1 INTRODUCTION

Pesticides are a group of substances with heterogeneous toxicity, whose desired activity is the killing of unwanted living organisms, in a more or less specific manner. In order to review the toxicity of pesticides, some method of classification is needed. In this chapter, they are divided by class of action, into insecticides, fungicides and herbicides, molluscicides and rodenticides, these groups being subdivided by chemical group. The terms acaricide or miticide are used for substances that kill mites: most are also insecticides. Some chemical groups have more than one type of pesticidal activity, and therefore appear in more than one category, for example, the carbamates and organophosphates (OPs) which include insecticides, herbicides and fungicides and the phosphides used as both fumigants and rodenticides.

The very definition of pesticides may vary, particularly in relation to regulatory affairs. Some veterinary products, for example, compounds used as ectoparasiticides on cattle, sheep and domestic pets, are regulated in many countries under different legislation than when the same active ingredients are used on arable commodities. Moreover, pesticide legislation often controls substances such as plant growth promoters and defoliants: some of these will be briefly discussed here.

There are a number of possible ways in which humans can be exposed to pesticides, thus the toxic effects of pesticides may have consequences for consumers of food, as well as farmers and other applicators. Moreover, pesticides used domestically in wood preservation or as household insecticides may be important sources of exposure of the general public. Furthermore, pesticides may get into the water supply. These various routes of exposure may be isolated or may need to be considered in combination when assessing potential effects in humans. It should also be remembered that the more acutely toxic pesticides have been used for suicide and murder.

The effects of pesticide residues in food and water probably cause the greatest public concern. However, reports of clinical poisoning by residues seem to be extremely rare, certainly by comparison with occupational intoxication and deliberate and accidental poisonings. The reasons for this are complex, but may reflect a true rarity of poisoning or the fact that occupational poisonings are far more easily identified. Occupational intoxications would be expected to be more severe than food-borne poisonings, and the proximity of cause and effect in occupational poisoning certainly makes diagnosis easier. Food-borne pesticide intoxication, especially where clinical signs are nonspecific or trivial, would probably pass unnoticed or may not be attributed to pesticides. This would be particularly likely where the signs and symptoms could be ascribed to a microbiological cause. Acute poisoning, where pesticides had been used in accordance with regulations, seems likely to be a very uncommon occurrence, if it occurs at all, at least in developed countries. The problem of consumers who eat high levels of some foodstuffs is taken into account when residue levels are pronounced to be toxicologically acceptable by comparison with the acceptable daily intake (ADI) or the more recently developed concept of the 'acute reference dose (ARfD)'. Bearing in mind that, as a minimum, a 100-fold safety factor is used in calculating ADIs and ARfDs from animal studies (WHO, 1990a), residues of many multiples of the maximum residue limit (MRL) would probably be necessary to produce acute poisoning. Thus it would seem highly unlikely that extreme consumption, by itself, could give rise to pesticide poisoning from approved uses. In fact, analysis of reported consumer poisonings by pesticides shows that most reported instances occur from:

1. Spillage of pesticides on to food during storage or transport
2. Eating grain or seed potatoes treated with pesticides, where the food article was not intended for human consumption
3. Improper application of pesticides or failure to observe pre-harvest intervals.

The pesticides responsible have often been ones with low LD_{50}s (<20 mg (kg body weight)$^{-1}$), such as the insecticides endrin, parathion or aldicarb or the rodenticides such as thallium sulfate or sodium fluoride. Other pesticides that have produced morbidity by ingestion with food include organic mercury fungicides (Ferrer and Cabral, 1991).

Weighed against the disadvantages of pesticides that accrue from their toxic effects is the fact that insects and fungi are important sources of agricultural loss and give rise to much damage to buildings, particularly in those countries such as the USA and Canada, where construction is often of wood. Furthermore, many insects carry diseases such as malaria and sleeping sickness, which in the absence of control measures may render land uninhabitable or agriculturally unusable; despite control measures these diseases continue to be major sources of morbidity and mortality. In addition, fungal contamination of agricultural produce can give rise to such conditions as ergotism and aflatoxicosis.

The key to a successful pesticide is selective toxicity. An ideal pesticide will interfere with a biological system in the pest which has no counterpart in nontarget species; this is the advantage of the juvenile-hormone-analogue insecticides. In the case of agricultural insecticides, the pesticide should be toxic to insects, but less toxic to plants, to humans and to other nontarget organisms. Thus, the neuroactive insecticides exploit the relative accessibility of the insect nervous system to xenobiotics,

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

when compared to humans, together with the lack of a nervous system in plants.

In this text it is not possible to give more than an outline on the toxicology of the main groups of pesticides, pointing out major problems which occur in regulation of the use of pesticides and allowable residues in food and the treatment of poisoning.

1.1 Nomenclature of Pesticides

Pesticides have, as well as chemical names, national (for example British Standards Institute (BSI)) common names, as well as International Organization for Standardization (ISO) common names (ISO, 1965; ISO, 1981). ISO names are allocated in the English and French languages and the English language ISO name is not always the same as the BSI or US common name. A few pesticides are used as drugs, either in human or veterinary medicine. As such they have international nonproprietary names (INNs). In some cases these differ from the ISO pesticide names; thus trichlorfon, a pesticide, is the same as metrifonate, a pharmaceutical used in human medicine. INNs are bestowed by the World Health Organization (see WHO, 2008). Pesticides are commonly sold under trade names, given by their manufacturers.

2 INSECTICIDES

Many insecticides affect the nervous system of insects and, since many have some activity against the mammalian nervous system, in man, the neurotoxic effects of insecticides are often prominent. The main groups of insecticides are listed in **Table 1**.

2.1 Organochlorines

This group was formerly of great importance and includes dichlorodiphenyltrichloroethane (DDT), hexachlorocyclohexane (HCH), the cyclodienes, dieldrin, endrin, heptachlor and toxaphene. However, the use of organochlorines (OCs) has, in recent years, been severely restricted in most countries. This has mainly been due to the persistence of OCs in the environment and wildlife, as well as in humans, rather than to their toxicity to mammals. Despite the fact that OCs are less used than formerly, their toxicology is still important because they continue to be present in the environment and because, in foodstuffs on sale in, or exported from, developing countries, residues, sometimes above international maximum residue limits (MRLs), continue to arise (Working Party on Pesticide Residues, 1997). OCs are excreted in breast milk (Siddiqui and Saxena, 1985) and their persistence is shown by the continuing presence of OCs in human milk, though usually at declining levels (Working Party on Pesticide Residues, 1982). The most recently used OC in agriculture was lindane, the γ isomer of HCH, but DDT is still used in vector control for malaria (see Rogan and Chen, 2005; Ross, 2005; WHO, 2007).

The most prominent effects of the OCs are those referable to the nervous system, where OCs have an effect on Na^+ channels. DDT produces tremor and incoordination in lower doses and convulsions in high doses, with a clear incremental dose response. By contrast, HCH and the cyclodienes may produce convulsions as the first sign of intoxication, as well as fever, by a central effect possibly linked to disturbances in γ-aminobutyric acid (GABA)-mediated inhibitory neurotransmission (Cole and Casida, 1986). OCs have been associated with a chronic toxicity syndrome, which includes apathy, headache, emotional lability, depression, confusion and irritability (Proudfoot, 1996).

OC poisoning is treated symptomatically and diazepam is usually used to deal with the convulsions.

2.1.1 Carcinogenic Effects of OCs

Chlorinated hydrocarbons produce microsomal enzyme induction and characteristic histopathological changes in the livers of experimental animals (hepatocellular hypertrophy with accumulation of lipid). If administration is prolonged and at high enough doses, liver nodules may appear and tumours are seen in rodents. These tumours do not appear to be indicative of genotoxic carcinogenicity. In human populations OCs have been linked with non-Hodgkin's lymphoma (Axelson, 1987; Cantor *et al*., 1992) but where a link between non-Hodgkin's lymphoma and OC exposure has been observed, the association has been weak, and some studies, for example, Rothman *et al*. (1997) have shown no such association. Some OCs have weak oestrogenic properties. The suggestion has been made that exposure to OCs is related to increased susceptibility to breast cancer. Some epidemiology studies showing a link between high fat levels of DDT/DDE (1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene) and breast cancer and there is a similar link between β-HCH and breast cancer. The studies linking DDT/DDE and breast cancer were summarized by Key and Reeves (1994), who concluded that it was unlikely that DDT increased the risk of breast cancer. Suspicion has also fallen upon dieldrin, where Høyer *et al*. (1998) showed a doubling in the risk of developing breast cancer in women with the highest serum diedrin concentration compared to those with the lowest; moreover, Høyer *et al*. (2000) found that high serum dieldrin was associated with an adverse effect on survival and breast-cancer-specific survival. A review of the postulated association between OCs and cancer found

Table 1 The main groups of insecticides

Group	Subgroups	Examples
Organochlorines (OCs)	—	DDT Endrin Aldrin Dieldrin Endosulfan γ-Hexachlorocyclohexane (lindane)
Anticholinesterases	Organophosphates (OPs)	Malathion Fenitrothion Dichlorvos Diazinon
	Carbamates	Carbaryl Aldicarb
Cholinergic group	Nicotine and the neonicotinoids	Nicotine Imidacloprid
Pyrethrins and synthetic pyrethroids	—	Pyrethrum Permethrin Cypermethrin Flumethrin
Natural compounds, other than pyrethrins and nicotine	—	Abamectin Ivermectin Rotenone
Substances which interfere with systems specific to insects	Juvenile hormone analogues Chitin synthesis inhibitors Ecdysone agonists	Cyromazine Diflubenzuron Tebufenozide
Miscellaneous synthetic insecticides	Formamidine $GABA_A$-blocker	Amitraz Fipronil

no convincing evidence of an association (Committee on Carcinogenicity of Chemicals in Food, Consumer Products and the Environment, 2004).

2.1.2 Specific OCs

2.1.2.1 Lindane (γ-HCH)

Lindane is an OC insecticide, used as a wood preserver, in arable agriculture and in human and veterinary medicine as an ectoparasiticide. It is the γ isomer of 1,2,3,4,5,6-hexachlorocyclohexane, which is sometimes known as benzene hexachloride. 1,2,3,4,5,6-hexachlorocyclohexane has eight stereoisomers of which the α, β and γ are the most important. Of these isomers, only lindane (>99% γ isomer), is still approved in the West, but in some countries preparations of lesser purity continue to be available and these contain other isomers. Lindane is less biologically persistent than DDT and, in rodents, the α and β isomers of HCH accumulate more readily than does lindane (Eichler *et al*., 1983). As well as differences in pharmacokinetics between the isomers, there are qualitative differences in toxicology: thus the effect of lindane on the central nervous system (CNS) is stimulatory, causing convulsions, whereas the α and β isomers have a depressant effect (Coper *et al*., 1951; van Asperen, 1954).

As with other OCs, lindane produces histopathological changes in the livers of experimental animals. The mutagenicity of lindane *in vitro* and *in vivo* has been reviewed and the preponderance of evidence is that the compound is not mutagenic (FAO/WHO, 1990). Over the years its usage on arable crops and in veterinary medicine has become more and more restricted, but its uses have long outlived those of DDT.

The European Union decided to withdraw lindane in 2000 (European Commission, 2000), while the United States Environmental Protection Agency (USEPA) cancelled all remaining registrations for lindane in 2006 (USEPA, 2006).

2.2 Anticholinesterases

Two groups of anticholinesterases, the OPs and the carbamates, are widely used as agricultural insecticides and veterinary medicines (Marrs, 1996); in addition

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat140
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

some anticholinesterases are used as human drugs, for example, malathion in the treatment of headlice and metrifonate in schistosomiasis (Aden-Abdi *et al*., 1990). Several carbamates are used in human medicine, for example, pyridostigmine in myasthenia gravis. The anticholinesterases are often more acutely toxic than the OCs, although some OPs, especially the P=S phosphorothioates (see below), are of low acute mammalian toxicity. The action is respectively to phosphorylate or carbamylate esterases, particularly the enzyme acetylcholinesterase, causing accumulation of the neurotransmitter, acetylcholine. A variety of cholinergic symptoms and clinical signs occurs at parasympathetic effector sites, including bronchorrhoea, salivation, constriction of the pupil of the eye and abdominal colic. Sympathetic effects can also ensue, together with signs of central nervous system involvement, such as confusion and apprehension. Convulsions will occur in severe poisoning. Actions at the neuromuscular junction result in muscle fasciculation and later paralysis. The terminal event in fatal poisonings seems to be respiratory paralysis, which may be of central or peripheral origin, although with pesticidal OPs both will usually contribute. It is generally believed that, provided the patient survives (without suffering cerebral anoxia), the symptoms and clinical signs of the cholinergic syndrome of anticholinesterase poisoning are reversible. Moreover, histopathological changes from the anticholinesterase effects of OPs and carbamates are *per se* exiguous and, in acute lethal poisoning, specific pathological changes are usually not noteworthy. However, there is recognition that survival after high, perilethal doses of OPs and perhaps also lower doses and after overt carbamate intoxication may result in long-term clinical and electrophysiological changes in the central nervous system.

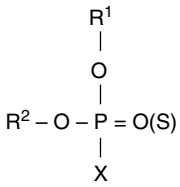
It is often stated that the main difference between the OPs and the carbamates is that the former produce irreversible inhibition of acetylcholinesterase, whilst the latter produce reversible inhibition: this is only true in a relative sense. With certain exceptions (see below), reactivation of the dialkylphosphoryl–enzyme complexes produced by OP-induced inhibition of cholinesterases is produced by hydrolysis, but the stability of the phosphorylated enzyme is generally greater than that of the carbamylated one, so that carbamate poisoning is less long-lasting.

The numerous cholinesterases in the body show different intensities of sensitivity to inhibitors. Although by no means always the case, plasma cholinesterase is usually the cholinesterase most open to inhibition and it reactivates slowly (Skrinjarič-Spoljar *et al*., 1973), so that this enzyme is a useful marker of exposure. However, correlation with cholinergic symptoms is poor, so that plasma cholinesterase inhibition can be taken as a marker of exposure and no more. Erythrocyte acetyl cholinesterase inhibition often correlates better with cholinergic symptomatology, but reactivation can take place sufficiently quickly to interfere with the validity of blood tests, both in clinical and experimental situations, unless care is taken (Mason *et al*., 1993; FAO/WHO, 1993), reactivation occurring *ex vivo* in blood samples. The great sensitivity to inhibition and poor correlation with clinical cholinergic effects of inhibition of erythrocyte cholinesterase and, even more so, plasma cholinesterase have caused the Joint Meeting on Pesticide Residues (JMPR) to prefer inhibition of brain cholinesterase in the derivation of ADIs for OPs (WHO, 1990a). It is uncertain if such an approach will cover the implications of peripherally mediated intoxication (Ligtenstein, 1984) and the policy has since been modified (Herrman, 1998).

2.2.1 Organophosphates

OP anticholinesterases are esters of phosphoric, phosphonic or phosphorothioic or related acids.

Their general formula is:



The R groups in pesticides are generally either both methyl groups or both ethyl groups. The X or leaving group can be any one of large variety of moieties. The OP pesticides have some similarities with the chemical warfare nerve agents, but these are often phosphonofluoridates. Many pesticidal OPs are phosphorothioates and those containing P=S groups, such as malathion tend to be of lower acute mammalian toxicity than their corresponding phosphates and phosphonates. Thus, paraoxon is much more toxic than parathion, as is malaoxon compared to malathion. The reason for this is that the P=S phosphorothioates are inactive as anticholinesterases *in vitro* and only acquire toxicity after conversion of the P=S moiety to a P=O moiety, forming the oxon (WHO, 1986). Although OPs share their cholinergic symptomatology with the carbamates, the toxicology of OPs has certain features which do not resemble the effects of carbamates. These features are organophosphate-induced delayed polyneuropathy (OPIDP) and the so-called intermediate syndrome. Since the OP pesticides all have the same qualitative anticholinesterase action, and this property is responsible for their acute lethal toxicity, quantitative differences in toxicity are partly due to differences in absorption, distribution and metabolism. However, the rates of formation of the OP–acetylcholinesterase complex, of hydrolysis of this complex and of the ageing reaction (see below) must also be considered.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2.2.1.1 Anticholinesterase Activity

Inactivation of cholinesterases by OPs involves a reaction in which the leaving group (X) is lost, typically producing a dialkylphosphoryl enzyme. Since most insecticides contain two methyl or two ethyl R groups, inactivation of cholinesterase produces a dimethoxyphosphorylated enzyme or a diethoxyphosphorylated enzyme and the kinetics of reactivation are the same for each derivative regardless of the structure of the leaving group of the OP. Reactivation of the dimethoxy phosphorylated enzyme will occur within a few hours and is considerably quicker than the diethoxy equivalent, while phosphorylated complexes containing one alkylthio group and one alkoxy group reactivate faster than those containing two alkoxy groups. By contrast, spontaneous reactivation of complexes containing larger R groups, for example isopropoxy and di-*sec*-butoxy is slow or nonexistent (WHO, 1986; Wilson *et al*., 1992; Mason *et al*., 1993), although large halogen-containing groups are an exception and seem to reactivate. With soman (pinacolyl methylphosphonofluoridate), a phosphonofluoridate nerve agent that has as one of its R groups a pinacoloxy moiety, reactivation fails to occur, but the mechanism is somewhat different: a further reaction takes place after dialkylphosphonylation of the enzyme in which the pinacolyl group is lost to leave a monoalkylphosphonyl enzyme. Such derivatives are refractory to oxime-induced reactivation and do not undergo spontaneous reactivation. With soman-inhibited enzyme the half-time for ageing is a few minutes. No pesticidal OP gives rise to a complex that ages at such a rate, but therapeutic failure with oximes has been attributed to ageing with certain pesticides (Glickman *et al*., 1984; Gyrd-Hansen and Kraul, 1984), and ageing half-lives for dimethoxyphosphorylated cholinesterases are in the region of 2–9 hours (Wilson *et al*., 1992).

2.2.1.2 Intermediate Syndrome

Senanayake and Karalliedde (1987) reported a syndrome that followed therapy for and resolution of the cholinergic effects of OP intoxication. As the syndrome developed before the late effects of OPs, the authors called this syndrome the intermediate syndrome. Since 1987, other examples have been recorded, for instance that by Karademir *et al*. (1990), and this phenomenon is probably the same as the Type II syndrome described by Wadia *et al*. (1987). The syndrome comprises a proximal limb paralysis starting one to four days after poisoning. The progression is not altered by atropine or oximes and, as the respiratory muscles are affected, respiratory support is necessary. A myopathy has been described *post mortem* in cases of human poisoning (de Rueck and Willems, 1975) and in experimental animals (Preusser, 1967; Wecker *et al*., 1978), but Karalliedde *et al*. (2006) concluded that intermediate syndrome was probably caused by down-regulation of nicotinic acetylcholine receptors at the neuromuscular junction as a consequence of acetylcholine accumulation. The myopathy appears to be initiated by calcium accumulation in the region of the motor endplate (Inns *et al*., 1990) again as a consequence of acetylcholine accumulation. So that rather than being causally related, intermediate syndrome and myopathy have a common origin in acetylcholine accumulation.

2.2.1.3 Organophosphate-Induced Delayed Polyneuropathy (OPIDP)

OPIDP is a symmetrical sensory-motor axonopathy, tending to be most severe in the long axons, occurring 7–14 days after exposure. It is a polyneuropathy in that there are central and peripheral components. There is degeneration of axons and Schwann-cell proliferation in the peripheral nervous system (Bouldin and Cavanagh, 1979a; 1979b; Cavanagh, 1982), and also changes in the spinal cord and medulla oblongata (Barrett *et al*., 1985). Clinically, the most disabling feature is the paralysis of the legs which may result. Less severe cases exhibit a characteristic high-stepping gait, and some recovery may occur, but there is no specific treatment (Barrett *et al*., 1985). The initial event in the pathogenesis of the syndrome appears to be inhibition of neuropathy target esterase (NTE). This is followed by an ageing reaction similar to that described for soman with acetylcholinesterase above (Johnson, 1975). On the basis of studies with NTE-null mice and *Drosophila*, Glynn (2006) hypothesized that OPs producing OPIDP caused a transient loss of NTE activity, disrupting membrane phospholipid homeostasis and endoplasmic reticulum functions, such as glial–axonal interaction and axonal transport; the distal parts of long axons would be particularly susceptible to loss of these functions. It should be noted that the structural requirements for inhibition of acetylcholinesterase and NTE are different as shown by the fact that many OPs with powerful anticholinesterase properties are devoid of the ability to produce OPIDP. It should be noted that the nerve agents, which are powerful anticholinesterases, have little propensity to cause OPIDP (Gordon *et al*., 1983), while tri-*o*-cresyl phosphate, which has little anticholinesterase activity, is powerfully neuropathic.

Regulatory authorities typically demand the use of tests to detect propensity for the development of OPIDP and this has resulted in the disappearance of most OPs that are capable of producing OPIDP from the market. The usual test that is carried out is one using hens, the reason for the use of hens being that these creatures are very susceptible to the syndrome. However, mice and rats also develop OPIDP (Veronesi *et al*., 1991) and the reported resistance of rodents to the development of OPIDP has been attributed to the use of young animals in studies (Moretto *et al*., 1992). Several OPs not in current use as pesticides produce OPIDP, including mipafox and diisopropyl phosphorofluoridate, while leptophos, also not currently used in most countries, has been consistently reported

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat140
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to produce OPIDP. There is some limited experimental and clinical evidence that a few OPs currently used in some countries can produced OPIDP, for example, *O*-ethyl *O*-(4-nitrophenyl) phenylphosphonothioate (EPN), methamidophos, cyanofenphos and trichloronat (El-Sebae *et al*., 1981; Gallo and Lawryk, 1991). There is some evidence that the hen test may give misleading results with chiral OPs, which are usually used as insecticides as racemic mixtures (Battershill *et al*., 2004); the vast majority of insecticidal OPs are not optically active, but a few, for example methamidophos, are.

2.2.1.4 Other Delayed Effects of OPs on the Nervous System

The behavioural neuropsychiatric toxicity of anticholinesterases, *inter alia* OPs, has been reviewed (D'Mello, 1993; Lader, 2001). Since acute intoxication with OPs can cause major effects, such as convulsions, respiratory failure and cardiac arrhythmias, all of which can result in cerebral anoxia, it is hardly surprising that major intoxication is sometimes associated with long term CNS changes (Tabershaw and Cooper, 1966; Bartels and Friedel, 1979; Korshak and Sato, 1977; Hirshberg and Lerman, 1984; Holmes and Gaon, 1956; Burchfiel *et al*., 1976; Duffy *et al*., 1979; Durham *et al*., 1965; Savage *et al*., 1988). More information has come available in studies following up survivors of the use of sarin, an OP ester, in Tokyo (see Okumura *et al*., 2007). More debatable is whether long-term low-dose exposure produces delayed or chronic effects. Such an outcome is biologically less plausable than delayed effects of acute exposure, but the two problems have frequently been conflated. Studies pertaining to long-term low-dose exposure, such as those by Stephens *et al*. (1995), Beach *et al*. (1996), Ames *et al*. (1995) and Fiedler *et al*. (1997) have been reviewed (Eyer, 1995; Steenland, 1996; IEH, 1998; Committee on Toxicity of Products in Food, Consumer Products and the Environment, 1999). Steenland (1996) concluded that studies had shown chronic subclinical effects in the central and peripheral nervous system in individuals previously poisoned by OPs, but that the outcome after long-term low-level exposure was less consistent, although some studies had shown effects. Further, the effects of low-level exposure to OP pesticides on foetal and childhood health have also been reviewed (IEH, 2002). A number of OP pesticides (and other compounds) have been tested in the USEPA's developmental toxicity study in the rat (Makris, 2006) and the results of these studies are starting to become available (FAO/WHO, 2003).

