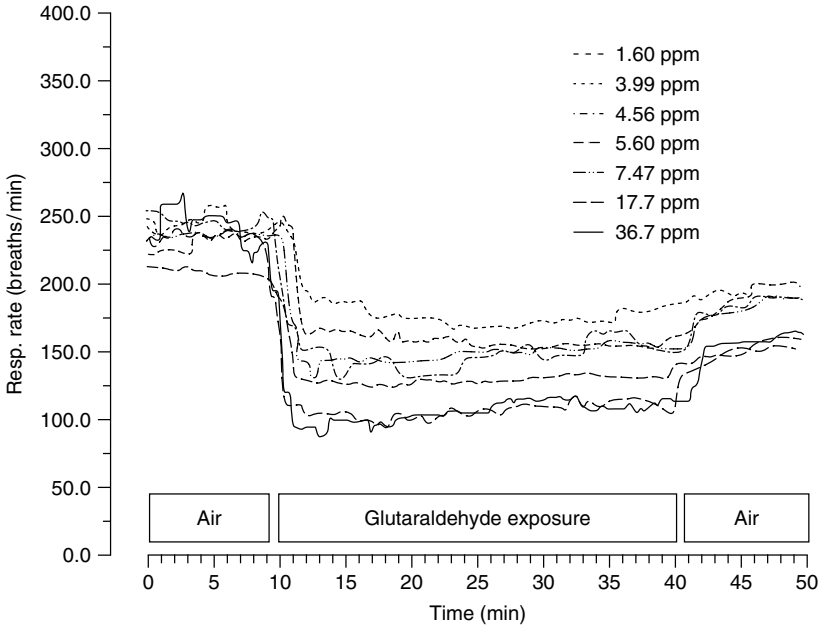

Figure 13 Average time–response curves for changes in breathing rate as a function of exposure time for male ND-4 Swiss–Webster mice exposed to air for 10 minutes, followed by a 30 minutes exposure to various concentrations of glutaraldehyde vapour, and then exposed postglutaraldehyde to air. (Data after Werley *et al*., 1995.)

of receptors in the nasal mucosa and the concentration that is required to stimulate pulmonary receptors. In most cases, and in the intact conscious animal, the nasal trigeminal afferent response will predominate. It follows that a determination of the difference between the concentration causing a nasal response and that causing pulmonary irritation could be used as an index of the margin of warning for potential lung injury. This has been studied by using intact mice to determine the PCSI response from trigeminal stimulation and comparing the result with that resulting from exposure of tracheal-cannulated mice to determine the pulmonary response (Alarie, 1981c). The mouse, unlike other species, develops a decrease in breathing rate in response to pulmonary receptor stimulation due the development of a pause between the end of expiration and the start of the subsequent inspiration. The duration of this pause increases with exposure concentration. The decrease in breathing rate in the tracheal-cannulated mice and calculated RD_{50} (tRD_{50}) are performed as for the nasal exposure route (nRD_{50}). The ratio of RD_{50} values in the tracheal-cannulated and intact mice (tRD_{50}/nRD_{50}) can be used as the warning margin produced by the intact PCSI response. The closer this ratio is to unity, the closer is the concentration to cause pulmonary irritation to that causing nasal trigeminal stimulation. Examples are shown in **Table 3** for several monoamines. It can be seen that only one primary saturated aliphatic monoamine, *t*-octylamine, has close nRD_{50} and tRD_{50} values, with a tRD_{50}/nRD_{50} (t/n) ratio of 1.2. However, three secondary saturated aliphatic amines have tRD_{50}/nRD_{50} ratios <1.0; namely, di-isopropylamine (0.63), di-*n*-butylamine (0.61) and di-isobutylamine (0.96), indicating that OEG for these chemicals need to be strictly controlled. Methods that maybe used for a determination of concentrations of irritant-induced structural and/or functional pulmonary injury for a direct comparison with nRD_{50} values include ultrastructural changes, alterations in lung function (including resistance; Matijak-Schaper *et al*., 1983), detection of pulmonary oedema by a sensitive method based on the intravenous injection of ^{51}Cr-ethylenediamone tetra-acetate following lung lavage (Valentini *et al*., 1983), and measurement of protein and lactate dehyrogenase in lung lavage fluid.

8.3 Studies in Human Volunteer Subjects

8.3.1 General Comments

The animal studies discussed above (Section 8.2) in general allow the detection of substances that have a potential to cause objective PCSI effects. They do not, however, permit for the assessment of subjective effects such as discomfort or pain that are experienced in human subjects. In view of this, and because the human may be more sensitive to some PCSI substances than is estimated in animal models, it may be desirable to conduct PCSI tests in human volunteer subjects. These studies allow, not only an assessment of subjective responses, but, when appropriately planned and conducted, permit a quantitation of the PCSI response at threshold and suprathreshold levels and allow a determination of group variability and of the influence of environmental conditions. Additionally, the physiological and potential medical effects of exposure can be monitored simultaneously; for example, systemic reflexes (such as blood pressure and heart rate). These tests should, of course, only be conducted in volunteer subjects who have been fully informed of the nature and conduct of the tests, are aware of any possible discomfort and risks, have been fully informed that they may withdraw from the study at any time and have not been attracted by possible overcompensation if the volunteers are to be paid. The toxicology and pharmacology of the test substance should have been fully investigated, the potential for adverse health effects should be fully understood, and any possible side effects should carry the minimum of risk for the subjects. The protocol should be reviewed and approved by an appropriate independent institutional review board (Ballantyne, 2005).

8.3.2 Cutaneous Exposure

Measurement of PCSI of the skin has been discussed in detail by Green (2000) and Green and Bluth (1995). Various concentrations of test material are applied to the skin and the subjective degree of discomfort assessed. It should be remembered that there are anatomical regional variations in the sensitivity of the skin to PCSI substances (Ballantyne *et al*., 1973a). Because the epidermis acts as a barrier to the access of PCSI materials to the subepidermal sensory nerve endings, a method was devised to overcome this and obtain comparative evaluation of different substances. This is the blister base technique and involves the creation of a blister on the forearm by covering the area of skin with tape having perforations at regular intervals, and to which is applied a paste of 0.2% cantharidin in kaolin. The tape and paste are removed after a 6 hour contact period and the blisters allowed to develop overnight. Human facial sensory discomfort (sting) testing has been used as an approach for product assessment of cosmetic formulations (Dang *et al*., 2007).

8.3.3 Eye Irritation

Human ocular chemoreceptors are located mainly in the central area of the cornea (Coe and Douglas, 1984). As with animal *in vivo* models, in the human it is possible to determine the concentration of PCSI material that causes blepharospasm. However, in addition, in the human it is possible to assess the degree of discomfort or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

pain produced at various concentrations and to calculate concentrations that are thresholds for sensation and also incapacitating (e.g. TC_{50} and IC_{50}). PCSI effects of solutions on the eye are relatively easy to determine by careful sequential applications of small measured volumes of solutions to the surface of the cornea (Ballantyne and Swanston, 1973a; 1973b). For vapour and gases, tests can be conducted in a chamber with the subject wearing oronasal respiratory protective equipment or in a chamber with specially constructed eye ports (Bender *et al*., 1983). Also, specially designed goggles are available for localized exposure of the eye and prevention of simultaneous exposure of the respiratory tact (Kjaergaard, 1992; Hempel-Jørgensen *et al*., 1996; 1999). Some examples of EC_{50} values for blepharospasm are shown for humans and compared with animal findings in **Table 9**; values for subjectively assessed discomfort are shown in **Table 11**. These values indicate that, for the species studied, the blepharospasm-inducing effects of the test materials were greater in the human; that is, the human is more sensitive. Also, sensory discomfort was a more sensitive indicator of exposure to a PCSI material than was blepharospasm.

Kjaergaard *et al*. (1990) described a potentially valuable technique for measurement of what they described as sensory irritation of the eye, in which they undertook photographic measurement of changes in conjunctiva redness before and after exposure to an airborne irritant. It is a sensitive and reproducible approach. Using a series of volatile organic compounds, Hempel-Jørgensen *et al*. (1998) found that the degree of conjunctival hyperaemia in human volunteer subjects was positively related to the exposure concentration. This noninvasive method may be a valuable approach for studies on the irritating potential of environmental pollutants. It has been used, for example, to study exposure to formaldehyde, *n*-decane, tobacco dust and birch pollen (Bach *et al*., 1988; Kjaergaard and Pederson, 1989; Kjaergaard *et al*., 1989; 1990).

8.3.4 Respiratory Tract Exposure

For exposure to airborne PCSI materials it is usual to determine the concentration causing discomfort within the respiratory tract. Depending on the reason for conducting the study this may be nasal irritation, cough or chest discomfort. Nasal irritation may be experienced principally as an uncomfortable sensation and stinging (pungency). There are a variety of approaches for exposures, the most frequently used being whole body chambers of sufficient size to house the volunteers comfortably with any required monitoring equipment. In some cases, and when available, the use of a wind tunnel may offer a more convenient approach to exposure control and to alter the concentration of airborne test material. To avoid complications of interpretation due to ocular irritation either comfortable airtight goggles may be worn, or the test material can be delivered by mask. The latter approach, however, may have psychological disadvantages with some subjects. Comparative measurements of nasal pungency in those with normal olfaction vs. anosmics suggest that the presence of normal olfactory function may decrease the threshold for nasal pungency (Cometto-Muñiz and Cain, 1990). They also found that eye irritation thresholds were very close to nasal pungency thresholds in anosmics (Cometto-Muñiz and Cain, 1995), and suggested that eye irritation data may serve as a basis for assessing potency for the induction of nasal pungency; that is, nasal trigeminal threshold. Eye irritation thresholds generally do not differ significantly between those with normal olfaction and anosmics of similar age, gender and smoking status (Cometto-Muñiz and Cain, 1998). In this respect it is of interest to note that human pungency thresholds correlate with some RD_{50} values in animal studies (Cometto-Muñiz and Cain, 1994).

Techniques to evaluate and differentially compare both olfactory and chemosensory irritant thresholds have been described. One of these depends on the observation that if a volatile compound is sniffed into one nostril, and simultaneously air is sniffed into the contralateral nostril, then only if the material is a PCSI (stimulating the nasal trigeminal nerve receptors) can it be readily identified which nostril is being stimulated; olfaction by itself does not permit this spatial discrimination (Dalton *et al*., 2000; Roscher *et al*., 1996; Wysocki *et al*., 1992). Nasal localization thresholds in those with normal olfactory function, in general, are approximately equivalent to nasal pungency thresholds in anosmics, and the threshold for nasal localization thus offers a suitable way to measure nasal irritation in those with normal olfaction (Cometto-Muñiz and Cain, 1998). The lateralization, or monorhinal stimulation, technique was used by Wysocki *et al*. (1997) to study the odour and sensory irritant thresholds for acetone. In acetone-exposed workers (36 699 ppm) they found that lateralization thresholds were elevated compared with a control group not occupationally exposed (15 758 ppm), indicating that acetone is a weak sensory irritant and that adaptation is an important factor in the response. Olfactory adaptation was also noted (855 vs. 41 ppm).

Table 11 Concentrations for solutions of 2-chlorobenzylidene malononitrile (CS) and dibenz[b.f]-1,4-oxazepine (CR) to produce threshold sensations in the human eye[a]

Material	TC_{50} (M)[b]
CS	$7.3\ (4.2–11.2) \times 10^{-7}$
CR	$4.9\ (3.8–6.5) \times 10^{-7}$

[a] Data after Ballantyne and Swanston (1973a, 1973b).
[b] Threshold concentration 50% (with 95% confidence limits).

8.3.5 Total Body Exposure

With unprotected workers in the occupational environment, PCSI materials in the atmosphere may come into contact with the skin, eye and respiratory tract and thus produce PCSI responses in one or all of these sites. Hence, for such situations it is meaningful for studies to be conducted by whole body exposure, simulating the workplace. Such studies can indicate if any particular tissue is more susceptible to the PCSI potential of an airborne material and would thus be a determinant for sensitivity as a warning effect. Appropriately planned, such studies can yield significant amounts of information. For example, Lundquist *et al*. (1992) investigated the effects on human volunteer subjects of diethylamine vapour that was increased in concentration in the atmosphere from 0 to 12 ppm over a 1 hour period (average concentration over this period was 10 ppm). A moderate to strong olfactory response with distinct subjective nasal and ocular irritation was noted. Some, but not all, subjects showed an adaptation. Nasal irritation appeared to be a slightly more sensitive index, and a significant correlation existed between nasal and ocular irritation ($r = 0.87$; $p < 0.001$). To study acute physiological changes in the nasal mucosa, they exposed adult male volunteers to 25 ppm diethylamine vapour in a chamber for 15 minutes. Changes in nasal volume and nasal resistance were measured by acoustic rhinometry and rhinomanometry. No reaction occurred for either nasal volume or resistance, indicating that these procedures are not useful measures for the detection of PCSI effects at lower (near threshold) concentrations.

9 APPLIED RELEVANCE OF PERIPHERAL CHEMOSENSORY IRRITANT EFFECTS

The biological effects of PCSI are of relevance in the following practical situations.

9.1 Occupational Exposure and Protection

As noted above, both the local sensory and reflex effects resulting from the PCSI response may be detrimental to safe and efficient working conditions, and in many cases measured values for PCSI effects may be a basis for assigning airborne OELs (discussed in detail below (Section 10.2).

9.2 Harassing Agents

The use of PCSI materials for warning purposes by mixing with other materials not giving a warning on contact has been mentioned above (Section 5.1). More frequent is the use of certain PSI materials as riot-control agents. By the very nature of their intended usage, riot-control agents produce marked PCSI effects, which result in harassment, hindering the conduct of unlawful activities, and causing malefactors to leave the contaminated area. These aspects of PSI have been discussed in detail elsewhere (Ballantyne, 1977; Ballantyne and Salem, 2005; Salem *et al*., 2005).

9.3 Combustion Products

Many chemically differing materials are produced during the processes of combustion, the nature and amounts of which depend on the circumstances of the fire. Some of these materials may produce PCSI effects; for example, hydrogen chloride, sulphur dioxide, isocyanates. The resulting harassing or incapacitating effects may impede escape from a fire. This may be additive to other factors hindering escape from a fire; for example, obstacles, physical injury, hypoxia and absorbed products which produce a disturbance of consciousness, such as carbon monoxide, hydrogen cyanide and volatile organic solvents (Ballantyne, 1981; Norris and Ballantyne, 1999).

9.4 Environmental Considerations

Many airborne chemicals in the environment can evoke chemosensory irritant effects. Perceived irritation, particularly in the indoor environment, is a common symptom and resembles the effects experienced in 'sick building syndrome (SBS) or in multiple chemical sensitivity (MCS) (Koren *et al*., 1992; Otto *et al*., 1992; Dalton *et al*., 1997; Anderson and Anderson, 1999; Sparks, 1999). Trigeminally medited ocular, nasal and pharyngeal irritation is generally regarded as an important component of symptom reporting with indoor 'problem buildings' (Shusterman, 2006). Imputed agents include extremes of temperature and humidity, the presence of volatile organic compounds, combustion products (including cigarette smoke) and ozone from electronic equipment. In addition to the primary irritation, mucosal irritants trigger various secondary reflexes, such as nasal congestion, rhinorrhoea and cough.

There are several syndromes, including SBS and MCS, that are classified together by some authorities as idiopathic environmental intolerance (IEI) (Sparks, 1999) and that are characterized by irritation of the face (burning sensation), sore eyes and throat, difficulty with breathing

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat060
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(including asthma), often (particularly with MCS) neurological problems including confusion, fatigue, difficulty with concentration and poor memory. The considerable overlap of symptoms related to PCSI, pulmonary irritation and airflow limitation with the various types of IEI has led to proposals that common air pollutant mixtures (occupational, domestic and environmental) can cause these various syndromes. The term IEI has been preferred by organizations such as the World Health Organization (WHO) and International Labour Organization (ILO) because 'sensitivity' is a description that implies an immunological basis; the relation between environmental exposure and symptomatology is, as yet, not totally proven, and the underlying pathophysiological mechanisms and criteria for diagnosis are yet to be fully defined. However, it is established that air samples taken from domestic sites associated with repeated human complaints of poor air quality have caused sensory irritation, pulmonary irritation and airflow limitation in mice (Anderson and Anderson, 1997a; 1997b; 1998; 1999). Also, behavioural changes have been detected by functional observation battery studies in mice after exposure to product emissions or air from sites where individuals have made complaints. Findings of these types suggest that many symptoms of SBS and MCS could be the result of exposure to airborne irritant chemicals, such as those liberated by common commercial products and found in polluted air, For example, Kjaergaard *et al*. (1989) found that *n*-decane caused a concentration-dependent irritation of mucosae and increased the sensation of odour intensity. They showed that even at low concentrations, *n*-decane caused symptoms similar to those of SBS. Many individuals with MCS have been reported to have a heightened sense of smell or lower odour threshold (Fielder *et al*., 1996). However, Caccappolo *et al*. (2000) were not able to demonstrate lower olfactory threshold sensitivity or enhanced ability to identify odour accurately compared with age and gender-matched healthy controls. Where many relatively nonreactive chemicals are present in the atmosphere at concentrations below their respective PCSI thresholds, their combined effect could induce irritation of the mucosae (Cometto-Muñiz *et al*., 1997). Anderson and Anderson (1999) have noted that repeated exposures (two or three 1 hour exposures over 24 hours) of mice to certain airborne mixtures of chemicals (e.g. emissions of a solid air freshener) yielded the same degree of irritation, whereas repeated exposures to other mixtures (e.g. emissions from some fabric softeners, disposable nappies and vinyl mattress covers) resulted in increased sensory irritant responses (two- to fourfold). Thus, in the latter cases the intensity of each exposure was constant in magnitude, but the magnitude of the sensory irritant response was increased, leading the authors to conclude that the sensitivity of the mice to chemical mixtures had changed. The response is specific to certain mixtures of chemicals.

Individuals who complain of symptoms of IEI are a heterogeneous group, and more than one mechanism may operate in different cases (NIEHS, 1997). The suggested pathogenesis has included exposure to an airborne mixture of materials having PCSI properties, as discussed above, and to preceding or concurrent psychiatric illness, sensitivity to odours or combinations of these factors. However, the role of exposure to airborne materials having PCSI properties, notably in mixtures, offers a major aetiologic avenue, for which there is some laboratory support. IEI has increasingly impacted the overall burden of chronic disability, and deserves further medical and scientific investigation and evaluation.

10 PERIPHERAL CHEMOSENSORY IRRITATION AS A FACTOR IN DETERMINING OCCUPATIONAL EXPOSURE GUIDELINES

10.1 General Considerations on Occupational Exposure Guidelines

OEGs are usually recommended on the basis of providing protection from adverse health effects of overexposure for a working lifetime of exposure. Depending on the major adverse health effects determining the quantitative value of the guideline, they may be set as permitted average exposure values or may be further qualified for additional restriction of exposure potential. Thus, the threshold limit values (TLVs) recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) (ACGIH, 2007) may be set as time-weighted average (TWA) exposure values to be permitted over an 8 hour work day (TWA over 8 hours for a 40 hour workweek; TWA_8). Further considerations may lead to additional qualifications as follows:

1. The recommended guideline is a set (fixed) value that may not be exceeded during any part of the working period, a ceiling (C) value.
2. The TWA is qualified (supplemented) by an additional concentration, to which it is believed that workers can be exposed for a short period without developing irritation, narcotic effects or chronic or irreversible tissue damage, providing that the daily TWA_8 is not exceeded. This qualification is the short-term exposure limit (STEL) and is usually set for a period of 15 minutes that should not be occur for more than four times a working day, with a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat060
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

period of at least 60 minutes between successive STEL exposures.

3. A written 'notation' of certain effects may be given in order to draw attention to these particular potential adverse effects and that specific precautionary measures may be required; for example, these have been cited for irritation, narcosis, sensitization. Also, carcinogenic effects are indicated by the notations give in **Table 12**.

TLVs are based on credible information derived from *in vivo* and *in vitro* toxicology laboratory investigations, controlled human volunteer studies, in-use occupational medical studies and experience, epidemiology studies and available industrial hygiene observations. The values are usually recommended on the basis of the most sensitive index of potential adverse effects that may occur in exposed workers. These may sometimes be toxic effects causing an impairment of health of variable concerns and the result of either acute and/or repeated exposure; examples include carcinogenic effects, nononcogenic chronic health effects, neurological effects, reproductive effects, developmental toxicity, immune-mediated effects (including asthma) and other organ-specific or enzyme-specific pathology. In other cases the effects may have a physiological or pharmacological basis, such as PCSI or narcosis, both of which are detrimental to efficient working conditions and may result in accidents due to impairment of vision or locomotion, or from distraction. In yet other cases, a qualified TLV may be assigned on the potential for differing adverse effects from the same material. In reaching conclusions concerning the most appropriate value for a TLV-TWA, in addition to the particular substance-related adverse effect(s), it is necessary to take into account how other workplace or personal factors may influence the expression of adverse effects, and how a hypersusceptible proportion of the exposed worker population would react; from these considerations the TLV is appropriately modified. These additional considerations will include, for example, the possible influence of age, gender, smoking habits, genetic factors and general state of health. For many diverse effects resulting from repeated exposure, the TLV-TWA provides the most satisfactory and convenient method for controlling workplace exposure. These values should take account of both the inhaled dose of material and, where relevant and data is available, the possible percutaneous absorption of the material, which in some cases may make a significant contribution to the systemic toxicity from airborne gases, vapours or mists. Information on the possible relevance and quantitative contribution from percutaneous absorption can be derived from repeated cutaneous and percutaneous toxicokinetic studies in laboratory animals, or from exposed human volunteer subjects by wipe sampling and measurement of parent material or metabolite in sequential blood samples (Leung and Paustenbach, 1994; McDougal *et al*., 1990). Excursions permitted on the TWA_8 depend on a number of factors, including the nature of the workplace, the duration of the excursion periods and whether higher concentrations produce acute toxicity. TWA excursions are permitted above the TLV if they are compensated for by equivalent excursions below the TLV-TWA during the workday. The magnitude of the excursions is not usually definable with any degree of precision based on toxicological data. However, Leidel *et al*. (1975) reviewed numerous industrial hygiene surveys conducted by the National Institute of Occupational Safety and Health (NIOSH) and found that short-term exposure measurements were, in

Table 12 ACGIH classification categories for notations of grades for carcinogenic potential

Grade	Notation	Definition
A1	Confirmed human carcinogen	Epidemiological evidence for carcinogenicity in humans.
A2	Suspect human carcinogen	Human data are adequate, but conflicting or insufficient to confirm human carcinogen. Carcinogenic in experimental animals at doses, by exposure routes, at sites, of histopathological or mechanisms relevant to worker exposure. Limited human data but sufficient animal data.
A3	Confirmed animal carcinogen	The substance is carcinogenic in experimental with unknown relevance to animals at high doses by route(s), at sites, of humans histopathological types, or by mechanism(s) that may be relevant to human exposure. Available epidemiology does not confirm an increased risk of cancer in exposed humans.
A4	Not classifiable as a human	Lack of information excludes a definitive carcinogen assessment of potential carcinogenicity in humans. *In vitro* or animal studies do not provide positive Indications of a carcinogenic potential.
A5	Not suspected as a human	Based on credible epidemiology studies, or when carcinogen, the evidence suggesting a lack of carcinogenicity in experimental animals is supported by mechanistic studies.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat060
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

general, log normally distributed with geometric standard deviations generally in the range 1.5–2.0. If short-term exposure values in a given situation have a geometric standard deviation of 2.0, then 5% of all values will exceed 3.13 times the geometric mean. This forms the basis for excursions permissible on TLV-TWA values that do not have a qualifying STEL; that is, excursions may exceed three times the TLV-TWA for no more than a total of 30 minutes during a workday and under no circumstances should they exceed five times the TWA, provided the TLV-TWA is not exceeded. The STEL supplements the TWA where acute effects are recognized from a material whose more serious effects are primarily of long-term or chronic nature; a STEL is usually only assigned where toxic effects have been established from high concentration–short duration exposures. The ceiling (C) value is appropriate for acute effects (principally PCSI), usually occurring at low concentrations, which have a demonstrable threshold that is below the exposure concentration [no observed adverse effect level (NOAEL)], which may result in cumulative or long-term toxicity. A variety of other, mainly environmental, exposure guidelines exist, which are designed to protect individuals who may be incidentally exposed from workplace or transport releases. These include acute exposure guideline levels (AEGLs) which are derived to protect the population from adverse effects in the case of a single exposure due to an accidental release of chemicals into the environment. They are intended to provide estimates of exposure concentrations for a range of exposure durations (10 and 30 minutes, 1, 4 and 8 hours) that are predicted to result in various categories of severities of adverse effects; that is, mild (AEGL-1); severe, irreversible, potentially disabling adverse health effects (AEGL-2) or life-threatening (AEGL-3) (Krewski *et al*., 2004; Bos *et al*., 2006). PCSI effects may play a determinant role in AEFL-1 assessments (Alexeeff *et al*., 2008).

Countries other than the US have different approaches and terminologies for their own national exposure limits for the workplace. In the UK, for example, under the Control of Substances Harmful to Health (COSHH) Regulations, the Health and Safety Executive (on advice from an independent Advisory Committee on Toxic Substances, ACTSs) set OELs. COSHH defines two types of OELs—the occupational exposure standard (OES) and the maximum exposure level (MEL). OESs are set for materials for which it is possible to identify a concentration at which there are no significant risks to health, and MELs are set for materials that have serious implications for health (notably carcinogens and asthmagens), and for which an OES cannot be set (Topping, 2001).

10.2 Peripheral Chemosensory Irritation in the Assignment of Occupational Exposure Guidelines

Because PCSI materials induce distracting, harassing and/or incapacitating effects that are not conducive to efficient working conditions and may predispose to accidents, this is the basis for assigning OEGs to many substances causing PCSI. This is particularly valuable when PCSI effects occur at concentrations lower than those resulting in toxicity by acute or repeated exposure, because sensory irritants then give a warning of potential overexposure. About 40% of ACGIH TLVs are set on the basis of PCSI as the most sensitive index. Since a threshold exists for a PCSI effect and the slope on the exposure concentration–response data varies between different substances, a TWA_8 by itself is not appropriate for workplace protection. Therefore, either a C-value is recommended for a substance having a potent PCSI effect as the main biological factor, or if a TWA_8 is recommended based on other toxicity that can be qualified by a STEL. For a limited number of substances, quantitative information is available on the peripheral chemosensory irritant potential in humans, which permits a reasonable estimate of threshold and incapacitating effects, and allows a reliable OEG to be assigned. Where data are available, attention should be paid to the threshold and incapacitating concentrations, slope on the exposure concentration–response relationship and ERs. Also, with both animal and human-derived data, consideration should be given to the following and how they may influence the value of the OEG: development of tolerance, environmental conditions, the nature of the workplace, type of occupation and the physical characteristics and pattern of the workplace exposure.

In the absence of reliable human data, or else to support and confirm human data, PCSI studies in animals have been widely used. Most frequently employed have been nRD_{50} studies in mice. Those who recommend the value of nRD_{50} studies have supported their case by comparing these values with TLVs for known PCSI substances that have been assigned by ACGIH or other recognized agencies (Barrow *et al*., 1977; Alarie *et al*., 1980; Kane *et al*., 1980; de Ceaurriz *et al*., 1981; Alarie, 1984; Steinhagen and Barrow, 1984; Nielsen and Yamagiwa, 1989; Schaper, 1993). Predictive conversion methods that have been proposed include the following:

1. The TLV should lie between 0.01 nRD_{50}, where it is predicted that there will be either no sensory irritation or it will be at threshold levels, and 0.1 nRD_{50}, which is likely to be an uncomfortable, but tolerable concentration (Barrow *et al*., 1977; de Ceaurriz *et al*., 1981). At the nRD_{50} the predicted response in humans is intolerable or incapacitating.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat060
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2. Since there is a good correlation between the then available TLVs, 0.03 nRD_{50} was recommended for establishing a TLV based on chemosensory irritation (Alarie, 1981b; Schaper, 1993).
3. Because at an airborne concentration of 0.1 nRD_{50} it is anticipated that humans will experience slight discomfort, this should be the highest exposure concentration, and form the basis for a STEL to qualify the TLV-TWA_8 defined on the basis of 0.03 nRD_{50} (Gagnaire *et al*., 1994).
4. Where data are available from tracheal-cannulated animals, and the tRD_{50} is close to the nRD_{50}, because of the prediction of pulmonary irritation, somewhat grater caution is recommended, with the TLV set at 0.01 tRD_{50} (Weyel *et al*., 1982; Weyel and Schaffer, 1985; Nielsen, 1991).

The need for a safety margin between the measured nRD_{50} and the recommended OEG is supported by the observation that respiratory histopathological inflammatory lesions may be induced at the nRD_{50} concentration. For example, Buckley *et al*. (1984) found that with 10 sensory irritant substances of widely differing mouse nRD_{50} values, short-term repeated exposures at the RD_{50} caused inflammatory lesions in the reparatory tract. The materials studied (with nRD_{50} values) were 2,4-toluene di-isocyanate (0.4 ppm), acrolein (1.7 ppm), formaldehyde (3.1 ppm), chloropicrin (8.0 ppm), sulphur dioxide (117 ppm), ammonia (303 ppm), hydrogen chloride (309 ppm), dimethylamine (5111 ppm) and epichlorohydrin (687 ppm). After exposure of the mice for six hours per day for five days, all irritants produced lesions in the nasal mucosa with an anterior–posterior severity gradient. The lesions ranged from slight epithelial hypertrophy or hyperplasia to epithelial erosions and ulceration with variable subepithelial inflammatory cell infiltration. Only chlorine, chloropicrin and epichlorohydrin caused lesions in the lower respiratory tract.

Some illustrative examples of the use of measured RD_{50} values in mice to derive OEGs are as follows:

1. Rydzynski and Jedrychowski (1994) established an nRD_{50} of 5.9 mg m^{-3} (95% confidence limts1.3–13.0; slope 1.37) for cyanuric chloride, indicating the material to be a potent PCSI substance and suggested an OEG of 0.17 mg m^{-3} for the substance (0.03 nRD_{50}).
2. The respiratory PCSI potential of chlorine and of nitrogen trichloride were studied by mouse plethysmography by Gagnaire *et al*. (1994), who found respective nRD_{50} values of 3.5 and 2.5 ppm. Based on 0.03 and 0.1 of the nRD_{50} they proposed TWA_8 (and STEL) values of 0.1 (0.5 ppm) for chlorine and 0.1 (0.3 ppm) for nitrogen trichloride.
3. Werley *et al*. (1995) determined the nRD_{50} for glutaraldehyde vapour in ND-4 Swiss–Webster mice as 13.86 ppm (95% CL 9.86–23.58 ppm), which is in the range of nRD_{50} values measured for other aliphatic aldehydes (Bos *et al*., 1992). Using a correlation factor of 0.03 nRD_{50}, this suggests an OEG of 0.42 ppm, which is close to the threshold irritancy concentration of 0.3 ppm found for exposed human volunteer subjects (Ballantyne and Jordan, 2001). The current ACGIH TLV for glutaraldehyde is 0.05 ppm as a C value; although this is in part based on PCSI effects, the value is recommended mainly because of a suggested potential for respiratory sensitization by glutaraldehyde (ACGIH, 2007).
4. Steinhagen *et al*. (1982) found the nRD_{50} value for dimethylamine vapour to be 573 ppm in male Fischer 344 rats and 511 ppm in male Swiss–Webster mice. Use of the RD_{50} value from the mouse, and the range of 0.01–0.1 RD_{50} as a guideline interval in which the OEG should be set, suggested an OEG between 5 and 51 ppm; the current ACGIH TLV for dimethylamine is 5 ppm with a STEL of 15 ppm (ACGIH, 2007). The next higher alkylamine, diethylamine, has the following mouse RD_{50} values (Nielsen and Yamagiwa, 1989); an nRD_{50} value of 550 mg m^{-3} (184 ppm; i.e. approximately one-third that of dimethylamine) and a tRD_{50} of 1650 mg m^{-3}. These would suggest TLV values of 16.5 mg m^{-3} (0.03 RD_{50}) and 5.5 mg m^{-3} (0.01 RD_{50}), respectively. It is relevant to note that a 1 hour exposure of human volunteers to an average concentration of 30 mg m^{-3} diethylamine vapour caused a distinct nasal and eye sensory irritation. The current ACGIH TWA_8 for diethylamine is 5 ppm (15 mg m^{-3}) and a STEL of 15 ppm (45 mg m^{-3}) (ACGIH, 2007). Di-isopropylamine is a secondary monoamine whose tRD_{50} (102 ppm) is lower than the nRD_{50} (161 ppm) with a t/n ratio of 0.63, indicating a potential for lung injury at a concentration below that giving a typical nasal PCSI warning (**Table 3**). Therefore an OEG of 0.01 tRD_{50} would be most appropriate; that is, 1.0 ppm. However, the current ACGIH TLV is set at a TWA_8 of 5 ppm (ACGIH, 2007), a value that is more appropriate for one derived from the nRD_{50} ($\times 0.03 = 4.83$ ppm).

RD_{50} values for aerosols can be measured readily in mice. For example, Ballantyne *et al*. (1994) exposed mice, nose-only, for 30 minutes to triethylene glycol aerosols of MMAD of 2.45–3.10 µm. Maximum decrease in breathing rate occurred at 15–25 minutes of the start of exposure and were sustained. The nRD_{50} was calculated to be 5.14 mg l^{-1}, from which it would be calculated (0.03 nRD_{50}) that the OEG for irritation would be 150 mg m^{-3}.

A comparison of isocyanates provides an instructive example of the use of PCSI data for establishing

OEGs and the additional influence of pulmonary irritation on establishing the values. James *et al*. (1987) determined the nRD_{50} for methyl isocyanate was 2.9 ppm in mice, and Ferguson *et al*. (1986) established a value for the nRD_{50} of 1.3 ppm and for the tRD_{50} of 1.9 ppm. These RD_{50} values indicate that methyl isocyanate is a potent PCSI substance. With respect to nasal irritancy, methyl isocyanate is not as potent as (60 minutes values) the aliphatic hexyl di-isocyanate and the following aromatic mono- and di-isocyanates: phenyl isocyanate (0.9 ppm), *p*-toluene isocyanate (0.84 ppm) and toluene di-isocyanate (0.39 ppm). It is, however, more potent than hexyl isocyanate (9.2 ppm; Sangha *et al*., 1981). Although the nRD_{50} for methyl isocyanate (1.3 ppm) is numerically larger than that for toluene di-isocyanate (0.39 ppm), the main difference between these two isocyanates is that there was no evidence for pulmonary irritation with the toluene compound (even in cannulated mice inhaling $5 \times RD_{50}$) (Sangha and Alarie, 1979), but the methyl compound had a tRD_{50} of 1.9, and thus the ratio of tRD_{50}/nRD_{50} was 1.46, indicating that methyl isocyanate is a potent pulmonary as well as sensory irritant. In comparison with other potent PCSI substances, such as acrolein (nRD_{50} 1.7 ppm) and formaldehyde (nRD_{50} 3.7 ppm), methyl isocyanate is much more hazardous by inhalation, as indicated by the respective tRD_{50}/nRD_{50} ratios of 142, 31 and 1.46. The current ACGIH (2007) TLV values for isocyanates agree with measured nRD_{50} values as follows:

1. Methyl isocyanate; 0.03 $nRD_{50} = 0.04$ ppm; 0.01 $tRD_{50} = 0.0$ ppm; TLV = 0.02 ppm
2. 1,6-Hexamethylene di-isocyanate: 0.03 $nRD_{50} = 0.0066$ ppm; TLV = 0.005 ppm (also a respiratory sensitizer)
3. Toluene-1.4-di-isocyanate: 003 $nRD_{50} = 0.00$ 75 ppm; TLV = 0.005 ppm (also a respiratory sensitizer).

Several investigators have expressed reservations about the suitability of the RD_{50} test as a basis for assigning OEGs. For example, Bos *et al*. (1992) have questioned the suitability of this approach based on considerations of interlaboratory variations, the finding that toxicity (inflammation) may be seen at or below RD_{50} concentrations, and the rationale for deriving an OEG from RD_{50} data is based on empirical findings. Nikula and Lewis (1994), for example, demonstrated that exposure to pyridine, six hours per day for four days, at 5 ppm (ACGIH TLV) produced lesions in the olfactory mucosa which were only slightly less than those produced by comparable exposures to pyridine vapour at 444 ppm. Histology demonstrated vacuolar degeneration of sustentacular cells; focal and marked attenuation of the epithelium; loss of neurons; presence of intraepithelial luminal structures. As noted above, although effects may be observed at nRD_{50} concentrations, using a correction factor up to 0.1 nRD_{50} allows, at least in part, for slight effects at the RD_{50}. Bos *et al*. (1992) recommended the following procedures with respect to the use of the sensory irritation procedure:

1. In view of interspecies variations, two species (rat and mouse) should be used, with the results from the most sensitive species being chosen.
2. Time–response and log concentration–response curves should be obtained.
3. Exposure should be continued until a plateau is obtained.
4. There should be verification that no pulmonary irritation is occurring.
5. For every material tested, it should be verified whether the observed response is due to irritation or toxicity, and that toxicity is not occurring below the concentration causing sensory irritation.

It has been stressed that many nonsensory factors, such as exposure history, attitudes and expectations, and personality variables can significantly alter the perception of odour and irritation following exposure to volatile chemicals (Arts *et al*., 2006; Dalton, 2002). Objective measures of irritation obtained in conjunction with subjective responses can lend valuable input to determinations on OELs, but should take into account other factors, such as cognitive or emotional, that may modulate the subjective response (Dalton, 2002). It is suggested that studies evaluating chemosensory irritation should take the following into account: (i) distinguish between annoyance elicited by odour sensation and that elicited by true sensory irritation; (ii) evaluate exposure-related factors that affect odour and irritancy responses and (iii) separate true adverse health effects from those mediated by psychosocial factors (Dalton, 2003).

The latter point is important, and it cannot always be assumed that by preventing irritation the occurrence of other manifestations of systemic irritancy can be prevented. For example, the mouse nRD_{50} values for 1,2-dichlorobenzene and hexachloro-1,3-butadiene were found to be 181 and 211 ppm, respectively. The median active level of exposure (MAL) for 1,2-dichlororbenzene to produce a 50% decrease in hepatic glucose-6-phosphate dehydrogenase (an index of hepatotoxicity) was 598 ppm, and the MAL for hexachloro-1,3-butadiene to cause a 50% renal tubular injury (based on alkaline phosphatase histochemistry) was 7.2 ppm. Thus the MAL for 1,2-dichlorobenzene hepatotoxicity is about 3.3 times that of the nRD_{50}, and hence this material can be treated as a PCSI substance from the OEG point of view. However, the nRD_{50} for hexachloro-1,3-butadiene vapour is 39.3 times higher than the MAL for nephrotoxicity, and thus the latter

should receive greater consideration in the assignment of an OEG (de Ceaurriz *et al*., 1988).

OEGs are generally based on irritancy and toxicology information collected at ambient temperature. However, in some workplace situations there may be an elevated environmental temperature; for example, tropical conditions. Also, certain industrial processes may not have been totally investigated. For example, thermoplastic resins are heated to liquefy them for processes such as blowing, extrusion or injection molding. This can result in the liberation of residual monomers, additives or thermal decomposition products, to which workers may be exposed. Schaper *et al*. (1994) conducted a study on the respiratory responses to the thermal degradation products of thermoplastics. They measured nRD_{50} values at processing temperatures between 200 and 300 °C for four resins: polyacrylonitrile-polybutadiene-polystyrene, polypropylene-polyethylene copolymer, polypropylene homopolymer and plasticized poly(vinyl chloride). The respective nRD_{50} values were 21.10, 3.51, 2.60 and 11.51 mg m^{-3}. Based on these findings, the authors recommended exposure limits of 0.63, 0.11, 0.08 and 11.51 mg m^{-3} (0.03 nRD_{50}). Although such studies yield valuable practical information relevant to certain specific workplace activities, Muller and Black (1995) cautioned against the routine use of extreme generation conditions. They investigated the PCSI potential of various samples of indoor materials (including carpets, ceiling tiles and wall coverings) that were ventilated at either 23 or 70 °C. Using mouse plethysmography procedures (nRD_{50} measurements) they found irritation at 70 °C, but not 23 °C. They concluded that increasing the environmental temperature increased the concentration of chemical emissions, which accounted for the sensory irritant effects. They consider that ambient temperature generation conditions were more appropriate for assessing emissions in relation to such indoor situations.

In the workplace or general environment, exposure to several different materials may occur simultaneously. Hempel-Jørgensen *et al*. (1999) produced ocular irritation by interactive additive effects. Although, in the context of use of nRD_{50} measurements to assign OEGs, PCSI materials probably act on the same trigeminal chemoreceptors, several considerations suggest that a predictive approach by an additive process may not always be reliable. For example, competition of the same chemoreceptors may result in a decrease in breathing rate that is less than that predicted on the basis of an additive consideration. Thus, Cassee *et al*. (1996) found that sensory irritation in rats resulting from exposure to mixtures of aldehydes (formaldehyde, acrolein and acetaldehyde) was more pronounced than that caused by each aldehyde separately, but less than the sum of the individual potencies. Competitive antagonism has been demonstrated for acrolein and formaldehyde (Kane and Alarie, 1978) and for cumene and *n*-propanol (Nielsen *et al*., 1988). Also, different materials may display different desensitization patterns, Cassee *et al*. (1996) measured the decrease in breathing rates in rats for formaldehyde, acetaldehyde and acrolein and for mixtures of these aldehydes. They found that sensory irritation was more pronounced for mixtures than for than for each compound tested separately, but less than for the sum of individual components. They concluded that the decrease in breathing rate as a result of exposure to mixtures of PCSI substances could be predicted with a model for competitive antagonism. Threshold responses for odour and nasal pungency (in anosmics), and eye irritation were measured by Cometto-Muñiz *et al*. (1997) for single chemicals (1-propanol, 1-hexanol, ethyl acetate, heptyl acetate, 2-pentanone, 2-heptanone, toluene, ethyl benzene and propyl benzene) and for various component mixtures of them. They found various degrees of stimulus agonism for the three sensations when testing mixtures. Also as the number of components and the degree of lipophilicity of the compounds in the mixtures increased, so did the degree of agonism. Synergistic agonism characterized the eye irritation response for the most complex and most lipophilic mixtures. Korpi *et al*. (1999) reported that microbial volatile organic compounds may have some synergistic effects for sensory irritation, and also if a particular component of a mixture is much more potent than the other components of a mixture it may dominate the PCSI effect. In addition to the use of such information for determining OEGs in the workplace, it may also be of value for investigating situations such as the 'sick building' syndrome, and the authors suggest that the combined action of many relatively nonreactive substances at concentrations below their respective PCSI threshold could induce irritation in mucosae.

Responses of the Kidney to Toxic Compounds

Edward A. Lock

CONTENTS

1 INTRODUCTION

The mammalian kidney is an extremely complex organ, both anatomically and functionally, and plays an important role in the control and regulation of homeostasis. In this regard it has a key role in the regulation of extracellular fluid volume and electrolyte composition. The kidney is also the site of synthesis of hormones and certain vasoactive prostaglandins and kinins that influence systemic metabolic function. For example, renin, the stimulus for the formation of angiotensin, and aldosterone are formed in the kidney. 25-Hydroxyvitamin D_3 undergoes hydroxylation specifically in the kidney to 1,25-dihydroxyvitamin D_3 which plays a key role in promoting bone resorption and calcium absorption from the gut. Erythropoietin, an important stimulus for erythrocyte formation in the bone marrow, is also synthesized in the kidney.

A toxic insult to the kidney may affect some or all of these functions, but, in general, it is markers of excretory function such as creatinine or blood urea nitrogen and the presence of glucose, proteins or enzymes and electrolytes in urine which are commonly monitored as indicators of renal dysfunction.

2 RENAL STRUCTURE AND FUNCTION

The kidney can be divided into two major anatomical areas—the cortex and the medulla. The cortex forms the major part of the kidney and receives most of the blood supply and, hence, nutrients. Thus, when a foreign chemical enters the bloodstream, a high percentage will be delivered to the cortex and, hence, have a greater chance of altering cortical function than medullary. Some chemicals, however, will be delivered to the medulla and, because of the anatomy of the vasa recta and loops of Henle, can become trapped by the countercurrent system in this region of the nephron. Thus, a foreign chemical could achieve relatively high concentrations in the medulla although the blood flow is relatively poor.

The functional anatomy of the kidney is based on the nephron structure, which has three separate elements, the vasculature, the glomerulus and the tubular component (**Figure 1**). All nephrons have their major vascular components and glomeruli in the cortex. The proximal convoluted tubules (pars convoluta) are located in the cortex, with the straight portions of the proximal tubules (pars recta) extending into the outer stripe of the outer medulla (**Figure 2**). Those nephrons whose glomeruli are close to the cortical surface (cortical nephrons) send their loops of Henle down into the inner stripe of the inner medulla, while those with glomeruli close to the medulla (juxtamedullary nephrons) send their loops of Henle deep into the medulla (**Figure 2**). For a more detailed consideration on renal structure and function, see Brenner (2004), Sands and Verlander (2004) or Alpern and Hebert (2008).

Each anatomically distinct part of the nephron has a specific function or functions, all of which can

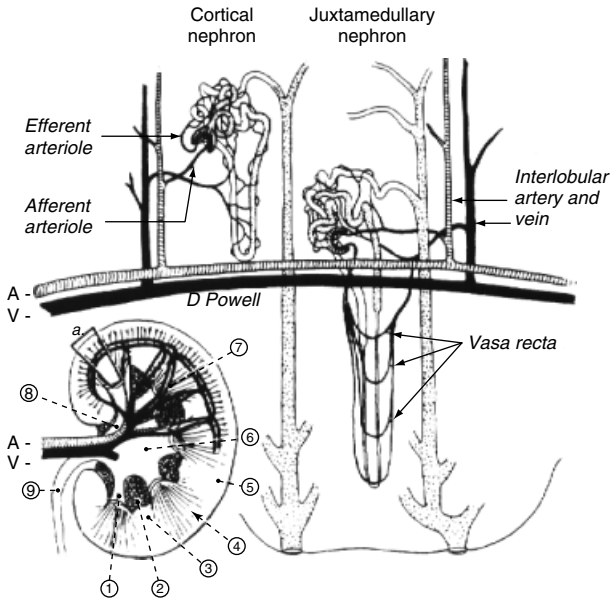

Figure 1 A saggital section of a human kidney is illustrated diagrammatically (lower left). Numbers (1)–(9) indicate the following: (1) minor calix, (2) fat in sinus, (3) renal column of Bertin, (4) medullary ray, (5) cortex, (6) pelvis, (7) interlobar artery, (8) major calix and (9) ureter. The letter A indicates the renal artery, and the letter V indicates the renal vein. Insert (a) from the upper pole is enlarged to illustrate the relationships between the juxtamedullary and the cortical nephrons and the renal vasculature. (Reproduced from Tisher, 1976. © Elsevier.)

be perturbed by a nephrotoxic insult. The vascular component serves to deliver oxygen and metabolic substrates to the nephron for maintenance of its function, while certain end products of metabolism and other materials are delivered to the tubule for excretion. The blood supply also enables reabsorbed materials and those synthesized in the kidney to be returned to the systemic circulation.

The glomerulus contains a specialized capillary network, which is relatively porous and acts as a selective filter of components from plasma. On the basis of molecular weight and net charge, certain materials and chemicals will be filtered into the tubular lumen, while others will be retained in the circulation. The tubular part of the nephron selectively reabsorbs the majority, about 98%, of the salts and water in the filtrate. In a normal healthy kidney there is almost complete reabsorption of filtered glucose and amino acids and selective elimination of end or waste products of metabolism. The proximal tubule is also able to actively secrete certain chemicals into the urine; the excretion of some organic compounds and the elimination of hydrogen and potassium ions occur primarily via this route (see Moe *et al*., 2000; Sica and Schoolwerth, 2000; Wright, 2005).

Depending on the size of a toxic insult, chemicals may produce changes in renal function that are mild and reversible or which are permanent, and if severe enough they may cause death. For example, nephrotoxicity may be expressed as a minor perturbation in tubular reabsorption, such as a mild or transient glucosuria or proteinuria, as a decreased concentrating ability (i.e. polyuria) or, following a more severe insult, as acute renal failure associated with anuria and elevations in creatinine and blood urea nitrogen.

3 SUSCEPTIBILITY OF THE KIDNEY TO TOXIC INSULT

The two kidneys comprise about 1% of the body weight, but receive about 25% of the cardiac output, and about one-third of the plasma water that reaches the kidney is filtered. Maintenance of renal function requires delivery of large quantities of oxygen and metabolic substrates to the kidney. Thus, the kidney, especially the pars recta of the proximal tubule, is particularly susceptible to agents that produce cellular anoxia—for instance, a decrease in blood pressure or blood volume, as in shock, or haemorrhage (Glaumann and Trump, 1975; Venkatchalam *et al*., 1978). Similarly, dehydration, due to either increased heat output or decreased water intake, or a chemical which causes a decrease in plasma volume (Lock, 1979) can lead to a marked alteration in renal function.

Potentially toxic chemicals present in the bloodstream will be delivered to the kidneys in large quantities, especially to the cortex, which receives about 80% of the total renal blood flow. This, together with the ability of the kidney to concentrate tubular fluid, may enhance the toxic effect on the proximal tubular cells, by generating a high concentration of the chemical in the tubular lumen. In addition, if a chemical which has been filtered at the glomerulus and concentrated within the tubule is then reabsorbed, by a passive or active mechanism, it will pass through the cells of the nephron at relatively high concentrations and could potentially lead to intracellular toxicity. Finally, many organic chemicals undergo active transport from the blood into proximal tubular cells and then diffuse into the tubular lumen. Thus, the proximal tubular cells can be exposed to higher concentrations than those present in plasma. This active transport occurs in all three segments of the proximal tubule, although considerable variation exists from segment to segment depending on the species (Wright, 2005; Hiasa *et al*., 2006).

The renal medulla receives a much lower blood flow and therefore receives relatively less potential toxic chemical via the bloodstream. However, as the chemical passes down the nephron into the medulla, the countercurrent mechanisms may lead to a chemical becoming

concentrated in this region and the papilla to a concentration many times greater than that in the plasma.

Once a chemical has become concentrated in a renal cell, it may act directly or require further metabolism to produce a toxic response. A direct-acting chemical presumably acts by interfering with important metabolic events—for instance, inhibition of mitochondrial function or of key enzymes involved in energy metabolism. Alternatively, the chemical may be converted to a reactive species that may bind covalently to critical sites in proteins or initiate lipid peroxidation leading to cellular damage. In the latter case, the chemical could have already undergone metabolism in another organ and the stable metabolite enters the kidney where further metabolism to generate a reactive species occurs.

Most of the common enzymes involved in the metabolism of foreign compounds, such as cytochrome(s) P450 and glutathione S-transferases, are present in renal tissue, although the specific activities of these enzymes are usually lower than those found in the liver (Lock and Reed, 1998; Rankin and Valentovic, 2004; Korashy *et al*., 2004; Pavek and Dvorak, 2008). However, the nephron has a very marked cellular heterogeneity and there are major differences in the relative amounts of certain enzymes in the different regions of the nephron (Guder and Ross, 1984; Lock and Reed, 1998). Thus, any measurement of enzyme activities in whole kidney as opposed to renal cortex or medulla, or isolated glomeruli or proximal tubular cells can grossly underestimate the metabolic capabilities of these regions of the kidney. As a foreign chemical passes down the nephron, it may undergo metabolism by a number of different enzymes. For example, paracetamol (acetaminophen), on entering a proximal tubular cell, can undergo oxidation by cytochromes P450, whereas once it has entered the medulla, it may undergo co-oxidation via the prostaglandin H synthase pathway (Tarloff, 1997). Frequently the intrarenal location of injury represents the site of accumulation of either the chemical or its metabolite, or the location of the enzymes which are responsible for activating it.

The kidney is also under the influence of the sympathetic nervous system (DiBona, 1994), and

chemicals which have a direct action on renal sympathetic nerves can alter renal vascular resistance or renin secretion and influence renal function *per se*.

4 MEASUREMENT OF THE EFFECT OF CHEMICALS ON RENAL FUNCTION

A number of noninvasive techniques are available to assess whether a chemical has had a marked effect on the kidney in both experimental animals and man. A battery of simple tests has evolved which can be applied to urine to give an indication of renal injury. These measurements can be conducted on a temporal basis during feeding studies in experimental animals, or in man exposed to a potentially harmful compound in the workplace, or during drug therapy. The various advantages and disadvantages of these techniques will not be discussed in detail in this chapter. Readers are referred to the following articles and papers therein: Bonventre, 2007; Vaidya *et al*., 2008; Lock and Bonventre, 2008. Traditionally a battery of measurements has been used for both experimental animals and man, which includes plasma creatinine and urea, urine volume, osmolality, pH and the excretion of the electrolytes Na^+ and K^+. The presence of glucose or excess protein in urine and changes in urinary sediment all indicate abnormalities in renal function. However, many of these markers of renal injury are rather insensitive and only change after significant kidney injury and then with a substantial time delay. The increased excretion of specific proteins or enzymes of renal origin in urine can indicate abnormality of function. Certain enzymes that increase in the urine can be of postrenal origin—for instance the bladder—and as such are not indicative of renal damage. *N*-acetyl-β-glucosaminidase (NAG), a proximal tubule lysosomal enzyme, has been extensively studied and has proven to be a sensitive, persistent and robust indicator of tubular injury. More recently, a number of novel proteins have been identified in urine which have potential as markers of renal injury in experimental animals and humans. These proteins include kidney injury molecule-1 (Kim-1), human neutrophil gelatinase-associated lipocalin, interleukin-18, cystatin C, clusterin, fatty-acid-binding protein and osteopontin (Vaidya *et al*., 2008; Dieterle *et al*., 2008). Kim-1 has been examined in preclinical and clinical studies and appears to be an excellent early diagnostic indicator of kidney injury when compared with many of the conventional biomarkers, for example plasma creatinine, blood urea nitrogen, glycosuria, increased proteinuria or increased urinary NAG (Zhou *et al*., 2008; **Figure 3**). Sensitive high-throughput assays have been developed for Kim-1, which is an important requirement for clinical use (Vaidya *et al*., 2008). Proteomic technology with mass spectrometry has enabled the identification of proteins that may also be useful as markers of renal injury (Bandara *et al*., 2003; Witzmann and Li, 2004; Betton *et al*., 2005; Korrapati *et al*., 2007). In an analogous manner, gene expression profiling has also provided insight into predictive markers of nephrotoxicity. For example, kidney gene expression profiling in male Sprague–Dawley rats with 64 nephrotoxic or non-nephrotoxic compounds identified a gene signature consisting of 35 genes which predicted future development of renal tubule injury. These gene changes occurred 76% of the time before the injury was detected histologically or was detected by clinical chemistry (Fielden *et al*., 2005). Thus genomic data can be more sensitive than traditional methods for the early prediction of chemically induced renal injury and hence is a valuable tool in preclinical research and development.

Once an indication of renal dysfunction has been observed, it may be necessary to examine in more detail this effect on renal function and to quantify the response. More specific information indicating whether the insult has occurred to the proximal tubule and/or the glomerulus can be gained by characterizing the proteins excreted in urine on a molecular weight basis, low-molecular-weight proteinuria being indicative of a tubular site of injury, while excretion of high-molecular-weight protein (>80 000) is indicative of glomerular injury (Stonard, 1987; Lauwerys and Bernard, 1989; Emeigh-Hart and Kinter, 2004). Further information on renal function can be obtained by measuring: (i) renal clearance of inulin or creatinine to determine glomerular filtration and (ii) renal clearance and excretion of *p*-aminohippuric acid to determine renal plasma flow, from which renal blood flow can be estimated. Alternatively, radiolabelled microspheres or an electromagnetic flowmeter may be used to specifically measure renal blood flow in experimental animals. Imaging of the kidneys in man and experimental animals is also available (Grenier *et al*., 2003; Dieterle *et al*., 2008) and has been used to identify analgesic nephropathy (Elseviers *et al*., 1995). High-resolution ^{1}H nuclear magnetic resonance (NMR) spectroscopy is now widely used to detect abnormal patterns of metabolites in plasma and urine to help identify renal injury (Williams *et al*., 2003; Lenz *et al*., 2004; Portilla *et al*., 2006), and this, in conjunction with high-performance liquid chromatography–time-of-flight mass spectometry (HPLC-TOF/MS) and pattern recognition techniques, can provide valuable information regarding the probable site of toxic action of a chemical in the nephron. **Figure 4** shows ^{1}H NMR spectra from rats dosed with hexachloro-1,3-butadiene, showing increased excretion of glucose and amino acids indicative of proximal tubule damage and for rats dosed with propyleneimine, showing increases in acetate, succinate, trimethylamine *N*-oxide (TMAO), dimethylamine (DMA) and *N*-*N*-dimethylglycine (DMG) associated

with papillary necrosis (Gartland *et al.*, 1989) For recent reviews on the use of the technique and its applications see Beckonert *et al.* (2007) and Coen *et al.* (2008).

These techniques will enable the detection of abnormal renal function *in vivo*; however, it can be difficult to ascertain whether this malfunction is a direct effect of the chemical, or secondary to altered renal haemodynamics. The direct toxic effect of chemicals may be evaluated *in vitro* by adding the chemical or its metabolite(s) directly to renal cortical slices or isolated proximal tubular cells/tubules in suspension or in primary culture (Zalups and Lash, 1996 and references therein; Lash, 1998). Our understanding of transport systems which enable organic molecules to enter and exit renal tubule cells is now much greater. Advances in molecular biology have identified and cloned many renal transport systems that transport organic cations (organic cation transporters; OCTs), organic anions (organic anion transporters; OATs) and amino acids into renal tubule cells (Wright, 2005; Anzai *et al.*, 2006; Nigam *et al.*, 2007; Bröer, 2008). Several substrates for these transport systems, such as tetraethylammonium (TEA), *p*-aminohippurate (PAH) or aminoisobutyric acid have been used as indices of nephrotoxicity in cell preparations or renal cortical slices (Kacew, 1987). Leakage of lactate dehydrogenase, loss of intracellular adenosine triphosphate (ATP), altered transport of the nonmetabolized sugar α-methyl-glucose, changes in mitochondrial membrane potential and stress protein responses (van de Water *et al.*, 2006) have also been used to indicate cytotoxicity.

Histopathological examination of the kidneys following exposure can identify structural alterations that may have occurred and will also provide valuable information on the area affected. For instance, light microscopy can identify selective damage to the nephron caused by chromium (pars convoluta), gentamicin (pars convoluta and pars recta) (**Figure 5**), 4-aminophenol (pars recta) or propyleneimine (papilla). Light microscopy can also provide information concerning the appearance of protein casts, lysosomal involvement, cellular regeneration and repair or the presence of crystals or stones in the kidney or urine.

Histochemical, immunocytochemical (**Figure 5B** and **D**) and *in situ* hybridization techniques are also valuable in evaluating the response of the kidney to a toxic insult. Depending on the objective of the study, electron microscopy can be used to gain information concerning the subcellular localization of the tubular injury or to probe the glomerulus or papilla for changes that may have occurred following exposure to a nephrotoxin. Changes in mitochondria can be easily identified, as can proliferation of smooth endoplasmic reticulum or alterations in the other organelles such as peroxisomes.

Thus, there is a large battery of tests, many noninvasive, some only requiring small blood samples, which can be used to assess alterations in renal function. In experimental animals these findings can be supported by histopathology and *in vitro* studies with renal tissue.

5 CHEMICALLY INDUCED RENAL INJURY

This section will discuss certain specific nephrotoxic compounds. These chemicals may act either directly or require metabolism to produce the ultimate nephrotoxin. This metabolism may occur solely in the kidney or may involve initial biotransformation in an extrarenal organ followed by activation in the kidney. In some of these examples alterations in renal function may be secondary to changes in blood pressure or blood volume, or to hormonal or neural effects. It is not the intention of this section to discuss all known chemicals which have been reported to cause renal injury. Instead the focus will be on areas where there is some understanding of the mechanisms of nephrotoxicity.

5.1 Heavy Metals

Several heavy metals are nephrotoxic, since the kidney concentrates them prior to excretion and several of them are potent inhibitors of metabolic processes (Barbier *et al*., 2005; Sabolić, 2006). However, several mechanisms exist which protect the kidney against heavy metals—for example, the presence of metallothionein and other high-affinity metal-binding proteins, and the compartmentalization of the metals into lysosomes. The precise mechanism of metal transport into proximal renal tubular cells is not fully understood. Metals can enter proximal tubular cells by endocytosis following the binding of the metal itself or a metalloprotein complex such as Cd–metallothionein to the brush-border membrane (Foulkes, 1988). Transport can also occur via the divalent metal transporter (DMT-1) (Ferguson *et al*., 2001; Abouhamed *et al*., 2006), which is located on the endosomes/lysosomes, and toxic divalent cations, such as Cd^{2+}, Pb^{2+}, Co^{2+}, Ni^{2+} and Pt^{2+}, can enter renal cells by this route. Recent studies using RNA interference to knock down DMT-1 in renal tubule cells, showed some protection against the cytotoxicity produced by Cd-metallothionein-1, confirming a role for this transporter in metal toxicity (Abouhamed *et al*., 2007). Once inside the cell the metal can then be released from the protein–metal complex by lysosomal degradation. Metals may also enter renal cells following conjugation with glutathione to form cysteine or *N*-acetylcysteine conjugate and/or cystine and *N*-acetylcystine conjugates, which can enter renal cells by specific transport systems located on brush border (amino acid transporters) and basolateral membranes (organic anion transporters) (**Figure 6**) (Bridges and Zalups, 2005 and references therein). The intracellular distribution of the metal will then depend on the presence of various high-affinity binding sites or sinks within the cell (Cain, 1987; Fowler, 1989; Zalups and Lash, 1994).

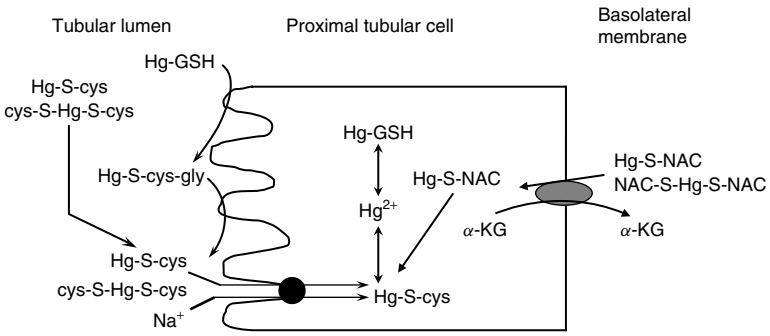

Figure 6 Proposed routes of entry of mercury into proximal renal tubular cells. Hg-cysteine (Hg-S-cys) and Hg cystine (cys-S-Hg-S-cys) in the tubular lumen, can enter via an Na-dependent amino acid transport system, while the *N*-acetylcysteine conjugate of Hg (NAC-S-Hg) and Hg di-*N*-acetylcystine conjugate (NAC-S-Hg-S-NAC) in the plasma can enter via the basolateral membrane organic anion transport system OCT1, in exchange for α-ketoglutarate. Low doses of a number of heavy metals produce a similar response—for example, leakage of glucose and amino acids into urine and diuresis. If the dose of metal is increased, then renal tubular necrosis occurs which can lead to renal shutdown, a marked elevation in blood urea and ultimately the death of the animal. The histological pattern of injury is one of necrotic proximal tubules with dilation of the tubular lumen, which contains proteinaceous casts. This necrosis is thought to be due to a combination of ischaemia secondary to vasoconstriction and a direct cytotoxic action of the heavy metal, since renal ischaemia produced by temporary clamping of the aorta or sustained hypotension causes renal tubular necrosis which is mainly localized to the pars recta region (Glaumann and Trump, 1975; Kriesberg *et al*., 1976; Venkatchalam *et al*., 1978). The fall in blood pressure is thought to trigger the release of renin, which activates angiotensin, a potent vasoconstrictor. The site of renal necrosis produced by ischaemia is the same as that seen with several heavy metals, which suggests a vascular component in the acute renal failure. However, chronic salt loading of rats, which depletes intrarenal renin prior to administration of a heavy metal, can protect against the functional impairment without affecting the extent of necrosis (DiBona *et al*., 1971; Flamenbaum *et al*., 1973), which indicates a role for the direct action of heavy metals on the tubular epithelium. There is also frequently a good correlation between the renal localization of a heavy metal and the site of morphological damage. On the basis of the above it seems plausible to conclude that the nephrotoxicity of heavy metals occurs by two distinct mechanisms: (i) acute renal failure mediated through the release of renin, which can be prevented by depletion of intrarenal renin and (ii) proximal tubular necrosis, which seems to be due to accumulation of the metal in the proximal tubular cells.

5.1.1 Inorganic Mercury

Extensive data are available on the nephrotoxicity of mercuric chloride ($HgCl_2$), primarily because of its use as a model compound to produce acute renal failure in experimental animals. Functional impairment probably results from both vasoconstriction and a direct cytotoxic effect of the metal. Small nephrotoxic doses of $HgCl_2$ produce a selective necrosis histologically located in the pars recta of the proximal tubule (Rhodin and Crowson, 1962; Gritzka and Trump, 1968). The location of the lesion in this region is consistent with the localization of the metal (Taugner *et al*., 1966). However, as the dose of $HgCl_2$ is increased, the injury extends into the pars convoluta (Rhodin and Crowson, 1962). The basic biochemical mechanism whereby $HgCl_2$ produces renal cellular damage is unclear. $HgCl_2$ will readily react with the thiol groups in proteins and enzymes (Webb, 1966), in the latter case, causing inhibition of cellular function. It has, however, been difficult to identify *in vivo* those proteins most sensitive to mercury (Vallee and Ulmer, 1972). The earliest pathological changes following $HgCl_2$ are loss of brush-border membranes, dispersion of ribosomes and the clumping of smooth membranes in the cytoplasm (Ganote *et al*., 1975; McDowell *et al*., 1976). These changes are followed by the appearance of vacuoles in the cytoplasm and clumping of nuclear chromatin. Rupture of the plasma membrane and mitochondrial changes are late changes associated with the onset of renal necrosis. Histochemical studies have shown that enzyme activities associated with the brush-border membranes—for example, alkaline phosphatase and 5′-nucleotidase—were decreased as early as 15 minutes following $HgCl_2$ administration (Zalme *et al*., 1976). Thus, the changes following $HgCl_2$ are first associated with the brush-border membranes and apical vacuole and only later with mitochondria and other structures within the cell. The protein Kim-1, which is located on brush-border membranes, has been shown to be a sensitive marker of renal injury in rats exposed to a low dose of $HgCl_2$ (Zhou *et al*., 2008; **Figure 3**). The uptake of mercury from the tubular lumen probably occurs as cysteine (Hg-S-cys) or cystine (cys-S-Hg-S-cys) complexes via an Na^+-dependent amino-acid transport system (**Figure 6**). In addition, homocysteine or homocystine conjugates of mercury, if formed, may also enter via this amino-acid transport system. Mercury as cys-S-Hg-S-cys, Hg-S-NAC and NAC-S-Hg-S-NAC are also substrates for the organic anion transporter, primarily OCT1 and enter proximal tubular cells by this route (**Figure 6**) (see reviews by Bridges and Zalups, 2005; 2006). The precise intracellular targets for mercury have not been ascertained, the resultant cell toxicity probably results from a cascade of events, including a reduction in cellular glutathione, ascorbate and vitamin E making the cells more susceptible to oxidative stress, plus inhibition of critical thiol residues in mitochondria leading to reduced ATP synthesis (Diamond and Zalups, 1998 and references therein).

5.1.2 Organomercurials

The rate of decomposition of organomercurials to form Hg^{2+} appears to reflect the relative nephrotoxicity of these chemicals, the ranking order (from least to most toxic) being $MeHg^+ < EtHg^+ < PhHg^+ <$ MeoEtHg $< Hg^{2+}$ (Magos, 1982). The alkyl mercurials, which decompose quite slowly, can produce renal injury, although their primary action is on the nervous system. For example, the victims of the ethylmercury epidemics in Iraq showed polyuria or oliguria with urinary casts and excretion of albumin (Jalili and Abbasi, 1961). However, in the large epidemics following methylmercury exposure, the kidneys of even the most severely affected people were spared (Bakir *et al*., 1973). Nevertheless,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat061
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

chronic administration of methylmercury will produce renal damage in rats (Magos and Butler, 1972; Mitsumori *et al*., 1984) and mice (Mitsumori *et al*., 1990). Chronic administration of methylmercury to rats produced ultrastructural damage to the pars recta of the proximal tubule, which included proliferation of smooth endoplasmic reticulum, degeneration of mitochondria and cellular necrosis. These lesions are also seen following inorganic mercury exposure to rats (see above), which supports the view that it is the release of inorganic mercury that is responsible for the renal injury. Methylmercury also has a high affinity for thiol groups and readily reacts with glutathione and cysteine, and the cysteine conjugate is a molecular mimic for the amino acid methionine, whereby it can enter renal cells on an amino-acid transport system (Bridges and Zalups, 2005; 2006).