2.2.1.5 Other Effects of OPs

It should never be forgotten that OPs may have properties, some of which may be entirely independent of their anticholinesterase effects including mutagenicity and carcinogenicity as well as organ specific toxicity to the heart and kidney and other organs (Singer *et al*., 1987; Baskin and Whitmer, 1992; Pimentel and Carrington da Costa, 1992; Wedin, 1992). Pancreatitis has frequently been reported as a complication of acute OP poisoning (Dagli and Shaikh, 1983).

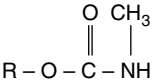
2.2.1.6 Treatment of OP Poisoning

The treatment of OP poisoning involves symptomatic treatment and the use of antidotes. Atropine, an anticholinergic compound, and an oxime enzyme reactivator such as pralidoxime chloride (2-PAM) or obidoxime is used (Bismuth *et al*., 1992; Szinicz *et al*., 1996), while convulsions and muscle fasciculation respond to diazepam (Johnson and Vale, 1992). The antidotal treatment is only effective against acute poisoning and specific treatment is not available for OPIDP or other long-term effects (see reviews by Marrs and Vale, 2005; Roberts and Aaron, 2007).

2.2.2 Carbamates

Carbamates are used as insecticides, herbicides and fungicides, but only the first group has marked anticholinesterase activity. Methiocarb (section 6), an anticholinesterase, is used as a molluscicide.

The anticholinesterase carbamate pesticides are closely related to human drugs such as physostigmine and pyridostigmine. The general structure of most carbamate insecticides is as follows:



In most cases, the R group is a substituted phenol or heterocycle, notable exceptions being aldicarb, which has an *N*-alkyl R group, and pirimicarb, which has two *N*-methyl groups.

In general, the carbamates produce toxicity similar to that of OPs, but less severe. A major difference is that carbamate-inhibited cholinesterases reactivate more rapidly than enzyme-inhibited by OPs, with the result that the effects do not last as long in carbamate poisoning. Indeed reactivation of carbamylated enzyme may be quick enough to render detection of cholinesterase depression difficult in both experimental animals and clinical situations. However, an insecticidal carbamate, aldicarb, is one of the few pesticides that has given rise to poisoning in consumers of treated food. Residues have occurred in cucumbers, watermelons, squashes and similar products, sufficient to cause illness, in some cases severe. Outbreaks have occurred in the USA and Canada (Hall and Rumack, 1992) and in the Irish Republic (Department of Agriculture and Food, 1992). The reason for these problems is that aldicarb, in other respects a satisfactory pesticide, has a high mammalian toxicity, with an acute oral LD_{50} of about 1 mg (kg body weight)$^{-1}$. Atropine is effective in carbamate poisoning, but it is unclear whether oximes are, or are not, beneficial

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat140
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Mercurio-Zappala *et al*., 2007). Due to the rapid reactivation of carbamoylated acetylcholinesterase, the value of oximes is questionable from a theoretical point of view.

2.3 Nicotine and the Neonicotinoids

2.3.1 Nicotine Sulfate

Nicotine is extracted from tobacco (*Nicotiana tabacum*) or other *Nicotiana* species and is one of the oldest botanical insecticides. Nicotine is very toxic to mammals by mouth (oral rat LD_{50} 52–56 mg (kg body weight)$^{-1}$ Lazutka *et al*., 1969), and it is readily absorbed through the skin (rabbit dermal LD_{50} 50 mg kg^{-1}, Negherbon, 1959). When nicotine was widely used as an insecticide it was responsible for many suicides and accidents (see review by Ujváry, 2001). In some parts of the world nicotine is permitted in organic agriculture.

2.3.2 Neonicotinoids

The neonicotinoid group of insecticides comprise what is regarded by some as the most important new class of synthetic insecticides of recent times, and the history of this group of compounds has been reviewed (Tomizawa and Casida, 2003). These insecticides are structurally related to nicotine and the first to be commercialized was imidacloprid. As with nicotine, this group of compounds acts as agonists at the cholinergic nicotinic receptor, but the neonicotinoids are safer for humans than nicotine. This reduced toxicity in mammals is possibly associated with the different receptor binding characteristics (see below). The cholinergic nicotinic receptor has many subtypes in organisms, including mammals, and these receptors are part of a superfamily of ligand-gated ion channels with γ-aminobutyric acid A ($GABA_A$) receptors and glycine receptors (Ortells and Lunt, 1995). Each receptor comprises five subunits arranged around a channel that passes through the cell membrane (for reviews see Kaminski and Ruff, 1999; Kalamida *et al*., 2007). There is evidence that the toxicity of neonicotinoid insecticides may involve action at multiple subtypes and that minor changes in molecular structure may confer selectivity towards insects (Tomizawa and Casida, 1999). An extensive quantitative structure–activity study was undertaken by Debnath *et al*. (2003) using electrotopological state atom indices. This study showed that nitroimines, nitromethylenes and cyanoimines exhibited selectivity towards the *Drosophyla malanogaster* nicotinic receptor and predicted that such structures would be relatively safe for mammals, whereas *N*-substituted imines had greater affinity for an important subtype ($\alpha_4\beta_2$) of mammalian nicotinic receptor. It has also been hypothesized that the ionized nicotine binds at the anionic subsite in the mammalian nicotinic receptor, while the negatively charged neonicotinoids bind at a cationic subsite on the insect nicotinic receptor (Zhang *et al*., 2002).

2.3.2.1 Imidocloprid

Commercially, the most important of the neonicotinoids is imidacloprid. The selective toxicity of imidacloprid to insects and not to mammals is partly attributable to differences in the binding affinity or potency at the nicotinic acetylcholine receptor (Chao and Casida, 1997; Tomizawa and Casida, 2005; see also Ohno *et al*. 2009). Also, imidacloprid is poorly ionized in neutral media, in which respect it differs from nicotine, and thus passes easily through insect lipophilic barriers (Sone *et al*., 1994; Roe *et al*., 1999). The toxicology of imidacloprid has been reviewed (Sheets, 2001; FAO/WHO, 2002). Imidacloprid is of moderate acute toxicity in rats (LD_{50}, 380–650 mg (kg body weight)$^{-1}$) and mice (LD_{50}, 130–170 mg (kg body weight)$^{-1}$) (FAO/WHO, 2002). In repeated-dose studies, reductions in body weight gain were seen in mice, rats, rabbits and dogs. The other changes observed were in the liver, where induction of hepatic microsomal enzymes, disturbance of hepatic function and/or histological changes, such as mild hepatocellular hypertrophy and necrosis, cell nuclear swelling and round-cell infiltration were seen. Increased liver weight was also apparent. Imidacloprid was neither carcinogenic nor teratogenic, nor was it a reproductive toxin. In the full range of genotoxicity studies required premarketing, imidacloprid was not genotoxic. The JMPR concluded that imidacloprid was unlikely to be genotoxic because an adequate range of assays for genotoxicity *in vitro* and *in vivo* gave negative results. Weak induction of sister chromatid exchange was found in one test with Chinese hamster ovary cells *in vitro,* but not *in vivo* (FAO/WHO, 2002). Karabay and Oguz (2005) reported that imidacloprid and an imidacloprid/methamidophos mixture were mutagenic in *Salmonella typhimurium* strain TA 98, with or without S9; furthermore imidacloprid and the mixture both induced micronuclei in rat erythrocytes and chromosomal aberrations in rat bone-marrow cells, both after 90 days dietary administration. In a single-dose rat neurotoxicity study, clinical signs of cholinergic toxicity were seen. These included tremor and uncoordinated gait; nasal staining was also observed. A few cases of human poisoning with imidacloprid have been reported in the literature, including three fatal cases (Proença *et al*., 2005; Huang *et al*., 2006; Agarwal and Srinivas, 2007; David *et al*., 2007). In the case reported by David *et al*. (2007), where poisoning was caused by intentional ingestion and which was nonfatal, the main findings were drowsiness, tachycardia (followed by bradycardia) and vomiting. In the other nonfatal case, that described by Agarwal and Srinivas (2007), there were severe psychiatric manifestations, which the authors ascribed to central

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat140
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

nicotinic stimulation; the patient also had rhabdomyolisis, which the authors suggested could have been caused by nicotinic actions at the neuromuscular junction or by fever. Exposure in this case was by inhalation. The two cases described by Proença *et al*. (2005) were both found dead, hence there were no descriptions of clinical signs and symptoms; however, the presence of imidacloprid in body fluids and tissues was established and there was circumstantial evidence that they had ingested imidacloprid. The case described by Huang *et al*. (2006) was a woman who drank about 200 ml of a 9% solution of imidacloprid. The patient had hypertension for six years; in addition, eight months before the poisoning, she had a stroke. On admission she was disorientated and vomiting. She developed intermittent ventricular fibrillation and died 12 hours after admission.

Both the data from experimental animals and from human poisonings suggest that imidacloprid is capable of producing cholinergic signs, so that specificity towards insects is clearly not complete. However, imidacloprid has achieved widespread usage and is clearly a comparatively safe compound under approved conditions of use.

2.3.2.2 Other Neonicotinoids

A number of other neonicotinoids have been developed. These include acetamiprid, nitenpyram, thiacloprid, chlothianidin, nithiazine and thiamethoxam. Kayser *et al*. (2004) found that while acetamiprid, nitenpyram, thiacloprid, chlothianidin and nithiazine displaced ^{3}H-imidacloprid competitively from specific binding sites on membranes from the aphids *Mysus persica* and *Aphis craccivora*, thiamethoxam did so noncompetitively, suggesting that the last-named compound bound at a different site or in a different way to the aphids' nicotinic receptor. Thiamethoxam has been observed to cause liver tumours in long-term studies in mice, but not rats (Green *et al*., 2005a). It has been hypothesized that this effect is produced by a metabolite and is exacerbated by a second metabolite, which is an inhibitor of nitric oxide synthase; blood concentrations of these metabolites were much lower in rats than in mice in metabolic studies (Green *et al*., 2005b).

2.4 Pyrethroids (and Pyrethrins)

Pyrethrins are natural insecticides produced from *inter alia* pyrethrum, a plant of the Compositae group, and are esters of pyrethric or chrysanthemic acids. Pyrethrins are broken down and deactivated very readily in the environment, particularly by sunlight. The synthetic pyrethroids are structurally similar compounds rendered photostable by various substituent groups, such as chlorine, bromine or cyanide. Some of the newer ones bear a more distant structural relationship to the pyrethrins. Because of their low mammalian toxicity, high insecticidal potency and lack of persistence in the environment, the synthetic pyrethroids have achieved widespread usage in agriculture, as household insecticides and in wood preservation. Synthetic pyrethroids are also used in mosquito control (White, 1993). They have also been widely used on humans to treat such conditions as scabies, and as veterinary ectoparasiticides. However they are very toxic to aquatic organisms (Zitko *et al*., 1979) and their lack of persistence can be a problem when used as wood preservatives. The advantageous properties of the synthetic pyrethroids result from the fact that they hydrolyse relatively easily, both in the mammalian body and in the environment. Consequently, bioaccumulation does not occur to a significant extent, nor do they persist in soils.

In general, by the oral route, the synthetic pyrethroids are of low acute toxicity, but this is not the case when they are administered to mammals parenterally when they are neurotoxic by virtue of their action upon voltage-dependent sodium channels (Vijverberg and van den Bercken, 1990; Vijverberg, 1994). As a result, there is often a large difference between the oral LD_{50} and LD_{50}s by parenteral routes. Despite the neurotoxicity of this group of compounds, underlying pathological changes in the nervous systems of animals exposed to pyrethroids are slight (Aldridge, 1990). Pyrethroids can be separated into two classes on the basis of the central neurotoxic syndrome that they produce by parenteral routes in experimental animals (Vijverberg, 1994). Type I synthetic pyrethroids, which include permethrin and resmethrin as well as the components of natural pyrethrum, lack an α-cyano group and give rise to T-syndrome. The T-syndrome is characterized by fine tremor, hypersensitivity to stimuli and aggressive sparring, progressing to coarse whole-body tremor; this syndrome is rather similar to that produced by some of the OCs. Type II compounds, which include deltamethrin, flumethrin, cyfluthrin and γ-cypermethrin have an α-cyano group and give rise to CS syndrome. The CS syndrome consists of initial pawing and burrowing and later marked choreoathetosis, salivation, course tremor and convulsions (Aldridge, 1990; Joy, 1994). As well as these central effects in experimental animals, pyrethroids cause peripheral nerve damage (in rats) with functional impairment when administered repeatedly at near-lethal dose levels. (Rose and Dewar, 1983). Axonal degeneration has been described, but generally at near lethal doses and there is no evidence that pyrethroids can produce delayed neuropathy of the OP type (Aldridge, 1990).

Despite the findings in the central and peripheral nervous systems of animals, in humans the most prominent effect of the pyrethroids is to cause transient paraesthesia, mainly in the face, and there is little evidence of any permanent effects in man. Pruritis with blotch erythema, itching, rhinorrhoea and lachrymation have also been described (Aldridge, 1990). Deltamethrin seems more potent and permethrin less so, in producing these effects. Additionally, the pyrethroids are potent allergens

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and allergic rhinitis, asthma and extrinsic allergic alveolitis have been reported (Bismuth *et al*., 1987).

Specific treatment of the effects of synthetic pyrethroids is rarely necessary, as systemic effects are very unusual in humans and where reported these are transient.

Table 2 Insecticides of natural origin

Group	Active ingredients
Avermectin group	Abamectin
	Ivermectin
Spinosins	Spinosad
Derris and similar insecticides	Rotenone
Cholinergic group	Nicotine
Pyrethrum	Pyrethrins

2.5 Insecticides of Biological Origin Other than Pyrethrum and Nicotine

A number of insecticides are available that are of biological origin. The pyrethrins, discussed above with the synthetic pyrethroids, form one group. Of the others, only the avermectins, spinosad and derris are at all widely used (see **Table 2**).

2.5.1 Avermectins

Abamectin is the common name for a mixture of avermectin B1a and B1b, macrocyclic lactone disaccharide antibiotics from *Streptomyces avermitilis*. Abamectin is an insecticide and acaricide used in crop protection, while, in veterinary medicine, it is used as an anthelmintic. The dihydro derivative, ivermectin, is used to control nematodes and arthropods, in animals, and, in man, for the control of onchocerciasis (Wright, 1986) (see below). The insecticidal activity is based on action upon GABAergic nerve transmission; because mammals only have GABAergic synapses in the CNS, the mammalian blood–brain barrier ensures a degree of specificity. A notable feature of this group of compounds is their low LD_{50}s; thus, the oral LD_{50} for abamectin in mice is $14–24\,mg\,kg^{-1}$ and for ivermectin is $25–40\,mg\,kg^{-1}$ (Lankas and Gordon, 1989). The acute oral toxicity of abamectin was shown to be directly related to the expression of P-glycoprotein genes; homozygous negative CF-1 mice were over an order of magnitude more sensitive than heterozygous and homozygous positive CF-1 mice (WHO, 1998). Abamectin and ivermectin are neurotoxic, producing tremors, weakness and incoordination, and can induce malformations in offspring in teratological studies in CF-1 mice and in cultured embryos (Lankas and Gordon, 1989; FAO/WHO, 1993; Chaconas and Smoak, 1997). Ivermectin, used in human infestations with parasites, rarely gives rise to effects related to outcomes observed in animal toxicology studies; thus, reactions (encephalopathy) reported to the use of ivermectin in infestation with *Onchocerca volvulus* were correlated to the load of microfilaria of *Loa loa*, and were probably not a direct toxic effect of ivermectin (Gardon *et al*., 1997). Both abamectin and ivermectin are nongenotoxic and almost certainly not carcinogenic (WHO, 1991; 1996; FAO/WHO, 1993).

2.5.2 Spinosad

Spinosad is the ISO name for a mixture of compounds from fermentation carried out by a soil organism *Saccharopolyspora spinosa*. It causes rapid excitation of the insect nervous system. Spinosad is of low acute toxicity by mouth, administered dermally or by inhalation in experimental animals. In repeated-dose studies, spinosad caused increased liver weights in rodents. In dogs, increased thyroid weights and histopathological changes in the lymphatic system (vacuolation of cells in the spleen and lymph nodes) were seen. Also in dogs, in the liver there were vacuolated hepatocytes and Kupffer-cell proliferation and in the pancreas, vacuolated acinar cells. Vacuolation was seen in other organs. Spinosad gave negative results in an adequate range of assays for genotoxicity *in vivo* and *in vitro*. The JMPR concluded that spinosad is not genotoxic and unlikely to pose a carcinogenic risk to humans. Spinosad was only foetotoxic at maternally toxic doses and was not embryotoxic or foetotoxicity in a multigeneration study (FAO/WHO, 2002; see review by Huang *et al*., 2009).

2.5.3 Derris and Similar Insecticides

The other insecticide of biological origin that is very well known is rotenone, under the name derris. It has acquired this name as the garden insecticide marketed under this name is derived from two Asiatic plants, *Derris eliptica* and *Derris mallaccensis*. Another plant *Lonchocarpus utilis*, from South America, is a further source of an insecticide containing rotenone. Rotenone blocks mitochondrial electron transport at Complex I and this is responsible for the toxic effects in mammals, including humans. It can also cause dermatitis. In severe human poisoning, the main effects that have been observed have been vomiting, depressed respiration and eventually apnea (DeWilde *et al*., 1986). Intravenous infusion of rotenone into rats at doses of $1–12\,mg$ (kg body weight)$^{-1}$ day^{-1} was reported to produce cardiovascular toxicity. Lower doses produced nigrostriatal dopaminergic lesions in the CNS. The

Table 3 Insecticides that interfere with insect growth and development

Group	Examples
Insect growth regulators (juvenile hormone analogues)	Methoprene Hydroprene Fenoxycarb Cyromazine Dicyclanil
Chitin-synthesis inhibitors	Diflubenzuron
Ecdysone agonists	Tebufenozide

relevance of this observation to human illnesses such as Parkinson's disease is dubious in the light of the dose and route of administration (Betarbet *et al*., 2000).

2.6 Juvenile Hormone Analogues, Chitin Synthesis Inhibitors and Ecdysone Agonists

The attraction of these groups of insecticides is that they have no direct target organ or system in mammals analogous to those that the insecticides target in insects. The toxicity is therefore generally nonspecific and requires relatively high exposures. Examples are given in **Table 3**.

2.6.1 Insect Growth Regulators

The insect growth regulators (juvenile hormone analogues) are esters of long-chain fatty acids, in the case of hydroprene and methoprene, or trazines in the case of cyromazine, while dicyclanil is a cyclopropylaminopyrimidine. Fenoxycarb is a carbamate. They prevent metamorphosis of insect larvae into viable adults, when applied to the larvae. They are generally of low acute mammalian toxicity (oral LD_{50} about 5 g (kg body weight)$^{-1}$. They are usually nonteratogenic and nongenotoxic, and are without endocrine activity in mammals (FAO/WHO, 1985; Ray, 1991). Methoprene caused changes such as bile duct proliferation in the livers of rats during a two year study at doses of about 220 mg (kg body weight)$^{-1}$ day^{-1} (FAO/WHO, 1985). Cyromazine (Vetrazine®), which is used as a sheep ectoparasiticide, is of low acute toxicity. In short-term studies in rats and dogs and in long-term studies in mice and rats, effects on body weight were seen. Red blood cell counts and haemoglobin levels were reduced in dogs at high dietary concentrations. In a rat multigeneration study, cyromazine did not affect fertility, but there was increased perinatal pup mortality and reduced pup weight, at maternally toxic doses. Abnormalities, including cyclopia with multiple head anomalies in two foetuses, were observed in a rabbit study seen by the JMPR, but there was no clear dose response and JMPR did not consider cyromazine to be teratogenic, nor was it genotoxic (FAO/WHO, 1991). Dicyclanil is also used on sheep. Dicyclanil is slightly hazardous by mouth (LD50 >2000 mg (kg body weight)$^{-1}$). In a three month study in dogs, neurotoxity (ataxia and tremor), decreased food consumption and body-weight gain, and changes in clinical chemistry and erythrocyte parameters (reduced haemoglobin and haematocrit with microcytosis and erythrocytic hypochromasia) at the high doses, while severe liver toxicity was seen in a one year dog study. The Joint Expert Committee on Food Additives (JECFA), considered that dicyclanil was not genotoxic nor did it pose a carcinogenic risk to humans. Dicylcanil was not a reproductive toxin, while the NOAEL (no observable adverse effect level) for pup toxicity (reduced body weight gain) was slightly below the NOAEL for parental toxicity. Dicyclanil was not teratogenic and was only foetotoxic at dose above those that were maternally toxic. The carbamate, fenoxycarb, exerts most of its insecticidal activity as a juvenile hormone analogue and is of low mammalian toxicity (Evans, 1993; Tomlin, 2006).

2.6.2 Chitin Synthesis Inhibitors

Chitin synthesis inhibitors, such as diflubenzuron, are also generally of low toxicity. These insecticides, which are benzoylphenylureas, act by interfering with the formation of the insect cuticle and the action is very specific, in that the compounds do not appear to inhibit hexosamine transferases, which are responsible for connective tissue glycosaminoglycan formation in mammals (FAO/WHO, 1982; Tomlin, 2006). A notable toxicological effect of diflubenzuron in experimental animals is to cause changes in haematological parameters, such as methaemoglobinaemia and sulfhaemoglobinemia, together with a fall in the red blood cell count and increased Heinz-body formation. This probably results from the metabolism of the compound to *inter alia* 4-chloroaniline (FAO/WHO, 1982).

2.6.3 Ecdysone Agonists

Tebufenozide mimics the action of ecdysone by binding to its receptor and bringing about a lethal unsuccessful moult. It is of low toxicity to rodents, but in experimental studies in laboratory animals it causes mild haemolytic anaemia. Methaemoglobinemia is seen in mice. The compound is neither carcinogenic nor genotoxic (FAO/WHO, 1997; 2004).

2.7 Miscellaneous Synthetic Insecticides

2.7.1 Amitraz

Amitraz is a formamidine compound, has resulted in a number of intoxications (Aydin *et al*., 1997). The main feature is central nervous system depression, which is accompanied by hypotension, hypothermia and bradycardia. Hyperglycaemia also occurs.

2.7.2 Fipronil

Fipronil is an insecticide with many uses. It is used as a malarial control agent and to control fleas on cats and dogs. Fipronil has a novel mode of action, acting on the $GABA_A$ receptor (FAO/WHO, 1998). At high doses in experimental animals, neurotoxicity is observed. Mohamed *et al*. (2004), who reported a series of poisonings from Sri Lanka, found that fipronil poisoning was characterized by vomiting, agitation and convulsions; in most cases the outcome was favorable.

3 FUNGICIDES

The fungicides are a heterogeneous group of chemicals that defy convenient chemical classification; their action is often upon the cytoskeleton and therefore relevant to both fungi and mammals. The main classes of fungicides are given in **Table 4**.

3.1 Metals

3.1.1 Inorganic Metallic Fungicides

Some of the first fungicides used in agriculture were neutralized copper sulfate preparations such as Bordeaux mixture, which was introduced in the nineteenth century and consists of lime and copper sulfate. Compounds of mercury, both mercurous chloride (calomel) and mercuric chloride have long been used as fungicides, but have now been withdrawn in many countries due to their toxicity and environmental concerns.

3.1.2 Organometals

The organometals are in general fairly toxic compounds, many being neurotoxic. Trimethyltin and triethyltin are highly neurotoxic, but not used as pesticides. Tributyltin oxide (TBTO) was, for a time, extensively used in wood preservatives and in antifouling paints on boats, but use has been considerably restricted some countries, for example, the UK (Advisory Committee on Pesticides, 1990; Cavanagh and Nolan, 1994). Substances such as fentin (triphenyltin) and fenbutatin oxide, which are used in agriculture and horticulture, are poorly absorbed by mouth, and are of low oral toxicity (FAO/WHO, 1992; 1993), and any neurotoxicity they possess is mild and nonspecific (Manzo *et al*., 1981; Bock, 1981). Organotins are immunotoxic; thus, fentin causes lymphopenia and lymphocyte depletion of the spleen and thymus in experimental animals (FAO/WHO, 1992). The immunotoxicity of TBTO was reviewed extensively by WHO (1990b).

Organic compounds of copper and zinc are also used as fungicides, especially as wood preservers.

3.2 Carbamate Fungicides and Thiabendazole

A number of carbamates, predominantly the dithiocarbamates and benzimidazole derivatives, possess fungicidal activity.

3.2.1 Dithiocarbamates

The dithiocarbamates include three main groups of fungicides, methyl dithiocarbamates, metam, dimethyl dithiocarbamates, ferbam, thiram and ziram, and ethylenebis(dithiocarbamate)s (EBDCs), maneb, zineb and mancozeb, the last group being degraded to ethylene thiourea. Propineb is closely related to the last group and is polymeric zinc propylenebis(dithiocarbamate). All dithiocarbamates seem to have the potential to affect the thyroid, decreasing plasma thyroxine levels and increasing TSH levels; the active compounds being the alkyl-thiourea metabolites.

The dimethyldithiocarbamates, ferbam, thiram and ziram, contain the same core molecule, together with iron, in the case of ferbam, and zinc in the case of ziram. Amongst their metabolites is carbon disulfide, which may account for hepatotoxicity. The dithiocarbamates are generally not highly toxic, but they interact with alcohol in humans. In this context, it should be noted that the drug disulfiram (Antabuse), used to treat alcoholism, is the ethyl analogue of thiram (tetramethylthiuram disulfide). Both thiram and ziram, but, on the basis of limited studies, apparently not ferbam, have shown mutagenic potential in bacteria. Thiram and ziram are considered not to be mutagenic in mammalian systems *in vivo* (FAO/WHO, 1993; 1997).

Maneb is polymeric manganese EBDC, zineb is the same compound with zinc replacing the manganese, while mancozeb is a complex of the two. A notable feature of the EBDCs is that one of their metabolites is ethylene thiourea and this substance forms a major part of the residues, to which consumers are exposed. The EBDCs reduce iodine uptake by the thyroid

and repeated administration produces thyroid hyperplasia that is initially reversible and is associated with decreased plasma thyroxine and triiodothyronine levels; these effects are also observed in studies of ethylene thiourea (FAO/WHO, 1994). Prolonged dosage produces thyroid tumours in animals (FAO/WHO, 1994). Propineb is similarly metabolized in plants and animals to propylene thiourea, which is goitrogenic and interferes with thyroid function in the same was as ethylene thiourea (FAO/WHO, 2000). Maneb is one of a number of pesticides where an association with exposure and development of Parkinson's disease has been suggested (see review by Barlow *et al*., 2007; IEH, 2005). Manganese is itself associated with Parkinsonism (Perl and Olanow, 2007).

3.2.2 Benzimidazole Carbamates

The benzimidazole carbamates include benomyl and its hydrolysis product carbendazim, as well as thiophanate and thiophanate-methyl. Thiabendazole, although not strictly a carbamate, shares many of the properties of the benzimidazole carbamate fungicides. The acute toxicity of carbamate fungicides of this type is usually low. Thus thiophanate has an oral LD_{50} of more than 5 g (kg body weight)$^{-1}$ in rodents (Hashimoto *et al*., 1970). Carbendazim and benomyl have detrimental effects on fertility of male rats (Carter and Laskey, 1982; Carter *et al*., 1987) and these two fungicides have been shown to be embryotoxic and teratogenic, under experimental conditions; thus, in rats, benomyl produces craniocerebral and ocular abnormalities (Kavlock *et al*., 1982; Janardhan *et al*., 1984; Cummings *et al*., 1990; Hoogenboom *et al*., 1991; FAO/WHO, 1996). Both carbendazim and benomyl have produced microphthalmia in certain experimental studies using high dose levels (FAO/WHO, 1996). With benomyl and carbendazim, a major area of concern has been the possibility of these two pesticides being spindle poisons and both pesticides cause numerical chromosomal changes *in vitro* and *in vivo* (Georgieva *et al*., 1990; Pandita, 1988; FAO/WHO, 1996). Some of these effects may be related to the effects of benomyl and carbendazim upon microtubules and thus to the fungicidal effects, which are mediated through an effect in binding to fungal tubulin and preventing polymerization.

3.2.3 Other Compounds Similar to Carbamates

Iprodione is a dicarboximide, of low acute toxicity. It is not genotoxic, but in long-term studies, high doses produced skin lesions in dogs, and increased liver and testicular tumours in rodents. In dogs, a reduced red blood cell count was seen, with, in some studies, Heinz-body formation (FAO/WHO, 1993; 1996). There are some reports that iprodione may disrupt androgen functions.

3.3 Chloroalkylthio-Containing Fungicides

This group consists of captan, folpet and captofol. They are of low acute mammalian toxicity. However, because of the similarity of their molecules to thalidomide, there was considerable concern over their effect on reproductive and foetal development. The negative results of reproductive studies into the chloralkylthio fungicides at doses not producing maternal toxicity, suggest that another part of the thalidomide molecule is responsible for the teratogenicity of that drug (Edwards *et al*., 1991). There also have been concerns over the ability of some fungicides of this class to induce gastrointestinal tumours in experimental animals, and captan and folpet are mutagenic *in vitro,* but not *in vivo* (FAO/WHO, 1991; 1996). Indications are that the gastrointestinal tumours are related to the irritant effects of the thiophosgene moiety (FAO/WHO, 1996).

3.4 Phenols

One of the most widely used wood preservers has been pentachlorophenol, which is a potent fungicide. Due to concerns over its persistence and content of chlorinated dibenzo-*p*-dioxins, pentachlorophenol is now severely restricted in some parts of the world and banned in others. Other phenolic derivatives with fungicidal properties include dinocap, which is an ester of an alkyl-substituted dinitrophenol and dinitro-*o*-cresol. The main mammalian toxic action of this group of compounds is to cause uncoupling of oxidative phosphorylation and hyperthermia, with collapse and death at high dose. Liver and kidney involvement occurs in fatal human poisoning, while in experimental animals the onset of *rigor mortis* is notably fast after death. Some compounds of the phenol group of fungicides induce cataracts in experimental animals, for example dinocap (FAO/WHO, 1990).

3.5 Hydantoins

This group includes vinclozolin, which has been a cause of concern because of its reproductive toxicity (Advisory Committee on Pesticides, 1992). In a long-term study in rats, there was atrophy of the accessory sex glands and an increased incidence of Leydig cell tumours, while in multigeneration studies in the same species, there was infertility in the males associated with feminization of the external genitalia. Changes have been observed in other species and it is likely that vinclozolin acts as an antiandrogen (FAO/WHO, 1996).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat140
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.6 OPs

Pyrazophos, although an anticholinesterase OP, is used as a fungicide. It has anticholinesterase properties and, insofar as mammalian toxicity is concerned, has many features in common with OP insecticides (FAO/WHO, 1993). Tolclofos-methyl is an OP fungicide, which has limited anticholinesterase properties and low mammalian toxicity (PSD, 1993).

3.7 Azoles

Fungicides of this group (the 'conazoles') inhibit sterol synthesis in fungi and they have some activity on steroid metabolism in animals. The toxicology of all members is rather similar, effects on the liver (hypertrophy and enzyme induction) being noted in subacute and long-term studies and, with some compounds, effects on the reproductive system, such as delayed parturition, which are mild and do not appear adversely to affect reproductive performance. Anaemia is seen, for example, with hexaconazole. The compounds are mostly not carcinogenic, although Leydig cell tumours are sometimes observed and fenbuconazole produces effects on the thyroid, including tumours via effects on thyroxine metabolism (FAO/WHO, 1998). Foetotoxicity is seen at maternally toxic doses and, in some cases, for example, tebuconazole and diniconazole, teratogenicity, although again generally only at maternally toxic doses (Advisory Committee on Pesticides, 1990; 1993).

Hexaconazole, a fairly typical triazole, produces effects on the female and male reproductive systems. From studies *in vitro,* it is believed that hexaconazole inhibits testosterone production. Nevertheless, reproductive parameters are not affected in multigeneration studies. This compound is not genotoxic and probably not carcinogenic, although the frequency of Leydig cell tumours appeared to be treatment related in rats (FAO/WHO, 1991). The compound is foetotoxic at maternally toxic doses, but it is not teratogenic, although in a rabbit study there was reported to be some delayed ossification in rabbit foetuses. The toxicology of penconazole is similar; with this compound, delayed ossification was observed more consistently than with hexaconazole (FAO/WHO, 1993). Cataracts were observed in the eyes of dogs fed tebuconazole (Advisory Committee on Pesticides, 1993). Imazalil was reported to have effects on the liver in a long-term rat study; furthermore there was a decreased number of live births at the top dose in a multigeneration study (FAO/WHO, 1978; 1985). This fungicide is been used in humans and in veterinary medicine under the name enilconazole (INN). It appears to have been well tolerated (Edwards *et al*., 1991).

3.8 Morpholines

This group of fungicides has a similar action in fungi to the azoles. Dodemorph, fenpropimorph and tridemorph all inhibit the synthesis of ergosterol. They are of low acute toxicity, although tridemorph is reported to be teratogenic and foetotoxic in rodents (Barbiere and Ferioli, 1994).

3.9 Miscellaneous Fungicides

3.9.1 Chlorothalonil

Chlorothalonil is a nitrile of low acute toxicity but severe irritant potential. There has been concern about findings from long-term rat and mice studies. In rats, there were gastric and renal changes, including renal epithelial hyperplasia, adenomas and carcinomas, forestomach hyperplasia and hyperkeratosis, and gastric papillomas (FAO/WHO, 1991; 1993).

3.9.2 Creosote

Coal-tar creosote, a widely used wood preserver in English-speaking countries, is a complex mixture, which contains quantities of various carcinogens and phenols. The amount of benz(a)pyrene in some preparations has caused some concern and is subject to limits in a number of countries: the use of creosote has been banned in the European Union. However, it is likely that the irritancy reduces the potential of creosote for causing skin cancer and it probably presents little hazard to the public.

4 HERBICIDES

Herbicides are substances that kill plants, and are of variable degrees of specificity. The main groups of herbicides are given in **Table 5**.

4.1 Inorganic Herbicides

Substances such as common salt (sodium chloride) have, for many years, been used as nonselective herbicides and sodium chlorate, continues to be used in this way. If ingested by humans, sodium chlorate produces immediate vomiting, abdominal pain and diarrohea. A noteworthy feature is that acute poisoning with sodium chlorate produces methaemoglobinaemia and intravascular haemolysis may also occur (Proudfoot, 1996).

Table 5 Main groups of herbicides, with examples

Group		Examples
Inorganic		Sodium chlorate
Bipyridylium		Paraquat Diquat
Organic acid	Phenoxy	2,4-D 2,4,5-T Mecoprop Fenoprop Haloxyfop
	Other organic acids	Dicamba
Substituted anilines		Alachlor Propachlor Propanil
Ureas and thioureas		Diuron Linuron Monolinuron
Nitriles		Ioxynil Bromoxynil
Triazines and triazoles	Triazines	Atrazine Simazine
	Triazoles	Amitrole
Organophosphate group	Phosphonic acid derivatives	Glyphosate
	Phosphinic acid derivatives	Glufosinate

4.2 Bipyridylium Herbicides

The two well-known pesticides in this group are paraquat and diquat. The mechanism of action involves cyclic reduction–oxidation reactions producing reactive oxygen species and depletion of NADPH.

4.2.1 Paraquat

Paraquat is selectively toxic to the lungs, producing an acute alveolitis followed by fibrosis. Both Type I and Type II alveolar cells, as well as the Clara cells are destroyed. Associated with this process, it has been noted the lung tissue accumulates paraquat by a saturable uptake process (Rose *et al*., 1974; 1976; Smith, 1982; Smith *et al*., 1990). In experimental animals, the main result of paraquat toxicity is histologically a proliferative pneumonitis with fibroblasts, alveolar oedema, perivascular and peribronchial oedema and accumulation of neutrophils and macrophages (Schoenberger *et al*., 1984). The precise histological changes observed in rats depend upon the dose of paraquat and time to death. In those dying early, haemorrhage and oedema is very prominent, while those dying later show greater evidence of fibrosis. These changes appear to occur largely independently of the route of administration of the paraquat and it should be noted that, in mice, similar histopathological findings have been observed after exposure to paraquat aerosol (Popenoe, 1979).

Many cases of paraquat poisoning, mostly due to deliberate ingestion of the agricultural concentrate, have been reported since this herbicide was introduced (FAO/WHO, 2004). Poisoning with paraquat in man initially produces damage to the gastrointestinal tract, including the mouth and pharynx, and to the liver and kidneys. Often partial recovery occurs and then from 10 days onwards, clinical signs and symptoms referable to the respiratory tract develop (Higenbottam *et al*., 1979; Schuster *et al*., 1981). Death occurs normally from respiratory failure. There is no effective treatment for paraquat-induced lung damage and the only effective measures involve efforts aimed at the prevention of absorption of the herbicide from the gastrointestinal tract.

Paraquat is one of a number of pesticides where an association with exposure and development of Parkinson's disease has been suggested (see reviews by Barlow *et al*., 2007; IEH, 2005)

4.2.2 Diquat

Diquat poisoning differs from paraquat poisoning in that renal effects are more prominent and lung changes do not generally occur, because diquat does not have the nitrogen atoms in the correct spatial positions to permit active uptake by the lung. Cataractogenesis has been observed in long-term experimental animal studies, but not in humans (FAO/WHO, 1994). In man, death in overdose is caused by renal failure (Vanholder *et al*., 1981).

4.3 Organic Acid Herbicides

4.3.1 Phenoxy Herbicides

The phenoxy herbicides, which are widely used to destroy broad-leaved weeds, are chemical analogues of plant growth hormones (auxins) of the indole acetic-acid type, and are used for the selective control of broad-leaved plants in monocotyledenous crops. Herbicides of this type have no hormonal action in animals. The phenoxy herbicides include 2, 4-dichlorophenoxyacetic acid (2,4-D), 2, 4, 5-trichlorophenoxyacetic acid (2,4,5-T), mecoprop and fenoprop. Similar compounds are used as rooting powders (i.e. they stimulate rooting of cuttings). One herbicide of the group, namely 2,4,5-T, has come under a cloud as result of contamination with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, levels of which are now subject to strict limits. The whole group has attracted some suspicion, because of certain epidemiological studies linking non-Hodgkin's

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat140
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

lymphoma and soft-tissue sarcoma with herbicide manufacture or application. 2,4,5-T is rarely used nowadays, but 2,4-D is extensively used as a selective pesticide on lawns and on monocotyledonous crops. The mammalian toxicology of all the members of the group is quite similar and appears to mediated by several mechanisms, including cell membrane damage, uncoupling of oxidative phosphorylation and disruption of acetylcoenzyme A metabolism (see reviews by Bradberry *et al*., 2004a; Marrs, 2004).

4.3.1.1 2,4-D

2,4-D is a moderately toxic compound with LD_{50}s >400 mg (kg body weight)$^{-1}$. It may be used as the acid (2,4-dichlorophenoxyacetic acid) or as esters, amine salts or the sodium salt. In subacute and chronic studies in experimental animals, changes were found in the kidneys and sometimes the liver. Mutagenicity tests on 2,4-D have produced somewhat contradictory results (Pilinskaya, 1974), so that IARC (1977) concluded that results on mutagenicity and carcinogenicity were inadequate for a proper evaluation. However, it seems unlikely that pure 2,4-D is mutagenic. The JMPR (FAO/WHO, 1997) observed that mutagenicity test results indicated that 2,4-D was not genotoxic, although conflicting results had been obtained for mutation in *Drosophila melanogaster*. In man, large doses are necessary to produce major toxic effects, which include alterations in consciousness, muscle fasciculation, vomiting and convulsions. Gross overdose produces stupor, muscle hypotonia and coma, which may be prolonged, metabolic acidosis, hypotension and pulmonary oedema may occur (Ecobichon, 1994; Proudfoot, 1996). There is some evidence that alkaline diuresis is beneficial in 2,4-D poisoning and also with mecoprop.

4.3.1.2 2,4,5-T

2,4,5-T is not much used in Western countries any more. The toxicology is similar to that of 2,4-D, however human case reports must be studied in the context of the content of TCDD in the material. At high dose levels, 2,4,5-T is reported to be teratogenic to rats and mice, but not rabbits, monkeys and sheep (FAO/WHO, 1980).

4.3.1.3 Other Phenoxy Herbicides

The main target organs for fenoprop in experimental animals are the liver and kidneys (USEPA, 1988), and the material is not carcinogenic. By contrast, the toxicology of haloxyfop is notable for the production of liver tumours; these are observed in mice and are associated with peroxisome proliferation (FAO/WHO, 1996). The animal toxicology of mecoprop is very similar to 2,4-D (PSD, 1994). A case of combined 2,4-D and mecoprop poisoning was reported by Kerr *et al*. (1997). The main features were gastrointestinal effects, hypotension, coma, muscle weakness, hyperthermia and tachycardia.

4.3.2 Other Organic Acid Herbicides

Dicamba is a herbicide of low acute toxicity, and the few poisoning cases observed in humans have been complicated by ingestion of phenoxy herbicides at the same time. In animals, muscular spasms and dyspnea occur in acute studies, whilst in long-term studies, organ-specific effects are few (Stevens and Sumner, 1991). Dicamba is reported to cause peroxisome proliferation in experimental animals (Espandiari *et al*., 1998). In a prospective questionnaire-based cohort study, although associations between exposure and lung and colon cancer were observed, Samanic *et al*. (2006) did not find clear evidence of an association between cancer risk and dicamba exposure.

4.4 Substituted Anilines

These are used as herbicides and include alachlor, propachlor and propanil. Some herbicides of this group have the general property of causing methaemoglobinaemia, as do many other aniline derivatives (Kiese, 1970). The probable mechanism of the methaemoglobinaemia is *N*-hydroxylation to the corresponding hydroxylamine, which then takes part in an intraerythrocytic cycle with the corresponding nitroso derivative, at the same time generating methaemogloblin. If this is the mechanism, for propanil the proximate methaemoglobin former would be *N*-hydroxy-3,4-dichloroaniline (McMillan *et al*., 1990). In the case of propachlor, which is a tertiary amine, it would seem unlikely that the above mechanism would operate, and rat data suggest that this is indeed the case (Panshina, 1973). However, it must be remembered that the rat is not a good experimental animal for demonstrating methaemoglobinemia (Calabrese, 1983), with the dog considered a more appropriate model for man. As well as causing methaemoglobinaemia, propanil causes reduced red-cell survival (McMillan *et al*., 1991).

4.4.1 Alachlor

Alachlor is, like other substituted aniline herbicides, not a substance of high acute toxicity (Tomlin, 2006). The substance is carcinogenic in rodents, producing posterior nasal and stomach tumours, possibly by a nongenotoxic mechanism (Berry, 1988).

4.5 Ureas and Thioureas

The herbicidal ureas, such as diuron, linuron and monolinuron, are of low acute toxicity. They appear to interfere with photosynthesis in plants. In man, they cause methaemoglobinemia, intravascular haemolysis and haemoglobinuria (Proudfoot, 1996).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.6 Nitriles

The nitrile herbicides include ioxynil and bromoxynil and they may act as toxicants partly by uncoupling oxidative phosphorylation and as inhibitors of oxidative phosphorylation (Stevens and Sumner, 1991; Proudfoot, 1996).

4.7 Triazines and Triazoles

Atrazine and simazine are triazines, while amitrole is a closely-related triazole; they are a very widely used group of herbicides, which inhibit photosynthesis. These compounds are of low toxicity and the effects of ingestion by humans are nonspecific. In rats, mice and sheep, amitrole has effects upon the thyroid (hyperplastic changes) (FAO/WHO, 1994).

4.8 OP Herbicides

Two OPs, both of which have low or nonexistent ability to produce cholinesterase depression, are used as herbicides. Glyphosate (*N*-phosphonomethyl glycine) is an inhibitor of amino-acid synthesis in plants. In mammals, it appears to be very nontoxic, with LD_{50}s in the 5 g (kg body weight)$^{-1}$ range (Atkinson, 1985; FAO/WHO, 1987). El-Demerdash *et al*. (2001) reported that glyphosate, at high concentrations *in vitro* (IC_{50} about 700 mM) could inhibit 'serum acetylcholinesterase', however there is no indication that significant cholinesterase inhibition occurs in mammals *in vivo*. Indeed, structure–activity consideration would not lead to the expectation that glyphosate would inhibit cholinesterases. In repeated-dose studies in experimental animals, the toxicity tends to be rather nonspecific, failure to gain weight being the most frequent observation. As very high dietary concentrations were used in some of these studies, this effect may be due to unpalatability of the diet and caloric dilution. There is no evidence of carcinogenic potential in long-term studies, nor of teratogenic potential. There is little evidence of genotoxicity in a variety of *in vitro* and *in vivo* tests (Williams *et al*., 2000). Dallegrave *et al*. (2007) found that exposure to glyphosate induced adverse effects on the reproductive systems of rats at puberty and during adulthood, these rats having been exposed to glyphosate *in utero* and during lactation. Glyphosate is of low acute toxicity in humans, and most case reports and series have shown that high doses are necessary to produce fatality (see review by Bradberry *et al*., 2004b). However, the lethal dose in humans seems somewhat variable, some patients surviving doses which were fatal in others. Massive overdose of glyphosate produces gastric irritation, hypotension and pulmonary insufficiency, for which constituents of the formulation other than glyphosate may be to blame (Talbot *et al*., 1991). Damage to the larynx can occur following respiratory aspiration (Hung *et al*., 1997). It has been suggested that the trimethylsulfonium salt is more toxic than the other salts in humans (Sørensen and Gregersen, 1999). Glufosinate ammonium is a nonselective phosphinic acid herbicide. It is a substance of natural origin from the tripeptide L-phosphinothricyl-L-alanyl-L-alanine, which was first isolated from *Streptomyces viridichromogenes* or *Streptomyces hygroscopicus* (Hoerlein, 1994). Glufosinate ammonium acts as an inhibitor of glutamine synthetase in plants. It has some inhibitory action on glutamine synthetase in experimental animals, especially in the kidney (FAO/WHO, 1992). On the basis of studies in mice, Matsumura *et al*. (2001) suggested that the convulsions caused by glufosinate ammonium were mediated through *N*-methyl-D-aspartate (NMDA) receptors. Serious acute poisonings in humans do not appear to be particularly common. Watanabe and Sano (1998) reported a case of a 64-year-old man who ingested glufosinate with suicidal intent. Initially there were mental disturbances and haematological changes, together with gastrointestinal effects and he later developed generalized convulsions, impaired respiration and circulatory failure. During recovery he exhibited loss of short-term memory. A range of genetically modified crops with resistance to glyphosate and glufosinate ammonium are being developed.