5.1.3 Mercury-Induced Glomerulonephritis

Mercury has been reported to produce an immunologically mediated glomerulonephritis in both man and experimental animals (Druet *et al*., 1987a; 1987b). The cause of this glomerulonephritis is not well understood and different mechanisms may operate depending upon species and strain. Administration of $HgCl_2$, $1\,mg\,kg^{-1}$ three times a week, to the Brown Norway strain of rat produces an autoimmune response with an increase of circulating IgE, IgG and anti-glomerular-basement membrane antibodies; these latter antibodies can be found deposited along the glomerular capillary wall and this deposition is associated with the occurrence of marked proteinuria and nephrotic syndrome. This autoimmune disease in the Brown Norway rat is not dose-dependent, since lower doses induce the same response, nor does the route of administration (oral, topical or parenteral) influence the response. Also important is the fact that several mercurials ($HgCl_2$, methylmercury or various pharmaceuticals containing mercury, such as thimerosal) all induce this response to various degrees. The autoimmune response is under genetic control, the Brown Norway rat being the only strain out of 22 tested which responded. However, glomerular lesions have also been induced with $HgCl_2$ in various other strains of rats and genetically susceptible mice, the immune response being different from that seen in the Brown Norway rat. In these strains it was characterized as an immune-complex-type glomerulonephritis with the presence of antinuclear antibodies. $HgCl_2$ induces in mice an autoimmune syndrome with T-cell-dependent polyclonal B cell activation and hypergammaglobulinaemia, which is associated with a dose- and H-2-dependent production of autoantibodies targeting the 34 kDa nucleolar protein fibrillarin and causing systemic immune-complex deposits (Havarinasab *et al*., 2007). This response is also seen with methylmercury and ethylmercury in the form of thimerosal, which are converted to the immunogen Hg^{2+} in the body. See Rowley and Monestier (2005) for a review of this topic.

5.1.4 Cadmium

Damage to proximal renal tubules is a characteristic feature of long-term, but not acute, cadmium exposure in both humans and experimental animals (Lauwerys *et al*., 1980; Goyer, 1989; Fels *et al*., 1994 and references therein). Acute doses of Cd^{2+} accumulate predominantly in the liver, whereas following chronic exposure in the diet it is the kidney which ultimately accumulates the highest concentration of Cd^{2+}. Cd^{2+} or Cd^{2+}–protein complexes accumulated by hepatic parenchymal cells induce the synthesis of metallothionein, a low-molecular-weight cysteine-rich protein (Kagi, 1993; Klaassen *et al*., 1999), which binds cadmium very avidly. This Cd^{2+}–metallothionein complex is then thought to be very gradually released from the liver and taken up by endocytosis into renal proximal tubular cells, where free Cd^{2+} can be generated due to lysosomal degradation of the complex. The kidney is able to accumulate large concentrations of Cd^{2+}–metallothionein without obvious damage, until a critical concentration of between 100 and 200 µg $Cd^{2+}\,g^{-1}$ renal cortex is attained, at which renal injury is initiated (Friberg, 1984). Proximal tubular cells can synthesize metallothionein in response to a rise in intracellular Cd^{2+} concentration and the onset of renal injury may reflect a saturation of all the available binding sites in the cell (both constitutive and induced). The toxic species which precipitates the renal damage is almost certainly free (nonmetallothionein-bound) cadmium. It is known that Cd^{2+} *per se* is a very potent inhibitor of enzymes and biochemical pathways (Vallee and Ulmer, 1972; Webb, 1977), whereas Cd^{2+}–metallothionein is not.

Administration of Cd^{2+}–metallothionein to rats produces a very marked nephrotoxicity at much lower doses than Cd^{2+} itself. Similarly administration of Cd^{2+} complexed to either glutathione or cysteine produces very selective toxicity to the pars recta of the proximal tubule, suggesting that the metal complexed in this form may be actively transported into renal cells, analogous to that described for mercury (Bridges and Zalups, 2005). Cd^{2+} can also complex with glycine and thereby reduce its uptake in renal cells (Tang *et al*., 2006). In these acute models considerably more Cd^{2+} is delivered to the kidney than in the low-level chronic situation such that the defence mechanism(s), for example, metallothionein, may not be adequately induced to afford protection; see Cain (1987), Klaassen and Liu (1997) and references therein. Recent studies with metallothionein transgenic mice, which have increased renal metallothionein content, or with metallothionein null mice have shown them to be as susceptible to

Cd^{2+}–metallothionein-induced renal injury as control mice (Liu *et al*., 1996; Klaassen and Liu, 1997). These findings indicate that metallothionein appears to play little or no protective role in acute Cd^{2+}–metallothionein nephrotoxicity. More recent studies, using Cd^{2+}-resistant MT(−/−) (metallothionein knockout) and CdR revertant cell lines has indicated a role for the T-type calcium channel Cacnα1G in uptake of cadmium (Leslie *et al*., 2006). Thus Cd^{2+} can enter renal cells by a number of routes, via the DMT-1 transporter and T-type Ca^{2+} channel, as a glutathione-derived conjugate via the apical and basolateral membrane, and via endocytosis.

5.1.5 Other Metals

Two other metals which are nephrotoxic should be mentioned—these are chromium and lead. Acute necrosis of the proximal convoluted tubule has been reported in man following exposure to hexavalent chromium (Cr^{6+}) (Franchini *et al*., 1978; Jao *et al*., 1983) and following chronic exposure in the workplace (Wang *et al*., 1994). Various studies have confirmed these findings in rodents. The primary site of action of Cr^{6+} is on the convoluted portion of the proximal tubule (Evan and Dail, 1974; Berndt, 1975), which is different from that seen with mercury. These morphological findings are supported by functional studies where, for example, glucose reabsorption, a function of the convoluted part of the proximal tubule, is severely affected, leading to marked glucosuria (Berndt, 1975). As with the other metals, the earliest morphological change following Cr^{6+} administration is to the brush-border membrane (Evan and Dail, 1974; Kirschbaum *et al*., 1981). How the metal is transported into renal cells is not understood, but there have been some studies indicating that glutathione may play a role (Standeven and Wetterhahn, 1991). Little recent information has been reported on the mechanism of nephrotoxicity of Cr^{6+}; however, the urinary biomarker Kim-1 does appear to be a sensitive and early indicator of Cr^{6+}-induced renal injury (Zhou *et al*., 2008; **Figure 3**).

Lead is probably the most abundant nephrotoxic metal and because of industrial exposure there is considerable clinical data. Lead-induced nephrotoxicity is characterized morphologically by the presence of lead intranuclear inclusion bodies, karyomegaly, cytomegaly and ultrastructural changes in mitochondria, primarily in the pars recta of the proximal tubule. These changes are accompanied in severe cases by functional changes in glucose, amino acid and phosphate reabsorption (Goyer, 1982). Chronic exposure of experimental animals to lead salts produces a similar spectrum of renal changes to those seen in man (Goyer and Rhyne, 1973). The majority of lead present in blood is located in the red cell; only lead bound to proteins or ligands which are filterable at the glomerulus is available for uptake into renal cells. Like other metals, lead is taken up by endocytosis via the DMT-1 transporter into renal proximal tubular cells, where free Pb^{2+} can be generated due to lysosomal degradation of the protein complex. See Bridges and Zalups, 2005 for a more detailed discussion on transport systems for lead into renal cells. Studies in male rats have shown that lead is bound to the protein α_{2u}-globulin (Fowler and DuVal, 1991), which is synthesized in the liver and transported to the kidney (see later) where a proportion is taken up into renal proximal tubular cells. A lead-binding protein in human kidney has recently been identified as diazapine-binding inhibitor, which has similar properties to α_{2u}-globulin, but is not a member of the same gene family (Fowler and Squibb, 1997). Once inside the cell, any free metal will initially bind to certain high-affinity lead-binding proteins which are present in the kidney in high concentrations. These proteins are thought to carry lead into the nucleus, where *de novo* synthesis of a unique acidic protein results in metal precipitation to form the classical lead intranuclear inclusion bodies (Fowler, 1998).

Mitochondria are extremely sensitive to lead and, following chronic *in vivo* administration, mitochondrial swelling, which is associated with decreased respiratory control, has been reported (Goyer and Krall, 1969; Fowler *et al*., 1980). Certain enzymes involved in haem biosynthesis are also very sensitive to lead—in particular, δ-aminolaevulinic acid dehydratase. Inhibition of this enzyme *in vivo* results in urinary excretion of δ-aminolaevulinic acid and forms the basis of biological monitoring for lead.

5.2 Antineoplastic Agents: Cisplatin

The platinum antitumour drugs—for example, cisplatin (*cis*-dichlorodiamine platinum II)—are widely used for the treatment of a range of cancers (Loehrer and Einhorn, 1984; Rosenberg, 1985), but nephrotoxicity is frequently a side effect, which limits the dosage (Borch, 1987; Arany and Safirstein, 2003; Yao *et al*., 2007). Clinical manifestation of renal functional impairment includes elevation in blood urea and creatinine, some proteinuria and enzymuria and, in severe cases, the presence of cells and casts in the urine. Electrolyte disturbances are also common, particularly hypomagnesaemia, which may be related to impaired renal tubular absorption (Goldstein and Mayor, 1983; Litterst and Weiss, 1987). Histopathology of the human kidney showed focal tubular necrosis primarily to the distal tubule and collecting ducts, with some dilatation of the convoluted tubules and the presence of casts (Gonzalez-Vitale *et al*., 1977; Dentino *et al*., 1978). In experimental animals cisplatin produces marked impairment of renal function (Arany and Safirstein, 2003); however, the onset of this renal lesion is delayed.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat061

Following a single dose to the rat, histopathological alterations were minimal over the first two days, but by day 3 changes to brush-border membranes occurred selectively in the pars recta of the proximal tubule. By day 5 the predominant pattern of injury was widespread necrosis to the pars recta of the proximal tubule, which by day 7 had started to show extensive regeneration (Dobyan *et al*., 1980). No histopathological changes were seen in the distal tubule, in contrast to the findings in man.

The mechanisms underlying cisplatin nephrotoxicity (Arany and Safirstein, 2003; Hanigan and Devarajan, 2003; Bonegio and Lieberthal, 2004; Yao *et al*., 2007) and the basis of the delayed onset of toxicity are not fully understood. The platinum moiety *per se* may not be responsible for the nephrotoxicity, as the trans isomer of cisplatin is not nephrotoxic (Daley-Yates and McBrien, 1985). Platinum complexes are characterized by their slow rates of ligand substitution in comparison with other metal complexes. When cisplatin is dissolved in water, the more labile chloride ligands are displaced in a stepwise fashion to form aquated complexes. In plasma at a chloride concentration of 110 mM, cisplatin would be expected to exist predominantly as the neutral dichloro complex. In contrast, the aquated species would be expected to dominate at the lower chloride concentration of the cytosol. An important property of the aquated platinum complexes is that the water ligands are far more reactive than the chloride ligands and are readily replaced by a variety of biological nucleophiles. Cisplatin itself, as well as the aquated species will readily react with thiol groups in proteins (enzymes) and with glutathione, cysteine and methionine. Thus, a metabolite of cisplatin rather than the platinum moiety itself may mediate the nephrotoxicity of the drug. Support for the nephrotoxicity of a glutathione-derived conjugate comes from studies showing that inhibition of γ-glutamyltransferase in rats and mice will prevent cisplatin-induced renal injury (Hanigan and Devarajan, 2003); however, the role of other enzymes responsible for the further processing of glutathione conjugates is not clear.

What is known is that Pt from cisplatin accumulates in the kidney via the organic cation transporter in rats (rOCT2) (**Figure 7**) and humans (hOCT2). However, cisplatin is not a substrate for the multidrug and toxin extrusion transporter in rats (rMATE1) or humans (hMATE1 or hMATE2-K; **Figure 7**), suggesting cisplatin can be readily transported into renal tubule cells, but not out (Yokoo *et al*., 2007).

Cisplatin causes apoptosis in renal tubule cells and many studies have examined the cascade of events, such as caspase activation and cytochrome C release (Arany and Safirstein, 2003; Hanigan and Devarajan, 2003; Yao *et al*., 2007). Mitochondria seem to be an important intracellular target for cisplatin (Zhang and Lindup, 1993) and inhibition of oxidative phosphorylation (**Figure 5**) may be the primary event, with loss of intramitochondrial

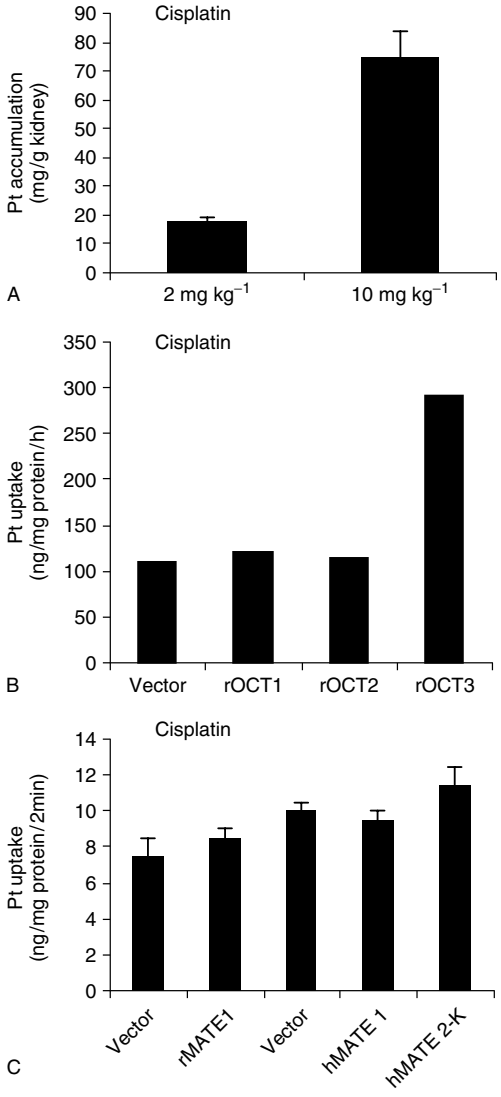

Figure 7 Cisplatin accumulation in rat kidney and uptake in human embrionic kidney (HEK) 293 cells expressing various transporters: (A) Renal platinum concentration 48 hours after 2 or 10 mg kg^{-1} cisplatin; (B) uptake of cisplatin (500 μM) by HEK 293 cells expressing the empty vector, rOCT1, rOCT2 or rOCT3 for one hour; (C) uptake of cisplatin (500 μM) by HEK 293 cells expressing the empty vector, rMATE1, hMATE1 or hMATE-2K for two minutes. glutathione and generation of reactive oxygen species a subsequent phenomenon (Kruidering *et al*., 1997). One of the earliest responses in renal tubule cells to cisplatin is activation of the MAPK (mitogen-activated protein kinase) cascade and stress-response genes, followed later by genes associated with cell cycle and inflammation (Arany and Safirstein, 2003; Yao *et al*., 2007; Wang *et al*., 2008; Suzuki *et al*., 2008).

DNase I knockout mice are significantly protected against cisplatin nephrotoxicity and it appears that endonuclease G (endo G) is also involved in mediating

cell death as gene silencing of endo G *in vitro* protects against cell death (Yin *et al*., 2007). Selenium (Baldew *et al*., 1989) and a number of thiol ligands, such as glutathione, diethyldithiocarbamate (Borch and Markman, 1989), 4-methylthiobenzoic acid (Boogaard *et al*., 1991a) and metallothionein (Boogaard *et al*., 1991b) have been shown to afford some protection against the nephrotoxicity produced by cisplatin. Similarly, administration of cisplatin in hypertonic saline reduced the nephrotoxicity and lowered the kidney platinum concentrations in both rat (Litterst, 1981) and human (Borch and Markman, 1989). Thus, the data suggest that the retention of platinum or an aquated platinum complex in renal tubular cells and its reactivity with cellular nucleophiles, in particular in the mitochondria, may account for the nephrotoxicity. Numerous other agents have been shown to ameliorate cisplatin nephrotoxicity and the reader is referred to a recent review by Ali and Al Moundhri (2006).

5.3 Immunosuppressive Agents: Cyclosporine

Cyclosporine is a highly lipophilic, cyclic undecapeptide of fungal origin with potent immunosuppressive activity. It is widely used in solid organ transplantation. The major clinical problem associated with cyclosporine usage is nephrotoxicity, which is manifested as a decrease in glomerular filtration rate. This effect is, in part, due to altered renal haemodynamics; several studies in experimental animals (Murray *et al*., 1985; Barros *et al*., 1987; Whiting and Thomson, 1989) and man (Curtis *et al*., 1986) have shown that cyclosporine causes an increase in renal vascular resistance and a reduction in renal blood flow. Cyclosporine causes both acute and chronic toxicity and these may occur by different mechanisms. Acute nephrotoxicity is a functional abnormality related to a local imbalance of vasoconstrictor and vasodilator mediators of which there are many. The mechanisms underlying the altered renal function are still not entirely clear but the renin–angiotensin–aldosterone system seems to play a pivotal role with studies focussed on factors such as eicosanoids, endothelin and nitric oxide (see Cattaneo *et al*., 2004; Charney *et al*., 2004). There is also a growing body of evidence suggesting a role for free radicals in acute cyclosporin nephrotoxicity, where functional changes are accompanied by increases in malondialdehyde, lipid hydroperoxides, radical oxygen species and depletion of glutathione (Cattaneo *et al*., 2004).

Morphological studies of experimental acute cyclosporine nephrotoxicity have shown early sublethal cellular changes confined to the pars recta of the proximal tubule. However, whether these degenerative changes are a direct result of the chemical or are secondary to the ischaemia is currently unclear (Myers, 1986; Mihatsch *et al*., 1989).

Acute cyclosporine nephrotoxicity is related to the concentration of the circulating drug. Although it is still unclear as to whether the unchanged drug or metabolite is responsible for the toxicity, most information supports the view that it is the parent compound (see Burke *et al*., 1989). There is good evidence that alteration of the hepatic metabolism of cyclosporine in both man and experimental animals can affect the extent of renal functional impairment. For example, inducers (e.g. phenobarbitone) or inhibitors (e.g. ketoconazole) of cyclosporine metabolism will either lower or raise the cyclosporine circulating blood level and thereby reduce or potentiate the nephrotoxicity (Burke *et al*., 1989).

In vitro studies, in which cyclosporine has been added to renal cells, have indicated that the chemical can have a direct action on cellular systems. Cyclosporine will prevent the uptake of glucose by LLC-PK_1 cells (Scoble *et al*., 1979), which suggests that the glycosuria seen *in vivo* (Grieve *et al*., 1990) could be due to a direct effect of the chemical. Cyclosporine is a potent inhibitor of the mitochondrial matrix enzyme peptidyl-propyl cis–trans isomerase (cyclophilin) and thereby inhibits mitochondrial membrane transport (Griffiths and Halestrap, 1991). Inhibition of renal mitochondrial peptidyl-propyl cis–trans isomerase will disrupt the Ca^{2+}–calmodulin–calcineurin signalling pathway which may be relevant to the mechanism of nephrotoxicity.

Chronic cyclosporin nephrotoxicity is characterized by an irreversible and potentially progressive nephropathy (Hall *et al*., 1985; Mihatsch *et al*., 1989; Mason and Moore, 1997). Morphologically the nephropathy is characterized by a diffuse interstitial fibrosis or striped fibrosis with glomerular and arteriolar thrombi (Mihatsch *et al*., 1989). The haemodynamic consequences are a persistent renal vascular resistance associated with a marked decline in glomerular filtration rate and renal blood flow, and systemic hypertension. Angiotensin II may play a role in cyclosporin-induced chronic nephrotoxicity, at least in animals, while cyclosporin stimulates renal and systemic overproduction of TGF-β (transforming growth factor β). This cytokine plays a major role in the generation of renal fibrosis by directly stimulating extracellular matrix components and reducing collagenase production, leading to renal scarring (Islam *et al*., 2001).

5.4 Therapeutic Agents

5.4.1 Aminoglycosides

Nephrotoxicity related to aminoglycosides is still a major limitation in their clinical use. Kahlmeter and Dahlager (1984) reviewed over 10 000 patients in clinical

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat061
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

trials with aminoglycosides and found a frequency of nephrotoxicity resulting from gentamicin and tobramycin of about 14%, and from netilmicin and amikacin of 9%. Similarly, Hall *et al*. (1983) reviewed cases of hospital-acquired acute renal failure and showed that 11% of over 2000 cases were attributable to aminoglycosides. In more recent surveys using elevation of serum creatinine as the marker of renal impairment, lower incidences of renal injury were found (Blaser *et al*., 1995), although others consider that nephrotoxicity is still a complication in 10–20% of therapeutic courses (Swan, 1997; Martínez-Salgado *et al*., 2007).

The aminoglycosides consist of two or more amino sugars which are cationic at physiological pH joined by a glycosidic linkage to a hexose nucleus (**Figure 8**). The clinically relevant aminoglycosides are gentamicin, tobramycin, netilmicin, amikacin, kanamycin, streptomycin and neomycin C. These antibiotics are primarily excreted by glomerular filtration. A small amount of the cationic drug binds to anionic phospholipids (primarily phosphatidylinositol) located on the brush-border membrane of the proximal tubule, and the bound aminoglycoside then enters the renal tubular cell by endocytosis and is stored in secondary lysosomes. This process leads to the accumulation of the antibiotic in proximal tubular cells (Cojocel, 1997 and references therein), where it can persist for days. Location of the drug in the pars convoluta and pars recta of the proximal tubule is in agreement with the histopathological location of necrosis in this region of the cortex. Ultrastructural examination of the renal cortex showed marked hypertrophy of the lysosomes in the proximal tubules and the presence of concentric lamellar material (myeloid bodies) within these organelles (Kosek *et al*., 1974; De Broe *et al*., 1984).

The earliest functional changes are alterations in renal concentrating ability, proteinuria and enzymuria and in acid–base balance (Kaloyanides, 1984; Cojocel, 1997; Zhou *et al*., 2008). In addition to renal tubular necrosis, functional and ultrastructural changes occur in the intraglomerular mesangial cells following gentamicin (Cojocel, 1997; Martínez-Salgado *et al*., 2007).

The biochemical events leading to renal tubular necrosis are believed to be initiated by the binding of the cationic aminoglycoside to negatively charged phospholipid bilayers and to the protein megalin a multiligand, endocytic receptor which is abundant in renal proximal tubule cells (Rougier *et al*., 2004; Nagai and Takano,

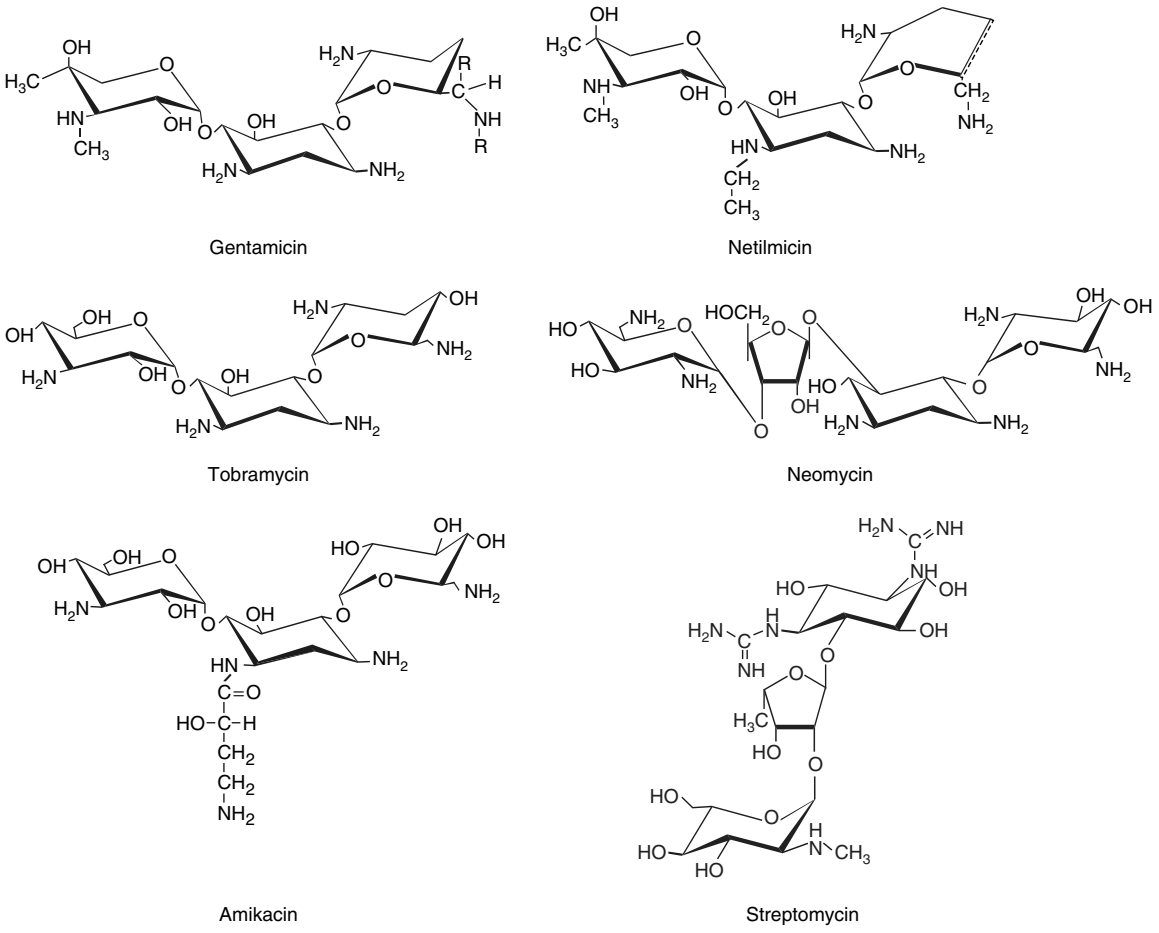

Figure 8 Structural formulae of some aminoglycosides used in clinical practice.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat061
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2004). This impairs the degradation of phosphatidylinositol by binding to phosphatidylinositol-4,5-biphosphate and preventing its metabolism to the triphosphate (Kaloyanides and Ramsammy, 1989). The binding of the aminoglycosides also alters the activation and redistribution of the protein kinase C complex. Impairment of phosphoinositol metabolism probably results in altered Ca^{2+} membrane transport, which can lead to cellular injury and slow repair to damaged cell membranes. Calcium has been shown to inhibit the binding of gentamicin to renal membranes, and calcium loading can protect against the renal injury produced by this drug (Humes *et al*., 1984). Aminoglycosides also compete with Ca^{2+} for binding to megalin (Nagai *et al*., 2001), which may reduce the accumulation of the aminoglycoside by megalin-mediated endocytosis. Administration of an anionic polypeptide such as poly-L-aspartic acid with gentamicin will protect against the nephrotoxicity (Ramsammy *et al*., 1989; Swan *et al*., 1993). It is believed that poly-L-aspartic acid binds gentamicin, thereby displacing it from negatively charged membrane lipids and relieving the inhibition of phospholipid metabolism. Recent studies in megalin knockout mice has shown that in the absence of megalin the concentration of gentamicin in the kidneys is drastically reduced, strongly indicating that megalin-mediated endocytosis is the major pathway for the accumulation of aminoglycosides in the kidney (Schmitz *et al*., 2002). Many strategies have been tried to protect against gentamicin nephrotoxicity, see the review by Ali (2003).

Gentamicin inhibits oxidative phosphorylation in renal cortical mitochondria *in vitro* (Simmons *et al*., 1980). This may be due to altered mitochondrial calcium transport, which can influence mitochondrial respiration. At concentrations which are found in proximal tubular cells, gentamicin will induce the release of iron and enhance the generation of hydrogen peroxide by isolated mitochondria (Walker *et al*., 1999) implicating a role for free radicals in aminoglycoside nephrotoxicity. More recent studies examining changes in gene expression in the kidney after gentamicin have shown increases in oxidative stress genes in primary rat proximal tubule cells 24 hours after exposure (Suzuki *et al*., 2008) with some of these changes seen *in vivo* in the kidney (Wang *et al*., 2008). Genes associated with regeneration, such as Kim-1, IGFBP-1 (insulin-like growth factor binding protein 1), neutrophil gelatinase-associated lipocalin and osteopontin, were also markedly elevated five days after gentamicin exposure (Wang *et al*., 2008).

Thus the following cascade of events is still thought to occur (Tulkens, 1986; **Figure 9**), the major new information being the binding of the drug to megalin. The drug is filtered at the glomerulus and enters the tubular lumen, where it binds to megalin. These complexes undergo endocytosis, thereby developing high intracellular concentrations of the antibiotic, and become incorporated into lysosomes and inhibit phospholipid metabolism. Interaction with mitochondria can lead to generation of reactive oxygen species that can alter cellular function and lead to necrosis. The balance between the repair of the cellular injury and the extent and duration of the necrosis determines the extent of the renal failure.

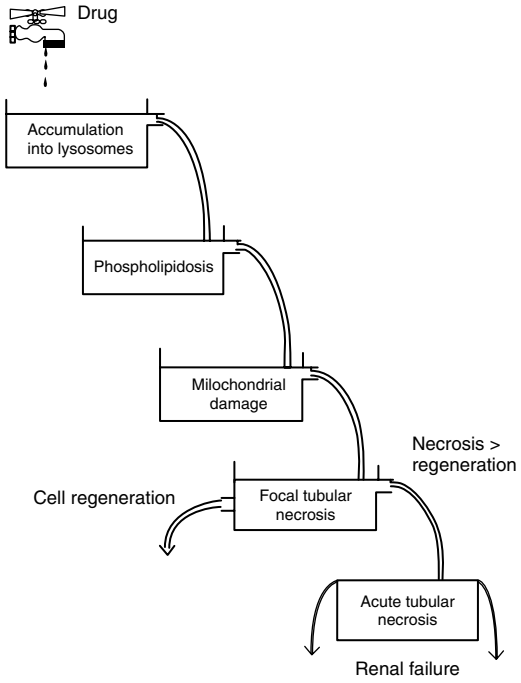

Figure 9 The aminoglycoside nephrotoxicity cascade, which occurs during exposure to low therapeutic doses of aminoglycosides. It is important to note that there is a threshold for each event; once this is reached it can induce the next event. For example, acute tubular necrosis develops only after the degree of focal necrosis outweighs the compensatory regeneration. (Reproduced from Tulkens, 1986. © Elsevier.)

5.4.2 β-Lactam Antibiotics

The β-lactam antibiotics include the penicillins, cephalosporins, carbapenems and several structurally related compounds. At least two cephalosporins (cephaloridine and cephaloglycin) and a carbapenem (imipenem) have proved to be highly nephrotoxic, while several other cephalosporins and carbapenems have mild to moderate nephrotoxicity.

The cephalosporins have two side-group substituents on the β-lactam structure, designated R_1 and R_2 (**Figure 10**). Those that are nephrotoxic do not share common or even similar R_1 or R_2 groups, although no cephalosporin with $R_2 = H$ is nephrotoxic. One common feature of the nephrotoxic cephalosporins is a comparatively unstable bond between the β-lactam ring and the R_2 substituent, which favours release of the R_2

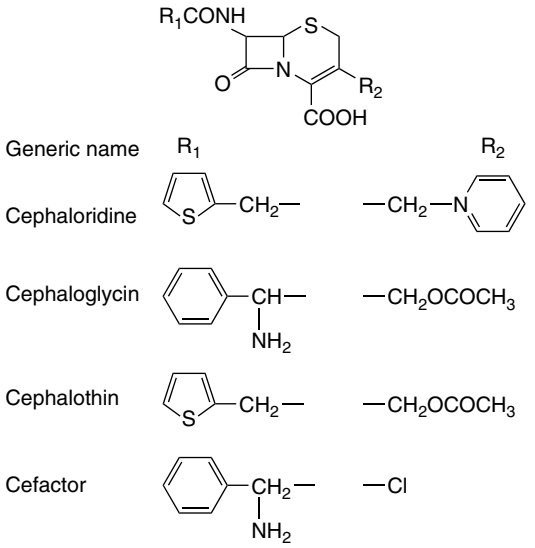

Figure 10 Structure of some cephalosporin antibiotics.

group. The acylating potential of the leaving group is an important factor in determining nephrotoxicity (Tune, 1986; 1997).

Cephaloridine causes renal tubular injury in both experimental animals and man which is characterized by a decreased glomerular filtration rate, glycosuria, enzymuria and proteinuria. These changes are frequently accompanied by histological evidence of necrosis to the proximal convoluted tubule (Silverblatt *et al*., 1970). Cephaloridine accumulates in the renal cortex to a much greater extent than in other organs (Wold and Turnipseed, 1980; Tune, 1986) and the extent of the accumulation is species dependent. Following administration to rabbits, guinea pigs and rats, the renal cortical cephaloridine concentration was highest in rabbit and lowest in rat. These findings parallel the susceptibility to nephrotoxicity.

Many cephalosporins are substrates for the organic anion transport system (OATs). A range of cephalosporins dose-dependently inhibit organic anion uptake into cells stably expressing human OATs and rat OAT2 (Takeda *et al*., 2002; Khamdang *et al*., 2003). Human OAT1, OAT2 and OAT3 are located on the basolateral membrane of the proximal tubule, while human OAT4 and rat OAT2 are located on the brush-border membrane. Cephaloridine decreases the viability of cells stably expressing human OAT1, OAT2, OAT3 and OAT4 and the cytotoxicity can be prevented by probenecid, except in the cells expressing OAT2 (Khamdang *et al*., 2003). Competitive inhibition of OATs by probenecid in the rabbit protects against the effects of cephalosporins (Tune and Hsu, 1990). Some cephalosporins, such as ceftizoxime and cefazolin, require ATP for transport and are substrates for the multidrug resistance-associated protein 4 (MRP4). Studies in MRP4 knockout mice have shown higher concentrations of the antibiotics in the kidney, indicating a role for this transporter, as well as OATs in the tubular secretion of some cephalosporins (Ci *et al*., 2007). Thus, not only transport into a renal cell, but also its rate of efflux into the tubular fluid is an important factor in determining the toxicity. With different β-lactams, the renal concentration can vary by several orders of magnitude and it is the area under the concentration–time curve (AUC) in the tubular cell that is important with regard to toxicity. For example, β-lactams that are rapidly and efficiently transported across the basolateral membrane and then rapidly transported from the cell into the tubular lumen have comparatively low AUCs—for example, cephalothin and cefaclor. Lower rates of secretion can be caused either by restricted movement from the cell into the tubular lumen giving very high AUCs (e.g. cephaloridine) or by little or no secretory transport into the cell, resulting in very low intracellular antibiotic concentrations (e.g. ceftazidime). As a consequence of these widely different intracellular AUCs, cephaloridine is very toxic and ceftazidime nontoxic to the kidney (Tune and Hsu, 1990).

The nephrotoxic β-lactams share two important properties, one or both of which are lacking in the nontoxic β-lactams (Tune, 1986; 1997). The first, as discussed above, is the ability to concentrate within cells in the proximal tubule and the second is their acylating potential. For example, the nephrotoxic β-lactam cephaloglycin covalently binds to proteins within renal tubular cells to a far greater extent than do the nontoxic β-lactams, such as cephalothin (Browning and Tune, 1983). Consistent with this is the finding that cephaloridine depletes glutathione levels in the renal cortex (Kuo *et al*., 1983). Prior treatment with agents that deplete glutathione will potentiate the nephrotoxicity of cephaloridine, which suggests that glutathione plays a protective role by scavenging the acylating moiety (Kuo and Hook, 1982). It has been postulated that cephaloridine can generate superoxide anion via a redox cycle, catalysed by NADPH–cytochrome P450 reductase (Kuo *et al*., 1983; Goldstein *et al*., 1986). The superoxide anion formed ultimately leads to lipid peroxidation (Cojocel *et al*., 1985), and the consequent oxidation of reduced glutathione in the renal cortex (Kuo *et al*., 1983). In support of the lipid peroxidation hypothesis are the findings that animals fed diets deficient in vitamin E or selenium are more susceptible to the nephrotoxicity of cephaloridine. The lipid peroxidative injury mechanism has been shown to be limited mainly to cephaloridine.

Several lines of study suggest that the toxic cephalsporins and imipenem produce their injury by an action on mitochondria: (i) respiration is reduced in mitochondria isolated from animals dosed with the nephrotoxic β-lactams; (ii) the mitochondrial respiratory toxicity is an early event occurring 0.5–1 hour after administration of a single dose; (iii) it is associated with a marked

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

depletion of cortical ATP by 1.5 hours and (iv) it precedes the first indications of ultrastructural damage by five hours. The resulting lesion resembles that produced by ischaemic injury to the kidney (Tune, 1986). Subsequent studies have indicated that cephaloridine can selectively acylate and inactivate the transport systems that carry anionic substrates into the mitochondrial matrix (Tune *et al*., 1988; 1989; Tune and Hsu, 1990). Cephaloridine also inhibits mitochondrial accumulation of carnitine and its fatty acyl esters (Tune and Hsu, 1994), however cephalosporins which lack structural homology with cephaloridine, and hence carnitine, have no effect on mitochondria or the transport of carnitine or acylcarnitine (Tune, 1997). Cephaloridine also inhibits mitochondrial cytochrome C oxidase (Kiyomiya *et al*., 2002), and enzymes involved in glutamine metabolism (Guitton *et al*., 2005).

5.5 Industrial Chemicals

5.5.1 Chloroform

Chloroform is both hepatotoxic and nephrotoxic in most mammalian species, including man (Pohl, 1979; Davidson *et al*., 1982). The magnitude of chloroform-induced nephrotoxicity varies with species, and in mice there are unique sex and strain differences. Male ICR (imprinting control region) mice are susceptible to chloroform-induced renal injury, while female mice are resistant (Smith *et al*., 1983; 1984). The renal lesions induced in male mice by acute doses of chloroform include swelling of the tubular epithelium, increased renal weight, marked necrosis of the proximal tubular epithelium and the presence of tubular casts (Hewitt, 1956). Changes in renal function include glucosuria, proteinuria, an elevation of blood urea nitrogen and a decreased secretion of organic anions and cations (Plaa and Larson, 1965; Kluwe and Hook, 1978; Rush *et al*., 1984).

The mechanism of chloroform-induced nephrotoxicity has recently been shown to be similar to that established in the liver—namely generation of phosgene (see Smith, 1986, for a review). Studies with renal cortical slices from rats (Paul and Rubinstein, 1963) and rabbits (Bailie *et al*., 1984), and renal microsomes from male, but not female, mice (Smith and Hook, 1984) have demonstrated that [^{14}C]-chloroform is metabolized to [$^{14}CO_2$], a known degradation product of phosgene. Furthermore, studies in male mouse renal homogenates showed that phosgene can be trapped by two molecules of glutathione to form diglutathione-dithiocarbonate, which undergoes further metabolism to 2-oxothiazolidine-4-carboxylic acid (OTZ) (Branchflower *et al*., 1984; Pohl *et al*., 1984). Administration of chloroform to male mice causes renal glutathione depletion (Branchflower *et al*., 1984), which suggests that phosgene is also formed *in vivo*. The metabolism of chloroform requires NADPH and oxygen and can be inhibited by carbon monoxide and metyrapone (Smith and Hook, 1984). Thus, in the kidney, chloroform can undergo oxidative dechlorination catalysed by cytochrome P450 2E1 (Bailie *et al*., 1984) to give phosgene. This can covalently bind to nucleophiles (glutathione or cellular macromolecules) at or near the site of generation and cause cellular injury.

The marked sex and strain difference in chloroform-induced nephrotoxicity in the mouse appears to be related to the rate of metabolism via cytochrome P450 (Pohl *et al*., 1984). The concentration of cytochrome P450 is about fivefold greater in the kidneys of male as compared with female mice (Smith *et al*., 1984). Castration of male mice converted their pattern of cytochrome P450 expression to that seen in females (Henderson *et al*., 1990) and reduced their susceptibility to chloroform (Smith *et al*., 1984). Similarly, testosterone pretreatment of female mice resulted in a suppression of the female cytochrome P450 profile and induction of the male pattern (Henderson *et al*., 1990), thus rendering them susceptible to the nephrotoxic effects of chloroform (Smith *et al*., 1984). These findings, plus those of Clemens *et al*. (1979), suggest that the androgen-induced renal susceptibility to chloroform is mediated via the androgen receptor, which may control the expression of cytochrome P450 genes. Confirmation that metabolism of chloroform in the mouse kidney is responsible for the toxicity comes from elegant studies using mice, where cytochrome P450 reductase has been specifically deleted from the liver (Fang *et al*., 2008). Mice with deleted hepatic cytochrome P450 reductase were more sensitive to chloroform-induced nephrotoxicity compared to wild-type mice, indicating renal metabolism of chloroform is responsible for the nephrotoxicity *in vivo*.

In other species, the primary target organ for chloroform is the liver, with nephrotoxicity being either absent or only mild (Kluwe, 1981). This suggests that perhaps the cytochrome P450 which can metabolize chloroform to phosgene is either absent or present in low concentrations in the kidney of these species. Following chronic low-level exposure to chloroform, an increased incidence of renal tumours has been reported in male rats and, in one study, in male mice (see Davidson *et al*., 1982). The mechanism of renal carcinogenicity is thought to result from cytotoxicity and compensatory cell proliferation in the proximal tubules (Larson *et al*., 1994; 1995; Golden *et al*., 1997).

5.5.2 Haloalkenes

Hexachloro-1,3-butadiene (HCBD) is a byproduct formed during the manufacture of chlorinated solvents. The kidney appears to be the primary target for HCBD toxicity in rats, mice and other mammalian species (Lock, 1988). In the rat HCBD produces a well-defined

lesion in the pars recta of the proximal tubule, the earliest morphological changes occurring in the mitochondria (Ishmael *et al*., 1982). The morphological changes are associated with renal functional impairment such as glucosuria, proteinuria and loss of concentrating ability (Lock, 1988).

Treatment of rats with inducers or inhibitors of hepatic and/or renal cytochrome P450 prior to HCBD administration had little or no effect on the nephrotoxicity, indicating that activation of HCBD by cytochrome P450 was not responsible. HCBD administration to male rats causes a depletion of hepatic, but not renal, glutathione, studies *in vitro* with rat liver microsomes and cytosol indicated that HCBD underwent direct conjugation with glutathione to form *S*-(1,2,3,4,4-pentachloro-1,3-butadienyl) glutathione (PCBD-GSH) (Wolf *et al*., 1984). Administration of PCBD-GSH, or its further metabolites, the cysteine conjugate (PCBD-CYS) or mercapturate (PCBD-NAC), or bile from a HCBD-treated rat, all produced necrosis to the pars recta of the proximal tubule, identical to that seen with HCBD (Nash *et al*., 1984; Ishmael *et al*., 1986). These data suggest that HCBD undergoes conjugation with glutathione in the liver, and is then eliminated in bile. In the bile and gastrointestinal tract it can undergo further metabolism to PCBD-CYS. Following enterohepatic circulation, it may be delivered unchanged to the kidney or may be *N*-acetylated in the liver prior to renal uptake (**Figure 11**). Metabolism of PCBD-GSH may also occur in the brush border of proximal tubular cells to afford PCBD-CYS, prior to renal uptake. For more detail on the intraorgan metabolism of glutathione and of HCBD-derived glutathione conjugates see Dekant *et al*. (1990), Commandeur *et al*. (1995) and Lash (1997).

The susceptibility of the proximal tubule to glutathione-derived conjugates of HCBD appears to be related to their ability to accumulate in that part of the nephron. PCBD-NAC appears to enter proximal tubular cells via the OAT system (Lock *et al*., 1986; Pombrio *et al*., 2001) and treatment of rats with probenecid completely prevents the accumulation and nephrotoxicity of HCBD or PCBD-NAC (Lock and Ishmael, 1985). Once accumulated within the cell, PCBD-NAC undergoes deacetylation to PCBD-CYS and then becomes covalently bound to renal macromolecules (**Figure 11**). The enzyme responsible for the activation of PCBD-CYS, and indeed other halolkene cysteine conjugates, is cysteine conjugate β-lyase. Metabolism of cysteine conjugates by this enzyme results in the formation of pyruvate, ammonia and an electrophilic mercaptan moiety, which will readily react with thiols (glutathione) and intracellular proteins (see reviews by Cooper *et al*., 2002; Anders, 2004). These latter events are believed to account for the cytotoxicity and carcinogenicity of HCBD. The critical proteins with which the reactive moiety interacts have not been identified, but PCBD-CYS impairs mitochondrial function *in vitro* (Jones *et al*., 1986; Schnellmann *et al*., 1989a), which leads to changes in mitochondrial membrane potential and intracellular calcium levels. Morphological evidence suggests that the mitochondria are early markers of renal damage (Ishmael *et al*., 1982). The localization of cysteine conjugate β-lyase in the mitochondria, as well as the cytosol (Stevens, 1985; Lash *et al*., 1986), plus the recent finding of a high-molecular-weight cysteine conjugate β-lyase with strong activity in the pars recta of the rat nephron, as well as in mitochondria (Abraham *et al*., 1996; Kim *et al*., 1997), may explain the selective localization. A sulfoxide metabolite of the mercapturate of HCBD has been identified in rat urine following administration of HCBD and studies with this metabolite showed it was cytotoxic to kidney cells *in vitro*, and, further, that inhibition of cysteine conjugate β-lyase did not afford any protection (Birner *et al*., 1998). Administration of the sulfoxide metabolite of the mercapturate of HCBD to rats also

produced nephrotoxicity, indicating a possible role for a β-lyase-independent mechanism of renal toxicity (Birner *et al*., 1998).

Several halogenated chemicals undergo metabolism to form glutathione conjugates which can then be processed to cysteine conjugates: examples include trichloroethylene to *S*-1,2-(dichlorovinyl)-L-cysteine, tetrachloroethylene to *S*-1,1,2-(trichlorovinyl)-L-cysteine and tetrafluoroethylene to S-1,1′,2,2′-(tetrafluoroethyl)-L-cysteine. It has also been shown that certain anaesthetics undergo degradation with the bases in the carbon dioxide absorbents in the anaesthesia circuit; examples include trichloroethylene to dichloroacetylene, halothane to 2-bromo-2-chloro-1,1-difluoroethylene and sevoflurane to 2-(fluoromethoxy)-1,1,3,3,3-pentafluoro-1-propene (Compound A). These degradation products form glutathione conjugates, which are then processed to cysteine conjugates: dichloroacetylene to *S*-1,2-(dichlorovinyl)-L-cysteine and halothane to *S*-(2-bromo-2-chloro-1,1-difluoroethyl)-L-cysteine, while sevoflurane forms diastereoisomers, *S*-[2-(fluoromethoxy)-1,1, 3,3,3-pentafluoropropyl]-L-cysteine and *S*-[2-(fluoromethoxy) -1,3,3,3-tetrafluoro-1-propenyl]-L-cysteine. These halogenated cysteine conjugates are all substrates for renal cysteine conjugate β-lyase and result in renal injury (see Odum and Green, 1984; Dekant *et al*., 1986; Green *et al*., 1997; Anders, 2004; 2005; 2008).

5.5.3 Petroleum Hydrocarbons

Acute exposure to unleaded petrol and a variety of light hydrocarbons present in petrol produces a nephropathy in male rats characterized by: (i) an excessive accumulation of protein (hyaline droplets) in epithelial cells of the proximal tubule, (ii) accumulation of casts at the corticomedullary junction and (iii) evidence of mild tubular regeneration (Swenberg *et al*., 1989). This nephropathy only occurs in male rats; female rats and mice of either sex do not show any renal pathology. A number of chemicals present in unleaded petrol when tested alone have been shown to produce the nephropathy (Halder *et al*., 1985) and in particular 2,2,4-trimethylpentane and decalin have been used as model compounds. Certain other industrial chemicals (1,4-dichlorobenzene, isophorone), natural products (d-limonene) and pharmaceuticals (levamisole) also produce this male-rat-specific nephropathy. Chronic exposure of male rats to unleaded petrol, 1,4-dichlorobenzene, isophorone or d-limonene ultimately leads to the induction of a low incidence of renal adenomas and carcinomas (Swenberg *et al*., 1989; Hard and Whysner, 1994; Lehman-McKeeman, 1997; Lock and Hard, 2004).

Studies on the mechanism of pathogenesis have shown that the protein which accumulates in the proximal tubular cells is α_{2u}-globulin, a low-molecular-weight protein (18 700 daltons) that is synthesized in the liver of adult rats and is freely filtered at the glomerulus (see Swenberg *et al*., 1989; Lehman-McKeeman, 1997 for references). Female rats excrete less than 1% of the α_{2u}-globulin that male rats excrete (Vandoren *et al*., 1983). The chemical itself, or a metabolite, has been shown to bind reversibly to α_{2u}-globulin (Lock *et al*., 1987; Lehman-McKeeman *et al*., 1989; Borghoff *et al*., 1991; Lehman-McKeeman and Caudill, 1992) and this chemical–protein complex is then thought to be taken up by the proximal tubular cells (primarily in the S_2 segment) by endocytosis. These complexes appear to be quite resistant to, or impair, lysosomal degradation, which leads to accumulation as polyangular droplets. Lysosomal overload is thought to lead to individual cellular necrosis, which is followed by repair and regeneration (Short *et al*., 1989; Dietrich and Swenberg, 1991b). It has been suggested that a sustained increase in renal cell proliferation can promote initiated cells to form preneoplastic foci and lead to renal neoplasia (Swenberg *et al*., 1989). Strong support for this hypo thesis comes from studies in the National Cancer Institute (NCI) Black–Reiter strain of male rat which cannot synthesize α_{2u}-globulin and is refractory to the nephrotoxicity and carcinogenicity (Ridder *et al*., 1990; Dietrich and Swenberg, 1991a; 1991b). Recent studies with decalin, propylene glycol mono-*t*-butyl ether and Stoddard solvent IIC indicated that the relationship between the extent of α_{2u}-globulin nephropathy and cell proliferation following 90 days exposure does not correlate well with the extent of renal tumour incidence at two years, the latter being lower than expected. The tumour incidence does, however, show some correlation with the extent of α_{2u}-globulin nephropathy-associated linear mineralization of the papilla and with the severity of chronic nephropathy (Doi *et al*., 2007). These findings do not undermine the hypothesis of a male-rat-specific phenomenon, but do suggest that in addition to the renal injury caused by the accumulation of the male-rat-specific protein, other changes occurring in the kidney following chronic exposure may also contribute to renal tumour formation. Other species that do not synthesize the protein do not develop the toxicity. Man does not synthesize α_{2u}-globulin and therefore it is reasonable to conclude that α_{2u}-globulin nephropathy is unique to male rats. This is supported by detailed studies with other human proteins of the same superfamily as α_{2u}-globulin, which do not bind the xenobiotics or their metabolites (see Lehman-McKeeman, 1997). These findings provide compelling evidence that α_{2u}-globulin nephropathy is unique to male rats and unlikely to be relevant to humans (**Figure 12**), and that chemicals such as d-limonene are unlikely to be carcinogens in humans (Hard and Whysner, 1994).

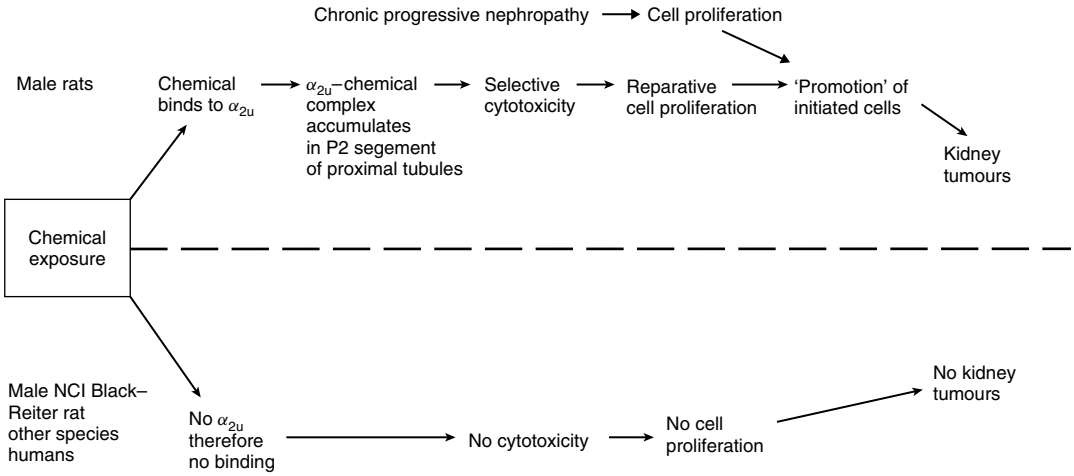

Figure 12 Proposed mechanisms for α_{2u}-globulin chemically induced renal tumours in male rats and its relevance to humans and other animals. The nephrotoxic chemical or metabolite reversibly binds to α_{2u}-globulin, altering the structure of the protein and decreasing its lysosomal catabolism in S_2 segment renal epithelial cells. This results in α_{2u}-globulin accumulation, lysosomal overload and cytotoxicity. Sustained increases in compensatory cell proliferation associated with chronic exposure result in greater 'fixation' of spontaneous DNA change and promotion of such initiated cells to renal tumours. Chronic progressive nephropathy may also contribute to the cell proliferation and promotion of initiated cells. Absence of the protein (NCI Black–Reiter rat) or absence of binding of the chemical or its metabolites to human proteins of this family means renal cell injury does not occur, along with all the downstream consequences.

5.6 Other Chemicals

It is not possible in this chapter to review all chemicals that cause renal injury; there are, however, some others worthy of note and the reader is are referred to recent reviews. Balkan endemic nephropathy is a chronic tubulointerstitial disease described only in some rural parts of southeastern Europe (Stefanovic and Radovanovic, 2008). The basis for this disease is not understood, but certain mycotoxins have been implicated, such as ochratoxin A, which is a potent renal carcinogen in the rat (Mally *et al*., 2007). The herbal drug aristolochic acid, derived from *Aristolochia* spp., has been associated with the development of a novel nephropathy and urothelial cancer in humans (Arlt *et al*., 2002) and there is increasing evidence to indicate that aristolochic acid is a significant risk factor in Balkan nephropathy (Arlt *et al*., 2007; Grollman *et al*., 2007; Shibutani *et al*., 2007).

Paracetamol (*N*-acetyl-4-aminophenol; acetaminophen) is a widely used analgesic and antipyretic drug. It is the major active metabolite of phenacetin, which has been used in analgesic mixtures and implicated in the aetiology of analgesic nephropathy (Bach and Bridges, 1985; Schnellmann, 1998; De Broe, 2004). Paracetamol at high doses also causes renal tubule necrosis in experimental animals and humans. The mechanism of toxicity is believed to be analogous to that in the liver, namely formation of *N*-acetyl-*p*-benzo-quinoneimine, which reacts with glutathione (**Figure 13**), once glutathione becomes depleted it will then acylate proteins, causing renal tubule injury (Josephy, 2005; Mazer and Perrone, 2008). Other mechanisms have also been proposed, such as the deacetylation of paracetamol to produce 4-aminophenol, which is about five times more nephrotoxic than paracetamol itself (see Fowler *et al*., 1991 and references therein). 4-Aminophenol can undergo one-electron reduction and hydrogen abstraction to form the 4-aminophenoxy radical, which in turn may undergo further oxidation to form 4-benzoquinoneimine, which will react with glutathione and acylate proteins (**Figure 13**). Paracetamol-glutathione-derived conjugates may also play a role in renal injury as the cysteine conjugate of paracetamol has been shown to deplete renal, but not hepatic glutathione and further that prior administration of cysteine conjugate potentiates the nephrotoxicity of a subsequent dose of paracetamol (Stern *et al*., 2005).

Bromobenezene has been shown to undergo metabolism to form glutathione conjugates, which are nephrotoxic see Monks and Lau (1997), Lau and Monks (1997), Van Vleet and Schnellmann (2003).

Ethylene glycol is known to cause renal injury in experimental animals and humans; the toxicity is ascribed to the terminal metabolite oxalic acid, which precipitates in the tubule lumen in the form of calcium oxalate crystals, causing physical injury to the renal tubule cells (Corley *et al*., 2005).

Radiological procedures requiring intravascular administration of iodinated contrast media is becoming a common source of nephropathy, and studies to try and ameloriate this condition and to identify risk factor is of increasing importance (Kaperonis *et al*., 2004; Pannu

et al., 2006; Toprak, 2007). The possible mechanism whereby injury occurs is unclear, but hyperosmolality and direct cytoxicity of some of these agents to renal cells in culture as been reported (Heinrich *et al*., 2005).

Allergic Asthma and Rhinitis: Toxicological Considerations

Jean F. Regal

CONTENTS

1 INTRODUCTION

1.1 Definitions

Toxicity to the immune system can involve suppression of the normal immune response with a reduced ability to defend against pathogens and cancerous cells. Conversely, immunotoxicity can involve immunoenhancement, leading to reactions against self (autoimmunity) or reactions to normally innocuous substances (hypersensitivity). In the case of hypersensitivity, exposure to a xenobiotic results in the initiation of a specific immune response leading to sensitization with the potential for immune-mediated tissue damage (hypersensitivity) and the normal sequel of inflammation. For the purposes of this contribution, we will use the terms allergy and hypersensitivity interchangeably as requiring a specific immune response, whether humoral or cell-mediated immunity is involved. By strict definition, however, the term allergy is defined as a 'hypersensitivity reaction initiated by specific immunological mechanisms', whereas the term hypersensitivity does not require involvement of a specific immune response (Johansson *et al.*, 2004).

Allergic reactions in general are divided into two phases: (i) The induction or sensitization phase, characterized by immune system recognition of allergen as foreign, resulting in generation of allergen-specific antibody and/or allergen-specific T lymphocytes. (ii) The effector phase, characterized by allergic symptoms due to allergen exposure of a sensitized individual. The induction phase is responsible for the latent period between initial allergen exposure and the appearance of allergic symptoms in the effector phase. The presence of a latent period is evidence that a specific immune response is required.

1.2 Types I–IV Hypersensitivity

In the 1950s, Gell and Coombs divided allergic reactions into four basic mechanistic types; Types I–III were transferred by serum, that is, antibody mediated, and Type IV required transfer of lymphocytes to transfer the reactivity, that is, cell-mediated immunity. With the explosion of information in immunology, this classification has expanded to include three subdivisions under the Type IV hypersensitivity reaction: Th1 (T-helper Type 1), Th2

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(T-helper Type 2) and CD8 (CD—cluster of differentiation) (Janeway *et al*., 2008). Clinically, most allergic diseases involve a combination of these mechanisms to describe the pathophysiology of the disease.

Type I hypersensitivity (immediate hypersensitivity) is mediated by cytophilic antibody (IgE in human), bound to Fc (crystallizable fragment of immunoglobulin) receptors on mast cells and basophils. Atopic is a term referring to those individuals with a genetic predisposition to produce IgE (immunoglobulin E) antibody in response to ordinary exposure to allergens commonly encountered in the environment. Allergen crosslinking of IgE antibody bound to Fc receptors leads to an explosive release of mediators within minutes of exposure. This includes mediators preformed and secreted from the mast cell, such as histamine, as well as those immediately synthesized (arachidonate metabolites, platelet activating factor, etc.). These mediators are of primary importance in the immediate allergic reaction. In addition, the release of numerous cytokines, chemokines and adhesion factors from mast cell activation leads in part to the delayed reactions some 6–10 hours later. Type I hypersensitivity is a major mechanism leading to the acute symptoms of allergic asthma and allergic rhinitis.

Type II hypersensitivity is mediated by IgG (immunoglobulin G) antibody directed towards cell-surface antigens (e.g. drugs or haptens bound to a cell surface). The IgG antibody leads to clearance of the cell by Fc receptors on macrophages or to lysis of the cell in conjunction with complement. Haemolytic anaemia and thrombocytopaenia are examples of pathological reactions caused by Type II hypersensitivity.

In Type III hypersensitivity, specific antibody formed in response to soluble antigens leads to the formation of immune complexes. Small immune complexes formed in antigen excess can lead to deposition of the immune complexes in tissues, along with complement activation and neutrophil infiltration. Hypersensitivity pneumonitis or allergic alveolitis is an example of a Type III hypersensitivity reaction in the lung leading to compromised lung function (Ismail *et al*., 2006). Mechanistically, it is differentiated from Type I hypersensitivity in its more delayed time course in days and the lack of participation of IgE.

Type IV hypersensitivity is referred to as cell-mediated immunity because it requires the transfer of T lymphocytes to mimic the pathology. Currently, Type IV hypersensitivity is divided into pathology mediated by CD4+ Th1, CD4+ Th2 and CD8+ cells (Janeway *et al*., 2008). CD4+ cells recognize extracellular antigens presented in the context of major histocompatibility complex (MHC) II molecules, with subsequent activation of macrophages, chemokine and cytokine release and inflammation characterized by neutrophil influx. Mosmann *et al*. (1986) described differentiation of two primary types of CD4+ cells, Th1 and Th2. Exposure to allergen can lead to polarized immune responses of either the Th1 or Th2 type, depending on the extracellular milieu. IL-4 (IL—interleukin) and IL-13 favour the differentiation of Th2 lymphocytes, and IL-12 favours differentiation of Th1 lymphocytes. Th1 lymphocytes are associated with contact hypersensitivity reactions in the skin, and Th2 lymphocytes favour IgE production by the B cell, leading to Type I hypersensitivity reactions. CD8+ T cells will attack cells with modified intracellular proteins on their cell surface, presented in the context of MHC I antigens. Delayed type hypersensitivity refers to the Th1 and CD8 responses that can take 24–48 hours to develop after the individual is sensitized. As knowledge of immunology increases, the role of the inflammatory Th17 cell and Treg cells in immune-mediated disease will also be revealed.

This classification of allergic reactions is only intended to act as a guide or outline for the determination of mechanisms that are operating clinically. Allergic disease in response to either chemical or protein allergens can occur using any of these mechanisms, and most disease states are some combination of these hypersensitivity types. Thus, they should not be considered mutually exclusive, but should be used as a guide to focussing mechanistic studies and therapeutic interventions. The remainder of this section will focus on allergic asthma and allergic rhinitis as examples of allergic disease that can be caused by toxicants and that involve both Type I and Type IV allergic reactions in the acute and chronic stages, respectively (**Figure 1**).

2 ALLERGIC ASTHMA

2.1 Description and Clinical Features

Asthma accounts for approximately 5000 deaths per year in the United States, a figure that is well below the ~2 25 000 deaths caused by chronic obstructive pulmonary disease (National Heart Lung and Blood Institute, 2007). However, the true cost of asthma is in morbidity of the disease. In the USA, 4–8% of the population has asthma, and the toll on quality of life, missed work and missed school days is tremendous. The prevalence in children is greater than in adults and the cause of the increased prevalence over the last 20 years is unclear. Besides environmental causes, asthma can also be caused by workplace exposures (Bernstein *et al*., 2006). Estimates indicate that approximately 9–15% of adult asthma is due to occupational exposure (Mapp *et al*., 2005). Primary and secondary prevention measures to limit allergen exposure and prevent sensitization and symptoms, respectively, have met with variable success (Institute of Medicine, 2000). Asthma cannot be cured, but with insight into mechanisms of the disease, our attempts to control it therapeutically have improved.

Asthma is a lung disorder characterized by cough, wheezing, chest tightness and breathlessness. The effector

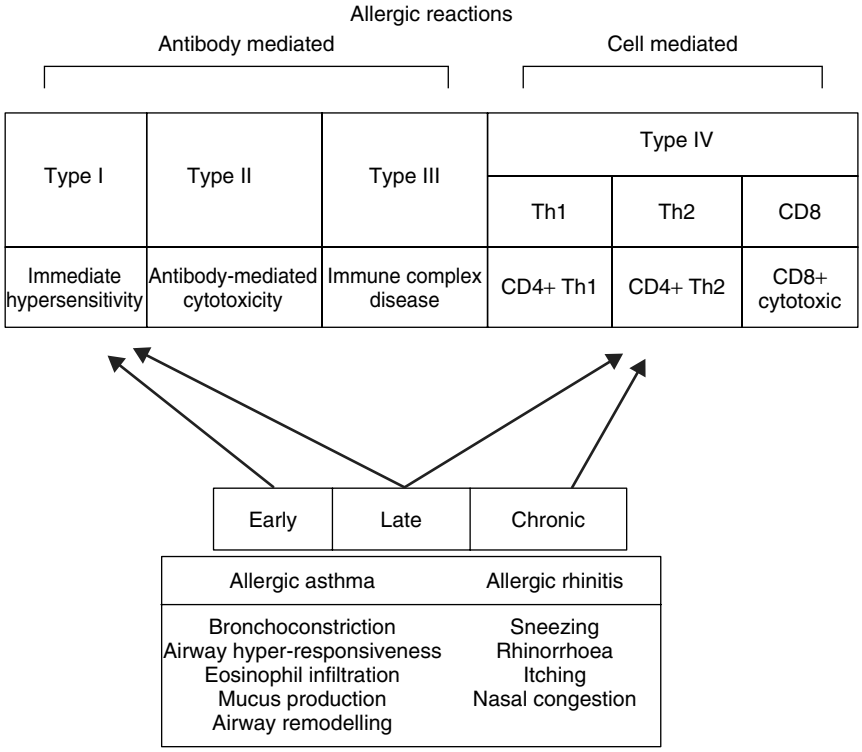

Figure 1 Allergic reactions are classified as Type I–IV, with most disease states involving a combination of mechanisms. Allergic asthma and rhinitis involve mechanisms described in Type I and Type IV hypersensitivity, depending on the time after allergen exposure and the allergen. Involvement of Th1 and CD8+ cells may also contribute to allergic asthma, depending on the allergen and severity of the disease.

phase of asthma is characterized by reversible airway obstruction, airway hyper-responsiveness, inflammation in the lung characterized by eosinophilia, mucus production and airway remodelling (National Asthma Education and Prevention Program, 2007). Numerous cell types are involved, including immune and inflammatory cells, as well as fibroblasts, airway epithelial cells and airway smooth muscle cells (Holgate, 2008). Asthma is a heterogeneous lung disorder with some patients presenting with all of the above-mentioned components, and others presenting with only a subset. Multiple asthma phenotypes have been described and Wenzel (2006) has categorized them in physiological terms (severe, treatment resistant), by inflammatory type (eosinophilic or neutrophilic) or by trigger (allergic, occupational, aspirin induced, exercise induced). Not all asthma is triggered by allergen exposure. Asthma is divided into allergic (extrinsic) and nonallergic (intrinsic) asthma, and estimates indicate that anywhere from 50 to 80% of asthma is triggered by allergen (Arbes *et al*., 2007). The focus of this chapter will be allergic asthma, but regardless of whether the asthma trigger is allergen or not, symptoms of asthma are the same and pharmacologic treatment is similar.

Development of asthma is not limited to inhalation exposure to allergen. The immune system is readily accessible, and sensitization by routes such as the gastrointestinal tract, bloodstream or skin can also result in allergic asthma. For example, animals sensitized by dermal exposure with trimellitic anhydride (Zhang *et al*., 2004) or toluene diisocyanate (Farraj *et al*., 2007) develop increased airway hyper-responsiveness, a symptom of asthma, when challenged with allergen by the respiratory route. Even dermal exposure with diisocyanates in the sensitization and challenge phase results in asthma symptoms, that is, airway hyper-responsiveness in the lung (Selgrade *et al*., 2006). Individuals with food allergy can respond with an asthmatic reaction to ingestion or even inhalation of the offending substance (James and Crespo, 2007). In addition, these individuals will have a positive skin-prick test response to the allergen. Thus, the immune system is sensitized and the location of the effector response is dictated by many factors, including the site of allergen challenge.

Allergens are often classified as respiratory allergens or contact allergens. This terminology does not dictate the route of exposure but is intended to reflect whether allergen exposure will result in respiratory pathology (respiratory allergen) or dermal pathology (contact allergen), regardless of route of exposure in the sensitization or challenge phase. A number of allergens can clearly cause both respiratory tract and dermal pathology. For example, latex exposure by skin and/or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat062
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

inhalation can result in skin or respiratory tract pathology in different individuals (Hamann *et al*., 2004; Nettis *et al*., 2004; Vandenplas, 1995). Dental workers exposed to methacrylates by inhalation or by skin contact can develop asthma and skin hypersensitivity (Dearman *et al*., 2007; Jaakkola *et al*., 2007). Human exposure to acid anhydrides and diisocyanates primarily results in asthma (Bardana, 2008; Zeiss *et al*., 1977; 1990; 1992), but in animal models, these molecules can cause both skin and respiratory tract symptoms (Herrick *et al*., 2003; Lauerma *et al*., 1997). Reports of allergic contact dermatitis to diisocyanates have increased as uses for the compounds have expanded and occupational dermal exposure has increased (Bello *et al*., 2008; Goossens *et al*., 2002; Stingeni *et al*., 2008). Multiple factors dictate the allergenicity of xenobiotics, and predicting substances that result in allergic reactions in the lung and elsewhere is an area of active investigation.

Our focus is allergic asthma. However, there is evidence that many allergens may cause symptoms of asthma by a combination of allergic and nonallergic mechanisms. For example, plicatic acid is a component of Western red cedar (*Thuja plicata*) that activates the complement system resulting in mediators that can cause asthma symptoms (Chan-Yeung *et al*., 1973). However, it is also clear that plicatic acid exposure initiates a specific immune response that is responsible for allergic asthma due to Western red cedar (Chan-Yeung *et al*., 1980). Toluene diisocyanate in general requires a latent period to induce asthma, indicating a specific immune response is required. However, toluene diisocyanate may also cause asthma symptoms in the absence of sensitization by stimulating the release of Substance P and other neuropeptides, as well as inhibiting the enzyme neutral endopeptidase to prolong their actions (Mapp *et al*., 1991; Nadel, 1991; Sheppard *et al*., 1988). Hexamethylene diisocyanate activates peripheral blood monocytes in humans in the absence of a specific immune response, altering gene/protein expression and potentially contributing to a nonallergic component of the diisocyanate respiratory pathology (Wisnewski *et al*., 2008). Trimellitic anhydride exposure initiates a specific immune response in animal models, but trimellitic anhydride–protein conjugates can also activate the complement system in the absence of specific antibody and contribute to asthma-like symptoms (Fraser *et al*., 1995; Larsen *et al*., 2001).

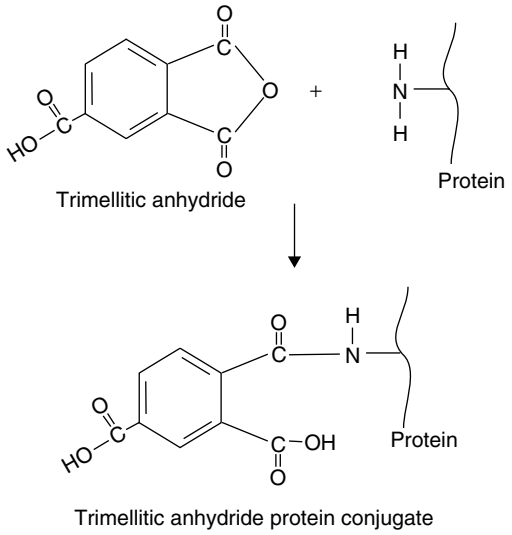

Figure 2 The low-molecular-weight allergen trimellitic anhydride acts as a hapten and reacts with side chains of amino acids, including amino groups, to form a hapten protein conjugate that is recognized by the immune system.

2.2 Sensitization Phase

Both genetics of the individual as well as characteristics of the chemical or protein are important in determining if sensitization occurs and allergic disease develops. For example, not all individuals exposed to ragweed pollen will become sensitized and/or develop allergy symptoms. The properties of chemicals and proteins that determine whether or not they will result in an allergic response are a subject of intense investigation (see **Laboratory Recognition of Potential Xenobiotic Respiratory Sensitizers**). An allergen is defined as an antigen that causes allergic disease (Johansson *et al*., 2004). Development of an allergic response initially requires sensitization or engagement of a specific immune response, and this process differs for low- and high-molecular-weight allergens. In the case of low-molecular-weight allergens, the substance is too small to be recognized by the immune system itself so it must react with a larger molecule, most often a protein, to form a hapten protein complex. As illustrated in **Figure 2**, trimellitic anhydride, a known cause of occupational asthma, reacts with side groups on proteins, including amino groups, to form a hapten protein conjugate. The immune system then responds to the hapten, or to new antigenic determinants formed when the hapten reacts with the protein (Zeiss *et al*., 1980), to initiate a specific immune response and sensitization. A limited study of five chemicals by Hopkins *et al*. (2005) suggests that allergens that cause contact dermatitis via a cell-mediated immune response preferentially react with cellular proteins, whereas substances such as trimellitic anhydride that cause primarily respiratory allergy have a greater tendency to react with extracellular proteins. Thus, the preferred reactivity of low-molecular-weight chemicals with particular proteins is an area of future investigation to predict chemicals that may result in skin vs. respiratory allergy. For protein allergens, recent studies have demonstrated that they are distributed to relatively few protein families and have a limited number of biochemical functions (Radauer *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat062
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2008). A large proportion of the protein allergens have enzymatic or metal ion, lipid or actin binding activity, and these activities may contribute to their allergenicity (Hammad and Lambrecht, 2008; Radauer *et al*., 2008; Vermaelen and Pauwels, 2005).

The lung is exposed to numerous substances with each breath, and inhalation of most foreign substances does not lead to an immune response, that is, a state of tolerance ensues. However, inhalation of some substances results in the bypassing of the normal tolerogenic mechanisms in the lung and establishment of allergic disease. Secondary properties of molecules such as irritancy or enzyme activity have been hypothesized as being important in leading to sensitization by inhalation exposure and ultimately allergic disease (Kheradmand *et al*., 2002; Mapp *et al*., 2005; Radauer *et al*., 2008). Enzymes used in the detergent and food industry are known to cause asthma with inhalation exposure (Kirchner, 2002; Schweigert *et al*., 2000). A major allergenic component of the common environmental allergen house dust mite (Der p 1) has cysteine protease activity and can cleave the tight junction protein occludin, leading to increased permeability of the epithelial barrier and access of the allergen to the dendritic cells for antigen processing and presentation (Janeway *et al*., 2008). Because of secondary signals associated with such molecules, the dendritic cells are activated to migrate to the local lymph node where they present the antigen in conjunction with MHC molecules to a CD4+ T cell (Hammad and Lambrecht, 2008; Vermaelen and Pauwels, 2005), which differentiates into a Th2 type cell and produces Th2 cytokines, IL-4, IL-5 and IL-13. These cytokines influence T cell differentiation and B cell function with the end result that the B cell becomes an IgE antibody-producing cell. In contrast, other allergens such as the protein ovalbumin are taken up by dendritic cells, but the cells are not stimulated to migrate to the local lymph node for presentation to the T cell—a state of tolerance to the inhaled allergen ensues. If exposure to allergens such as ovalbumin occurs in conjunction with a 'danger' signal such as damage to the epithelium, addition of a protease (Kheradmand *et al*., 2002) or stimulation of toll receptors on the epithelium by microbial factors (Eisenbarth *et al*., 2002), then the dendritic cell is stimulated to migrate to the local lymph node to present the antigen and initiate the specific immune response. Low-molecular-weight allergens such as acid anhydrides and isocyanates conjugated to protein are readily recognized as foreign by the dendritic cell. The ability of these molecules to bypass the normal tolerogenic mechanisms may relate to their irritative properties or their ability to cause epithelial disruption and access to the subepithelium.

Sensitization itself is not a guarantee that respiratory symptoms will occur with subsequent allergen exposure. In the detergent industry, a positive skin-prick test indicating sensitization does not require removal of the worker from exposure, or predict that the worker will develop respiratory symptoms (Schweigert *et al*., 2000). In the general population, it is estimated that 30% of the individuals are atopic and produce high concentrations of IgE. However, asthma prevalence in the general population is 10–12%. Thus, atopy is considered a risk factor for the development of asthma (Hammad and Lambrecht, 2008).

2.3 Effector Phase

2.3.1 Clinical Characteristics

In the effector phase of asthma, symptoms are divided into acute and chronic phases. The acute reaction to allergen (**Figure 3**) involves both an early phase (within minutes of allergen challenge) and a late phase (maximizing at 6–12 hours). Chronic asthma can develop over days and is likely the result of persistent and repetitive allergen exposure, with chronic inflammation and long-term changes in the lung, that is, airway remodelling. The late phase may be indistinguishable

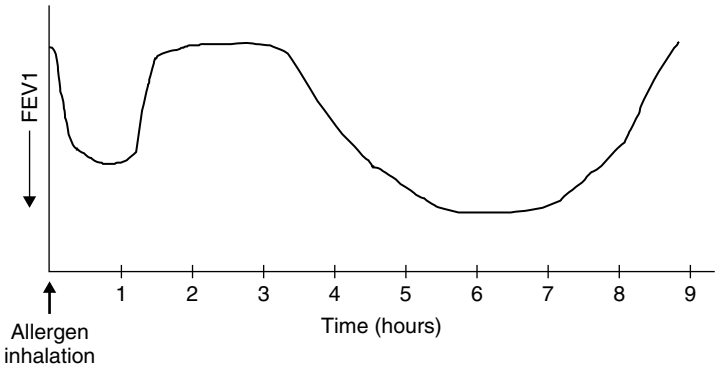

Figure 3 Airway obstruction in allergic asthma—immediate and late-phase reaction. After allergen exposure, airway obstruction occurs in phases in allergic asthma with an immediate phase occurring within minutes and a late phase hours later. Clinically, airflow limitation is measured as the forced expiratory volume in 1 second (FEV1).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat062
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

from the chronic phase, and individuals may present with any combination of phases. The mechanism and mediators for each of these phases have commonalities and differences. The early-phase response is characterized by wheezing and airflow limitation due to allergen challenge, and is generally responsive to therapy with bronchodilating β_2 agonists. The initial bronchoconstriction can resolve and is then followed 6–12 hours later with a late-phase reaction characterized by continued airflow limitation. Airflow limitation in the early phase is primarily due to airway smooth muscle contraction or bronchoconstriction. In the late phase, besides airway smooth muscle contraction, increased mucus production, increased microvascular permeability and swelling of the airway wall secondary to eosinophilic inflammation can also contribute to airflow limitation. In some asthmatics, neutrophilic inflammation predominates. Airway hyper-responsiveness is also a factor in airflow limitation in the late and chronic phases of asthma. Airway hyper-responsiveness refers to an exaggerated airway constriction to known smooth muscle constrictors such as cholinergic agonists and histamine and is expressed as a PC20 (the provocative concentration of agonist that causes a 20% decrease in the forced expiratory volume at 1 second (FEV1)). Asthmatic airways have a lower PC20 for methacholine and respond with significant constriction to concentrations of agonist that have minimal effects on airways from control subjects (National Asthma Education and Prevention Program, 2007). In the chronic allergic inflammation stage of asthma, structural changes can occur, that is, airway remodelling. These changes may make the lung less responsive to the bronchodilating effects of β_2 agonists. Airway remodelling includes thickening of the basement membrane, mucosal oedema, hypertrophied and hyperplastic smooth muscle and subepithelial fibrosis.

Historically, asthma is considered an airway smooth muscle disease, but the current asthma paradigm centres on inflammation with airway obstruction and airway hyper-responsiveness resulting (National Asthma Education and Prevention Program, 2007). The mainstay of therapy is bronchodilating β_2 agonists and inhaled anti-inflammatory steroids. A single agent to target a single mediator (antihistamine, antileukotriene, etc.) has generally been ineffective in treatment of asthma, whether due to low- or high-molecular-weight allergens.

2.3.2 Animal Models

Numerous animal models have been used to study mechanisms of the effector phase of asthma. No animal spontaneously develops asthma, and each species has its advantages and disadvantages (Johnson and Luster, 2006; Zosky and Sly, 2007). In modelling asthma in rodents, we are looking for similarities to the human in both the immune (Mestas and Hughes, 2004) and respiratory system (Finkelman and Wills-Karp, 2008). This is especially difficult in developmental studies of asthma because the immune and respiratory system mature at different times comparing rodents and humans. Optimally an animal model involves cytophilic antibody and mast cells (IgE and IgG1 in mice and guinea pigs), eosinophil infiltration into the lung, increased airway resistance in response to allergen (early and late phase) and increased airway hyper-responsiveness in response to a bronchoconstrictor such as methacholine. Realistically, most animal models assess the eosinophil infiltration into the lung and airway hyper-responsiveness to methacholine days after multiple allergen challenges. In addition, the immediate bronchoconstrictor response may be assessed within minutes of allergen exposure. Monitoring late-phase bronchoconstriction 6–12 hours after allergen challenge has been technically difficult. In addition, attempts to mimic chronic asthma and airway remodelling have met with limited success due to the long-term nature of the experiments. Clearly animal models are meant to predict the pathophysiology in the human, and the usefulness of the animal model is only established with direct testing of the predictions in the human.

Airway hyper-responsiveness is measured clinically by determining the concentration of methacholine that results in a 20% reduction in FEV1. Events in the lung that can result in a reduction in FEV1 include, but are not limited to, narrowing of small and/or central airways or plugging or closure of small airways and alveoli. Thus, airway hyper-responsiveness involves a number of changes in the lung, and has in general been attributed to alterations in airway smooth muscle function. In animal models, different physiological mechanisms, beyond simple airway narrowing, are operative in causing airway hyper-responsiveness (Wagers *et al*., 2007). However, in general, measurement of airway hyper-responsiveness in animal models has concentrated on measuring increased airway resistance in response to methacholine administration (Finkelman and Wills-Karp, 2008). Since airways are the primary site of airflow limitation, a single compartment model to measure increased total lung resistance in a tracheotomized animal is used to reflect increased airways resistance. Other more complex techniques and models have been developed measuring lung impedance to estimate the airway resistance and the tissue resistance contribution to total lung resistance (Wagers *et al*., 2002). Direct measures of airway resistance require control of respiratory frequency and the use of an anaesthetized animal. Development of unrestrained barometric plethysmography allowed use of an unanaesthetized animal to measure the pressure change inside a box as an animal breathes. Analysis of the breathing pattern then generates a dimensionless parameter called enhanced pause (Penh) that reflects changes in inspiratory and expiratory timing. Hamelmann *et al*. (1997) demonstrated that the change in Penh paralleled the increase in airway resistance in adult Balb/c mice, and thus Penh has

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat062
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

been used in numerous studies as an indicator of airway hyper-responsiveness in animal models. However, in a number of instances, Penh changes do not reflect more direct measures of airway resistance and caution needs to be used in over-interpreting the information provided (Bates *et al*., 2004; Finkelman, 2008; Finkelman and Wills-Karp, 2008; Mitzner *et al*., 2007). Penh measures changes in breathing patterns that suggest changes in airway calibre, but it is not a measure of pulmonary mechanics.

2.3.3 IgE and Mast Cell Involvement

As knowledge of immunology has grown, the view of asthma as simply Type I hypersensitivity and mast cells has been replaced by a view of asthma as a combination of Type I hypersensitivity and Th2 Type IV hypersensitivity (**Figure 1**). In general, asthma in humans is associated with increased allergen-specific IgE. The work of Ishizaka *et al*. (1966) was instrumental in establishing the importance of IgE and the mast cell in immediate hypersensitivity reactions. IgE was identified as the important reaginic antibody responsible for transfer of allergic reactions in human skin, in isolated cells and in animal models. IgE binds to Fcε receptors (Fcε–Fc receptor for IgE) on mast cells and basophils. Subsequent crosslinking of IgE molecules by allergen results in a rapid secretion of preformed mediators from granules, including histamine. In addition, arachidonate metabolites are immediately synthesized by the mast cell and released (Liu *et al*., 1990). IgE has a very high affinity for FcεRI on mast cells, basophils and dendritic cells. A lower affinity IgE FcεRII is also present on numerous cell types such as platelets and macrophages and is thought to play an important role in mobilizing a variety of cells and mediators in allergic reactions (Kraft and Novak, 2006). IgE binding to FcεRI and FcεRII is not limited to immune cells. Stimulation of FcεRI and FcεRII on airway smooth muscle cells leads to release of substances that are chemotactic for eosinophils (eotaxin and IL-5) as well as increases in intracellular calcium, suggesting activation of contractile elements (Gounni, 2006). Clear evidence in humans regarding the importance of IgE in asthma comes from the effectiveness of therapy with anti-IgE (omalizumab) in inhibiting both the early and late-phase asthmatic reactions to inhaled allergen as well as benefitting chronic persistent asthma (**Figure 1**; Holgate *et al*., 2005; Strunk and Bloomberg, 2006). However, increases in IgE are not readily apparent in all allergic asthmatics, including asthma initiated by low-molecular-weight allergens such as toluene diisocyanate. Using animal models, the importance of IgE in the asthmatic reaction is also unclear. Systemic anaphylaxis can occur in mice deficient in IgE (Oettgen *et al*., 1994), and passive sensitization experiments indicate that the immediate bronchoconstrictor response to allergen is dependent on allergen-specific IgG1, not IgE (Crosby *et al*., 2002). Numerous studies in mouse models of asthma using transgenic animals and antibody depletion techniques have clarified that different mechanisms are operative depending on the protocol for sensitization and challenge. If mice are sensitized repeatedly by inhalation with ovalbumin, the airway hyper-responsiveness that develops is dependent on IgE and mast cells with minimal IL-13 involvement. However, mice sensitized with ovalbumin with alum adjuvant develop airway hyper-responsiveness that is independent of IgE and largely dependent on the Th2 cytokine IL-13 (Finkelman and Wills-Karp, 2008). As might be predicted by the heterogeneous nature of asthma, multiple mechanisms are likely operative, and differ amongst individuals.

2.3.4 T Cell Involvement

Not all aspects of allergic asthma are explained by IgE and mast cells, and allergic eosinophilia can develop in the lungs of B cell-deficient mice (Korsgren *et al*., 1997). Increasing evidence indicates that T cells, particularly Th2 cells, are also very important for the development of the late and chronic phases of the asthmatic reaction. Th2 lymphocytes are operative both in the sensitization and effector phases of the asthmatic response. In the sensitization phase, allergen exposure can result in a polarized immune response in some individuals, leading to differentiation of CD4+ T cells to the Th2 type. IL-4 and IL-13 favour differentiation to the Th2 phenotype and IL-12 favours differentiation to the Th1 phenotype. Th2 cells produce cytokines such as IL-4, IL-5, and IL-13 that facilitate the production of IgE antibody by the B cell. The factors that dictate whether an immune response develops a polarized Th2 component leading to IgE production and lung pathology is unclear but has revolved around the 'hygiene hypothesis', which suggests that environmental factors limiting exposure to microbial challenges may result in the skewing of the immune response to a Th2 response (National Asthma Education and Prevention Program, 2007). In the effector phase, activation of the mast cell by allergen crosslinking of IgE molecules leads to production of Th2 cytokines by the mast cell, in addition to histamine, platelet activating factor and leukotrienes. All of these mediators play an important role in the ensuing late phase and chronic response (Brusselle *et al*., 1995; Foster and Chan, 1991; Gulbenkian *et al*., 1992; Watson *et al*., 1993). Besides activating mast cells in the effector phase, allergen activates antigen-specific Th2 cells and the elaboration of IL-4, IL-5 and IL-13 (Cousins *et al*., 2008; Larche *et al*., 2003). These CD4 T cell mediators are important in the late phase and chronic response as demonstrated in mouse models using anti-CD4 antibody depletion of T cells (Hogan *et al*., 1998; Larche *et al*., 2003). Evidence also indicates that the number and type of mast cells is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat062
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

under T cell control, with a Th2 phenotype stimulating proliferation of mast cells and promoting their survival (Boyce, 2003).

The involvement of other T cell lineages besides Th2 cells has been considered in the pathophysiology of asthma. For example, the production of Th2 cytokines does not necessarily correlate with the ability of a particular diisocyanate to increase airway hyper-responsiveness (Selgrade *et al*., 2006). Evidence from animal models is conflicting regarding the role of Th1 cells and/or cytokines in allergic asthma, with some studies indicating that Th1 cells increase the severity of the allergic response in the lung (Hansen *et al*., 1999; Randolph *et al*., 1999), and other studies suggesting that Th1 cells decrease the lung pathology (Huang *et al*., 2001). Certainly increased numbers of Th1 cells are observed in the allergic lung, and the involvement of Th1 cells may increase with the severity of the asthma (Holgate, 2008). In animal models of isocyanate-induced occupational asthma, a mixed Th1/Th2 phenotype has been observed (Matheson *et al*., 2005a; 2005b). In addition, studies have provided evidence that CD8+ T cells also influence allergic inflammation, both in the toluene diisocyanate model (Matheson *et al*., 2005a; 2005b) as well as in models of protein allergy to ovalbumin (Hamelmann *et al*., 1996). The Th lineages are increasingly complex (Chatila *et al*., 2008), and a role for pro-inflammatory Th17 cells and T regulatory cells cannot be discounted.

The recognition from animal studies that Th2 cytokines were critical mediators of asthmatic events led to the introduction of therapies targeting Th2 cytokines in humans, particularly IL-4 and IL-5. However, the results in humans of such monotherapies were particularly disappointing (Finkelman and Wills-Karp, 2008). A broader approach targeting multiple cytokines may be more effective. Numerous cell types are activated in the lung, including epithelial cells, mast cells, macrophages, T cells and eosinophils (Larche *et al*., 2003). IL-4 and IL-13 have been implicated in multiple pathologies of asthma and interact with multiple cell types including Th2 cells, mast cells and eosinophils, resulting in production of chemokines such as eotaxin and MCP (monocyte chemoattractant protein) that attract inflammatory cells to the lung (Zimmermann *et al*., 2003). IL-4 Rα is a common signalling chain for both the IL-4 and IL-13 receptors, and recent studies targeting this receptor show promise in alleviating asthma symptoms in both mouse models and clinical trials (Gavett *et al*., 1997; Karras *et al*., 2007; Wenzel *et al*., 2007).

The importance of eosinophil infiltration in the development of airway hyper-responsiveness is debated. Some studies dissociate the two events (Hayes *et al*., 1993; Milne and Piper, 1994; Pretolani *et al*., 1994; Regal *et al*., 2006), and other studies show a clear association (Djukanovic *et al*., 1990; Ishida *et al*., 1989). Changes in neuroregulation and alterations in airway structure due to inflammation and airway remodelling have been suggested as causes of airway hyper-responsiveness, but no general consensus regarding the mechanism is evident (Leguillette and Lauzon, 2008; National Asthma Education and Prevention Program, 2007).

2.4 Asthma in Response to High- and Low-Molecular-Weight Allergens

Whether the allergen is low or high molecular weight, asthma symptoms are similar and therapeutic strategies the same. Comparing gene expression profiles in mice sensitized and challenged with different allergens including ovalbumin, *Aspergillus* antigen, or the low-molecular-weight chemical allergen trimellitic anhydride revealed substantial differences in expression profiles (Greene *et al*., 2005; Regal *et al*., 2007), suggesting that allergens cause asthma symptoms via different mechanisms. Differences in allergens may also account for a portion of the heterogeneity seen in asthma. Mechanistic differences in low-molecular-weight allergens are also exemplified by trimellitic anhydride and toluene diisocyanate, two known causes of occupational asthma. They are both reactive molecules and act as haptens to induce an immune response. Studies by Zeiss (Zeiss *et al*., 1977; 1990; 1992; Zeiss, 2002) indicated that trimellitic anhydride can cause a variety of immunologically mediated lung diseases, including allergic asthma associated with IgE. Trimellitic anhydride-induced asthma in the mouse is also associated with elevated IgE (Regal *et al*., 2001). In contrast, allergen-specific IgE is not consistently detected in toluene diisocyanate-induced asthma (Mapp *et al*., 2005; Pronk *et al*., 2007). This lack of detectable IgE has been noted with toluene diisocyanate as well as other low-molecular-weight allergens, and plausible explanations that have been investigated include: (i) Non-IgE antibody is critical for toluene diisocyanate-induced asthma. (ii) Local production of IgE antibody is critical and not detected by measurement of serum antibody. (iii) Cell-mediated immunity is a greater component of the response than humoral immunity. (iv) Assays evaluating allergen specific antibody do not measure the important antigenic determinants responsible for IgE production. Certainly evidence in animal models suggests that antibody other than IgE mediates some components of the allergic asthmatic response. Also, evidence in humans suggests that toluene diisocyanate-specific IgG is associated with the asthmatic response (Park *et al*., 1999), not allergen-specific IgE. Other studies have suggested that allergen-specific IgG is a measure of exposure rather

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

than a critical determinant of the allergic response (Mapp *et al*., 2005). The state of sensitization to a given allergen is often assessed by allergen-specific serum antibody or skin-prick test. However, an immune response and class switching to IgE production can occur locally in the nasal or bronchial mucosa (Chvatchko *et al*., 1996; Takhar *et al*., 2005; 2007), so that systemic indicators such as circulating antibody may not always be evident. It is also possible that T cell activation plays a more prominent role than antibody, and some studies have shown increases in both Th1 and Th2 cells in the blood after inhalation challenge in occupational asthma with low-molecular-weight allergens (Mamessier *et al*., 2007). Development of assays that can reliably measure allergen-specific antibody has been difficult for low-molecular-weight chemicals in particular, because with most reactive chemicals, a wide variety of hapten protein conjugates are formed, and the critical antigens formed *in vivo* may not be formed under *in vitro* conditions used to develop the assays (Ott *et al*., 2007). The methodology for preparation of conjugates has not been standardized and can clearly influence the detection of antibodies in patients (Campo *et al*., 2007). Thus, much work is needed to establish allergen-specific antibody assays for different occupationally relevant allergens, and to determine if the antibody being assayed is critical to the development of allergic asthma.

Individuals with occupational asthma do not always recover after removal from exposure to the offending agent (Piirila *et al*., 2008), and this has led to the idea that low-molecular-weight chemical exposure results in asthma that is irreversible. A recent review of some 40 studies revealed variable outcomes after removal of asthmatics from exposure (Rachiotis *et al*., 2007). Surprisingly, the prognosis for recovery after removal from exposure to high-molecular-weight allergens such as snow crab was considerably poorer when compared to the low-molecular-weight allergens studied. Thus, strategies for allergen avoidance need to be carefully considered, depending on the allergen and the available evidence.

2.5 Causes of Allergic Asthma

Numerous substances can act as allergens and cause allergic asthma. Selected high- and low-molecular-weight substances are listed in **Table 1**. A more comprehensive listing of substances with references and likely occupational exposures can be found in recent reviews (Health and Safety Executive, 2008; Malo and Chan-Yeung, 2006; Mapp *et al*., 2005). Many of these substances may also cause Type I or Type IV hypersensitivity reactions in the skin, as well as Type II or Type III hypersensitivity reactions.

Table 1 Examples of low- and high-molecular-weight allergens

Low-molecular-weight allergens	High-molecular-weight allergens
Anhydrides	Laboratory animals
Diisocyanates	Mites
Plicatic acid	Natural rubber latex
Methacrylates	Wheat proteins
Platinum salts	Enzymes
Penicillins	Snow crab
Reactive dyes	Egg proteins
Formaldehyde	Moulds

2.6 Secondary Effects of Toxicants

Besides acting as allergens and triggering allergic asthma, toxicants can contribute indirectly to sensitization as well as to exacerbation of asthma symptoms. Because of airway hyper-responsiveness in asthmatics, toxicants that are not allergens can cause bronchoconstriction in asthmatic airways though they would not cause bronchoconstriction in a normal airway. The link between air pollution and increased numbers of emergency-room visits for asthmatics is well established (National Asthma Education and Prevention Program, 2007). In addition, toxicants can indirectly contribute to asthma by enhancing sensitization. For example, IgE production in response to allergens can be increased by coexposure to substances such as lipopolysaccharide (Eisenbarth *et al*., 2002), particulate matter or environmental tobacco smoke (Gilmour *et al*., 2006). Particles from wood smoke and road traffic can also act as adjuvants and increase the IgE response to ovalbumin administration (Samuelsen *et al*., 2008). Some of these effects may reflect epigenetic changes as evidenced by a study of Liu *et al*. (2008). Diesel exhaust enhanced IgE production in response to the allergen *Aspergillus,* and also resulted in hypermethylation of the IFN-γ promoter (IFN—interferon), and hypomethylation of the IL-4 promoter in CD4+ T cells, suggesting a new paradigm to explain environmental influence on the polarization of Th1/Th2 cytokine profiles and IgE production.

3 ALLERGIC RHINITIS

3.1 Description and Clinical Features

Allergic rhinitis is inflammation of the nasal mucosa due to an adaptive immune response. Allergic rhinitis is not associated with mortality, but clearly has a very negative effect on quality of life. In the United States, estimates indicate that 17% of the population is affected by allergic rhinitis (Greiner and Meltzer, 2006), and economic losses

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat062

due to healthcare costs and lost work time for allergic rhinitis are thought to surpass the costs of allergic asthma (Bousquet *et al*., 2003; Lamb *et al*., 2006). Symptoms of allergic rhinitis often precede those of allergic asthma, but not all who have allergic rhinitis go on to develop asthma. Amongst patients who have allergic rhinitis, 20–50% of them have allergic asthma. Amongst patients with asthma, estimates indicate that anywhere from 50 to 100% also have rhinitis (Gaugris *et al*., 2006; Malo *et al*., 1997; Scadding *et al*., 2008). In a Finnish study, the risk of asthma was found to increase three-fold in individuals who had developed allergic rhinitis in the workplace (Karjalainen *et al*., 2003). Knowledge of the mechanisms and markers of allergic rhinitis may be useful in predicting exposures that may lead to asthma, with the end result of reducing morbidity and mortality from asthma as well.

Inhalation exposure of xenobiotics generally involves exposure to the nasal mucosa and the lung. The upper respiratory tract includes the nasal passages, nasopharynx, sinus and larynx. The function of the nasal passages is to filter out large particles and allergens and warm and humidify the air. If nasal passages are obstructed, then mouth breathing ensues with increased exposure of the lungs to substances that are normally eliminated in the upper respiratory tract. The airway mucosa is continuous from the nasal passages to the lower airways and the term 'united airway concept' is used to reflect the fact that inflammation in the nasal mucosa can have an effect on asthma, and asthma symptoms can worsen allergic rhinitis (Baraniuk, 2001; Bousquet *et al*., 2003).

Symptoms of allergic rhinitis include itchy eyes and nose, with sneezing, rhinorrhoea, lacrimation and nasal congestion. Just as with allergic asthma, there is an induction phase responsible for the latent period as the immune system is sensitized. A subsequent allergen exposure then results in the symptoms of allergic rhinitis. Rhinitis can also occur in the absence of a specific immune response and in this case is called nonimmunologic or nonallergic rhinitis. As with asthma, rhinitis symptoms in any given individual can be a combination of allergic and nonallergic components. The substances that are associated with allergic asthma (**Table 1**) can also cause allergic rhinitis.

As with asthma, allergic rhinitis can be divided into an early phase that occurs within minutes, a late phase 6–12 hours later, and chronic rhinitis. The early phase with sneezing, rhinorrhoea and nasal obstruction is attenuated by H1 histamine receptor antagonists, suggesting a critical role for histamine in causing the symptoms. However, the acute nasal obstruction is only partially relieved with H1 histamine receptor antagonists (Greiner and Meltzer, 2006). This is consistent with the fact that the vasodilatory properties of histamine are due to stimulation of both H1 and H2 receptors. Treatment with a combination of H1 and H2 antagonists does not relieve nasal congestion appreciably more than use of an H1 antagonist alone, suggesting that mediators other than histamine are critical for nasal obstruction. Nasal obstruction in rhinitis is due to dilation of venous sinusoids, leakage of post capillary venules with fluid exudation, and mucus secretion. Vasoconstrictors such as pseudoephedrine can reverse the vasodilation, but adverse effects associated with use of these drugs limit their usefulness for chronic treatment (Greiner and Meltzer 2006; Scadding *et al*., 2008). The most effective treatment to date for symptoms of allergic rhinitis is intranasal administration of anti-inflammatory steroids, indicating the key role for inflammation in the pathology.

3.2 Animal Models of Allergic Rhinitis

Animal models have been extensively used for the study of asthma, but are not as well established for studies of allergic rhinitis, particularly for measurements of nasal obstruction. Rodent nasal passages differ from humans in the shape of the nasal turbinates, the airflow patterns as well as the fact that the sensory neuroepithelium in rodents is especially well developed for olfactory function (Wagner and Harkema, 2007). For the early phase of allergic rhinitis, investigators have used the number of nasal rubbings or sneezing as an indicator of the severity of the disease (Al Suleimani *et al*., 2007; Hiromura *et al*., 2007). Magnetic resonance imaging (MRI) scans have been used to assess thickening of the nasal mucosa as an indicator of chronic allergic rhinitis (Hellings *et al*., 2001). Nasal lavage can detect increased eosinophils in animals after repeated intranasal administration of allergen (Al Suleimani *et al*., 2007; Hellings *et al*., 2001). Histopathology looking for inflammation and eosinophil infiltration has been most extensively used. Limitations of this technique include the lack of standardization of sites sampled in the complex upper respiratory tract, as well as the length of time it takes to prepare the nasal passages for sectioning because of the bony structures.

Measurement of nasal obstruction is an important end point given its central role in human allergic rhinitis. Intranasal pressure has been used as an indictor of early-phase nasal obstruction in the guinea pig (Al Suleimani *et al*., 2007). In the mouse, Miyahara *et al*. (2005) used a forced oscillation technique to determine total resistance in the upper respiratory tract of the Balb/c mouse. Repeated allergen challenge resulted in increased nasal resistance, and this change was paralleled by a decrease in respiratory frequency. Because of this parallel, measurements of respiratory frequency in whole body plethysmography were also used by Miyahara *et al*. (2005; 2006) as an indicator of nasal obstruction in their mechanistic studies. Unrestrained whole body barometric plethysmography, or measurement of Penh, has also been used as an indicator of nasal obstruction (Johnson *et al*.,

2007; Kishi *et al*., 2007; Wagner and Harkema, 2007). If small volumes of allergen are delivered intranasally in an unanaesthetized mouse, the allergen is largely confined to the nasal mucosa, resulting in no detectable inflammation in the airways (Miyahara *et al*., 2005; 2006). Under these conditions in an obligate nose breather such as the mouse, the change in Penh will reflect the changes in the upper respiratory tract because the lower airways are not contributing to the obstruction. The same concerns that were raised for the use of Penh as an indicator of airway obstruction apply to the use of Penh for the measurement of nasal obstruction. Penh is measuring changes in breathing patterns and is not a measure of airway mechanics.

3.3 Pathophysiology of Allergic Rhinitis

As with allergic asthma, IgE production and mast cell mediator release are thought to be central to the allergic rhinitis mechanism, with an additional contribution by Th2 cells to the late and chronic phases. Mice lacking the FcεRI receptor do not develop an early nasal obstruction in response to ovalbumin and the late-phase nasal obstruction is also reduced, suggesting that IgE interaction with FcεRI is essential to these responses (Miyahara *et al*., 2005). Continued studies indicated that reconstituting the mice with bone marrow-derived mast cells restored the early-phase response, but not the late-phase response, indicating that FcεRI on mast cells are important for the early-phase response, and suggesting that FcεRI on some other cell type besides the mast cell is important for the late-phase response (Miyahara *et al*., 2008). IL-13 was important for the late-phase response but not the early-phase response (Miyahara *et al*., 2006). In ovalbumin-sensitized and challenged mice, IL-21 administration inhibited sneezing and eosinophil infiltration due to decreased IgE production by the B cell and decreased eotaxin production by fibroblasts (Hiromura *et al*., 2007).

Studies of allergic rhinitis using low-molecular-weight allergens are limited. Chemical exposures are difficult because of the irritant potential of many of the vehicles necessary for dissolving the chemical and the difficulty in conducting inhalation exposures. Farraj *et al*. (2004) used an acetone/olive oil vehicle to intranasally instil trimellitic anhydride, dinitrochlorobenzene or oxazolone into the mouse. Trimellitic anhydride administration resulted in a significant increase in the mRNA (messenger RNA) for Th2 cytokines and total serum IgE, suggesting that the mechanism for trimellitic anhydride parallels that of ovalbumin. Lung inflammation in this model was not apparent, suggesting that trimellitic anhydride did not distribute to the lower respiratory tract because of the viscosity of the acetone/olive oil vehicle.

Johnson *et al*. (2007) developed an allergic rhinitis model due to toluene diisocyanate inhalation in C57Bl/6 mice. Chronic inhalation exposure to 50 ppb toluene diisocyanate vapour for four hours per day for 12 consecutive weekdays resulted in eosinophils in the nasal mucosa, decreased respiratory frequency and increased Penh suggesting nasal obstruction, mucosal thickening, increased total serum IgE, increased toluene diisocyanate-specific IgG and a mixed Th1/Th2 cytokine response with increased IL-4, IL-5, IL-13 and IFN-γ mRNA in the nasal mucosa. No lung inflammation was apparent, suggesting that any Penh changes were due to nasal obstruction rather than increases in airway resistance. More prolonged exposure to toluene diisocyanate vapour will result in pulmonary inflammation and immune-mediated effects in the lung with a mixed Th1/Th2 cytokine profile (Matheson *et al*., 2005a; 2005b). Studies of Tsumuro *et al*. (2006) and Kishi *et al*. (2007) in a Brown Norway rat model of toluene diisocyanate-induced allergic rhinitis demonstrated increases in Penh that peaked at one hour after toluene diisocyanate intranasal challenge with a suggestion of a later-phase Penh response at four hours. Using antagonists, cysteinyl leukotrienes and thromboxane were important mediators of both the early- and late-phase Penh response, but contributed little to the immediate sneezing response. However no direct evidence is presented in this rat model to indicate that the measured change in Penh reflects changes in nasal resistance. Respiratory frequency increased in these animals with an increase in Penh, as opposed to decreases in respiratory frequency seen with increased nasal resistance in the mouse model (Miyahara *et al*., 2005). Thus, species differences exist and indirect measures of nasal resistance need to be confirmed using direct measures of nasal resistance.

4 SUMMARY

Allergic asthma and rhinitis are informative examples of immunotoxicity. Toxicants can operate as allergens to evoke a damaging immune response in the respiratory tract, or can influence the pathophysiology by enhancing sensitization to allergens and exacerbating airway hyper-responsiveness. A wide variety of allergens have been identified that can cause allergic asthma and rhinitis, and studies clearly indicate that mechanisms vary and include both antibody and cell-mediated components to explain the respiratory tract pathology.

Ophthalmic Toxicology

Bryan Ballantyne

CONTENTS

1 INTRODUCTION

Materials may come into contact with the eye either by direct surface contact from solids, liquids and airborne materials, or via the circulatory system following systemic absorption by another route of exposure. In addition, and related mainly to physicochemical properties, materials coming into direct surface contact with the eye may be absorbed into the systemic circulation and exert toxic and/or pharmacological effects at sites remote from the eye. Thus, the eye may

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be a target of, or route for, toxic effects under various exposure conditions, as follows.

1. Direct local (topical) contact of a material with the surface of the eye (cornea, conjunctiva and palpebral surface) that may result in different tissue responses depending on the physical and chemical nature of the material. These may include:
   (a) a peripheral chemosensory effect
   (b) injury and/or an inflammatory reaction of the eye and its surrounding structures (local irritation)
   (c) a sensitization reaction (allergic conjunctivitis)
   (d) possible injury or functional changes to deeper ocular tissues, if materials penetrate surface structures at the site of contact.
2. Depending mainly on physicochemical properties of the material, there may be absorption into the systemic circulation through surface periocular vessels, or nasal and alimentary mucosa after drainage through the nasolacrimal duct. If of high toxicological or pharmacological potency, the absorbed parent material and/or metabolites may cause postabsorption systemic effects remote from the eye. This is descriptively referred to as transocular systemic toxicity.
3. Absorption of materials into the systemic circulation following exposure by routes other than direct ocular contact can result in systemic exposure of the eye to parent material and metabolites. Systemic toxicity to the eye and its adnexa may result.

This chapter reviews the above general aspects of toxicology as related to the eye, and gives illustrative examples of specific target sites for toxic effects, including iris, ciliary body, aqueous humour, lens, retina and extraocular muscles.

2 LOCAL IRRITANT EFFECTS ON THE EYE

2.1 General Considerations

Injuries to the eye resulting from local contamination with materials of various chemical categories are common in occupational, domestic, group recreational and general environmental situations (Saunders *et al*., 1996; Safranek *et al*., 2007; Teir, 1984). In the USA, eye injuries account for 3.3% of all occupational injuries resulting in lost workdays. One study of work-related eye injuries in the USA recorded that during 1999 there were about 280 000 work-related eye injuries treated in hospital emergency departments, with foreign bodies in the eye and chemical burns being the most common types of ocular injuries (Xiang *et al*., 2005). Occupational eye injuries from chemicals can, and should be, minimized by the use of appropriate precautionary and protective measures. However, domestic incidents are usually due to the use, handling, and storage of materials in an uncontrolled manner. For example, in one study it was found that 84.4% of eye injuries from chemicals occurred in the home, with predominant accidental exposures in children; the proportion of industrial chemical eye injuries in the series was 14.2% (Kersjes *et al*., 1987). In general, domestic chemical eye injuries are not usually a serious medical problem (Palmborg, 2005). This was also borne out by a Swedish Poison Information study that found chemically-induced eye injuries in the home setting are usually not a serious medical problem, with the majority of cases having no or mild symptoms, and advice to undertake water irrigation is sufficient. However, in spite of knowledge of the risks together with the availability of protective measures, occupational eye injuries often show more severe symptoms. US Poison Control Center reports indicate that there are more than 100 000 cases of chemical eye injuries annually, which accounts for about 6.5% of all Poison Control Center consultations (Litovitz *et al*., 1993). Similar proportionate values are seen in other countries that have good records systems, for example Sweden (Palmborg, 2005). In a detailed prospective follow-up interview study of ocular chemical injuries reported to the San Francisco Bay Area Region Poison Control Center, it was noted that the modes of exposure were quite varied, but the four most common substance groupings were personal care/medicinal products (15%), solvents (11%), strong acids or bases (7%) and hypochlorite bleaches (7%). The most common exposure patterns were by splash or drip, followed by spray can or aerosol (Saunders *et al*., 1996). With respect to occupational eye injuries, in 2002 there were 42 286 such injuries reported to the US Bureau of Labor Statistics (Harris, 2004); of these, 4811 (11.4%) were chemically induced. One cause of recreationally induced eye irritation and injury is exposure to swimming pools with inadequately controlled water chemistry; for example with respect to chloramines and free chorine (Petersson *et al*., 2008; Safranek *et al*., 2007).

Both the time to onset and the severity of chemically induced ocular injury vary with different chemical groupings and certain specific chemicals. For example, rapid onset and severe eye injury occurs with alkaline materials (Smally *et al*., 1992), whereas certain dyestuffs (e.g. gentian violet) may be associated with a latency of several days before the onset of severe eye injury (Ballantyne *et al*., 1973). Although the potential to cause eye injury with liquids and solids is well known, it should also be appreciated that exposure to many irritant vapours or gases can produce injury to the eye; examples include tetramethylbutanediamine (Ballantyne *et al*., 1992), 2-formyl-3,4-dihydro-2*H*-pyran (Myers *et al*., 1993) and acrolein (Hathaway *et al*., 1991). One

example of vapours causing occupationally hazardous ocular effects is that resulting from exposure to the vapour of certain amines resulting in a condition known as glaucopsia, in which there is transient increase in corneal thickness causing blurring of vision. This condition, which is of practical occupational significance, is discussed later in more detail in Section 7.2.2.

Local contamination of the eye with chemicals or formulations may occur accidentally or, as with ophthalmic medicinal preparations, be deliberate. It follows that there is a need to know what is the potential for chemicals and formulations to produce eye injury by acute and repeated topical contamination of the eye, in order that (i) appropriate warnings can be given in product safety literature and on labels, (ii) advice given about first aid and medical management of eye injuries, and (iii) recommendations be developed for protective and precautionary measures when using or handling a particular material or formulation. In the special case of ophthalmic medicinal products, it is necessary to ensure that the in-use preparation does not cause structural and/or functional injury to the superficial and/or deep structures of the eye by acute and repeated deliberate ocular application (discussed further in Section 2.4). Additionally, it is also necessary to determine if medicinal products applied topically to the eye can be absorbed into the circulation and result in systemic toxicity (see Section 6.3).

2.2 Tests for Eye Irritating Potential

For many years the testing of chemicals and formulations for their potential to cause local injury and irritation to the eye by topical contamination was a simple procedure and usually conducted as an acute study. Following exposure of the eye to the test material (as solid, liquid or airborne material) the macroscopically visible ocular and periocular tissues were examined periodically for signs of inflammation and/or injury, and the effects noted were given subjective scores and noted as a function of time after exposure. In addition to recording macroscopic indications of eye irritation, ancillary methods have been developed and used to increase sensitivity for the detection of injury and to allow objective quantitation of the response. Additionally, and because of test-animal discomfort and stress associated with the conventional eye irritating test procedure, several alternative approaches for the determination or prediction of the eye irritating potential of chemicals have been proposed and developed. This work on alternatives to conventional eye irritation testing has been encouraged and facilitated by the expressed views of many professional toxicologists and by the opinions of several informed animal rights organizations. As a consequence, the numbers of conventional eye irritation tests that have been conducted have been progressively and significantly reduced over the past few years. Also, the sensitivity and specificity of alternative methods for assessing eye irritating potential have been investigated in detail. The following sections are devoted to a description of the conduct and interpretation of standard eye irritation test procedures, and to an evaluation of alternatives that have been proposed for assessing the eye injuring potential of chemicals and formulations.

2.3 *In Vivo* Eye Irritation Tests

Most studies have been conducted as single dose (acute) procedures, although repeated exposure studies have been carried out where this has been dictated by the use pattern of the test material. Although clinical reports of eye injury to humans have been published for many decades, it was not until the early 1940s that eye irritation testing became formalized as an animal laboratory procedure (Draize *et al.*, 1944). The basis of macroscopic *in vivo* eye irritation tests, and variants on such tests, is exposure of the eye to the test material followed by periodic sequential inspection of the eye for signs of ocular and periocular inflammation and injury, in order to note the onset, progression, severity and resolution of the eye effects. With respect to the last of these considerations, it is essential to know if any induced ocular injury is irreversible (permanent) or reversible (heals). If reversible there should be a determination of the time for healing to occur, and if first aid or medical treatment measures (e.g. eye irrigation) or the use of ocular anti-inflammatory agents are of therapeutic benefit. The more important elements of conventional *in vivo* eye irrigation studies are summarized and discussed below. There are differences in detail, with specific protocols recommended by various regulatory agencies and conducting contract laboratories (see Ballantyne, 1999; Daston and Freeberg, 1991).

2.3.1 Selection of Test Species

Some structural and functional differences between the human eye and those of common laboratory animals require that caution is necessary when extrapolating the results from laboratory animal eye irritation studies to the human. Most studies have been conducted using the rabbit as a test animal, for the following reasons:

1. Ease of handling.
2. Relatively large surface area of the eyeball and periocular tissues available for inspection.
3. There exists a large background literature on the effects of chemicals and drugs on the rabbit eye, allowing comparative evaluations.
4. The species is recommended in many regulatory agency protocols.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

Disadvantages include the following:

1. The rabbit has a nictitating membrane. The significance of this is debatable. Some authorities believe that the nictitating membrane removes irritant materials from the surface of the eye, but others consider that it acts as a tap (Buehler and Newmann, 1964).
2. The tearing mechanism in the rabbit is less effective than in the human (Buehler and Newmann, 1964), a factor of importance in relation to the degree and duration of contact of foreign material with the surface of theeye.
3. The pH and buffering capacity of the aqueous humour differ between man and rabbit (Carpenter and Smyth, 1946), which could explain why the rabbit is more susceptible to chemically induced iritis.
4. The rabbit has a slow blink reflex (Mann *et al*., 1948).
5. Both the thickness and the histology of the cornea differ between rabbit and man (Carpenter and Smyth, 1946). The rabbit corneal thickness averages 0.37 mm and that of the human 0.5 mm (Marzulli and Simmon, 1971). Histological differences include the rabbit corneal epithelium being several layers thinner, and Bowman's membrane is an order of magnitude thinner; both of these factors facilitate the penetration of materials through the rabbit cornea. Also, the area of the eye occupied by cornea is 25% in the rabbit, but only 7% in humans.
6. The rabbit eye is more readily anaesthetized by irritants than is the human eye, and hence more susceptible to reduction of protective blinking (Daston and Freeberg, 1991). Comparative studies using a variety of substances have shown that the eye of primates responds differently compared to that of the rabbit; the latter species usually has a more marked reaction (Buehler and Newmann, 1964). Comparative studies on the rabbit, monkey and human have demonstrated that the ocular reactions in the monkey are more akin to that of the human (Beckley *et al*., 1969). Thus, for critical purposes, such as the testing of ophthalmic preparations for use in humans, confirmatory studies on the results from animal (rabbit) tests may need to be undertaken in nonhuman primates.

2.3.2 Material to be Tested

For the majority of purposes it is usually recommended that the material be tested as 0.1 ml of liquid or 100 mg of solid, which is placed in the inferior conjunctival sac. In some cases, for example if it is suspected that the material will produce severe eye injury, then it is appropriate that 0.01 or 0.005 ml or mg of test material be used initially. It should be noted that 0.1 ml is close to the maximum volume that can be accommodated in the inferior conjunctival sac of the rabbit eye, and hence the use of smaller volumes has been proposed to be more appropriate for comparison with the practical aspects of splash contamination of the human eye. For example, it has been shown that the volume capacity of the human eye is 0.01 and 0.03 ml, with and without blinking, respectively (Wright and Megers, 1962; Misham *et al*., 1966). Using different volumes of several chemicals of varying irritant potential that were applied to the rabbit cornea, Griffith *et al*. (1980) determined the dose–response relationship for irritancy and compared the findings with the known human ocular irritancy to the chemicals used. They found that a dose volume of 0.01 ml produced irritation in the rabbit eye which was consistent with that observed in human, and used this volume in a low volume eye test (LVET). Subsequently, other investigators confirmed the reliability of the LVET for determining eye irritating potential (Allgood, 1989; Freeberg *et al*., 1984; 1986a; Walker, 1985; Williams, 1985). Also, it was demonstrated that the LVET correlates with the conventional Draize procedure (Blein *et al*., 1991). Cormier *et al*. (1995) reviewed consumer eye irritation comments (1985–1992) on more than 70 commercial products and found that the LVET correlated well with experience for human eye data. They also examined intra- and inter-laboratory reproducibility with the LVET and found it to have similar degrees of reproducibility to the Draize procedure (Cormier *et al*., 1996). Results from 70 parallel Draize and LVET tests indicated a strong positive association between the tests for corneal, iridial and conjunctival scores (r = 0.60, 0.73, 0.68, respectively; $p < 0.0001$).

For exposure to gas, vapour, aerosol or smoke, appropriate exposure chambers with sampling and analytical facilities are required. Since acute ocular irritancy with aerosols may vary with particle size (Punte *et al*., 1963), it is important that samples be collected for measurements of particle sizes as well as for substance concentration measurements. Also, for practical purposes, it may be necessary to measure ocular irritation as a function of particle size. In order to reduce the numbers of animals used, eye irritation observations should be routinely incorporated into acute and repeated-exposure general toxicology studies involving airborne materials.

When formulations are tested, it is ideal to know if eye injury is due to the active ingredient alone, to vehicle, or the formulation. However, in order to reduce the number of tests necessary, from a product safety viewpoint only the formulation may need to be tested. Clearly, and also for product safety reasons, if a formulation causes eye injury it may be required to determine if the in-use dilution of the formulation is irritant (Ballantyne and Swanston, 1977). It follows that if a material is required to be tested in solution, then a nonirritant solvent should be used; for example saline, low-molecular-weight molecular weight (MW) polyethylene glycol (PEG), propylene glycol or glyceryl triacetate (Ballantyne *et al*., 1972).

Based solely on physical and/or chemical characteristics, some regulatory authorities may consider that there is sufficient information from these characteristics to allow an assumption that the material will produce a positive result on rabbit eye irritation testing. In such cases the material may be classified as having a potential to cause eye injury, and there is no requirement for standard eye irritation testing. For example, many regulatory authorities allow classification of a material as an eye irritant if its pH is <2.0, or >11.5. However, pH alone may not be a sufficient criterion for classification, and buffering capacity may be an important additional factor. For example, Neun (1993) conducted eye irritation studies with solutions of pH 11.5 having alkalinities of 0.5, 1.0 and 2.0 mEq g^{-1} using bicarbonate buffer systems. The results showed that the maximum 'Draize score' and median days to resolution indicated that the solutions with low buffering capacity are not necessarily irritant or corrosive at a pH considered to indicate a high irritant potential. The investigator suggested that with materials of extreme pH, at least knowledge of the buffering capacity is also needed.

2.3.3 The Test Procedure

Most studies are conducted as acute (single-exposure) procedures. Control and test animals for eye irritation studies need to be acclimated for about one week before testing to ensure recovery from any stress caused by transportation, including corneal dehydration. Animals are housed in cages designed to prevent accidental eye injury, including the use of wire mesh floors in place of sawdust or wood chippings. On the day before testing, animals should be examined to ensure the absence of ocular abnormalities.

Studies have been conducted to determine the smallest number of animals that can be used to adequately characterize the eye irritating potential of chemicals. DeSousa *et al*. (1984) examined the ability of two-, three- and five-animal subsets to accurately predict the outcome of six-animal tests for a large number of petrochemicals, and found that the three-rabbit subsets were 93% accurate in predicting the six-rabbit eye irritation tests. A similar finding was obtained by Talsma *et al*. (1988), and also confirmed by Bruner *et al*. (1992). It was found by Berdasco *et al*. (1966) that the number of animals can be reduced in standard ocular irritation tests, especially if a sequential approach is adopted using *in vitro* tests and structure-activity considerations first. However, if the findings from a particular three-animal test show a wide variability, then it may be necessary to undertake additional testing. For example, Dalbey *et al*. (1993) conducted a detailed evaluation of the influence of animal numbers on irritation classification criteria, and found that a significant number of incorrect classifications were made on the basis of the three-rabbit subsets. The authors advised that investigators should carefully evaluate the effects on accuracy of results before reducing the numbers of animals in a given eye irritation study.

Test materials are usually placed in the inferior conjunctival sac (larger amounts), or on the surface of the cornea, after which the eyelids are gently held together for a few seconds. One eye of each rabbit is used for test material instillation, and the contralateral eye serves as a control. It is generally considered that application of the test material to the surface of the cornea, rather than instillation into the inferior conjunctival sac, is a more practical method for mimicking the actual exposure conditions, with the exception of ophthalmic medicinal preparations that may deliberately be instilled into the inferior conjunctival sac (Chan and Hayes, 1985). Special devices for applying measured amounts of test material to the eye have been described (Buehler and Newmann, 1964; Battista and McSweeney, 1965).

After applying the test material, eyes are periodically and sequentially examined, under standard conditions of illumination, to determine and record the nature, severity, time to onset, duration and possible resolution of any induced ocular and periocular injury and/or inflammation (see Sections 2.3.4 and 2.3.5). The principal ocular and periocular lesions that should be recorded are as follows: excess lacrimation, blepharitis (hyperaemia and oedema), inflammation of the conjunctivae and nictitating membrane (injection, congestion, chemosis and sloughing), corneal injury (opacity/ulceration, vascularization, and area of involvement) and iritis (injection and congestion). In addition to macroscopic evidence for inflammation and injury, the eye should also be examined for any pharmacological effects that may have been produced, for example mydriasis and cycloplegia with anticholinesterase (antiChE) agents (Ballantyne, 2006a). Additionally, and with potentially biologically potent materials, the test animals should be inspected for signs of systemic toxic and/or pharmacological effects following transocular absorption. Periodic inspection of the eye following contamination is essential for extrapolation to possible in-use clinical situations, and for comparative evaluations between different materials and formulations. The original Draize protocol specified that eyes should be inspected at 1, 24, 48 and 96 hours, and if necessary at seven days post instillation. Other protocols specify alternative inspection periods. However, early inspections are essential to detect initial signs of injury and their progression. A minimum of one week of observations is required to ensure that any latent injury is detected.

The use of local anaesthesia has been proposed as a means to alleviate discomfort in eye irritation tests. However, some authorities believe that local anaesthetics may exacerbate ocular irritation, There is also evidence that local anaesthetics, to variable degrees, may delay healing of the cornea and themselves produce corneal injury, and hence potentiate ocular irritation (Daston and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Freeberg, 1991). Also, local anaesthetics inhibit the blink reflex. Corneal injury produced by local anaesthetics was reviewed by Etter *et al*. (1992), who noted that oxybuprocaine experimentally produced a concentration-related increase in corneal permeability. Additionally, Lapalus *et al*. (1990) found that oxybuprocaine was cytotoxic to corneal epithelial cells *in vitro*. However, Choksi *et al*. (2007), based on a study with 97 proprietary formulations, found the use of 0.5% (w/v) tetracaine hydrochloride as a pretreatment in the *in vivo* Draize rabbit eye test had no effect on the variability of rabbit irritancy classification, and they consider their findings support the routine use of this local anaesthetic.

Most standard recommendations for the first-aid management of chemically induced eye injury include the use of extensive ocular irrigation (Herr *et al*., 1991). Whilst postexposure irrigation of the eye generally reduces or prevents eye irritation, in some cases increased ocular irritation has been noted following water irrigation (Gaunt and Harper, 1964). Because of this, some regulatory authorities have recommended that subgroups of animals be used to assess the efficacy of eye irrigation on the development and severity of chemically induced eye injury. Other therapeutic procedures which reduce or prevent ocular injury can be incorporated into conventional eye irritation studies, for example the use of anti-inflammatory preparations (Ballantyne *et al*., 1976).

2.3.4 Scoring Ocular Lesions

Several schemes have been proposed for the grading and scoring of ocular lesions observed in standards eye irritation tests. That introduced by Draize has been the one used most frequently (Draize *et al*., 1944; Draize, 1959), particularly for product development. The Draize system assigns values to effects seen on the cornea, iris and conjunctiva, usually at various specified periods (**Table 1**). There are three major concerns with this scoring system:

1. Only a limited number of effects in the three tissues are described. Thus, the cornea is graded separately for opacity and area of involvement, the iris is considered as an entity, and there are separate grades for conjunctival hyperaemia, chemosis and discharge. The limited number of effects recorded may give an incomplete description of the ocular reaction to a chemical.
2. The range of grades differs with the effect recorded. Thus corneal effects, both opacity and area of involvement, are graded 0–4; the iris is graded 0–2; and effects on the conjunctiva are graded 0–3 for discharge and hyperaemia, and 0–4 for chemosis. This nonuniformity in grading can lead to difficulties in comparative interpretations.
3. Results are not reported as scores as seen, but as arithmetically derived, biased (weighted) numbers calculated from the score as seen. For example, corneal scores are a product of grade for opacity and area of involvement, with a bias factor of five; iris is scored for five times the grade observed; and the conjunctival score is twice the sum of grades for hyperaemia, chemosis and discharge. Thus, for a possible total maximum score of 100 pints, 73% is derived from the corneal score, 18% from the conjunctival score and 9% for the iris. Thus, this nonuniformity in scoring results in a bias ratio of 8 : 2 : 1 with respect to the cornea, conjunctivae and iris.

The Draize approach was modified by The US Food and Drug Administration (FDA) for enforcing the Hazardous Substances Labeling Act; The FDA system does not differentiate between opacity and area of involvement of the cornea, and the scores are presented as the actual grades observed and are not arithmetically biased total scores (**Table 2**). To facilitate the scoring of injury between different laboratories and to obtain better reproducibility, colour photographs equivalent to the scores were published by the FDA (1965). Ballantyne and Swanston (1977) developed a more detailed scoring system (**Table 3**) using a large number of effects to be recorded, which included lacrimation, blepharitis, chemosis, conjunctival hyperaemia, iritis, keratitis, and corneal neovascularization; in order to obtain a more uniform approach, each effect is recorded on a six-point scale (0–5). Different scoring systems have been developed by other workers (see Ballantyne, 1999).

2.3.5 Recording, Presentation and Interpretation of Ocular Irritation Tests

The conventional eye irritation study is a subjective evaluation of macroscopic observations, and therefore it is hardly surprising that there have been considerable inconsistencies between the results obtained from differing laboratories, even using the same test protocol (Russell and Hoch, 1962; Weil and Scala, 1971). Such differences are due to a variety of factors which may include: variable methods of training in different test laboratories; the use of groups with different sized test animal populations; and differences in age, strain and sometimes the gender of animals used. Many effects seen, such as pannus formation, keratoconus, conjunctival haemorrhages and corneal neovascularization, may not readily lend themselves to scoring. Such effects are, however, functionally significant, and are usually tabulated separately or as footnotes.

The numerical systemic recording and presentation of scores involves tabulating as a function of the time of inspection. Values should be recorded for individual animals (e.g. **Table 4**) as well as group mean scores

Table 1 Draize system for the scoring of ocular lesions[a]

Cornea	
(A) *Opacity—degree of density* (most dense area taken for reading)	
No opacity	0
Scattered or diffuse area, iris details clearly visible	1
Easily discernable translucent areas, iris details slightly obscured	2
Opalescent areas, iris details not visible, pupil size barely discernable	3
Opaque, iris not visible	4
(B) *Area of cornea involved*	
One quarter or less, but not zero	1
Greater than one quarter, but less than one half	2
Greater than one half, but less then three quarters	3
Greater than three quarters, up to whole area	4
Corneal score **= A × B × 5 (maximum total score = 80)**	
Iris	
(A) Normal	0
Folds above normal, congestion, swelling, circumcorneal injection, iris reacting to light	1
No reaction to light, haemorrhage, gross destruction	2
Iris score **= A × 5 (maximum total score = 10)**	
Conjunctivae	
(A) Vessels normal	0
Vessels definitely injected above normal	1
Diffuse, deep crimson red, individual vessels not readily discernable	2
Diffuse beefy red	3
(B) No chemosis	0
Any swelling above normal (includes nictitating membrane)	1
Obvious swelling with partial eversion of lids	2
Swelling with lids about half closed	3
Swelling with lids about half closed to completely closed	4
(C) No discharge	0
Any amount of discharge different from normal	1
Discharge with moistening of the lids and hairs adjacent to lids	2
Discharge with considerable moistening around the eyes	3
Conjunctival score **= (A + B + C) × 2 (maximum total score = 20)**	
Total possible maximum score **(cornea + iris + conjunctiva) = 110**

with ranges (e.g. **Table 5**). In some published papers and reports only cumulative scores have been presented. In view of variability between animals and resultant interpretational difficulties, this is a practice to be avoided and prevented by reviewers. Scores may also be presented graphically, providing that the range of responses is not large, and used to compare the effect of differing concentrations of the same material or to compare the effects of the same dose of differing materials (e.g. **Figure 1**). Additionally, dose–response histograms (Macrae *et al*., 1970) can be used to demonstrate the relative proportions of animals having different reactions at each inspection period and hence permit a ready appreciation of the rate of development and resolution of eye injury, as well as group variability (e.g. **Figure 2**).

Several problems may be encountered in the interpretation of the Draize scoring system. Thus, scores are not usually recorded as the grade of effects seen, but as biased numbers derived by calculating arithmetic means using different biases for each eye component recorded. Because of this method of scoring, identical values may result from different eye lesions. For example, since the

Obvious swelling with eversion of lids	[2][a]
Swelling with lids about half closed	3
Swelling with lids more than half closed	4

[a]The figures in parentheses indicate the lowest grade considered positive.

cornea is graded separately for the degree of opacity and area of involvement, and because this is presented as a biased product, a diffuse minor keratitis affecting the whole of the cornea may obtain a score identical with that produced by localized punctate lesions in one quadrant. This emphasizes the requirement to record each effect individually.

There have been attempts to reduce scoring to a single numerical value for the rating of irritancy. Since these schemes involve further arithmetic manipulation of the score, they give values even more remote from the actual biological response. Several authors have given a scale of rating; for example, Kay and Calandra (1962) described seven ratings from minor to severe. Such rating schemes usually have fixed standards and do not give any indication of the nature, severity and/or duration of ocular lesions. Hence, whilst such ratings may have some value in product development, they are not sufficiently precise and representative for regulatory purposes or publication of data, and do not provide a clinical description of eye injury to be expected from contamination of the eye with a particular chemical.

Schemes where precisely defined grades of effects are presented as a function of time permit a ready appreciation of the onset, duration, resolution, severity and nature of adverse effects on the eye. The FDA system requires that results should be presented in this way and defines, for regulatory purposes, what constitutes a positive response. Thus, a tissue is regarded as having a positive reaction if there is, at any reading, opacity or ulceration of the cornea, iritis, obvious chemosis with partial eversion of the lids or a deep crimson red appearance to the conjunctivae with individual vessels not being discernable. A material is considered irritant if four in a test group of six rabbits exhibits a positive reaction in any ocular tissue. A material that has produced lesions of the cornea and/or iris that have not cleared by the seventh day post-treatment is considered a severe eye irritant.

In a critical review of the Draize rabbit eye test, York and Steiling (1998) stressed the subjective judgment inherent in the procedure, and noted that the most important factors causing variability in results are group size and the fact that the methods for assessment cannot reflect the complex nature of the irritation reactions and the use of an algorithm is not valid and leads to misrepresentation of the true biological response. They suggested the establishment of a scientifically valid factor that encompasses the complexities of the total *in vivo* response, and that recovery could be a factor. They also suggested the generation of controlled human data to provide a benchmark for irritation against which Draize data could be compared.

2.3.6 Ancillary Methods to Eye Irritation

In order to obtain a more definitive evaluation of the presence and nature of ocular injury in standard eye irritation tests, several ancillary procedures have been proposed and adopted. The most relevant of these are summarized below.

2.3.6.1 Fluorescein Staining

The normal corneal epithelium presents a barrier to fluorescein, but when breached it allows fluorescein to penetrate into the underlying stroma. Hence the detection of

Table 3 Equal grade scoring system for ocular lesions in eye irritation tests[a]

Effect	Grade	Observations
Lacrimation	0	Normal
	1	Slight excess at lower tarsal margin
	2	Slight wetting of periorbital hair
	3	Obvious wetting of lid margins and periorbital hair
	4	Gross wetting of periorbital hair
	5	Gross wetting of hair with fluid running down face
Blepharitis	0	Eyelids normal
	1	Slight reddening of lid margins
	2	Diffuse redness and slight swelling of lid margins
	3	Diffuse redness with moderate swelling of lids
	4	Diffuse bright redness with marked thickening and deformity of lids
	5	Diffuse bright redness with marked thickening and irregular deformity of lid margins; contracted palpebral fissure
Chemosis	0	No swelling of conjunctivae or nictitating membrane
	1	Minimal swelling with no eversion of lids
	2	Moderate swelling with eversion of lids
	3	Moderate swelling with moderate eversion of lids; swollen tissue encroaching over periphery of cornea
	4	Marked swelling and eversion with tissues almost completely obliterating the cornea
	5	Gross swelling and eversion of lids with complete obliteration of cornea
Congestion of conjunctivae and nictitating membrane	0	Vessels normal
	1	A few injected vessels
	2	Diffuse and moderate injection of blood vessels
	3	Diffuse and marked dilation, but individual vessels still discernable
	4	Diffuse and gross dilation with individual vessels barely discernable
	5	Diffuse intense redness
Sloughing	0	Absent
	1	Patchy detachment of film
	2	Diffuse detachment of fine membrane
	3	Diffuse detachment of fine film with slight contamination of lacrimal fluid
	4	Obvious stripping of membrane with moderate contamination of lacrimal fluid
	5	Gross detachment of membrane and gross contamination of lacrimal fluid
Iritis	0	Normal iris
	1	Slight injection of iris blood vessels
	2	Slight thickening of folds with diffuse and moderate injection; still reacting to light
	3	Moderate thickening of folds with diffuse and moderate injection; slight reduction in response to light
	4	Diffuse and gross erythema with obvious thickening; sluggish reaction to light
	5	No reaction to light; distorted pupil; gross inflammatory change with haemorrhages
Keratitis	0	Normal cornea
	1	Just detectable haziness of cornea
	2	Obvious opacity of cornea (local or general) but iris clearly visible
	3	Local or general opacity of cornea almost obscuring iris
	4	Local or general opacity of the cornea totally obscuring the iris
	5	Gross opacification of the cornea with deformity and/or ulceration

Table 3 (*continued*)

Effect	Grade	Observations
Vascularization of the cornea	0	Avascular
	1	Localized ingrowth of vessels for 1–2 mm
	2	Generalized ingrowth of vessels for 1–2 mm
	3	Generalized ingrowth of vessels for 3–4 mm
	4	Ingrowth of vessels to within 1–2 mm of centre of cornea, but without confluence
	5	Complete vascularization of cornea with confluence of vessels at centre of cornea

[a]After Ballantyne and Swanston (1977).

Table 4 Results from individual animals in a rabbit eye irritation study with 5% (w/v) 1-chloroacetophenone (CN) dissolved in polyethylene glycol 300, and scored by the method of Draize *et al*. (1944)

[a]Maximum tissue scores: cornea = 80, iris = 10, conjunctiva = 20.
[b]Maximum possible total score = 110.

fluorescein staining of the cornea is a valuable guide to early corneal injury. One or two drops of 2% fluorescein are applied directly to the cornea and washed off a few seconds later with isotonic saline. The injured cornea retains more dye than the intact epithelium, and appears a brighter yellow in colour. This is facilitated by examination under ultraviolet (UV) light, or using a blue filter in a slit-lamp biomicroscope. Yellowish green areas stained by fluorescein indicate regions where the dye has penetrated epithelial lesions and diffused into normal tissue. Rose Bengal has been recommended to stain areas of degenerate epithelial cells and Alcian Blue for the demonstration of mucous.

2.3.6.2 *Corneal Permeability Studies*

The presence of fluorescein in aqueous humour may give an indication if corneal permeability has been increased

[a]Scored by the method of Ballantyne and Swanston (1977; see **Table 3**).

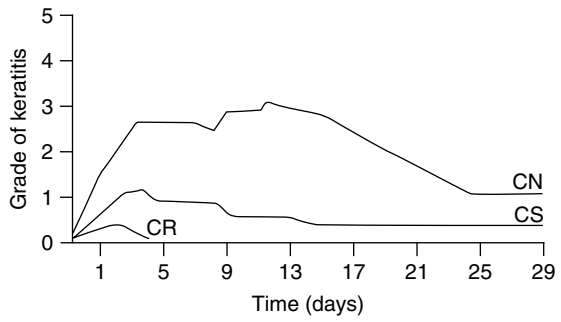

Figure 1 Comparative graphical representation of the average grades plotted as a function of time for corneal injury from dosing rabbits (10 per group) with 0.1 ml of 5% solutions of 1-chloroacetophenone (CN), 2-chlorobenzylidene malononitrile (CS), or dibenz [b.f]-1,4-oxaxepine (CR). Corneal injury scored by the method described by Ballantyne and Swanston (1977; see **Table 3**).