5 DEFOLIANTS AND DESSICANTS

A number of substances are used as defoliants and dessicants in agriculture. Thus, sulfuric acid is widely used to destroy potato haulms. *S,S,S*-tributyl phosphorotrithioate (DEF) and *S,S,S*-tributyl phosphorotrithioite (merphos) are OPs used as cotton defoliants, since they produce leaf abscission. A notable feature of the toxicity of DEF and merphos is that in hens they produce OPIDP (Baron and Johnson, 1964).

6 MOLLUSCICIDES

Certain pesticides are used to kill slugs and snails. One of the more noteworthy is metaldehyde. This quite commonly causes mild poisoning when ingested by children and sometimes more severe poisoning in pet animals. Severe intoxication with metaldehyde is primarily due to its breakdown to acetaldehyde and is characterized by convulsions, hyperpyrexia and metabolic acidosis (Proudfoot, 1996). Poisoning is not infrequently reported in pet animals, especially dogs. Thus Yas-Natan *et al*. (2007) reported a case series of

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

14 dogs from Israel. Clinical signs observed included convulsions, hyperthermia, tachycardia and muscle tremor. Serum biochemistry abnormalities including acidaemia were seen. Methiocarb is a molluscicide with cholinesterase-inhibiting properties and relatively high acute oral toxicity (LD_{50}s 20–300 mg (kg body weight)$^{-1}$, FAO/WHO, 1999).

7 RODENTICIDES

7.1 Anticoagulant Rodenticides

Many rodenticides are anticoagulants and include warfarin, as well as newer substances, such as brodifacoum, bromadialone and chlorophacinone. The main difference between warfarin and the newer compounds is the increased single-dose toxicity and persistence of anticoagulant action. The mechanism of action is inhibition of the synthesis of blood-clotting factors VII, IX and X, the vitamin-K-dependent ones. Poisoning in humans is similar to that seen in the rodents and usually follows ingestion. Spontaneous haemorrhages occur from the nose, into the skin and into internal organs. The prothrombin time is prolonged. Oral vitamin K_1 (phytomenadione) can be used as an antidote or alternatively, in extreme cases, transfusion of fresh frozen plasma or blood may be indicated.

7.2 Nonanticoagulant Rodenticides

7.2.1 α-Chloralose

α-Chloralose causes hypersalivation, increased muscle tone, hyper-reflexia, opisthotonus and convulsions. Rhabdomyolysis is a possible complication and coma may occur.

7.2.2 Phosphides

These are used as fumigants in grain stores, and so on, and as rat poisons. Zinc and aluminium phosphides both give rise to phosphine on combination with stomach acid or moist air. Phosphine is very toxic by inhalation, producing local irritation to mucous membranes, together with hepatic effects and reductions in the red blood cell count. By the oral route the phosphides affect the liver and cause convulsions in experimental animals. In humans, exposure to phosphine causes coughing, dyspnoea, tight chest, headache, giddiness and retrosternal pain; pulmonary oedema, with resultant cyanosis may be seen. Ingestion of metallic phosphides causes nausea, vomiting, hypotension and shock (Proudfoot, 1996). The mechanism of the poisoning is unclear. There is some evidence for inhibition of cholinesterases in cases of human poisoning; thus, Rastogi *et al*. (1990) found that plasma cholinesterase was decreased in patients poisoned by aluminium phosphide by the oral route. Brain cholinesterase was not affected. Plasma cholinesterase inhibition did not appear to influence prognosis and aminotransferase estimation did not suggest liver disease, so that a hepatic origin for the decreased cholinesterase activity seems unlikely. Some epidemiological work has reported an increased incidence of chromosomal aberrations following occupational exposure to phosphides or phosphine gas (Garry *et al*., 1989; 1992) although other work has not confirmed this finding (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment, 2001).

8 TOXICITY OF COMBINATIONS OF PESTICIDES

There has been some concern as to the possibility of deleterious effects from multiple pesticides exposure, either as residues in food or at the workplace. The former seems unlikely to be much of a problem, as clinical effects from exposure to pesticide residues in food are exceedingly uncommon, although it has been suggested that adverse effects of long-term exposure to multiple residues, even at low doses, may be a problem. The workplace is more of a potential concern, raising the question of the safety of tank-mixing of pesticides and other sources of combined exposure. Frequently, data on a particular combination are scanty and general principles are necessary for predictive purposes. The possible types of toxicological combined action with pesticides are: (i) additivity, (ii) potentiation (synergy) and (iii) antagonism. Often, compounds with the same toxic effects act additively and the observed effect is dose additivity. If toxic effects were only determined by actions at receptors, this would probably always be the case. However, one has also to consider alteration by one pesticide of the pharmacokinetics or metabolism of the other, and as a result interactions may be exceedingly complex. However, at doses below NOAELs, combined effects other than dose addition are unlikely to occur. Thus, in combination, the acute toxicity of OCs at moderate dose levels is usually additive, although potentiation and antagonism can occur. With pairs consisting of one OP and one OC, the same is true (Keplinger and Deichmann, 1967). It has been shown that some pairs of OPs exhibit greater than additive toxic effects when administered together (Dubois, 1961). Because of the predictive difficulty, experimental approaches have been proposed (GIFAP, 1988). A major problem in this area is the poor design of many studies in the literature (Borgert *et al*., 2001).

The problem of exposure to mixtures of pesticides was first systematically addressed in practical terms in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

the USA. The Food Quality Protection Act (FQPA) of 1996 (USA, 1996) mandated the consideration of all sources of pesticide exposure when carrying out risk assessments, and also the consideration of the effects of combined exposure to different pesticides. The act also introduced the terms aggregate exposure assessment (consideration of all sources) and cumulative exposure assessment (consideration of combined exposure to different pesticides); both terms have been much criticized, especially the latter, but they have both passed into general use. The USA has made considerable progress in delineating groups of pesticides with common mechanisms of action (common mechanism groups (CMGs)), where dose additivity might be expected (USEPA, 1998; 1999; 2000a; 2000b; 2001). The first group to be tackled was that comprising OP compounds (USEPA, 2002a), and more recently the *N*-methyl carbamate compounds were evaluated (USEPA, 2007). Much less has been done in the European Union. The UK Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment (2003) prepared a report on the subject and this was followed by a rather impractical action plan (FSA, 2007). Germany (Federal Institute for Risk Assessment, 2005) and other member states of the EU are also addressing the problem in an uncoordinated way, for example the Netherlands (Boon and van Klaveren, 2003) and Denmark (Danish Veterinary and Food Administration, 2003). Even when the CMGs have been defined, there remains the question of how to do cumulative risk assessment. Available methodology has been reviewed (Wilkinson *et al*., 2000). The European Food Safety Authority is taking steps to provide a European approach to combined assessments following a symposium held in 2006 (EFSA, 2007) and the setting up of a working group. To date, none of the combined assessments performed has identified significant risks from combined exposures that merited immediate risk-management action.

9 MICROBIAL PEST CONTROL AGENTS

Microbial pest control agents (MPCAs) are plant protection products that have a micro-organism as the active substance. The micro-organism can be a bacterium, fungus, virus, protozoan, microscopic nematode or microsporidium. An extensive compilation of basic information on biopesticides can be found in Copping (1998).

The first MPCAs are reported to have been introduced commercially in the 1930s (Jarvis, 2001). The majority of MPCAs have a specific action against a limited range of pests, resulting in limited use, often in niche markets. However, due to the loss of older pesticides following review programmes and public pressure against traditional pesticides, interest in biological pesticides has been increasing. Currently, the only products with significant usage are those based on *Bacillus thuringiensis* (Bt) representing approximately 88% w/w of the MPCAs applied in California (Rubin, 2001). Possibly because of the limited use, and the fact that to gain approval they should be benign, there is little information in the public domain on the toxicity, infectivity or pathogenicity to mammals of most MPCAs, the exception being Bt.

Generic concerns relating to microbial pesticides include: production of antibiotics/toxins, ability to infect mammals, sensitizing potential due to the presence of antigenic macromolecules and contamination with pathogenic organisms.

9.1 Toxicity of Particular Organisms

9.1.1 *Bacillus Thuringiensis*

Bt is a spore-forming, aerobic, gram positive bacillus closely related to *B. cereus,* an organism which has been associated with human infections. Bt produces crystalline protein inclusion in its spores that is absent in *B. cereus;* in other respects Bt and *B. cereus* are closely related and Giffel *et al*. (1997) showed that six out of 20 isolates previously identified as *B. cereus* by classical biochemical techniques were more correctly Bt. There is thus a degree of uncertainty about whether Bt can produce infections in humans. The properties of Bt strains differ and it is important to relate data to specific strains of Bt wherever possible.

Protein crystals produced by Bt spores are in the form of a protoxin that becomes active only after it is ingested, solubilized by the alkaline conditions, and activated by enzymes, in the insect gut. The C-terminal of the protein binds to receptors on the gut epithelial cells, is variable and provides species specificity in terms of pesticidal activity. The N-terminal is conserved between strains of Bt and produces a pore in the gut epithelial cells, leading to cell lysis and death (IPCS, 1999).

Some strains of Bt also produce other toxins. The 'β-exotoxin' is a heat stable nucleotide that inhibits RNA polymerases and is toxic to most animal phyla, including insects and mammals. An enterotoxin, similar to that produced by *B. cereus* is thought to be responsible for producing diarrhoea and vomiting in mammals. Several other poorly characterized toxins have also been reported (IPCS, 1999). The Bt strains supplied for insecticidal use are reported to be 'β-exotoxin' free.

In addition to the animal studies on toxicity, pathogenicity and infectivity, a range of studies have been performed on Bt strains used as MPCAs. These indicate that use of Bt as a pesticide is without significant risk to human health, though some preparations

have been found to possess irritant properties (IPCS, 1999; McClintock *et al*., 1995). Green *et al*. (1990) investigated reports of infection over a two year period of Bt spraying. Out of a total of 95 bacillus-positive cultures, 55 contained Bt. Of these, 52 were considered to have been associated with contamination of skin, tissue, surfaces or plates. In the three remaining cases where Bt involvement could not be entirely discounted, the medical history indicated the immune system may have been compromised. Noble *et al*. (1992) performed an epidemiological investigation to monitor any health effects relating to the widespread use of Bt *kurstaki* to eradicate the Asian Gypsy moth in British Columbia. The authors concluded that though there was clear evidence of exposure to Bt *kurstaki* and occasional reports of irritation, in both workers and the general population, there was no case indicating pathogenicity or infection. Damgaard *et al*. (1997) reported the presence of four strains of Bt in infections in burn wounds and from fluid used to treat the burns. None of the strains had insecticidal activity. It is not clear whether these strains of Bt were involved in producing the infection or were merely present as contaminants.

A number of adverse findings relating to Bt have been reported, however, it is not always clear how these reports relate to the actual use of Bt strains as MPCAs. A French soldier injured by a land mine was found to have Bt serotype H34 in necrotic soft tissue from the site of injury. Initial studies with this strain in immunosuppressed mice showed it to induce myonecrosis following cutaneous administration (Hernandez *et al*., 1998). Four strains of Bt related to those used in pesticide formulations were found to give positive results in tests for *B. cereus* enterotoxin. (Carlson *et al*., 1994). Investigations into the levels of *Bacillus* diarrhoeal enterotoxin in one strain of *B. cereus* (positive control) and 10 strains of Bt (one pure strain HD-1; an isolate from a case of bovine mastitis; and eight commercial preparations were performed). The enterotoxin titres in Bt strains varied between 15 and 242, with the *B. cereus* strain having a titre of 1629 (see review by Rosas-Garcia, 2009).

9.1.2 Beauveria Bassiana

Beauveria bassiana ATCC 74040 has activity against a wide range of insect pests, possibly involving the production of beauvericin, a proteinaceous toxin that enhances membrane permeability. Intraperitoneal, oral, dermal or intratracheal administration at up to 2.5×10^9 CFU per animal did not produce any indications of infectivity. An inflammatory response was noted in the lungs of animals dosed intratracheally, but this is considered to be a normal reaction to the presence of large titres of foreign material. A formulation based on ATCC 74040 was found to be a skin sensitizer, although no hypersensitivity incidents have been reported (USEPA, 2000c).

9.1.3 Granulosis Viruses and Nuclear Polyhedrosis Viruses

Granulosis viruses and nuclear polyhedrosis viruses are members of the family of baculoviruses, complex viruses that are protected by a protein overcoat and forming an occlusion body. A number of baculoviruses have insecticidal uses, primarily against moths. Susceptible insect larvae ingest the virus, which becomes active only after ingestion of the occlusion bodies. In the larval gut, the protein overcoat quickly disintegrates, and the viral particles proceed to infect digestive cells and interfere with food absorption. Larvae die after a few days. These viruses occur naturally and are considered to present no known risks to humans or other mammals, as they are unable to jump between phyla (USEPA, 2002b).

9.1.4 Pseudomonas Chloraphis

Pseudomonas chloraphis MA342 has activity against fungi that attack crop roots and can be used to protect cereal seed. The precise mechanism of action has not been identified, but is believed to involve the secretion of an iron-chelating protein and the production of 2,3-deepoxy-2,3-dihydrorhizoxin (DDR). MA342 is not toxic or pathogenic to rats via the oral or inhalation routes and is not closely related to any organisms considered to be pathogenic to humans. The metabolite DDR has been found to be a potent *in vitro* aneugen, inducing a significant increase in c-mitotic cells at concentrations of >25 pM in Chinese hamster V79 cell cultures. This aneugenicity was reproduced *in vivo* with oral doses of 2 and 18.6 mg (kg body weight)$^{-1}$, producing increases in micronucleated polychromatic erythrocytes in NMRI mice. However, DDR is only produced in contact with the target fungi and hence the use of *Pseudomonas chloraphis* MA342 as a seed treatment results in negligible human exposure to DDR (SCP, 2002).

The views expressed in this chapter are those of the authors and do not necessarily reflect the views of any UK Government Department or agency.

Toxicology of Biocides

Bryan Ballantyne

CONTENTS

1 BACKGROUND

The definition of biocides, sometimes referred to as antimicrobials, can be confusing because of the regulatory use and misuse of this term and what materials are included in approved listings. Generally, biocides are defined as chemicals or biological agents that are capable of destroying, preventing or rendering harmless pathogenic organisms. They were originally defined in relation to antimicrobial activity, but in regulatory language the spectrum of activity and the types of organisms affected has widened considerably, to the extent that biocides can be interpreted as nonagricultural pesticides. Thus, the Biocidal Products Directive (BPD) of the European Union (EU) defines biocidal products as 'active substances or preparations containing one or more active substances—intended to destroy, deter, render harmless, prevent the action of, or otherwise exert a controlling effect on any harmful organism by chemical or biological means'.

In the USA, industrial biocides require approval by the Environmental Protection Agency (EPA) for use, are regulated by the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), and require extensive chemical, efficacy and toxicological testing before approval. In Europe, biocides are regulated through the EU by the BPD, 98/8/EC. This covers a multitude of different products in four main groupings: disinfectants, preservatives, pest control agents and 'other biocidal products' (see **Table 1**). Authorization by the BPD is a two-step process; active substances are evaluated and listed under the aegis of the EU commission, and products are authorized at a national level with individual member states. For a product to be authorized for marketing it requires to be proven that it is sufficiently effective against the intended target organisms, imposes no unacceptable effects on nontarget organisms, exhibits no unacceptable effects on human or animal health, and does not impose unacceptable effects on the environment. Within this process are a multitude of legal and administrative contortions that make the actual scientific and public-health consequences pale into insignificance. The required data for registration of chemical biocides generally includes, but is not necessarily limited to, physicochemical properties, relevant human toxicology, ecotoxicity, environmental fate and behaviour, results from exposure modelling studies and biocidal efficacy studies.

2 USE PATTERNS

Many industrial processes, such as pulp and paper manufacturing, use large amounts of recirculated water that, if left untreated, will become contaminated, leading to odours, equipment fouling, and failure and contamination of the finished product. Aside from general contamination, bacteria in untreated systems can attach to equipment surfaces. The initial interaction of the bacteria with the surface is reversible, but eventually

Table 1 Main grouping of biocidal products covered by the European Union Biocidal Products Directive 98/8/EC

Main group 1: *Disinfectants and general biocidal products*
1. Human hygiene biocidal products
2. Private area and public-health area disinfectants and other biocidal products
3. Veterinary hygiene biocidal products
4. Food and feed area disinfectants
5. Drinking water disinfectants
Main group 2: *Preservatives*
6. In-can preservatives
7. Film preservatives
8. Wood preservatives
9. Fibre, leather, rubber and polymerized materials preservatives
10. Masonry preservatives
11. Preservatives for liquid-cooling and processing systems
12. Slimicides
13. Metalworking-fluid preservatives
Main group 3: *Pest control*
14. Rodenticides
15. Avicides
16. Molluscicides
17. Insecticides, acaricides and products to control other arthropods
19. Repellents and attractants
Main group 4: *Other biocidal products*
20. Preservatives for food or feedstocks
21. Antifouling products
22. Embalming and taxidermist fluids
23. Control of other vertebrates

becomes irreversible due to adhesion of exopolysaccharide polymers (Costerton *et al*., 1987). The attached bacteria form a biofilm on the surface that may cause major problems in a given system, such as clogging of equipment, breaking off to move into downstream systems, adding pressure to the system and slowing down the process. In addition, there can be costly down time associated with cleaning out systems plagued by biofilm. Also, biofilms may tend to harbour anaerobic bacteria under the biofilm layer. These sulfate-reducing bacteria (SRB) cause additional corrosion problems in tanks and pipes, leading to process leaks and potentially dangerous situations. In many cases, the problems created by biofilms (sessile bacteria) are much more serious and detrimental than those caused by free-floating (planktonic) bacteria. Sessile and SRB, however, are typically more difficult to kill than planktonic bacteria. This is due, in part, to transport limitations into the biofilm and potentially phenotypic changes in bacteria, and making the bacteria more resistant to certain biocides (Grobe and Stewart, 2000; Costerton *et al*., 1987). Accordingly, industrial biocides vary in their ability to control these bacteria.

Industries that use biocides include oil-field water flooding, pulp and paper mills, cooling towers, retort processing systems, wastewater treatment and textile processing. These systems are dynamic in nature with periodic turnover of the treated water that requires a sump-side addition of the biocide. Biocides used in these systems do need to sterilize the systems, but must be able to reduce micro-organism load and maintain low enough levels to help prevent biofilm formation. Some biocides are added continuously at low doses to maintain control, while others are added as slug doses (higher concentrations added quickly with repeated additions over time). The type of addition will depend on the system being treated, as well as the biocide.

Aside from treating dynamic systems, biocides are also used to preserve formulations used for personal care products (e.g. shampoos and cosmetics), detergents (e.g. fabric softeners) and industrial applications (e.g. concrete admixtures, paints, adhesives and lubrication fluids). When used as a preservative, a biocide must have long-term activity, as it is added only once to the product and is intended for long-term storage and repeated insult. Preservatives used in these applications include isothiazolones, glutaraldehyde (GA), 2-bromo-2-nitropropane-1,3-diol (BNP), *o*-phenylphenol, formaldehyde and formaldehyde-releasing compounds, carbamates and parabens.

Sanitizers, disinfectants and sterilants represent another class of biocides. Many countries have specific criteria that must be met to qualify for these labels. The level and type of organism reduction is important. In general, sterilants are required to completely kill bacterial spores, which, aside from prions, are considered amongst the most difficult of organisms to kill, followed by mycobacterium, nonlipid or small viruses, fungi, vegetative bacteria, and lipid or medium-sized viruses. The Center for Disease Control and Prevention (CDC, Atlanta, Georgia, US) classifies sterilization and disinfection processes using liquid chemicals as follows:

- Sterilization: sporicidal chemical, prolonged contact (e.g. GA, chlorine dioxide, hydrogen peroxide, peracetic acid (PAA)).
- High-level disinfection: sporicidal chemical, short contact time (e.g. GA, chlorine dioxide, hydrogen peroxide, PAA).
- Intermediate-level disinfection: some tuberculocidal activity (e.g. phenolics, iodophors or chlorine compounds).
- Low-level disinfection: No tuberculocidal activity, kills most bacteria and viruses quickly, can include sanitizers (e.g. quarternary ammonium compounds, some iodophors and some phenolics).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

For sterilization, autoclaving is typically the method of choice, unless the instrument is heat sensitive. In that case ethylene oxide (EO), as gas plasma sterilization, is used. The low-temperature liquid chemical sterilants referred to here (GA and PAA), are typically used for high-level disinfection rather than full sterilization, even though both chemicals are sporicidal under certain conditions. High-level disinfectants are used to disinfect semicritical devices which enter the body and may come into contact with mucosal surfaces, but do not, in general, break through these membranes and enter the normally sterile areas of the body. In the USA, high-level disinfectants must be able to kill spores under some conditions, and must be able to kill some spores and all mycobacteria under the label conditions.

3 CHEMISTRY OF BIOCIDES

Biocides are typically separated into two main classes; oxidizers such as halogens, and nonoxidizers such as isothiazolones, GA, 2,2-dibromo-3-nitrilopropionamide (DBNPA), quarternary ammonium compounds, tetra-(hydroxymethyl)-phosphonium sulfate (THPS), BNP and methylenebisthiocyanate (MBT). Industrial biocides are chemically diverse compounds and include many classes of chemicals such as phenolics, surface-active agents, aldehydes, halogens, heavy metals and many other miscellaneous compounds. They can be nucleophiles or electrophiles, oxidizing agents or reducing agents. Because of this diversity, there is no general mechanism that can be used to describe the mode of action of these chemicals (Denzer, 1995). While individual metabolic processes may be affected by biocides, the broad spectrum of lethality exhibited by many of the most successful biocides suggests a certain lack of specificity. For example, GA is known to nonspecifically react with amine and thiol groups of cellular and membrane proteins and enzymes. Phenolics interact with the cell wall, interfere with membrane potential, and react with thiols and amines. Surface-acting agents, such as quarternary ammonium compounds, affect general membrane permeability (Denzer, 1995; Favero, 1994).

Because of the nonspecific nature of the mechanisms of action of the many industrial biocides, micro-organisms do not develop genetic resistance to biocides, as do organisms to antibiotics and other chemotherapeutic agents. There are, however, many instances of organisms developing some degree of resistance or tolerance to particular biocides (Chapman, 1998; Chapman *et al.*, 1998; Grobe and Stewart, 2000). The mechanisms for this resistance presumably differs with each biocide. In some cases it may be opportunistic growth of a tolerant subclass, in others the stress induced by the biocide or inclusion in a biofilm may trigger phenotypic changes in the organism making it more difficult to kill. In any case, the biocide industry has developed strategies to deal with these issues, such as alternating biocides to prevent development of tolerance and using synergistic blends.

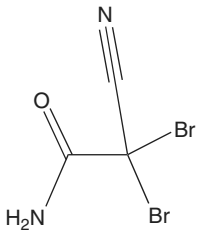
Since biocides have many differing mechanisms of action, they also have differing degrees of activity against the organisms of interest. Therefore, not every biocide is suitable for each application, and in some cases biocides are used together or in succession in order to obtain optimum biocidal activity. Some biocides are primarily used for long-term preservation, whilst others are used for quick kill and short half-life. Some of the more important and widely used biocides are discussed below.