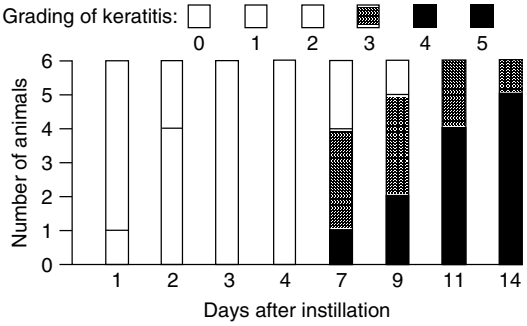

Figure 2 Response–duration histogram for the development of corneal injury in the rabbit eye following instillation of 2% Crystal Violet in water. Scoring system after that of Ballantyne and Swanston (1977; see **Table 3**).

since, as noted above, corneal epithelial damage may increase the rate of penetration of fluorescein through the cornea. An increased accumulation of fluorescein in the anterior chamber can be detected by a 'fluorescein flare' in the aqueous humour using a blue filter in the slit-beam path of a biomicroscope. Measurement of fluorescein in aqueous humour has been used as a basis for a quantitative evaluation of corneal permeability (Maurice, 1967; 1968). Sulforhodamine B has been preferred to fluorescein because of its lower lipid solubility at physiological pH, and hence its decreased permeability in the undamaged eye, and also because the red wavelength emitted by rhodamine allows better quantitation (Maurice and Singh, 1986). Changes in fluorescein concentration in aqueous humour can be quantified using a fluorophotometer attached to a slit-lamp

biomicroscope; this permits an objective test for eye injury (Easty and Mathalone, 1969). Etter and Wildhaber (1985) used fluorimetry to quantify corneal permeability in mice following treatment with a series of surfactants, and found a good agreement between fluorescein penetration and *in vivo* irritancy. The use of corneal permeability studies as an objective sensitive method for the early evaluation of corneal injury is discussed in more detail in Section 3.2.3.

2.3.6.3 Slit-Lamp Biomicroscopy

Slit-lamp examination of the eyes is a valuable aid for the detection of early and minimal changes in the cornea, and allows a more precise evaluation of the structural condition of the cornea, iris, lens and aqueous humour; for example, the presence of a flare in aqueous humour due to excess protein (McDonald *et al*., 1972).

2.3.6.4 Confocal Microscopy

Confocal microscopy allows optical sectioning through intact living tissues such as the cornea and lens with enhanced resolution and contrast compared to conventional microscopy, and is without preparation artefacts. Coupled with rhodamine 123 fluorescence staining, this approach can be used to study the distribution and morphology of mitochondria.

2.3.6.5 Measurement of Corneal Thickness

The *in vivo* measurement of corneal thickness (pachymetry) is an objective method for determining injury to the cornea, particularly in the early stages of the injury process. Although it can be used as an ancillary method to supplement eye irritation studies, it is an approach that can stand alone for the objective quantitative detection and evaluation of corneal injury. This is discussed in detail in Section 3.2.1.

2.3.6.6 Corneal Epithelium Healing Rate

Following injury of the corneal epithelium, re-epithelialization occurs and corneal thickness increases; toxic substances, however, may retard the normal rate of healing. It has been suggested that measurement of corneal thickness and healing rate can be used as a method for the evaluation of potential eye irritants, particularly with ophthalmic preparations which may be applied therapeutically to the injured eye. The method involves creating a standard epithelial wound using a trephine and stripping the corneal epithelium. Test material is then applied to the corneal surface. The contralateral eye is also de-epithelialized and used as an untreated control. Corneal healing rate is followed by fluorescein staining, photographing the wounded area and assessing its size by planimetry. Corneal thickness is measured before and sequentially after wounding. The technique has been described in detail by Ubels *et al*. (1982). Several investigations have shown that chemicals of various categories delay return of corneal thickness to normal and retard epithelial healing rate (Fujihara *et al*., 1993; Green *et al*., 1989; Ubels *et al*., 1982).

2.3.6.7 Histology

At the end of the observation period of an eye irritation study it is useful to sacrifice animals for removal of the treated eyes to allow a detailed histological examination to confirm, or otherwise, that healing has occurred. In some studies, sequential sacrifices over the inspection period are conducted to allow a determination of the pathogenesis of ocular lesions.

2.4 Management of Chemically-Induced Eye Injuries

Standard eye irritation tests may have provision in the protocol for determining some aspects of appropriate first aid and medical management of the material under test. For example, although it is standard practice to recommend that chemically contaminated eyes are irrigated (Herr *et al*., 1991; Sharma, 2004), in a few instances irrigation with water has been shown to result in increased eye irritation and may lead to an exacerbation of the corneal injury (Gaunt and Harper, 1964). Thus, some protocols have specified that subgroups of animals be used to determine the efficacy of eye irrigation on the development, severity and resolution of eye injury. As discussed earlier, other therapeutic procedures can be incorporated into conventional *in vivo* eye irritation studies; for example, the use of anti-inflammatory agents (Ballantyne *et al*., 1976). Monitoring of such procedures may involve simple direct macroscopic visual determination of efficacy, or more sophisticated approaches such as measurement of aqueous humour prostaglandins (Spampinato *et al*., 1991).

When topical medicinal preparations are recommended for use in the treatment of local ocular injury it is clearly important to determine if such materials themselves have any potentially adverse effects on the eye which could interfere with the healing process or even exacerbate the injury. For example, over-the-counter (OTC) ophthalmic decongestion preparations may by themselves be a cause of conjunctivitis (Soparker *et al*., 1997). Such decongestion preparations usually contain an α-adrenergic vasoconstrictor (e.g. naphthazoline, tetrahydrozoline or phenylephrine), and some contain H_1 blockers. These materials have been shown to produce conjunctival hyperaemia, follicular conjunctivitis and/or blepharoconjunctivitis. This evaluation of the safety of materials that may come into direct contact with the eyes also applies to the possible development of corneal and/or conjunctival injury and of aseptic endophthalmitis (toxic anterior segment syndrome) caused by disinfectants such

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

as glutaraldehyde and *o*-phthalaldehyde used to sterilize ophthalmic surgical instruments (Ayaki *et al*., 2007; Ballantyne, 2004a; Mamalis *et al*., 2006).

To reduce the potential for chemically induced eye injuries, personal protective eyewear such as goggles, face shields, safety glasses and, with occupational situations, full-face respirators should be used when an eye hazard exists. Contact lenses do not provide protection (Peate, 2007). The eye protection chosen for a specific work condition depends on the nature and extent of the hazard, the circumstances of exposure, other protective equipment used and personal vision needs allowing for sufficient peripheral vision (NIOSH, 2009).

3 ALTERNATIVES TO CONVENTIONAL EYE IRRITATION TESTS

3.1 General Considerations

Criticism of eye irritation tests has come from concerned scientists, informed individuals and self-interest groups. The primary cause for such criticism is an appreciation of the discomfort and deliberate induction of injury to the eye produced in standard tests, and the apparent trivial misuse of the approach for testing products such as cosmetic formulations. Such informed pressure, compounded by uninformed and media comments, together with the concern expressed by several practising toxicologists, led to a proliferation of investigations in attempts to modify conventional approaches in order to reduce discomfort, or to replace eye irritation tests with alternative methods to detect the ocular injuring potential of chemicals. As a consequence, there has been a proliferation of publications in which investigators report what they considered to be suitable alternatives with the ability to predict *in vivo* ocular injury. Some of these approaches have merit in being biologically and mechanistically based, but others displayed a lack of understanding of basic biological principles as applied to toxicological problems and of the mechanisms of induction of eye injury by chemicals. It is still generally believed that no one method, particularly *in vitro*, can reliably predict eye irritating potential for a differing series of chemical classes. Several methods, taken together, may assist in the prediction of eye irritating potential, but ultimately for potentially high risk situations the results (particularly if negative) may require confirmation by *in vivo* procedures (Secchi and Deligianni, 2006). Total reliance on many of the currently used alternative procedures is not likely to be conclusively helpful in, for example, litigation involving human eye injury from a material judged to be nonirritating by these procedures. Also, and paradoxically inhibitory to the development and validation of alternative procedures, many regulatory authorities, whist supporting the requirement for such alternative approaches for ocular irritancy testing, still will not accept results from alternative procedures for the purposes of human health hazard evaluation and related regulatory actions.

Table 6 Groups of alternative approaches to conventional *in vivo* eye irritation testing

In vivo threshold irritant methods
Isolated ocular preparations
Isolated nonocular preparations
In vitro cytotoxicity assays
Nonbiological methods
Analogy

Alternatives to conventional *in vivo* eye irritation testing can conveniently, though generally not mechanistically, be divided into *in vivo* alternatives, *in vitro* alternatives and the use of nonbiological models (**Table 6**).

3.2 *In Vivo* Threshold Alternatives

These methods, whilst using whole animals, are aimed at significantly reducing discomfort to animals by employing lower doses of the test material and by increasing the sensitivity for the detection of injury by the use of noninvasive techniques. Most approaches have the advantage of allowing an objective quantitative evaluation of the monitor for ocular injury.

3.2.1 Measurement of Corneal Thickness (Pachymetry)

In vivo measurement of the thickness of the cornea is a particularly sensitive method for the early detection of corneal injury. Corneal thickness, hydration and transparency are inter-related, with corneal thickness and hydration being linearly related (Medbys and Mishima, 1966). Increase in cornel thickness following acute chemical injury to the eye indicates the development of oedema within the corneal stroma, which may reflect damage to the epithelium, endothelium or limbic vessels (McDonald *et al*., 1983). Such damage facilitates the passage of water into the stroma, causing an increase in corneal thickness. Corneal oedema can result, for example, from epithelial and/or endothelial damage, increase in intraocular pressure (IOP) and inhibition of Na^+-K^+-ATPase (adenosine triphosphatase); such factors may be found in various types of chemically induced corneal injury (Chan and Hayes, 1985). Measurement of corneal thickness has several advantages, which include:

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064

1. Quantitative data are obtained which may be subjected to statistical analysis for comparative evaluation of different materials.
2. The method is noninvasive and causes the minimum of discomfort to animals.
3. Increase in corneal thickness usually occurs at test material concentrations below those producing macroscopic evidence for eye irritancy.
4. Examination of concentration–response curves allows prediction of irritant potency.

Corneal thickness may be measured *in vivo* by a simple optical device attached to a slit-lamp biomicroscope (optical pachymetry; **Figure 3**), or by means of an ultrasonic probe (ultrasonic pachymetry), both of which show good reproducibility (Chan and Hayes, 1985; Martins *et al*., 1992). The ultrasonic pachymeter uses a signal that penetrates corneal tissue, and from which the thickness is calculated based on corneal density and the change in reflectance at the junction of cornea and aqueous humour. In a detailed evaluation of methods and conditions for measuring corneal thickness, Myers *et al*. (1998) found that the best method was by the use of an ultrasonic pachymeter in rabbits that had been preconditioned to remain calm with mild restriction (a 'cat bag'). Sedation was found not to be necessary with these conditions. The use of local anaesthesia of the eye resulted, by itself, in a decrease in corneal thickness. Comparing the effect from an irritant alone with that resulting from irritant plus local anaesthesia demonstrated

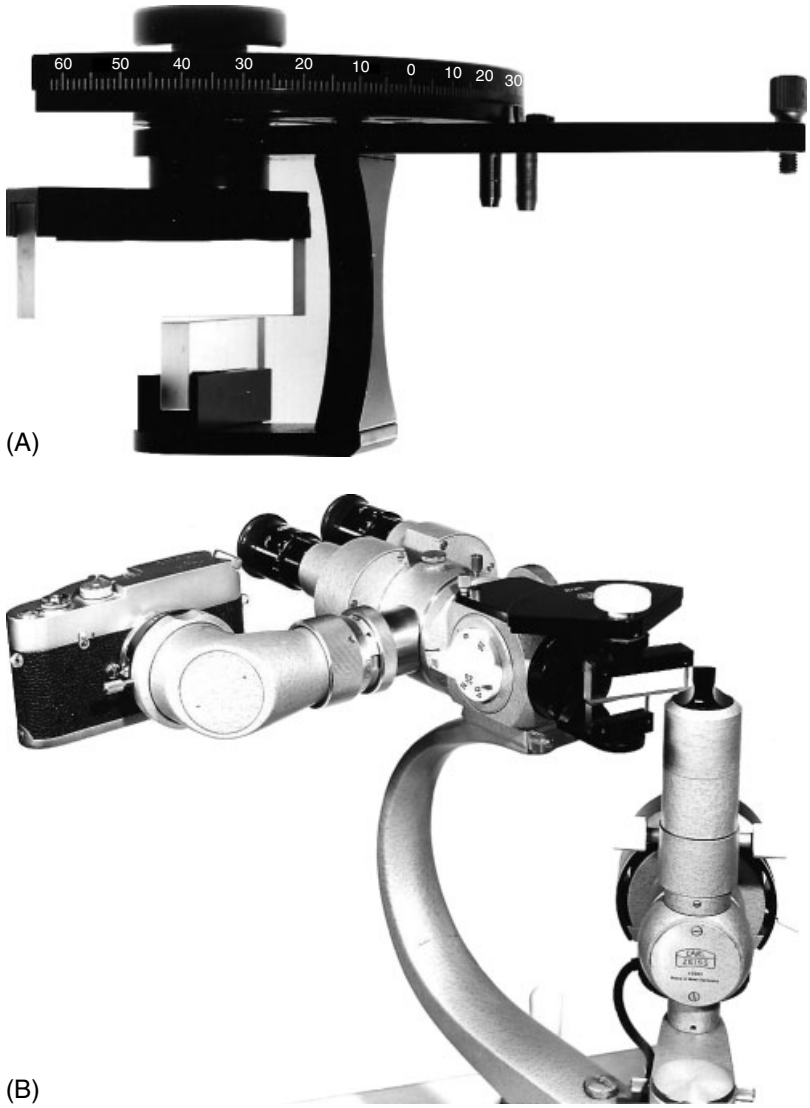

Figure 3 (A) Optical pachymeter. The slit beam from a biomicroscope is passed through two parallel-aligned glass blocks, which results in an image of the slit beam being visible on the surface of the corneal epithelium and a second image on the endothelium. One of the plates is rotated until the two images align, and the degree of rotation necessary to produce alignment is proportional to the thickness of the cornea (epithelial surface–endothelium distance). (B) Optical pachymeter mounted on slit-lamp biomicroscope.

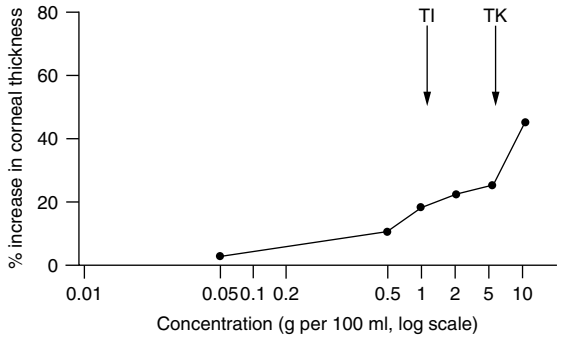

Figure 4 Peak increases in corneal thickness plotted as a function of the concentration of dibenz(b.f)-1,4-oxazepine (CR) in polyethylene glycol 300 applied to the rabbit cornea. Increase in corneal thickness occurs at concentrations below those at the threshold for irritation to the conjunctiva (TI, threshold for irritation) and even lower than those producing macroscopic evidence of corneal injury (TK, threshold for keratitis). (After Ballantyne, 1999.)

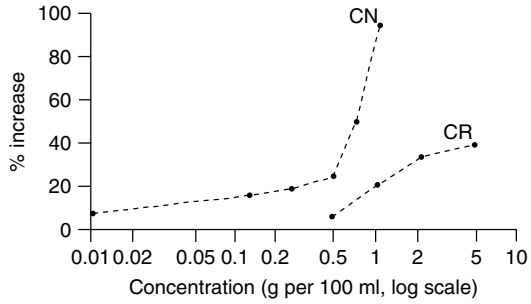

Figure 5 Increase in corneal thickness as a function of the concentration of 1-chloroacetophenone (CN) and dibenz(b.f)-1,4-oxazepine (CR) applied to the rabbit eye. For CN, the more irritant material, increase in thickness can be measured at lower concentrations than for the less irritant CR. Also, at any given concentration, the proportionate increase in corneal thickness is greater for CN than for CR. (After Ballantyne, 1999.)

that the use of topical anaesthesia may substantially affect the response of the cornea to a point of confounding both the corneal thickness and subjective Draize evaluations. It follows that if topical anaesthesia is used, the findings should be interpreted with caution because of the effect of local anaesthetics *per se* on corneal thickness, and since they may alter corneal permeability (Mauger, 1992; Nam *et al*., 2006). The rat was found to be a less suitable model for corneal thickness measurements. For example, and unlike the rabbit, corneal thickness in untreated eyes showed a variation with time. Although the rat cornea showed an increase in corneal thickness following the topical application of an irritant material, the inherent variability in corneal thickness made interpretation of the findings more difficult.

Several studies have shown a good predictive correlation between corneal thickness increase and ocular irritant potential. Thus, Burton (1972) found that measured changes in corneal thickness agreed well with subjectively assessed eye irritation, and that persistent corneal injury was associated with a greater degree of corneal thickening; Conquet *et al*. (1977) and Morgan *et al*. (1987) reached similar conclusions. Jacobs and Martens (1989) also found that a good correlation existed between mean proportionate corneal swelling and corneal opacity and hyperaemia scores. Using ultrasonic pachymetry on gently restrained animals, Myers *et al*. (1998) demonstrated a good correlation between corneal thickness and macroscopically assessed ocular irritation, and confirmed that measurement of corneal thickness is a useful and sensitive objective method for assessment of eye irritating potential of chemicals.

Increases in corneal thickness are concentration related (Ballantyne *et al*., 1975; 1976), and can be measured at concentrations less than those causing macroscopic evidence of irritant effects on the cornea or conjunctiva (**Figure 4**). The method can also be used to detect corneal thickness changes by exposure to vapours (Ballantyne *et al*., 1976; Chun and Ballantyne, 1997). With minor irritants, increases in corneal thickness are small and the concentration–effect curve has a plateau around those concentrations just producing macroscopic evidence of eye injury; moderate eye irritants produce a concentration-related increase in corneal thickness above the irritant threshold, and severe irritants produce concentration-related linear increases in corneal thickness up to the macroscopically visible irritation concentration and then show an abrupt increase with a marked change in the slope of the concentration–effect curve (Ballantyne *et al*., 1975; **Figure 5**). Thus, the shape and slope of the concentration–effect curve can in many cases be used to predict the potential severity of eye irritation of a test material. Since increases in corneal thickness can be measured at concentrations significantly below those causing a macroscopic irritant effect, the procedure may be carried out with the minimum of discomfort to the test animal. Also, Martins *et al*. (1992) demonstrated a high sensitivity with good correlation and reproducibility between corneal thickness and clinical observations for irritancy, and they consider that the method may be used with low application volumes without loss of sensitivity. The technique of confocal microscopy through focussing (CMTF) was developed to permit quantitation of the depth and thickness of different tissue layers and structures of the cornea (Li *et al*., 1996; Maurer and Jester, 1999). In this technique automated rapid focussing through the cornea at high speed allows the generation of a z-axis profile, and allows a three-dimensional reconstruction of the corneal thickness. Using a series of surfactants, Maurer *et al*. (1997) applied the test materials to the rabbit eye and assessed epithelial cell size, epithelial layer thickness, total corneal thickness and depth of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

keratinocyte necrosis. They found significant differences in the area and depth of injury with different surfactants of varying irritancy. They noted that observations taken at three-hour postinstillation can be used to distinguish different degrees of ocular irritation. The method can also be applied to *in vitro* preparations and used to assess and quantitate human eye injury.

3.2.2 Measurement of Intraocular Pressure

An increase in IOP can result from a variety of causes, including obstruction of the aqueous outflow tract, increase in aqueous humour production, and an increase in aqueous humour solute concentration (Chan and Hayes, 1985). It is also known that when the eye is exposed to an irritant material there is an increase in IOP followed by a return of the pressure to preirritant values; the magnitude of the increase in IOP and its duration usually depend on the severity of the irritant response (Ballantyne *et al*., 1977; Walton and Heywood, 1978). IOP has been measured by cannulation of the anterior chamber, but this procedure has many disadvantages; these include the development of leaks, that general anaesthesia is necessary, it is not suitable for long-term measurements and it is invasive (Ballantyne *et al*., 1977). More convenient are tonometric methods, which involve either measuring the amount of deformation of the cornea produced by a standard force applied to the cornea (indentation tonometry) or measuring the force necessary to produce a standard degree of corneal flattening (applanation tonometry). Indentation tonometry has several disadvantages compared to applanation methods, which include:

1. The applied indenting force displaces fluid, stretching and increasing tension in the wall of the eye, and thus producing an artefactual increase in IOP.
2. Most indentation tonometers have been designed for human clinical use with the patient in the supine position. Thus when used with experimental animals there may be considerable handling and restraining problems to align the eye and tonometer, which may lead to compression of cervical blood vessels and release of catecholamines, both of which may artefactually increase IOP (Perkins, 1965).
3. Instruments generally have footplates averaged for the human eye, and this may lead to errors in reading with animal use.

In view of the above disadvantages, applanation is the preferred method for measurement of IOP in experimental animal situations. Pneumotonometry is now available as a noninvasive, readily conducted technique for the measurement of IOP, and is reliable and reproducible (Avilla *et al*., 2005). The rabbit is a suitable animal model because of the large amount of documented information available concerning the influence of topically applied irritant materials on IOP.

Table 7 Values for intraocular pressure (IOP) in various species

Species	IOP value (mm Hg)	Reference
Rhesus monkey	17.1 ± 3.0 SD[a]	Schiavo (1973)
Beagle dog	19.0 (range 10.0–31.0)	Heywood (1971)
New Zealand white rabbit		
Male	15.77 ± 1.28 SD	Ballantyne *et al*. (1977)
Female	16.00 ± 1.46 SD	Ballantyne *et al*. (1977)

[a]SD: standard deviation.

In order to permit the continual recording of changes in IOP, McLaren *et al*. (1995) described a telemetric method that used a fluid-filled catheter inserted into the anterior aqueous chamber through an opening near the limbus. The method was limited by the fact that the tip of the catheter rotates, producing corneal and iris irritation. Subsequently, Percicot *et al*. (1996) used a method based on implantation of a catheter into the posterior chamber to allow long-term measurements of IOP. The procedures involved implantation of a miniaturized pressure transducer radiotelemetry system into the cervical subcutaneous (sc) tissues, from which a cannula was tunnelled subcutaneously to the superior conjunctival sac and inserted behind the corneoscleral junction to a midvitreous position. They used the preparation to study IOP in ocular normotensive animals (Schnell *et al*., 1995) and also investigated the effect of antiglaucoma eye drops in the chronic ocular hypertensive rabbit model, induced by posterior chamber injection of α-chymotrypsin (Percicot *et al*., 1996).

Values for IOP are available for several species as shown in **Table 7**. A normal frequency distribution is observed with IOP measurements in various strains and species (e.g. **Figure 6**). A circadian rhythm has been described for IOP in the rabbit (Ballantyne *et al*., 1977) and the rat (Moore *et al*., 1995). It follows that in experimental situations and for comparative evaluations, treatments and measurements should be made at similar times in the different groups, including the controls.

Increases in IOP with a given material depend on the total dose applied to the eye; that is, the response will vary with both the volume applied to the eye and the concentration of active ingredient (**Figure 7**). It follows that for a comparative evaluation of IOP changes, the conditions should be similar with respect to dosing. Also, if materials are to be tested in solution, then solvents that do not produce an effect on IOP should be used; examples include saline, PEG 300, glyceryl

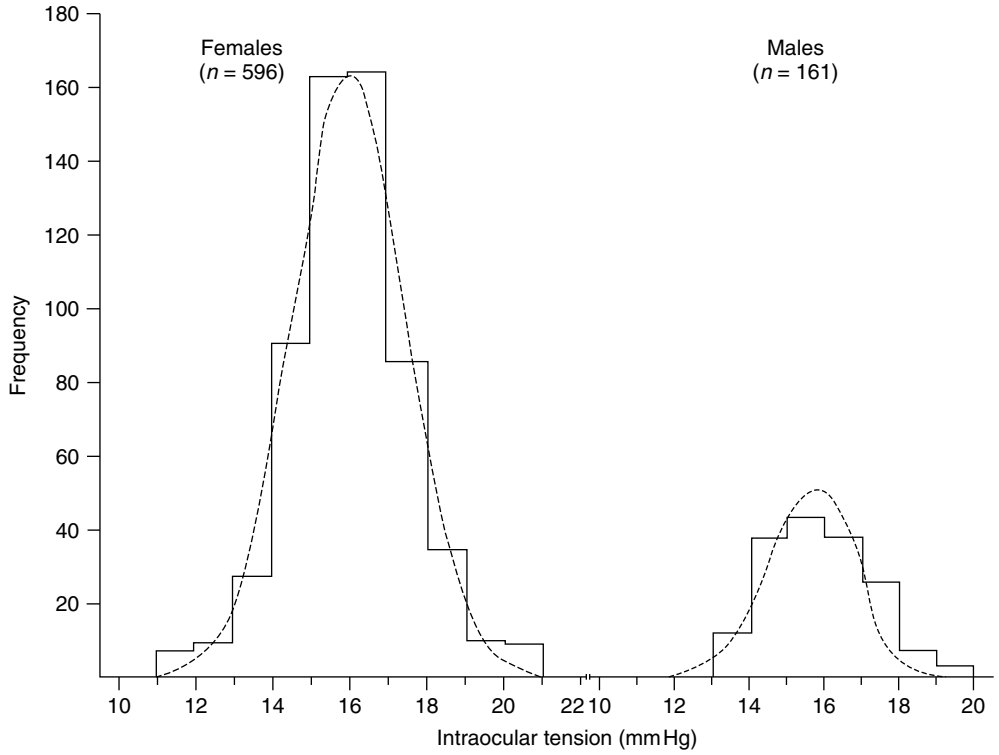

Figure 6 Frequency histograms to demonstrate the distribution of intraocular pressures in 596 female and 161 male New Zealand white rabbits. The broken line is the normal distribution with a mean ± SD of 16.00 ± 1.46 mm Hg for females and 15.77 ± 1.28 mm Hg for males.

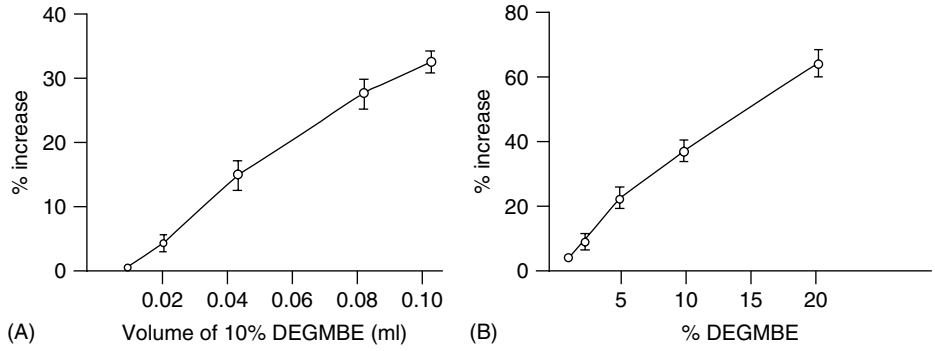

Figure 7 Increases in intraocular pressure (IOP), measured at 10 minute postapplication, produced by diethylene glycol monobutyl ether (DEGMBE). (A) Increase in IOP as a function of the volume of test material (10% DEGMBE) applied. (B) Increase in IOP following application of 0.1 ml of different concentrations of DEGMBE. In both instances the increases in IOP are dose dependent. (Data after Ballantyne, 1984.)

triacetate, tri(2-ethylhexyl) phosphate, corn oil and 1,1,1-trichloroethane (Ballantyne *et al*., 1972).

Increases in IOP are usually measurable within a few minutes of contaminating the eye with an irritant material. The time for IOP to return to control values depends on the concentrations of material applied, its irritant potential and the ability to penetrate the cornea to produce deeper structural and functional injury; times may vary from about an hour to several days. It follows that measurements should be made early after contaminating the eye and followed by sequential measurements. In general, the increase in IOP at a specific time after exposure is greater the more irritant the material (**Figure 8**). Also, as with corneal thickness measurements, mild to moderate irritant materials produce a linear increase in IOP with incremental increases in concentration, whereas with severely irritant materials at low concentrations there is a shallow dose–response curve which shows an abrupt change to a steep curve at higher concentrations (**Figure 9**). Thus, comparison of the magnitude of

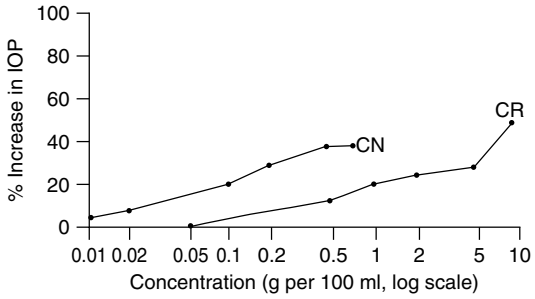

Figure 8 Proportionate increases in intraocular pressure (IOP) in the rabbit eye as a function of concentration from instilling 0.1 ml volumes of various concentrations of solutions of 1-chloroacetophenone (CN) or dibenz[b.f]-1,4-oxazepene (CR). The magnitude of increase in IOP is concentration-dependent, and for the more irritant CN, increases are measurable at lower concentrations than those for the less irritant CR.

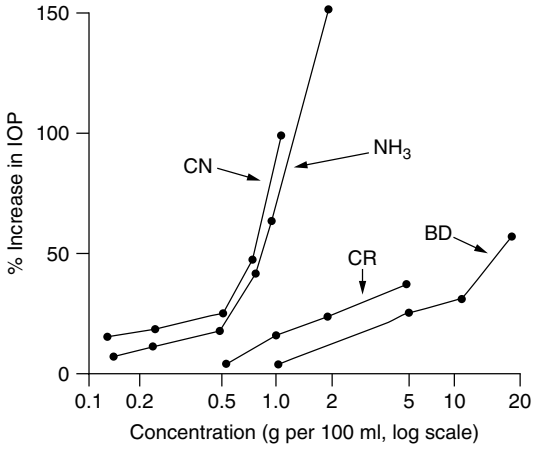

Figure 9 Peak increases in intraocular pressure (IOP) measured at about 10 minutes, as a function of concentration of material applied to the eye. Comparison of 1-chlororacetophnone (CN), aqueous ammonia (NH_3), diethylene glycol mono-*n*-butyl ether (BD), and dibenz[b.f]-1,4-oxazepine (CR). For BD and CR, increases in IOP begin to occur at higher concentrations than for CN and NH_3 and are essentially linear with concentration and have shallow slopes. With CN and NH_3, for which increases in IOP occur at lower concentrations, the initial part of the curve is shallow and then abruptly becomes steep; these two materials are severe irritants.

changes in IOP and the slopes on the dose–response curves can be used to predict the likely severity of irritation that will be produced by a given material.

3.2.3 Corneal Permeability Studies

Corneal permeability studies are sometimes used as an ancillary to standard eye irritation tests as discussed in Section 2.3.6.2, but with sensitive analytical methods the approach can be adopted as an alternative for the detection of early corneal injury, and thus for prediction of eye irritation. For example, Etter and Wildhaber (1984) described a method for use in conscious restrained mice based on measurement of fluorochrome penetration following brief topical contact with test material. As an extension, Maurice and Brooks (1995) described the use of a mouse corneal permeability procedure on the eyes of animals left *in situ* immediately following nitrous oxide euthanasia. Penetration was assessed using the fluorochrome sulforhodamine. The test involved applying a 'drop' of test material to the epithelium, which was washed off one minute later, and then a drop of fluorophore was applied to the epithelium for a further one minute. Measurement of fluorophore penetration was undertaken using a specially adapted fluorometer in which the proptosed eye was inserted into a 3 mm diameter circular opening in the equipment. They found the method to be reproducible and, in general, to give a good agreement with the known irritant potential of a wide range of materials. The investigators claimed the following advantages for the method: simple, rapid, gives an objective numerical assessment, economic, uses a biologically relevant tissue, and uses euthanized animals. Possible interpretive problems include that the process is limited to corneal epithelium and ignores deeper corneal structures, it measures only an immediate response, it is indirect, and it ignores the possible contribution of lacrimation. However, the authors consider that the approach may be of value for screening proposes.

3.3 *In Vitro* Isolated Ocular Tissues

3.3.1 Enucleated Eyes

A method was described by Burton *et al.* (1981) that involved the direct application of test substance to the cornea of rabbit eyes removed immediately after sacrifice of the animal, and subsequent evaluation of the cornea for swelling, opacity and fluorescein staining, followed by histological examination of the eye. The eye was mounted on a clamp in a temperature-controlled superfusion chamber with isotonic saline being dripped on to the corneal surface. After a 30–45 minute equilibration period, test material was applied to the cornea and then washed off. Eyes were subsequently inspected macroscopically, and then with a slit-lamp biomicroscope, corneal thickness was measured and fluorescein staining observed. Price and Andrews (1985) measured corneal thickness in enucleated rabbit eyes and found the method to be a reliable predictor of eye irritation potential. In a comparative study of the isolated ocular preparation in several laboratories, Koëter and Prinsen (1985) validated the test system against Draize eye results using 34 compounds. Whittle *et al.* (1992)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

found that the predictive value of the test and the consistency of results between different laboratories were good. A 10 second exposure allowed most irritant substances to be identified, and a 60 second exposure increased the corneal response and could therefore be useful for testing products of low irritancy. In a study conducted under the auspices of the Commission of the European Communities (CEC, also known as the European Commission, EC), involving 10 laboratories examining 21 reference compounds, it was found that there was consistency in the findings and across the various laboratories, and in general the results predicted the correct grades of the compounds (CEC, 1991). Prinsen and Koëter (1993) examined the suitability of the chicken eye in the enucleated eye test, because of the ready availability of tissues from chicken slaughterhouses. Using 21 compounds, and assessing injury by corneal thickness measurements, fluorescein retention and corneal opacity, they found the chicken eye results to correctly classify ocular irritation according to EC classification. Subsequent experience (Prinsen, 1996) with 44 test materials showed an excellent correlation with a standard *in vivo* rabbit eye irritation test (0.1 ml). Since nonirritant and severely irritant compounds were correctly identified, it was suggested that the chicken enucleated eye test could be useful as a screen for these two groups, which would not require further *in vivo* testing. Pérez-Rivera *et al*. (2008) also found that the chicken enucleated eye test correlated well with historically available animal *in vivo* and clinical eye irritation data.

3.3.2 Isolated Cornea and Corneal Epithelial Cell Lines

Gautheron *et al*. (1992) used the isolated cornea from bovine eyes. The preparation was held in place in a specially designed holder having compartments in front of and behind the mounted cornea, and incubated in a chamber. Corneal injury was assessed by opacity, and measured by light transmission and fluorescein permeability from the anterior to the posterior chamber of the corneal holder. The results demonstrated a good assessment of ocular irritating potential. Vanparys *et al*. (1993) tested 50 materials in a bovine corneal opacity–permeability preparation, and used opacity measurements and permeability to sodium fluorescein as the monitors. They obtained a 77% concordance using a four-level irritation classification (nonirritant, and mild/moderate/severe irritation), and a 95% correct classification using two categories (nonirritant and irritant). Because many alternative methods to *in vivo* eye irritation tests do not consider the question of reversibility, Gilotti *et al*. (2007; 2008) used a modified excised porcine cornea model to assess irritancy and its reversibility. Corneas in culture were treated one day after excision with undiluted ethanol, 3% sodium dodecyl sulfate (SDS), 1 N sodium hydroxide, or 1% benzalkonium chloride (BAC). The area of damage was visualized by brief fluorescein staining under UV light. With the exception of sodium hydroxide, the area of damage decreased over time, and histology demonstrated re-epithelialization. Decrease in fluorescein retention area correlated with time to recovery as determined by previously published Draize scores, and the investigators concluded that this approach may be of value since it has the potential to determine recovery after initial ocular injury.

Working on the basis that an irritant chemical may cause disruption of epithelial tight junctions, Xu *et al*. (2000) used bovine corneal culture models to assess epithelial responses to surfactants and for possible use for predicting ocular irritancy in humans. The approach was based on a belief that disruption of tight junctions could trigger cell stress-response modulated transcription factors such as AP-1 and NF-HB. They assessed the effects of SDS and BAC on corneal epithelial permeability and DNA-binding activity of AP-1 and NY-κB in cultured bovine corneas. Epithelial barrier integrity was assessed by a surface biotinylation method (Chen *et al*., 1997). Both SDS and BAC induced tight-junction disruption and increased permeability of corneal epithelium as assessed by surface biotinylation in a concentration and time-related manner. Increased DNA-binding activity was detected when corneas were treated with surfactants causing minimal to mild ocular irritation, indicating epithelial stress response. Also, exposure to SDS and BAC at concentrations causing severe ocular irritancy resulted in a decrease in DNA-binding activity of the transcription factors. These findings indicate that a combination of isolated corneal culture and measurements of corneal epithelial permeability and DNA-binding of stress response transcription factors following exposure to chemicals has the potential to be used as a mechanistically based *in vitro* isolated ocular tissue alternative for eye irritancy prediction.

Working with a series of six organosilicone compounds having different functional groups, Cassidy and Stanton (1997) obtained a correct classification using opacity and permeability measurements. They also found these monitors to accord with the histology of the cornea. Eurell *et al*. (1991), in preliminary work with cryomicrotome sections of rabbit and human corneas, used iso-electric focussing to assess effects on corneal protein profiles. They found that acetic acid and ammonia solutions produced a similar acid-base effect on a common rabbit and human corneal protein band, and thus aid in the extrapolation of findings. Kruszewski *et al*. (1995) described the use of a cell line grown from human corneal epithelium, which was grown as a three-dimensional culture on a collagen membrane. Effects on the preparation were measured using fluorescein retention. Using 12 chemicals they found a good

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

correlation with Draize ratings and, supported by subsequent studies (Kruszewski *et al*., 1997). Schneider *et al*. (1997), described a complex *in vitro* corneal preparation prepared by establishing primary and subcultures of endothelial, stromal and epithelial cells from the foetal pig eye. A three-dimensional *in vitro* corneal model was established in culture plates by sequentially adding endothelial cells, stromal cells and epithelial cells. The cytotoxic response of the preparation was assessed by mitochondrial activity using an MITT assay [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide]. Based on calculated E_{50} values (concentration causing 50% inhibition of mitochondrial capacity) they found a good correlation between E_{50} values and the Draize classification.

Using a rabbit corneal cell line (SIRC), Takahashi *et al*. (2008) developed an easy-to-perform short time exposure (STE) cytotoxicity test, with cell viability as the end point for irritation potential. Exposure time was five minutes, and when compared with Draize values there was good correlation. Comparing results from three laboratories, the investigators found the STE cytotoxicity test to have good reproducibility and transferability.

3.3.3 Isolated Lens

Using lenses cultured *in vitro,* several studies have shown a correlation between toxicity and lens optical function, and that with several materials there is a much higher sensitivity in detecting irritancy at lower concentrations than by the standard corneal irritation test (Bantseev *et al*., 2003; Sivak *et al*., 1992; 1994). This implies that the *in vitro* isolated cultured lens system can be used as a predictive and more sensitive indicator of eye irritation than the *in vivo* eye irritation test. On the basis that the lens is embryologically derived from the same source as corneal and conjunctival epithelium, Sivak *et al*. (1992) used an automatic scanning laser system to monitor spherical aberration and transmission of the lens in culture. Using five alcoholic test materials, the investigators considered that this method of measuring lens damage compared favourably with standard Draize scores for irritation. Bantseev *et al*. (2003) used the cultured bovine lens to investigate the effects of the surfactant SDS on lens optical properties by automated scanning laser system, and mitochondrial integrity as assessed by confocal microscopy. Loss of sharp focus was evident immediately following exposure, and loss of lens transparency, increased lens weight and increased axial length were seen at 24 hours postexposure. Confocal analysis at 24 hours postexposure showed a concentration-related increase in the numbers and lengths of mitochondria in lens epithelial and superficial cortical fibre cells. Thus, the results of this study demonstrated a correlation between lens optical properties and metabolic functions, and indicate this approach is a sensitive *in vitro* model of ocular chemical toxicity. The cultured bovine lens technique has been shown to be of value for assessing eye irritation potential of consumer products (Wong *et al*., 2003).

3.4 Isolated Nonocular Preparations

3.4.1 Chorioallantoic Membrane

The chorioallantoic membrane (CAM) of the hen's egg is a highly vascular tissue and has been used to determine the irritant response to substances as a predictor for eye irritation. It is a borderline *in vitro/in vivo* system and does not conflict with ethical and legal standards (Leupke, 1985). Basically the test involves the use of fresh fertile eggs, from which the shell is gently removed from around the air cell on day 10 of incubation. The vascular CAM is exposed by removing the inner egg membranes, and test substance is dripped on to the membrane. The blood vessels and albumin are subsequently scored for irritant effects (hyperaemia, haemorrhage, coagulation) at 0.5, 2 and 5 minutes post-treatment. Details of the methodology and scoring have been presented by Leupke (1985), who found a good correlation with Draize irritation scoring. Blein *et al*. (1991) found the method to be too sensitive with undiluted materials, but with a 10-fold dilution there was a reasonable correlation with *in vivo* eye irritation results, and under these conditions the method gave good discrimination between mild, moderate and severe irritants. Bagley *et al*. (1989) found that the CAM assay for surfactants correctly classified these materials, and they showed the method had a high sensitivity, specificity and predictive value.

Martins *et al*. (1992) used a combined approach of the excised bovine eye and CAM assay to assess the eye irritating potential of chemicals; corneal injury was assessed by opacity, fluorescein stain and epithelial detachment. The combined assay was developed to simulate both corneal injury (bovine eye) and mucosal response (CAM). They found a limited correlation using this dual approach, with fewer than 40% of the substances tested being in agreement with *in vivo* results. In contrast, Van Erp and Weterings (1990) found a good correlation between the combined assay and *in vivo* results. Problems that have been described with the CAM procedure have included variations in the application of the test material and the use of rinsing, which can damage the membrane. Gilleron *et al*. (1996) modified the procedure by using a test substance applicator and microscopic examination. With 46 compounds they obtained a sensitivity of 80% and a concordance with the Draize test of 80.4%.

3.4.2 Other Tissues

A good correlation was found between bovine erythrocyte haemolysis, blocking of ileal contractions, and *in vivo*

Table 8 Examples of end-point measurements used in cytotoxicity assays as alternatives for eye irritation tests

Method	Basis/end point	Reference
Microphysiometry	Metabolic rate measurement	Bruner *et al*. (1991a; 1991b)
Uridine uptake inhibition	Membrane damage	Shopsis and Sathe (1984)
Neutral red uptake	General cytotoxicity	Borenfreund and Puerner (1987)
Neutral red release	Cell membrane injury	Rohde (1992)
Leucine incorporation	General cytotoxicity	Sina *et al*. (1992)
Total protein	General cytotoxicity	Riddell *et al*. (1986)
Fluorescein leakage	Cell membrane injury	Rohde (1992)
Colony-forming efficiency	Lethal cytotoxicity	North-Root *et al*. (1982)
MTT dye reduction	Mitochondrial damage	Sina *et al*. (1992)
Crystal violet staining	Lethal cytotoxicity	Itagaki *et al*. (1991)
Alkaline phosphatase release	Membrane injury	Scaife (1985)
Intracellular ATP	General metabolic toxicity	Kemp *et al*. (1985)

eye irritation by various surfactants (Muir *et al*., 1983). However, the biological basis of this approach makes its use for predicting eye irritating potential somewhat suspect.

3.5 Cytotoxicity Assays

Cytotoxicity assays measure loss of some cellular, or intercellular, structure and/or functions, including lethal cytotoxicity. They are generally simple to perform, reproducible and have clearly defined end points. In view of these considerations, several investigators have used cytotoxicity assays as the basis for the development of *in vitro* 'predictive' alternative approaches to eye irritation studies. However, predictability based on comparisons with *in vivo* standard eye irritation tests may be variable for a variety of reasons, including the fact that assay systems are continually exposed, whereas *in vivo* there are biological protective mechanisms in operation. Some assays may not be universally capable of detecting all chemical classes of irritants because of the end point used.

A variety of cell lines have been used, including corneal epithelial cells, lung fibroblasts, Chinese hamster ovary (CHO) cells, canine renal cells, HeLa cells, and microorganisms. In each case where nonocular cell lines have been employed, investigators have attempted to justify the reason for choosing the line used. For example, the use of canine renal cells was justified by Shaw *et al*. (1991) on the basis that the integrity of corneal epithelial cells depends on tight and desmosomal junctions, which are also seen in canine renal epithelial cells and form an impermeable barrier. They are thus considered appropriate to detect chemicals that may cause an increase in transepithelial permeability. These investigators used fluorescein leakage to assess injury to tight junctions, and neutral red release to detect renal membrane injury. A considerable number of differing end points have been used in cytotoxicity assays, some examples of which are listed in **Table 8**. A multiplicity of cytotoxicity assays have been described, and some illustrative examples are discussed below.

3.5.1 Crystal Violet Staining

Itagaki *et al*. (1991) employed a simple technique with lethal cytotoxicity as the end point, using cultured HeLa cells or SIRC cells (established line of rabbit corneal cells) in the presence of serial dilutions of the test material. After incubation, crystal violet (methyl violet) was used to stain residual viable cells. The IC_{50} was calculated: that is, concentration of test material inhibiting growth of cells by 50%. Using various surfactants they found a good correlation between the IC_{50} and the maximum *in vivo* eye irritation scores for the materials tested.

3.5.2 Silicon Microphysiometry

The silicon microphysiometer is a light-addressable sensor device, which can be used to measure the rate of acidic metabolite production from cells placed in a biosensor flow chamber. The end point calculated is the MRD_{50}; that is, the concentration of test material required to reduce the metabolic rate by 50% (Bruner *et al*., 1991b). Mouse fibroblasts have been used as the test cell. Bagley *et al*. (1992) found the MRD_{50} for a variety of materials to correlate with the maximum average score for *in vivo* eye irritation. Rougier *et al*. (1992), working with 41 commercial products, established MRD_{50} values in mouse fibroblasts and found a good correlation with Draize scores (r^2 = 0.81–0.91, depending on the class of the material). Catroux *et al*. (1993a; 1993b) also obtained a good correlation using surfactants and commercial products (r = 0.89). Bruner *et al*. (1991a; 1991b) also obtained excellent agreement between Draize rating and MRD_{50} for surfactants using human epidermal keratinocytes. This method appears to have good promise.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.5.3 Microtox Test

This test utilizes changes in luminescence from *Photobacterium phosphoreum*, which is generated through a process linked to respiration by reduced nicotinamide adenine dinucleotide (NADH) and flavin mononucleotide (Bulich, 1979). Light output is measured photometrically before and after addition of the test substance, and an EC_{50} value calculated; that is, concentration of test substance causing a 50% reduction in light emission. Bagley *et al*. (1992) found that, in general, test substances with the highest *in vivo* irritation gave the lowest EC_{50} values.

3.5.4 Plasminogen Activation

This assay uses the release of plasminogen activator from primary rabbit corneal epithelial cells as the quantitative index of toxicity. Some studies have shown a good correlation with known irritant potential (Bagley *et al*., 1994).

3.5.5 Neutral Red Uptake Assay

In this procedure cells, often mouse fibroblasts or CHO cells, are exposed to the test substance and then to neutral red (toluylene red). Retention of neutral red indicates cell viability. Bagley *et al*. (1992) found that, in general, the concentration of test material required to reduce neutral red uptake decreased as the *in vivo* irritant potential of the test material increased. Blein *et al*. (1991) found that correlations with materials of extreme pH were underestimated due to buffering in the culture medium, and volatile materials were also underestimated, probably because of loss of material.

Several intertest comparisons have been conducted. For example, Sina *et al*. (1992) compared leucine incorporation, MTT (3-(4,5-Dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazolium bromide) dye reduction and neutral red uptake in corneal epithelial cells and Chinese hamster lung fibroblasts. None of the end-point target cell combinations accurately predicted *in vivo* eye irritation in this series, but the MTT dye reduction method gave the overall best correlation. In a review, Christian and Diener (1996) noted that the neutral red assay appears to have merit for ranking potential ocular irritations, especially weak ones. The method is easily standardized, but interlaboratory variation occurs. Highly soluble simple substances appear to be more reliably predicted than complex pharmaceutical substances.

3.5.6 Comment on Cytotoxicity Assays

Cytotoxicity assays give an assessment of the effect of the test material on a particular aspect of cell or intercellular function or of lethal toxicity. They therefore give a measure of potential to cause cell and tissue injury, and as such may be used as a screen for predicting tissue injury, including eye injury. Appropriate choice of the test cell and end-point indicator for certain chemical classes may give a reasonable prediction of the potential for eye irritation. The choice of the cytotoxicity assay, or assays, should at least in part be determined by past experience, the likely mechanism for a positive response and the chemistry of the material tested.

3.6 Nonbiological Approaches

One example of nonbiologically-based approaches is the use of synthetic protein membranes, based on the fact that protein denaturation may be a contributory factor in corneal injury with several materials. The reactive component is a synthetic protein-globulin matrix. In one series of studies, the predictability of ocular irritation was 89% and in another 93% (Soto and Gordon, 1990).

3.7 Prediction by Analogy

3.7.1 Computer-Based Modelling

Structure–activity and structure–property analyses have been recommended for many years as possibly being predictive in ocular irritation, and used in the early stages of assessment procedures. The initial processes looked at chemical structure and class in terms of known Draize scoring, and used any correlations as a basis for predicting eye irritating potential with materials having the same chemical structure or class features. Following this simplistic approach, there have been several proposals that computer-based structure–activity relationships (SARs) could be used as a basis for predicting the eye irritating potential of chemicals. Quantitative structure–activity relationship (QSAR) analysis is a method used to relate the magnitude of a particular property (in this case ocular irritation) to one or several physicochemical and/or structural features of a molecule. The initial QSAR models to predict eye irritation were limited to a series of chemical analogues for which the dependent property (ocular irritation) was derived from a set of intramolecular descriptors based on an assumed common mechanism of action. Since eye irritation assessments are frequently sought for structurally diverse compounds, the standard QSAR approach is somewhat limited in utility in applications that estimate ocular irritation for diverse classes of chemicals. For example, Sugai *et al*. (1990) used a QSAR model to analyse the correlations between chemical structure and eye irritation in rabbits. They claimed 86.3% accuracy in classifying with respect to eye irritancy, and believe that the QSAR is of value in predicting irritating potential. Barratt (1997) described a QSAR for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the eye irritating potential of neutral organic compounds based on the perturbation of ion transport across the cell membrane being related to dipole movements of the causative agent, the model parameters chosen were log P_{ow} (log octanol–water partition coefficient) and the internal axes R_y and R_x (representing the cross sectional area of the molecule). The results provided support for the validity of the QSAR model.

It has been suggested that a better predictive estimate of ocular irritation with chemically diverse materials is possible if the QSAR model includes receptors linked to the irritation response. Also, uptake and diffusion of an irritant into the corneal epithelium may be a significant related factor, and thus interactions between the irritant molecule and corneal epithelial cell membranes could be a determinant, and form the basis for a predictive approach known as membrane-interaction quantitative structure–activity relationship (MI-QSAR). Kulkarni *et al*. (2001) simulated the uptake and interaction of various solute molecules with a model phospholipid membrane. In these simulations the estimated membrane–solute interaction properties from the molecular simulations are added to the intramolecular physicochemical property descriptors. Their findings demonstrated that inclusion of parameters to model membrane interactions of potentially irritant chemicals provides a significantly better prediction of eye irritation for structurally diverse compounds than does modelling based solely on physicochemical properties of chemicals. The investigators noted that the MI-QSAR models can be used with high reliability to classify compounds of low and high predicted eye irritation. However, the value of a MI-QSAR model depends on the number, nature and reliance of the QSAR descriptors. Thus, in a study by Li *et al*. (2005), 13 structurally diverse drugs of known *in vivo* eye irritation potential were chosen for comparison in a MI-QSAR analysis for investigating the relationship between corneal permeability and ocular irritation. The investigators found no meaningful relationship between *in vivo* eye irritation potency and corneal permeability, with an R^2 of 0.0232 between predicted values of log P_{cornea} versus known *in vivo* eye irritation potency. It was suggested that the difference in findings between their study and that of Kulkarni *et al*. (2001) was, in part, due to differences in the two QSAR models, with no descriptor related to reactivity potency in the Li *et al*. (2005) model.

Although the SAR approach could be a useful adjunct with chemicals in a class of known irritancy, there still exits the possibility for litigation based on a product safety assessment consisting solely of QSAR analysis.

3.7.2 Prediction Based on Skin Irritation Analogy

It has been suggested that materials shown to be primary skin irritants should be regarded as being eye irritants, and therefore do not require to be tested for ocular irritation *per se*. Whilst such an approach is overcautious in that some skin irritants have been shown not to be irritant to the eye, the converse is of more concern since materials might be mistakenly classified as nonirritant to the eye. Several studies have shown that there may not be a good correlation between skin- and eye-irritating potential, and that some eye irritants are not skin irritants (Dalbey *et al*., 1993; Rhodes, 1987). Kennedy and Banerjee (1992) studied 72 fibre finish materials and found a 10.5% error in predicting that a severe skin irritant was a severe eye irritant, and commented on a poor predictive association between skin and eye irritancy for the compounds they investigated. Williams (1984) reviewed 60 materials that were severe irritants or corrosive to the skin; of these 36 were severe eye irritants, 6 moderate eye irritants and 18 mild or nonirritant. He concluded that to suggest materials are eye irritants on the basis of their skin irritating potential could be misleading. There is thus no simple relation between skin and ocular irritancy, and in several cases it may be misleading to attempt to predict one from the other (Daston and Freeberg, 1991).

3.8 General Review Comments on Alternative Tests

Currently, no single alternative test or combination of them can completely and unequivocally predict the eye irritating potential of all test substances. Indeed it has been suggested that expectations for a uniform test should be discouraged (Reinhardt, 1990). However, with an appropriate tiered scheme there may be significant reductions to *in vivo* eye irritation testing. Approaches to such schemes have been proposed (Jackson and Rutty, 1985; Reinhardt, 1990), and they should follow a sequential approach to include:

1. Consideration of the physical and chemical characteristics of the material being tested, along with comparison of materials in the same chemical class whose *in vivo* eye irritating potential are known.
2. Use of appropriate cytotoxicity studies, based on known predictivity for specific chemical classes.
3. Confirmation of potential for corneal injury using *in vitro* enucleated eye and/or corneal preparations.
4. In critical cases, such as high volume chemicals or therapeutic ophthalmic preparations, ultimate confirmation may be necessary by *in vivo* studies with objective evaluations.

On the basis of a comparison of several alternative methods with 37 materials, Sina *et al*. (1995) concluded that screening for chemicals with diverse structure and properties is best conducted using mechanistically based

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

as opposed to cytotoxic assays. In a review of alternatives, Christian and Diener (1996) came to the following conclusions:

1. None of the methodologies has been accepted for regulatory classification purposes.
2. No single *in vitro* assay is considered capable of replacing the conventional *in vivo* eye irritation test.
3. The greatest potential methods (at that time) for screening were the hen's egg CAM test, the chicken or bovine enucleated eye test, neutral red or plasminogen activation assays for cytotoxicity, and the silicon microphysiometer.
4. Choosing a specific test method(s) will depend on the material to be tested.

In a review article, Hutak and Jacaruso (1996) also suggested that no single test system will supplant animal testing. The method to be chosen will depend on the physical and chemical characteristics of the material to be tested and the sensitivity and specificity of the method. The continuing comparative evaluation of animal eye irritation tests against alternative methods and approaches will refine an acceptable alternative method or 'test battery'.

4 PERIPHERAL CHEMOSENSORY EYE IRRITATION

Chemical stimulation of corneal and conjunctival sensory nerve receptors will cause local pain or discomfort and the associated reflexes of increased lacrimation and blepharospasm. These effects are biologically protective in that they give warning of exposure to a potentially noxious material and provide some degree of protection against further exposure. However, pain, excess lacrimation and blepharospasm also impair vision and are distracting; they therefore predispose to physical accidents and impede efficient working conditions. Thus considerations on peripheral sensory effects on the eye can be important, for example, in assessing workplace safety, and may need to be taken into account in assigning workplace exposure guidelines (Kuwabara *et al*., 2007). Also, from a product safety viewpoint, it is important to know if there is an adequate margin (of safety) between the exposure conditions causing sensory irritation of the eye and those leading to eye injury. It is relevant to know that some materials may give little, or no sensory warning on contact with the eye, for example bis(2-chloroethyl)sulfate, dimethyl sulfoxide and methyl bromide. Clearly with such chemicals there is a need to emphasize the requirement for protective and precautionary measures.

Objective aspects of the sensory irritant response, for example blepharospasm, can be investigated in experimental animals. However, subjective responses (e.g. discomfort and pain) require carefully controlled studies in human volunteer subjects. Peripheral chemosensory irritation in general, and of the eye in particular, is discussed in detail in **Peripheral Chemosensory Irritation: Fundamentals, Investigation and Applied Considerations**; see also Ballantyne (2006b).

5 THE EYE AS A TARGET ORGAN FOR SYSTEMIC TOXICITY

5.1 General Considerations

Many materials, including drugs and industrial chemicals, can produce structural and/or functional injury following systemic distribution of the material and/or its metabolites after absorption from routes of exposure remote to the eye. Some illustrative examples are listed in **Table 9**. As shown in this table, a diversity of toxicopathological effects can be produced at different anatomical sites in the eye. With some substances there are highly site-specific effects, and with others a series of sites in and related to the eye may be affected by the same chemical. With multiple site systemic ocular toxicity, the combination and severity of lesions varies with different specific chemicals and with different chemical classes. Additionally, the same lesion complex may be produced by a multiplicity of differing absorbed chemicals. A good example of this is seen in some drug treatments in the human leading to the Stevens–Johnson syndrome, first described in 1922, in which there is severe bullous erythema multiforme with mucosal involvement of the mouth, eyes, gastrointestinal tract, lower respiratory tract, vagina and urethra (French, 2006; Schofield and Rees, 2006). Most authorities consider that the Stevens–Johnson syndrome and toxic epidermal necrolysis are different manifestations of the same disease (Parrillo and Parrillo, 2008). Ocular involvement usually occurs in the form of acute and late ocular manifestations and complications (Yip *et al*., 2007), and is present in 43–81% of patients treated, depending on the nature of the therapy and the particular study (Robin and Dugel, 1988). The ocular manifestations are characterized by an acute inflammatory reaction, which may result in scarring and obstruction of the nasolacrimal ductules and loss of goblet cells, leading to a later complication of the 'dry eye' syndrome and trichiatic lashes (Yip *et al*., 2007). There may be corneal opacification, with vascularization, keratinization and attenuation. Also reported are anterior uveitis, scleritis and conjunctival cicatrization (De Rogas *et al*., 2007; Parrillo and Parrillo, 2008). The Stevens–Johnson

Table 9 Examples of chemicals and drugs producing systemic toxicity to the eye

Chemical	Effect
Methanol	Retinopathy Retrobulbar optic neuropathy
Butyl 2-chloroethyl sulfide	Retinopathy
Imipramine	Retinopathy
Chloroquine	Retinopathy Corneal opacities
Methylhydrazine	Corneal endothelial injury
Chlorpropamide	Corneal opacities Lens opacities
Methylphenidate	Cataract Glaucoma
Dimethyl sulfoxide	Corneal opacity
Methylphenyltetrahydropyridine	Retinopathy
Oxygen	Retrolental fibroplasia
Methotrexate	Blepharoconjunctivitis Optic neuropathy
Corticosteroids	Cataract Glaucoma Visual field defects
Chlorpromazine	Keratopathy Cataract Pigmentary retinopathy
Ethambutol	Optic neuropathy
Aconitine	Myelo-optic neuropathy
Amiodarone	Keratopathy Lens opacities Optic neuropathy
Penicillamine	Ptosis and diplopia
Tamoxifen	Corneal deposits Retinopathy
Disulfiram	Optic atrophy
Metronidazole	Optic neuritis
Retinoids	Blepharoconjunctivitis Optic disc hyperaemia

syndrome is an immune-complex-mediated hypersensitivity condition with various known aetiologies which include drugs, infections (viral, bacterial and fungal) and malignancies. Over 200 drugs have been reported to produce the Stevens–Johnson syndrome, including sulfonamides, penicillins, ampicillin, isoniazid, carbamazepine, anticoagulants, salicylates, antiretrovirals, phenylbutazone and cocaine (Cac *et al*., 2007; Chia and Leong, 2007; Fraunfelder, 1989; Hofbauer *et al*., 2000; Metry *et al*., 2001; Mockenhaupt *et al*., 2005; Power *et al*., 1995; Roujeau *et al*., 1995; Tilden *et al*., 1991).

With any specific chemical, the potential to produce ocular injury, its site(s) and its severity, may have markedly differing conditions for its genesis. Major factors determining the potential of absorbed chemicals, and metabolites, to induce systemic toxicity to the eye are as follows:

1. Total absorbed dose and its determinants, notably the frequency, duration and magnitude of the environmental exposure dose.
2. The route of exposure, depending in part on whether the parent molecule or its metabolite(s) is responsible for the ocular injury.
3. The biotransforming capacity of the eye. Watkins *et al*. (1991) reviewed the xenobiotic transforming capacity of ocular tissues and experimentally extended the biochemical database. The role of ocular metabolism in the mechanism of ocular toxicity from xenobiotics is, in general, poorly understood but clearly is a factor to be considered in all cases of ocular toxicity.

It is clear from the above discussion that observations for systemic injury to the eye are required in general toxicological studies, particularly, though not exclusively, for materials that are to be used medicinally, as food additives, and chemicals with a potential for exposure domestically and occupationally. The necessity to undertake, at least, routine examination of the eye in general toxicology studies has been stressed by Barnett and Noel (1969). Systemic ocular effects can often be suspected in general toxicology studies, providing that the protocol allows for examination of the eye. Investigations into specific aspects of ocular injury may require that satellite or additional studies be conducted with appropriate detailed monitoring procedures (Peiffer *et al*., 2000). Depending on the lesion(s) produced, monitoring may include, for example: slit-lamp biomicroscopy, histology and cytohistochemistry, transmission and scanning microscopy, angiography, tonometry, pachymetry, electroretinography, visual evoked potentials (VEPs) and electro-oculography. Electroretinography is a valuable functional supplement to histopathology in investigations of retinal pathology (Maertins *et al*., 1993). Also, isolated tissue preparations have been employed, for example the retina and lens (Chiou, 1992). Specific ocular lesions may require the use of a range of investigational techniques. For example, studies of lenticular toxicity have included the use of various forms of microscopy, biochemical investigations and metabolic studies. Morphological and biochemical changes may be followed sequentially by magnetic resonance imaging and spectroscopy (Schliech *et al*., 1985), tryptophan fluorescence spectroscopy (Lerman and Moran, 1988) and scanning lens monitoring (Mitton *et al*., 1990). Lens biochemical changes that have been investigated include aldose reductase, sorbitol dehydrogenase, phosphofructokinase, glutathione reductase, glutathione (GSH), NADH, NADPH (reduced nicotinamide adenine dinucleotide phosphate), calcium, cholesterol, phospholipids and protein (Chiou, 1992).

In some instances, laboratory experimental studies may not be able to detect certain subjective aspects of systemic ocular toxicity, and these can only be

discovered on detailed clinical examination of exposed humans. For example, using this approach it has been shown that colour recognition and discrimination is affected by exposure to a number of chemicals, especially to industrial organic solvents. Thus, workers exposed to styrene vapour may develop dyschromatopsia (Gobba *et al*., 1991; Iregren *et al*., 2005; Triebig *et al*., 2001), and styrene vapour concentrations of the order of 25 ppm can lead to impairment of colour vision (Fallas *et al*., 1992). It was concluded by Triebig *et al*. (2001) that styrene-induced colour vision dysfunction is reversible after an exposure-free interval of four weeks. With styrene, the current US threshold limit value (TLV), TWA_8 (time-weighted average concentration for an 8-hour workday, and a 40-hour workweek) of 20 ppm with short-term exposure limit (STEL) of 40 ppm (ACGIH, 2007) may not give adequate protection against adverse effects of styrene vapour on colour vision. There is clinical evidence that acrylamide monomer may cause slightly reduced light sensitivity and reduced colour discrimination (Mapp *et al*., 1977; Goffeng *et al*., 2008). Perchloroethylene vapour exposure also leads to colour vision deficits (Cavalleri *et al*., 1994). Defective colour discrimination, mainly blue-yellow, was found in 12 of 15 workers exposed to *n*-hexane by Raitta *et al*. (1978), who also examined carbon disulfide-exposed viscose workers and found impaired colour discrimination occurred more often in the workers than in nonexposed controls (Raitta *et al*., 1981). The adverse effects on colour vision resulting from exposure to *n*-hexane were confirmed by Chang (1990), and to carbon disulfide by Vanhoorne *et al*. (1996), who also described the presence of retinal microaneurysms. Although there is clinical evidence for toluene producing a neurotoxic effect on visual pathways by high concentration vapour exposures (Keane, 1978; Toyonaga *et al*., 1989), the evidence for this occurring at lower concentrations is equivocal (Muttray *et al*., 1995; 1999), suggesting that there is a threshold for the effect of toluene on the visual system (Schäper *et al*., 2004). This should be of the order of the lowest reported concentrations with significant differences between exposed individuals and nonexposed control; these values are 8.4 and 35.8 ppm, respectively, by Campagna *et al*. (2001) and 42 ppm by Cavalleri *et al*. (2000). At a then current exposure concentration of 26 $\pm$ 21 SD ppm, and after pre-exposures of about 43 ppm for 22 years, Schäper *et al*. (2004) found no effects of toluene on colour vision. These findings suggest that the current US TLV at a TWA_8 of 50 ppm provides sufficient protection against possible disturbance of colour vision (ACGIH, 2007). It has also been demonstrated that occupational exposures to multiple volatile solvents sufficient to cause the condition of chronic solvent encephalopathy also results in significantly impaired colour discrimination in the presence of otherwise normal visual function, suggesting that the effect may be mediated via higher level visual processing, possibly colour selective regions of the cerebral cortex (Päällysaho *et al*., 2007). The possible relationship between exposures to organic solvents and impairment of colour vision has been reviewed in detail by Gobba and Cavalleri (2003), Iregren *et al*. (2002), Lomax *et al*. (2004) and Paramei *et al*. (2004).

5.2 Examples of Substances Producing Systemic Toxic Effects on the Eye

The following examples of substances producing systemic ocular toxicity demonstrate the wide range of chemical substances that can produce such effects, and the wide spectrum of ocular pathology that can be induced.

5.2.1 Antineoplastic Agents

Several cancer chemotherapeutic agents have been reported to adversely affect ocular structure and function. Thus, a high proportion of patients on carmustine develop retinopathological effects including pigment abnormality, infarction, periarteritis and macular oedema (Chiou, 1992; Kupersmith *et al*., 1992; Shingleton *et al*., 1982). High doses of tamoxifen produce retinopathy with refractile opacities in the macular and perimacular areas (Gerner, 1989; Bourla *et al*., 2007), keratopathy (Vinding and Nielsen, 1983), corneal subepithelial opacities, cataract (Inada *et al*., 2005) and colour vision loss (Salomão *et al*., 2007). Long-term low dose tamoxifen use (20 mg day^{-1}) was associated with corneal depositions in three-quarters of the patients (Muftuoglu *et al*., 2006; Paganini-Hill and Clark, 2000). It has been reported that the keratopathy of tamoxifen is reversible, appears to be dose related, and is attributed to the cationic and amphiphilic nature of the molecule (Dua *et al*., 1996). Like other retinotoxic drugs, such as chloroquine and imipramine, tamoxifen is amphiphilic. It has been postulated that amphiphilic materials bind with polar lipids, causing abnormal metabolism of such lipids and a resultant accumulation in lysosomes (Lullman *et al*., 1975); that is, drug-induced phospholipidosis. Once within lysosomes, the materials, and metabolites, bind to cellular lipids and form complexes, leading to the accumulation of lysosomal inclusions, eventually observed as depositions. Retinal histopathology shows lesions in the neuroretina (nerve fibre layer and inner plexiform layer), with the paramacular region being particularly susceptible, possibly because of its highly vascularized proximity (Kaiser-Kupfer *et al*., 1981). In general, the incidence of retinopathy is low (Tang *et al*., 1998). 5-Fluorouracil has been reported to cause photophobia, excess lacrimation, ocular irritation, blepharoconjunctivitis, keratitis, punctual-canalicular

stenosis and cicatricial ectropion (Caravella *et al*., 1981; Eiseman *et al*., 2003). Vincristine has produced ptosis and diplopia due to cranial nerve paresis (Vizel and Oster, 1982). Ocular complications of systemic cancer chemotherapy are not uncommon, affecting various components of the eyeball, optic nerve and extraocular muscles, and have been discussed in several reviews (Fraunfelder and Meyer, 1983; Imperia *et al*., 1989; Al-Tweigeri *et al*., 1996).

5.2.2 Ethambutol

Ethambutol, an antitubercular drug (Innes and Reid, 2006), produces an optic nerve toxicity that may be reversible in some patients, although the possibility for optic neuropathy reversibility is controversial (Chan and Kwok, 2006). The possibility that the lesion is irreversible is suggested by a study from Tsai and Lee (1997). They reviewed 10 consecutive cases with severe visual defects due to ethambutol, and in which the drug had been discontinued. Only five patients experienced improvement of their vision after one to three years of follow-up, with older patients having a poorer prognosis. The majority of patients had received a dosage in the range of 13–18 mg kg^{-1}, and therefore the authors questioned the existence of a 'safe dosage', which is likely to be small. They also questioned the use of ethambutol as a routine first line of defence for the treatment of tuberculosis. On the basis mainly of the ocular toxicity of ethambutol, Sivakumaran *et al*. (1998) had recommended that the daily dose should be 15 mg kg^{-1} (rather than 25 mg kg^{-1}) and that the drug should be discontinued if optic neuropathy develops. That reversibility is variable was suggested by the observations of Goyal *et al*. (2003), who noted ocular toxicity in 10% of the patients they examined and, when it occurred, visual recovery was in the first six to eight weeks after stopping ethambutol treatment; visual recovery was complete in only one patient, and partial in two as judged by visual fields, contrast sensitivity, and VEPs remaining abnormal. That ethambutol ophthalmic toxicity affects retinal elements as well as the optic nerve was shown by multifocal electroretinogram (ERG) studies by Kardon *et al*. (2006) and Behbehani *et al*. (2005a). This is supported by the clinical and electrophysiological findings of Vistamehr *et al*. (2007), who also demonstrated that ethambutol toxicity to the eye is expressed as a neuroretinopathy. Using ERG, electro-oculogram (EOG) and visual field testing, they detected retinal pigment epithelial changes, macular oedema and retinal haemorrhages. ERG findings included decreased amplitude and abnormal wave pattern. In patients with ethambutol-induced optic neuropathy it is possible to obtain some assessment of the degree of optic nerve damage just after the onset of visual loss by measuring a decrease in retinal nerve fibre layer thickness using optical coherence tomography (Chai and Foroozan, 2007). Clinically, there is evidence that in a few cases of ethambutol-induced optic neuropathy it may subsequently progress to involve the optic chiasma, causing a bitemporal hemianopia (Lim, 2006).

Early onset toxicity with ethambutol has been suggested to be due to an idiosyncratic reaction (Karnik *et al*., 1985; Kahana, 1987). Delayed onset optic neuropathy has been associated with zinc depletion (Chatterjee *et al*., 1986; Schild and Fox, 1991). In rat, studies on the mechanism of ethambutol retinal toxicity by Heng *et al*. (1999) found specific lesions to retinal ganglion cells *in vitro* and *iv vivo*, and that endogenous glutamate is required for full expression of ethambutol toxicity, and also that glutamate antagonists prevented ethambutol-mediated cell loss. The drug caused a decrease in cytosolic calcium and an increase in mitochondrial calcium, with an increase in mitochondrial membrane potential. The investigators suggested that the visual loss associated with ethambutol may be mediated through an excitatory pathway, in that ganglion cells are rendered sensitive to normally tolerated levels of extracellular glutamate. Also, they noted that ethambutol perturbs mitochondrial function, and its toxicity may be associated with decreased ATPase activity and mitochondrial energy homeostasis. They suggested that glutamate antagonists might be of use to limit the side effects seen with ethambutol. Yoon *et al*. (2000) used rat primary retinal cultures to study the mechanism of ethambutol-induced ocular toxicity, and obtained findings at variance to some of those noted above. Exposure of cultures to ethambutol for 24–48 hours induced cytoplasmic vacuolar changes and neuronal loss, with the vacuolar changes being partially reversible on termination of ethambutol exposure. Thy-1(+) neurones were more vulnerable than γ-aminobutyric acid (GABA) neurones. Glutamate antagonists, an antioxidant (trolox), or cycloheximide, did not attenuate either the vacuolar changes or neurone loss. A cell-permeant zinc chelater, TPEN (*N*, *N*, *N′*, *N′*-tetrakis(2-pyridylmethyl)-ethylenediamine), markedly attenuated vacuolar degeneration and neuronal loss, whilst the addition of zinc augmented both of these effects. Thus, in this study ethambutol-induced retinopathy was mediated not by excitatory processes or zinc deficiency, but by a mechanism requiring intracellular zinc. Additionally, features of the ethambutol-induced cytolethality were not consistent with those of apoptosis.

A few cases of Leber's hereditary optic neuropathy have been reported which were apparently precipitated by ethambutol, leading to a proposal that the drug could be a risk factor for this optic neuropathy (Ikeda *et al*., 2006). Also it has been reported that the primary mitochondrial DNA mutation at the nucleotide (nt) site nt-11778 in Leber's hereditary optic neuropathy has been shown to be present in patients with ethambutol-induced optic neuropathy. As a follow-up to this association, Hwang *et al*. (2003) studied patients with ethambutol-induced

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

optic neuropathy for the presence of mitochondrial DNA mutation at nt-11778, nt-14484, nt-3460, nt-15257, nt-9438 and nt-9804. None of the patients were found to have any of these mutations, thus excluding an association between ethambutol-induced optic neuropathy and Leber's hereditary optic neuropathy mutations.

Ethambutol optic neuropathy has been reviewed by Fraunfelder *et al*. (2006).

5.2.3 Amiodarone

Amiodarone, a di-iodinated benzofuran used in the treatment of certain cardiac arrhythmias, produces intracytoplasmic lamellar deposits in the cornea and lens, and more rarely the retina and optic nerve (Ikäheimo *et al*., 2002; Ingram *et al*., 1982; Mäntyjärvi *et al*., 1998). Common ocular symptoms in patients on amiodarone include coloured haloes around lights and visual blurring. Some regard these ocular complications as not presenting a significant threat to vision (Ingram, 1983), although as discussed below other authorities take a more cautious approach. Frequent ocular signs are 'cat whisker' corneal epithelial opacities (verticillata) and lens opacities, often without impairment of visual acuity (Mäntyjärvi *et al*., 1998; Nielsen *et al*., 1983). Ingram (1983) investigated the occurrence of complications of long-term therapy, and found that keratopathy developed in 98% of patients, but only 6% of the affected individuals developed visual symptoms (photophobia, haloes and visual blurring). Uçakhan *et al*. (2005) found that corneal deposits were detectable using slit-lamp biomicroscopy and confocal microscopy by two months after the onset of amiodarone treatment, and deposition was correlated with duration and cumulative dose. Unilateral optic disc oedema, presenting with blurred vision, has been reported in a patient on amiodarone (Eryilmaz *et al*., 2000), as have bilateral optic nerve swelling with variable reduction in visual acuity or visual fields (Garrett *et al*., 1988; Johnson *et al*., 2004; Nagra *et al*., 2003; Nazarian and Jay, 1988). In one series of case descriptions (Johnson *et al*., 2004), most instances of optic neuropathy commenced within 12 months of starting amiodarone treatment, with a median onset of four months. Optic neuropathy is detected in only a small proportion of amiodarone-treated patients, and is reversible in about half of patients after discontinuing treatment (Turdamambetova *et al*., 2005). In a clinical study by Domingues *et al*. (2004), involving measurement of VEPs, there was a statistically significant difference ($p < 0.001$) between amiodarone-treated patients and age-matched controls with respect to pattern visual evoked potential latency (L-VEP) and amplitude of visual evoked potential (a-VEP). However, there was no significant correlation between prolonged L-VEP and duration of amiodarone ($r = 0.07$). After a one-year follow-up there was an average increment in L-VEP of 1.96 ms and a-VEP measurements showed a decline of 0.69 μV. In a group of patients having moderately high dosages of amiodarone (600–800 mg day^{-1} for up to 18 months), lens opacities were found in half of the patients; these opacities were punctate anterior subcapsular and within the papillary aperture (Flack *et al*., 1983). Confocal microscopic examination of the cornea in patients with amiodarone-induced keratopathy showed the presence of highly reflective, bright intracellular inclusions in the epithelium, particularly in the basal cell layers. With advanced keratopathy, bright microdots were seen within the anterior and posterior stroma and on the endothelial cell layer, with an irregular appearance to the stromal nerve fibres (Ciancaglini *et al*., 2001; Uçakhan *et al*., 2005). Ultrastructural examination of corneal and conjunctival biopsies from patients with amiodarone keratopathy demonstrated lipid deposits in lysosome-like intracytoplasmic inclusions in the epithelium, conjunctival fibroblasts, and vascular endothelium (D'Amico *et al*., 1981). It was proposed that the changes were a consequence of the cationic amphiphilic properties of amiodarone, which induces a generalized intracytoplasmic accumulation of polar lipids. A more widespread distribution of intracytoplasmic membrane-bound bodies, similar to myelin, was described by Ghosh and McCulloch (1984); they were present in corneal epithelium and endothelium, conjunctiva, lens, iris, ciliary body, choroid and retina.

5.2.4 Aconitine

Aconitine is the major constituent of aconite, a herbal remedy used in the Far East. Kim *et al*. (1991) showed that the material causes a myelo-optic neuropathy in rabbits. Principal findings were a delay to onset and peak latency of VEP, with reduction in amplitude, and histopathological evidence of myelin injury of the visual pathway, spinal cord and peripheral nerves. Retinal and optic nerve effects of aconitine given systemically (intraperitoneal (ip)) were studied in rabbits by means of VEP, ERG and electron microscopy (Kim and Kim, 1990). VEP amplitude was decreased, and optic nerve ultrastructure showed disorganization of the lamellar structure of the myelin sheath, diffuse mitochondrial swelling and vacuolization of myelinated nerve fibres. There were no significant ultrastructural changes in the retina.

5.2.5 Ethanol

Ingestion of ethanol can result in a reduced IOP (Grant, 1969; Peczon and Grant, 1965), and also affects extraocular muscle activity. Acute ethanolic intoxication results in a variety of visual disturbances, including nystagmus, transient convergent strabismus, diplopia, esophoria, and possibly transient change in colour vision (Bittencourt and Wade, 1980; Hogan and Linfield, 1983; Wilson and Mitchell, 1983). Pursuit movements of the eye

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

are markedly affected by ethanol, with saccadic movements being slowed within 30 to 60 minutes of ethanol ingestion; smooth following movements are impaired and replaced by jerky movements, thereby reducing visual acuity through temporary loss of macular vision (Wilkinson *et al*., 1974). It has been reported that 50 ml of ethanol as a minimum is required to induce nystagmus (Howells, 1956). Colour vision tests on normal subjects after consumption of ethanol have shown a specific effect on blue-sensitive cones (Zrenner and Riedel, 1988). Acute administration of ethanol also can also affect the rate of recovery from exposure to bright lights (Adams and Brown, 1978; Sekuler and MacArthur, 1977). Acute dosing with ethanol has been shown to modify the ERG in rabbits, primates and humans (Knave *et al*., 1974; Textorious *et al*., 1985; Van Norren and Padmos, 1977). An effect on the c-wave of the ERG suggested that there was involvement of the retinal pigment epithelial cells (Knave *et al*., 1974; Skoog *et al*., 1975). Ethanol appears to retard dark adaptation of retinal cone cells (Van Norren and Padmos, 1977). A study of the effects of ethanol on functional magnetic resonance imaging (fMRI) during a visual perception test was conducted by Calhoun *et al*. (2004). Ethanol caused a dose-dependant decrease in activation amplitude over much of the visual perception network, and the anterior and posterior cingulate, precuneus and middle frontal areas. There was a dose-dependent activation in the insula, dorsolateral prefrontal cortex and precentral regions.

In rat studies, peroral (po) dosing with 1% ethanol for eight weeks produced an optic neuropathy (Taneda *et al*., 1988). In humans, chronic ethanolic intake can cause a toxic amblyopia that may be related to vitamin B complex deficiency (Grant and Schuman, 1993). Characteristically, there is bilateral onset of visual clouding, with a papillomacular distribution that is horizontal; the peripheral field usually remain normal (Grant and Schuman, 1993). Disturbance of colour vision has been reported in chronic alcoholism, sometimes with undisturbed visual acuity, and tending to disappear on abstinence from ethanol (Francq *et al*., 1979; Swinson, 1972). Pattern visual evoked potential (PVEP) recordings were conducted in chronic alcoholics by Nazliel *et al*. (2007), who found that detection of PVEP in asymptomatic chronic alcoholics might be useful for the early detection of central nervous system (CNS) changes and for follow-up progress of patients.

Foetal alcohol syndrome is characterized by prenatal and postnatal growth delay, craniofacial abnormalities, hypotonia, CNS deficits, and there is particular concern that ocular malformations may occur in the children of mothers who abuse alcohol during pregnancy. Up to 90% of children suffering from foetal alcohol syndrome have eye abnormalities (Hinzpeter *et al*., 1992), with two malformations being typical: hypoplasia of the optic nerve and increased tortuosity of retinal arteries (Chan *et al*., 1991; Ribeiro *et al*., 2007; Strömland, 1985; Strömland, 1987; Strömland and Pinazo-Duran, 2002). Also common are shortness of the palpebral fissures, ptosis, epicanthus, blepharoptosis, microphthalmus, coloboma, and convergent or divergent strabismus (Grant and Schuman, 1993; Hinzpeter *et al*., 1992; Ribeiro *et al*., 2007; Strömland, 2004a; 2004b). Glaucoma has resulted from abnormalities of the anterior chamber angle (Martin and Rabineau, 1990). Strömland (1987) has suggested that the ocular effects have shown a development timing indicating the risk to be present from early gestation to complete development. Ocular complications of foetal alcohol syndrome have been reviewed by Grant and Schuman (1993) and Irvine (2003).

5.2.6 Drugs of Abuse

There is a significant incidence of ocular complications in drug abusers (Gastaud *et al*., 1989; McLane and Carroll, 1986; Urey, 1991). For example, marijuana causes conjunctival hyperaemia, blepharospasm, diplopia and decreased IOP (Colasanti *et al*., 1984; Green, 1982; Green and McDonald, 1987; Hepler *et al*., 1972). Aerosolysed crack cocaine has been associated with corneal ulceration (Ghosheh *et al*., 2007; Pilon and Scheiffle, 2006; Sachs *et al*., 1993). Bilateral retinal artery occlusion has been reported following smoking of crack cocaine, possibly due to abrupt intense vasospasm (Catenacci and Tuckler, 2005; Wallace *et al*., 1992). Causes of noninfectious retinal artery complications following the use of illicit drugs given intravenously (iv) have been discussed by Raspiller *et al*. (2005) under two major mechanisms, namely microparticle embolization and arterial vasospasm. Embolization of microparticles causing obliteration of retinal vessels results from the presence of bulking filler materials such as talc (magnesium silicate) and flour, or from tablets that have been crushed and injected after partial dilution and filtration; tablets that have been associated with talc retinopathies include methylphenidate, pentazocine, codeine, methadone and meperidine. Following iv injection there is embolization to the pulmonary circulation, and particles $<5\,\mu m$ are not retained in the lung and may further embolize. Arterial vasospasm can affect retinal arteries directly or the cerebral circulation with indirect effects on the retina due to emboli resulting from disruption of atheromatous plaques; active ingredients responsible for vasospasm include cocaine, amphetamines and quinine. Peripheral retinal neovascularization has been described following iv drug abuse, including heroin and cocaine (Tran and Ilsen, 2007).

5.2.7 Butyl 2-Chloroethyl Sulfide

In the rat, systemically absorbed butyl 2-chloroethyl sulfide causes a swelling of the inner retinal layers, mitochondrial swelling and disarray of the outer segments of photoreceptors. Radiolabelled material is found in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064

the retina, choroid, sclera, lens and cornea. Structural effects are preceded by an increase in thiobarbituric acid reactive products, which is an indicator of lipid peroxidation (Klein *et al*., 1991). Systemic exposure to the material produces metabolic and histological changes consistent with oxidative stress and lipid peroxidation.

5.2.8 Sildenafil Citrate

Sildenafil citrate (Viagra) is used in the treatment of male impotence based on its major inhibitory effect on cyclic guanosine monophosphate (c-GMP)-specific phosphodiesterase (PDE) 5 in the corpus cavernosus and subsequent facilitation of penile erection. The drug also exerts a lesser inhibitory effect on retinal PDE 6, which controls the level of c-GMP in the retina (Laties and Fraunfelder, 1999; Marmor and Kessier, 1999). Histological studies by Vatansever *et al*. (2003) using male Wistar rats dosed with sildenafil citrate (8 mg kg^{-1} day^{-1}, po) on alternate days over four weeks, showed that this treatment caused vascular dilation and congestion in the choroid; 3.44 $\pm$ 1.68 µm versus a control value of 1.78 $\pm$ 1.36 µm ($p < 0.001$). The retina showed no histopathology. There is a general opinion that sildenafil does not affect visual acuity, visual fields or contrast sensitivity (Laties and Sharlip, 2006). However, some men using sildenafil have experienced bluish haze vision, increased light sensitivity and blurry vision (Laties and Sharlip, 2006; Marmor and Kessier, 1999). Transient, mild impairment of colour discrimination can occur at the time of peak plasma concentration (Laties and Sharlip, 2006). Clinical observations have shown several other, but much rarer, side effects associated with the use of sildenafil; these include nonarteritic anterior ischaemic optic neuropathy developing within minutes to hours after ingestion (Akash *et al*., 2005; Bella *et al*., 2006; Carter, 2007; Cunningham and Smith, 2001; Pomeranz *et al*., 2002) and serous macular detachment with perimacular vitelliform deposits (Quiram *et al*., 2005). Relevant to the use of sildenafil by men with established glaucoma is a study by Grunwald *et al*. (2001), who demonstrated that in patients with chronic open-angle glaucoma given a 100 mg dose of the drug, there was no change in IOP. In healthy human adult volunteer subjects it was found that a 50 mg dose of sildenafil caused a significant increase in retinal arterial and venous diameters 30 minutes postdosing (5.8%, $p < 0.001$), with diameters returning to control values within 120 minutes (Pache *et al*., 2002).

5.2.9 Chloroquine Salts

Chloroquine derivatives are used as antimalarials and have been employed in the treatment of rheumatoid arthritis and lupus erythematosus (Jamshidzadeh *et al*., 2007; Sweetman, 2005). Chronic administration of chloroquine can produce fine corneal deposits that are visible in the corneal epithelium on biomicroscope examination, particularly in the region of the palpebral fissure, but are generally of little functional significance and resolve on cessation of treatment or reducing the dosage (Grant and Schuman, 1993). Although these deposits do not usually cause any visual disturbances, occasionally they may result in a slightly reduced visual acuity. Ultrastructural studies have shown the cytoplasmic inclusions in the epithelial cells to be similar to those produced by amiodarone and other cationic amphiphilic drugs (Section 5.2.3). Chloroquine keratopathy has been classified as a drug-induced phospholipidosis (Pulhorn and Thiel, 1976). More significant is that long-term dosing with chloroquine can result in the appearance of a retinopathy that, with high dosages, can seriously interfere with vision; this is discussed in more detail at Section 7.7.4.

5.2.10 Chlorpromazine

A phenothiazine drug, chlorpromazine like many other antipsychotic drugs can cause lens and corneal opacities with long-term treatment (Rasmussen *et al*., 1976; Sharpe and Potts, 2006). Confocal microstructural analysis of the cornea following a 20-year period of chlorpromazine therapy (mean daily dosage 400 mg day^{-1}), revealed irregular hyper-reflective deposits on the posterior surface of the endothelium, which ranged from 1 to 70 µm in diameter; otherwise the endothelium was normal (Phua *et al*., 2005).

5.2.11 Corticosteroids

It is well known that corticosteroids when applied topically to the eye can result in ocular hypertension and secondary open angle glaucoma (Skuta and Morgan, 1996). Increased IOP by topical application has been recorded for cortisone, hydrocortisone (Goldman, 1962), prednisone, prednisolone (Frandsen, 1964), β-methasone (Becker and Mills, 1963), dexamethasone (Armaly, 1963), triamcinolone (Becker and Mills, 1963), tetrahydrotriamcinolone and flurandrenolide (Brubaker and Halpin, 1975). It is now appreciated that in addition to such ocular effects being produced by local application of corticosteroids to the eye, they can also be produced with several corticosteroids by a systemic toxic effect to the eye following absorption by dosing at sites remote from the eye (Carnahan and Goldstein, 2000). Thus, ocular complications occur with corticosteroids when given by the oral route and they can also occur, probably to a lesser extent, when steroids are delivered by the inhalation but not nasal route. The use of inhaled glucosteroids has significantly improved the management of asthma (Vergnenègre *et al*., 2008), and intranasal steroids have been an important route of dosing for the management of rhinitis

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Mabry, 1992). Other routes of exposure and absorption to corticosteroids that have been associated with ocular hypertension and open-angle glaucoma include oral and periocular skin and topical application to the face (Skuta and Morgan, 1996).

Inhaled and topically applied steroids may be absorbed through the nasal mucosa, oropharynx and lung, and by these routes have limited hepatic first-pass metabolism. Increased concern has been expressed over possible systemic adverse effects resulting from the use of inhaled and topically applied nasal corticosteroids. Case reports have indicated that the systemic absorption of steroids may result in development of posterior subcapsular cataracts, ocular hypertension and open-angle glaucoma (Dreyer, 1993; McGhee *et al*., 2002; Opatowsky *et al*., 1995). In a case-controlled study, Garbe *et al*. (1997) found that prolonged (greater than three months) dosing with inhaled steroids increased the risk of ocular hypertension or open-angle glaucoma. They did not observe an increased risk with topical nasal steroids, possibly because of the lower dosage by this route. Recommended dosages for intranasal administration do not exceed $400\,\mu g\ day^{-1}$, whereas inhaled steroids are recommended in doses of $1500-2000\,\mu g\ day^{-1}$ (Brogden *et al*., 1992). Several other studies have assessed the likelihood for development of ocular complications by various routes and modes according to age. There is good evidence that those using oral corticosteroids are at increased risk for the development of cataract (Derby and Maier, 2000). The use of inhaled steroids by children with asthma is not a major concern for the development of cataract or ocular hypertension (Behbehani *et al*., 2005b). For individuals older than 40 years, the risk of cataract development from the use of inhaled steroids was increased (Jick *et al*., 2001). In another study it was also found that the use of inhaled steroids by adults older than 49 years was associated with an increased risk for posterior subcapsular cataract development (Cumming *et al*., 1997). The risk of cataract in those using intranasal steroids is generally considered not to be increased (Derby and Maier, 2000). Differential absorption of various steroids appears to be a less important determinant since, for example, with flunisolide the systemic bioavailability is 39% of the administered dose by inhalation and 49% following intranasal dosing (Pakes *et al*., 1980). Garbe *et al*. (1997) suggest that those receiving inhaled steroids should be monitored by IOP measurements. Although there is still discussion about the possible mechanism by which corticosteroids increase IOP, it is generally considered that there is increased resistance to aqueous humour outflow (Becker and Mills, 1963; Kass and Johnson, 1989). It has been proposed that corticosteroids inhibit glycosaminoglycan metabolism, which leads to the accumulation of polymerized glycosaminoglycans in the trabecular network (Kass and Johnson, 1989).

Cumming *et al*. (1997) described an association between the use of inhaled steroids and the development of posterior subcapsular and nuclear cataracts, and have described the implications with respect to prevention and management (Cumming and Mitchell, 1999). Steroid-induced posterior subcapsular cataracts are associated only with steroids possessing glucocorticoid activity (James, 2007). In a self-reported population study with 2446 responders having long-term glucocorticoid use ($\geq$60 days) the incidence of cataracts was 15% (Curtis *et al*., 2006).

5.2.12 Organophosphate Anticholinesterases: Saku Disease

Attention was drawn to the potentially hazardous effect on the human eye from uncontrolled exposure of humans to pesticides, including organophosphate (OP) antiChE materials, by observations in the 1950s and 1960s, notably in children, that there was a probable correlation between a broad range of ocular complications and exposure to OP pesticides sprayed in fields in the Saku region of Japan. Under such circumstances the routes of exposure were probably multiple, inducing topical eye contact, inhalation, and possibly, though to lesser extents, percutaneous and peroral doses following swallowing of contaminated food and/or saliva. The range of adverse effects for Saku disease included blurring of vision, progressive myopia and astigmatism. Blood cholinesterase (ChE) inhibition, altered ERG, optic nerve atrophy, optic disc oedema and retinal degenerative changes (Dementi, 1994; Ishikawa, 1972; 1978; Ishikawa and Ohto, 1972; Ohto, 1974). Schoolchildren from Saku had a 65% incidence of optic neuritis and/or chorioretinal atrophy (Ishikawa *et al*., 1971). The OP insecticides applied near the regions of reported cases included dichlorvos (2,2-dichlorovinyl dimethyl phosphate (DDVP)), diazinon (*O*,*O*-diethyl *O*-2-isopropyl-6-methylpyrimidin-4-yl phosphorothioate), *O*-ethyl-*O*-*p*-nitrophenyl thiophosphonate (EPN), fenitrothion (*O*,*O*-dimethyl *O*-4-nitro-*m*-tolyl phosphorothioate), fenthion (*O*,*O*-dimethyl *O*-4-methylthio-*m*-tolyl phosphorothioate), malathion (diethyl (dimethoxyphosphinothioylthio)succinate), parathion (*O*,*O*-diethyl-*O*-4-nitrophenyl phosphorothionate), parathion-methyl (*O*,*O*-dimethyl *O*-4-nitrophenyl phosphorothioate)- and trichlorfon (dimethyl (*RS*)-2,2,2-trichloro-1-hydroxyethylphosphonate). Similar large studies on the potential for antiChEs to produce oculotoxic effects by occupational and environmental exposure have been documented from outside Japan; see Section 7.7.4. Also, several experimental studies with OPs accord with much of the ocular toxicity reported, and several epidemiological studies on the affected populations did establish a reasonable probability of an association between an increased incidence of adverse ocular effects and the greater use of OPs in Japan (Dementi, 1994; Ishikawa, 1973; Ishikawa and Miyata, 1980; Tamura and Mitsui, 1975). There also exists the

possibility that there is an increased susceptibility of Oriental populations to antiChE-induced ocular adverse effects.

5.3 Developmental Ocular Toxicity by Maternal Exposure

A specialized aspect of ocular systemic toxicity is the investigation of developmental defects that may occur during gestation as a consequence of maternal exposure, which may result in foetal exposure to the absorbed molecule or its metabolite(s). One known example with humans, foetal alcohol syndrome, has been mentioned above (Section 53.5.2.5). An experimentally produced dramatic example of ophthalmic teratogenesis in the rat foetus is provided by nickel carbonyl. Sunderman *et al*. (1975) demonstrated that exposure to the vapour of nickel carbonyl for 15 min day^{-1} on gestational day (GD) 7 or 8 was sufficient to produce ocular abnormalities, including anophthalmia or microphthalmia, with a low incidence of extraocular abnormalities. Since nickel carbonyl can cross the alveolar membrane and blood–brain barrier, they considered it could also cross the maternofoetal barriers. However, ocular teratogenesis may be species dependent. Thus, in a developmental toxicity study in Syrian hamsters with nickel carbonyl, Sunderman *et al*. (1980) dosed pregnant animals (0.06 mg Ni l^{-1} 15 min^{-1}) on GD 4, 5, 6, 7 or 8, sacrificed them on GD 15, and found evidence for nickel carbonyl being teratogenic and embryotoxic, but with only a low incidence of ocular abnormalities. Exposure on GD 4 or 5 resulted in cystic lungs and exencephaly, but only one instance of anophthalmia; exposure on GD 6 or 7 caused a low incidence of fused ribs and hydronephrosis. Ocular teratogenesis has also been demonstrated in *Xenopus laevis* embryos exposed to a medium containing nickel chloride (180 µmol l^{-1}); the predominant lesion was loss of pigmented epithelial cells with secondary agenesis of the outer segments of photoreceptors and focal growth of neuroretina through gaps in the destroyed pigmented epithelium. Coloboma and cataract were also noted (Hauptman *et al*., 1991).

Cocaine use by pregnant women is known to be associated with a variety of structural and functional abnormalities in the offspring; these include perinatal mortality, craniofacial abnormalities, brain infarction, motor inability, seizures, hyperactivity, hydronephrosis and delay of growth (Chasnoff *et al*., 1986; 1988; Bingol *et al*., 1987; Dow-Edwards, 1991). Additionally, a wide spectrum of effects has been noted with cocaine, both experimentally and in human cases; these have included optic hypoplasia, anophthalmia, coloboma, retinal dysgenesis and retinal gliosis (Mahalik *et al*., 1980; Ferriero *et al*., 1989; Silva-Araujo *et al*., 1994). In an experimental study involving prenatal exposure of rats to cocaine (Mendez-Armenta *et al*., 1997), detailed histopathological observations in the retina were described, which included interstitial oedema, necrosis, hyperchromatic ganglion cells, reduced numbers of retinal cells, and alterations in the photoreceptor and bipolar cell layers. They concluded that cocaine produced alterations in the development and organization of neuroblasts in all layers of the retina.

For systemically absorbed substances, and with respect to the genesis of lens abnormalities, access of material to the lens depends on whether exposure is during the prenatal or postnatal period. Prenatally, the developing lens has a blood supply, which begins to degenerate on the first postpartum day, and is complete before adulthood is reached. The adult lens has no local blood supply and thus access of cataractogenic substances to the lens is via the aqueous humour or, to a lesser degree, through the vitreous humour. Cataractogenesis can be induced *in utero* by a serotonin antagonist, RG 12195 (Lerman *et al*., 1995), but the adult lens is resistant to the cataractogenic effect. RG 12195 is a selective 5-HT_3 antagonist that had been proposed for use in the management of nausea and emesis associated with cancer chemotherapy. Pregnant rats were given the material by gavage over GD 6–17, at dosages of 0 (control group), 1, 10 and 100 mg kg^{-1} day^{-1}. Postnatally, lens opacities were detected in the pups of the high dosage group. A repeat study conducted with dosages of 0, 10, 30, 60 and 100 mg kg^{-1} day^{-1} showed a dosage-related incidence of nuclear cataracts in the 60 and 100 mg kg^{-1} day^{-1} groups (respective litter incidences were 6 and 45%). In a subsequent perinatal/postnatal developmental toxicity study, RG 12195 was dosed from GD 15 to postpartum day 21, at dosages of 5, 20 and 80 mg kg^{-1} day^{-1}; lens opacities occurred in the high dose group. Since the common treatment period for all these groups was GD 15–17, and because the major organogenesis period for the lens is GD 11–15, it was suggested that the sensitive period for cataract induction by RG 12195 in the rat might have been close to GD 15. In the rat, lens capsule formation begins on GD 18, and the blood supply to the lens starts to degenerate on postpartum day 1 and is complete by 21 days. It is of interest to note that the serotonin agonist lysergic acid diethylamide (LDS) is also cataractogenic *in utero* (Hanaway, 1969), and that serotonin itself has been reported to produce reversible lens opacities in rats following acute ip dosing (Dietze and Tilgner, 1973). Additionally, *p*-chlorophenylalanine, a 5-hydroxytryptamine (5-HT) biosynthesis inhibitor, induced cataracts in weanling rats (Gralla and Rubin, 1970), and low tryptophan diets induce cataracts in weanling rats (Bunce *et al*., 1978). Other materials known to produce cataracts *in utero* include the chlorinated hydrocarbon insecticide, mirex (Rogers and Grabowski, 1983), azothioprene (Tuchmann-Duplessis and Mercier-Parot, 1964) and phenytoin (Wagner *et al*., 1983).

Evidence for teratogenic effects, including ocular developmental abnormalities, based on epidemiological studies requires care with interpretation. For example, public concern followed media reports (Paduano *et al*., 1993) of alleged clusters of anophthalmia and microphthalmia that might have been linked with exposure to the fungicide benomyl (methyl 1-(butylcarbamoyl) benzimidazol-2-yl carbamate). Developmental studies in rats had shown that benomyl can induce anophthalmia and microphthalmia (Hoogenboom *et al*., 1991), but apparently only at doses approximately 1000 times greater than that expected to occur with farm workers handling the material (Mariman, 1998). Subsequent to the allegation of clusters of ophthalmic abnormalities, Dolk *et al*. (1998) investigated the geographical variation in anophthalmia and microphthalmia in England over the period 1988–1994. They found an overall prevalence of anophthalmia and microphthalmia of 1.0 per 10 000 live births. Regional variations in prevalence did not reach statistical significance. However, prevalence was higher by about two-fold in rural compared with urban areas. Whilst they did not specifically state that there was no association between benomyl exposure and ocular developmental defects, they state that there is very little evidence to support the presence of strongly localized environmental exposures of causing clusters of children to be born with anophthalmia or microphthalmia. In an Italian ecological study (Spagnolo *et al*., 1994), there was no evidence for an association between the regional use of benomyl and the prevalence of anophthalmia or microphthalmia. Also, a Norwegian study (Kristensen and Irgens, 1994), using a cohort of farming families, found only one case of anophthalmia/microphthalmia from the potentially exposed families. Official statements have recorded that low dose exposures to benomyl do not constitute a risk to humans (Ministry of Agriculture, Fisheries and Food, 1992; WHO, 1993).

6 THE EYE AS A PORTAL FOR SYSTEMIC TOXICITY (TRANSOCULAR TOXICITY)

6.1 General Comments

Most materials do not, or are unlikely to, produce systemic toxicity by topical application to the eye (Brown and Muir, 1971), principally because of the small volume that can be accommodated on the surface of the eye and in the conjunctival sac, even following deliberate instillation. Additionally, lacrimation and blepharospasm may reduce the degree of contamination and dosing. However, with materials of high toxicity or pharmacological potency, topical contamination of the eye with a sufficient material may result in enough material being absorbed to produce systemic effects. This may be a consequence of accidental (unintended) contamination of the eye with xenobiotics, and sometimes as a result of the deliberate introduction of drugs onto the eye for intended local therapeutic effects; examples of chemicals producing systemic effects by either accidental or deliberate ocular contact are given in Section 6.3. In addition to systemic toxic and unwanted pharmacological effects, such as those discussed as examples in Section 6.3, that may result from transocular absorption of xenobiotics, the deliberate use of the transocular route as a means to deliver dugs for systemic distribution has received therapeutic interest; this is further discussed in Section 6.4. Some sources for exposure having a potential for systemic toxicity may be unexpected or unusual. For example, Nir *et al*. (1992) investigated Kohl, an eye cosmetic used in Israel, which is frequently applied to infants. They found the lead content of samples of Kohl varied from 17.3 to 79.5%; blood concentrations of lead were high in infants that had been exposed to Kohl (11.2 vs. 4.3 $\mu g\ dl^{-1}$ for controls; $p < 0.001$).

In some instances, the potential for absorption of a material following topical application to the eye can be quantitatively assessed by identification of the parent compound and/or metabolites in body fluids. For example, with tropicamide (*N*-ethyl-3-hydroxy-2-phenyl-*N*-(pyridin-4-ylmethyl) propanamide), which is an anticholinergic muscarinic antagonist producing transient mydriasis, adverse effects have not been frequently reported but a myasthenia gravis-like syndrome has been described following topical application to the eye (Meyer *et al*., 1992). Plasma concentrations of tropicamide, and muscarinic receptor occupancy, have been investigated following the ocular administration of two 40 µl drops of 0.5% tropicamide into the inferior conjunctival sac of eight women (Vuori *et al*., 1994). The material was rapidly absorbed, with a measured peak plasma concentration of 2.8 ± 1.7 SD ng ml^{-1} at 5 minutes postinstillation. There was rapid plasma clearance, with the tropicamide concentration at 60 and 120 minutes being 0.46 ± 0.51 ng ml^{-1} and <240 pg ml^{-1}, respectively. There was a maximum tropicamide plasma receptor occupancy of around 8%. The authors stated that the low affinity of tropicamide for muscarinic receptors, and the negligible receptor occupancy in plasma, explains the low incidence of side effects following topical application of tropicamide eye drops.

6.2 Sites of Absorption

Materials contaminating the eye will come into contact with conjunctival blood vessels, then pass via the nasolacrimal drainage system into the nasal cavity, and thence through the naso-pharynx and be swallowed. The

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

relative contribution of the conjunctivae, nasal mucosa and alimentary tract to the total absorbed dose may vary with the chemical species and formulation.

Absorption can occur through the conjunctival blood vessels, and this may be facilitated if materials also produce a conjunctival hyperaemia. Absorption from this site is also influenced by the rate of lacrimation, blepharospasm, and patency of the nasolacrimal drainage system. In many cases the nasal mucosa, with its large surface area and high vascularity, may be a major site of absorption of materials applied to the eye. It is well known that many pharmacologically active materials can be absorbed following introduction into the nasal cavity (Chien, 1985). For drugs having high systemic pharmacological activity when given by nasal dosing then this may offer a convenient route for dosing, and is discussed in more detail in Section 6.4. Hydrophobicity may be an important determinant for nasal mucosal absorption; for example, the hydrophobic drugs alprenolol and propranolol are well absorbed through the nasal mucosa (Duchateau *et al*., 1986; Hussain *et al*., 1980) whereas hydrophilic metaprolol is not (Duchateau *et al*., 1986). The rate of drainage of material from the conjunctival sac into the nasal cavity depends on a number of factors that include the rates of lacrimation and blinking, both of which may be increased by irritant materials. Also, the volume of material instilled into the sac will be a determinant of the amount transferred. Lacrimation and instilled fluid dynamics in the rabbit eye in relation to drainage from the eye have been investigated by Chrai *et al*. (1973). Since the drainage capacity of the eye exceeds the normal rate of lacrimation, drops placed in the conjunctival sac may be rapidly transferred to the nasal cavity (Shell, 1982). Reducing the rate of drainage may decrease systemic absorption. For example, Zimmerman *et al*. (1984) studied the effects of eyelid closure and manual nasolacrimal occlusion on the absorption of topically applied timolol and on the permeation of the eye to topically applied fluorescein. They found, with both eyelid and nasolacrimal occlusion, that the plasma concentration of timolol was significantly reduced and the anterior chamber fluorescein increased in comparison with ordinary eye drop procedures. For timolol, Chang and Lee (1987) found that the nasal mucosa was about 2.5 times more effective than the conjunctival mucosa in contributing to the total systemic absorption. That materials applied topically to the eye may reach the alimentary tract and be absorbed there is indicated by several studies. Thus, Wilensky *et al*. (1967) found that after ecothiophate iodide and isofluorophate were instilled into the eye, the greatest inhibition of ChE outside the eye was in the intestine. Also, in humans, antiChEs applied to the eye produced symptoms of intestinal distress (Humphreys and Holmes, 1963). The systemic absorption of epinephrine (adrenaline) and dipiveprin applied topically to the eye was studied by Anderson (1980), who found that a high concentration of material was present in the wall of the intestine and in the faeces. She suggested that the alimentary tract is not only a major elimination route, but also probably a major absorption pathway.

6.3 Examples of Substances Producing Systemic Toxicity by Transocular Absorption

6.3.1 General Comments

Whilst the potential for industrial and domestic chemicals to produce systemic toxicity following topical contamination of the eye is well known, the main human experience comes from the use of ophthalmic preparations deliberately applied to the eye. Some examples of differing types of materials are given to illustrate the variability in systemic toxicity that may be produced by transocular absorption of topically applied materials of high biological activity. They draw attention to the need for detailed monitoring of toxicological studies with materials that may be deliberately applied to the eye, or which may accidentally contaminate the eye. For such materials there is a need for precautionary statements to be developed.

6.3.2 Cyanides

Low MW cyanides can readily diffuse across biological membranes and systemic toxicity may occur by their instillation into the conjunctival sac. So potent are they by this route of exposure that they can produce mortality from which it is possible to calculate LD_{50} (LD—lethal dose) values by instillation into the conjunctival sac. **Table 10** compares the acute lethal toxicity of HCN and NaCN by instillation into the conjunctival sac of female rabbits with other routes of exposure in this species. It demonstrates that by the transocular route, at least in laboratory mammals, these cyanides are lethally potent, with HCN being as lethally toxic by conjunctival instillation as it is when given by iv injection, and more toxic than by the peroral and percutaneous routes.

6.3.3 Timolol

L-Timolol is a nonselective β-adrenoceptor antagonist used in the treatment of glaucoma, and usually available in preparations containing 0.25–0.5%. The use of timolol eye drops has been associated with a variety of potentially serious adverse effects to various body systems (**Table 11**). It has been shown that the oxidation of timolol exhibits genetic polymorphism, and those with low metabolism have higher plasma timolol concentrations and intensified β-blockade (Huupponen *et al*., 1991). That systemic absorption occurs following ocular instillation of timolol has been shown in several studies.

[b]CL: Confidence limits.
[c]Percutaneous times in hours.

Table 11 Systemic adverse effects associated with the topical application of timolol to the eye and its transocular absorption

System	Effect
Cardiovascular	Arrhythmias
	Bradycardia
	Cardiac failure
	Hypotension
	Raynaud's phenomenon
Pulmonary	Asthma (exacerbation)
	Bronchospasm
CNS	Confusion
	Depression
	Dizziness
	Hallucinations
	Aggravation of myasthenia gravis
Gastrointestinal	Diarrhoea
	Nausea
	Vomiting
Genital	Impotence
	Decreased libido
Skin	Alopecia
	Urticaria
	Maculopapular rash
Metabolic	Hyperkalaemia
	Alerted diabetic hyperglycaemic response

Thus, Kaila *et al*. (1985) instilled 20 µl of 0.5% timolol into the conjunctival sac of six volunteers, and found that at 8 min postinstillation all but one subject had plasma timolol concentrations of >25 pg ml^{-1}. They also found that nasolacrimal occlusion reduced, but did not eliminate, systemic absorption of the drug (Kaila *et al*., 1980). Chang and Lee (1987) found that 75% of a 25 µl dose appeared in the blood steam of rabbits, and that the nasal mucosa was more effective than the conjunctivae in contributing to systemic absorption of timolol. Recommendations have been proposed to reduce the incidence of adverse effects from topical ocular application of timolol; these have included reduced medication, eyelid closure, and nasolacrimal occlusion (Fraunfelder and Meyer, 1987). Improved systemic safety has been shown by using a timolol hydrogel (0.1%) compared with an aqueous solution of timolol (0.5%); peak heart rate, head-up tilt test results and plasma concentrations of timolol were significantly lower with the hydrogel formulation (Uusitalo *et al*., 2006). The absorption of ocular topical timolol appears to be dependant on time of day, with the absorption at noon in the rabbit being about twice that measured at 6 a.m., 6 p.m. or 12 p.m. (Ohdo *et al*., 1991). Using a γ-scintographic method to monitor changes in precorneal solution retention, Lee *et al*. (1996) examined the basis for the time dependence. They found that precorneal solution drainage was slowest at noon, but that, in contrast, there was no statistically significant time-of-dosing influence on systemic timolol absorption following intranasal dosing. They concluded that changes in precorneal solution drainage might be the major factor underlying the diurnal incremental changes in ocular and systemic timolol absorption in the rabbit.

6.3.4 Sulfonamides

Several cases of Stevens–Johnson syndrome have been described following the use of ophthalmic preparations containing sulfacetamide (Rubin, 1977; Sewell *et al*., 1992). In some of these cases there may have been previous exposure to oral sulfonamides.

6.3.5 Chloramphenicol

Cases of aplastic anaemia have been reported from the use of topical chloramphenicol ophthalmic preparations (Abrams *et al*., 1980; Carpenter, 1975; Fraunfelder *et al*., 1982; Rosenthal and Blackman, 1965), some of which were fatal (Abrams *et al*., 1980; Fraunfelder *et al*., 1982). The response has been recorded for use of both drops and ointment. Fraunfelder (1989) suggested that physicians should carefully weigh the risk–benefit ratio for 27 lethal events that may occur for 1 in 30 000–50 000 cases, and proposed that chloramphenicol be used only for cases

with organisms resistant to other antibiotics. At the time, Rayner and Buckley (1996) stated in a review that the available evidence for a relationship between ocular chloramphenicol and the development of aplastic anaemia was not conclusive. Currently, it is generally believed that haematological adverse effects from chloramphenicol are a reversible dose-dependent bone marrow depression with doses of $\gg 4\,g\,day^{-1}$ or cumulative dose $>25\,g$, and severe aplastic anaemia in 11 : 25 000–40 000 treatment regimes, unrelated to dose, duration of therapy or route of administration (Todd *et al*., 2006).

6.3.6 Cyclopentolate

Cyclopentolate (2-dimethylaminoethyl 2-(1-hydroxy cyclopentyl)-2-phenylacetate), a potent anticholinergic drug, is used to produce rapid mydriasis and cycloplegia. Signs of CNS involvement, usually developing within minutes or less than an hour, include ataxia, dysarthria, disorientation, hallucinations, amnesia and drowsiness, The effects are particularly notable in children, although they have been described with adults (Awan, 1976; Shihab, 1980). Gastrointestinal effects (vomiting, distension and ileus) were noted in premature twin neonates given cyclopentolate eye drops for eye examination after receiving oxygen. Blood samples taken 24 hours after the instillation of the eye drops gave plasma concentration values of 2 and $22\,\mu g\,ml^{-1}$ (Bauer *et al*., 1973). In a study involving 40 patients and a double blind trial with 35 subjects, Birkhorst *et al*. (1963) showed a statistically significant incidence of reactions.

6.3.7 Ecothiophate Iodide

Ecothiophate iodide (2-diethoxyphosphorylsulfanylethyl-trimethyl-ammonium iodide) is an antiChE used in the treatment of glaucoma. Long-term use of ecothiophate iodide eye drops can lead to inhibition of erythrocyte AChE (acetylcholinesterase) and serum BChE (butyrylcholinesterase), which raised a suggestion that there is a need for periodic blood ChE (cholinesterase) measurements in those receiving topical ocular antiChE treatment (Leopold, 1984). Humphreys and Holmes (1963) investigated 24 patients receiving ocular ecothiophate iodide and found a direct correlation between symptoms (nausea, diarrhoea, abdominal cramps and weakness) noted in 38% of patients, and decrease in blood ChE. Diarrhoea may be the fist indication of systemic toxicity from ecothiophate iodide eye drops (Markman *et al*., 1964). More serious indications of a cholinergic effect include vomiting, muscle weakness, fasciculations, excess lacrimation, hypersalivation, seizures, miosis, bronchospasm, bradycardia and cardiac arrest (Hiscox and McCulloch, 1965; Hallett and Cullen, 1972). A case report of severe cholinergic poisoning resulting from the use of ecothiophate iodide eye drops has been described by Manoguerra *et al*. (1995), in which the patient presented with profound muscle weakness, nausea and dysphagia, for which an initial diagnosis of myasthenia gravis was made. Subsequent investigations showed marked decreases in erythrocyte and plasma ChE activities. The symptoms of the patient spontaneously reversed after the ecothiophate iodide eye drops were discontinued. Asthmatic patients may experience an exacerbation of bronchospasm (Prakash and Rosenow, 1990), which may be accentuated by the coadministration of timolol (Gerber *et al*., 1990).

6.3.8 Proparacaine

Proparacaine is a topical local anaesthetic used to alleviate discomfort during eye examinations. Cydulka and Betzelos (1980) reported a case of tonic-clonic convulsions in a 28-year-old woman following the instillation of two drops of 0.5% proparacaine hydrochloride.

6.3.9 Atropine

Children may experience potentially serious systemic toxicity following the use of atropine eye drops to cause mydriasis. Induced systemic effects include flushing, tachycardia, agitation and hyperthermia (Sydow *et al*., 2008).

6.4 Therapeutic Applications of Transocular Absorption of Drugs

Transocular absorption is finding practical and potential applications in therapeutics. Thus several therapeutic substances when applied topically to the eye may be absorbed in amounts sufficient to exert pharmacological effects. For drugs showing high biological activity through the nasal route and which may have a high first-pass hepatic metabolism by the peroral route, the nasal mucosa may offer a useful therapeutic route of exposure. For example, Pillion *et al*. (1992) found that glucagon eye drops, containing 0.25% saponin, produced a rapid and dose-related increase in blood D-glucose in the rat. Chiou *et al*. (1990) also showed that glucagon may be readily absorbed following ocular instillation, and that this may be facilitated by permeation enhancers. Similar work with insulin demonstrated that whilst plain insulin eye drops had little effect on blood glucose concentrations, when combined with permeation enhancers the blood glucose concentration was markedly reduced in both normal and hyperglycaemic diabetic rabbits and rats (Chiou and Chuang, 1989; Yamamoto *et al*., 1989; Chiou *et al*., 1991; Pillion *et al*., 1991). As an extension of this work, Chiou and Li (1993) investigated the long-term delivery (twice daily for three months) of insulin by the transocular route in rabbits using 0.5% BZ-9 or Brij-78 as absorption

enhancers. They found no evidence for the development of tolerance, local irritation or allergic responses. In normoglycaemic human volunteer studies, in which eight subjects received 50 µl of sterile saline solutions containing various concentrations of porcine insulin, no adverse effects to the anterior segment of the eye were detected by slit-lamp microscopy (Bartlett *et al*., 1994). Developmental work has been conducted on the transocular route as a possible means for dosing with oxytocin and vasopressin (Chiou *et al*., 1991). Although poorly absorbed as such by the ocular route, the addition of polyoxyethlene-20-stearyl ether markedly enhances their absorption.

Other experimental approaches to investigating the potential for delivery of therapeutic agents by the transocular route have included the use of parenteral ophthalmic antimuscarinic agents in acute antiChE poisoning. Thus, Bryant *et al*. (2006) studied the effect of a 5-minute pretreatment of Sprague Dawley rats with ophthalmic atropine sulfate (10 mg kg^{-1}) or homatropine sulfate (20 mg kg^{-1}) followed by the sc injection of dichlorvos (2,2-DDVP; 10 mg kg^{-1}). Survival rates for rats pretreated with ophthalmic homatropine and atropine sulfate were 100% ($p < 0.001$) and 90% ($p < 0.01$), respectively, compared to saline controls (20% survival). For comparison, pretreatment with atropine given by ip injection was 100%. The investigators concluded that pretreatment with parenteral ophthalmic homatropine or atropine sulfate was equal to standard ip pretreatment with atropine in preventing OP lethality in the rat model for acute OP poisoning, and shows promise as an alternative for antidotal therapy. In a further study they investigated the efficacy of the anticholinergic agents tropicamide and cyclopentolate in a similar rat acute OP poisoning protocol with 15 mg kg^{-1} dichlorvos given sc (Bryant *et al*., 2007). Survival in rats receiving pretreatment with ophthalmic tropicamide (20 mg kg^{-1}) and with cyclopentolate (20 mg kg^{-1}) was 90% ($p < 0.001$) for both anticholinergics compared to saline controls (10% survival). It was considered that the results indicated that pretreatments with tropicamide or cyclopentolate were promising as alternative sources of antidotal therapy for acute OP poisoning.

7 OPHTHALMIC TOXICITY AT SPECIFIC MORPHOLOGICAL AND FUNCTIONAL SITES

7.1 General Comments

Chemicals and/or their metabolites may produce injury at various sites in the eye following topical contamination or systemic absorption. Some chemicals produce mixed ocular lesions and others may result in pathologies at specific sites within the eye (Table **9**). General toxicology studies, particularly by repeated exposure conditions, can generally detect any potential for ocular pharmacological effects and for ocular injury at various anatomical sites, providing that appropriate monitoring is undertaken to detect morphological and functional lesions. In this section, examples of chemically induced structural and functional injuries at specific locations and on ocular physiological functions are discussed.

7.2 Cornea

The majority of instances of injury to the cornea by xenobiotics relate to injury that expresses itself in the form of an inflammatory response, and sometimes may be visible macroscopically. Such corneal lesions may be the result of topical contamination of the eye, or from systemically induced ocular toxicity (Hollander and Aldave, 2004). Additionally, more subtle effects may occur and also toxicity may result by other mechanisms. For example, and discussed below, ocular phototoxicity is not common but when it occurs can be of occupational significance. Likewise transient minor corneal epithelial oedema from exposure to low concentrations of vapour from certain chemicals can be a nuisance effect. Examples of corneal lesions resulting from phototoxic reactions, from low vapour concentration exposures and as a consequence of systemic toxicity are presented below.

7.2.1 Phototoxic Keratoconjunctivitis

In this process there is excitation of electrons in the causative sensitizing molecule(s), usually aromatic compounds, by UV radiation (320–400 nm). Phototoxic keratoconjunctivitis has been described from ocular exposure to coal tar pitch fumes with subsequent exposure to sunlight (Curtis and Greenberg, 2005). Coal tar pitch is a mixture of high MW aliphatic and aromatic hydrocarbons. Clinical presentation is as an increasing discomfort, burning sensation and pain in the eye, excess lacrimation, and photophobia, with conjunctival hyperaemia and central corneal abrasions; signs and symptoms develop within minutes to hours after ocular exposure to UV radiation. Treatment usually requires ophthalmic antibiotics and cycloplegics.

7.2.2 Glaucopsia

One practical example of a minor transient effect on the cornea, but which is of significant practical occupational significance, is that of glaucopsia, which is also referred to as blue-grey haze. In this condition there is a transient disturbance of vision resulting from the development of corneal epithelial oedema and associated microcysts following exposure to the vapour of certain

Table 12 Chemicals known to be a cause of occupational glaucopsia

Chemical	Reference
N-ethylpiperidine	Jones and Kippling (1972)
Morpholine	Albrecht and Stephensen (1988)
N-Methyl morpholine	Dernehl (1966)
N-Ethyl morpholine	Dernehl (1966)
Dimethylamine	Munn (1967)
Diethylamine	Grant and Schuman (1993)
Dimethylethylamine	Warren and Selchan (1988)
Triethylamine	Åkesson *et al*. (1985)
Dimethylaminoethanol	Page *et al*. (2003)
Di-isopropylamine	Grant and Schuman (1993)
3-Dimethylaminopropylamine	Spaeth and Leopald (1964)
Dimethylisopropanolamine	Page *et al*. (2003)
Tetramethylethylenediamine	Mastromatteo (1965)
Tetramethyl-1,3-butanediamine	Mastromatteo (1965)
Ethylenediamine	Grant and Schuman (1993)
Triethylenediamine	Dernehl (1966)
tert-Octylamine	Munn (1967)
Bis[2-(dimethylamino)ethyl]ether	Ballantyne (2005)

industrial chemicals, notably aliphatic, alicyclic and heterocyclic amines (Ballantyne, 2004b). Chemicals cited as causing glaucopsia are listed in **Table 12**. Following a latent period of about 30 minutes to a few hours, clinical features include a blurring or haziness of vision followed by a more marked difficulty with visual discrimination and accompanied by a partial loss of colour discrimination, resulting in objectives assuming a blue-grey appearance. This may be followed by the development of haloes around bright objects. In more severe cases, photophobia may develop (Grant and Schuman, 1993). Macroscopic examination of the eyes during an episode demonstrates diffuse corneal cloudiness (Dernehl, 1966) and mild conjunctival injection (Jones and Kippling, 1972). Slit-lamp biomicroscopy reveals diffuse corneal epithelial oedema with subepithelial small vesicular collections of fluid (microcysts), but the endothelium appears normal. Exposure to high concentrations of causative chemicals may result in a slight decrease in objectively assessed visual acuity, and contrast sensitivity may be reduced at lower concentrations (Järvinen and Riihimäki, 1999). Pachymetry reveals an increase in corneal thickness, the magnitude of which is concentration related. On cessation of exposure to the causative vapour, vision returns to normal within a few hours without any permanent ocular sequelae.

The pathogenesis of glaucopsia involves a local effect of the causative vapour on the superficial cornea with diffusion of material into the epithelium, causing epithelial oedema, subepidermal microcysts and fluid accumulation in the superficial cornea. These changes cause scattering of light and blurring of vision. Corneal epithelial oedema is characterized by large increases in the forward scattering of light (Feuk and McQueen, 1971). With some materials it is possible that systemically absorbed chemical may be excreted in lacrimal fluid and in this manner contribute to the local corneal changes of glaucopsia. For example, in studies involving exposure of human volunteer subjects to triethylamine (TEA) vapour, the average lacrimal fluid TEA concentration was 41 times higher than the serum concentration (Järvinen *et al*., 1999). However, in another study in which volunteer subjects were exposed to TEA vapour the lacrimal fluid concentration of TEA was inversely proportional to lacrimal fluid volume, suggesting that increased lacrimal fluid TEA may have been a consequence of local solubility in the fluid (Åkesson and Skerfving, 1990). Also, there were no ocular symptoms following an acute oral dose of TEA, for which the pharmacokinetic constants were C_{max} of 1.17 µmol l^{-1} at t_{max} of 45 minutes, and plasma $t_{1/2}$ ranging from 2.4 to 3.5 hours (Åkesson *et al*., 1989). For experimental purposes, the rabbit is a suitable animal model to study the effects of vapours on corneal morphology. Thus, for example, studies on the effects of vapour from bis[2-(dimethylamino)ethyl]ether (DMAEE) showed that by corneal pachymetry it was possible to follow increases and subsequent decreases in corneal thickness, and to define a no-effects vapour concentration between 4.6 and 8.8 ppm (Ballantyne and Chun, 1996; Chun and Ballantyne, 1997).

Although glaucopsia is transient and does not result in any permanent effects on vision, the condition causes a temporary nuisance disturbance of vision which may be incapacitating and impair efficient and safe working conditions. This may secondarily cause a difficultly with reading initially, and subsequently result in a predisposition to physical accidents and impair the ability to undertake coordinated and skilled tasks. For example, this could result in potentially dangerous situations with driving a motorized vehicle because of the impairment of skilled movements and, with dusk or night driving, the hazard may be exaggerated by the brightness and haloes around oncoming lights (Ballantyne, 2004b). Most chemicals producing glaucopsia are also peripheral chemosensory irritant (PCSI) materials, but for a given material glaucopsia develops at vapour concentrations below those known to cause a PCSI effect, and PCSI occurs at concentrations below those acutely inducing corneal inflammation, and hence glaucopsia may be a more sensitive index of ocular effects (Ballantyne, 2004b;2005). It should be noted, however, that with longer term repeated exposure the vapour concentration causing ocular inflammatory change may be reduced compared with acute exposure conditions, and come closer to that causing

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

glaucopsia. Thus, glaucopsia is of considerable industrial hygiene interest, and the visual effects may be taken into consideration when establishing a permissible exposure standard with a chemical producing this effect. As an example, based on correlation between measured DMAEE vapour concentrations and clinical symptoms and signs the American Conference of Governmental Industrial Hygienists (ACGIH) have adopted an 8-hour TWA_8 of 0.05 ppm with a STEL of 0.25 ppm as being appropriate for protection against visual disturbances (ACGIH, 2001; 2007). This is significantly lower than the vapour concentration causing acute PCSI effects on the eye (68 ppm; Chun and Ballantyne, 1997), but close to that concentration causing mild keratitis by subchronic vapour exposure (1.25 ppm; Losco *et al*., 1996). Also citing vision as a basis, ACGIH have adopted a TWA_8 of 1.0 ppm with STEL of 3.0 ppm for TEA (ACGIH, 2007). Contact lenses may act as a reservoir for some chemicals capable of causing glaucopsia, and thus prolong exposure. It has been advised specifically that contact lenses should not be worn when there is likely to be exposure to the vapour of TEA (Järvinen *et al*., 1999).

7.2.3 Corneal Injury from CGS 24565 Dosed Perorally

CGS 24565 was originally evaluated as a potential hypolipidaemic agent; chemically it is (11 R)-*N*, 15-dideoxo-1-deoxy-1,15-epoxy-11-hydroxy-4-0-methyl -8-0-(2,2-dimethyl-1-oxopropyl)-3-[4-{(2,4,6-trimethyl-phenyl)methyl}-1-piperazinyl]rifamycin. For a three-month po toxicity study CGS 24565 was dosed at 10, 50 or 300 mg kg^{-1} day^{-1} to beagle dogs by gelatine capsule. At week 12 there were bilateral adnexal and corneal changes at the high dose. Corneal changes were characterized as posterior stromal oedema, and stromal infiltrates in the area of Decement's membrane. These changes were interpreted as representing permanent and irreversible changes, being confirmed by subsequent ophthalmoscopic examination at weeks 15 through 26. Light microscopy confirmed irreversible corneal neovascularization, vacuolar degeneration of keratocytes, and polymorph infiltrates in the region of Decement's membrane. These findings terminated further development of CGS 24565 as a therapeutic agent (Schiavo and Bentley, 2000).

7.3 Iris

Effects on iris function are illustrated by exposures to vapour from OP compounds. The miosis caused by such exposures usually starts during exposure, and the degree and duration of miosis are generally related to the exposure dose, although this is not necessarily the general effect. Thus, certain concentrations of antiChEs in contact with the eye may cause extreme miosis but affect accommodation only to a moderate extent (Erickson-Lamy and Grant, 1992). For example, human volunteers exposed to sarin (isopropyl methyl phosphonofluoridate) vapour had marked miosis but only 2.3 D of induced accommodation compared with a potential maximum of 7–10 D (Moylan-Jones and Thomas, 1973). If marked, the inability of the pupil to fully dilate in darkness may persist for several weeks and the affected subject may complain of 'dim' vision and periocular pain (Sidell, 1994; Rengstorff, 1985). Stewart *et al*. (1968) found that topically applied sarin caused a decrease in light sensitivity that correlated with a decrease in pupil size, and proposed that miosis alone was responsible for the decreased light sensitivity. However, Rubin *et al*. (1957) found that topical application of sarin did not decrease dark adaptation, but inhalation of the vapour with the eyes protected decreased dark accommodation in the absence of miosis (Rubin and Goldberg, 1958). Also, systemic dosing with atropine, which penetrates the blood–brain barrier, reversed this decrease (Rubin and Goldberg, 1958). These findings suggest that cholinergic mechanisms proximal to the pupil, such as those in the retina or visual pathways, are responsible for the visual changes.

On occasion, contact with antiChEs can cause iritis that is usually associated with conjunctival hyperaemia. This complication responds to cholinergics (Aldridge *et al*., 1947), but in some cases the response to anticholinergics is slow despite treatment with mydriatics, corticosteroids and 2-pyridine aldoxime methiodide (2-PAM) (Becker *et al*., 1959). Iritis with the formation of posterior synechiae after long-term antiChE treatment has been reported (Kadin, 1963; Leopold, 1984; Werhahn and Schnarr, 1987). Morphological changes that have been reported in humans as a consequence of repeated application of antiChEs are iris cysts of the papillary border (Grant and Schuman, 1993; Werhahn and Schnarr, 1987). Typically they are multiple and 0.1–1.0 mm in diameter, and may develop within 1 to 40 weeks (Abraham, 1954). Pupillary cysts may interfere with vision, particularly in association with extreme miosis (Werhahn and Schnarr, 1987). Histologically, Straub and Conrads (1955) found that in cystic areas two posterior epithelial layers of the iris were separated in some places, forming fluid-filled cysts. This accords with the suggestion that the pathogenesis of the cysts is a result of miosis pinching the iris pigment epithelium against the lens, with retention of fluid between the layers producing cysts. The simultaneous use of phenylephrine drops with antiChEs can enlarge the pupil slightly and reduce the tendency to form iris cysts (Abraham, 1967; Chin *et al*., 1964; Ellis, 1985).

7.4 Ciliary Body

AntiChEs topically applied to the eye can result in various changes in accommodative capacity of the eye (see Ballantyne, 2006a). In glaucoma, contraction of the ciliary muscle reduces the resistance to outflow and antiChE eye drops potentiate this action (Becker *et al*., 1959; Bito, 1968). In addition to pharmacological and toxic actions on the ciliary body from chemicals applied topically to the eye, there are several examples of systemic toxicity to the ciliary body. Examples are those of the OPs disulfoton and fenitrothion, briefly presented below.

7.4.1 Disulfoton

Susuki and Ishikawa (1974) described ultrastructural changes in the ciliary body of dogs chronically dosed orally (by capsule) with disulfoton (ethylthiodemeton; *O*,*O*-diethyl *S*-[2-(ethylthio)ethyl]-phosphorodithioate) at doses of ~0.5 to ~1.5 mg kg^{-1} day^{-1}, five days a week for two years. All dogs developed myopia within a year. Ultrastructure of the ciliary muscle cells showed membranous meshwork structures, considered to be the cause of the myopia by the investigators. Tokoro *et al*. (1973) studied dogs dosed with disulfoton for two years at doses of 5, 10 and 15 mg kg^{-1} day^{-1}. Myopic changes were noted, the onset of which was related to the degree of erythrocyte AChE inhibition. Chronic peroral studies in dogs at doses in the range 0.5–1.5 mg kg^{-1} day^{-1} resulted in decreases in refractive error and corneal curvature suggestive of myopia (Kawamura *et al*., 1974; Otsuka and Tokara, 1976), increase in IOP, and decreased erythrocyte AChE (Tokoro *et al*., 1973).

7.4.2 Fenitrothion

Fenitrothion (*O*,*O*-dimethyl *O*-4-nitro-*m*-tolyl phosphorothioate), was dosed orally (capsule) to Beagle dogs at 10, 20 and 100 mg kg^{-1} $week^{-1}$ for one year (Ishikawa and Miyata, 1980). Myopia was significantly increased in dosed versus control animals by nine months of dosing, and was still present at one year after the cessation of dosing. Lens thickness and IOP were also increased. Histology of the ciliary body showed muscle fibre swelling at all doses, and was morphologically similar to that seen with disulfoton (Section 7.4.1). Both erythrocyte AChE and serum BChE were slightly decreased during the dosing period but returned to normal three months after the cessation of dosing. Ciliary body AChE was significantly reduced.

7.5 Aqueous Humour and Intraocular Pressure

Aqueous humour is secreted by the ciliary processes and passes behind the ciliary muscle into the posterior compartment of the aqueous chamber, then flows between the fibres of the suspensory ligament into the anterior aqueous chamber, and is then reabsorbed into the canal of Schlemm. The trabecular network of the canal is opened, and reabsorption of aqueous humour is facilitated by contraction of the sphincter pupillae of the iris and the ciliary muscle, both of which have a cholinergic innervation. Thus, antiChE agents can pharmacologically cause an accumulation of acetylcholine (ACh) at the sphincters of the iris and ciliary body, resulting in their contraction, producing miosis and ciliary spasm with accommodation for near vision, and facilitating aqueous humour reabsorption and decrease in IOP. The increased IOP in glaucoma can be reduced by the use of antiChE drugs, due to their ability to increase cholinergic activity in the sphincter muscles of the iris and ciliary body. They can therefore be used for the emergency treatment of acute narrow-angle glaucoma and in long-term therapy for chronic wide-angle glaucoma (Koelle, 1994). They are generally not recommended for the long-term treatment of narrow-angle glaucoma because they may produce hyperaemia of the iris and trabecular network (Ellis, 1985). Since it was noted clinically that the continual use of long-acting antiChEs resulted in the development of lenticular opacities (see Section 7.6.8), they have generally been replaced by drugs operating through other mechanisms. These include parasympathomimetic agents (e.g. pilocarpine), which cause a contraction of the ciliary body, relaxation of the lens zonules and forward movement of the lens (Hung *et al*., 1995; Yang *et al*., 1997), and β-adrenergic receptor blocking agents (e.g. timolol) that decrease the rate of production of aqueous humour (Coakes and Brubacker, 1978; Wang *et al*., 1997). Although antiChEs reduce IOP in the normal and glaucomatous eye, a paradoxical transitory increase in IOP may occur in some patients as a result of breakdown of the blood–aqueous humour barrier (Erickson-Lamy and Grant, 1992). This can also be demonstrated experimentally in the rabbit eye. Thus, application of physostigmine, neostigmine or diisopropyl phosphorofluoridate (DFP) to the rabbit eye initially causes hyperaemia of the iris, an increase in IOP and an increased capillary permeability, permitting the entry of proteins that may result in an aqueous humour flare (Bárány, 1947; Von Sallam and Dillon, 1947), which may be prostaglandin-mediated (Erickson-Lamy and Grant, 1992).

Angle-closure glaucoma is probably precipitated in eyes with a shallow anterior aqueous chamber and narrow angle, which can be accentuated to the point of angle closure by miosis and anterior movement of the lens.

Cases have been described in which young individuals have developed angle-closure glaucoma (François and Verbraeken, 1977; François and Verbraeken, 1978; Jones and Watson, 1967). In these cases, glaucoma was a consequence of the iris closing the anterior chamber angle and obstructing the outflow of aqueous humour. However, contraction of the ciliary muscle probably also had a role by loosening the lens zonules and permitting the lens and iris to move forward (Erickson-Lamy and Grant, 1992). Treatment with anticholinergic drugs was effective in these cases, probably as a result of tightening of the lens zonules resulting from ciliary muscle contraction.

7.6 Lens and Cataractogenesis

7.6.1 General Comments

Cataracts may be detected in general toxicology studies providing sufficient detail is given to ocular examination is such studies. For this and other reasons it is desirable that the protocol for a repeated exposure study should allow for routine ocular examinations by a veterinary ophthalmologist. Specific studies on the determinants and mechanisms of cataractogenesis can be carried out *in vivo* and *in vitro* using a variety of specialized approaches. These include various forms of microscopy, biochemical measurements and metabolic studies; these may be followed by magnetic resonance imaging and spectroscopy (Schliech *et al*., 1985), tryptophan fluorescence spectroscopy (Lerman and Moran, 1988), scanning lens monitoring (Mitton *et al*., 1990) and isolated lens preparations with biochemical analyses. Biochemical changes in the lens that have been investigated include aldose reductase, sorbitol dehydrogenase, phosphofructokinase, glutathione reductase, GSH, NADH, NADPH, calcium, cholesterol, phospholipids and protein (Chiou, 1992).

Cataract formation may result from the penetration of materials applied topically to the eye, with diffusion of materials into the anterior aqueous chamber, or be a consequence of systemic toxicity from materials, or their metabolites, absorbed at sites remotes from the eye. In some cases, such as corticosteroids, both local and systemic routes may be effective (see Section 5.2.11). Also, as noted in Section 5.3, with respect to systemic toxicity to the lens there may be differences in lens access depending on whether exposure is prenatal or postnatal. Postnatally, the cataractogenic material must be capable of penetrating the blood–aqueous humour barrier, and thus the necessity for slow excretion of the material and/or long-term repeated exposure, except with potent cataractogenic materials. The likelihood for the development of a cataract, and its nature, varies between species, which is possibly related to differences in metabolic activity in the lens. Also, with a given material the potential for development of a cataract and its time frame to develop may also vary between species, and thus comparative evaluations and extrapolations need to be undertaken with considerable thought.