4 INDIVIDUAL BIOCIDES

4.1 2,2-Dibromo-3-nitrilopropionamide (DBNPA)

4.1.1 Identities and Physicochemical Properties

Structural formula:



Molecular formula: $C_3H_2Br_2N_2O$
CAS No: 10222-01-2
Chemical family: Halogenated cyanoacetamide
Synonyms: 2,2-Dibromo-2-cyanoacetamide, Dibromo-2-carbamoylacetonitrile, DBNPA
Molecular weight: 241.86
Melting point: 123–125 °C
Thermal decomposition: > about 60 °C
Vapour pressure: 8.25×10^{-4} mm Hg (25 °C)
Specific gravity: 2.375 (21 °C)
Appearance: White crystalline powder
Odour: Mild antiseptic
Solubility: acetone: 35 g $100\,g^{-1}$; ethanol: 25 g $100\,g^{-1}$; dimethylformamide: 120 g $100\,g^{-1}$; polyethylene glycol 200: 120 g $100\,g^{-1}$; soluble in water to $17\,g\,l^{-1}$ (25 °C)
K_{ow}: 6.3
DBNPA is available commercially as a powder, or 5–20% solutions containing 40–60% glycol.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Sources of information: Clearon Corporation (2000), (Paulus (1993), pp. 241–249) and Wuzhou International Company (2002).

4.1.2 Mechanism of Action

DBNPA has been demonstrated to bind to living and dead cells, suggesting it is not transported into cells, but binds to the surface membrane. DBNPA reacts with thiols, and most likely inhibits proteins and enzymes on the cell surface by reacting with key groups within these enzymes. In particular, DBNPA has been shown to interfere with the transport of *o*-nitrophenyl-β-D-glycosidase and ^{14}C-glucose into bacteria (Friend and White Kettle, 1980).

4.1.3 Stability and Decomposition

DBNPA is stable at acidic pH, but begins to degrade quickly as the pH is raised ($t_{1/2}$ at pH 6.0 = 155 hours; $t_{1/2}$ at pH 9.0 = 0.3 hours) (Friend and White Kettle, 1980). DBNPA is not very stable in the presence of organics, nucleophiles or UV light (Blanchard *et al*., 1986), and is particularly sensitive to thiols and sulfides. DBNPA degrades to dibromoacetamide and ultimately to CO_2, NH_3 and Br. In a secondary pathway, DBNPA is debrominated by UV light to cyanoacetamide (Blanchard *et al*., 1986; Exner *et al*., 1973).

4.1.4 Biocidal Uses

DBNPA has a broad spectrum of biocidal activity against Gram-negative and Gram-positive bacteria, yeast and moulds. Because of its relatively short half-life in neutral to alkaline formulations, DBNPA is typically used in industrial applications, such as cooling towers, pulp and paper processing, water recirculating systems and RO membranes. DBNPA can be added at a low concentration continuous dose (0.5–5 ppm) or at a higher slug dose (5–20 ppm), added periodically, as needed for control. Laboratory studies have shown that DBNPA is effective in destroying *Legionella pneumophilia* at concentrations of 10^5–10^6 viable cells ml^{-1} (Anonymous, 1979; Skaliy *et al*., 1980).

4.1.5 Toxicology

4.1.5.1 Acute Toxicity

Peroral: DBNPA is of moderate acute peroral toxicity, with an LD_{50} of 308 mg kg^{-1} in the rat. Upper alimentary tract corrosive effects may develop.
Percutaneous: By 24 hour occluded contact, DBNPA is of slight acute percutaneous toxicity, with an LD_{50} of >2000 mg kg^{-1} in the rat.
Vapour exposure: A low acute toxicity is reported in the rat with a 4 hour LC_{50} of 0.32 mg m^{-3} (Clearon Corporation, 2000).

4.1.5.2 Primary Irritation

Skin: Undiluted DBNPA is reported as being moderately irritating to the skin (Clearon Corporation, 2000).
Eye: The undiluted material is reported as corrosive to the rabbit eye (EPA, 1994).

4.1.5.3 Subchronic Repeated Peroral Toxicity

An NOEL (no observed effect level) of 15 mg kg^{-1} day^{-1} was reported for a 13 week peroral study in the rat (Clearon Corporation, 2000).

4.1.5.4 Chronic Toxicity

No information available.

4.1.5.5 Oncogenicity

No information.

4.1.5.6 Genetic Toxicology

Not mutagenic in an Ames test. Not clastogenic in a chromosomal aberration test with Chinese hamster ovary (CHO) cells or a chromosomal aberration test with human lymphocytes. Did not induce unscheduled DNA repair *in vitro* with rat hepatocytes (Clearon Corporation, 2000).

4.1.5.7 Developmental Toxicology

Reported as being not teratogenic in rabbits, in which test an NOAEL (no observed adverse-effect level) of 10 mg kg^{-1} day^{-1} was reported for foetotoxicity (Clearon Corporation, 2000).

4.1.5.8 Reproductive Toxicology

In a two-generation study with rats, a NOEL for reproductive effects was cited as $\geq$30 mg kg^{-1} day^{-1} (Clearon Corporation, 2000).

4.1.5.9 Human Toxicology

By local contamination, DBNPA will produce moderate to severe skin irritation and severe (corrosive) lesions to the eye. Those handling the material should wear appropriate protective clothing and eye goggles. Because of its corrosive properties, swallowing of DBNPA should be regarded as an emergency medical situation, since complications of upper alimentary corrosive lesions may develop and there is a potential aspiration hazard. Because of these considerations, vomiting should not be induced in cases of ingested DBNPA.

No American Conference of Government Industrial Hygienists ACGIH threshold limit value (TLV) is available.

US Department of Transportation (DOT) Packing Group II, Class 6.1

4.1.6 Ecotoxicology

Values for aquatic toxicity are as follows:

Rainbow trout: 96 hour $LC_{50} = 2.3\,mg\,l^{-1}$
Sheepshead minnow: 96 hour $LC_{50} = 3.4\,mg\,l^{-1}$
Bluegill sunfish: 96 hour $LC_{50} = 0.72\,mg\,l^{-1}$
Mysid shrimp: 96 hour $LC_{50} = 0.72\,mg\,l^{-1}$
Eastern oyster: 96 hour $LC_{50} = 0.37\,mg\,l^{-1}$
Daphnia magna: 48 hour $EC_{50} = 0.86\,mg\,l^{-1}$

Values for avian toxicity are as follows:

Bobwhite quail, acute oral $LD_{50} = 354\,mg\,kg^{-1}$
Mallard duck, dietary $LC_{50} > 5620$ ppm
Bobwhite quail, dietary $LC_{50} > 5620$ ppm.

4.2 Methylenebisthiocyanate (MBT)

4.2.1 Identities and Physicochemical Properties

Structural formula: NCS-CH_2-SCN
CAS No: 6317-18-6
Molecular weight: 130.13
Melting point: 101–105 °C
Appearance: Yellow powder
Solubility: Water—poorly
Sources of information: Paulus (1993, pp. 421–422).

4.2.2 Mechanism of Action

MBT interferes with cell metabolism by complexing with iron in enzymes such as cytochromes and disrupts energy transfer reactions that rely on iron-containing enzymes.

4.2.3 Stability and Decomposition

MBT is commercially available as a dilute liquid or in a dry powder form (95% active) (Friend and White Kettle, 1980; Hugo and Russell, 1982). MBT is more stable at acidic pH than at alkaline pH ($t_{1/2}$ at pH 6 = 288 hours; $t_{1/2}$ at pH 9 = 1 hour), rapidly hydrolyzing at alkaline pH to cyanide and thiocyanate (Friend and White Kettle, 1980).

4.2.4 Biocidal Uses

MBT has been used as a biocide for over 30 years. It has a broad spectrum of activity against bacteria, yeast, moulds, algae and anaerobic SRB (Friend and White Kettle, 1980; Wehner and Hinz, 1971). MBT is usually formulated as a liquid in organic solvent or aqueous suspension. It is primarily used in slug doses of 2–10 ppm in cooling towers, pulp and paper processing and leather applications. Because of its antifungal activity, it is also used, at higher concentrations, as an antisapstain wood preservative for short-term preservation of freshly sawn wood.

4.2.5 Toxicology

4.2.5.1 Sensitizing Potential

Skin: Shown to have a strong sensitizing potential in a guinea-pig maximization test (Andersen and Hamann, 1983). Human cases of possible allergic contact dermatitis have been described (Jappinen and Eskelinen, 1987).

4.2.5.2 Subchronic Toxicity

Peroral: Male and female Fischer 344 rats and $B6C3F_1$ mice were given MBT by gavage at dosages of 1, 2, 4, 8 or 16 $mg\,kg^{-1}$ daily for five days per week for 13 weeks. Mortalities occurred at 2, 4, 8 and 16 $mg\,kg^{-1}$ with rats and 8 and 16 $mg\,kg^{-1}$ with mice. Histology demonstrated squamous mucosal hyperplasia and hyperkeratosis in the forestomach, with an NOEL of 4 $mg\,kg^{-1}$ for male rats and 2 $mg\,kg^{-1}$ for female rats, and male and female mice (NTP, 1993a).

4.3 Quarternary Ammonium Compounds (Quats)

There are many different biocidally active quarternary ammonium compounds in use. Each may differ in some properties, such as specific efficacy, sensitivity to organic load or salt, and degree of foaming. Quats are available commercially as clear to yellow liquids and are very soluble in water (Paulus, 1993, pp. 375–387).

4.3.1 Mechanism of Action

Quats are cationic compounds containing a nitrogen bonded to four alkyl or heterocyclic groups and a small counterion. In order to have antibacterial efficacy, at least one group must be C_8-C_{18} in length

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Hugo and Russell, 1982). Variation in chain length and type can significantly affect biological activity. Quats are considered surface-active agents. The hydrophobic chains are able to orientate themselves in the cell wall with the hydrophilic portion remaining outside the cell. In this manner, quats disrupt cytoplasmic membranes, releasing K^+ ions and other constituents (Merianos, 2001). Quats also dissociate conjugated proteins in the membrane, and in this manner alter membrane permeability.

4.3.2 Stability and Decomposition

Quats have varying sensitivities to hard water (salt) and organic load. The extent of inactivation varies with the chain length or substitution on the benzyl ring of *N*-alkyl-*N*,*N*-dimethylammonium chloride (ADAC) (Merianos, 2001). They tend to be more active under alkaline conditions, and less soluble as the hydrophobic chain increases in length. They tend to be inactivated and potentially precipitate in the presence of anionic surfactants (Hugo and Russell, 1982).

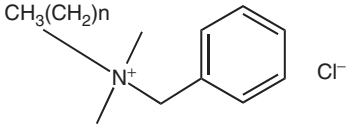
4.3.3 Biocidal Uses

Quats are more active against Gram-positive bacteria (minimum inhibitory concentration (MIC) > 50 ppm). Quats are used as hard surface disinfectants in household products, food processing, hospitals and animal housing. Quats are not normally used as high-level disinfectants or instrument sterilants since they lack mycobacterial and sporicidal activity (Hugo and Russell, 1982; Merianos, 2001; Paulus, 1993). Quats are active against lipophilic viruses and fungi, and are used in pools against algae. In addition to disinfection, quats are used as preservatives in personal care products (e.g. shampoos) as well as household products, and in water recirculating processes and cooling towers. Because quats have a tendency to foam, they require care when applied in large systems. Quats are often used in combination with other biocides for synergistic effects, For instance a GA/quarternary ammonium formulation is used in cooling towers and pulp and paper processing. Two representative quats are discussed below.

4.3.4 N-Alkyl-N,N-Dimethyl Ammonium Chloride (ADAC)

4.3.4.1 Identities and Physicochemical Properties

Structural formula:

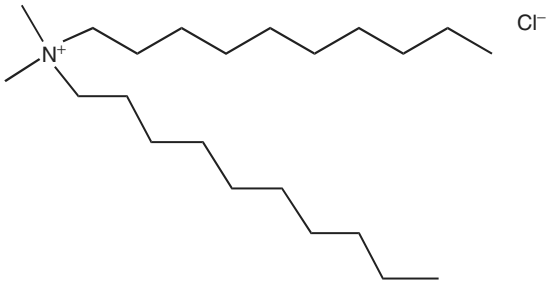


$n = 8–16$
CAS No: 68391-01-5
Molecular weight: 354
Freezing point = +5 to −12 °C
Boiling point: 80 °C (50%)
Flash point: 34 °C
Density: 0.95 g cm^{-3}
Viscosity: 860 mPa

4.3.5 Di-N-Decyl-Dimethyl Ammonium Chloride (DDAC)

4.3.5.1 Identities and Physicochemical Properties

Structural formula:



CAS No: 7173-51-5
Molecular weight: 362.09
Freezing point: −20 °C
Flash point: 29 °C
Density: 0.91 g ml^{-1}
Viscosity: 52 mPa

4.3.5.2 Toxicology

Sensitizing potential

Skin: A few cases of occupational allergic contact dermatitis have been described (Dejobert *et al*., 1997).

4.3.5.3 Ecotoxicology

The following acute toxicity values have been obtained for aquatic species (Farrell *et al*., 1998):

Acipenser tyransmontanus: 24 hour $LC_{50} = 1–10$ ppm
Pimephales promelas: 96 hour $LC_{50} = 0.39$ ppm
Platichthys stellatus: 96 hour $LC_{50} = 2.0$ ppm
Daphnia magna: 48 hour $LC_{50} = 0.037$ ppm
Mysidopsis bahia: 48 hour $LC_{50} = 0.039$ ppm
Hyalella azteca: 48 hour $LC_{50} = 0.106$ ppm
Neomysis mercedis: 48 hour $LC_{50} = 0.947$ ppm

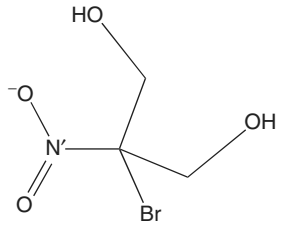
General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.4 2-Bromo-2-nitropropane-1,3-diol (Bronopol; BNP)

4.4.1 Identities and Physicochemical Properties

Structural formula:



Molecular formula: $C_3H_8BrO_2N$
Molecular weight: 200
Melting point: 130–133 °C
Appearance: White crystalline solid
Aqueous solutions of BNP release 30% formaldehyde over time.
Sources of information: (Paulus, 1993, pp. 55–57, 70–72)

4.4.2 Mechanism of Action

Formaldehyde released from BNP is not the active species that kills the micro-organisms. BNP is electrophilic in nature, and its activity is due primarily to oxidation of thiols in proteins to form disulfides. BNP also causes membrane damage (Stretton and Manson, 1973). Because BNP activity is seen mainly with dividing cells, the primary effect likely involves metabolic processes. Specifically, BNP has been shown to inhibit the dehydrogenases involved in glucose metabolism located in cell membranes and the thiol-acetylation of CoA (Stretton and Manson, 1973). BNP is active against Gram-positive and Gram-negative bacteria, as well as yeast and fungi. The effect is primarily biostatic instead of biocidal, but a change in mechanism may occur. Cell death occurs as the oxidized thiols produce peroxide and superoxide radicals. Cidal concentrations of BNP are typically 10 times those of biostatic (preservative) concentrations (Gutherie, 1997; Shepherd *et al*., 1988). The activity increases with increasing pH, from 5.5 to 8.0.

4.4.3 Stability and Decomposition

Aqueous solutions of BNP are more stable at an acidic than an alkaline pH. As pH increases (>9.0), BNP decomposes, releasing formaldehyde to form bromonitroethanol and, eventually, Br, nitrite and nitroalcohols (Bryce *et al*., 1978; Challis and Yousaf, 1991; Paulus, 1993, pp. 55–57, 70–72). BNP also loses activity in the presence of thiols. When thiols are added to a formulation containing BNP, they can reverse the effects of BNP on the enzymes (Bryce *et al*., 1978; Stretton and Manson, 1973).

4.4.4 Biocidal Uses

Because of its biostatic properties, BNP is typically used as a preservative in slightly acidic formulations, which include cosmetics, toiletries and household products, as well as paints and adhesive (Bryce *et al*., 1978). BNP is particularly effective against Gram-negative bacteria such as *Pseudomonas aeruginosa* (MIC ≈ 50 ppm). It is used at 50–500 ppm against bacteria and 200–2000 ppm against fungi (Paulus, 1993, pp. 55–57, 70–72).

4.4.5 Toxicology

4.4.5.1 Acute Toxicity

Peroral: BNP has a moderate peroral toxicity in the rat, with LD_{50} values in the range 254–342 mg kg^{-1} (Eriksson *et al*., 1995).
Percutaneous: In aqueous solution, BNP is of low acute percutaneous toxicity in the rat, having an LD_{50} of >1600 mg kg^{-1} (Eriksson *et al*., 1995).
Subcutaneous: By subcutaneous doing BNP is of moderate toxicity, with an LD_{50} of 200 mg kg^{-1}.

4.4.5.2 Primary Irritation

Skin: At 2% and above BNP is a severe skin irritant.
Eye: Causes severe eye irritation at 5% and above.

4.4.5.3 Sensitization

Skin: Animal studies indicate that BNP has a skin-sensitizing potential. Controlled human studies and cases of occupational exposure show that BNP can cause allergic contact dermatitis. Although some studies suggest that BNP is a common cause of skin sensitization (Peters *et al*., 1983; Storrs *et al*., 1989), others show a low incidence of sensitization, For example, in a study of 8149 patients in Europe, patch testing showed an incidence of only 0.21% reaction to BNP (Frosch *et al*., 1990). A similar low reactivity rate of 0.46% in 2152 patients for patch testing to BNP was found in the United Kingdom (Shaw, 1997).

4.4.5.4 Toxicokinetics and Metabolism

In vivo studies in the rat using ^{14}C-BNP showed that about 40% of an epicutaneously applied dose was absorbed through the skin in 24 hours. Of the applied

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

radioactivity, about 19% was excreted in urine, faeces and expired air. The 24 hour recoveries of ^{14}C in urine and expired air were 15 and 2%, respectively, after the cutaneous application, compared with 74 and 9% for ^{14}C-BNP given intravenously. Urine thin layer chromatography (TLC) showed three metabolites, but no unchanged ^{14}C-BNP, following both epicutaneous and intravenous dosing (Buttar and Downie, 1980).

4.4.6 Ecotoxicology

BNP has a low volatility (vapour pressure 1.6×10^{-3} Pa). A logP_{ow} of 0.18 indicates a low bioaccumulation potential. BNP is hydrostable at pH 4 and 6. At pH 8 the $t_{1/2}$ is two months (Eriksson *et al*., 1995). Photolysis occurs at a high rate, with a $t_{1/2}$ of about 35 hours. Biodegradation of 1.0 mg l^{-1} of ^{14}C-BNP at 22 °C resulted in rapid transformation (78%) after three days. Cited acute aquatic toxicity values are as follows:

Scenedesmus subspicatus: 72 hour-$EC_{50} = 0.02$ mg l^{-1}; No observed effect concentration (NOEC) = 0.01 mg l^{-1}
Daphnia magna: 48 hour $LC_{50} = 1.4$ mg l^{-1}
Misido bahia: 96 hour $LC_{50} = 5.9$ mg l^{-1}
Brown shrimp: 96 hour-$LC_{50} = 121$ mg l^{-1}
Oyster larvae: 48 hour-$EC_{50} = 0.69$ mg l^{-1} (abnormal larvae); 48 hour $LC_{50} = 1.7$ mg l^{-1}

A reproduction study with *Daphia magna* gave a 21-day NOEC of 0.27 mg l^{-1}. The Swedish National Chemicals Inspectorate has calculated a predicted no-effect concentration (PNEC) for aquatic ecosystems of 0.2 μg l^{-1} based on the lowest NOEC for algae.

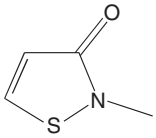
4.5 Isothiazolones

Most commercially available isothiazolone biocides contain both 2-methyl-4-isothiazolin-3-one (MIT) and 5-chloro-2-methyl-4-isothiazolin-3one (CMIT). Most tests for efficacy, mammalian toxicology and ecotoxicology have been conducted using formulations containing both molecular species.

4.5.1 Identities and Physicochemical Properties

MIT

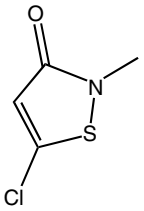
Structural formula:



CAS No: 2682-20-4
Molecular weight: 115.16
Melting point: 47–50 °C
Boiling point: 93 °C

CMIT

Structural formula:



CAS No: 26172-55-4
Molecular weight: 149.60
Melting point: 52–55 °C
Sources of information: (CIREP (Cosmetic Ingredients Review Expert Panel), 1992; Lewis *et al*., 1991).

4.5.2 Mechanism of Action

Isothiazolones are immediately bacteriostatic, but take several hours to achieve biocidal activity. The sulphur atom of N-substituted isothiazolones is electrophilic and reacts with nucleophiles (Crow and Gorman, 1969). These electrophilic molecules target dehydrogenase enzymes in the Krebs cycle, affecting cellular metabolism (Chapman and Diehl, 1995). Cell damage can be measured by the loss of protein thiols. The following mechanism has been proposed:

- Covalent modification via direct electrophilic attack of thiols
- Generation of a secondary electrophile by disulfide exchange and tautomerization to a thioacyl chloride
- Intracellular generation of free radicals, stressing free-radical defence mechanisms.

Bacteria act as a sink for CMIT, concentrating 1.0 ppm as much as 400-fold, and leading to strong association of CMIT within the cell. As the concentration of CMIT increases, the rate of association and the rate of cidal effects increases (Diehl and Chapman, 1999).

4.5.3 Stability and Decomposition

CMIT and MIT are less stable at alkaline pH, with hydrolysis beginning at pH 8. MIT is more stable at alkaline pH than CMIT. Cu^{2+} can be added as a stabilizer for CMIT, protecting it from nucleophilic attack. CMIT and MIT are also sensitive to thiols, reversing biostatic activity and preventing cell death (Chapman and Diehl, 1995).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.5.4 Biocidal Uses

MIT/CMIT has broad spectrum antimicrobial activity. The MIC for *Staphylococcus aureus*, *Escherichia coli* and *Candida albicans* have been determined to be 30 $\mu g\,cm^{-3}$ (Zeelie and McCarthy, 1983). Commercially available isothiazolones usually contain both CMIT and MIT in the ratio of 2.7:1 respectively. CMIT is the more effective biocide, being 100–1000-fold more active than MIT. The CMIT is very water soluble and the mixture is commercially available in 1.5 to ≈14% active solutions (Paulus, 1993, pp. 321–326). Other isothiazolones containing different alkyl chains or other modifications are available for particular applications.

Isothiazolones are used as preservatives in cosmetics and personal care. They are supplied to cosmetic manufacturers in the form of a mixture containing 0.35% MIT and 1.15% CMIT (1.5 MIT/CMIT; CIREP (Cosmetic Ingredients Review Expert Panel), 1992). They are also used in paints, slurries, adhesives and other industrial applications at 5–15 ppm active. In pulp and paper applications, cooling towers and recirculating systems, 0.5–1 ppm isothiazolones are added either continuously or as a fast-feed slug dose. Isothiazolones are sometimes added in combination with, or alternated with, GA or DBNPA. To help prevent the development of bacterial tolerance. at least one preservative formulation is available in combination with BNP. Isothiazolones are also used to prevent marine biofouling of piers and boat hulls, and certain formulations are used in wood preservation. Details of the uses of MIT/CMIT in cosmetic and noncosmetic applications are given in CIREP (Cosmetic Ingredients Review Expert Panel) (1992).