The mechanisms involved in the development and pathogenesis of a cataract may be complex, and are often variable between different xenobiotics. The cataractogenic effects may be due to the parent absorbed (or penetrating) material or to metabolites formed distally to the eye. In other cases, the parent molecule may require metabolic activation in the lens to a locally acting metabolite. A common aetiological factor in the genesis of opacities often includes changes in osmotic pressure caused by electrolyte shifts, resulting in errors of refraction or lens protein denaturation. Major factors that appear to be involved in some cataractogenic processes include oxidative stress (Vinson, 2006), lens hydration, inhibition of Na^+-K^+-ATPase and calpain activation. This last mechanism involves proteolysis by Ca^{2+}-dependent calpains, which cleave proteins into fragments that decrease lens transparency. It is of interest to note that several photosensitizing agents have been implicated as being cataractogenic. Thus, methoxsalen (8-methoxypsoralen) causes anterior cortical cataracts in mice and guinea pigs having UV exposure (Cloud *et al*., 1960; 1961). Other substances that have been associated with photosensitization-induced cataractogenesis include nafoxidine, haematoporphyrin and bleomycin (Millichamp, 1992).

Several examples of cataractogenic substances, determinants for their activity, and possible modes of action are given below.

7.6.2 Naphthalene

Naphthalene is a well-known cataractogenic material, probably with a dihydrodiol metabolite as the major factor in cataract formation (Xu *et al*., 1992a; 1992b). This metabolite accumulates in the lens of naphthalene-fed rats (Xu *et al*., 1992a) and induces cataracts in rat lenses in culture (Xu *et al*., 1992b). An aldose reductase inhibitor (ALO1576) inhibited both the cataractogenesis and the accumulation of naphthalene dihydrodiol in naphthalene-fed rats (Xu *et al*., 1992b). It was speculated that the site of action of AOL1576 might be lens naphthol dihydrodiol dehydrogenase. Studies by Sato (1993) suggested that aldose reductase inhibitors prevented naphthalene cataractogenesis by inhibiting aldose reductase. Lou *et al*. (1996) fed rats both galactose and naphthalene, or incubated rat lenses in cultures containing high concentrations of galactose and naphthalene dihydrodiol. They found that both cortical and perinuclear cataracts developed. With naphthalene-fed rats, an aldose reductase inhibitor prevented cataract formation. One inhibitor, sorbinil, containing a spirohydantoin group, was less effective,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and tolrestat, containing a carboxyl group, was ineffective. With an *in vitro* dual cataract model (galactose and naphthalene), tolrestat prevented the galactose cataract, but did not protect against the naphthalene cataract; ALO1576 prevented both cataracts. It was concluded that the prevention of naphthalene cataracts resulted from an inhibition of the conversion of naphthalene dihydrodiol to 1,2-dihydroxynaphthalene, and that the effect of aldose reductase inhibitors cannot be explained by the dihydrodiol dehydrogenase activation of aldose reductase.

The toxic effects of naphthalene have been suggested as being due to oxidative stress caused by the generation of reactive oxygen species (ROS) during its Phase I metabolism by cytochrome P450 and redox cycling of its metabolite, 1,2-naphthoquinone (Doherty *et al*., 1985; Wells *et al*., 1989). Naphthoquinone metabolites generated during cytochrome P450-mediated metabolism of naphthalene have a higher cataractogenic potential than the parent naphthalene (Wells *et al*., 1989). Consistent with the role of cytochrome P450 mechanisms in naphthalene cataractogenesis is the fact that P450 inhibitors prevent naphthalene-related cataract formation whilst P450 inducers augment the cataractogenic process with naphthalene. It has been shown that naphthalene causes DNA damage and lipid peroxidation (Bagchi *et al*., 1998), which is consistent with ROS involvement in the mechanism of its toxicity. Additionally, prevention of naphthalene cataractogenesis by pro-cysteine drugs and depletion of GSH in the lens during naphthalene-induced cataractogenesis also accords with the concept that oxidative stress is a causative factor in naphthalene cataractogenesis (Rathbun *et al*., 1996; Wells *et al*., 1989). Because of its known antioxidant effects and inducer effects on GSH-linked detoxification pathways, Pandya *et al*. (2000) studied the effect of curcumin, a constituent of turmeric, on naphthalene cataractogenesis. They found that rats treated with naphthalene and kept on a low dietary concentration of curcumin (0.005% w/w) had significantly less opacification of the lens than rats treated only with naphthalene. The authors noted that it was probable that curcumin protects against naphthalene-induced cataractogenesis through a combination of its antioxidant properties and its effects on GSH-linked pathways. Additionally, they were able to demonstrate that naphthalene-initiated cataract is accompanied by apoptosis of the lens epithelial cells, and that this apoptotic effect is attenuated by curcumin.

7.6.3 Acetaminophen

Cataracts were produced by acetaminophen (paracetamol) when injected into mice having cytochrome P450 mono-oxygenases induced by pretreatment with 3-methylcholanthrene or β-naphthoflavone, but they did not occur in mice not having such pretreatment (Schichi *et al*., 1978). The induction of cataracts by acetaminophen has been attributed to the generation of a reactive metabolite, probably *N*-acetyl-*p*-benzoquinonimine (Dahlin *et al*., 1984). Cataract formation in rabbits has also been demonstrated using high doses of acetaminophen, although the material is not hepatotoxic in this species. Conversely, with D2 mice, acetaminophen in high doses is hepatotoxic but not oculotoxic (Lubek *et al*., 1988). They suggested that cataractogenesis might involve a mechanism different to that causing liver injury. Zhao and Schichi (1995) investigated acetaminophen cataractogenesis in mice that were either cytochrome 450 inducer responsive or nonresponsive. They found acetaminophen to be cataractogenic in C57BL/6 mice (responsive strain) pretreated with β-naphthoflavone, but not in DBA/2 mice (nonresponsive). They therefore considered that the induction of cytochrome P450 enzymes, which metabolically activate acetaminophen, is essential for cataractogenesis. Subsequent observations, using light and electron microscopy, showed that tissue injury occurs first to the ciliary epithelium, and then the iris, corneal epithelium and lens, with mitochondria being the major target subcellular organelle. These findings suggest that the cytotoxic metabolite of acetaminophen passes through the ciliary epithelium to the aqueous humour and is then transported to the lens, and that inhibition of mitochondrial metabolism contributes to the acetaminophen-induced cataractogenesis.

7.6.4 Serotonin Antagonists

Certain serotonin (5-HT) antagonists are cataractogenic. For example, the 5-HT_3 antagonist SDZ ICT 322 (indole-3-carboxylic acid scopine ester), a gastric motility stimulant, has been reported to induce posterior subcapsular lens opacities in a 26-week feeding study in the rat (Langle *et al*., 1993). Histologically the lens fibres were grossly and irregularly fragmented, and there was marked vacuolation of the lens epithelium. The reduced GSH/oxidized GSH ratio was reduced, suggesting a possible role of oxidative stress in the cataractogenic process. Cataractogenesis can also be induced *in utero* by at least one serotonin antagonist, RG 12195 (Lerman *et al*., 1995; see Section 5.3).

7.6.5 Tamoxiphen

Tamoxiphen, a nonsteroidal antioestrogen, has been shown to be cataractogenic in the rat (Furr and Jordan, 1984). There is evidence that the lens opacity cased by tamoxiphen is caused by blockade of chloride channels in the lens fibre cells (Zhang *et al*., 1994). That chloride channel activity is necessary for maintenance of adequate cell hydration is indicated by the fact that removal of extracellular chloride, or addition of channel blockers, both result in lens opacities (Zhang and Jacob, 1994). An *in vitro* comparison was made between tamoxiphen and ICI 182,780 a structural analogue of oestrogen.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Whereas tamoxiphen caused maximum inhibition of chloride channel activity at 10 μM, ICI 182,780 had no effect up to 30 μM (Zhang *et al*., 1995). Light transmission measurements with the lens showed that tamoxiphen caused a dose-related decrease in transmission from 5 to 100 μM, but ICI 182,780 only caused a light transmission decrease at >10 μM, and significantly less than occurred with tamoxiphen at comparable doses. These findings suggest that the channel-blocking and lens-opacification effects of tamoxiphen are independent of antioestrogenic activity.

7.6.6 4-Hydroxynonenal

Studies with 4-hydroxynonenal (4-HNE) may be relevant to the aetiology and pathogenesis of senile and diabetic cataract formation, particularly in relation to the role of free radical generation and lipid peroxidation. Free radicals initiate lipid peroxidation to produce lipid peroxides in certain types of cataract (Babizhayev and Costa, 1994). One highly reactive β-unsaturated aldehyde formed is 4-HNE (Benedetti *et al*., 1980), which is known to be cataractogenic (Srivastava *et al*., 1996). The highly reactive α,β-unsaturated region of 4-HNE can react with the sulfhydryl groups of GSH and proteins, imidazole group of histidine, and amino groups of lysine (Uchida and Stadtman, 1994). A resultant modification of membrane protein and lipid can alter membrane fluidity (Choe *et al*., 1995), which can be the basis for cell injury leading to lens opacity. Srivastava *et al*. (1996) showed that, *in vitro*, pretreatment with butylated hydroxytoluene (BHT) attenuates the cataractogenic effect of 4-HNE, suggesting that BHT-mediated induction of lens epithelium glutathione-5-transferases may be an important component of the protective effect.

7.6.7 Tacrolimus

An interesting indirect cause of cataract formation is seen with tacrolimus, an immunosuppressant, which may be cataractogenic through a diabetogenic effect. It is generally considered that diabetic cataract involves the accumulation of sorbitol, produced through the action of aldose reductase on glucose. Treatment with an aldose reductase inhibitor suppresses the development of diabetic cataract (Tsuji *et al*., 1990). Cataract formation was noted from tacrolimus in a 52-week rat oral study (Ohara *et al*., 1992). It has also been demonstrated to be diabetogenic in the rat (Hirano *et al*., 1992). In a study in which rats were dosed orally with tacrolimus at 0, 2, 5 or 10 mg kg^{-1} day^{-1} for 13 weeks, cataracts developed in the high dose group (26%) with increased sorbitol and reduced GSH (Ishida *et al*., 1997). They also measured an increase in blood glucose with glucose intolerance and decreased insulin. Coadministration of zenarestat, an aldose reductase inhibitor, decreased the incidence of cataract and decreased lens sorbitol. The findings suggest that tacrolimus-induced cataract in the rat is a consequence of increased sorbitol accumulation, and secondary to the diabetogenic action of tacrolimus.

7.6.8 Anticholinesterases

The long-term use of antiChEs for the treatment of glaucoma has resulted in the development of changes in the transparency of the lens and the development of opacities (Chiou, 1999; Harrison, 1960). In general, antiChEs dosed perorally do not result in the development of lens change (Lieberman *et al*., 1971), which may be a consequence of high concentrations of materials reaching the anterior aqueous chamber through the cornea following topical application and/or related to metabolism following peroral dosing. The development of lens changes is age related, with the elderly being more susceptible, and children showing changes only rarely (Axelsson and Nyman, 1970; Chamberlain, 1975; Harrison, 1960; Pietsch *et al*., 1972; Wolter and Lee, 1978). Slit-lamp biomicroscopy of the eye after several months of daily applications of antiChE eye drops demonstrates anterior and posterior subcapsular vacuoles or small opacities in around 50% of patients (Erickson-Lamy and Grant, 1992). Some patients are resistant to the adverse effects of antiChEs on the lens, and maintain normal visual acuity and lens transparency after many years of treatment (Deroetth, 1996; Shaffer and Hetherington, 1966). Also, eyes treated with pilocarpine before antiChEs are protected to some degree from the effects of antiChEs on the lens (Nordmann and Gerhard, 1970; Shaffer and Hetherington, 1966).

Several experimental studies have been conducted on the possible pathogenesis of antiChE-induced lens opacities. With rabbit lens in culture, Michon and Kinoshita (1968a; 1968b) found that concentrations of antiChEs sufficient to inhibit all lens ChE did not produce changes in transparency, but at 1000 times this concentration caused anterior, posterior and equatorial vacuoles to appear associated with increased lens permeability, increased Na^+ content and decreased K^+. Ecothiophate iodide produced these changes without altering lens metabolism, but demarcarium bromide caused anaerobic metabolism to predominate (Michon and Kinoshita, 1968a; Michon and Kinoshita, 1968b). A 50% inhibition of O_2 consumption was reported for the pig, rabbit and human lens treated with paraoxon. Rabbit eyes chronically exposed to ecothiophate iodide eye drops do not show macroscopic eye changes, but Härkönen and Tarkkanen (1970; 1976) found a decrease in ATP and lactate but no change in glycogen, and Firth *et al*. (1973) found no change in lens GSH. Daily applications of 0.25% ecothiophate iodide eye drops to the primate eye produced anterior and posterior opacities within 2–14 weeks (Kaufman and Bárány, 1975; Kaufman *et al*., 1977). Pretreatment iridectomy increased the incidence

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of opacities, but addition of atropine to the ecothiophate iodide eye drops reduced the number of opacities and delayed their development. It has also been demonstrated that ecothiophate iodide eye drops applied daily to primates produced subcapsular opacities and also caused swelling of the anterior cortex of the lens (Albrecht and Bàràny, 1979; Philipson *et al*., 1979).

7.7 Retinal Toxicity

7.7.1 General Comments

As shown in **Table 9** and discussed in Section 5.2 a variety of materials or metabolites can produce toxic effects on the retina by reaching the eye systemically. Some materials having a potential to produce retinotoxic effects may do so as a component of a general toxic effect, but others may have relatively specific effects with the retina being a target tissue. Thus, the effects may be limited to the retina with some substances, but with others materials may be associated with other intraocular pathologies. Also some materials or their metabolites may produce highly selective lesions within the retinal elements. For materials having an effect at more than one distinct anatomical site in the eye, the mechanism responsible for retinopathy may be primary, secondary, or of unknown causation. Some retinotoxic effects have been a consequence of patient management, such as hyperoxia of prematurity (Section 7.7.2), or of long-term medicinal dosing, as with hydroxychloroquine in the management of systemic lupus erythematosis or rheumatoid arthritis (Section 5.2.9).

Most guidelines for repeated exposure toxicity studies include provision for examination of the eye by ophthalmoscopy and histology, and hence some retinotoxic effects may be detected in conventional toxicology studies. However, the sensitivity of ophthalmoscopy for retinal lesions may be low if not carried out by an experienced ophthalmic veterinarian. Also, general pathologists reviewing histology sections in routine toxicology studies may not detect some of the more subtle retinal cytological lesions, which could be of toxicological significance. A variety of techniques of differing degrees of sophistication are available to detect, or confirm, a retinotoxic effect. These include retinoscopy, papillary light reflex, fluorescein fundus angiography, electroretinography and light and electron microscopy. Electroretinography is now well established as a noninvasive clinical procedure for investigating functional retinal defects (Armington, 1974; Shirao and Kawasaki, 1995). However, the above methodologies have differing diagnostic limitations and sensitivities for lesion detection. For example, Maertins *et al*. (1993) compared various approaches to the assessment of amoscanate-induced retinopathy, and found that ophthalmoscopic fundus examination did not yield any characteristic correlates. Time-dependent and dose-dependent effects were found using ERGs and light microscopy, with signs of retinal changes occurring earlier and more distinctively with ERGs. Animal models for human retinopathy with specific chemicals may not be available, or may be less sensitive than in humans. This is illustrated with methanol (see Section 7.7.2).

Reports of retinotoxic effects based on clinical reports need a detailed interpretive evaluation, because of the possible influence of a multiplicity of other possible operative factors in a patient. For example, sparsomycin, an antibiotic produced by *Streptomyces sparsogenes* and *S. cuspidosporus* (Owens *et al*., 1962; Argoudelis and Herr, 1962) apparently produced blurred vision in two of five patients in a Phase 1 clinical study. This was attributed to degeneration of the pigment epithelium, and resulted in the study being discontinued (Close and McFarlane, 1964; McFarlane *et al*., 1966). However, interest continued in the use of sparsomycin and its derivatives, notably ethyldeshydroxy-sparsomycin (EdSm), because of their ribosomal peptidyl transferase centre blocking activity (Goldberg and Mitsugi, 1966), and ability to enhance the antitumour activity of cisplatin (Theocharis and Coutogeorgopoulos, 1992; Zylicz *et al*., 1986). Studies in rats and monkeys, carried out under the auspices of the National Cancer Institute (NCI), have been conducted using histology and ERGs as monitors for ocular toxicity. Abnormal ERG activity was seen only in moribund rats; neither species showed any histological abnormality in the retina (NCI, 1967). Additionally, Hofs *et al*. (1995) found no evidence for a refractive dysfunction due to sparsomycin or EdSm, based on histology and measurement of opsin and rhodopsin activity.

7.7.2 Methanol Retinopathy

Methanol is a well-known cause of visual dysfunction and blindness in humans, in whom it produces optic nerve and retinal lesions. Rats and other nonprimates may not simulate the same ocular toxicity of methanol; however see below for description of a rodent model for methanol-induced retinal and optic nerve toxicity. In humans the ocular toxicity may be variable, for example, retinal histopathology has been observed in the absence of optic nerve pathology (Fink, 1943), and conversely optic nerve demyelination has been observed without retinal lesions (Sharpe *et al*., 1982). Differing findings have also been produced in primates. Thus, optic nerve lesions have been demonstrated after perorally dosed methanol (Baumbach *et al*., 1977), but other studies have shown retinal injury by ERG and histology, but without optic nerve involvement (Khosla *et al*., 1983). In mammals the metabolism of methanol involves sequential conversion to formaldehyde, formic acid and carbon dioxide. It has generally been believed that the accumulation of formate has been responsible for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

both the ocular and the systemic toxicity of methanol, including acidosis (McMartin *et al*., 1978; Martin-Amat *et al*., 1978). The metabolism of formate to carbon dioxide is mediated through a tetrahydrofolate-dependent pathway (Eells *et al*., 1982), and it has been demonstrated that folic acid depletion in the rat increased formate accumulation (Eells, 1991; Murray *et al*., 1991). In this way, the sensitivity of the rat to the ocular toxicity of methanol can be increased, and thus the rat may be used as a laboratory model (Eells, 1991; Murray *et al*., 1991). A number of suggestions have been advanced in order to explain the retinopathy of methanol, including retinal ischaemia secondary to optic nerve (disc) oedema (Hayreh and Weingerst, 1980), and effects on bipolar cells or Müller cells (reviewed by Garner and Lee, 1994). There has been speculation concerning the possible role of cytochrome oxidase inhibition in the optic nerve, leading to stasis of axoplasmic flow (Baumbach *et al*., 1977). In a major study by Garner and Lee (1994) involving a detailed comparison of ERG oscillatory potentials in folate-sufficient and folate-deprived rats, there was no evidence for retinal ischaemia in methanol-induced visual system toxicity. The basic causation of methanol-induced retinopathy remains unclear, as does the possible inter-relationship between optic nerve and retinal toxicity.

As noted above, rats and other nonprimate species may not serve as a suitable model for studying the mechanism of methanol toxicity for the more sensitive human and nonhuman primates. The greater sensitivity of humans and nonhuman primates to methanol toxicity is a consequence of the limited capacity of primates to oxidize, and hence detoxify, formic acid (Eells, 1992; Eells *et al*., 1983). Thus the syndrome of methanol toxicity in primates consists of formic acidaemia, metabolic acidosis and serious visual impairment. Nonprimate species are usually resistant to the accumulation of formate and the associated metabolic and visual toxicity. Eells *et al*. (2000) developed a nonprimate model of methanol toxicity, using rats in which formate oxidation had been selectively inhibited by treatment with nitrous oxide (Eells *et al*., 1983; 1996; Seme *et al*., 1999). Subanaesthetic concentrations of nitrous oxide inactivate methionine synthase (Deacon *et al*., 1980), reducing the production tetrahydrofolate, the cosubstrate for formate oxidation, thus allowing the accumulation of formate to toxic concentrations following dosing with methanol. Nitrous oxide treatment selectively reduces hepatic tetrahydrofolate concentrations in rats to concentrations that are in the region of those measured in humans and nonhuman primates. This rodent model closely replicates the metabolic and neurotoxic effects characteristic of acute human methanol intoxication, and developed formic acidaemia, metabolic acidosis, and visual toxicity. Visual dysfunction was demonstrated as reductions in the ERG and flash-evoked cortical potential, and occurred coincident with blood formate accumulation (Eells, 1992; Eells *et al*., 2000). Histology demonstrated mitochondrial disruption and vacuolation in the retinal pigment epithelium, photoreceptor inner segments and optic nerve. The functional and morphological characteristics in the methanol-intoxicated rats are consistent with the suggestion that formate acts as a mitochondrial toxin in the retina and optic nerve.

7.7.3 Hyperoxic Retinopathy

There has been considerable concern and interest in the retinopathy that accompanies prenatal neovascularization in premature infants: retrolental fibroplasia. Hyperoxia, resulting from the management of prematurity, has long been recognized as a prime causative factor. Also, increased arterial CO_2 has been suggested as an additional risk factor (Bauer, 1982; Holmes *et al*., 1994; 1997a; Wolbarsht *et al*., 1983). Using a neonatal rat model for oxygen-induced retinopathy, Holmes *et al*. (1997b) found that exposure to high concentrations of CO_2 resulted in an increased incidence and increased severity of neovascularization (85%) compared with a hyperoxia group exposed to low concentrations of CO_2 (57%). These findings suggest that hypercarbia may be an additional risk factor in the retinopathy of prematurity. In a further study, Holmes *et al*. (1998) found that 19% of rats in high inspired CO_2 conditions (10% CO_2, 21% O_2) developed preretinal neovascularization, compared with 14% in a pure hypercarbia group (10% CO_2, 12.5% O_2). These findings support the concept that hypercarbia is also a risk factor for the retinopathy of prematurity, and the authors stated that hypercarbia may also be an independent cause of retinopathy.

7.7.4 Chloroquine Retinopathy

Chloroquine is used an antimalarial, and has been employed as an immunomodulator in rheumatoid arthritis, has a selective effect on lysosomes and shows a marked affinity for pigmented tissues. Retinopathic changes occur first in the perifoveal area, shown as a change in granularity of the retinal pigment cell layer. At this stage, a subtle change in paracentral retinal function can be demonstrated, whilst central visual acuity may still be entirely normal. Subsequently a 'bull's eye' pattern and thinning of retinal pigment occurs around the fovea in the macular area. This often results in an annular scotoma within 2° to 3° of fixation (Grant and Schuman, 1993). Changes in peripheral pigmentation and peripheral visual fields occur at later stages. When retinopathy is diagnosed early and chloroquine therapy discontinued, visual loss may not recover, although in a small proportion of cases recovery may occur. Dosage appears to be a major risk factor in retinopathy, and generally retinopathy occurs with doses of >250 mg daily for chloroquine phosphate and >200 mg chloroquine sulfate

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat064
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to a total >100 g chloroquine base (Marks, 1982), or a maximum dose of 4 mg kg^{-1} day^{-1} (Gottlieb, 1990). There have been many suggestions as to how to monitor patients taking chloroquine or its derivates for the early detection of retinopathy. These have included instructing the patient in how to test their own central vision with a grid chart, coupled with review by an ophthalmologist at six to nine-month intervals. The latter should include biomicroscopy and detailed visual field testing. ERG and EOG are generally considered as adjuncts to biomicroscopy and visual field evaluations, rather than as prime indicators of incipient retinopathy (Henkind *et al*., 1964; Percival and Behrman, 1969). Fluorescein fundus angiography can be used to demonstrate the macular retinopathy (Kearns and Hollenhorst, 1966), but may not be of use for the early detection of retinopathy (Oosterhuis and Boen-Tan, 1969).

Histopathological examination of autopsy specimens from patients with chloroquine retinopathy demonstrated rod and cone destruction, with evidence for pigment migration from the retinal pigment epithelium to accumulate in cells in the nuclear and plexiform layers of the retina, with the perifoveal area being particularly affected (Bernstein, 1967; Wetterholm and Winter, 1964). Ultrastructural observations (Ramsey and Fine, 1972) revealed the retinal ganglion cells to contain membranous cytoplasmic bodies resembling those seen in drug-induced phospholipidosis, and being present in the inner nuclear layer and inner segments of the photoreceptor cells.

Several studies have described a pigment retinopathy that may be irreversible and associated with permanent loss of vision in a dose-dependent manner (Kraff *et al*., 1990; Meier-Ruge, 1965; Okun *et al*., 1963). Although in general dose dependent following peroral dosing, the variability in presentation is possibly due to perturbations in drug bioavailability. Since serum chloroquine concentrations are about four-fold greater following ip dosing compared with po doing (Zhang *et al*., 2003), in order to facilitate an increased rate of drug absorption Gaynes *et al*. (2008) studied retinal light and electron microscopical histopathology in mice following ip chloroquine dosing (10 mg kg^{-1}) daily for 62 days. They found all treated animals developed a well-defined chloroquine retinopathy during the treatment period, suggesting that ip chloroquine dosing facilitates retinopathy due to heightened drug absorption and bioavailability. Thus increased rate of tissue accumulation and bioavailability of chloroquine leads to an increased risk of retinal injury. The increased rate of chloroquine accumulation in the retina may lead to an increased lysosomotrophic effect due to the inability of the lysosome to compensate for a chloroquine-induced elevation of pH through re-acidification of the intralysosomal contents (Reasor and Kacew, 2001). The histopathological lesions produced by chloroquine have been described for several animal species. For example, in the mouse, the outer retinal layers show a loss of the outer plexiform layer and of photoreceptors and photoreceptor nuclei; loss of Müller cells and the presence of membranous cytoplasmic bodies in the inner retina; and focal atrophy with loss of nuclei and pigmentation in the pigmented epithelium. In humans on long-term chloroquine therapy, scanning laser polarimetry has shown that the retinal nerve fibre layer is significantly reduced, and correlated with chloroquine daily dosage (Bonanomi *et al*., 2006).

The details of the mechanism for the production of chloroquine retinopathy are not clearly understood, although progressive phospholipidosis may be a contributory factor (Hallberg *et al*., 1990; Mahon *et al*., 2004; Toler, 2004). Chloroquine is lysosomotrophic, and this may lead to loss of the degradative function of the lysosome, and can block the action of aliphatic esterases including phospholipase A_1 and A_2, resulting in an increase in the phospholipid content in the lysosome (Hostetler *et al*., 1985). Such disruption of lysosomal function has been demonstrated to occur in retinal neurones and the retinal pigmented epithelium (Mahon *et al*., 2004).

7.7.5 Anticholinesterase Retinopathy

7.7.5.1 General Comments

The retina has AChE and cholinergic activities (Hutchins, 1987), and choline uptake and conversion to ACh is documented (Atterwill *et al*., 1975). Also, it is relevant to note that ACh and its agonists cause ERG effects that include an initial increase followed by a decrease in b-wave amplitude, and antiChEs have a similar effect. However, retinal neurotransmission is complex, and at least five neurotransmitters have been identified: GABA, glycine, dopamine, idolamine and ACh. Thus, the potential for the biochemical pathogenesis of retinal lesions may be complex. Boyes *et al*. (1994) noted that several studies have demonstrated retinal degeneration in photoreceptors in the outer nuclear layers. Since these are devoid of cholinergic innervation, it is possible that if OPs are producing this effect they do it indirectly, such as by altering blood flow or its distribution. Examples of documented retinal effects produced by antiChEs are presented below.

That uncontrolled and potentially hazardous exposures to antiChEs can result in adverse effects on the human eye has been discussed with specific reference to Saku disease in Section 5.2.12. Several subsequent human clinical and epidemiological studies outside Japan have also drawn attention to a potential for retinal toxicity in groups having occupational or incidental (due to proximity) exposure to pesticides, including antiChEs. As with Saku disease, exposure could be via a quantitatively variable combination of routes, including local eye contact, inhalation, percutaneous and peroral. Several

examples of documented accounts of multiple uncontrolled or poorly controlled exposures leading to regional occurrences of optic toxicity follow.

A cross-sectional study of Indian workers spraying fenitrothion (*O*,*O*-dimethyl *O*-4-nitro-*m*-tolyl phosphorothioate), demonstrated macular degeneration in 16% of the workers (Misra *et al*., 1985). Morse *et al*. (1979) described ocular toxicity, including a 22% incidence of macular degeneration, in workers exposed to methomyl ((1-methylsulfanylethylideneamino) *N*-methylcarbamate) in a pesticide manufacturing plant. Fluorescein angiography suggested that the macular lesion was a consequence of injury to the pigment epithelium. In a general cohort study on the possible relationships of retinal degeneration to pesticide application by licensed applicators in Iowa and North Carolina, Kamel *et al*. (2000) found that retinal degeneration was associated with fungicide use (odds ratio of 1.8; 95% confidence interval 1.3–2.6). Risk increased with cumulative days of fungicide use (p for trend was 0.011). Retinal degeneration was also related to the use of organochlorine and carbamate insecticides, but these associations were less consistent. In a subsequent follow-up of this Iowa/North Carolina study, the potential for eye injury in the wives of pesticide applicators was investigated, since they may be incidentally and/or indirectly exposed through carry-home contamination or spray drift from nearby fields (Kirrane *et al*., 2005). Self-reported cross-sectional data obtained by questionnaire between 1993 and 1997 from 31 173 wives were used. Self-reported retinal degeneration was associated with the wife's fungicide exposure.

Many studies have demonstrated that antiChEs can produce abnormal ERG alterations and/or retinal structural damage. Thus, in the cat, chlorphenvinphos ([2-chloro-1-(2,4-dichlorophenyl)ethenyl] diethyl phosphate) at dosages in the range 1–16 mg kg^{-1} increased a-wave amplitude, and at dosages >4 mg kg^{-1} increased b-wave amplitude (Takeda *et al*., 1976). The retina of dogs dosed chronically (two years) with disulfoton (0.5–1.5 mg kg^{-1}) was examined ultrastructurally (Uga *et al*., 1977). Degenerative changes were seen, principally in pigment epithelial cells in the area around the papilla, and myelin-like material was observed in retinal cells. Wistar rats dosed with chlorpyriphos (diethoxy-sulfanylidene-(3,5,6-trichloropyridin-2-yl)oxy-phosphorane) showed ERG changes of decreases in a-wave and b-wave amplitudes of >50% and increased latencies of 10–20%, which were associated with inhibition of plasma, erythrocyte and brain ChE activities. Neuropathological lesions included optic nerve demyelination, partial necrosis of pigmented epithelial cells, and cytoplasmic oedema and degeneration of ciliary muscle myofilaments (Kono *et al*., 1975; Mukuno and Imai, 1973). Although some studies have indicated that there may be a causal relationship between retinal AChE inhibition and the subsequent development of retinopathy, other repeated exposure studies have suggested that such an AChE inhibition may not be a major aetiological factor in the production of retinal toxicity. Thus, in a subchronic (six-month) study in which beagle dogs were given daily po doses of ethyl parathion (2.4, 7.9 or 794 µg kg^{-1} day^{-1}) by gelatine capsule, there was inhibition of plasma, erythrocyte and retinal ChEs at the high dose, but no evidence for functional impairment of ocular function during the six-month period as assessed by ophthalmoscopy, slit-lamp biomicroscopy, refraction, tonometry, ERG and ocular histology (Atkinson *et al*., 1996). In a chronic po study (one year), beagle dogs were dosed with disulfoton (*O*,*O*-diethyl *S*-[2-(ethylthio)ethyl]-phosphorodithioate) in the diet, with average daily consumptions of 0.00, 0.015, 0.121 and 0.321 mg kg^{-1} (Jones *et al*., 1999). Erythrocyte, plasma, corneal and brain ChEs were significantly decreased at 0.121 and 0.321 mg kg^{-1} day^{-1}; the no-effect level (NOEL) for ChE inhibition was 0.015 mg kg^{-1} day^{-1}. However, there were no adverse clinical neurological effects and no ophthalmological findings by ERG, refractivity, tonometry or pachymetry.

A few, more detailed, examples of retinopathy from specific antiChEs follow.

7.7.5.2 Diazinon Retinopathy

In what was essentially an environmental study, Hamm *et al*. (1998) investigated the effect of the OP diazinon on AChE activity and embryonic retinal cells in the teleost (*Oryzias lapites*); concentrations used were 1.8×10^{-5}, 4.4×10^{-5} and 8.8×10^{-5} M. They found that diazinon significantly inhibited AChE in a dose-related manner in whole embryos and in homogenates of retinae. Histology demonstrated that as the retina underwent differentiation into distinct cells, small foci of necrotic cells appeared within the inner nuclear layer, and isolated pyknotic cells were seen in the ganglion layer. Quantitation of the necrotic calls by image analysis revealed a dose-related increase in the number and area of these lesions that was statistically significant at 8.8×10^{-5} M diazinon. Enzyme histochemistry localized AChE activity to regions corresponding to those of sites of necrosis.

7.7.5.3 Fenthion Retinopathy

Various studies have been conducted on the retinotoxic potential of fenthion. Imai (1975a; 1975b) demonstrated ERG changes in rats given acute im injections of 5, 25 and 50 mg kg^{-1} fenthion. At the low dose there was an increase in the amplitude of the a- and b-waves that persisted up to 10 days postinjection; thereafter latency and peak times were lengthened and did not return to normal until 40 days postinjection. At the mid-dose, the a- and b-waves increased, and by postinjection day 4 the latency and peak times increased; the amplitudes

recovered by 60 days, but the peak time remained increased. At the high dose the a- and b-wave amplitudes were decreased and the latency and peak times were increased; no recovery of amplitudes was noted. At doses $>50\,mg\ kg^{-1}$, fenthion produced dose-dependent ERG changes, a decrease in retinal ChE activity, fundoscopic evidence of retinal degeneration and histopathological changes in the pigmented epithelium and sensory retina (Imai, 1977; 1978; Imai *et al*., 1983; Miyata *et al*., 1973). Imai (1975a; 1975b) studied the effects on the ERG and retinal ChE in rats of acute sc dosages of fenthion in the range 0.0005–500 mg k^{-1}. All rats at $500\,mg\ kg^{-1}$ died. At 50 and $100\,mg\ kg^{-1}$, subnormal ERG activity was obtained; $25\,mg\ kg^{-1}$ was a transitional dose (ERG normal), and at $<25\,mg\ kg^{-1}$ the ERG was supernormal. Minimal change was seen at the lowest dose of $0.005\,mg\ kg^{-1}$, and thus a NOEL for the ERG was not obtained. Retinal and cerebellar AChE activity was inhibited in a dose-related manner in the $0.5–100\,mg\ kg^{-1}$ range. Thus, ERG changes were observed at acute fenthion doses lower than causing inhibition of retinal AChE activity. Imai (1975a; 1975b) also studied the effects of acute sc dosages of fenthion in rats at a more restricted range of 0, 5, 25 and $50\,mg\ kg^{-1}$. At $5\,mg\ kg^{-1}$ supernormal ERGs were recorded that increased until 10 days postdosing and then decreased to normal by two months. A transitional ERG was confirmed at $25\,mg\ kg^{-1}$, and at $50\,mg\ kg^{-1}$ a subnormal ERG was obtained that was still present at 66 days postdosing. Measured serum BChE activity decreased to approximately 15% at four days postdosing. Retinal AChE activity was decreased for up to four days, and in the high dose group the ERG changes corresponded with the retinal AChE recovery curve. A repeated exposure study was conducted with fenthion ($50\,mg\ kg^{-1}$) given sc every four days to Long Evans black rats for one year (Imai, 1977; Miyata *et al*., 1979; Uga *et al*., 1979). By three months the ERG was subnormal, and at nine months the ERG a-waves disappeared. Fundoscopy revealed pallor of the papilla. Histology demonstrated disappearance of the pigmented epithelial layer, and outer granular layer. Ultrastructural examination showed a complete disappearance of photoreceptor cells.

7.7.5.4 Tacrine Retinopathy

Tacrine (1,2,3,4-tetrahydroacridin-9-amine) is a ChE inhibitor of potential use in Alzheimer's disease, based on the ability of the compound to facilitate cholinergic function in the CNS via direct stimulation of M- and N-receptors through AChE-inhibition (Avery *et al*., 1997; Newhouse *et al*., 1997). Since ACh plays a basic role in visual function (Famiglietti, 1983; Hutchins, 1987; Ross *et al*., 1985), and because some visual symptoms and optic nerve degeneration occur in Alzheimer's disease patients (Hinton *et al*., 1986), and decreased ACh found in the CNS may also occur in the retina (Strenn *et al*., 1991), it was considered appropriate by Alhomida *et al*. (2000) to investigate the effects of tacrine on human retinal AChE activity. *In vitro* studies on human retinal homogenates showed a concentration-dependent inhibition of AChE activity by tacrine, with an IC_{50} (concentration causing 50% inhibition) of approximately 50 nM. The Michaelis–Menten constant (K_m) for the hydrolysis of acetylthiocholine iodide by retinal AChE was 0.12 mM, which increased in the presence of tacrine. The V_{max} was determined to be $2.23\,\mu mol\ h^{-1}$ mg $protein^{-1}$, and was decreased by treatment with tacrine. Dixon and Lineweaver–Burk plots, and their secondary replots, indicated that the inhibitory process of tacrine on human retinal AChE was a combination of competitive and noncompetitive processes.

7.8 Extraocular Muscles

Toxic and pharmacological effects may involve extraocular muscles as a result of certain materials being applied topically to the eye and with some materials reaching them from the systemic circulation. Those materials causing myotoxic effects following local topical applications do so because they have the appropriate physicochemical characteristics for penetration to the periocular area, and are of sufficient potency to cause effects from the comparatively small amounts attaining the extraocular muscles by this route. Effects from topical application are well demonstrated by antiChEs, in part because of the very high AChE activity in the extraocular muscles (Hikita *et al*., 1973; Mukuno and Imai, 1973; Mukono *et al*., 1973). Thus, antiChE eye drops used in the treatment of glaucoma commonly cause a few minutes of eyelid twitching.

Systemic toxicity to the extraocular muscles has also been demonstrated with antiChEs. For example, Mukuno and Imai (1973) dosed dogs long term with disulfoton and found decreased extraocular muscle ChE activity, and ultrastructurally there was degeneration of nerve fibre bundles, neuromuscular junction, and muscle fibres, with mitochondrial degenerative changes. Dogs dosed with disulfoton in the range $0.5–1.5\,mg\ kg^{-1}\ day^{-1}$ had dosage-related inhibition of AChE and BChE in the extraocular muscles, and dose-dependent decreases in retinal ChE activity (Hikita *et al*., 1973). Suicidal poisoning using OPs has been reported to cause bilateral third or sixth nerve paralyses in 8/200 patients and facial nerve paralysis in 12/200 (Wadia *et al*., 1974).

Cutaneous Toxicology

Steven J. Hermansky

CONTENTS

1 INTRODUCTION

This chapter describes the general principles of the toxicological responses of the skin to cutaneously encountered xenobiotics. This discussion will be augmented by an abbreviated description of the methods used in the predictive testing currently used to identify potential cutaneous irritants and sensitizers. However, because of the large amount of information available, there will be no attempt to make these discussions complete. Several comprehensive references are available (Hobson, 1991; Marzulli and Maibach, 1991c; Chilcott and Price, 2008).

When addressing the effect of chemical substances on the skin, there are several fundamental factors to be considered. These include such variables as humidity, temperature, air currents (wind), exposure to radiation (including light), nutrition of the organism, friction, pressure, trauma (lacerations) and, perhaps, electromagnetic current. These variables influence the overall appearance and function of the skin, as well as the response of the skin to toxic insult. Physical agents (friction, pressure, electrical currents and trauma), thermal factors (excessive heat and cold), and living organisms (bacteria and parasitic insects) produce pathological responses in the skin. Literature often deals with toxic responses of the skin to chemicals as a series of discrete, mechanistically based entities. In reality, there can be several concurrent, pathological processes that influence the immediate response of the skin to chemicals. This confounds the diagnosis and treatment of the skin ailments. For example, chemical irritants have been shown to increase the allergic contact dermatitis response and, thus, may have profound effects on the

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

diagnosis of skin ailments (McLelland *et al*., 1991). Furthermore, physical trauma to the skin, such as pressure or friction, can alter the response of the skin to chemical irritants, while the converse is also true (Susten, 1985; Lebwohl and Herrmann, 2005). Genetic factors can also influence an individual's susceptibility to irritation following chemical exposure (Ishii *et al*., 1990; Farage *et al*., 2006; McGrath and Uitto, 2008).

This chapter will deal primarily with the effects of chemicals, natural or synthetic, on the skin and will not, in general, address the interaction of the resulting toxicological responses with other pathological processes. Interesting developments are occurring in the realm of thresholds of skin effects, both irritant and sensitization, that may change many aspects of risk assessment and management of skin diseases in the near future (Safford, 2008). The European REACH (Registration, Evaluation and Authorization of Chemicals) project requires the review and registration of thousands of chemicals and products and will also contribute to a significant revolution in the global management of chemicals and risk assessment (Louekari *et al*., 2006). As such, the entire area of toxicology, including toxic responses of the skin, is a rapidly developing and evolving field.

Toxic responses of the skin are of significant importance to the organism because the skin is one of the largest organs of the body and possesses functions vital to survival. In humans, the skin comprises approximately 10% of the normal body weight. The skin is constantly exposed to environmental conditions and consequently possesses several important functions related to the interaction of an organism with its surroundings. These include protection from adverse conditions, regulation of the body temperature and a role in the retention or loss of body water (Rongone, 1987; Norlen, 2006). Several biochemical functions have also been attributed to the skin, including metabolism, melanin production, and protein and lipid synthesis and metabolism (Rongone, 1987; Lerner and McGuire, 1961; Johnson and Fusaro, 1972). The skin is also known to act as a storage depot for glucose (primarily when blood glucose concentrations are elevated).

The skin displays several toxicological responses to chemical and/or physical insult. Responses produced by insults of vastly different mechanisms and resulting from fundamentally different physiological and structural changes in the skin often appear outwardly to be very similar. Therefore, the clinical classification of skin ailments has historically been by morphology (appearance) rather than by mechanism. The functional changes produced by the insult to the skin and the impact of these changes on the behaviour and survival of the organism are not well understood. Mechanistic research, often employing *in vitro* skin equivalent models (see later in this chapter), into these changes is a rapidly evolving field (Roberts and Aptula, 2008; Uchino *et al*., 2008).

A significant number of environmentally related diseases and injuries involve the skin. Skin problems constitute approximately 34% of all occupational diseases, but may be as high as 70% in some occupations, including healthcare workers (Mathias, 1985; Hogan and Lane, 1986; Suskind, 1990; Kampf and Loffler, 2007). These statistics are based on reported incidences of skin diseases and injuries and generally omit laceration, burns and reactions of short duration. Thus, actual numbers have been estimated to be anywhere from 10- to 50-fold higher than medically reported (Mathias, 1985).

In addition to occupational hazards, surveys have indicated that greater than 20% of women and 10% of men claimed to have experienced adverse reactions to cosmetics and toiletries in the preceding five years (DeGroot, 1987; Orton and Wilkinson, 2004). Generally, the incidence of nonoccupation adverse reactions of the skin to xenobiotics is unknown. However, owing to the potential for exposure to a wide variety of chemicals, it can be speculated that nonoccupational exposure to xenobiotics results in a significant amount of adverse reactions. The cosmetic industry recognizes these reactions, and is constantly attempting to minimize the risk of sensitization and irritation (DeGroot *et al*., 1988).

2 STRUCTURE OF THE SKIN

The skin is a heterogeneous organ that consists of two different layers derived from separate germ-cell lines (**Figure 1**). The thin, outermost layer, or epidermis, is comprised primarily of loose connective tissue. The innermost layer or dermis is of variable thickness that contains both connective and adipose tissue. Normal skin also contains appendages, blood vessels and neuronal components.

2.1 Epidermis

This outer layer of the skin is a stratified cellular tissue derived from the ectoderm and has no direct blood supply. Therefore, the epidermis must be completely penetrated and the dermis injured for bleeding to occur. The epidermis receives all of it nutrients from the dermis. The primary cells of the epidermis (keratinocytes) are constantly evolving and forming a cornified, protective barrier or stratum corneum (the horny scales). The stratum corneum is several layers thick and composed of flattened keratinocytes that are no longer viable or metabolically active. The intercellular spaces in the

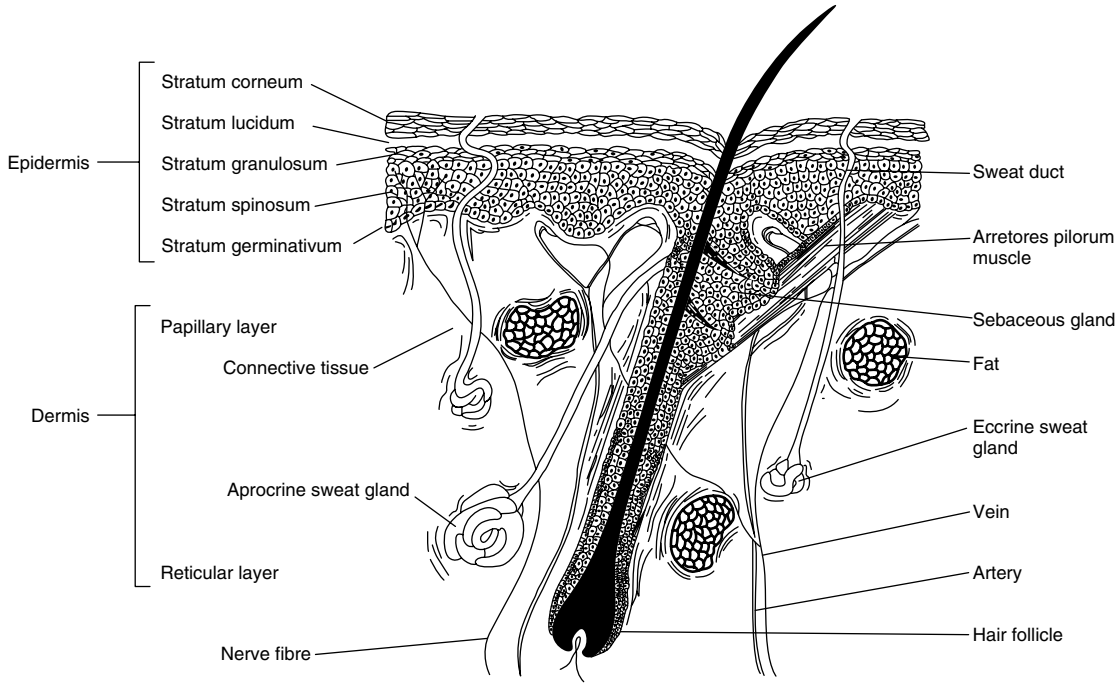

Figure 1 Schematic representation of the structure of the skin.

stratum corneum are filled by a matrix of materials including ceramides (a class of lipids that do not contain glycerol). This combination of cells and intercellular components plays a key role in the protective nature of the epidermis.

The primary keratinocyte proteins are keratin and filaggrin, that together contribute approximately 80–90% of the mass of the epidermis. Recently, a major breakthrough in the genetics of skin barrier diseases was achieved by the sequencing of the genes of the epidermal differentiation complex (EPC) and identification of loss-of-function mutations of these genes. Filaggrin plays an integral part of the epidermis in engineering and maintaining the barrier function (Rodriguez *et al*., 2008). Mutations that result in significant changes in the structure and function of profilaggrin and, ultimately, filaggrin represent an important risk factor in allergic disease (McGrath, 2008). These discoveries and advancements will ultimately add important aspects to genetic counseling and management of skin diseases.

Beneath the stratum corneum are several layers of viable, extremely metabolically active keratinocytes that form the remainder of the epidermis. Lying adjacent to the dermis is the innermost or basal cell layer (the stratum germinativum), that consists of a single layer of columnar epithelial cells. Presumably, keratinization begins in this layer by synthesis of fibrous prekeratins. When the cells of the basal cell layer divide, they travel outward to become part of the prickle cell layer (the stratum spinosum), which is several cell layers thick. By the time the cells reach the outermost areas of this layer, aggregated filaments extend the length of the cell. As the cells move closer to the surface of the skin, they form protein aggregates and keratohyalin granules and increase in size to form the stratum granulosum, which is two to four cell layers thick. In this layer, the number of cytoplasmic granules increase and the nuclei of the cells either break apart or are dissolved and the cells die.

Between the outermost layer (the stratum corneum) and the stratum granulosum lies the stratum lucidum, which varies in size and appearance. The stratum lucidum is most prominent in thick skin such as that found in the ball of the foot. Eleidin, presumably a product resulting from the transformation of keratohyalin, is found in this layer and is transformed into keratin as the stratum corneum is formed. The stratum corneum, which is continually being worn away, is constantly replaced in this manner. In the stratum corneum, the keratinocytes are filled with a filamentous network of proteins, including keratin and filaggrin. These proteins are buried in an array of mucus and lipids encapsulated by the chemical-resistant cell membrane. It has been estimated that it takes 26–28 days for a cell from the basal cell layer to progress through the layers of the skin to the outmost region of the stratum corneum (Rongone, 1987).

Approximately, 10% of the cells of the epidermis are Langerhans cells, which are dendritic cells primarily responsible for antigen recognition (Emmett, 1991; Kalish, 1991; Roberts and Aptula, 2008). New research is expanding the understanding of the role and biological importance of the Langerhans cells. These cells are now known to interact with viruses and play a role in viral

immunity and infection including HIV, herpes simplex and varicella-zoster virus (Cunningham *et al*., 2008).

2.2 Dermis

Beneath the thin, protective epidermis is the much thicker dermis. This inner layer of the skin is derived from the mesoderm and is composed of connective tissue, fibroblasts, collagen and elastic fibres. The dermis serves as a supporting unit for the epidermis and constitutes 90–95% of the mass of human skin. The dermis is composed of two layers. The papillary layer (so named because of its prominent papillae) is the outer, thinner layer that contains a finer network of collagen fibres than the inner or reticular layer.

Capillaries are prominent around the papillae of the outer layer of the dermis. The exchange of nutrients and waste products between the blood and epidermis occurs by diffusion through the large surface area of this section of the dermis. Although not completely understood, it appears that the dermis may also serve as a reservoir of nutrients for the epidermis.

The predominant cell in the dermis is the fibroblast, which synthesizes fibrous proteins and several granular substances including hyaluronic acid and mucopolysaccharides. The dermis also contains several other cell types including macrophages, histiocytes, mast cells and fat cells. Blood vessels, nerve fibres and nerve endings that are associated with the skin are also located in the dermis.

2.3 Appendages Associated with the Skin

Two types of skin, differentiated by their structure and cutaneous appendages are recognized. Glabrous skin, found only in the palms and soles, has a thick, highly protective stratum corneum as well as sweat glands and encapsulated nerve endings. Hairy skin, found throughout the rest of the body, has a relatively thin stratum corneum and contains hair follicles, sweat glands and sebaceous glands but does not contain encapsulated nerve endings. Sweat glands secrete an aqueous solution (sweat) that aids the body in cooling by evaporation. There are two types of sweat glands. The eccrine sweat glands are located over the entire surface of the body and have ducts that lead directly to the epidermal surface. Secretion by the eccrine sweat glands is under autonomic control and sweating is induced by emotional or thermal stimuli or in response to certain tastes. Apocrine sweat glands are located only in the area of the axilla, genitalia and nipples and have a duct that leads to a hair canal. The secretory product of the apocrine sweat glands is initially odourless, but it acquires odour following degradation by bacteria found on the surface of the skin. There is no function of the apocrine sweat glands in humans except for possible communication within or between species (as a sex attractant or as a territorial marker).

Sebaceous glands are generally associated with hair follicles and, as with hair follicles, are found over the entire surface of the body except for the glabrous skin of the palms of the hands and soles of the feet. Sebaceous glands are under hormonal control and excrete sebum, a mixture consisting primarily of lipid breakdown products, into the hair canal. The process of sebum secretion, termed holocrine secretion, does not account for all lipids found on the surface of the skin. Some lipids are contributed by the desquamation of keratinocytes from the stratum corneum. Therefore, the quantity of lipids on the surface of the skin is dependent on the local concentration and activity of the sebaceous glands, as well as the amount of desquamation in the area. In areas where the sebaceous glands are numerous and actively secreting sebum, nearly 90% of the lipids on the surface of the skin can be derived from sebum. The primary function of sebum is as an antibacterial agent, but the lipid components may also act as a waterproofing compound (primarily in hairy mammals) and may prevent the loss of water from the epidermis in humans (Monteiro-Riviere, 1991; Schittek *et al*., 2008).

Hair follicles have three primary layers, including the inner root sheath, outer root sheath and the connective tissue sheath. Hair follicles undergo regular phases of growth (anagen) and atrophy (catagen) separated by periods of inactivity (telogen). The phases of hair growth are generally recognized to be under complex hormonal control. The cells of the deepest part of the hair follicle (sometimes termed the germinal matrix) are one of the most metabolically active areas of the body (Emmett, 1991). Therefore, the response of the skin to cutaneously encountered xenobiotics may be affected by the amount and growth of hair present at the site of contact. For this reason, hair growth should be synchronized within animals in a cutaneous toxicity study. This is best accomplished by clipping all animals the day before treatment (and at regular intervals during a repeated study), which induces a new hair growth cycle in all animals. This is especially important in studies of tumour initiation and promotion where metabolism can be critical to the outcome of the study (Monteiro-Riviere, 1991).

The nails and hair are important to the forensic toxicologist in the identification of poisonings, particularly involving arsenic (Blanke and Poklis, 1991). Biomonitoring, or the process of inferring chemical exposure through measurement of exceedingly low levels of chemicals in biological systems, is increasingly playing a role in the evaluation of environmental exposures. Data involving nails, hair, urine and other biological samples collected from humans is being used more frequently by researchers to measure and evaluate exposure to various

chemicals (Esteban and Castano, 2008). Unfortunately, these data are often misused by the media, regulatory agencies and legislative bodies, who misinterpret exposure, regardless of how low, as an indicator of toxicity. As such, the importance of biomonitoring, including that using hair and nails, is likely to expand in the future.

Piloerection, where the hair tends to stand vertical to the plane of the skin, is an important effect of some neuroactive agents. This condition is produced following stimulation of the adrenergic receptors and resulting contraction of the arrectores pilorum muscle (Weiner, 1980). Other than these specific examples, these appendages are not generally of major concern to the toxicologist and will not be addressed further in this chapter.

3 FUNCTION OF THE SKIN

As stated earlier, the skin is the primary location where an organism interfaces with the physical, chemical and biological environments (Suskind, 1977; Proksch *et al*., 2006). It is vulnerable to toxic effects from agents encountered in the environment, especially those that may be absorbed into and through the skin. Thus, the primary function of the skin is not absorption, but rather the protection of the body (Zesch, 1987; Suskind, 1990; Rodriguez *et al*., 2008).

The keratinized stratum corneum, which exists as a layer of loosely packed dead epidermal cells, acts as a diffusion barrier against the absorption of chemicals into the skin (Dugard, 1987; Rawlings, 2003). Chemicals encountered by the intact skin may slowly pass into and then through this diffusion barrier and be gradually released into the body, eventually producing toxicity. The intact stratum corneum also provides a significant defence against the loss of water from the body. Additionally, the dermis contains an abundance of water that is systemically available during times of water deprivation. The dermal blood supply is substantially larger than that required for the metabolic activity of the skin. Therefore, radiation of heat from the body, controlled by the rates of blood flow to the skin, as well as the evaporation of sweat, aid in the thermal regulation of the body. Elastic and collagen fibres provide the skin with a physical barrier against trauma (Suskind, 1990) and a barrier to invasion by micro-organisms (related, in part, to the secretory products of the sebaceous glands).

Melanin, produced by melanocytes, is found in varying concentrations in the skin. Following production by the melanocyte, the melanin is transferred to keratinocytes in a specialized organelle (the melansome). These organelles are normally broken down in light-skinned people, but not in dark-skinned people. It is unknown if pigmentation plays a significant role in modifying chemical damage to the skin. However, melanin certainly plays a role in protection against ultraviolet radiation (Emmett, 1991). A dark-skinned person may be protected from the damaging effects of the sun similar to a light-skinned person who has applied a sun protection factor (SPF) 4 sunscreen. However, this is not sufficient protection to prevent skin damage after significant sun exposure and, as with fair-skinned individuals, persons of colour should be encouraged to protect themselves from overexposure to the sun. Finally, melanin is also known to act as an oxygen scavenger and may decrease the concentration of mutagenic and carcinogenic reactive oxygen species found in the skin (Nordland *et al*., 1989).

The skin, particularly the epidermis, is capable of metabolizing significant amounts of chemicals. This can have a protective effect in metabolizing potentially harmful xenobiotics to less toxic metabolites, or a detrimental effect by activating less toxic compounds to more toxic metabolites (for example, proximate carcinogens can be metabolized to highly reactive ultimate carcinogens). The metabolic activity of the skin may also produce harmful results by changing an innocuous chemical into a hapten and inducing allergic contact dermatitis. Thus, the metabolizing capability of the skin is important to the pharmacology and toxicology of externally contacted xenobiotics and cannot be discounted in the evaluation of the potential health effects of environmental compounds.

The maintenance of an intact and fully functional skin is essential to survival. Alteration of the skin by any of several mechanisms, induced by physical, biological or chemical means, can have serious implications for the health and wellbeing of the organism.

4 DERMATOLOGICAL EFFECTS OF TOXIC AGENTS

Cutaneous exposure of humans or animals to a xenobiotic substance may result in a toxicological reaction or dermatitis (defined as any pathological process of the skin). Toxic agents can include medicinal compounds, food constituents, environmental agents (natural or synthetic contaminants) and a host of other sources. Exposure can be accidental, suicidal or homicidal (Espinoza and Fenske, 1988). Effects of cutaneous exposure may be apparent immediately or may develop after days, weeks or years, and the severity may vary from mild ‘subjective irritation’ where no gross or histological changes are observed (for example, the burning and stinging experienced following a topical application of astringents) to life-threatening effects (Bruner, 1991). By a wide margin, the most common reactions to agents that contact the skin are inflammatory

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

reactions to irritants, allergens and photosensitizers (Suskind, 1990).

In general, a chemical substance must be absorbed into at least the outermost layers of the skin to produce a reaction and, as discussed above, the skin (especially the stratum corneum) has evolved several protective mechanisms to retard the movement of chemicals. One of the most important mechanisms retarding the movement of chemicals in the skin is the complex mixture of stratum corneum lipids (Bouwstra *et al*., 2001). The most characteristic features of the stratum corneum lipid composition are its heterogeneity, presence of a high proportion of saturated lipids, large amounts of cholesterol and complexity of ceramide chemistry (Rawlings, 2003). Cholesterol modulates the mobility of the lipids and is important to the barrier function of the skin.

In spite of the complexity of the lipids that comprise much of the stratum corneum, the rate and extent of absorption and subsequent skin reaction depend on several externally determined or extrinsic factors and two primary intrinsic factors determined by characteristics of the skin (Dugard, 1983; Bouwstra *et al*., 2001; Fluhr *et al*., 2008). The extrinsic factors are often related to the chemistry of the substance in contact with the skin and include chemical concentration, molecular size, ionization and polarity (which affect lipid solubility), p*K* and pH of the chemical (Wester *et al*., 1985; Berner *et al*., 1988).

Environmental variables are also considered extrinsic factors and can play an important role in the irritation potential of a chemical. For example, low environmental humidity or increased humidity and warmth secondary to occlusion may enhance the irritation potential of a chemical (Rothenborg *et al*., 1977). Other extrinsic properties may be related to the vehicle in which the chemical is dissolved or suspended when it contacts the skin. These factors can include the partition coefficient of the chemical between the stratum corneum and the vehicle, antioxidants and preservatives within the vehicle, the corrosive properties of the vehicle and several other properties of the vehicle that affect the chemical or the skin (Zesch, 1987; Suskind, 1990). New research is shedding additional light onto the important contribution of the vehicle to the effectiveness and irritation potential of topical drugs and cosmetics (Gloor, 2004; Surber and Smith, 2005). Intrinsic factors are related to the properties of the skin and are primarily concerned with a diffusion constant for the chemical and the thickness (number of cell layers) of the stratum corneum. Intrinsic factors can be related to genetic background, age, sex, race, concomitant disease states, neurological factors, dietary state of the individual and medication (Mathias, 1987), as well as the location in the body where the chemical contact occurs.

It is generally recognized that the skin reactivity of children may be higher than in adults (Marcussen, 1963). Conversely, the skin of the elderly is often dry and irritated (itchy) and may be slower to react to an irritant (or the irritation may be less perceptible) than in younger adults. The mechanisms of these age differences are poorly understood, but the decreased water content and altered lipid composition may be important in the decreased reactivity of elderly skin (Elias, 1981). Furthermore, epidermal proliferation tends to be decreased in the elderly resulting in changes to the stratum corneum and overall epidermal thickness.

Clinically, black (African American) skin appears to be less irritable than white skin (Weigand and Gaylor, 1974). However, comparisons between black and white skin irritation based on visual evaluation of skin changes may not be valid because of the difficulty in identifying erythema in black skin. Black skin may contain a thicker (more cell layers) stratum corneum and altered electrical skin resistance as compared with white skin (Lammintausta and Maibach, 1988). Grimes *et al*. (2004) demonstrated differences between black and white skin only for the degree of photodamage and hyperpigmentation, but no differences for all other measures evaluated, including sebum concentration, pH, moisture or transepidermal water loss (barrier function). Thus, differences in irritability may be more perceived than real.

While it has been suggest that women are more susceptible to skin irritation than men (especially to soaps and detergents), this is most likely related to the greater exposure to irritants (both in frequency and quantity) and not to any real difference in skin irritability. However, clinical experience has suggested that women may have an increased susceptibility to skin irritation during the premenstrual period (Lammintausta and Maibach, 1988; Farange *et al*., 2005).

Most skin irritation appears to be due to solids (primarily powders) and liquids that contact the skin. Skin irritation from contact with airborne particles or vapours is possible, but rarely described. This may be due to the fact that irritation from airborne substances may be missed clinically (Lammintausta and Maibach, 1988) except in cases of occupational exposures where this issue is becoming more recognized. Most skin irritation resulting from contact with a liquid or powder is attributed to chemical reactions, but the physical characteristics (including sharp or rough edges) of the particle within a powder or suspension may play an important role in the irritability of the substance. The repeated damage to the outer layers of the skin by such particles can also significantly increase concurrent chemically induced irritation, which can confound the diagnosis and treatment of skin ailments.

While the diagnosis of dermatological reactions and/or toxicity is difficult because of the similar appearances of many types of skin changes, it is most useful for this discussion to classify these effects by their mechanism of action: cutaneous immunologically mediated, or mediated by unknown mechanisms.

Table 1 Selected irritant-induced responses that may be observed

Exfoliation: dandruff-like scales
Excoriations: superficial scratches or cracks on the skin
Fissures: deep cracks in the surface of the skin
Ulcer: open sore
Erythema: reddened skin
Oedema: raised, swollen skin
Eschar: scab formation
Ecchymosis: haemorrhage into the skin or bruising
Necrosis: areas of dead skin

4.1 Irritant Dermatitis

Irritant dermatitis resulting from contact of the skin with chemicals is the most common form of xenobiotic-induced skin irritation. Nevertheless, the exact nature of the injury is not well defined, although research into the biochemistry of normal and irritated skin is demonstrating important differences (Agner and Serup, 1987; Lebwohl and Herrmann, 2005). In general, the concentration of the chemical, circumstances of contact (for example, occlusive conditions and length of time of exposure) and presence of other physically acting agents may be more important than how deeply the offending agent diffuses into the skin (Zesch, 1987). The current status of the stratum corneum and, therefore, the effectiveness of the skin barrier also play an important role (Kampf and Loffler, 2007). Virtually any chemical substance, under the appropriate conditions, can produce cutaneous irritation. In both humans and laboratory animals, erythema (redness) and oedema (swelling) are the most common signs of contact irritation (especially in animals). Vesiculation, scaling and thickening of the epidermis can also be observed (**Table 1** lists a number of irritant-induced clinical responses that may be observed on the skin).

4.2 Chemical Burns

Following contact of the skin with an irritant, a continuum of effects occurs, but two general patterns of reaction can be identified. The first involves the contact of skin with the corrosive agent of sufficient strength (often an acidic or alkaline solution) to cause an active and rapid response (often rapid cell death). In this 'primary irritation', pain, heat and erythema are often observed clinically. Microscopic changes can include varying degrees of tissue destruction, vascular permeability changes (often resulting in oedematous changes) and inflammatory cell infiltration. The extreme of this type of injury is often described as a 'chemical burn' and the exact appearance of the lesion (both on gross and microscopic observation) varies with the offending agent. Eliminating the chemical from contact with the skin is imperative to limiting the amount of tissue damage. This is usually best accomplished by repeatedly washing the affected area with copious amounts of soap and water. However, some xenobiotics may react vigorously with water (for example, calcium oxide), that could result in further tissue damage.

Knowledge of the chemistry of the compounds that may contact the skin is useful to the prevention of serious injury. Specific therapeutic interventions, based on the chemistry of the compounds, are required for many cutaneous irritants. Therefore, it is important for industrial health and safety personnel and medical practitioners, as well as individuals handling these substances to be aware of the potential dangers and recommended treatments in the case of accidental exposure. Every employer in the USA is required by the US Labor Code, Section 6390, to maintain a material safety data sheet (MSDS) for each substance located and used at the work site (Adams, 1990). These documents provide information on the precautions for the use of a substance and recommendations for treatment in case of accidental exposure. Importantly, the MSDS is not a comprehensive reference and substances in mixtures at a concentration of less than 1% are not required to be listed at all. Nevertheless, the MSDS indicates initial emergency procedures and usually lists a telephone number to gain additional information. All employees should be trained on the proper method of retrieving and reading an MSDS in their workplace.

4.3 Cumulative Dermatitis

At the other end of the cutaneous irritation scale is repeated contact with the skin with mildly to moderately irritating substances (often termed marginal irritants). This type of chemical contact often results in slow, insidious changes in the skin that may result in thickening with or without wrinkling and/or changes in pigmentation. Many of the changes observed are the indirect effects of cutaneous inflammation and may not result from direct cellular damage caused by the chemical. Frequent and extensive exposure to a marginal irritant may produce a form of desensitization known as 'hardening' (Rothenborg *et al*., 1977; Lammintausta and Maibach, 1988). This reaction appears to be chemical specific and the biological mechanisms are unclear, but thickening of the skin following repeated chemical exposure may be an important factor. New research has demonstrated differences in the lipid composition of the stratum corneum after experimental induction of hardening revealing a possible biochemical mechanism to this phenomenon (Heinemann *et al*., 2005).

Table 2 Selected microscopic changes that may be observed following exposure to irritants

Herperkeratosis: thickening or overgrowth of the stratum corneum
Parakeratosis: retention of the nuclei in a thickened stratum corneum
Acanthosis: increased thickness of the epidermal layer of the skin
Epidermitis: inflammation, as evidenced by the presence of inflammatory cells, in the epidermis
Dermal oedema: presence of excess intercellular fluid in the skin
Dermatitis: inflammation, as evidenced by the presence of inflammatory cells, in the dermis
Folliculitis: inflammation of the hair follicles
Ulceration: loss of outer layer(s) of the skin, exposing the dermis or subcutaneous tissue
Congestion: swelling of the small blood vessels supplying the skin resulting in decreased blood flow to the affected area
Hydropic degeneration: presence of excess entracellular fluid within the cells of the epidermis
Dermal haemorrhage: presence of blood (fluids and cells) in the extravascular space of the dermis
Dermal fibrosis: abnormal formation of fibrous connective tissue

Microscopic changes that occur following repeated contact of the skin to marginal irritants include thickening of the entire epidermis (hyperplasia) and hyperkeratosis (thickening of the stratum corneum). This type of pathological change may be referred to as cumulative insult dermatitis and the cause may be difficult to elucidate because of the many factors usually involved and the often low acute irritancy of the offending agent(s).

A list of some common microscopic changes that may be observed following exposure to irritants is presented in **Table 2**.

4.4 Characterization of Skin Irritation

The concept of irritation or inflammation has a very long history, mainly because of its close relationship to the perennial human problem of infection. Egyptian scrolls, dated perhaps as early as 2650 BC, have several references to a word indicating inflammation that is associated with wounds (Ryan and Manjo, 1977). It was not until medical advances in the late nineteenth and early twentieth centuries that the separation of the inflammatory response from infections occurred.

The current description of the response of the skin to an irritant has evolved over the past 100 years and continues to change as advances in technology allow further insight into the process. One of the most important concepts, initially grasped in the later 1800s, is that the inflammatory response is a process and not a state.

In 1889, Julius Cohnheim described inflammation as a series of changes to the affected area, including redness, swelling, pain, warmth and altered function. Each of these descriptions was accompanied by a discussion of microscopic changes and causative factors that have been modulated by modern medicine, but not significantly altered. While these descriptions were intended to describe general inflammation, they describe skin inflammation in response to irritation equally well.

Attempts in the past century to further characterize skin irritation have led to greater awareness of the causes of the irritation and specific cutaneous changes following contact with an irritant. It is now clear that the initial changes in the skin can be related to a chemical mediator (for example, histamine, serotonin or the kinins) released into the vasculature in response to chemical contact or direct vascular damage cause by various mechanisms (e.g. a thermal or chemical burn).

Several authors have attempted to characterize the sequence of events following the contact of a chemical irritant with the skin. Steel and Wilhelm (1966; 1970) described skin irritation produced by organic solvents in terms of three phases of the response. These authors considered the first phase of irritant inflammation to be an increased permeability and blood flow to the region between zero and two hours. The increased blood flow and permeability appeared to occur simultaneously. Inflammatory cells generally infiltrated the area within five minutes. The initial erythematous response faded rapidly and vascular permeability slowly returned to normal by 90 minutes. The second phase of irritation occurred between two and 10 hours after exposure and was defined as a return to normal vascular permeability, accompanied by leucocytosis and the return of erythema (increased blood flow to the area). The third phase of the irritant response occurred some time between 10 and 36 hours and consisted of increased vascular permeability.

More recent studies do not support the concept that chemical irritation can be separated into distinct phases (Patrick *et al*., 1985; Agner and Serup, 1987). The irritation of the chemical and the resulting effects on the skin appear to be related to the specific irritant applied. Furthermore, skin irritation appears to be produced by multiple mechanisms resulting in variable patterns of response. Advances in analytical testing and *in vitro* modelling of the skin structure are providing additional information on the baseline changes that occur during and after the appearance of skin irritation. This research continues to provide examples of cellular and molecular changes that occur in response to skin irritation (Fluhr *et al*., 2008; Rawlings, 2003).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat065
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

As indicated earlier, the ability of a compound to provoke irritation is related to the chemical stability, purity, unique chemical properties and current condition of the skin barrier (Mathias, 1987). Several factors, including sunlight, temperature and oxidation (extrinsic factors) may alter the chemical, rendering it more or less irritating. Furthermore, alterations of intrinsic factors within an individual or population may contribute to the apparent irritability of a chemical (Agner and Serup, 1989a). Variations of these factors are especially important with marginal irritants and can partially account for the wide range of reported reactions to certain compounds.

4.5 Skin Sensitization

4.5.1 Definition and Description

Skin sensitization (allergic contact dermatitis) is the result of an elaborate interaction between the complicated pathophysiological mechanisms of Type IV cell-mediated immunity and environmental sensitizers (allergen). Characteristic structural changes in the skin are induced following contact of the skin with an allergen (Schmidt, 1989). While skin changes due to irritant dermatitis are generally produced by a direct interaction of the chemical with the constituents of the skin, allergic dermatitis results when the chemical elicits an immune reaction that, in turn, results in changes in the skin. The diffusion of the compound into the skin is often considered the determining parameter in whether a compound will produce allergic dermatitis (Zesch, 1987), but many factors are at play and the ability of a compound to covalently bind to a carrier protein may be the major determinant of skin sensitization potential (Roberts and Aptula, 2008). In any event, the structure and reactivity of the chemical are as important as the potential for exposure to the skin.

Chemicals that are potential allergens are continually being developed and introduced into the human environment. Therefore, allergic contact dermatitis can be expected to continue to be a dermatological problem, especially in the workplace. Allergens may be simple chemicals (haptens) that must interact with a chemical component of the organism before becoming allergenic or they may be complicated chemicals or biological substances that elicit the allergenic response without chemical modification. Allergic contact dermatitis remains one of the most common occupational diseases that may become debilitating if the causative agent is not identified and exposure controlled (Nethercott and Holness, 1989; Slavin and Ducomb, 1989; Roberts and Aptula, 2008). While the condition is notable because of the extremely low concentration of chemical required to induce a reaction, new research is defining threshold levels for various chemicals with regard to development of allergic contact dermatitis (Arts *et al*., 2006).

Efforts to define the mechanism of T-cell mediated immune response of skin sensitization have been ongoing for nearly a century, with a continuing incomplete understanding of this process (Roberts and Aptula, 2008). Several excellent summaries of current understanding are available (Roberts *et al*., 2007; Rustemeyer *et al*., 2006). The current understanding of the mechanism of skin sensitization was briefly summarized by Roberts and Aptula (2008) as follows:

> *A sensitizing chemical reacts with skin protein in the epidermis so as to make it antigenic. The antigenic protein is processed by Langerhans cells in the epidermis and these Langerhans cells are consequently stimulated to migrate to a lymph node where they present the antigen to naïve T-cells. T-cells with receptors able to specifically recognize the antigen are stimulated to proliferate and circulate throughout the body. Sensitization has now been induced, i.e. the subject is now sensitized. These events take place during the induction stage of a sensitization test, and are collectively referred to as the induction phase or afferent phase.*
>
> *On subsequent exposure to the same sensitizer, or a second sensitizer, or second sensitizer cross-reactive with the first, reaction with protein and processing of the resulting antigenic protein by Langerhans cells again occurs, after which the antigen presented by the Langerhans cells is recognized by the circulating T-cells, triggering a cascade of biochemical and cellular processes that produce the clinical sensitization response. These events take place at the challenge stage of a sensitization test and are collectively referred to as the elicitation phase or efferent phase.*

The period between initial contact with the causative agent and the development of skin sensitivity (the induction period) may be as little as two or three days for strong sensitizers like poison ivy, or as long as several years for a weak sensitizer like chromate. Following a short sensitization period, if sufficient allergen remains from the initial contact, a spontaneous reaction may occur at the site of exposure. This is demonstrated by the occasional presence of an allergic reaction following the first exposure to poison ivy. Once the sensitivity to an allergen has been established, it generally persists for many years. Following the initial development of sensitivity, the time between re-exposure to the causative agent and the occurrence of clinically observable effects is generally between 12 and 48 hours, but may be as short as 4 hours or as long as 72 hours. Thus arises the term 'delayed hypersensitivity' (Slavin and Ducomb, 1989). For reasons that are not entirely clear, but possibly related to particular

intrinsic factors, an individual may be repeatedly exposed to an allergen and not develop sensitivity to the substance for many years, while other individuals develop sensitivity following a single or very short exposure period to the same substance. The time between initial exposure and development of sensitivity is termed the 'refractory period' (Emmett, 1991).

Acute contact dermatitis is characterized by papules and sharply demarcated erythema. Blisters are also frequently produced following the release of cytotoxic compounds by white blood cells attracted to the affected site. Therefore, the vesicle fluid is not antigenic and contact of this fluid with unexposed areas of the skin will not result in additional dermatitis (Slavin and Ducomb, 1989). Oedema may also occur in areas of loose tissue.

Acute (short-term) and chronic (long-term) allergic contact dermatitis are gradations of the same condition. As allergic contact dermatitis increases in duration (usually from repeated exposure to the causative agent), the prevalence of blisters are gradually replaced by the formation of a crust (scaling) and/or lichenification (thickening of the epidermis). Erythema may or may not persist during chronic allergic dermatitis. The key element in the formation of subchronic or chronic allergic dermatitis is recurrent exposure to the causative agent. If the agent can be identified and exposure eliminated, the disease state will resolve. Unfortunately, because of the wide range of potential exposure to antigenic compounds, including metals and metal-containing compounds, cosmetics, deodorants, clothing dyes, food additives, adhesives, oils, plants or animals and their products (lanolin) and fragrances to name just a few, this is often an extremely difficult, if not monumental, task. The success of corticosteroids in treating allergic contact dermatitis has generally eliminated this condition from the list of serious disorders. However, owing to the difficulty of identifying and eliminating allergens, as well as the prevalence of potential allergens, this skin reaction is a potentially serious disease that will continue to be a major cause of cutaneous eruptions (Menne and Nieboer, 1989; Sicherer and Leung, 2008). Furthermore, exposure via the skin to potentially allergenic chemicals has also been suggested as a major route of sensitization for respiratory allergy (Kimber and Cumberbatch, 1992).

4.5.2 Chemistry of Haptens

Haptens are low-molecular-weight environmental chemicals that form covalent bonds with cutaneous carrier proteins or other cellular macromolecules. When this carrier molecule is a normal endogenous entity, as is usually the case, the resulting chemical complexes are no longer identified by the system as 'self'. Therefore, this now foreign molecule is perceived as an intruder (the allergen) and elicits an allergic reaction. Examples of commonly occurring haptens include metals (nickel, cobalt and chromium), quinones, aldehydes and acrylates (Benezra, 1987; DeGroot, 1987).

The majority of haptens that are skin sensitizers have electrophilic properties. Thus, they are able to accept electron pairs from nucleophiles such as amino (NH_2) and thiol (SH) groups found in cutaneous proteins (Benezra, 1987). New useful information is being developed into the chemistry of haptens and use of structure–activity relationships based on the reactivity of the compound and resulting hapten–protein binding (Karlberg *et al*., 2008; Gerberick *et al*., 2008). These efforts are important to the continuing efforts to investigate the molecular basis of allergic contact dermatitis and development of new methods to identify the potential allergenicity of new compounds.

The potential allergenicity of many compounds is dependent on interaction of the compound with other biological processes and is not purely dependent on chemical reactivity. Some potential haptens must be transformed by metabolism or reaction with light before they are able to bind to cutaneous proteins and become allergenic. These compounds constitute a special class of allergic sensitizers and are often termed 'prohaptens'. A unique subgroup of prohaptens that must react with light to become allergenic belong to the class of photoreactive chemicals termed 'photosensitizers' or 'photoallergens' (see below). When photoallergens react with light, they often form free radicals that rapidly react with cutaneous proteins, forming the allergen. Other allergens may contain long, hydrophobic side chains that appear to form hydrophobic bonds within cell membranes. Examples of compounds that are this type of allergen include lanolin and the extremely allergenic pyrocatechols found in the *Rhus* genus of plants that includes poison ivy.

4.6 Light-Induced Cutaneous Toxicity

The most biologically active spectrum of light is found from 290 to 700 nm. This spectrum can be further defined as ultraviolet or UV (290–400 nm) and visible (400–700 nm). The UV spectrum is generally further divided into UV-A (315–400 nm), UV-B (280–315 nm) and UV-C (220–280 nm). UV-C wavelengths do not naturally occur on the surface of the earth, as this spectrum is absorbed in the stratosphere, predominantly by ozone. Generally, the longer the wavelength, the deeper the light penetrates into the skin (Stern, 1986; Kornhauser *et al*., 1991). The wavelengths of light found in the UV-B and UV-A spectra are generally considered the primary source of toxic changes in the skin. The specific wavelengths responsible for a particular biological response are termed the 'action spectrum' for that effect (Kaidbey, 1991). The action spectra for several light-induced cutaneous reactions have been clearly identified.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat065

There are several effects that result from the exposure of the skin to light, whether the light is natural or manmade (thus, the UV light found in tanning booths is no safer than UV light created by the sun). In some cases xenobiotics play a role in these effects, while in others, the interaction of light with the normal components of the skin is responsible. In either case, adverse reactions of the skin to light (UV or visible) is termed photosensitization (Emmett, 1991).

4.6.1 Photosensitization Not Related to Xenobiotics

The exposure of the unprotected skin to UV light (from sunlight or artificial sources) can result in several toxic responses of the skin. These include short-term, generally reversible effects such as sunburn (erythema) and tanning (enhanced pigment darkening) as well as long-term, generally irreversible effects such as premature skin ageing (actinic elastosis) and the development of skin cancer.

Exposure of the skin to UV-B radiation can selectively alter the immunological function of the skin (photoimmunotoxicity) and result in light eruptions with or without the intervention of an exogenous xenobiotic. Polymorphous light eruption is the most common photodermatosis not involving an exogenous xenobiotic, with estimates of incidence as high as 10–20% of the general population in the USA and Europe (Honigsmann, 2008). Skin interaction with light can also alter the immune response to contact allergens and micro-organisms (such as Herpes simplex types I and II). Furthermore, the altered immunological function induced by UV-B light exposure can facilitate the development and growth of skin cancer. Altered immune response related to UV-B light exposure, associated with concurrent chemical exposure, may result in a complex relationship to light and chemicals on the alteration of immune system function (Krutmann and Elmets, 1988; Marrot and Meunier, 2008).

4.6.2 Photosensitization Related to Xenobiotic Exposure

Xenobiotics localized within the skin can interact with light (generally UV-A but, perhaps, visible as well) and produce adverse reactions in the skin in many ways (Stein and Scheinfeld, 2007). These include phototoxicity, photoallergy, depigmentation, induction of endogenous photosensitizers and induction of photosensitivity disease states (Emmett, 1979). Of these, the most frequently observed are phototoxicity and photoallergy (Emmett, 1991) with phototoxicity being more prevalent than photoallergy (Stein and Scheinfeld, 2007).

4.6.2.1 Phototoxicity

Phototoxicity is defined as a nonimmunological, light-induced dermatitis to a photoactive chemical (Marzulli and Maibach, 1991a). The skin response to phototoxicity is likened to an exaggerated sunburn. After local absorption or distribution to the skin following systemic absorption from distant sites, the chemical reacts with light and the resulting light-altered compound produces skin irritation. It is possible that many phototoxic reactions are caused by the production of free radicals that can cause lipid peroxidation and localized inflammation (Hayes, 1989). As with any chemical irritant, erythema, oedema and desquamation may occur with or without hyperpigmentation. The affected area of the skin is generally limited to areas exposed to light (i.e. areas not covered by clothing). The severity of phototoxic reactions is usually dose-related. Furthermore, phototoxic reactions can be elicited in most individuals who are exposed to an adequate amount of the compound and the appropriate action spectrum. A list of phototoxic agents is presented in **Table 3**.

Table 3 Selected phototoxic agents

Tetracyclines and sulfonamides (antibiotics)
Furosemide and chlorothyazide (diuretics)
Chlorpromazine (antipsychotic agent)
Anthracene (constituent of many dyes)
Porphyrins (animal and plant respiratory pigments)
Psoralens (photochemotherapy agents for psoriasis)
Cadmium sulfide (colorant in tattoos)
Bergamot oil (essential oil)
Certain dyes
Coal tar
Fragrance ingredients (perfumes)

4.6.3 Photoallergy

Photoallergy is similar to allergic contact dermatitis with the exception that the xenobiotics must react with light prior to becoming allergenic. The role of light in the production of a photoallergen is most likely to be one of two types of reactions. The absorption of light by the chemical may, in itself, produce a potent allergen. Conversely, the absorption of light by the chemical may produce a reactive intermediate (hapten) that combines with cellular constituents resulting in an altered cellular component that is an allergen (Emmett, 1991). Clinically, photoallergy generally presents as dermatitis on light-exposed areas that often spreads to areas not exposed to light (i.e. photoallergy may occur in areas covered by clothing). The severity of the photoallergic reaction may not appear to be dose-related (the skin reactions may be very severe with relatively low exposure) and the reaction does not necessarily develop in all individuals exposed to the offending agent and appropriate action spectrum. A list of potential photoallergenic agents is presented in **Table 4**.

Table 4 Selected potentially photoallergic agents

Sulfonamides (antibiotics)
Phenothiazines (antipsychotic agents)
Coumarins (anticoagulants)
Anilides (components in medicines and dyes)
Fragrance ingredients (perfumes)

4.7 Cutaneous Carcinogenesis

Skin cancer is the most common form of cancer in humans and is becoming an increasingly important public health issue (Rigel, 2008). The principal cause of skin cancer in humans is UV radiation (Suskind, 1990). There are three primary types of skin cancer: carcinomas of the epidermal-basal and squamous cells, sarcomas of the mesodermal elements, and melanomas. Squamous cell carcinomas are most often associated with chronic exposure to UV light, and causation of nonmelanoma skin cancer with exposure to UV radiation, whether natural or artificial, has been well established (Hogan and Lane, 1986; Rass and Reichrath, 2008). The relationship between melanoma and UV radiation is less clearly defined (Berwick *et al*., 2008; Moan *et al*., 2008).

The production of chemicals that may cause skin cancer has been known for more than 200 years (Potter, 1963), and it is apparent that several chemicals modulate the carcinogenic effects of UV light (Emmett, 1973). Additionally, a past history of trauma or frostbite to the light-exposed area may also play a role in the development of skin cancer (Hogan and Lane, 1986; Rustin *et al*., 1984). Prevention and early detection are the foundations of skin cancer treatment. Chemical carcinogenesis is covered in other areas of this book and will not be addressed in detail here.

4.8 Acne-Like Eruptions

Acne is a well known effect of several cutaneous toxins (Espinoza and Fenske, 1988). Testosterone, chlorinated compounds and topical steroids are known to produce eruptions in humans similar to acne vulgaris. Although the potential of cosmetics to cause acne may be somewhat exaggerated (Jackson, 1991), a skin lesion termed 'acne cosmetica' has been described for acne-like eruptions caused by cosmetics. Like acne vulgaris, these reactions are initiated by the proliferation of the epithelium of the sebaceous gland and formation of keratin cyst resulting in that development of the pustule filled with fatty compounds and other products of sebaceous origin.

4.9 Atopic Dermatitis

Atopic dermatitis is a chronic dermatitis characterized by intense itching and excessive skin dryness that predisposes the patient to bacterial and viral infections (Wollenberg and Klein, 2007). Recent interest in this relapsing skin disease has been sparked by reports of its increasing prevalence and contribution to increasing health care costs. Various studies reveal that atopic dermatitis has a cause of multiple origins with the activation of complex immunologic and inflammatory pathways (Ou and Huang, 2007). Other studies suggest a complex interaction between the environment, chemical irritants, genetics and the autonomic nervous system (Cicek *et al*., 2008). Changes in the autonomic nervous system may result in decreased activity of the sweat glands contributing to the hallmark dry skin of atopic dermatitis. In any event, this increasingly common and recurring condition demands significant attention by the affected individuals, as well as the entire medical community. Further research into the potential for chemical irritants to contribute to the development or severity of this disease is required.

4.10 Chloracne

The skin reaction termed 'chloracne' may be one of the most sensitive measures of exposure to specific toxins known (Tindall, 1985; Poland and Glover, 1977; Pelclova *et al*., 2006). Chloracne, with accompanying, specific epidermal changes, is the most characteristic and frequently observed lesion resulting from primate, including human, exposure to the halogenated aromatic hydrocarbon class of toxins (Crow, 1970; Taylor, 1974). Owing to the specific cause of the lesion, chloracne is rarely observed in clinical practice (Zugerman, 1990) although the assumed dioxin intoxication of the Ukraine president, Victor Yushchenko, in 2004 garnered considerable media attention and public interest in this form of skin lesion (Pape and Stahlmann, 2007). In humans, this 'hallmark' of chlorinated hydrocarbon exposure is characterized by prominent, dense, large blackheads (comedones), abscesses and skin-coloured cystic lesions (Taylor, 1979). Almost every follicle in the affected area may be involved. The skin of the face, frequently areas near the eyes and behind ears, is usually involved first. Severe chloracne may involve the trunk, arms, legs, face, neck and back, is frequently refractory to treatment and scarring may be severe. Chloracne may appear as early as one to three weeks after the first exposure or may not manifest itself for several months. Mild cases clear up spontaneously within a few months, while severe cases persist for as long as 30 years (Scientific Review Committee of the American Academy of Clinical Toxicology, 1985). The lesion is so specific that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

if there is not medical history of chloracne, the likelihood of significant exposure or adverse health effects from halogenated aromatic hydrocarbons, specifically 2,3,7,8-tetraclorodibenzo-*p*-dioxin (TCDD), is considered remote (Council on Scientific Affairs, 1982).

5 EVALUATING CHEMICALS FOR POTENTIAL ADVERSE EFFECTS ON SKIN

It is essential that the toxicologist, healthcare professional and industrial hygienist understand the importance of the 'prior-to-use safety assessment' as the cornerstone of control of cutaneous hazards. This necessitates the evaluation of initial acute toxicity screening in animals followed by a tier of tests for safety dictated by the potential for and conditions of human exposure to the chemical. The tier assessment includes single and repeated exposure of laboratory animals and human subjects. Therefore, a discussion of the techniques of such safety assessment follows. While preclinical testing (*in vivo* or *in vitro* alternatives to animals) should always be conducted with new chemicals or new mixtures of chemicals before human exposure, human testing will be discussed first.

5.1 Human Testing

The diagnostic or predictive tool used most often for irritant or allergic contact dermatitis is patch testing (Slavin and Ducomb, 1989; Marzulli and Maibach, 1991b; Agin *et al*., 2008). The test is always performed on normal skin that is free of injury or disease. In predictive testing with untested chemicals, it is best to start with diluted solutions of the chemical and utilize an unoccluded test site. The first application should be limited to 30 minutes or one hour to minimize the risk to the subjects (Patrick and Maibach, 1991). As with most *in vivo* cutaneous techniques, comparison of the results between tests is extremely difficult because of the subjective nature of evaluating cutaneous irritation, the effect of environmental and genetic differences between individuals and groups, the effect of the specific vehicle, the application technique and the exposure period. Human studies with untested chemicals should always be conducted and monitored by medical personnel with ample experience in the appropriate discipline and informed consent must be obtained under these circumstances.

Irritant or sensitization patch testing is done for many reasons either in a clinical setting or in a laboratory setting. Diagnostic patch testing is done in the clinical setting to help identify pre-existing chemical sensitivities in a person with recurrent signs of skin irritation, thereby helping the affected individual avoid the offending agent in the future. Predictive patch testing is done in the laboratory setting with human volunteers to help prospectively identify skin irritants and sensitizers. In both cases, the general methods of applying patches, attention to detail and the importance of using well-trained technicians to observe and interpret the results are similar (Mowad, 2006).

Patch-testing procedures have the potential to produce adverse effects. For example, irritant patch tests causing serious irritation may rarely result in scarring or permanently altered pigmentation of the site. Rarely, the patch-testing procedure alone may be the cause of sensitization to a chemical. This has the potential to alter the lifestyle of the participants for the rest of their lives. Therefore, the necessity of diagnostic or predictive patch testing must be carefully evaluated before studies are initiated.

5.1.1 Sensitization Patch Testing

Whether for predictive or for diagnostic purposes, for patch testing to be a reasonably reliable tool in the identification of contact allergens, meticulous attention to detail must be maintained. The method involves the application of a small amount of one or several suspected allergens in relevant concentrations and in appropriate vehicles. The occurrence of the disease is then documented, in miniature, at the site of application. A standardized procedure for diagnostic patch testing was developed in Scandinavia and has been widely used in diagnosing contact allergies (Hjorth, 1991). Generally, a single application is sufficient for diagnosis of an allergic contact dermatitis. However, in predictive tests as part of pre-exposure testing, several occlusive patches are applied for one or two days as an induction to sensitization, followed by an approximate two week rest period and then challenge with a patch at a different skin site (Marzulli and Maibach, 1973). There are several alterations to these basic procedures for predictive tests in humans (Marzulli and Maibach, 1991b).

The most common site for diagnostic patch testing is the back, but the lateral or inner side of the upper arm, the thighs or the legs may also be used (Hjorth, 1991). A small aluminum cup fixed to a strip of tape (the Finn chamber) is a patch type used frequently throughout the world (Adams, 1990). A patch composed of a cellulose allergen-bearing disc attached to a polyethylene-coated aluminum paper backing is also often used (Slavin and Ducomb, 1989). Using these patches, 50–55 diagnostic tests can be performed on the back of the patient at the same time. For proper diagnostic evaluation, the chemical-treated patches must remain on the skin for at least 24 hours, but often are left on the skin for 48–96 hours owing to the latency of many skin reactions.

Following the exposure period, the patch is removed and 20–30 minutes allowed to elapse prior to the evaluation of the sites to allow nonspecific, mechanical irritation

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat065
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to subside. A positive reaction can include erythema, oedema, itching and, perhaps, vesicles at the application site. Local reactions that are irritant in nature will subside after several hours while a true allergic reaction will persist for several days (Slavin and Ducomb, 1989). The test sites should also be evaluated 7–10 days after patch removal as some reactions do not occur for 96 hours to a week after exposure.

Both false-positive and false-negative reactions occur, as several factors can influence the result. These include both intrinsic and extrinsic factors. For example, chemical concentration, current treatment with anti-inflammatory medications, UV light exposure, reaction to the adhesive tape used in the patch and hyperexcited skin states can alter the results of a diagnostic or predictive patch test (Oxholm and Maibach, 1990). The clinician or researcher can minimize these errors in diagnosis through appropriate training and qualification of technicians and use of follow-up testing for questionable results (Orton and Wilkinson, 2004). Furthermore, new techniques to aid the clinician or researcher to improve the diagnostic or predictive nature of the sensitization patch test are being developed. These include incorporation of biomarkers such as cytokine or IgE responses to the test protocols (Sicherer and Leung, 2008).

Because diagnostic patch testing is done primarily in patients with known chemical sensitivities, results of diagnostic testing do not necessarily represent the incidence of allergy in the general population (Agin *et al*., 2008). Thus, the potential of a chemical to induce sensitization in the general population should be based on an overall assessment of predictive patch testing combined with the incidence of positive findings observed in diagnostic patch testing.

Photopatch testing involves similar techniques to patch testing except that the treated site is exposed to a source of UV light following the application of the test substance.

5.1.2 Irritant Patch Testing

The potential of a chemical to produce cutaneous irritation is difficult to evaluate because all chemicals are irritating under some conditions. Indeed, merely increasing the water content of the skin by occlusion with impermeable tape often results in mild to moderate irritation (Olson, 1991). The changes in the skin resulting from the application of a mild irritant may be difficult to detect on gross examination, but they may result in significant alteration in function. The continually increasing focus on cleanliness in the home and workplace resulting in increased exposure to irritants such as water, detergents and alcohol-based solutions (Pedersen *et al*., 2005) has the potential to alter the prevalence of skin irritation in the general population. All of these exposures have the potential to influence the overall health of the skin and potential for irritation and new products must be evaluated for the potential to produce skin irritation prior to being marketed. The irritant patch test procedure is the most frequently used method to evaluate the irritant potential of new chemicals and products.

Original study designs for irritant patch testing in humans recommended the use of application periods of up to 48 hours (Kooyman and Snyder, 1942; Draize *et al*., 1944; Justice *et al*., 1961; Rostenberg, 1961). Currently accepted study designs have shorter exposure times and a four hour application period has been adopted by the National Academy of Sciences (1977). Patches, bandages or chambers are utilized to apply the test substance to the skin. Increasing the degree of occlusion will generally increase the severity of irritation and the use of highly occlusive tape to hold the patch in place can significantly affect the results of a study. Accordingly, the area of chemical exposure should be clearly marked to differentiate irritation or skin damage produced by the tape from that produced by the test chemical.

While it may be sufficient to predict the irritant potential of some compounds of limited human exposure, utilizing a single exposure study design, compounds proposed for consumer use are often tested utilizing cumulative (repeated exposure) irritation assays. Some chemicals that are nonirritating following a single contact with the skin may be highly irritating following repeated contact with the skin, especially in areas of friction or repeated motion such as the interior surface of the elbow or behind the knee. A consumer product that has been reported to be irritating can be separated into individual ingredients and the irritating component identified by the use of cumulative patch testing. The study design for these assays, including length of exposure period and number of treatments, varies between investigators (Patrick and Maibach, 1991). The specific study design (duration of contact, concentration of chemical, location of exposure, etc.) used in cumulative patch testing is often customized to the expected exposure pattern or suspected irritability and toxicity of the chemical.

Several modifications of patch testing have been developed for specific applications. The scarification test, in which the epidermis is abraded using the bevel of a needle, was developed to evaluate the irritability of compounds that may be applied to damaged skin (Patrick and Maibach, 1991). The soap chamber test was developed to compare the potential for soaps to produce drying and flaking, which are effects normally produced using conventional patch testing methodology (Frosch and Kligman, 1979). Flex washing tests or elbow crease washing tests do not involve the use of a patch and have been used by some investigators primarily for evaluating the irritation produced by soaps and detergents. The behind the knee test has been used and shown to be a reliable alternative to irritant patch and in-use clinical testing (Farage, 2006). These tests have been used as a replacement for the arm immersion test originally

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat065
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

proposed by Kooyman and Snyder (1942). Many other variations of the irritant testing have been utilized for miscellaneous purposes and, undoubtedly, more will be developed in the future.

Patch tests often over- or underestimate the irritant potential of the chemical. This is as a result of a wide variability in the susceptibility of individuals to develop irritation (intrinsic factors) as well as the multitude of possible exposure conditions, especially with a consumer product (extrinsic factors). Thus, the selection of subjects for testing and conditions of exposure must be controlled and carefully evaluated when assessing the results of irritant patch testing. Finally, it is important to confirm the acceptability of new topical therapies through in-use clinical testing of the product under the conditions of intended use in the marketplace. In-use studies involve distribution of the proposed product to a group of people representing the likely population of end-users and evaluating their skin and overall wellbeing before, during and after the use of the product as directed. These studies provide the most accurate information regarding the likely skin irritant effects of the product when used by the population at large.

5.1.3 Evaluation of Patch Test Results

Patch tests are generally evaluated visually by assigning grades of irritation to the occluded area. The clinician focuses on the centre of the patch for purposes of reproducible and accurate grading. The grades, based primarily on erythema, generally consist of a 0 for no response and a 1–4 or 5 for increasingly inflamed sites. This scale does not include vesicular, bullous or eschar formation. Therefore, more detailed grading systems with up to 16 possible grades have been proposed (Patrick and Maibach, 1991). Assigning too many descriptors of the test site can lead to confusion and reduce the ability of the test to clearly identify irritants of clinical and biological significance. Thus, efforts intended to increase the power of a simple patch test may actually reduce the overall ability of the test to identify irritants important to the clinician. These efforts are discouraged and should be carefully considered before implementation.

Several other mechanisms of evaluating the results of patch testing have been developed. These are briefly discussed below.

5.2 Animal Testing

When animals are used as models for human exposure to chemicals, the differences and similarities between species are important factors to consider. While the relationship of animal dose–response data to human toxicity is not always clear, an understanding of the potential of toxicity is essential to the development of human exposure guidelines. An important objective is to establish a relationship between animal data and epidemiological findings. This task is extremely difficult because of the poor availability of reliable data on the toxicity and irritability of most chemicals in humans. When both animal data and epidemiological findings exist for a chemical, the correlation of the information can aid in the assessment of laboratory data as it relates to humans.

5.2.1 Sensitization Testing in Animals

Historically, the most widely accepted animal model for predictive sensitization studies has been the guinea pig (Middleton, 1978). Tests using guinea pigs are now being widely replaced by the mouse local lymph node assay (LLNA) (discussed below). Because the toxicologist will be called upon to review data generated in older guinea-pig tests, this chapter will include general descriptions and principles of the tests for reference. There are varied guinea-pig methods used to evaluate the sensitization potential of a chemical, but most have not been used in many years. Only those tests the toxicologist is most likely to encounter will be further discussed.

To assess the potential sensitization properties of a chemical, guinea pigs are treated with an initial dose or several doses of the chemical (the induction phase) by intradermal and/or cutaneous application. Following a sensitization or incubation phase with no chemical treatment of approximately two weeks, the animals are treated with a second dose or series of doses of the same test chemical (the challenge phase). The chemical concentration and application site are often different between the induction and challenge phases. Sensitization is evaluated by examining the skin reaction following the challenge phase compared with any skin reaction immediately following the induction phase. The difference in the reaction between the two applications accounts for nonspecific skin irritation caused by the chemical. The relevance of the results of the tests to human exposure must be evaluated based on the severity and repeatability of the biological properties of the reaction. Often the number of animals that respond is a more important indicator of the sensitizing potential of a chemical than the severity of individual reactions. Practical experience is the best guide in this endeavour, as laboratory experiments may be conducted under extreme or unrealistic conditions. A fundamental understanding of the test procedures, along with the potential for false-positive and false-negative findings is also required for toxicologists to appropriately understand these tests.

Draize *et al.* (1944) were the first to describe standardized irritation and sensitization tests and several iterations to their original method were proposed. These early tests had several drawbacks, including a high incidence of false negatives with weak sensitizers (Marzulli

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat065
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and Maguire, 1982). Furthermore, the tests recommended consistent induction methods without regard to the use pattern or exposure potential of the chemical (Klecak, 1991).

The Buehler test was designed to reproduce a human patch test in animals and, therefore, allows variation of conditions to optimize the detection of moderate to strong sensitizers prior to testing in humans. This test utilizes induction and challenge phases of occluded epidermal doses of the test substance, which may be an allergenic chemical or a final product formulation. The results of this test can be very difficult to read and interpret, especially when low concentrations of test chemicals are used. This is primarily because of the high incidence of inflammatory reactions in both control and treated animals. This test may result in false-negative results, but these problems may be related to poor study conduct and may not be attributable to the design of the test (Robinson *et al*., 1989; 1990). Performed correctly, the Buehler test is relatively expensive, but is considered adequate to detect weak sensitizers (Botham *et al*., 1991).

While the Buehler test only applies the test article to the intact surface of the animals, many tests use a combination of injections and topical application of the test article as well as chemical means to increase the immunological response of the test animals. Freund's complete adjuvant (FCA; a mixture of heat-killed *Mycrobacterium tuberculosis*, paraffin oil and mannide monooleate) has been used to increase the immunological response of the guinea pig in a variety of tests. Most of these test methods are rarely used today, with the notable exception of the maximization assay discussed below. The use of FCA is intended to aid in the detection of weak sensitizers and is injected intradermally at different sites during the induction phase (Henningsen, 1991). Criticism of the methods employing FCA abound, including the open wounds produced at the site of injection as well as intradermal injection of the test article thereby bypassing the effect of the stratum corneum to limit the absorption of potential sensitizers. Thus, the use of FCA may cause the sensitizing potential of the test chemical to be overestimated.

The guinea-pig maximization test is the most widely used guinea-pig test in Europe and is generally considered to be very sensitive (Botham *et al*., 1991). As noted above, this test is being rapidly replaced by the LLNA (see below). The induction phase of the guinea-pig maximization test employs the simultaneous injection of FCA alone, test material in saline and test material in FCA into three different locations in close proximity to each other. This is followed seven days later by epicutaneous application of the test substance on a filter paper. The filter paper is occluded and held in place with tape and an adhesive bandage. The filter paper and bandaging are then left in place for 48 hours. The challenge phase, conducted with the test substance applied epicutaneously for 24 hours, is performed two weeks after the epidermal induction phase. The maximization test is considered to have good predictive value in humans, but does not lend itself well to use with final product formulations (Klecak, 1991). The maximization test may result in false-positive results. Indeed, the original classification scheme for the test did not allow for a test substance to be classified as a nonsensitizer; the lowest rating (0) corresponded to a weak sensitizer (Botham *et al*., 1991).

5.2.1.1 Local Lymph Node Assay (LLNA)

While guinea pigs remained the industry standard for evaluation of the sensitization potential of a compound for decades, the mouse has been studied extensively as a model for delayed-type hypersensitivity (Nakano and Nakano, 1978; Tanaka, 1980; Johnson *et al*., 1984). In 1968, the technique of measuring the swelling of the mouse ear as an indicator of delayed-contact hypersensitivity was developed (Asherson and Ptak, 1968). This mouse ear assay was further developed into a quantitative method in which cellular proliferation of draining lymph nodes was identified as an end point of sensitization.

The LLNA is a quantitative test developed using this end point and is based upon the biology of sensitization. This test is considered by many authors and regulatory agencies to be an acceptable alternative animal model to the guinea-pig tests in predicting the sensitization potential of chemicals in humans (Kimber *et al*., 2002). The LLNA is an *in vivo* method and, therefore, does not eliminate the use of animals. However, the LLNA provides certain advantages with regard to both scientific progress and animal welfare. Most importantly, the test studies the induction phase of skin sensitization and provides quantitative data suitable for dose–response assessment. There have been some questions raised regarding the potential for the test to produce false positives, especially when the test article is a skin irritant. Thus, it is important to carefully evaluate test results.

The basic principle underlying the LLNA is that sensitizers induce a primary proliferation of lymphocytes in the lymph node draining the site of chemical application (Gerberick *et al*., 2007). This proliferation is expected to be proportional to the dose applied combined with the potency of the allergen. The study design involves application of either 25 µL of the test article, or the positive or negative control to the dorsal surface of each ear on three consecutive days, followed by two days of rest (no treatments). On the sixth day of the study, the animals are injected with 20 µCi of ^{3}H-methyl thymidine or another suitable indicator of cell division and the animals are euthanized exactly five hours later. The auricular lymph nodes for each ear are removed and the degree of cell proliferation is analysed. A greater degree of cell proliferation in the local lymph nodes is considered an indicator of a greater degree of sensitization potential of the test article. Extensive international efforts have demonstrated consistency and repeatability of this assay to the degree

that this assay is now generally accepted as a validated alternative to the guinea-pig models (Basketter *et al*., 2002).

5.3 Irritation Testing in Animals

It is generally recognized that human skin and the skin of other animals are different and do not always react to chemicals in the same manner. Overall, the skin of laboratory animals is more easily irritated than the skin of humans, although this is not always the case (Phillips *et al*., 1972; Olson, 1991). Animal testing will reliably detect moderate to strong irritants but the degree of irritation often correlates poorly with the degree of skin response in humans. Therefore, comprehensive experimental protocols are required to establish the degree of risk to humans. Comprehensive animal testing can also aid in the identification of adequate labelling of chemical containers and suggest appropriate protective clothing for use in the workplace. Irritation testing in animals (especially acute, single-dose studies) is rapidly being replaced by *in vitro* techniques (discussed below). Animal studies to evaluate skin irritation continue to be most appropriate in some circumstances and will continue to be of historical importance and, therefore, are discussed below.

A low acute oral or inhaled toxicity may indicate that extensive cutaneous testing is not required, as the skin is generally a more effective barrier to absorption than the intestinal tract or lungs. This generalization is not always true and the degree of human exposure and chemistry of the compound must be carefully considered when making testing decisions. For obvious reasons, the evaluation of the compound for irritability in animals does not need to be performed with strongly alkaline or acidic substances. Severe skin irritation can be presumed with these compounds and specific precautionary measures recommended without the results of animal testing. Only limited irritation testing may need to be performed when the substance will not come into direct and close contact with the skin (Gelbke, 1987).

5.3.1 Selection of Animal Species

Selection of the proper species and strain of animals for use in a toxicology study of any design is very important to the usefulness (predictive value) of the results (Rao and Huff, 1990). The albino rabbit remains the species of choice in acute and repeated applications irritation testing. Several authors (Davies *et al*., 1972; Motoyoshi *et al*., 1979; McCreesh and Steinberg, 1991) have addressed the use of other species including guinea pigs, hairless mice, albino rats and miniature swine in cutaneous irritation testing. Considerable interspecies variability has been identified. The skin of rabbits is generally identified as the most sensitive of the species tested, while human skin is one of the least sensitive. The reactivity of the skin of the albino rat is considered to be similar to the reactivity of human skin. Thus, the albino rat is often utilized in repeated cutaneous toxicity studies.

5.3.2 Single Application Irritation Testing (Draize Test)

The test described by Draize *et al*. (1944), or slight modifications of this test, is the most widely used test for predicting the potential skin irritation of chemicals and chemical mixtures. The authors divided the various elements of irritation into distinct categories for grading (**Table 5**). In this test, the hair is clipped from the back of a rabbit and four distinct areas for the application of test substances are identified. Two of the four areas are abraded by making four epidermal incisions in the appropriate areas. All four areas are covered with gauze that is held in place with adhesive tape and the test substance is applied to the appropriate area under the gauze. The entire trunk of the rabbit is wrapped in impervious cloth or plastic to hold the patches in place

Table 5 Evaluation of skin reactions as described by Draize *et al*. (1944)

Erythema and eschar formation	
Very slight erythema (barely perceptible)	1
Well-defined erythema	2
Moderate to severe erythema	3
Severe erythema (beet redness) to slight eschar formation	4
Total possible erythema score	4
Oedema formation	
Very slight oedema (barely perceptible)	1
Slight oedema (edges of area well defined by definite raising)	2
Moderate oedema (area raised approximately 1 mm)	3
Severe oedema (raised 1 mm and extending beyond area of exposure)	4
Total possible oedema score	4
Total possible score for primary irritation	8

DOI: 10.1002/9780470744307.gat065
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and decrease the evaporation of volatile test substances. The rabbits generally remain wrapped for 24 hours after treatment and are evaluated for irritation at the time of unwrapping, and at 24 and 48 hours after being unwrapped. Generally, four test substances are evaluated in a series of six rabbits.

The Draize test for dermal irritation has been criticized for various reasons. The original purpose of the test was to identify substances that would not be irritating to human skin and was primarily designed to eliminate false negatives. While the occurrence of false positives is undesirable in the development of new consumer products, they are infinitely preferable to the occurrence of false negatives that could lead to disastrous results when an undetected irritant is added to consumer products. Several aspects of the standardized Draize test, including the abrasion of the skin and time of exposure, are disputed. This has resulted in several modifications to the method. As with the evaluation of patch testing in humans, the subjective nature of the evaluation of the treatment areas results in significant variations between laboratories, as well as between technicians (Weil and Scala, 1971). This impedes the comparison of results between laboratories and makes the job of the risk assessor more difficult. This variability of the results of test patching in animals as well as humans has hindered the identification of alternative methods, although these issues are being overcome.

5.3.3 Repetitive Application Irritation Testing

The use of repeated cutaneous applications over at least 7–14 days appears to be better able to predict the irritability of a test substance than a single application. This is especially true if the material is designated for use in a consumer product and will remain in contact with the skin for extended periods or if there will be repeated applications of the material. Additionally, the repeated application test to assess irritability can be combined with an assessment for systemic toxicity by the cutaneous route. In this case, three or more groups of 5–10 animals per sex (generally albino rats or rabbits) are used, with each group receiving a different dose of the test substance daily for two, three, four or 13 weeks (weekend doses may be omitted). An additional group of animals is handled similarly, but treated with the vehicle or, when no vehicle is used, with water to serve as a control group. The fur is removed from the back of the animals with a veterinary clipper and the test chemical is applied directly to the back. The animal is then wrapped with an occlusive dressing and returned to its home cage for a period of six hours. The wrapping is removed and the back gently wiped with a damp or dry cloth. The animals are observed daily for signs of cutaneous irritation (**Table 1**) and graded for the presence of erythema and oedema (**Table 5**). At termination of the study, both treated and untreated skin is collected and evaluated microscopically for signs of irritation. A list of common microscopic changes that may be observed following the application of irritating test substances is presented in **Table 2**.

Table 6 Clinical pathology measurements that may be affected by cutaneous irritation

Decreased values
Haemoglobin concentration
Haematocrit
Erythrocyte count
Serum calcium concentration
Serum inorganic phosphorus concentration
Serum creatinine concentration
Increased values
Total leucocyte count
Neutrophil count
Platelet count (rabbit only)
Serum globulin concentration (rabbit only)
Serum glucose concentration (rat only)
Values that are variably affected
Mean corpuscular volume (MCV)
Mean corpuscular haemoglobin (MCH)
Total serum protein concentration
Serum albumin concentration

An evaluation of repetitive application studies using mild to severe irritants indicates that several haematology and clinical-chemistry parameters may be affected by chemically induced skin irritation (Weaver *et al*., 1990; 1991; 1992; Hermansky *et al*., 1995). These changes, summarized in **Table 6**, do not appear to be related to systemic toxicity of the chemical, but correlate well with the degree of cutaneous irritation. The relationship of these parameters to cutaneous irritation is not clear, but may be related to the vascular and fluid balance alterations that may occur following cutaneous irritation. Regardless of the cause of these changes, their consistent occurrence emphasizes the relationship of the skin to the overall health of the organism. It is also essential that the risk assessor be aware of these irritation-induced changes when evaluating the findings of repeated cutaneous application studies.

6 METHODS OF EVALUATING *IN VIVO* IRRITATION RESULTS

As discussed above, the interpretation of both human and animal cutaneous testing relies heavily on visual scoring of areas of the skin treated with the test substance. The subjectiveness of visually graded results in human

patch testing and acute and repeated exposure studies in animals makes it very difficult to compare tests graded by different individuals and laboratories. This confounding experimental variable has led to complications for the toxicologist and risk assessor in evaluating the potential human hazard of cutaneous exposure to chemicals.

Therefore, methods other than visual scoring or grading of skin inflammation have been developed to aid in the interpretation of patch testing in dark-skinned humans, as well as in an attempt to decrease the subjective nature of visually grading skin irritation in all tests. Blood flow to the skin must generally increase three-fold or greater to be detected visually and reactions produced by mild or moderate irritants or weak sensitizers may not be detected by visual evaluation alone. Finally, the importance of differentiating an allergic reaction from an irritant reaction, especially in human diagnostic patch testing, cannot be overstated and methods of greater sensitivity than visual grading may increase the ability to differentiate these reactions.

Several methods developed for the evaluation of patch testing results have been examined in considerable detail. Contact thermography is the imaging of the temperature of the area of the skin where an irritant has been applied (Ring, 1986). The methodology is based on the premise that the greater the degree of irritation, the higher the relative temperature of the affected skin (that is, irritation and inflammation are fundamentally related). However, contact thermography has shown that different irritants produce lesions of different temperatures in humans. For example, croton oil produces a warm lesion while sodium lauryl sulfate results in the formation of a cold lesion (Agner and Serup, 1988). Because changes in the temperature of the affected skin are now considered a useful method for quantifying the degree of irritation, use of infrared thermography has shown promise in the differentiation of allergic and irritant responses, but more research is needed (Baillie *et al*., 1990).

Another method of evaluation of skin inflammation caused by irritant or allergic dermatitis is laser Doppler flowmetry or velocimetry (Staberg *et al*., 1984). The instrument is equipped with a hand-held probe that emits a laser light onto the skin and measures blood flow through the area. This technique is generally considered more sensitive than visual scoring in detecting erythema in humans (Wahlberg and Wahlberg, 1984). However, the technique often produces poor correlation with visual scoring. This is based partially on the dependence of visual scoring on parameters other than blood flow (i.e. blistering), as well as the fact that mild irritants often produce low increase in blood flow (Gawkrodger *et al*., 1991).

Transepidermal water-vapour loss, measured with an evaporimeter (Lammintausta *et al*., 1987), has also been used to evaluate patch tests. The technique, which evaluates the function of the stratum corneum as a barrier to water loss, is generally more sensitive to irritant dermatitis (indicating epidermal damage) than to allergic dermatitis. The technique has, therefore, been evaluated in humans as a method of differentiating irritant and allergic dermatitis. However, the variable severity of the allergic reaction does not allow this test to differentiate between allergic and irritant responses in all cases (Agner and Serup, 1989b).

Another technique that has been used in the evaluation of skin irritation is the erythema index, which quantifies the inflammatory response by comparing the reflection of red and green light from the skin (Diffey *et al*., 1984). Skin thickness measurements have also been used to evaluate oedematous reactions (Olson, 1991). Based on the observations that repeated exposure to irritants often results in an increased roughness and brittleness of the skin, measurements of physical changes to the cells of the stratum corneum following exposure to irritants have been evaluated (Olson, 1991). The loose, outer layer of cells of the stratum corneum are obtained from humans by noninvasive techniques (washing the site) and the cells are evaluated for shape, size and morphology under a light microscope. Because of the greater availability of intact skin samples, this technique appears to have more promise in animal testing.

To the risk assessor, a quantitative, objective measure of cutaneous inflammation remains a highly desirable goal. Alternative methods for evaluating inflammation in animals include many of the same methods used for evaluating the results of irritation patch testing in humans. However, owing to several factors, including thick and variable patterns of fur growth in most species (especially rabbits), these measurements have generally been unsatisfactory in animals and further increases the attractiveness of alternative (nonanimal) models.

Because of the availability of intact animal skin samples at study termination (following euthanasia), other methods of evaluating irritation, not currently practical for humans, have been developed for use in animal irritation studies. Evaluations of morphometry (the measurement of structural forms) on cells obtained from the full thickness of skin can be utilized in animals. Measurements of the average total cell volume, nuclear size and shape, as well as calculated parameters (e.g. the nuclear/cytoplasmic ratio) can be obtained with this method. Additionally, special fluorescent stains can be utilized to observe and grade the roughness of the surface of the skin.

Several biochemical markers have been evaluated as potential indicators of the degree of irritation. These include enzyme activity, tissue or serum concentration of prostaglandins and/or leucotrienes, and acute phase reactant proteins (Olson, 1991). Ideally, as with any clinical test, the biological sample should be easy to

obtain, objectively measured and the results should be consistent and repeatable. The most frequently cited biomarker evaluated for skin irritation is interleukin 1 alpha (IL-1α) (Gibbs *et al*., 2002). Results of studies with the above markers, including IL-1α, have shown some success with specific compounds or classes of compounds, but have generally been unsuccessful in identifying markers of inflammation that have broad applicability (Fulzele *et al*., 2007). As techniques and instrumentation improve, acceptable biochemical markers for evaluating cutaneous inflammation may be identified, resulting in enhanced evaluation and interpretation of the assessment of cutaneous irritation, preferably, in animals, humans and nonanimal, nonhuman (*in vitro*) techniques.

7 *IN VITRO* ASSAYS

The *in vivo* procedures employing animals used by the toxicologist and risk assessor to measure the potential of a material to produce cutaneous irritation have been increasingly challenged. The validity of these evaluations as they relate to humans, as well as the use of animals in these procedures, has been questioned. As a result, attempts to measure the irritant potential of test substances using *in vitro* techniques have significantly increased (Vinardell and Mitjans, 2008). Several technological developments have made the *in vitro* growth of skin into a well differentiated and complex artificial organ with relevant structural and/or functional activity possible. While a complete description of the methods and applications of these techniques is beyond the scope of this chapter, a description of the general principles is warranted because of the increasing importance of these *in vitro* techniques. It appears that cutaneous irritation is an area where alternative methods to whole-animal predictive testing may soon play a substantial role in risk assessment (Van den Heuvel and Fielder, 1990; Spielmann *et al*., 2007). Political pressures, especially in Europe, are driving development of alternative methods for risk assessment due to the huge numbers of chemicals involved in programs such as REACH and the seventh amendment to the Cosmetics Directive that mandates the elimination of animal testing for cosmetics (Hartung *et al*., 2004).

The purpose of developing *in vitro* techniques to predict the potential irritability of a test substance can be: (i) to evaluate specific aspects of the irritation or sensitization process, (ii) to provide supplemental information to *in vivo* evaluations for the risk assessor or (iii) to replace an *in vivo* procedure (Hobson and Blank, 1991). Furthermore, *in vitro* tests may be more cost effective and, if designed and used properly, provide more objective and meaningful results than whole-animal studies.

In reducing the number of animals used for toxicological experiments and predictive testing, *in vitro* methods have particular value (Gad, 1990; Purchase, 1990). The primary ethical consideration for the toxicologist, industry and governmental agencies is the protection of human health. Therefore, the change from *in vivo* to *in vitro* techniques requires a comprehensive process of evaluation of the performance characteristics of the *in vitro* methodology. This process of confirming the effectiveness of a new procedure' is termed 'validation'. The validation of any new toxicological technique, whether or not it be an *in vitro* process, requires an exhaustive comparison of the new technique with the results obtained in the previous or concurrent studies using established techniques of evaluation as well as comparison with existing relevant epidemiological data in humans. The selection of the test substances for the validation work must be done carefully and should represent a wide range of both chemical and toxicological classes. Based on the legal and ethical implications, this validation and the subsequent move from *in vivo* to *in vitro* techniques must be a careful, deliberate process (Van den Heuvel and Fielder, 1990; Hartung, 2006). The final acceptance or rejection of the *in vitro* test depends on the ability to utilize the results and the confidence in the decisions based on the information provided by the procedure (Soto and Gordon, 1991).

A validation scheme for alternative methods has been devised and includes three stages (Scala, 1986). The first stage develops a mechanistic relationship between the alternative assay and the end point of interest in the target organ and can involve the evaluation of up to a hundred chemicals. The accuracy and dependability of the assay procedures are determined in the second stage. Therefore, problems with the methodology are detected, evaluated and, if possible, corrected during this stage. The third and final stage is performed after the new assay has gained considerable regulatory and scientific acceptance. This phase involves many laboratories and the testing of up to more than 1000 chemicals. Several *in vitro* skin techniques are in this third and final phase of validation as alternative models.

Ideally, the validation of an *in vitro* technique should be performed, at least partially, using human data. There are generally little or no human toxicological data available on enough compounds to evaluate and validate an *in vitro* technique satisfactorily. However, there is a substantial amount of data available on the cutaneous irritability of a multitude of chemicals and chemical mixtures. Researchers attempting to develop new *in vitro* techniques can access this information and compare the results of their models with the known findings of these chemicals in humans (Bason *et al*., 1992). Indeed, individual reputations and the future of entire companies have been staked in the attempt to develop a reliable and economical *in vitro* alternative to predictive irritation testing in animals.

7.1 Types of *In Vitro* Alternative Methods

Several different types of *in vitro* models have been developed to predict the cutaneous irritancy and sensitization potential of compounds (Parish, 1986; Hobson and Blank, 1991; Vinardell and Mitjans, 2008). Structure–activity and biochemical models currently appear to have limited value, but increased mechanistic knowledge and technological advances may increase the usefulness of these models in the future. Computerized structure–activity models may have some applications, but have not received a great deal of industrial or regulatory acceptance for predicting skin irritation or sensitization. These models generally depend on the correlation of a toxic end point (in this case, cutaneous irritation or sensitivity) with specific chemical functional groups and/or a measured parameter of the molecule (e.g. rotational freedom of the functional group within the molecule). Based on an accumulated database of known chemicals, untested chemicals are evaluated for the potential to produce the toxic end point by comparison with the known chemicals of similar structural features. Obviously, these models rely heavily on the molecular interactions involved in production of the toxic end point. As the knowledge of molecular mechanisms of irritation and sensitization increases, the use of these databases for structure–activity modelling will also increase in accuracy and dependability. This methodology will undoubtedly have greater use in the future and scientific interest in structure–activity models continues to be intense.

The biochemical events involved in the production of an irritant response are exceeding complex and not well understood. It is clear that irritants from different chemical classes produce cutaneous changes leading to inflammation by vastly different mechanisms. Thus, development of an accurate structure–activity model for irritation of a wide range of chemicals is a monumental task. Similarly, production of a biochemical model to accurately predict the potential irritancy of chemicals and chemical mixtures is a considerably difficult undertaking. Current biochemical models emphasize the interaction between the irritant and an endogenous molecule of the skin. The interaction would, presumably, be required to initiate the irritant response. However, the identification of even one of the probably many biochemical events responsible for initiating irritation is difficult. Current biochemical models utilize mixtures of carefully selected organic chemicals organized into separate sections to simulate layers of the skin (Gordon *et al*., 1989). The test substance is added to the system and several parameters, including chemical reactivity, are evaluated. These biochemical models are rapidly being replaced by newer *in vitro* models using reconstructed skin models (El Ghalbzouri *et al*., 2008).

Mechanistically based computer or biochemical models used to predict the irritancy potential of a specific class of chemicals may provide valuable information in the selection of new chemicals for future work within that class. These models also add useful information on the mechanisms of irritation and inflammation and are currently being used to a limited extent in pharmacology and toxicology.

Cell-culture methodology has been adapted to *in vitro* irritation assays involving both cutaneous and ocular irritancy. Potential irritancy is evaluated by measuring the cytotoxicity of the chemical in the cell culture. Owing to the many cell varieties found in normal skin, the major complication encountered with this methodology has been the selection of the appropriate cell type(s) for use in the system. Furthermore, the effect of the stratum corneum in protecting viable cells of the epidermis from irritants is not taken into account by the cell-culture model (Hobson and Blank, 1991). Several cell types have been evaluated as models for cutaneous irritation with significant differences being identified (Gajjar and Benford, 1990).

Many of the problems with cell-culture systems are overcome by utilizing skin tissue models. Skin tissue models are represented by two major classes: (i) epidermal slices obtained from either human or animal sources and (ii) reconstructed human skin models. Epidermal slices are generally obtained from either human cadavers or from slaughtered animals and have limited utility due to availability. Furthermore, slaughtered animal skin is not always considered to provide acceptable alternatives to animal testing (Oliver and Pemberton, 1985). Thus, the reconstructed skin (or skin equivalent) models are becoming a focus of much effort to identify an alternative assay to human skin. These assays are 'manufactured' using cultured, normal human-derived epidermal keritinocytes cultured on an artificial membrane to form a highly differentiated model of the human epidermis. Once mature, the cultured human epidermis demonstrates morphological similarities to normal human epidermis, with multiple layers, including a well-developed stratum corneum. The cultured skin is also metabolically and mitotically active, with a lipid profile similar to normal human skin. Furthermore, characteristic markers of human skin and skin irritation can be readily identified and measured (Hoffman *et al*., 2005), These systems show promise as successful alternatives to *in vivo* skin irritation testing especially to replace single-dose (acute) studies (Hobson and Blank, 1991; Spielmann *et al*., 2007).

Several of these reconstructed skin models are currently commercially available. Two of the best known and most studied are EPISKIN (SkinEthic Laboratories, Nice, France) and EpiDerm (MatTek Corporation, Ashland, Massachusetts, USA). Both of these reconstructed skin models have successfully completed extensive validation studies by the European Centre for the Validation of Alternative Methods (ECVAM)

Table 7 Functional performance standards for reconstructed human-skin models intended for use in the irritation testing of chemicals

Viability	As measured by MTT or other metabolically converted dyes demonstrating that control tissues are stable in culture for the duration of the test exposure period.
Morphology	Histological examination of the reconstructed skin model should demonstrate human epidermis-like multilayer structure including a stratum corneum.
Barrier Function	The tissue stratum corneum and its lipid composition should be sufficient to resist the rapid penetration of cytotoxic marker chemicals, such as solium dodocyl sulfate (SDS), under standardized testing conditions.
Reproducibility	Testing of specific reference chemicals, as defined by the OECD, using the reconstructed skin model should demonstrate reproducibility over time and between laboratories.
Quality Control	Prior to acceptance for skin-irritation testing, each batch of the reconstructed skin model must meet defined production release criteria including measures of tissue viability and barrier function.

Adapted from OECD draft guidance, *In Vitro Skin Irritation: Human Skin Model Test.*

(Spielmann *et al*., 2007) and were recommended by the study authors as potential replacements for the Draize rabbit skin irritation test.

Essentially, chemical testing for skin irritation with these reconstructed models is a combination of standard skin irritation testing, in which the chemical is directly applied to the surface of the 'skin' and cell culture techniques. Prior to using the *in vitro* cultures, the cell viability is measured using 3-(4,5-dimethylthazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) or thiazolyl blue reduction testing. The resulting changes to the reconstructed skin model are measured by microscopic observation as well as biochemically through the release of cellular markers such as IL-1α and additional MTT reduction assays for cell viability. The predictive value of changes in the concentration of biochemical markers, as well as structure may not be as important as cell viability as measured by the MTT reduction assay. Because of the sensitivity of these models to environmental conditions and variations in test methods, the conduct and interpretation must be carefully transferred and validated within laboratories. As these assays continue to gain acceptance, this process will likely become more routine and less burdensome. In fact, the Organization for Economic Coordination and Development (OECD) has proposed a set of performance standards for reconstructed skin models. These functional performance standards are summarized in **Table 7**. Continued development of the reconstructed skin models and wider validation efforts is expected in the near future.

In summary, these assays clearly show promise as a replacement for the use of animals in skin irritation testing. Additional reconstructed skin models including those containing dendritic cells as possible *in vitro* skin sensitization assays (Uchino *et al*., 2008) and oral mucosal models (Maharamzadeh *et al*., 2007) are being developed and validated. The international regulatory acceptance of these assays, as well as other techniques such as the silicon microphysiometer (Parce *et al*., 1989; Bruner *et al*., 1991) remains to be seen.

Ototoxicity

Andrew Forge, Ruth Taylor and Ernest S. Harpur

CONTENTS

1 INTRODUCTION

The inner ear contains the end organs of hearing, in the cochlea, and of balance, in the vestibular system. It detects mechanical stimuli—sound vibrations in the cochlea, motion and changes in head position in the vestibular system—and converts them into neural signals. The term ototoxicity is used to refer to the process by which a number of therapeutically useful drugs and certain environmental agents such as industrial solvents cause damage to these peripheral end organs. Agents which cause hearing impairment or balance dysfunction through effects on the respective neural pathways and centres are not considered in this chapter.

Histologically, the inner ear is composed of: sensory epithelia; ion-transporting epithelia that maintain the environment in which the sensory cells function; nonspecialized epithelia; neurons; and connective tissue. Cells in connective tissues have a role in maintaining homeostasis. Broadly, agents that damage the inner ear may act on the sensory epithelia, the ion-transporting epithelia or both. Hearing loss is the common effect of ototoxins. Many affect the vestibular system as well but there are few agents known to be exclusively vestibulotoxic.

An understanding of the basic structure and function of the organs of hearing and balance and of the methods which have been used, or are currently available, for their study is necessary for full comprehension of ototoxicity. Thus, we begin with an account of the anatomy and physiology of the inner ear and then summarize techniques by which each of these may be studied. We attempt to explain why the inner ear is a selective target, focussing on the kinetics of ototoxic drugs in inner ear fluids and tissues, and current understanding of the physiological and biochemical mechanisms underlying ototoxic processes.

2 ANATOMY AND PHYSIOLOGY OF THE INNER EAR

The inner ear consists of a system of membranous canals (the membranous labyrinth) enclosed in bony channels in the base of the skull (**Figure 1**). In humans and higher primates, the inner ear is contained within the temporal bone that is fused with the base of the skull and is reputed to be the densest bone in the body. In other mammals, the inner ear, together with the middle ear, is contained in an auditory bulla that is not fused with the skull and thus can be relatively easily isolated (**Figure 2**).

The bony channels of the inner ear are filled with a fluid, perilymph, which has a high sodium ion (Na^+) content. The perilymphatic compartment connects to the subarachnoid space via the cochlear aqueduct. The fluid within the membranous canals, endolymph,

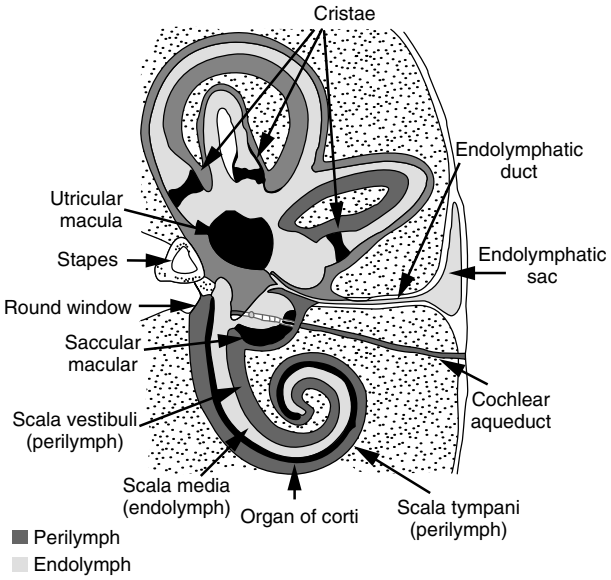

Figure 1 Diagrammatic representation of the human inner ear.

has a high potassium ion (K^+) concentration (about 140 mM). In the cochlea, but not the vestibular system, endolymph also has a high positive resting electrical potential of about +80 mV, the endocochlear potential (EP). The endolymphatic compartment terminates in the endolymphatic sac via the endolymphatic duct. In the cochlea, the canals coil in a spiral around a central axis, the modiolus, which contains the cochlea's nerve and blood supply. The number of turns of the spiral from base to apex varies with species. The endolymphatic canals and perilymphatic channels are continuous with those of the vestibular system, in which there are two sac-like chambers, the saccule and utricle, and the three semicircular canals.

2.1 The Cochlea

In the cochlea, the membranous canal is triangular in cross-section (**Figure 3A, B**) and creates three cochlear compartments (scalae). The lumen of the canal, which forms the scala media, contains endolymph. The scala vestibuli, above the scala media, and the scala tympani below it, contain perilymph. They connect at the apical end of the cochlear spiral at the helicotrema so that there is a continuous perilymphatic space (**Figure 1**). At the basal end of the cochlea, there are two openings through the bony wall from the middle ear space. The oval window over the scala vestibuli is filled with the stapes footplate that delivers sound vibrations displacing perilymph around the spiral. The round window over the scala tympani is covered with an elastic membrane that is displaced outwards and inwards in parallel with stapes movements inwards and outwards by sound vibrations.

The tissues of the cochlea form the walls of the membranous canal. The partition between the scala tympani and the scala media is formed of the acellular basilar membrane, and the sensory epithelium of the cochlea, the organ of Corti, that sits upon it (**Figure 3**). The basilar membrane is freely permeable to perilymph so that the cell bodies and nerves of the sensory epithelium are exposed to perilymph. The border between the perilymphatic and endolymphatic compartments is created by tight junctional sealing at the apical end of the epithelial cells. Hence the apical surfaces of the cells of the organ of Corti are bathed in K^+-rich endolymph, while the cell bodies are bathed in Na^+-rich perilymph. The scala media is separated from the scala vestibuli by the Reissner's membrane.

Along the lateral wall of the scala media is the stria vascularis, an ion-transporting epithelium that is responsible for the production and maintenance of endolymph.

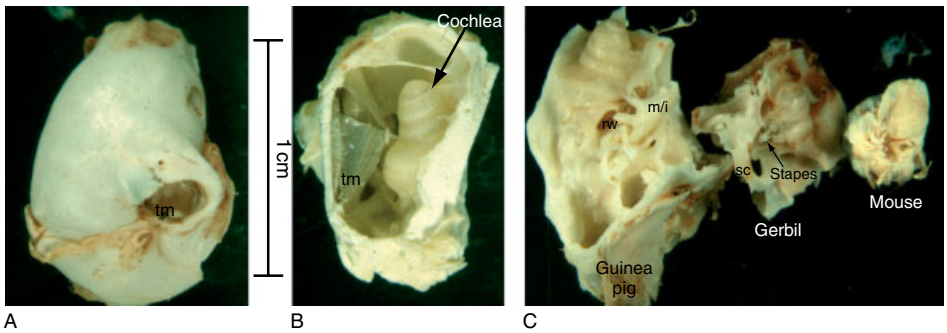

Figure 2 Isolated auditory bullae. (A) Intact bulla from guinea pig. The tympanic membrane (tm, ear drum) covers the opening into the middle ear space. (B) Guinea pig bulla opened to show the cochlea. The tympanic membrane is cone shaped, projecting into the middle ear space. The tip of the tympanic membrane cone is fixed to the first of the ossicles (bones of the middle ear). (C) Opened bullae of guinea pig, gerbil and mouse to show relative sizes. rw—round window, at base of the cochlea; m/i—malleus and incus, two of the middle ear bones which in humans are separate bones, but which are fused together in the guinea pig; sc—semicircular canal, one of three, which are part of the vestibular system.

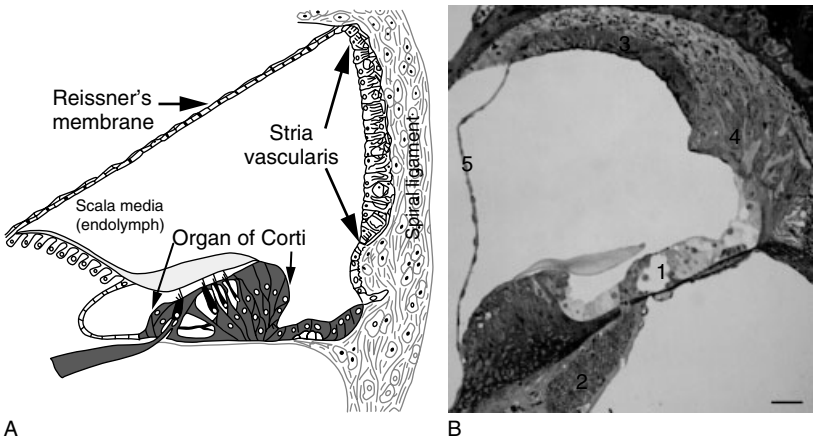

Figure 3 (A) Diagram of a cross-section of a single cochlear turn to illustrate positions of the various tissues. (B) Section of a single turn of the cochlea from a mouse: toluidine blue-stained plastic section. Scale bar 4 µm. The numbers refer to possible sites where pathological alterations might be observed. 1—organ of Corti (there is hair cell loss on this cochlea); 2—auditory nerves; 3—stria vascularis; 4—spiral ligament: the number is located in the approximate position where fibrocyte loss has been noted in some conditions; 5—Reissner's membrane: there is some evidence of distension towards the scala vestibuli in this section, but this may be a preparation artefact.

The stria vascularis rests on the spiral ligament that sits upon the lateral bony wall of the cochlea.

2.1.1 The Organ of Corti

The organ of Corti (**Figure 4**) is composed of sensory 'hair' cells (HCs) and various types of supporting cells. Each HC is separated from its neighbours by intervening supporting cells so no two HCs contact each other. This arrangement creates a regular mosaic of cells at the apical surface of the organ of Corti, that is called the reticular lamina (**Figure 4**). HCs, the mechanosensory cells of hearing and balance organs in all vertebrate classes as well as the neuromasts of the lateral line of fish and aquatic forms of amphibian, generally are elongated in shape and innervated at the their basolateral surface. They are characterized by the presence of an organized bundle of erect projections at their apical end. This hair bundle is formed of rows of 'stereocilia' that increase in height in one particular direction across the cell apex (**Figure 4C**). Stereocilia are not true cilia, but are modified microvilli, each one formed of closely packed parallel filaments of actin (**Figure 4D**). In the apical cytoplasm of the HC is a meshwork of actin filaments, the cuticular plate, into which the rootlets of the stereociliary microfilaments are crosslinked, providing support for the stereocilia. The apical surfaces of the HCs are bathed in endolymph, into which the stereocilia project, whilst the body of the cell is surrounded with perilymph (**Figure 3**). Deflections of the hair bundle stimulate the HC. Deflections towards and away from the longest row of stereocilia regulate the opening and closing of nonselective cation channels (Hudspeth, 1989). Fine tip-links stretching upwards from the distal end of a shorter stereocilium to the side of the longer stereocilium behind (Pickles *et al*., 1984) are thought to act as gating elements controlling the opening of the 'transducer' channel (Hudspeth, 1989; Gillespie, 1995).