4.5.5 Toxicology

4.5.5.1 Acute Toxicology

Peroral: MIT/CMIT mixtures are moderately toxic to rats, with LD_{50} values in the range of 40–79 mg ai (active ingredient) kg^{-1}. A 1.5% MIT/CMIT mixture had an LD_{50} of 3350 $mg\,kg^{-1}$. Signs of toxicity included those of severe gastric irritation, lethargy and ataxia (CIREP (Cosmetic Ingredients Review Expert Panel), 1992). A 1.5% solution of MIT/CMIT dosed in methylcellosolve to rabbits had an oral LD_{50} of 30 $mg\,kg^{-1}$. Signs of toxicity were decreased motor activity, decreased breathing and those of gastric irritation.

Intraperitoneal: In aqueous solution, acute intraperitoneal LD_{50} values to Wistar rats were 4.6 $mg\,kg^{-1}$ (males) and 4.3 $mg\,kg^{-1}$ (females). The major sign was decreased motor activity and the principal lesion was peritonitis.

Percutaneous: Several MIT/CMIT mixtures were tested, with resultant LD_{50} values determined to be >75, 87, 94, 112 and 130 mg ai kg^{-1}.

4.5.5.2 Primary Irritation

Skin: In New Zealand white rabbits and using standard occluded skin-irritation tests with concentrations in the range 1.1–13.7%, there was severe irritation. Aqueous dilutions of MIT/CMIT were tested on rabbit skin and 0.056% ai was found to be nonirritating, 0.28% ai was moderately irritating, 0.56% ai was severely irritating, and 5.6% ai was corrosive. In humans, the irritation potential of MIT/CMIT is concentration-dependant, with 400–800 ppm being strongly irritating, 200 ppm being slightly irritating, and 100 ppm essentially nonirritating (CIREP (Cosmetic Ingredients Review Expert Panel), 1992).

Eye: In rabbit eye irritation tests, mixtures of MIT/CMIT in the concentration range 1.1–14.0% produced severe irritation, 0.56–1.7% was moderately to severely irritating, 0.28% slightly irritating and 0.056% essentially nonirritating (CIREP (Cosmetic Ingredients Review Expert Panel), 1992). In a rabbit cumulative eye irritation test, 0.1 ml of 0.0056% MIT/CMIT was instilled into the conjunctival sac every 15 minutes for two hours, and this procedure repeated daily for five consecutive days. Mild intermittent conjunctivitis, comparable to tap-water controls, was seen. In a chorioallantoic membrane (CAM) test, 0.03% MIT/CMIT was nonirritating, but higher concentrations produced hyperemia, haemorrhage and coagulation (CIREP (Cosmetic Ingredients Review Expert Panel), 1992).

4.5.5.3 Sensitizing Potential

Skin: With guinea pigs receiving up to nine epicutaneous induction dosages given over three weeks and challenge doses two weeks later, it was found that delayed contact dermatitis developed, the incidence of which was dependant on both the induction and challenge concentrations. In one study, the EC_{50} (half maximal effective concentration) for guinea pigs challenged with 1000 ppm MIT/CMIT was 88 ppm (Chan *et al.*, 1983). The sensitizing potential of MIT/CMIT has been investigated extensively in humans (CIREP (Cosmetic Ingredients Review Expert Panel), 1992). There is general agreement that the MIT/CMIT complex has sensitizing potential, although the potency of CMIT in this respect may be greater than that of MIT. However there is some discrepancy in the cited eliciting concentration. Based on an extensive review of the extensive data, the Cosmetic Ingredients Review Expert Panel (CIREP) has concluded that for cosmetic preparations, MIT/CMIT may be safely used in 'rinse-off' products at a concentration not exceeding 15 ppm, and in 'leave-on' products at a concentration not exceeding 7.5 ppm; this conclusion refers to a mixture containing 23.3% MIT and 76.7%

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141

CMIT (CIREP (Cosmetic Ingredients Review Expert Panel), 1992).

4.5.5.4 Short-Term Repeated and Subchronic Toxicology

Inhalation: Male rats were exposed for six hours a day, five days a week for two weeks to an aerosolized aqueous solution of MIT/CMIT at 0, 0.03, 0.07 and 0.13 mg ai l^{-1}. Mid- and high-dose rats had decreased body-weight gain. There were a few deaths amongst low and high exposure-concentration rats. Lesions included pulmonary haemorrhages and enlarged livers. Thus, under the conditions of this study the NOEC was <0.03 mg l^{-1}.

Peroral: MIT/CMIT was included in the diets of rats for three months to give average daily dosages of 0, 3, 10 and 30 mg kg^{-1}. No mortalities occurred. There was a dosage-related increase in absolute and relative adrenal gland weights in females, and high-dose males had slight, but statistically significant increases in serum glutaric-oxaloacetic transaminase. There were no histopathological lesions. Beagle dogs had average daily dietary dosages of 0, 3, 10 and 30 mg kg^{-1} for three months. This resulted in no abnormal effects with respect to signs, chemical pathology or histology. In another study rats received MIT/CMIT in the drinking water at average daily dosages of 0, 3, 8 and 20 mg kg^{-1} for 13 weeks. There was no mortality, but water consumption was decreased in all MIT/CMIT-treated rats. A significant decrease in serum globulin concentration with increased A/G (albumin/globulin) ratio occurred in the high-dosage females. Relative liver and kidney weights were increased in males and females of the high-dosage group. Slight gastric irritation was seen in the high-dose males and females. The NOEL was 8 mg kg^{-1} day^{-1}, and the minimal effects dosage was 20 mg kg^{-1} day^{-1}.

Cutaneous: Male and female New Zealand white rabbits had cutaneous applications of 0, 0.1, 0.2 and 0.4 mg kg^{-1} daily, five days a week, for 13 weeks to both intact and abraded skin. Deaths, attributed to endemic respiratory disease, occurred in all treatment groups; 3/12, 5/12 and 4/12 respectively for the low-, mid- and high-dosage groups. There was dosage-related slight to severe local erythema and slight oedema, but no treatment-related findings at necropsy or histology.

4.5.5.5 Chronic Toxicology and Oncogenicity

A chronic skin-painting study was conducted in which 25 µl per rat of a distilled water solution containing 400 ppm MIT/CMIT was applied daily, three times a week, for 30 months to the dorsal skin of male Charles River CD-1 mice. A positive control group received 1000 ppm 3-methylcholanthrene in acetone, and a negative control received tap water. In the MIT/CMIT group there was no indication of an increase in local or systemic neoplasms, but all animals in the 3-methylcholanthrene group had local squamous cell carcinomas within six months of the start of treatment.

4.5.5.6 Genetic Toxicology

MIT/CMIT was mutagenic in *Salmonella typhimurium* strain TA 100 with and without metabolic activation, but not with strains TA98, TA1535, TA1537 or TA1538 (Wright *et al*., 1983). When tested separately, CMIT, but not MIT, was mutagenic in TA100 (Scribner *et al*., 1983). MIT/CMIT was also mutagenic, without metabolic activation, in *Escherichia coli* WP2uvrA(p) (Wright *et al*., 1983) and in mouse lymphoma L5178Y cells (CIREP (Cosmetic Ingredients Review Expert Panel), 1992). MIT/CMIT was not genotoxic in the following tests; unscheduled DNA synthesis using rat hepatocytes (Scribner *et al*., 1983); *in vitro* chromosomal aberration test with Chinese Hamster lung fibroblasts; DNA binding *in vitro* with mouse lymphoma cell line; gender-linked recessive lethal test with *Drosophila melanogaster* (Scribner *et al*., 1983); mouse *in vivo* cytogenetics assay; *in vivo* DNA binding with rat testis; and detection of induced cell transformation in mouse embryo fibroblast cell line C3H 10 T1/2 (Scribner *et al*., 1983; CIREP (Cosmetic Ingredients Review Expert Panel), 1992).

4.5.5.7 Developmental Toxicity

When given by gavage to Dutch belted rabbits over gestational days (GD) 6–18 at dosages of 0, 1.5, 4.4 and 13.3 mg ai kg^{-1} day^{-1}, MIT/CMIT was maternally toxic with dose-related mortalities and signs of toxicity (ataxia, diarrhoea and gastric irritation). There were decreases in the number of live foetuses, increased resorption sites and increased postimplantation losses, but no malformations. Thus, in this test, MIT/CMIT was embryofoetotoxic but not teratogenic at maternally toxic dosages (CIREP (Cosmetic Ingredients Review Expert Panel), 1992). When given by gavage to Sprague-Dawley rats over GD5–15 at dosages of 0, 1.5, 4.5 and 15 mg kg^{-1} day^{-1}, there was a low incidence of dosage-related mortalities and signs of toxicity, but no signs of embryofoetotoxicity or teratogenic effects. Male and female Charles River rats were given MIT/CMIT in drinking water at daily average dosages of 0, 3, 8 and 20 mg kg^{-1} for 15 weeks. Rats from the same dosage groups were then mated. There were no adverse effects on fertility, reproduction, foetal survival or foetal health (CIREP (Cosmetic Ingredients Review Expert Panel), 1992).

4.5.5.8 Toxicokinetics and Metabolism

With the Sprague-Dawley rat, ^{14}C-MIT/CMIT was rapidly distributed following intravenous dosing with a total recovery of 94–111%. A rapid elimination of ^{14}C from plasma with sustained maintenance of whole blood ^{14}C (3 µg g^{-1}) at 6–96 hours postdosing suggested ^{14}C to be erythrocyte-bound. In support of this was slow elimination of ^{14}C from the spleen

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and liver. Tissue elimination was biphasic, with a $t_{1/2}$ of >4 hours. By 96 hours faeces, urine and $^{14}CO_2$ accounted for 35, 31 and 4% of the administered dose, respectively. Following epicutaneous application, cutaneous recovery of ^{14}C-CMIT ranged 89–94% over a concentration range of 0.05–0.4%, and was 13% greater than ^{14}C-MIT at 0.2%. Approximately 50% of the radioactivity was associated with the treated skin. Elimination of ^{14}C from the application site had a $t_{1/2}$ of 13.1 days, suggesting a potential for local accumulation by repeated topical application. As the applied concentration was increased, the proportion of ^{14}C in skin decreased and that in excreta increased (Debethizy *et al*., 1986). Other comparative studies in the rat indicate that ^{14}C-MIT and ^{14}C-CMIT were similar in the degree of absorption, binding and excretory patterns following intravenous, peroral and cutaneous dosing. However, MIT produced higher blood concentrations after oral and cutaneous dosing, and a 45% greater relative absorption after peroral dosing than CMIT. Both dose-dependant and saturable processes governed absorption, distribution and elimination of MIT/CMIT in the rat (CIREP (Cosmetic Ingredients Review Expert Panel), 1992).

4.5.6 Ecotoxicology

MIT/CMIT is completely soluble in water, and has relatively high vapour pressure at 8.3 Pa for MIT and 2.4 Pa for CMIT. Henry's constant is calculated to be 9.56×10^{-7} Pa m^3 mol^{-1} for MIT and 3.59×10^{-7} Pa m^3 mol^{-1} for CMIT, indicating low volatility. At pH 5 and 7 CMIT is hydrolytically stable, but at pH 9 hydrolysis occurs with a $t_{1/2}$ of 22 days. MIT is hydrolytically stable at pH 5, 7 and 9. An aerobic degradation study in river water using ^{14}C-CMIT resulted in conversion of 25% to $^{14}CO_2$ after 29 days. Another aerobic degradation study with sediment/water at 25 °C and ^{14}C-CMIT at a concentration of 1.0 mg ai l^{-1} resulted in rapid transformation with a DT_{50} (degradation time with a 50% activity reduction) of 17.3 hours. After seven days, ≈2.8% of radioactivity had been evolved as $^{14}CO_2$ and 57% was bound to sediment. An aerobic degradation study with ^{14}C-MIT in water/sediment at 25 °C, and a test concentration of 1.0 mg ai l^{-1} gave a DT_{50} of 9.1 hours. At seven days ≈9% of radioactivity evolved as $14CO_2$ and 68% was bound to sediment. These studies indicate that MIT/CMIT is inherently, but not readily, biodegradable. MIT/CMIT has high water solubility and respective logP_{ow} values of −0.5 and 0.4, indicating a low potential for bioaccumulation. However, a bioaccumulation study in bluegill sunfish resulted in bioconcentration factors (BCF) of 102, 114 and 67 for CMIT at respective doses of 0.02, 0.12 and 0.8 mg l^{-1}, suggesting that CMIT bioaccumulates. The BCF for MIT is 2.3 at a dose of 0.12 mg l^{-1}, indicating the absence of bioaccumulation. Acute toxicity values for MIT/CMIT are as follows:

Skeletonema costatum: 72 hour $EC_{50} = 0.01$ mg l^{-1} with NOEC < 0.01 mg l^{-1}
Daphnia magna: 48 hour $EC_{50} = 0.18$ mg l^{-1}
Brachydanio rerio: 96 hour $LC_{50} < 0.27$ mg l^{-1} with NOEC = 0.084 mg l^{-1}
Cyprinodon variegatus: 96 hour $LC_{50} = 0.3$ mg l^{-1} with NOEC = 0.18 mg l^{-1}

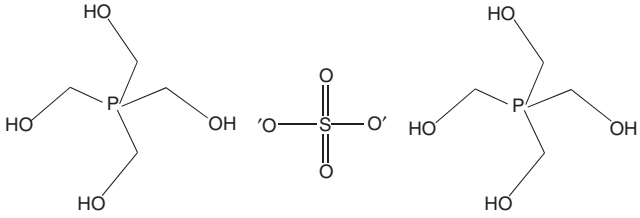
Prolonged testing indicates high toxicity:

Oncorhyncus mykiss: 24 hour $LC_{50} = 0.14$ mg l^{-1}; 14 day $LC_{50} = 0.07$ mg l^{-1}; NOEC = 0.05 mg l^{-1}
Pimephales promelas: Four day $LC_{100} = 0.23$ mg l^{-1}; NOEC = 0.02 mg l^{-1}
A reproduction study with *Daphnia magna* resulted in a NOEC (21 days) of 0.1 mg l^{-1}.

4.6 Tetra-(Hydroxymethyl)-Phosphonium Sulfate (THPS)

4.6.1 Identities and Physicochemical Properties

Structural formula:



CAS No: 55566-30-8
Molecular weight: 406.49
Boiling point: 108.5 °C (75%)
Density: 1.3 g ml^{-1} (75%)
Appearance: Clear straw coloured liquid
Solubility: Miscible with water
Sources of information: (Paulus, 1993, pp. 55–57, 137–138).

4.6.2 Mechanism of Action

Although THPS is a quarternary phosphonium compound, its mode of action differs from that of other quarternary ammonium compounds. THPS has an acidic β-proton that is cleaved by base to form

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

tris(hydroxymethyl)phosphine (THP) and formaldehyde (Hellman and Schumacher, 1960; Kirby and Warren, 1967). The phosphine is the biologically active species. It is known that Ph_3P reduces disulfides to thiols. THPS presumably acts as a reducing agent in a similar manner, disrupting the disulfide bonds in proteins and enzymes (Burns *et al*., 1991; March, 1992; Overman and Petty, 1975; Overman *et al*., 1974). After reaction with disulfide, THPO is formed, which is no longer active (Overman and Petty, 1975).

4.6.3 Stability and Deactivation

THPS is stable at acidic pH, but at alkaline pH it releases formaldehyde to form the active THP species. THP is unstable in the presence of disulfides, acting as a reducing agent to reduce disulfides and degrading to THPO. THPS is also unstable in the presence of oxidizers such as chlorine and peroxide. Both the oxidizer and THPS are consumed in these reactions. THPS is inactivated by reducing agents such as bisulfite. If used in the presence of the oxygen scavenger ammonium bisulfite, THPS has been known to react with the bisulfite in water resulting in an increase in the dissolved oxygen content.

4.6.4 Biocidal Uses

THPS is commercially available as an aqueous solution up to 75% active. Some formulations contain surfactants. THPS is a fast-acting biocide with activity against Gram-positive and Gram-negative bacteria, fungi and algae, as well as SRB. THPS can be added continuously or as a slug dose. It is used as an oil-field biocide at 10–300 ppm in slug doses. It is also used in pulp and paper manufacturing (15–350 ppm), although not in conjunction with oxidizing biocides. THPS has some nonbiocidal uses, such as leather tanning and as an FeS scavenger.

4.6.5 Toxicology

4.6.5.1 Subchronic Toxicity

In a 13 week gavage study F344/N male and female rats received doses of THPS ranging 5–60 mg kg^{-1} and B6C3F1 male and female mice received doses in the range 2–180 mg kg^{-1}. Mortality and reduced body-weight gain occurred in both sexes and both species. Vacuolar degeneration of hepatocytes and hepatocellular necrosis was a common histopathological finding (NTP, 1987).

4.6.5.2 Chronic Toxicity and Oncogenesis

F344/N rats and $B6C3F_1$ mice received 0, 5 or 10 mg THPS kg^{-1} in distilled water by gavage daily for five days a week for 103 or 104 weeks. Mean body weights of rats and mice were comparable to those of controls and no signs of toxicity were seen. There was a dosage-related increase in the incidence of cytoplasm vacuolization of liver cells in rats, of focal hyperplasia of the adrenal medulla in high-dose male mice, and of thyroid gland follicular cell hyperplasia in high-dosage female mice. There was no evidence for carcinogenicity of THPS in either sex of rats or mice (NTP, 1987).

4.6.5.3 Genetic Toxicology

THPS was not active in a *Salmonella typhimurim* reverse mutation test with and without metabolic activation (Ulsamer *et al*., 1980). THPS induced forward mutations in mouse lymphoma L5178Y cells (NTP, 1987). In a micronucleus test, THPS produced small increases in micronuclei at 700 and 1000 mg kg^{-1}, and in a dominant lethal assay using ICR mice, THPS produced a significant decrease in the number of pregnant females and an increase in the number of mortalities at 1000 mg kg^{-1}. There was no increase in the average number of implants per pregnancy (Ulsamer *et al*., 1980).

4.7 Peracetic Acid (PAA)

4.7.1 Identities and Physicochemical Properties

Molecular formula: CH_3-CO-O-OH
CAS No: 79-21-0
RETECS No: SD8750000
Synonyms: Peroxyacetic acid; acetyl hydroperoxide; ethaneperoxoic acid; PAA
Molecular weight: 76.05
Specific gravity: 1.15 (20 °C)
Viscosity: 3.280 cP
Freezing point: −30 °C
Boiling point: 105 °C (40% solution)
Vapour pressure: 2.6 kPa (20 °C)
Flash point: 40.5 °C
pK_a: 8.20
Appearance: Clear colourless liquid
Odour: Acrid type
Sources of information: (ICSC, 2000; Lewis, 1993; NAS, 1995; Paulus, 1993).

4.7.2 Mechanism of Action

PAA acts as a protein denaturant and oxidatively disrupts sulfhydryl and sulphur bonds within essential metabolic enzymes (Lefevre *et al*., 1992). In addition, PAA disrupts membrane transport by rupturing or dislocating cell membranes, and thereby altering their function (Fraser, 1986). The mechanism for this disruption is likely by radical formation.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.7.3 Stability and Decomposition

Lower concentrations of PAA are in equilibrium with acetic acid, peroxide and sulfuric acid. The sulfuric acid is added to favour an equilibrium towards PAA. Eventually the PAA decomposes to acetic acid and water (Block, 2001; Fraser, 1986). Concentrated PAA is not very stable unless stabilizers are added to prevent decomposition to acetic acid and water. PAA is less active in the presence of organics, and most stable at acidic pH. It is most active at pH 2.5–4.0, and inactivated by thiols and other reducing agents (Block, 2001; Paulus, 1993, pp. 430–432). Concentrated PAA requires handling with care because of the potential to be explosive at relatively low temperatures (Paulus, 1993, pp. 430–432).

4.7.4 Biocidal Uses

PAA is commercially available, for use as a general biocide, as an equilibrium mixture with acetic acid, hydrogen peroxide and sulfuric acid in water at about 50% PAA. It is also available as an ≈35% concentrate for instrument sterilization. PAA is regarded as a highly effective disinfectant, but experience with the substance is limited and it is suggested that it should be used in sealed or exhaust-ventilated facilities (Working Party (Report of a Working Party of the British Society of Gastroenterology Endoscopy Committee), 1998). It is more expensive than GA, less stable and larger volumes have to be stored. In a comparative study with chlorine dioxide, PAA was found to produce a high abatement of micro-organisms and considered to be a valuable alternative in the disinfection of wastewater (Stampi *et al*., 2001). Disinfection of wastewater with PAA has been reviewed by Kitis (2004).

PAA is considered more potent than peroxide and better able to control bacteria and spores at safe levels (Block, 2001). PAA has broad-spectrum activity. Aside from being active against bacteria, fungi and viruses, it is also mycobacteriocidal and sporicidal. Therefore, PAA is one of the few biocides capable of low-temperature-liquid high-level disinfection and sterilization (0.1–0.5% active). In addition, PAA vapour can also be used as a sterilant/high-level disinfectant. One commercially available sterilant uses concentrated PAA that is diluted to ≈0.2% active at 55 °C in a specially designed reprocessor (Schneider, 1994). This is a single-use process, requiring fresh PAA for each cycle. Another manufacturer makes a sterilant/ high-level disinfectant at a much lower concentration (0.08%). This formulation also contains 1% hydrogen peroxide and is reusable up to 14 days. Since PAA degrades into acetic acid and water, it is regarded as easy to use and to dispose of. It is, however, somewhat corrosive and repeated use as a sterilant requires the use of a corrosion inhibitor to preserve the integrity of the instruments (Schneider, 1994). PAA is used to disinfect food-processing equipment, including in meat processing, dairies and breweries. Because of the fast decomposition of PAA, these surfaces do not usually require rinsing after use. The low-concentration equilibrium formulations are used to treat cooling towers and water-recirculating systems in slug doses of 1–10 ppm. PAA is also one of the few biocides used to reprocess renal dialysers and to control mould growth on fruits and vegetables. It has also been convenient and effective as a sterilant for apparatus and equipment used to maintain gnotobiotic animals (Fordham, 1978).

4.7.5 Toxicology

4.7.5.1 Acute Toxicity

Peroral: Rat peroral LD_{50} is 1540 mg kg^{-1} for a 40% solution (Anonymous, 1982; NAS, 1995).
Percutaneous: LD_{50} for the rabbit is 1410 mg kg^{-1} (NAS, 1995).

4.7.5.2 Primary Irritancy

Skin: A 40% solution is corrosive (NAS, 1995).
Eye: At 0.1% in water, PAA is not irritating to the rabbit eye. A 10% solution causes ulceration and perforation of the cornea, and formation of synblepharon (Grant and Schuman, 1993). A 40% solution can cause severe eye burns (NAS, 1995).

4.7.5.3 Peripheral Sensory Irritation

PAA is a relatively potent peripheral sensory irritant. In mice, a one hour RD_{50} of 5.4 ppm has been determined (Gagnaire *et al*., 2002). The authors suggest that this value indicates a TLV-STEL (short-term exposure limit) of 0.5 ppm (0.1 RD_{50}) and a TLV-TWA (time-weighted average) of 0.2 ppm (0.03 RD_{50} (exposure concentration producing a 50% respiratory rate decrease)).