In addition to the tip link, the stereocilia in an individual hair bundle are connected by a variety of other extracellular crosslinks (Goodyear *et al*., 2005). One function of these lateral connections is to couple the stereocilia mechanically so that the bundle moves as a unit when deflected. The crosslinks may also play crucial roles in development and maintenance of the hair bundle. Mutations in genes that encode hair bundle crosslinking proteins cause hearing impairment and balance dysfunction, highlighting the importance of the crosslinks to HC activity, and being extracellular they might be considered likely sites of action for potentially ototoxic agents.

In the organ of Corti, the HCs are arranged in parallel rows along the length of the spiral and there are two types (**Figure 4**): a single row of inner hair cells (IHCs) and three to five rows (depending on the species) of outer hair cells (OHCs). In the CBA/Ca mouse strain (whose hearing acuity is maintained for most of its life span and is thus regarded as a 'normal' mouse strain for auditory investigation (Zheng *et al*., 1999)) there are on average 725 IHC and 2300 total OHC along the length of the organ of Corti (Ding *et al*., 2001). In the guinea pig, there are approximately 2000 IHCs and 7000 OHCs (Thorne and Gavin, 1984), while in humans there are about 3000 IHCs and 9000 OHCs (Wright *et al*., 1987). Overlying the organ of Corti and the HCs is another acellular, fibrous structure, the tectorial membrane. The longest stereocilia of the OHC are embedded in the underside of the tectorial membrane. The coupling of the stereocilia to the tectorial

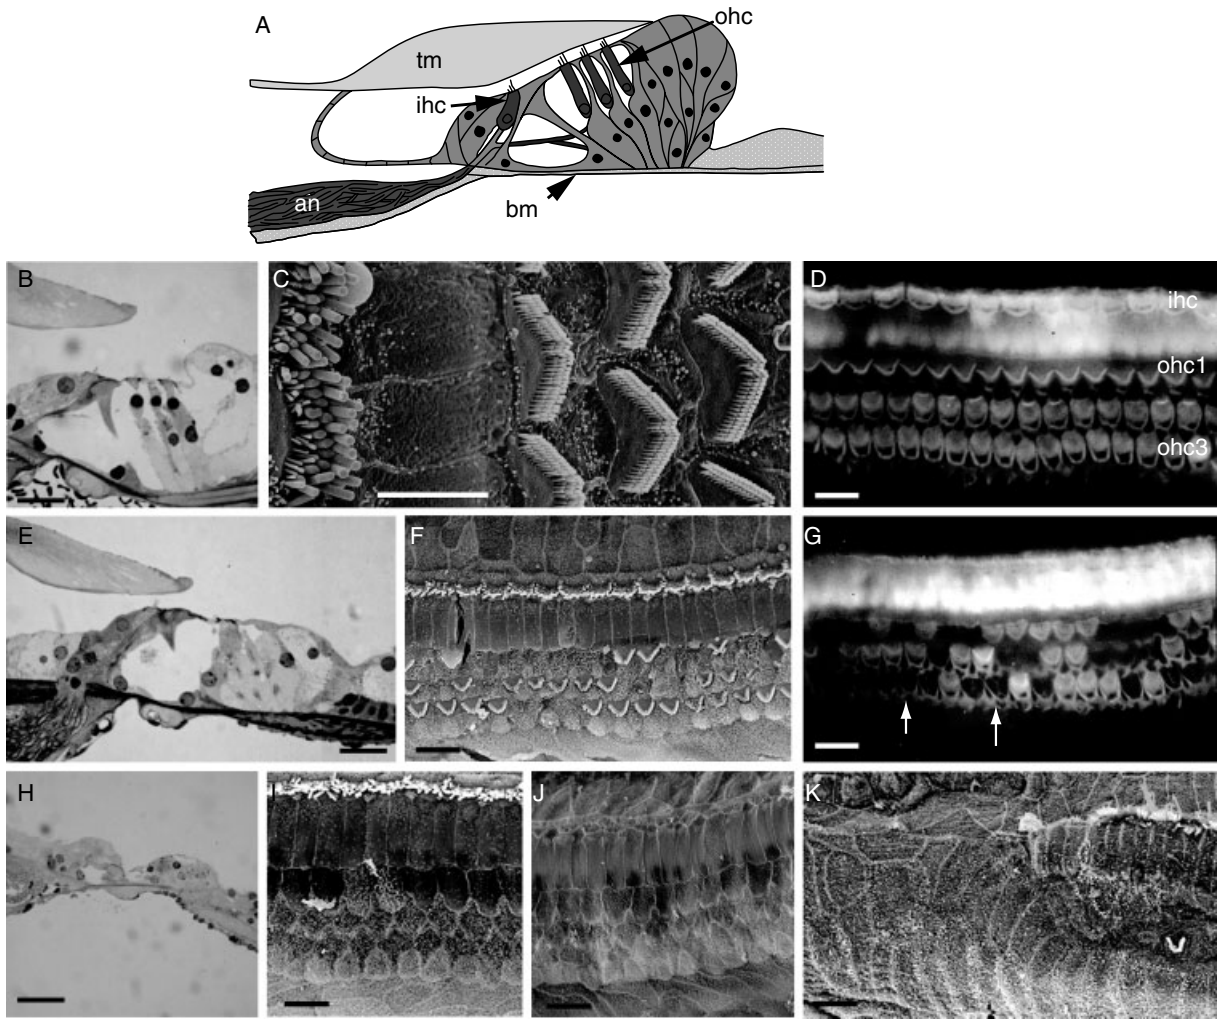

Figure 4 The organ of Corti. Illustration of different examination methods and of aminoglycoside-induced hair cell loss. Scale bars: (B) and (D–K) 20 μm, (C) 5 μm. (A) Diagram to illustrate the architecture. ihc—inner hair cell; ohc—outer hair cell; tm—tectorial membrane; bm—basilar membrane; an—auditory nerve. (B, E, H) Toluidine blue-stained plastic sections. The tectorial membrane tends to shrink away from the apical surface of the organ of Corti during tissue processing. (C, F, I, J, K) Scanning electron microscope (SEM) images of the apical (endolymph-facing) surface, the reticular lamina. Tectorial membrane removed. (D, G) Fluorescence microscopy of phalloidin-stained whole-mount preparations to show the apical surface (phalloidin interacts with actin and so highlights the actin-rich structures at the HC apex). ihc—inner hair cells; ohc1, ohc3—first and third row of outer HCs. (B, C, D) Normal, undamaged organ of Corti. SEM (B) and phalloidin-stained (C) whole mount show that each HC displays a bundle of stereocilia, organized in a W shape on each OHC and a wide curve on IHCs. In each hair bundle the stereocilia are organized in rows that increase in height from the innermost to outermost row (B). The surfaces of supporting cells intervene between each HC. (E–K) Stages during HC loss induced by an aminoglycoside, and subsequent reorganization of the sensory epithelium. (E) Section showing loss of all three OHCs, but persistence of IHCs. (F, G) Early stage of aminoglycoside-induced HC loss. SEM (F) and phalloidin labelling of whole mount (G) show scattered loss of OHC. Remaining OHCs are scattered along the organ of Corti, and SEM (F) reveals some signs of ongoing degeneration. The locations from which HCs have been lost are filled by expansion of the apical surfaces of supporting cells. Arrows in G indicate typical 'scar' formations, where labelling of actin associated with cell junctions reveals where all the supporting cells surrounding an individual HC expand into the lesion site to close it. IHCs are unaffected at this stage. (H) Section showing near complete loss of almost all the elements of normal organ of Corti and its replacement by a simple, flat epithelium. (I, J, K) SEM of stages in HC loss subsequent to that shown in (F) and (G). (I) All OHC lost, but IHC remain. (J) IHC as well as OHC lost. (K) Initiation of replacement of the elements of the severely damaged organ of Corti (to the right of the figure) with a simple epithelium (to the left), an area similar to that shown in section in (H).

membrane provides a mechanism for stimulating the HC during sound reception.

During sound stimulation, vibration of the stapes footplate displaces fluid along the scala vestibuli and scala tympani, resulting in displacements of the basilar membrane and the organ of Corti towards and away from the scala media. A relative shear motion between the tectorial membrane and the reticular lamina is thereby produced. The consequent deflection of the stereocilia alternately towards and away from the longest row of stereocilia as the basilar membrane is displaced up and down modulates a K^+ current flowing through the HCs from the K^+-rich endolymph at the apical surface to the Na^+-rich perilymph around the HC body. The opening of the transducer channels as the stereocilia are deflected towards the longest row leads to increased K^+ entry, resulting in depolarization of the HC; deflection in the opposite direction closes the channels and the HC becomes hyperpolarized. The potential changes stimulate HC activity. The large positive EP (+80 mV), coupled with a negative resting potential inside the HC, provides a driving force for the current flow increasing the sensitivity of the system (Davis, 1965). The alternating changes in HC potentials in phase with the sound vibrations can be recorded extracellularly from electrodes close to the round window as the cochlear microphonic (CM) potential.

The two HC types in the cochlea have different roles. The IHC is the primary receptor cell. IHCs are directly innervated exclusively by afferent fibres. Each IHC synapses with several different fibres, and about 90–95% of the total afferent innervation to the cochlea terminates on IHCs (Spoendlin, 1973). These Type 1 auditory neurons are myelinated where they exit the sensory epithelium and are bipolar neurons, their cell bodies localized in the spiral ganglia, located just inward of the sensory epithelium all along the cochlear spiral. The changes in electrical potential of IHCs upon stereociliary deflection lead to neural excitation. The activity of the auditory nerve upon sound stimulation recorded from extracellular electrodes as the compound action potential (CAP) is a measure of the neural output from the cochlea that derives primarily from IHC stimulation.

OHC, on the other hand, have a modulatory role. They have an extensive direct efferent innervation, about 80% of the efferent innervation to the cochlea terminating on OHCs. Only 5% of the cochlea's afferent neurons innervate OHC; these Type 2 neurons are thinner than the Type 1 neurons that innervate the IHCs. They are unmyelinated and pseudomonopolar, with their cell bodies also located in the spiral ganglion, and one Type 2 afferent neuron innervates several different OHCs (Jagger and Housley, 2003). Recording of the neural activity of individual cochlear afferent nerves in response to sound, which represents the output from a single IHC, shows that each neuron is extremely sensitive to one particular frequency, its 'characteristic frequency'. This 'tuning' of the neurons to a particular frequency is physiologically vulnerable and it has been found that when OHCs are lost but IHCs remain intact there is a loss of sharp neural tuning and in the ability to detect sounds lower than 60 dB in sound pressure level (i.e. there is a severe hearing impairment but loud sounds can be heard). It is believed that, *in vivo,* OHCs actively modulate the movement of the basilar membrane in response to sound, leading to amplification of the signal reaching the IHC, and increasing sensitivity (by about 60 dB) (Ashmore and Kolston, 1994; Dallos, 1996). The changes in OHC potential in response to sound drive this active response which is mediated by a 'motor' protein, called prestin (Zheng *et al*., 2000) that is unique to OHCs and is highly concentrated in their lateral plasma membranes.

The EP is thought to provide the power for the 'cochlear amplifier' function of the OHCs (Ruggero and Rich, 1991; Dallos, 1996). Thus, loss of EP will result in a hearing impairment because of a loss in amplification. This activity of the OHC results in the emission of acoustic signals from the ear (otoacoustic emissions, OAEs) in response to stimulating sounds (Kemp, 1978; Dallos, 1996). OAE recording provides a noninvasive, sensitive, objective means to assess cochlear function, which merely involves the insertion of a small probe consisting of a microphone and loudspeaker assembly into the external ear canal. It measures the activity of OHCs. CM recorded extracellularly is also dominated by the responses of the OHCs. There are three times as many OHCs as IHCs, and the resting intracellular potential of OHCs is much lower (−70 mV) than that of IHCs (−40 mV), so that CM potentials are much greater in OHCs than IHCs.

There are a number of systematic dimensional variations of the basilar membrane and organ of Corti along the length of the spiral, which affect the mechanical properties of the system such that for different frequencies of the sound stimuli, maximal vibration of the basilar membrane occurs at different locations: sounds of particular frequency cause maximal stimulation at a particular place; a place–frequency relationship or tonotopic organization along the organ of Corti. High-frequency (high-pitched) sounds cause maximum displacement, and thus stimulation, of the HCs at the base of the cochlea, and low frequencies are detected at the apical end (Pickles, 1988). This means that differential damage to the organ of Corti along its length will be reflected in differential loss of frequency perception; if HCs at the basal end of the cochlea are affected, a high-frequency hearing loss results but the ability to detect low frequencies may be unimpaired.

2.1.2 The Stria Vascularis and Spiral Ligament

The stria vascularis is the ion-transporting epithelium of the cochlea. It is composed of three cell types and

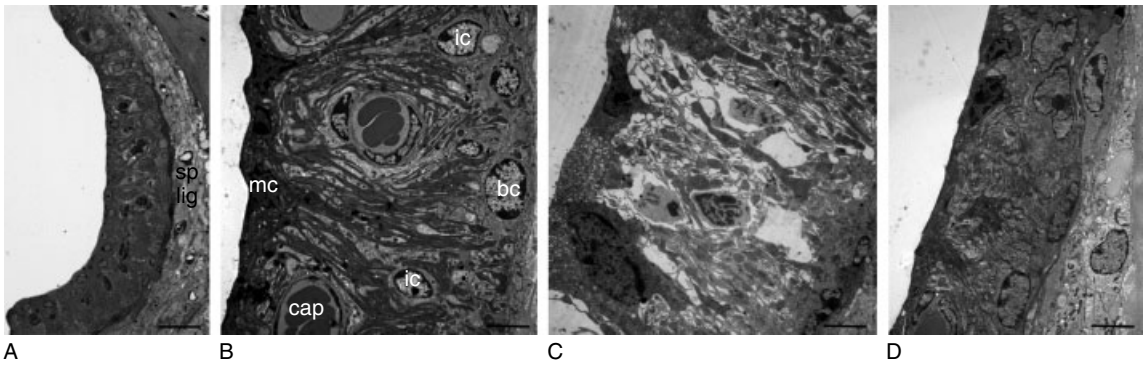

Figure 5 The stria vascularis, to illustrate normal histological features and some possible pathologies. (A) Light microscopy of toluidine-blue-stained section of plastic-embedded normal stria vascularis. sp lig—spiral ligament. (B) Transmission electron microscopy of thin section of mouse stria vascularis. mc—marginal cell, ic—intermediate cell, bc—basal cell, cap—capillary. Note the extensive basal infolds of the marginal cells. (C) Oedema in stria as a consequence of the effects of the loop diuretic, furosemide. Extracellular spaces are grossly enlarged, but the overall architecture of the tissue is undisturbed. (D) Atrophy of stria, 12 weeks after treatment with an aminoglycoside (kanamycin). The stria is much reduced in thickness, principally due to atrophy of the marginal cells, which show a great reduction in the extent of the basal infoldings seen in the normal tissue (B). Scale bars: (A) 20 µm, (B–D) 5 µm.

encloses its own capillary blood supply (**Figure 5A, B**). The stria vascularis is not only responsible for the maintenance of cochlear endolymphatic K^+, but also for the generation and maintenance of the EP. Damage to the stria vascularis will result in a loss of EP. The generation of EP is dependent upon the recycling of K^+ passing through the HCs from endolymph to perilymph and from perilymph back to endolymph via the stria vascularis (Wangemann, 2002). The endolymphatic compartment is lined by marginal cells that actively transport K^+ into endolymph. The basolateral membrane of the marginal cells is extensively infolded and contains high levels of Na^+-K^+-ATPase (adenosine triphosphatase) (Kuijpers and Bonting, 1969; Souter and Forge, 1998) and a Na-K-2Cl co-transporter (Ikeda *et al*., 1997), which are responsible for the entry of K^+ into the marginal cell, while KCNQ1 channels in the apical membrane provide an exit for K^+ from the marginal cell into endolymph (Wangemann, 2002). Tight junctions between marginal cells separate the stria cells from the endolymph. The intermediate cells are enclosed entirely within the stria and are melanocytic cells. The basal cells separate the stria vascularis from the underlying spiral ligament, which is freely permeable to perilymph. A complex network of tight, occluding junctions between adjacent basal cells acts to seal the intercellular spaces of the stria from the perilymph in the underlying spiral ligament. Thus, there is no direct diffusion pathway between the stria and either perilymph or endolymph, entry of oxygen and nutrients (and ototoxins) to the stria deriving from the enclosed vasculature. Numerous gap junctions connect adjacent basal cells, basal cells and cells in the spiral ligament, and basal cells and intermediate cells (Forge, 1984; Kikuchi *et al*., 1995; Forge *et al*., 2003).

The spiral ligament beneath the stria is part of the perilymphatic compartment. The ligament is formed of several subpopulations of fibrocytes, one of which is rich in Na^+-K^+-ATPase (Spicer and Schulte, 1996). These cells take up K^+ from the perilymph in the extracellular spaces of the ligament. K^+ is then passed through cells of the ligament via gap junctions between fibrocytes, and then into the basal cells of the stria vascularis via the gap junctions between strial basal cells and ligament fibrocytes. Basal cells are connected to strial intermediate cells also by gap junctions (Forge *et al*., 2003), and EP is generated by electrogenic K^+ passage across the membrane of the intermediate cells via channels composed of KCNJ10 (Kir 4.1) into the extracellular spaces of the stria (Marcus *et al*., 2002). The activity of the marginal cell Na^+-K^+-ATPase and the Na-K-2Cl co-transporter maintain the low levels of K^+ in the intrastrial spaces necessary for EP to develop, while the tight junctional sealing between marginal cells, between basal cells and between endothelial cells of the capillaries prevents dissipation of the potential. The marginal cell itself is 'electrically transparent', so that the potential generated in the intrastrial space extends into the endolymphatic space.

As well as a role in K^+ recycling, the various subpopulations of spiral ligament fibrocytes are involved in other aspects of cochlear homeostasis, including pH balance (Spicer and Schulte, 1996). Damage to the spiral ligament can therefore be detrimental to cochlear function more generally, and death of certain subpopulations of spiral ligament fibrocytes, along with death of OHC and permanent hearing deficits, has been noted both following exposure to excess noise and with ageing (Hequembourg and Liberman, 2001; Wang *et al*., 2002). Death of OHC in particular can be triggered by failures to maintain the

physiological environment within the cochlea. Mutations in genes encoding proteins whose activity is necessary for maintenance of the characteristics of endolymph that are localized in cells of the lateral wall can cause deafness, and progressive loss of HCs is often apparent (Steel and Kros, 2001; Boettger *et al*., 2002; Cohen-Salmon *et al*., 2002; Rozengurt *et al*., 2003). These proteins that are involved in maintaining the physiological environment of the cochlea are potential targets for xenobiotics.

2.2 The Vestibular System

The sensory epithelia of the vestibular system are the maculae of the utricle and the saccule, and the cristae which are located within swellings, the ampullae, at one end of each semicircular canal (**Figure 1**). The vestibular neuroepithelia are organized in two-dimensional arrays of HCs and supporting cells, but unlike the organ of Corti, the vestibular sensory epithelia are compact tissues with no large extracellular spaces, and the basement membrane, equivalent to the basilar membrane of the organ of Corti, sits directly upon connective tissue. The intercellular spaces of the vestibular sensory epithelia are continuous with the perilymphatic compartment, while the apical surface is bathed in endolymph. The maculae of the utricle and saccule are overlaid by an acellular fibrous membrane upon which sits a mass of calcium-containing, crystal-like structures, the otoconia, while the cristae of the semicircular canals are overlaid by a gelatinous structure, the cupula. As in the organ of Corti, the HCs are stimulated by deflections of their hair bundles, which in the vestibular system are initiated by changes in the relative position of the head. The utricular and saccular maculae detect static changes relative to the direction of the force of gravity. The cristae detect linear acceleration.

There are two types of vestibular HC. Type 1 HCs are flask shaped, with the basolateral membrane entirely enclosed in a single afferent nerve calyx. In certain respects they resemble cochlear IHCs. Type 2 vestibular HCs are cylindrical and innervated by afferent nerves with bouton-like endings, as well as directly by efferent nerves. Thus, they superficially resemble cochlear OHC. The two vestibular HC types also differ in the types of ion channel along their basolateral membrane which shape the cells' receptor potentials in response to the transduction currents that arise from deflection of the stereocilia (Eatock and Rusch, 1997). The hair bundles of vestibular HCs consist of, in addition to the ranked rows of stereocilia, a single true cilium—the kinocilium—that is located behind the row of longest stereocilia. (A kinocilium is present in hair bundles of the HCs in all other vertebrate classes and is present in the immature hair bundles of the mammalian organ of Corti, but it regresses during cochlear maturation to remain only as the basal body in the mature IHC and OHC.) The positions of the kinocilium and the longest stereocilia define the morphological and functional polarity of the hair bundle, and in the maculae of the vestibular organs there is an abrupt change in bundle polarity along the 'striola', a region running within the middle of the epithelium. Hair bundles on one side of the striola are oriented at 90° to all those on the other: in the utricular macula the kinocilia face each other across the striola; in saccular maculae the rows of shortest stereocilia are facing across the striola. In the maculae, the two HC types are differentially distributed with reference to the striola. Type 1 cells predominate across the striolar regions while Type 2 HCs are more prevalent towards the peripheries. In the cristae, the bundles of all the HCs are oriented in the same direction across the epithelium, but there is a similar differential distribution of the two HC types: Type 1 HCs predominate at the crest of the saddle-shaped structure (the central region), while there is a much higher proportion of Type 2 HCs down the skirts (the peripheral region).

Vestibular endolymph is maintained by the cells of the dark cell regions located around the utricular macula and at the base of the saddle-shaped cristae (but not in the saccule). The dark cell regions consist of a single layer of cells directly overlying connective tissue. The dark cells are equivalent to the marginal cells of the stria vascularis, and actively transport potassium from the perilymph, which surrounds their basolateral surfaces, into the endolymph, which bathes their apical surfaces. There is no separation of the dark cells from the perilymphatic spaces of the underlying connective tissue equivalent to that created by the strial basal cells of the cochlea, and there is no potential in the vestibular endolymphatic compartment equivalent to EP.

3 ACCESS OF OTOTOXINS TO THE INNER EAR

The complete enclosure of the inner ear structures within the bone means that they are not exposed directly to potentially damaging environmental agents. Access to the perilymphatic compartment of the inner ear is possible from the middle ear cavity via the membrane covering the round window at the base of the cochlea. The round window membrane is a three-layered structure, with two cell layers separated by a fibrous layer, but it acts like a semipermeable membrane (Salt and Plontke, 2005). Transfer of substances into perilymph across the round window membrane is mainly passive. After entry into the perilymphatic compartment of the inner ear, an agent would arrive in the vestibule, with access to the basal end of the cochlea (**Figure 1**). Subsequent drug distribution is somewhat complicated, influenced by a relatively slow diffusion rate away from the site of entry and localized

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat066
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

clearance rates (Salt and Plontke, 2005). Computerized modelling of drug distribution is being used to assess these parameters. Bacterial toxins associated with middle ear infections, as well as ototoxic drugs, may potentially enter the inner ear across the round window. Although this is rare for the former, application of ototoxic agents, in particular aminoglycoside antibiotics, to the middle ear cavity, thereby enabling entry of the drug to the inner ear, is used as a clinical procedure to ablate HCs in the vestibular system in cases of severe balance dysfunction such as that resulting from unilateral Ménière's disease (Blakley, 1997). This approach is also a potential means for introducing therapeutics that may inhibit the effects of agents that normally cause damage to the inner ear, or indeed agents that might stimulate the regeneration of lost HCs. For these reasons interest in the pharmacokinetics of the entry and distribution of drugs in inner ear fluids has been rekindled (Salt and Plontke, 2005).

Access to perilymph via the cochlear aqueduct from the cerebrospinal fluid (CSF) is also possible and this may be a route of entry again for bacterial toxins, such as those associated with meningitis. However, the cochlear aqueduct is not patent in many individuals, and tends to close as an individual ages. Ototoxic agents reach the inner ear predominantly through the blood supply. There are, however, restrictions on the entry of agents to the fluids of the inner ear. Perilymph is not simply an ultrafiltrate of blood plasma, nor does it derive from CSF. The composition of perilymph is different both from CSF and from blood plasma, and the composition of perilymph in the scala vestibuli differs from that in the scala tympani (Wangemann and Schacht, 1996). This indicates that perilymph is produced and circulated locally and that there is a so-called 'blood–perilymph barrier'. Glucose entry, for example, requires facilitated diffusion through glucose transporters (Ito *et al*., 1993; Wangemann and Schacht, 1996). This may limit access of potentially damaging agents to the perilymphatic compartment. However, relatively little is known about the characteristics of this blood–perilymph barrier, and of which and how substances can cross it, but again as possibilities for therapeutic interventions to prevent or ameliorate deafness have become apparent there is further interest in research in this area (Salt and Plontke, 2005). Nevertheless, if entry to perilymph is gained then, because the basilar membrane is freely permeable, there is direct access to the lateral membranes of the HCs, to their synaptic regions and the nerve fibres (**Figure 3B**).

Entry to endolymph in the internal compartment of the inner ear is even more restricted and endolymph composition is tightly controlled (Wangemann and Schacht, 1996). The principal boundaries between endolymph and perilymph, formed by selectively permeable membranes and tight junctions between adjacent cells, appear to be Reissner's membrane, at the level of the basal cells in the stria vascularis, and the network formed by the apical surfaces of the HCs and adjacent supporting cells in the organ of Corti. If an agent were to penetrate these boundaries, however, it would have access to the hair-bearing (apical) ends of the HCs.

4 METHODS OF STUDY

4.1 Physiology and Function

Techniques for assessing the activity of the inner ear have largely been developed for the cochlea. Physiological investigation of the vestibular system is more difficult to perform especially with experimental animals. In the context of ototoxicity this is probably not a significant drawback. There are no agents known to affect only the vestibular system without also being potentially damaging to the cochlea, and chemical agents which are cochleotoxic also have effects in the vestibular system. (Noise, of course, which some define as an ototoxic agent, predominantly affects the cochlea.)

The functioning of the cochlea can be assessed at a number of different levels. Auditory cues detected by the cochlea evoke responses at higher brain centres which can be monitored through the specific reflexes which are elicited (the Preyer reflex) or by behavioural audiograms; the electrical activity associated with the passage of neural signals in the brainstem can be monitored, or the biomechanical activity of the cochlea itself can be evaluated. Electrophysiological testing can provide further detailed analysis.

4.1.1 The Preyer Reflex and Behavioural Response Audiometry

The Preyer reflex is a twitching of the external pinna of the ear in response to sound. The test can be refined by presenting tones of differing frequencies and differing intensities, but clearly there is a subjective element in determining whether there is a response, and the twitching is elicited only at quite high sound pressure levels so that quite significant losses in hearing acuity can accrue before any effect on the reflex is noticeable. Nevertheless, the Preyer reflex is used as a first-level screen for hearing loss, particularly in strains of mutant mouse. For this routine screening a simple device—the 'click box'—has been devised, (Kiernan and Steel, 2000) which, at the push of a button, emits high-intensity (loud, about 90 dB), very high-frequency signals that are within the higher auditory frequency range of mice but which are inaudible to humans because they are above their auditory frequency range (i.e. they are ultrasonic to humans).

More sophisticated and sensitive estimation of the ability of an animal to 'hear' can be obtained through behavioural response audiometry to derive behavioural audiograms (Stebbins *et al*., 1981). For these, an animal is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat066
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

trained to perform some task when sounds are presented. The threshold of the response, that is the lowest sound pressure level at which a response is elicited, can be determined for a number of different frequencies over the frequency range to which the animal is sensitive. Any change in the threshold concomitant with the administration of some ototoxic agent can then be evaluated. Such procedures have the advantage that repeated testing of the same animal is possible, allowing preadministration and postadministration thresholds to be compared and the progression of alteration to be followed. However, the procedure is obviously time consuming, especially in the initial training, and is not applicable for many species such as guinea pigs, which in other ways are extremely good animals for ototoxic investigation but are impossible to train. On the other hand, procedures that involve training to respond to sounds are beginning to prove valuable in assessing animal, especially rat, models of tinnitus (Kaltenbach *et al*., 2005; Puel and Guitton, 2007). Tinnitus is the perception of sound in the absence of a sound signal. It is a reported side effect of some ototoxins and may accompany the development of deafness. However, its existence generally requires self-reporting and thus is usually almost impossible to identify in animals.

4.1.2 Auditory Brainstem Responses (ABR)

The stimulation of the auditory nerve following reception of a sound in the cochlea leads to successive stimulations of a number of centres along the auditory neural pathway in the brainstem to the auditory cortex. The electrical activity associated with such stimulations can be recorded with electrodes placed on the skull as a succession of waves of different amplitudes and latencies. The recording of these evoked electrical potentials is a noninvasive procedure that can be used repeatedly in an individual subject, thereby allowing examination of the progression of a hearing impairment following an ototoxic insult. The test involves presentations of sounds of different intensities at a variety of frequencies that cover the frequency range of the animal, and estimation of the lowest sound pressure level that provokes a just-detectable response, the threshold, at each tested frequency. It has been shown that permanent increases in the frequency thresholds of the auditory brainstem responses (ABRs) (louder sounds are necessary to elicit the response, indicating hearing impairment) correlate with loss of HCs at corresponding locations in the cochlea, and that it is possible to monitor transient, that is recoverable, changes in hearing acuity using this procedure (Canlon *et al*., 1993; Zheng *et al*., 1999). ABR reveals the neural output from the cochlea, which it has been argued is the most meaningful measure for rapid assessment of the functional effects of potentially ototraumatic agents (Liberman, 1990), and ABR testing has become the routine procedure for assessing auditory function and identifying hearing impairment in animals.

4.1.3 Otoacoustic Emissions (OAEs)

Activity of the OHCs, induced by sound stimulation, modulates the movement of the basilar membrane and leads to the emission of sounds from the ear, known as otoacoustic emissions. OAEs can be detected in the external ear canal some microseconds after the stimulating input signal (Kemp, 1978). Because OAE recording is a noninvasive procedure that involves only the insertion of a small probe consisting of a microphone and loudspeaker assembly into the external ear canal, it can be used repeatedly and reproducibly in individual subjects and has clinical application especially for testing cochlear function in newborn babies. There are a number of different types of OAE signal depending upon the stimulus parameters used, and for studies of animals the most useful is the distortion product otoacoustic emission (DPOAE). By using a variety of stimulating frequencies, DPOAEs of different frequencies, that is, emissions from different regions of the cochlea, can be obtained, enabling assessment of the active mechanical responses along the length of the cochlea. Recording of DPOAEs has been shown to be a sensitive, reproducible method for assessment of ototoxic effects in the cochleae of animals (Brown *et al*., 1989) and, like ABR testing, is becoming a widely used procedure for auditory assessment of animals in a variety of conditions including ototoxicity, noise trauma and with ageing (Martin *et al*., 2007).

Since OAEs are produced by OHC activity, any changes in OAE amplitude can be attributed either to damage to OHCs themselves and/or to impairment of the stria vascularis affecting EP generation and thus the driving force for the electromotile responses of OHCs that produce OAEs. Loss of OAEs will also be reflected in an increase in ABR threshold, since loss of the OHC activity that produces the OAE will result in loss of cochlear amplification. On the other hand, if OAEs are normal but ABR thresholds are increased, then the hearing impairment so revealed can be attributed to a defect at the level of the IHC or its synapses with the afferent innervation. Consequently the combined use of the two noninvasive procedures, ABR and OAE recording, can provide some diagnostic information on possible sites of damage in the cochlea.

4.1.4 Electrophysiological Activities of the Cochlea

More detailed assessment of the site of a functional lesion in the cochlea can be obtained from monitoring the resting EP or the sound-evoked electrical potentials that derive from the activity of particular parts of the transduction pathway. EP can be monitored via a potassium-filled glass electrode inserted into the scala

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat066
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

media, either through the round window membrane and the basal coil of the organ of Corti, or through the lateral wall, in anaesthetized animals. Alterations of the EP reflect an effect in the stria vascularis, and because the EP provides a driving force for current flow through the HCs as well as the power that drives the 'cochlear amplifier', a decline in the level of EP decreases the sensitivity of the organ of Corti to sound stimuli. The sound-evoked responses—CM potential and CAP—can be recorded remotely from (usually silver ball) electrodes placed near the round window. CM derives from the modulation of current flow through the HCs during transduction that produces an alternating extracellular electrical potential, which mimics exactly the original sound stimulus, that is, the frequency and polarity of CM follows precisely that of the stimulus (hence 'microphonic'). By varying the frequency of the acoustic stimulus, the CM originating from different regions of the cochlea can be assessed. The sound level at each frequency required to produce a constant CM output, or the amplitude of CM in relation to sound intensity at each frequency, can be measured. CM recorded extracellularly is dominated by the responses of OHCs and thus monitors the health of those cells. Neural excitation following sound stimulation results in the generation of action potentials in the auditory nerve. Remote electrodes placed close to the round window record the gross activity of all the afferent neural units responding to the particular sound stimulus as the CAP. Since the vast majority of those nerves innervate IHCs, the CAP is a measure of their activity.

The recording of EP, CM and CAP are invasive techniques. Generally, these procedures are used acutely and the animal has to be sacrificed after the recording has been made. This means that in examination of ototoxic agents, preadministration and postadministration levels of these potentials, or the progression of any alteration, cannot be made unless this occurs over a time period sufficiently short for the animal to be maintained under anaesthesia, which may be the case with some agents such as diuretics which produce acute effects on EP. It also means determination of abnormality must be made by comparison with untreated control subjects. However, these disadvantages can be overcome by permanently implanting a round window electrode for recording CM and CAP (Aran and Darrouzet, 1975). With such a procedure, long-term, continuous electrophysiological assessment of the effects of ototoxic agents in individual conscious animals can be undertaken.

4.2 Procedures for Examination of Cochlear Tissues

In most mammals the auditory bulla can be relatively easily isolated from the base of the skull and opened to expose the cochlea (**Figure 2B, C**). Breaking open the round window and removing the stapes from the oval window at the base of the cochlea and removing a small piece of bone from its apex provides access for direct perfusion of an appropriate fixative by gentle injection through these openings, before immersion of the opened bulla in fixative. It is also possible to use intravital perfusion of the whole animal with fixative prior to isolation of the bulla, opening the cochlea and then immersing the opened bulla in fixative, but generally fixation may not be as good as after direct perfusion.

The most straightforward means for assessing the neuroepithelia of the inner ear is to examine the features at the surface in whole mounts of the tissue. Following fixation, the bone enclosing the inner ear can be picked away and the neuroepithelia dissected out. Decalcification after fixation may assist dissection. The organ of Corti can be removed in segments, usually sequentially from apex to base. It can then be examined by either phase-contrast or differential interference contrast (DIC) microscopy, or by fluorescence microscopy following staining with fluorescently conjugated phalloidin. Phalloidin interacts with filamentous actin so the stereocilia and cuticular plates, actin-rich structures at the HC apex, are intensely labelled. The actin associated with the junctional complexes between the hair and supporting cells is also labelled, so the cell borders at the tissue surface are outlined (**Figure 4D, G**). Immunohistochemical procedures can also be applied directly to the whole mount preparations. Alternatively scanning electron microscopy (SEM) can be employed to examine the apical surface of the organ of Corti (**Figure 4B, F**) or vestibular sensory epithelia (Davies and Forge, 1987). These techniques can be used to draw up a 'map' depicting the position of each HC along the entire length of the organ of Corti (a 'cytocochleogram') (Viberg and Canlon, 2004), or across the vestibular sensory epithelia (Forge and Li, 2000). The extent and location of damaged or missing HCs can be determined. In the case of the organ of Corti, this can be related to physiological data from the same cochlea. SEM not only provides data for the construction of cytocochleograms, but also allows assessment of some of the earliest events in the progression of damage to the HCs, or of relatively minor alterations, especially to the stereociliary bundle, which would not be visible by light microscopy but may have quite significant functional implications. For example, with high-resolution SEM it is possible to identify the loss of the 'tip-links' between stereocilia, which can occur without there being any other significant alterations to the stereociliary bundle (Osborne and Comis, 1990; Assad *et al*., 1991), or the consequences of effects on the lateral crosslinks between stereocilia, or other components of the stereocilia, that can result in various distortions of the hair bundle (Bryant *et al*., 2005).

An alternative view can be obtained by examination of sections of the cochlea. After opening the bulla to expose

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat066
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the cochlea, and fixation, the inner ear is decalcified. The entire, decalcified inner ear can be embedded and sections cut parallel to the modiolus. When sections of the entire cochlea are taken, the tissues are retained in their original relationship and examination can be made not only of the organ of Corti (**Figure 4B, E, H**) but also other tissues which may be sites of action for ototoxic agents, or which are affected as damage following the initial ototoxic insult progresses (**Figure 3B**). Thus, as well as the presence or absence of HCs and the overall architecture in the organ of Corti, it is possible to examine for pathologies other than, or in addition to, HC loss that may account for an observed hearing impairment: for example, loss of, or injury to, afferent neural cell bodies in the spiral ganglion; swelling or atrophy of the stria vascularis; loss of spiral ligament fibrocytes; swelling or collapse of Reissner's membrane that may occur as a consequence of interference with the mechanisms that maintain the volume of cochlear fluids. It is also possible to obtain 'cytocochleograms' from cochlear sections by examining serial sections, reconstructing the length of the cochlear spiral and determining the absolute distance from the apex or base of any particular HC and of the other tissues in its vicinity. This technique is far more laborious than surface examination of whole mounts but gives a more complete picture of the overall pathology (Liberman, 1990).

4.3 Methods to Examine the Direct Effects of Ototoxic Agents

Many studies of the effects of ototoxic agents involve examination of structure and/or function after systemic application of the agent, a situation which mimics clinical conditions, particularly with regard to the important aspect of their distribution to cochear and vestibular tissues. However, such a regimen has disadvantages when investigating cellular or molecular mechanisms, not least that it is difficult to separate the initial interaction of the agent from the ensuing sequelae. Thus for mechanistic investigations, methods that permit the direct exposure of the tissue or cells of interest, either *in situ* or *in vitro*, have an important role to play.

Perfusion of the fluid spaces of the inner ear with ototoxic substances provides one means of assessing direct effects (Nuttall, 1981; Puel *et al*., 1990). In an anaesthetized animal, the cochlea is exposed and two small holes are made in the bony wall over the perilymphatic scalae. A solution of salts of similar composition to perilymph and containing the substance under study is gently pumped into the cochlea through one hole and flows out from the other. The effects can be determined by simultaneous monitoring of CM, CAP and/or OAE, and the reaction terminated at some specified point to examine the attendant structural correlates after perfusion of fixative.

To examine direct effects of ototoxic agents at a cellular level, HCs can be isolated and their morphological and physiological responses following exposure to agents of interest examined in the short term, over a few hours (Zajic and Schacht, 1987; Karlsson and Flock, 1990; Shehata *et al*., 1991; Clerici *et al*., 1993; Sha *et al*., 2001a). Explants maintained in organotypic culture, however, provide a means to examine over quite prolonged periods *in vitro* the responses to damaging agents of neuroepithelia in which the normal tissue architecture is retained. There are difficulties with culturing the mature organ of Corti, but the immature organ of Corti from early postnatal altricial rodents such as mice and rats (animals which are born deaf because the latter stages of cochlear maturation occur postnatally) can be maintained in organotypic culture and the differentiated HCs show responses to stimulation and to ototoxic agents broadly similar to those of HCs in mature tissue *in vivo* (Richardson and Russell, 1991; Richardson *et al*., 1997). Such cultures have been used to examine the effects of a number of different ototoxic agents as well as to test for agents that may prevent ototoxic damage (Richardson and Russell, 1991; Kotecha and Richardson, 1994; Zheng and Gao, 1996; Kopke *et al*., 1997). The mature vestibular organs can also be maintained in organotypic culture for some weeks, and show responses to ototoxins similar to those that occur *in vivo* (Li and Forge, 1995). Indeed, the vestibular sensory epithelia from humans, obtained during certain operative procedures, can be maintained in organotypic culture (Warchol *et al*., 1993), and this provides a rare opportunity for direct experimental studies of human inner ear tissues. In addition, inner ear tissues from nonmammalian vertebrates can be used to explore the effects of ototoxic agents upon HCs. The molecular and biochemical characteristics of all HC types are broadly similar, and the vulnerability of HCs to particular damaging agents is conserved across vertebrate classes. Thus, explant cultures of the inner ears from chickens have been used extensively to explore the molecular basis of HC susceptibility to ototoxins (Matsui *et al*., 2002; 2004; Mangiardi *et al*., 2004). The neuromast organs of the lateral line in fish also offer a potential model. HCs in the neuromasts of zebra fish are susceptible to aminoglycoside antibiotics in much the same way as are mammalian HCs (Williams and Holder, 2000). This has led to the possibilities of using the fish lateral line as a model for screening for agents that kill HCs (Ton and Parng, 2005; Ou *et al*., 2007; Chiu *et al*., 2008), and employing the power of zebra fish genetics to determine the molecular basis of susceptibility and resistance to ototoxic damage. The lateral line organs of living larval zebra fish are easily visualized by light microscopy, and particular fluorescent dyes, for example DASPEI (2-(4-dimethylamino) styryl)-*N*-ethyl pyridinium iodide),

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat066
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

are preferentially taken up into viable neuromast HCs. This provides an easy means to gain accurate counts of HC numbers and of the extent of HC death in response to potentially damaging agents.

5 EFFECTS AND ACTIONS OF OTOTOXIC DRUGS

A diverse range of therapeutically useful drugs and some environmental agents have been reported to be ototoxic (**Table 1**). For some of these chemicals the evidence for ototoxicity is limited; sometimes it derives from individual case reports, where other confounding factors may have contributed to the observed effect, and there are no confirmatory experimental studies in animals. The adverse effects of these agents vary between relatively minor reversible deficits to permanent functional impairment. Some, exemplified by the 'loop' diuretics and erythromycin, exert acute effects in the stria vascularis resulting in temporary hearing loss (temporary 'threshold shift' (TTS)). Others, such as salicylate and quinine, predominantly produce reversible impairment of HC function resulting in a TTS, which is often accompanied by tinnitus (the perception of sound in the absence of an auditory signal). These symptoms are completely relieved upon withdrawal of the drug. The third, and most significant, group of ototoxic agents cause death of the HCs and permanent hearing loss (permanent threshold shifts (PTSs)). Aminoglycoside antibiotics and *cis*-platinum, as well as organic solvents, fall into this category. Excess noise and ageing also cause HC death, and the effects of ototoxic drugs may afford models of the damaging activity of these nonchemical agents. In the cochlea, aminoglycosides, *cis*-platinum (Platinol-AQ, cisplatinum II, *cis*-diamminedichloroplatinum, *cis*-dichlorodiammine platinum II or *cis*-DDP) and trimethyltin (TMT) affect OHCs predominantly and high frequency (basal) regions of the cochlea are initially affected. They can also produce strial pathologies. Whereas the effects of aminoglycosides and *cis*-DDP generally develop only after repeated administration, effects of TMT become rapidly apparent after a single administration. Toluene and trichloroethylene, like aminoglycosides, damage OHCs following chronic exposures, but mid frequencies rather than high frequencies are initially affected. Carboplatin is of note because, although in many species the ototoxicity is similar to that of *cis*-DDP, in chinchillas at least it causes damage preferentially to IHCs rather than OHCs (Hofstetter *et al*., 1997). In fact it is the only agent yet identified that appears to cause

Table 1 Compounds known to be, or implicated in, ototoxicity (those discussed in detail in the chapter are indicated in bold lettering)

Classification	Compounds	Usual effects (for compound classes where ototoxicity is a frequently reported side effect)
Aminoglycoside antibiotics	Amikacin, dibekacin, dihydrostreptomycin, framycetin, gentamicin, kanamycin, neomycin, netilmicin, ribostamycin, sisomicin, streptomycin, tobramycin	Permanent hearing loss (progressive; high to low frequencies) Vestibular dysfunction
Macrolide antibiotics	Erythromycin, azithromycin, clarithromycin	Temporary hearing loss
Other antibiotics	Ampicillin, capreomycin, chloramphenicol, colistin (polymyxin E), minocycline, polymyxin B, rifampicin, vancomycin, viomycin	
Antitumour agents	***cis*-Platinum,** carboplatin, actinomycin, bleomycin, nitrogen mustards (e.g. mustine), misonidazole	Permanent hearing loss
Anti-inflammatory agents	**Salicylate (Aspirin),** fenoprofen, ibuprofen, indomethacin, naproxen, phenylbutazone	Temporary hearing loss and tinnitus?
Antimalarials	**Quinine,** chloroquine	Temporary hearing loss
Loop diuretics	Bumetanide, ethacrynic acid, frusemide (furosemide), piretanide	Temporary hearing loss
Iron chelators	Desferrioxamine	
Beta blockers	Practolol, propranolol	
Contraceptives	Medroxyprogesterone	
Industrial chemicals	Trimethyltin, toluene, trichloroethylene, styrene, xylene	Permanent hearing loss

damage preferentially to the IHCs. This has made it a useful tool to examine cochlear physiology (Trautwein *et al*., 1996; Liberman *et al*., 1997), but relatively little has been discovered about the basis of this selective action, which seems to be species specific, and it will not be discussed further. In mammals, the functional deficits resulting from the HC losses caused by these agents are permanent because, unlike the sensory epithelia in the inner ear in birds and other nonmammalian vertebrates (Cotanche, 1999; Staecker and Van De Water, 1998; Stone *et al*., 1998; Taylor and Forge, 2005), the organ of Corti does not spontaneously regenerate HCs to replace those lost, although the mammalian vestibular organs possess some capacity to regenerate HCs (Forge *et al*., 1993; 1998; Kopke *et al*., 2001).

The occurrence and extent of ototoxicity is to some degree dependent upon the dosing regime (or exposure conditions), but is compounded by the status of the patient receiving the drug, and multiple drug regimes. Malnourishment may increase sensitivity as may stress produced by infection (Forge and Schacht, 2000). Drug interactions can also result in much greater damage than would be expected from single drug regimes. A particular example is the interaction between loop diuretics and aminoglycosides that produces rapid, extensive HC loss (Taylor *et al*., 2008) and profound deafness. A number of ototoxic agents, including aminoglycosides, polypeptide antibiotics and antineoplastics, are also nephrotoxic, so that possible damage to the kidney may result in reduced drug clearance and higher serum levels potentially increasing the risk to the inner ear. In addition, certain genetic factors may predispose to ototoxin-related damage. Individuals under similar conditions and with similar drug-dosing regimes differ in their sensitivity to ototoxic side effects. Some of the mutations associated with such predisposition to drug-induced hearing loss have been identified, such as the 'A1555G' mutation in a mitochondrial gene that results in enhanced sensitivity to aminoglycosides (Prezant *et al*., 1993; Usami *et al*., 1998). For these reasons it is not always possible to predict a likely effect following administration of a potentially ototoxic drug.

The classification of ototoxic chemicals into the three broad groups as defined above provides a basis for illustrating the selective action of these different agents upon the inner ear.

5.1 Agents Affecting the Ion-Transporting Epithelia

Those agents whose primary site of action is on the ion-transporting epithelia, the stria vascularis in the cochlea and the vestibular dark cells adversely affect endolymph composition and, in the case of the stria vascularis, the EP. Such agents, exemplified by the loop diuretics, generally cause acute, completely reversible affects after a single drug administration (Rybak *et al*., 1991), although some cases of permanent deafness have been attributed to diuretic administration (Rybak, 1988). The stria vascularis has one the highest rates of oxidative metabolism in the body (Wangemann and Schacht, 1996), with oxygen delivered from the intraepithelial blood supply, so agents that induce anoxia or ischaemia will affect strial activity. Aminoglycoside antibiotics (Forge *et al*., 1987) and *cis*-DDP (Laurell and Engstrom, 1989), may induce permanent strial pathologies after prolonged drug administration although this does not necessarily correlate with effects on EP (see later).

All loop diuretics, that is those diuretics whose principal site of action is in the ascending limb of the loop of Henle, including ethacrynic acid, furosemide (frusemide), bumetanide and piretanide, produce a transient hearing loss across most of the frequency range. This usually occurs following intravenous administration of large doses. The effects are rapid in onset, within minutes or hours, and persist for some hours, but are usually completely resolved within one day if the drug is discontinued. Repeated diuretic administration does not appear to cause permanent damage to the inner ear.

Histological studies of the temporal bones from patients who have died while on diuretic treatment (Matz, 1976; Arnold *et al*., 1981) have shown extensive oedema and swelling of the stria vascularis. Experimental studies on animals have confirmed the stria as the principle site of action (**Figure 5C**), and that diuretics produce a rapid, reversible decline in EP. In experimental studies, EP is seen to decline within seconds of intravenous injection, or minutes following intraperitoneal injection, falling from the usual $+80\,\text{mV}$ to negative values as low as about $-40\,\text{mV}$, the K^+ diffusion potential (Pike and Bosher, 1980; Forge, 1981; Lee and Harpur, 1985). The rate of decline and the level of suppression are dependent upon the dose of drug administered (Rybak *et al*., 1991). The EP then recovers over a period of a few hours but takes several hours to return to normal levels after a single administration. In parallel with the decline in EP an extensive oedema occurs; the extracellular spaces become grossly enlarged (**Figure 5C**) and strial thickness can almost double. This oedema is also reversible, resolving within about two to four hours, prior to complete recovery of EP (Pike and Bosher, 1980; Forge, 1981). The decline in EP correlates with suppression of CM and CAP (Forge and Brown, 1982) and of OAEs, a finding that provides evidence that EP is the power that drives the active mechanical responses of the organ of Corti in response to sound (Ruggero and Rich, 1991). This illustrates the importance of EP maintenance to the cochlear amplification mechanism and why damage to the stria will cause hearing impairment.

The rapid onset of their effects suggests that the diuretics gain direct access to their site of action through entry from the strial vasculature. This mode of entry would give direct access to the basolateral membranes of the marginal cells. The development of oedema suggests that diuretics inhibit the ion-transporting processes: ions accumulating in the extracellular spaces would be confined by the tight junction sealing between basal cells and those between marginal cells, resulting in osmotic uptake of fluid. In the kidney, diuretics act on a Na-K-2Cl co-transporter. Using an *in vitro* perfusion system, Marcus *et al*. (1987) established that in both the vestibular dark cell layer (Marcus and Marcus, 1989) and isolated strial marginal cell epithelia preparations (Wangemann *et al*., 1995) diuretics act at the basolateral membranes of the dark cells and marginal cells to affect Cl^- transport by interaction with a Na-K-2Cl co-transporter. The ENaC3 (epithelial sodium channel 3)-type Na-K-2Cl co-transporter is expressed in the lateral wall of the cochlea (Ikeda *et al*., 1997). It is currently thought, therefore, that the diuretics reversibly inhibit the action of an electroneutral Na-K-2Cl co-transporter, in the basolateral membranes of strial marginal cells and vestibular dark cells, leading to inhibition of ion transport into endolymph.

Na^+-K^+-ATPase is also present at high concentration on the basolateral membrane of marginal cells. Inhibition of this might have a similar effect as inhibition of the co-transporter. Potassium cyanide, along with its other actions in the body, causes TTS with a symptomatology similar to that of loop diuretics, thought to result from inhibition of marginal cell Na^+-K^+-ATPase (Tawackoli *et al*., 2001). Macrolide antibiotics such as erythromycin also produce effects similar to those of diuretics: generally TTS (Brummett, 1993) of the order of about 50 dB maximum across all frequencies (McGhan and Merchant, 2003) following intravenous administration of a large dose; in animals, a rapid, dose-dependent decline in EP—though not as great a suppression as with diuretics (Kobayashi *et al*., 1997); an action on the basolateral side of the marginal cells affecting ion transport by these cells shown in isolated tissues maintained *in vitro* (Liu *et al*., 1996); and, consistent with inhibition of ion transport in the stria vascularis, sections of temporal bone from patients who have died during a course of erythromycin therapy have shown extensive oedema of the stria vascularis (McGhan and Merchant, 2003). However, the precise site of action of the macrolides in the stria vascularis has not yet been identified.

5.2 Agents Causing Reversible Effects on HCs

Salicylates and quinine cause TTS across most of the detectable frequency range, and tinnitus. Dizziness is reported as a symptom of their use, but there have been no experimental studies of their possible effects on the vestibular system. The ototoxic effects of these agents are generally reversible when treatment ceases; salicylates are rarely associated with permanent hearing loss (Garetz and Schacht, 1996). Although it has been reported that excessive doses of quinine or chloroquine may result in permanent deafness (McKenzie *et al*., 1968; Toone *et al*., 1965), quinine-induced ototoxicity is also usually completely reversible both in healthy volunteers and in patients with malaria (Tange *et al*., 1997).

Salicylates produce TTS across all frequencies simultaneously, indicating effects along the entire cochlear spiral. The shifts are usually no more than about 40–60 dB and almost equal across the frequency range or somewhat greater at higher frequencies. These symptoms are completely reversible within one to three days following withdrawal of the drug and usually develop only at the high dosage levels used in treating rheumatoid arthritis, 2–5 g day^{-1} (Garetz and Schacht, 1996). Salicylate enters perilymph rapidly after systemic administration, peak levels in perilymph being reached one to two hours after injection. There is a linear relationship both between the concentration in perilymph and the serum concentration (Jastreboff *et al*., 1986; Boettcher *et al*., 1990), and between the deterioration of CAP threshold and the perilymph salicylate concentration. Thus, the degree of TTS is quantitatively related to salicylate plasma concentration. These findings indicate that salicylate penetrates the blood–perilymph barrier readily, but the mechanisms of entry have not been examined.

Experimental studies in animals have shown that salicylate inhibits CM responses and CAP only at low stimulus intensities; responses to stimuli above about 60 dB appear to be unaffected. The tuning of responses of individual nerves to their characteristic frequency also is lost (Stypulkowski, 1990; Kujawa *et al*., 1992). In addition, OAEs are reversibly suppressed in humans (Long *et al*., 1986; Martin *et al*., 1988), and animals (Stypulkowski, 1990; Kujawa *et al*., 1992). These findings suggest effects on OHCs and inhibition of the activity that produces signal amplification in the cochlea. EP is unaffected following salicylate administration (Puel *et al*., 1989; Stypulkowski, 1990), and effects of salicylates on cochlear vasculature and the activity of the stria vascularis in generating EP are not considered to be a significant factor in their ototoxicity. Rather, OHCs appear to be the primary target of salicylate following its entry into the perilymph and access to a site of action on the OHC basolateral membrane. Investigation of basilar membrane mechanical responses to sound stimulation during salicylate perfusion *in vivo* (Murugasu and Russell, 1995) have confirmed direct effects on OHCs that adversely influence their active responses, and thus, auditory sensitivity. Salicylates inhibit electrically driven motile responses of isolated OHCs (Shehata *et al*., 1991; Tunstall *et al*., 1995). It is these responses that *in vivo* are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat066
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

thought to underlie the cochlear amplification mechanism (Ashmore and Kolston, 1994; Dallos, 1996) and that are driven by the prestin motor protein, unique to the OHC and packed into its basolateral plasma membrane (Dallos and Fakler, 2002). There is evidence that reversible interactions with anions produce conformational changes in prestin that result in the reversible electrically driven changes in OHC length (Oliver *et al*., 2001). Salicylate, an anion, appears able to interact with prestin and block this electromotility (Oliver *et al*., 2001).

Likewise, quinine, at therapeutic doses of about 200–300 mg day^{-1}, can cause threshold shifts at all frequencies, effects which are usually entirely reversible, disappearing upon withdrawal of the drug (Tange *et al*., 1997). As with salicylate, quinine enters perilymph rapidly (Alvan *et al*., 1991), reaching perilymph concentrations directly related to serum concentrations, and direct perfusion of quinine into the perilymphatic space produces decreases in CM and CAP, the magnitude of which is related to perilymphatic concentration of the drug between 10 and 100 μM (Puel *et al*., 1990). OAEs are also affected but EP is unchanged (Puel *et al*., 1990; McFadden and Pasanen, 1994), which considered together indicate a direct effect on OHCs. Consistent with this, electron microscopy of the organ of Corti in quinine-treated animals showed reversible morphological damage exclusively in OHCs (Karlsson *et al*., 1991). Isolated OHCs exposed to quinine undergo slow length changes (Karlsson and Flock, 1990), which, if they occurred *in vivo*, might decouple stereocilia from the tectorial membrane and reduce sensitivity to stimulation. However, these *in vitro* responses were elicited only at concentrations of quinine of between 4 and 5 mM, much higher than those which affect electrophysiological activity of the organ of Corti. In addition, unlike salicylate, quinine affects CM and CAP responses across all stimulus intensities, not just the lower ones, indicating a site(s) of action different from salicylate and not confined to the cochlear amplifier. It has been reported that at the lowest concentrations at which effects can be detected, about 0.05 mM, quinine does not affect OHC responses, OAE or CM, but produces a reversible elevation in threshold for the CAP, which derives from stimulation of IHCs, without affecting neural tuning (Mulheran, 1999; Zheng *et al*., 2001). Tuning derives from the activity of OHCs that produces amplification. This suggests that the initial site of action of quinine may be on the IHCs, synaptic transmission at the base of IHCs, or/and upon the spiral ganglion neurons themselves, with OHCs affected only at higher concentrations. An effect of quinine at the HC synapse could also explain the vertigo, as the ready entry of the drug into perilymph would enable it to gain access to the basolateral membranes of vestibular HCs. It has been found that quinine and its derivatives, such as chloroquinine, block nicotinic acetylcholine receptors (nAChRs) composed of $\alpha 9\alpha 10$ subunits (Ballestero *et al*., 2005), which is the predominant acetylcholine receptor subunit composition of HCs in both chicks and mammals (Fuchs, 1996; Jagger *et al*., 2000). Acetylcholine is the predominant efferent neurotransmitter in the cochlea. Efferent fibres synapse both with the afferent neurons of IHCs just below the HC body, modulating the responses of those afferent neurons to stimulation, and also directly with OHCs whose activity is regulated by the efferent system. Thus, at least some of the effects of quinine may result from its action at these efferent synapses. Nevertheless, since primarily CAP alone is affected at lower drug concentration, the initial effects of quinine may be at the level of the generation of action potentials by IHCs (Ballestero *et al*., 2005).

At present, it is not clear whether the tinnitus, which often accompanies the hearing impairment associated with salicylate and quinine, results from the same sites and modes of action, or represents action(s) at other yet-unidentified sites. The release of efferent control of afferent responses that may occur with quinine could lead to an increase in the spontaneous afferent neural activity (i.e. neural stimulation in the absence of an acoustic signal) that could be perceived as a sound signal. With salicylate, the alterations of cochlear mechanics resulting from inhibition of electromotility may affect the mechanical relationship of the OHCs and IHCs in such a manner as to stimulate activity in the IHCs. It has been shown that following systemic salicylate administration there is an increase in the spontaneous firing rate of auditory neurons (Evans and Borerwe, 1982). Although this may result from direct effects upon the afferent synapses, in other systems salicylates usually decrease and eventually block neural excitation (Neto, 1980). The perceived tinnitus in humans following systemic salicylate treatment is reported to be of high frequency, but as salicylate in perilymph has access to the entire organ of Corti and causes threshold shifts across most of the frequency range, it remains to be explained why it is only neurons which respond normally to high frequencies that show an increased spontaneous firing rate (Evans and Borerwe, 1982; Stypulkowski, 1990).

5.3 Agents that Cause Permanent Hearing Loss and Balance Disorders

The third, broad group of agents are those whose administration causes permanent hearing impairment and/or balance dysfunction resulting from death of the sensory HCs. The ototoxicity of most of these agents usually develops only after repeated systemic administration; single systemic application does not generally produce side effects.

5.3.1 Aminoglycoside Antibiotics

The aminoglycoside antibiotics constitute the clinically most important group of ototoxic agents (see Forge and Schacht, 2000 for a detailed review). They are toxic to HCs in all vertebrate classes. Indeed the nematocyst cells in marine and aquatic invertebrates, which are mechanotransducing cells thought to be evolutionarily related to vertebrate HCs, are also affected by aminoglycosides (Watson *et al*., 1997). Although all aminoglycosides are potentially both cochleotoxic and vestibulotoxic, the different aminoglycosides exhibit differences in their toxic potential and organ preference. Assessment of the degree and time course of suppression of CM following cochlear perfusion with different aminoglycosides (Schacht, 1986), and analysis of the extent of damage to cultured explants of the organ of Corti directly exposed to different aminoglycosides (Kotecha and Richardson, 1994) have established similar rank orders of cochleotoxic potency for different aminoglycosides. These have indicated that neomycin is the most toxic; gentamicin, kanamycin and tobramycin less so, and amikacin and netilmicin least toxic, but such differential toxicity may not apply in a clinical setting. Streptomycin and gentamicin are considered more vestibulotoxic than cochleotoxic to humans, whereas amikacin and neomycin are primarily cochleotoxic in the human inner ear. The reasons for such preferences are not known, but it is not related to any site-specific uptake mechanism or drug levels in the tissues (Forge and Schacht, 2000). There are also species differences in susceptibility to the different aminoglycosides (Harpur, 1987), of which dihydrostreptomycin provides the most striking example (Hawkins *et al*., 1977; Hawkins and Johnsson, 1981; Stebbins *et al*., 1981). In early clinical use dihydrostreptomycin proved to be markedly toxic to the human cochlea. However, the patas monkey (*Erythrocebus patas*) seems to be the only laboratory animal with a cochlea which is sensitive to the toxic action of dihydrostreptomycin. A significant feature of the response of the patas monkey to dihydrostreptomycin (Hawkins *et al*., 1977) is the fact that the hearing loss progresses long after the cessation of drug administration, resembling the situation in man. Streptomycin also produces hearing loss in patas monkeys when given at a dose which has been shown not to be toxic in man when administered for prolonged periods (Hawkins and Johnsson, 1981). However, in the pigtail macaque monkey (*Macaca nemestrina*) treated with large doses of dihydrostreptomycin for a prolonged period, there was only a very modest shift in threshold at the highest frequency tested, and less than 10% of the HCs were absent at the basal end of the cochlea (Hawkins *et al*., 1977).

The effects of aminoglycosides usually become manifest only after days or weeks of parenteral treatment. Single systemic administrations are not normally damaging to the inner ear, although topical application of a single dose of the drug to the middle ear cavity can almost immediately initiate the progressive damage observed after chronic systemic treatment (Wersäll *et al*., 1969; Forge *et al*., 1998). The severity of the effects increase progressively with time, continuing after drug administration has been stopped; insidiously, in some cases, hearing impairment may not even begin until after treatment has ceased. The initial effect in the cochlea is a hearing loss confined to the high frequencies (Fausti *et al*., 1984) indicating HC damage in the most basal region of the cochlea. The hearing loss then continues progressively to include successively lower frequencies, indicating a spread of the damage to HCs apicalwards along the organ of Corti spiral and involving frequencies in the human speech range to cause a permanent communication disability. A bilateral loss of 20 dB at two or more adjacent test frequencies is accepted as a hearing impairment (Wright, 1998). However, most clinical audiometry usually covers the frequency range only from about 8 kHz downwards, whereas in the average person the high-frequency limit is about 16–18 kHz, so that the initial ototoxic effects of the drug will be missed unless high frequency audiometry is used. Vestibular damage from systemic aminoglycoside administration results in severe unsteadiness which becomes worse in the dark. Perception of unreal movement, usually elicited by head motion, can also occur. Objective clinical assessment is, however, difficult and limited (Wright, 1998).

The degree of vestibular or auditory impairment with aminoglycosides may depend upon the drug itself, the unit or total dose, the route and period of administration and the patient's age or pathological state; for example, the risk is substantially increased by impaired renal function (Jackson and Arcieri, 1971). The situation is further complicated in that the aminoglycosides, to varying degrees, are nephrotoxic. A predisposition to aminoglycoside ototoxicity is also conferred by mutations in the gene that encodes 12s ribosomal RNA of mitochondria. The 'A1555G' missense mutation (an adenosine to guanosine substitution at base position 1555) (Cortopassi and Hutchin, 1994; Fischel-Ghodsian *et al*., 1997), a thymidine to cytosine mutation at 1095 (Zhao *et al*., 2004), cytosine to thymidine missense at 1494 (Chen *et al*., 2007b) and a cytosine insertion at position 961, all appear to confer particular sensitivity to aminoglycosides. In some cases profound hearing loss may occur after only a single parenteral injection rather than the usual situation where hearing loss occurs only after chronic administration. The presence of these mutations in the mitochondrial chromosome has been identified through maternal inheritance patterns. The A1555G mutation is prevalent in Chinese, Arab–Israeli, Japanese and North American families (Prezant *et al*., 1993; Usami *et al*., 1998). A carrier rate of 17% of those developing aminoglycoside-induced hearing loss has been estimated. However, the mutations appear to affect only the cochlea's sensitivity to aminoglycosides; there is no

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

enhanced effect on the vestibular system, and no other organ of the system is affected. The reasons why only cochlear HCs are affected or how the mutation enhances susceptibility are currently not known.

Aminoglycosides may also present a problem for patients with tuberculosis or cystic fibrosis. These antibiotics were first developed for use against tuberculosis and are still part of combination drug therapy against it. However, it has been estimated that as many as 80% of patients receiving aminoglycosides chronically to treat tuberculosis develop ototoxic side effects (Brouet *et al*., 1959). Cystic fibrosis patients also receive aminoglycosides on continuous, or frequently repeated, regimes to combat pneumonia. The incidence of hearing loss in these patients has been recorded as at least 16% using audiometric testing (Mulherin *et al*., 1991), but more sensitive measures using OAEs to examine OHC activity suggest a much higher proportion (Mulheran and Degg, 1997). A further consideration is that aminoglycoside antibiotics can cross the placenta. Thus there is a potential to cause deafness in the foetus. Studies of development in animals have suggested a 'critical period' in development, when sensitivity to the ototoxic agent is greatest, at around the time of the onset of auditory function during development. The existence and timing of a critical period in humans has not been identified, but based on anatomical findings comparing development of the human inner ear with that of experimental animals it has been estimated that a critical period for the human cochlea may be present in about week 18–20 of gestation. An ototoxic action of aminoglycosides during intrauterine life of human embryos has been reported (Rasmussen, 1969).

5.3.1.1 Pharmacokinetics

There is a linear relationship between serum concentration of aminoglycoside and the perilymph concentration, at least for gentamicin (Federspil, 1981) and ribostamycin (Harpur *et al*., 1981), but aminoglycosides enter perilymph relatively slowly, the peak concentration after extravascular injection to guinea pigs occurring much later in perilymph (about four hours) than in serum (about 15–30 minutes). Additionally, clearance from perilymph is delayed and the drug persists in the inner ear for some time. The half-life of aminoglycoside in the inner ear has been estimated as more than 30 days (Tran Ba Huy *et al*., 1986), whereas half-life in serum is approximately 3–5 hours. Harpur and Gonda (1982) studied the full kinetic profile of ribostamycin in perilymph and serum after a single dose and after the last of 14 doses under conditions of unchanged renal function. There was no accumulation of the drug in perilymph despite a long half-life (15 hours) after a single dose. This was attributable to a marked increase in the rate of transfer from perilymph to serum after multiple dosing. This indicates an effect of the drug on the cochlea that enhances its elimination from perilymph, but how this occurs is not known. The peak level reached in perilymph after multiple dosing has been reported to be about 50–250 μM (Harpur and Gonda, 1982; Ding *et al*., 2003). As pointed out by Brummett and Fox (1982), the concentration of aminoglycosides in perilymph associated with complete HC destruction following chronic drug administration is much lower than the cytotoxic drug concentration *in vitro*. They concluded that the cytotoxic effect of aminoglycosides on the HCs is highly selective.

Aminoglycosides also enter endolymph, but only after a prolonged period following entry into perilymph. Careful analyses of perilymph and endolymph during and after constant aminoglycoside infusions (Tran Ba Huy *et al*., 1983b; 1986) revealed drug in perilymph 45 minutes after the start of an infusion, with a continuing rise for up to 48 hours, but no drug was detectable in endolymph until after 10 hours and then there was very little further accumulation. This suggested that aminoglycosides probably enter endolymph from perilymph rather than directly from the strial vasculature. After termination of a 48 hour infusion, the drug persisted in endolymph for up to 15 days without significantly declining. It was thought that the slow elimination of the drug might be accounted for by slow release of the drug from binding sites in cochlear tissues. Redistribution of the drug into secondary cellular compartments was evidenced by the complex multiphase elimination kinetics. The half-lives of elimination from cochlear tissues were extremely long, varying from 10 hours to 30 days depending on the duration of drug administration. This may suggest that redistribution of the drug into susceptible cells, or cellular compartments, was an important factor in the development of the delayed toxicity. However, there are no obvious differences between different aminoglycosides in their ability to enter endolymph (Henley and Schacht, 1988), indicating that differential ototoxicity is not related to differential uptake of aminoglycosides into endolymph. Furthermore, *in vivo* pharmacokinetic studies (Dulon *et al*., 1986) of a number of drugs with varying vestibulotoxic and cochleotoxic potentials indicate that their toxicity is not related to different tissue concentrations. Dulon *et al*. (1986) found similar cochlear and vestibular drug levels for amikacin, gentamicin and netilmicin—drugs which exhibit quite different cochleotoxic and vestibulotoxic potentials.

The persistence in perilymph and delayed entry to endolymph may account for the delayed effects of aminoglycosides. The delayed responses and the progressive effects may result from slowly increasing endolymphatic concentrations of the drug to critical levels that can cause damage. Several pieces of evidence from a range of experimental models suggest that aminoglycosides affect HCs through access from their endolymphatic (apical) surface (see below).