4.7.5.4 Genetic Toxicology

When given by intraperitoneal injection at a dosage of 25 mg kg^{-1} day^{-1} for 35 days, PAA produced a slight increase in the rate of mouse sperm-head abnormalities (Koch *et al*., 1989). PAA did not induce DNA-repair synthesis (Coppinger *et al*., 1983).

4.7.6 Occupational Medical Aspects

Skin or eye contact with a 40% solution will cause serious burns. Inhalation of high vapour concentrations or mists will lead to burning sensations in the nose, throat and chest, and coughing, wheezing and shortness of breath (NAS, 1995). These clinical findings indicate that local exhaust ventilation is required, and protective clothing, gloves and eye protection are required when working with PAA (ICSC, 2000).

4.8 Glutaraldehyde (GA)

4.8.1 Identities and Physicochemical Properties

Molecular formula: OHC-CH_2-CH_2-CH_2-CHO
CAS No: 111-30-8
Synonyms: Glutaral; Glutaric dialdehyde
Molecular weight: 100.13
Freezing point: −21 °C (50%)
Boiling point: 100.5 °C (50%) (760 mm Hg)
Density (20 °C): 50% = 1.129 g ml^{-1}; 25% = 1.064 g ml^{-1}; 10% = 1.026 g ml^{-1}; 2% = 1.006 g ml^{-1}
Vapour pressure (25 °C): 50% = 0.116 mm Hg; 15% = 0.041 mm Hg; 2% = 0.0051 mm Hg
Vapour concentration (25 °C): 50% = 207 ppm; 15% = 53 ppm; 2% = 7 ppm; 0.1% = 0.3 ppm; 0.01% = 0.03 ppm
Henry's Law constant: 0.0000331 atm mol^{-1}
Odour: Apple-like
Odour threshold: 0.04 ppm
Solubility (20 °C): Miscible with water, acetone and isopropanol; methylene chloride = 36 g l^{-1}; ethyl acetate = 30 g l^{-1}; toluene = 4.4 g l^{-1}; *n*-hexane = 0.96 g l^{-1}
$P_{ow} = 0.98$

4.8.2 Mechanism of Action

GA is an aliphatic dialdehyde that is capable of reacting with amines and thiols. When GA reacts with amines, it forms a stable six-membered cyclic compound that can be further reacted with another GA molecule or nucleophile (Banin *et al*., 1992; Berrien *et al*., 1994; Francois *et al*., 1998). GA has been used to synthesize cyclic organic compounds in this manner (Banin *et al*., 1992; Berrien *et al*., 1994). GA reacts with amino acids (such as the free amine of lysine) in proteins in a similar manner, producing a crosslinked cell. The formation of a stable six-membered ring is likely to be the reason GA is a potent biochemical dialdehyde. In addition to crosslinking, there are indications that GA inhibits protein synthesis precursor uptake and some cellular enzymes (Scott and Gorman, 2001). The nonspecific nature of the mechanism of action of GA leads to broad-spectrum activity. GA biocidal activity increases at alkaline pH, presumably because, as the pH reaches the pK_a of the available amines, the unprotonated amines become more susceptible to reaction with GA.

4.8.3 Stability and Decomposition

GA is stable at pH 3.0–4.5. As the pH increases (>10), GA forms both soluble and insoluble polymers through aldol condensation. GA is inactivated by bisulfite and primary amines. Complex formation with bisulfite is reversible at elevated temperature (>55 °C). GA is manufactured commercially as a 50% aqueous solution because 100% GA is very unstable and forms clear glass polymers in a relatively short time.

4.8.4 Biocidal Uses

GA is commercially available in aqueous solutions (≈20–50%) (Paulus, 1993, pp. 37–38, 45–47). There are some formulations with ADAC quats at a ratio of 7:1 GA:ADAC. Instrument sterilant formulations are typically 2–4% active GA, some containing surfactants.

GA is used as a general biocide at 25–200 ppm active in pulp and paper processing, cooling water towers, water-recirculating systems, and oil-field recovery (Paulus, 1993, pp. 37–38, 45–47; Scott and Gorman, 2001). GA is also used in some industrial preservative applications at 100–1000 ppm active, and as an animal-housing sanitizer (1000 ppm). It also finds use in reprocessing renal dialysers. GA is sometimes used in conjunction with other biocides, such as quarternary ammonium compounds. GA is a fast-acting biocide, effective against Gram-positive and Gram-negative bacteria, yeast and fungi (>500 ppm) and SRB. GA has been shown to be effective against biofilm. Any reduced activity is linked to transport limitation rather than phenotypic change in the biofilm (Grobe and Stewart, 2000). Since GA is effective against mycobacterial spores, it is one of the few biocides available that can be used as a cold high-level disinfectant or sterilant for endoscopes and other thermosensitive devices (Scott and Gorman, 2001). When used as a sterilant, most acidic solutions of GA (≈2.5% active) are activated by a buffer system to produce an alkaline solution (Ballantyne *et al*., 1997). These sterilants are reusable for up to 28 days. They can be used for manual disinfection, as well as in automatic reprocessors. The instruments require at least a 20 minute soak in the sterilant at 20 °C and then copious rinsing to remove residual GA from the endoscope (Ballantyne and Jordan, 2001). Unlike many other biocides, GA also has many nonbiocidal uses, including leather tanning, tissue fixation, enzyme immobilization, embalming and crosslinking bioprostheses such as heart valves.

4.8.5 Toxicology

4.8.5.1 Acute Toxicity

4.8.5.1.1 Peroral

Aqueous solutions of 5% and higher are of moderate acute peroral toxicity, and those of 2% and lower are

[c]As contained glutaraldehyde dosed.

of slight toxicity, with the mouse being more sensitive than the rat (Ballantyne and Myers, 2001) Typical LD_{50} values are given in **Table 2**. Expressed as the volume of solution dose (ml kg^{-1}), the LD_{50} values increase with dilution, but when expressed as the amount of GA given (mg GA kg^{-1}) the values decrease with increasing dilution. This may have implications for the first-aid management of swallowed GA solutions. Mortality usually occurs within one to three days. Dilute solutions produce only minor irritation of the upper alimentary tract, but more concentrated solutions produce severe irritation and corrosive lesions of the upper alimentary tract. Signs of toxicity include piloerection, sluggishness, rapid breathing and diarrhoea. Survivors recover from these effects by one to five days postdosing, and generally do not show any gross pathology. Decedents usually show congestion and haemorrhage of the gastric mucosa with thickening of the pyloric area, and congestion of the small intestinal mucosa.

4.8.5.1.2 Percutaneous

Aqueous solutions of 45% and higher are of moderate acute percutaneous toxicity, those of 25% of slight toxicity, and 15% solutions do not produce systemic toxicity (**Table 3**; Ballantyne and Myers, 2001).

Table 3 Acute percutaneous lethal toxicity of various concentrations of aqueous glutaraldehyde for male rabbits[a]

4.8.5.1.3 Vapour Exposure

Exposure to vapour generated dynamically or statically at ambient temperature does not produce mortalities, and signs are limited to those of respiratory tract and ocular irritation (blepharospasm, lacrimation, nasal discharge, abdominal and mouth breathing). Typical exposure situations for ambient generation conditions are shown in **Table 4**. Definitive toxicity is seen only in animals acutely exposed to GA vapour generated at high temperature (Ballantyne and Myers, 2001). For example, when rats were exposed to GA vapour generated at 65 °C, they showed an exposure-concentration-related mortality pattern, allowing the calculation of four hour LC_{50} values of 23.5 ppm for males and 40.1 ppm for females. A further study compared the acute vapour exposure toxicity to rats of GA vapour generated at ambient (24 °C) vs. elevated (60 °C) temperature (Ballantyne and Myers, 2001). Under elevated temperature conditions there were four hour LC_{50} values of 36.9 ppm for males and 44.3 ppm for females. Signs included blepharospasm, lacrimation, mouth and audible breathing, and hypoactivity. In contrast, with ambient temperature conditions and GA vapour concentrations of 27.1 and 27.4 ppm, there were no mortalities. The marked differences between the elevated and ambient temperature generation findings may, in part, be due to the ability to generate higher vapour concentrations at the elevated temperature, but the possibility that a toxic

[b]As mean ± SD.
[c]As number dying/number exposed.

species is produced during the heating of GA solutions cannot be excluded. For example, in a four hour saturated vapour study (23 °C), in which the GA vapour concentration was 22.2 ppm, there were no mortalities. In contrast, in a study with vapour generation at 65 °C and a vapour concentration of 23 ppm 2/6 males and 2/6 females died. These findings, at comparable GA vapour concentrations, suggest the generation of a toxic species under the elevated temperature conditions.

4.8.5.2 Primary Irritation

4.8.5.2.1 Skin

Standard rabbit primary skin-irritation studies (four hours occluded contact with 0.5 ml) have shown concentration-related effects (**Table 5**). At 45–50%, aqueous solutions of GA produce severe local inflammation (erythema, oedema, desquamation) and corrosion; at 25% there is moderate inflammation, at 5–10% minor to moderate inflammation and 1% is threshold. Alkalinization of 2.2% aqueous GA solutions has no significant effect on skin-irritating potential (Ballantyne *et al*., 1997). In a controlled study with human volunteer subjects it was found that 0.5% aqueous GA solution was slightly irritant (erythema), 0.2% was marginal and 0.1% was not irritant (Ballantyne and Berman, 1984). Regional variations in cutaneous irritant effects occur, which are primarily related to the thickness of the skin (Juhlin and Hannson, 1968; Prigant *et al*., 1996; Reifenrath *et al*., 1985).

4.8.5.2.2 Eye

Rabbit eye irritation tests (Ballantyne and Myers, 2001) have shown the lowest concentration of GA to produce corneal injury is 1%, and the no-effect concentration is 0.5%. Corneal *injury* is mild at 2% GA, but severe at 5%. For conjunctival irritation, the threshold is 0.2% GA and the no-effects concentration is 0.1%. At 1–2%, conjunctival hyperemia and chemosis are marked. Alkalinization of 2.2% GA solution with buffer resulted in corneal injury and conjunctival inflammation being greater and persisting longer than with acidic solutions (Ballantyne *et al*., 1997). Only a few case reports of human eye injury from GA have been published (Dailey *et al*., 1993; Murray and Ruddy, 1985).

Table 5 Primary irritant effects of 0.5 ml of various concentrations of glutaraldehyde in water applied under occluded conditions to shaven dorsal trunk skin of rabbits[a]

GA (% w/w)	Contact time	Observations
50	4 h	Necrosis
50	1 h	Erythema, oedema, desquamation, alopecia, necrosis
50	3 min	Minor transient erythema
45	4 h	Moderate erythema, mild oedema, punctatenecrosis
25	4 h	Moderate erythema, mild oedema, punctatenecrosis
10	4 h	Moderate erythema, mild oedema, punctatenecrosis
5	4 h	Minor erythema and oedema
2	4 h	Minor erythema
1	4 h	None

4.8.5.3 Sensitizing Potential

4.8.5.3.1 Skin Sensitization

Evidence for a low incidence of skin sensitization comes from laboratory animal studies, controlled human volunteer studies, and clinical and occupational case reports. A contact hypersensitivity-type reaction has been demonstrated with the mouse ear swelling test (MEST) (Descotes, 1988; Gad *et al*., 1986; Sailstad *et al*., 1993). Mouse local lymph node proliferate assays (LLNAs) have show concentration-related stimulation of nodal activity, indicating a skin-sensitizing potential for GA (Ballantyne and Jordan, 2001; Dearman *et al*., 1999; Hilton *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1998a). A dosage-related hypersensitivity response was obtained in the guinea pig and mouse that was statistically significant at 0.3% in mice and 3% in both species (Stein *et al*., 1987). Unbuffered 2.2% GA had a greater skin-sensitizing potential than buffered GA (pH 7.8) in a guinea-pig maximization study (Ballantyne *et al*., 1997). Using an LLNA procedure, Hilton *et al*. (1998b) found GA had a greater potential to induce skin sensitization than did formaldehyde.

In a repeated-insult patch test with human volunteer subjects (Ballantyne and Berman, 1984) it was found that 0.1 and 0.2% GA did not cause a sensitizing reaction, but with 0.5% GA induction there was a challenge reaction in one of 109 subjects. There are several reports of allergic contact dermatitis from occupational exposure to GA and also cases of skin sensitizing reactions to GA when used in the treatment of various dermatological diseases (reviewed by Ballantyne and Jordan, 2001). There is some evidence for regional variations in susceptibility to skin sensitization with GA, and which appear to be related principally to differences in skin thickness (Maibach and Prystowsky, 1997). Cross sensitization to formaldehyde does not occur (Gordon, 1983; Lyon, 1971; Maibach, 1975), but cross sensitization to other dialdehydes is possible (Zemtsov, 1992). The available evidence indicates that GA has a potential to cause skin sensitization, with an eliciting threshold concentration of 0.5%. Alkalinization of GA solutions may reduce the incidence of skin-sensitizing reactions (Ballantyne *et al*., 1997). Rarely, allergic contact dermatitis has resulted from exposure to GA vapour (Fowler, 1989). GA does not produce phototoxic or photoallergic reactions (Ballantyne and Jordan, 2001).

4.8.5.3.2 Respiratory Sensitizing Potential

A guinea-pig bronchial hypersensitivity study did not show any change in breathing rate or respiratory waveform after GA vapour challenge exposures (Werley *et al*., 1995). However, a murine IgE induction study produced a concentration-related increase in serum IgE that was significant for 25 and 10% GA, but not 5% GA (Ballantyne and Jordan, 2001). Also, in a cytokine secretion profile study in BALB/c mice (Dearman *et al*., 1999), high levels of interleukins-4 and -10, but low levels of interferon-γ were produced, which is typical of a Th2 (T-helper cell 2) response. Several publications have drawn attention to the possibility that asthmatic-like symptoms may occur following exposure to GA vapour in the occupational environment (summarized by Ballantyne and Jordan, 2001). Some patients have been investigated with respect to the possible role of the immunological system (Curran *et al*., 1996; DiStefano *et al*., 1998; 1999). The correlation between specific IgE antibodies and clinical symptoms is poor, and the role of IgE in the pathogenesis of GA occupational asthma is currently unclear. In most cases the clinical findings are similar to those of reactive airways dysfunction syndrome (RADS), and result from overexposure to GA vapour. In situations where there are good industrial-hygiene controls on potential exposure, then occupational asthma does not occur. Thus, in an epidemiological study involving 218 workers assigned to GA production or drumming units, there was no indication of skin or respiratory sensitizations related to GA exposure (Teta *et al*., 1995). A cross-sectional study of 135 nurses using GA solutions for instrument cold sterilization was conducted in 26 hospitals in Australia (Pisannello *et al*., 1997). There was no evidence for an increased incidence of respiratory effects, including asthmatic symptoms, in the nurses exposed to GA. A large cross-sectional survey of endoscopy nurses was conducted in the UK, using 348 currently employed nurses (Vyas *et al*., 2000). Whilst nurses exhibited irritant symptoms, there were neither clinical nor investigational (respiratory function tests, specific IgE antibody studies) indications of asthma and no evidence that GA is a respiratory sensitizer. Paiczyński *et al*. (2001) evaluated changes in the cytogram, protein content, eosinophil cation protein and mast-cell tryptase concentrations in nasal lavage fluid (NLF) after GA challenge of patients with a positive history of GA-induced asthma. There was a significant increase in eosinophil absolute number and percentage, and in albumin eosinophil cation protein and tryptase concentrations in the NLF from the patients with occupational asthma and rhinitis. The authors concluded that the findings indicate an immunological mechanism of GA-induced asthma and the applicability of NLF analysis.

4.8.5.4 Peripheral Sensory Irritation

GA is a typical peripheral chemosensory sensory irritant (PCSI) material, and can interact with sensory nerve receptors in the skin and exposed mucosal surfaces, resulting in local sensations and related reflexes (see also Ballantyne 1999; **Peripheral Chemosensory Irritation: Fundamentals, Investigation and Applied Considerations**). Exposure to suprathreshold concentrations of GA vapour may result in eye discomfort, excess lacrimation, discomfort in the nose and chest, rhinorrhea, cough and sneezing. The PCSI effects of GA have been investigated by an animal model and by studies with human volunteer subjects. Measurement of the depression of respiratory rate in ND4 Swiss Webster mice gave a calculated RD_{50} of 13.86 ppm (Werley *et al*., 1995). Using a correlative correction factor of 0.03 (Alarie, 1984), it was calculated that 0.2 ppm is a value at which sensory irritation would be anticipated to be negligible in humans. A lower RD_{50} value of 2.6 ppm has been reported for Swiss OF1 mice (Zissu *et al*., 1994). One human study demonstrated a sensory irritant threshold for GA vapour of 0.24–0.26 ppm (Whitmore, 1976), another study gave a human irritation threshold of 0.3 ppm (Colwell, 1976) and Cain *et al*. (2007) obtained a 50% detection (which they called 'feel') in the eye and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

nose at 0.39 ppm and 0.47 ppm respectively in young adult females. Cain and Schmidt (2002) investigated the sensory detection of GA in drinking water, and reported that persons with normal sensitivity detected GA above chance at 6.25 ppm.

4.8.5.5 Subchronic Repeated Exposures

4.8.5.5.1 Peroral

Because the irritant effects of GA may limit dosing by the epicutaneous and inhalation routes of exposure, studies have been conducted by the peroral route to permit maximum dosage, and hence allow the greatest potential for the expression of toxicity. Drinking-water studies have been conducted in the rat, mouse and dog, with dosing up to three months and full monitoring for signs, body weight, food and water consumption, haematology, clinical chemistry, urinalysis, necropsy, organ weights and histology. Dosages were up to 1000 ppm for rats and mice and 250 ppm for dogs. The major, and only, findings in all species were decreased food and water consumption (probably related to an aversion to the taste and/or irritancy of GA), decreased body weight, and decreased urine volume with increased specific gravity. In no species was there any clinical, haematological, biochemical or morphological evidence for target organ or tissue systemic toxicity. All the findings are compatible with decreased urine production secondary to decreased water consumption resulting from an aversion to GA in the drinking water (Hermansky *et al*., 1995a).

4.8.5.5.2 Epicutaneous

Fischer 344 rats had 20 epicutaneous occluded applications (six hours a day) of aqueous GA solutions resulting in dosages of 50, 100 and 250 $mg\,kg^{-1}\,day^{-1}$ (Werley *et al*., 1996). There were no treatment-related mortalities or signs of systemic toxicity. Local skin irritation was minimal (minor erythema and slight oedema). There were slight decreases in body weight (at 250 $mg\,kg^{-1}\,day1^{-1}$), reduced body-weight gain (100 and 250 $mg\,kg^{-1}\,day^{-1}$), and slightly reduced food and water consumption (250 $mg\,kg^{-1}\,day^{-1}$). The only haematological findings (females only) were increased platelet and reticulocyte counts. Clinical-chemistry results showed a slight increase in blood urea nitrogen. Urinalysis was normal. Adrenal gland weights were slightly increased for the 100 and 150 $mg\,kg^{1}\,day^{-1}$ females. Histopathological findings were only seen in the dosed skin area, and consisted of acanthosis, hyperkeratosis, parakeratosis, dermatitis, epidermitis and dermal fibrosis. The minor effects noted are common findings in rodents receiving cutaneous applications of irritant materials (Hermansky *et al*., 1995b). There was no evidence for systemic target organ or tissue toxicity.

4.8.5.5.3 Vapour Exposure

Several short-term (9–12 days) repeated vapour-exposure studies have been conducted in rats and mice as preliminary investigations to definitive subchronic studies. These have been reviewed by Ballantyne and Jordan (2001). Although conducted under differing conditions of vapour generation, vapour analysis and monitoring, the following are common findings. For vapour concentrations of 2 ppm and greater, mortality was exposure-concentration related. The lowest concentration of GA vapour causing mortality was 0.63 ppm (1/20 rats), and all studies showed a steep slope on the vapour-concentration–mortality data. The available evidence suggests a greater degree of lethality for vapour generated at elevated temperatures (about 50 °C) than for vapour generated at ambient temperature. All studies showed effects on the respiratory tract typical of those for an irritant material. At $\geq$5 ppm, respiratory tract histopathology was extensive, but at $\leq$1.6 ppm, effects were generally restricted to the nasal mucosa. Threshold concentrations for effects in the nasal mucosa were 0.3 ppm (rats) and 0.5 ppm (mice), and the no-effect concentration was 0.16 ppm for both species. A detailed subchronic vapour exposure study was conducted with Fischer 344 rats at concentrations of 20, 50 and 200 ppb, with exposures for six hours a day, five days a week, for a total of 14 weeks. There were minimal signs of respiratory tract and ocular irritation, and slightly decreased body weight, at 50 and 200 ppb, but no evidence for respiratory-tract inflammation or systemic toxicity (Greenspan *et al*., 1985). In another study, $B6C3F_1$ mice were exposed to 100 ppb GA vapour for six hours a day, five days a week for 52 or 78 weeks. Lowered body-weight gain was measured for female mice, but males gained weight. Histopathological effects were seen in female, but not male, mice and were restricted to the nasal vestibule. The findings included hyperplasia of the squamous epithelium lining the dorsal wall and lateral aspect of the atrioturbinate, and was associated with intraepithelial and subepithelial cellular infiltration (granulocytes and lymphocytes). This lesion was significantly increased ($p < 0.05$) in female mice of the 52 week (15/48 vs. 2/49 controls) and 78 week (14/28 vs. 6/28 controls) exposure groups. Additionally, epidermal ulceration and erosions were seen with squamous cell and inflammatory exfoliation in the nasal cavity, but there was no squamous metaplasia. Also, there was no histological evidence for systemic toxicity (Zissu *et al*., 1998). In a more extensive study conducted under the US National Toxicology Program, Fischer 344 rats and $B6C3F_1$ mice were exposed for 6.5 hours a day, five days week, for 13 weeks, to GA vapour concentrations of 0, 62.5, 125, 250, 500 and 1000 ppb. Monitors for toxicity included signs, body-weight, haematology, clinical chemistry, sperm morphology, vaginal cytology, and gross and microscopic pathology. The only sign with rats was difficulty with breathing (1000 ppb). Mice were more susceptible, with 10% mortality at 500 ppb and all animals dying at 1000 ppb. Histopathology was restricted to the nasal mucosa and (mice only) larynx, and consisted of inflammation, hyperplasia and squamous

metaplasia. Effects were moderate at 1000 ppm and mild at ≤500 ppb. A no-effect concentration for nasal mucosal effects from GA vapour was established at 62.5 ppb for the male rat. Minimal inflammation was present in half of the female mice at 62.5 ppb (NTP, 1993b).

4.8.5.6 Chronic Toxicity and Oncogenicity

Studies have been conducted by the peroral and inhalation routes. The peroral study was conducted by lifetime (two-year) exposure of Fischer 344 rats to GA in the drinking water at concentrations of 50, 250 and 1000 ppm, resulting in respective average daily dosages of 3.6, 17.1 and 63.9 mg kg^{-1} for male rats and 5.5, 25.1 and 85.9 mg kg^{-1} for females (Van Miller *et al.*, 2002). Interim sacrifices were conducted at 12 and 18 months after the start of dosing. No dosage-related mortality occurred. Absolute body weights and body-weight gains of the 250 and 1000 ppm males and females were reduced over the study in a dose-related manner. Food and water consumption by the 250 and 1000 ppm groups were decreased in a statistically significant dose-related manner over the study, and mean water consumption by the 50 ppm rats was slightly reduced, but not with statistical significance. The 250 and 1000 ppm groups had a dosage-related decrease in urine volume with increased osmolality and slightly reduced pH. Absolute kidney weights were increased in the 250 and 1000 ppm groups at the 12 and 18 months sacrifices, and decreased at the two-year sacrifice. Relative kidney weights were increased at all sacrifice times for the 1000 ppm group, at 52 weeks for the 250 ppm group and at 72 weeks for the 50 ppm group. The urinalysis and renal weight changes are compatible with a physiological compensatory adaptation to reduced water consumption. Gross and histological evidence of gastric irritation was observed, principally in the 1000 ppm rats euthanized at two years and in animals dying during the study. Bone marrow hyperplasia and renal tubular pigmentation, seen in rats that died and in at the two year sacrifice, may have been secondary to a low-grade haemolytic anaemia in animals with large granular lymphocytic leukaemia (LGLL); (Stromberg *et al.*, 1983). The only neoplasm that showed a statistically significant increase was LGLL, which occurred at a high incidence in both sexes and in all groups, including controls, for both animals that died and at the two year sacrifice. The overall incidences for LGLL in the spleen of the 0, 50, 250 and 1000 ppm groups were, respectively, 43, 51, 40 and 46% for males, and 24, 41, 41 and 53% for females. In assessing the significance of the increased LGLL it needs to be noted that the increased incidence occurred only in females, that LGLL is a spontaneously occurring neoplasm in the Fischer 344 rat (Losco and Ward, 1984; Hermansky *et al.*, 1992) and that the incidence of LGLL in control Fischer 344 rats shows temporal intra-and interlaboratory variations (Hermansky *et al.*, 1992; Stefanski *et al.*, 1990). It is possible that the low incidence of LGLL in the control female rats was a consequence of random biological variation. However, even if the increase in LGLL was treatment-related, it is unlikely to have been the result of a genotoxic carcinogenesis. No clear dosage–response relationship was apparent and there was no increased incidence in males. Also, genetic toxicology studies have failed to demonstrate a mutagenic or clastogenic effect in the intact organism (see below). There is the possibility that the increased incidence of LGLL in female Fischer 344 rats was a consequence of the chronic dosing with GA having a modifying effect on one or more of the factors influencing the expression of this spontaneously occurring neoplasm the female rat.

A two year chronic toxicity and oncogenicity study was conducted with GA vapour by the inhalation route with Fischer 344 rats and $B6C3F_1$ mice (Van Birgulen *et al.*, 2000). For rats, groups of 50 males and 50 females rats were exposed to 0, 250 and 750 ppb GA vapour for 6 hours 25 minutes a day, five days a week for 104 weeks. The two year survivals for the 0, 250, 500 and 750 ppb groups were, respectively, 12/50, 14/50, 6/50 and 6/50 for males and 26/50, 3/50, 15/50 and 14/50 for females. Mean body weights of all males, and the 500 and 750 ppb females, were generally slightly reduced compared with the 0 ppb controls. Histopathological effects were mainly limited to the nasal mucosa and seen as exposure-concentration-related squamous epithelial hyperplasia, squamous metaplasia, inflammation, goblet cell hyperplasia and olfactory epithelial hyaline degeneration. Inflammation consisted of infiltrates of neutrophils, lymphocytes and plasma cells. Squamous epithelial hyperplasia and inflammation were present at 250 ppb with statistical significance. Similar sized groups of mice were exposed to 0, 62.5, 125 and 250 ppb GA vapour. The respective two year survival rates were 31/50, 27/50, 40/50 and 38/50 for males and 34/50, 37/50, 35/50 and 32/50 for females. Major findings were nasal histopathological effects, which were qualitatively similar to those for the rats. The incidence of respiratory epithelial squamous metaplasia was increased in the 250 ppb males and females and the 125 ppb females. Respiratory epithelial hyaline degeneration was increased significantly in all groups of GA-exposed females, but not in an exposure-related fashion. Nasal inflammation was increased in 250 ppb females. Turbinate necrosis was seen in 2/50 of the 125 ppb males and in all groups of exposed females. For rats and mice there was no other non-neoplastic histopathology. Under the conditions of this study, there was no evidence for an oncogenic potential with GA and no evidence for systemic toxicity.

4.8.5.7 Genetic Toxicology

Numerous *in vitro* and *in vivo* genetic toxicology studies have been conducted, and are summarized by Ballantyne and Jordan (2001) and Zeiger *et al.* (2005). Mutagenic activity, generally weak, has been demonstrated in *Salmonella typhimurium* strains TA100, TA102, TA104,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat141
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

TA1535/PSK1002, BA9 and BA13 and in *Escherichia coli* strain WP2uvrA. Results with *in vitro* CHO cells depend on the gene locus investigated, with no activity being seen at the hypoxanthine-guanine-phosphoribosyl transferase (HGPRT) locus and weak activity at the thymidine kinase (TK) locus. *In vitro* increases in CHO sister chromatid exchanges generally do not occur and the results from chromosomal aberration tests vary from no to weak activity. DNA damage and repair tests have shown variable results. *In vivo* studies have generally shown no evidence for genotoxic activity (micronucleus, chromosomal aberration, dominant lethal and *Drosophila* tests; Vergnes and Ballantyne, 2002). The absence of genotoxic effects *in vivo* may, in part, be related to the rapid metabolism and protein-binding characteristics of GA, and the fact that ^{14}C-GA cannot be detected in nuclei (Ranly *et al*., 1990). Speit *et al*.(2008) characterized the genotoxic potential of GA using an alkaline comet assay using V79 cells. They demonstrated the induction of DNA–protein crosslinking at a concentration of 10 μM and above. Crosslinking concentrations of GA were also cytotoxic; that is, inhibited cell growth of V79 cultures. They also showed a small, but statistically significant, increase in sister chromatid exchange and micronuclei.

4.8.5.8 Developmental and Reproductive Toxicity

Several developmental toxicology studies have been conducted in various species. Mice given GA by gavage on GD6–15 over a dosage range of 16–100 mg kg^{-1} day^{-1} showed maternal toxicity (mortality and decreased body weight) at 50 and 100 mg kg^{-1} day^{-1} with some indication of foetotoxicity (foetal body weight). However, foetotoxicity and teratogenic effects were not seen at maternally nontoxic doses (Marks *et al*., 1980). With rats given GA by gavage at daily doses of 25, 50 or 100 mg kg^{-1} over GD6–15, maternal mortality occurred at 50 and 100 mg kg^{-1} and body-weight gain was reduced at 100 mg kg^{-1}. There were no effects on implantations, resorptions or number of live foetuses. Foetal body weight was reduced at 100 mg kg^{-1}, but malformations were not seen (Ema *et al*., 1992). In another rat peroral developmental toxicity study, pregnant Wistar rats were given GA in drinking water at average daily dosages of 5.2, 25.7 and 68.0 mg kg^{-1} over GD6–16. The only effect noted was a reduction in drinking water consumption at the mid and high dosages (Ballantyne and Jordan, 2001). In a rabbit study, GA was given by gavage at daily dosages of 5, 15 or 45 mg kg^{-1} over GD7–19. At the highest dosage there were signs of maternal and embryofoetal toxicity, but no malformations. Neither maternal nor developmental toxicity was present at the mid and low dosages (Ballantyne and Jordan, 2001). With respect to reproductive toxicity, several subchronic repeated-exposure toxicity studies have not shown any toxicity to the male or female reproductive tract. Also, a dominant lethal assay in mice by gavage showed no evidence for reduced fertility and no effect on embryofoetal viability (Tamada *et al*., 1978). In a definitive reproduction study, rats received GA in drinking water over two generations at 50, 250 or 500 ppm. This resulted only in a dosage-related decrease in parental water consumption and body weight, with no effects on reproductive performance (Neeper-Bradley and Ballantyne, 2000). Also, two epidemiological studies in hospital workers showed that exposure to GA was not associated with a risk of spontaneous abortion or other risks to reproductive performance (Hemminki *et al*., 1982; 1985).

4.8.5.9 Toxicokinetics and Metabolism

An *in vivo* comparative intravenous and epicutaneous study was carried out using rats and rabbits (McKelvey *et al*., 1992). By cutaneous application, a high proportion of ^{14}C-GA was recovered from the skin (45–61% in the rat, 31–45% in the rabbit). Autoradiography showed activity over the stratum corneum, hair shafts and at foci of dermal necrosis. The proportion of GA absorbed percutaneously in the rat was calculated at 0.3–2.1%, and in the rabbit at 7.5–24.9%. Toxicokinetic profiles showed a bi-exponential form, suggesting a two-compartment model. The absorption rate constants were low in both species (range 0.2–2.0 hour^{-1}). That the rat is a more appropriate model for the human, and shows low skin penetration, as strongly suggested by comparative *in vitro* studies. With isolated human skin it was found that GA did not penetrate isolated thick stratum corneum (sole of foot), whereas 2.8–4.4% of GA penetrated isolated abdominal skin epidermis and 3.3–13.8% penetrated isolated thin stratum corneum from chest and abdominal skin (Reifenrath *et al*., 1985). A detailed *in vitro* species comparison (rat, mouse, guinea pig, rabbit and human) was undertaken with 1,5-^{14}C-GA (Frantz *et al*., 1993). Highest recovery was with the skin of male mice (1.73% with 0.75% GA) and lowest with rat (0.05–0.06% for females and males). Human female skin was low; 0.2% recovery with 7.5% GA and 0.16% with 0.75% GA. GA is metabolized extensively to CO_2, probably through a series of oxidation, decarboxylation and hydrolysis reactions. The major route of metabolism is probably by oxidation by kidney and liver to glutaric-γ-semialdehyde, and then to glutaric acid, which is used to synthesize glutaryl CoA, with further metabolism to glutaconyl CoA, crotinyl CoA, β-hydroxybutyryl CoA and acetyl CoA, and finally CO_2 (Beauchamp *et al*., 1992; Hjelle and Peterson, 1983; Karp *et al*., 1987; Myers *et al*., 1986; Ranly *et al*., 1990).

4.8.5.10 Human Occupational Medical Features

The use patterns of GA imply a potential for human contact with the liquid on skin and eye, as well as

exposure to vapour. Concentration-related skin and eye irritation, and allergic contact dermatitis, are well-known overexposure effects and are discussed earlier in the chapter. Sensory irritation and other symptoms have been documented extensively from exposure to the vapour (Binding and Witting, 1990; Guthua *et al*., 2001; Jachuck *et al*., 1989; Nayebzadeh, 2007; Norback, 1988). Typical are eye discomfort, excess lacrimation, blepharospasm, blepharitis, rhinorrhoea, irritation and dryness of the throat, sneezing, coughing, slight breathing difficulties, headache, nausea and fatigue. These effects are reversible within a few minutes to a few hours of the cessation of exposure. Epistaxis has been reported following vapour exposure (Wiggins *et al*., 1989) and allergic contact dermatitis from vapour contact with skin (Fowler, 1989). The occurrence of asthmatic symptoms has been discussed previously. Limited epidemiology studies on GA-exposed workers have not indicated an increase in malignant tumour incidence (Collins *et al*., 2006; Teta *et al*., 1995). Additionally, inadequately decontaminated endoscopes and medical instruments may be a source of exposure for patients, and lead to inflammatory complications (reviewed by Ballantyne and Jordan, 2001). This has been noted especially for colitis and proctocolitis (Burtin *et al*., 1993; Durante *et al*., 1992; McHanson *et al*., 1998; Stein *et al*., 2001; Zissin *et al*., 1999). Also, a potential has been noted for synovitis (Harner *et al*., 1989), oesophageal injury and dysphagia (Isserow *et al*., 1998; Leudtke *et al*., 2003), bowel injury following peritoneal contamination from a GA-contaminated laparoscope (Karpelowsky *et al*., 2006), laryngotracheitis (Belani and Priedkains, 1977) and ocular toxic anterior segment syndrome (Mamalis *et al*., 2006; Unal *et al*., 2006).

The TLV for GA (activated or unactivated) is 0.05 ppm ($0.2\,mg\,m^{-3}$) as a ceiling value, with irritation and sensitization notations, and an A4 notation (not classifiable as a human carcinogen) (ACGIH, 2007; Anonymous, 2001). The UK Health and Safety Executive has established a maximum exposure limit (MEL) of 0.05 ppm (Evans *et al*., 1997). Inasmuch as the odour threshold (usually cited as 0.04 ppm) is significantly lower than these values, it is likely that GA vapour will be detected by smell before reaching an overexposure concentration. Cain *et al*. (2007) found a greater sensitivity (higher odour potency) for GA vapour in young adult females with a 50% threshold for odour at 0.3 ppb.

4.8.6 Ecotoxicology

GA is hydrolyzable with a DT_{50} of 508 days at pH 5.0, 102 days at pH 7.0 and 46 days at pH 9.0. Photolysis in water at pH 5.0 shows a DT_{50} of 196 days (Eriksson *et al*., 1995). With a P_{ow} of 0.98, the potential for bioaccumulation is low. An aerobic metabolism study (water/sediment) indicated GA ($10\,mg\,l^{-1}$) to be oxidized to glutaric acid. The *t* 1/2 was 10.6 hours, indicating ready biodegradability. Toxicity to aquatic organisms has been determined as follows:

Scenedesmus subspicatus: 72 hour $EC_{50} = 0.85\,mg\,l^{-1}$; NOEL $= 0.31\,mg\,l^{-1}$
Daphnia magna: 48 hour $EC_{50} = 16\,mg\,l^{-1}$
Leptomis maccochirus: 96 hour-$LC_{50} = 12\,mg\,l^{-1}$
Oncorhynchus mykiss: 96 hour $LC_{50} = 12\,mg\,l^{-1}$
Cyprinodon variegatus: 96 hour $LC_{50} = 31\,mg\,l^{-1}$ (flow-through)
Crassostrea virginica: 48 hour $LC_{50} = 0.55\,mg\,l^{-1}$; 96 hour EC50 (shell growth) $= 0.87\,mg\,l^{-1}$ with NOEL $= 0.16\,mg\,l^{-1}$
Carcinus maenus: $LC_{50} = 465\,mg\,l^{-1}$
Palaemonetas bugio: $LC_{50} = 41\,mg\,l^{-1}$

A reproductive study with *Daphnis magna* showed moderate toxicity with a 21 day NOEL of $2.1\,mg\,l^{-1}$.

A PNEC of $6.2\,\mu g\,l^{-1}$ for GA to aquatic ecosystems has been suggested by the Swedish National Chemicals Inspectorate (Eriksson *et al*., 1995). This is based on the lowest NOEL for the most sensitive strain (algae).

Extensive summaries of the toxicology, occupational medical and industrial hygiene aspects of GA can be found in the following—Ballantyne and Jordan, 2001; CIREP (Cosmetic Ingredients Review Expert Panel), 1996; Evans *et al*., 1997; Jordan, 1995.

Dermal Toxicology of Cosmetics and Body-Care Products

David Basketter and Linda Lea

CONTENTS

1 GENERAL INTRODUCTION

There is a tendency in both regulatory thinking and in public perception towards the view that cosmetics are in some way different from other products. The reality of course is that they are formed from a combination of chemical ingredients, raw materials which, in fact, can be found in a very wide range of products. Consequently, the toxicology considerations which apply to other products also apply to cosmetics and body-care products. Application of appropriate toxicological review of product ingredients and of the final formulation is key to meeting the requirement that such products do not cause harm to the consumer. Failure to undertake such a review to an adequate standard gives rise to a risk of adverse reactions (reviewed in Modjtahedi *et al*., 2008). In this chapter, we set out some general thoughts on how a review of product safety generally should be approached for these types of product. Whilst details of its execution inevitably will reflect our own biases, we hope that it will serve to illustrate the basic concepts of what is necessary.

2 CHEMICAL PROPERTIES AND SPECIFICATION

In common with any toxicological review, the starting point is to have a clear chemical definition of the ingredient(s) in terms of chemical composition, chemical structure, purity and potential impurities. When evaluating toxicological data on existing chemicals, the toxicologist should consider the specification of the ingredient tested, as even small levels of impurities can effect the toxicity of the ingredient being tested. This is especially important when toxicological studies have been carried out at different time points by different investigators. Similarly, where new toxicological testing is being planned, the ingredient should be fully characterized chemically and all testing carried out on the same specification and, where possible, on the same manufacturing batch. This should also be representative of the ingredient to be used in the marketplace.

Physical chemical properties such as solubility, partition coefficient and so on can also be valuable to any toxicological evaluation as they can be predictive of some toxicological properties, for example small-molecular-weight-compounds are more likely

to penetrate the skin than are hydrophobic chemicals. Therefore, a good understanding of the chemical properties of an ingredient is required before the toxicological evaluation can begin.

3 ACUTE TOXICITY

Many ingredients used in cosmetic products have already undergone registration as new chemicals, as many are also used in other products. Where this is the case there will usually be acute toxicity data available and it is unusual for there to be a need to generate acute toxicity data. Quite often the data may be old and not meet current testing standards and/or be compliant with Good Laboratory Practice (GLP) standards. However, the data may still be of value in assessing acute toxicity and should be considered before embarking on new acute toxicity tests. The data from acute toxicity tests should be reviewed to identify any ingredients with low LD_{50} (median lethal dose) values against likely exposure levels. Given the generally low exposure to individual ingredients in a cosmetic product, acute toxicity is rarely a limiting factor in a safety evaluation of cosmetic ingredients.

If new data need to be generated then one of the three test methods now adopted by the Organization for Economic Cooperation and Development (OECD) for assessment of acute oral toxicity would have to be used. The tests are OECD 420: fixed dose method (OECD, 2001a), OECD 423: acute toxic class method (OECD, 2001b) and OECD 425: up and down procedure (OECD, 2008). All are considered to refinements to the traditional LD_{50} test.

4 DERMAL IRRITATION

Skin irritation is a complex matter (Chew and Maibach, 2003; Weltfriend and Maibach, 2008; Fluhr *et al*., 2008; Modjtahedi *et al*., 2008). Probably the overwhelming adverse reaction experienced in relation to cosmetics and body-care products comes under this all-encompassing banner. Skin irritation in fact represents a broad family of (unrelated) dermal reactions to direct chemical insult. What is measured in regulatory toxicology is the acute irritant response to a single contact with a high concentration of an individual substance. The contribution that such data makes to the assessment of risk is minimal. The types of adverse reaction experienced by consumers ranges from mild sensory effects (tightness, itching, burning, stinging), to urticaria (sometimes called immediate contact reactions), through to cumulative irritant responses (dryness, redness) and ultimately to severe irritation, even skin corrosion, the gross skin damage that can result, for example, from overexposure to strong alkalis present in hair-relaxing formulations. These cannot be addressed in a single assay and certainly not by the now largely redundant Draize rabbit skin irritation assay (Draize *et al*., 1944).

So, how does the toxicologist proceed? In the first place, although of limited utility, there is some merit in having information on the acute irritant potential of substances. *In vitro* methods for the identification of corrosive materials and those of stronger irritant potential are now well described and are generally accepted in regulatory toxicology (Basketter and Jones, 2008; Jones, 2008). These techniques permit the predictive identification of substances, which if used as ingredients at high concentration might well deliver significant irritant effects into the final formulation. However, in our experience, this is not a common issue for this type of product. As mentioned earlier, the acute irritant response is uncommon, even in occupational irritant contact dermatitis (Malten, 1981; Chew and Maibach, 2003). In reality, frank skin irritation arises as a consequence of repeated exposures, hence 'cumulative' irritant contact dermatitis is the more appropriate terminology. This skin reaction, characterized in its mild form as dryness and redness (erythema) is most commonly associated with repeated exposures to surfactants. So, surfactant-based products, such as liquid soaps, shampoos, shower gels and so on, can (and do) produce this reaction if exposure is sufficient. Much less commonly, and notably only in very susceptible individuals, nonsurfactant-based products with high levels of skin exposure can also produce irritation. The topic of individual susceptibility will be discussed later, but first, how can cumulative irritancy be assessed?

In the past, *in vivo* models of cumulative skin irritancy were developed, but they have no place in twenty-first century toxicology and will not be discussed further. Where inspection of a new product formulation gives rise to any concern (for example, the introduction of a new surfactant type or mixture), then the proper recourse for the toxicologist is to set up an appropriate human study. Clearly, such a course of action demands its own safety assessment, independent ethical review and medical oversight, but for cosmetics and body-care products it represents a safe and wholly appropriate strategy (Walker *et al*., 1996; 1997; Basketter and Reynolds, 1997). Detailed protocols are beyond the scope of this review chapter, not least since the products under question represent a very diverse community. However, a number of key principles can be mentioned. The aim of this type of clinical study typically will be to assess whether a formulation has an unexpected capacity to produce cumulative irritancy. Hence, the test must involve repeated exposures. Then, since the test aims to predict what may occur in a large exposed population by use of small group of volunteers, the exposures may need to be exaggerated compared to normal product use. Thirdly, to ensure that the test is scientifically robust, a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

positive control material will need to be incorporated. Typically, this might be a currently marketed product from the same category where there exists a substantial history of safe use. For example, if the new product is a liquid soap formulation, it could readily be compared to another marketed liquid soap which has an acceptable market history. Exaggerated repeated exposures to these formulations, for example, by hand immersion, would permit their relative irritancy to be compared simply as a function of the number of exposures necessary to produce a slight reaction. Such a type of protocol ensures volunteer safety by limiting the exposures to the point where no more than a slight reaction occurs, but nevertheless provides real data on the end point of concern in the species of concern. It is worth noting here that acute irritancy, such as that measured by conduct of a patch test in humans does not predict cumulative irritancy at all well (Hannuksela and Hannuksela, 1996). In addition, where products are already very mild in respect of effects on the skin, then it has to be recognized that this in itself can present a substantial challenge in terms of the design of a sufficiently sensitive and robust protocol (Farage, 2008).

Nonimmune immediate contact reactions (urticaria) represent another potential adverse skin reactions, typically appearing as redness and swelling (oedema) within minutes of contact and subsiding within an hour (Lahti and Basketter, 2006; Amin *et al*., 2008). There is little report that this is a significant adverse effect seen with the products covered in this chapter, although to an extent this may represent an absence of evidence rather than vice versa. To assess the end point, only a human study will suffice, as there are no animal models. However, as the effect arises from a single contact, is rapid and transient, and with no lasting effect, then a simple open-exposure protocol in a suitable panel of volunteers is sufficient for the assessment of urticarial potential (Basketter and Wilhelm, 1996; Amin *et al*., 2008). It is worth noting here that contact urticaria involves a number of mechanisms, many poorly characterized, with the consequence that individuals sensitive to one standard urticant material (e.g. ethyl nicotinate, cinnamal, benzoic acid) may not be particularly reactive to another. Thus, the identification of a 'sensitive panel' for this end point is complex (Amin *et al*., 2008; Coverly *et al*., 1998).

An important set of skin reactions, though, comprise sensory effects, the most commonly referred to of which is stinging, but which also include itching, burning, tingling and so forth (Coverly *et al*., 1998; Marriott *et al*., 2003; 2005; Peters *et al*., 2006; Modjtahedi *et al*., 2008). A common error is that these end points are all related, such that susceptibility to one will predict reactivity to another (Coverly *et al*., 1998; Marriott *et al*., 2003; 2005). Unfortunately, this is not the case, rendering the clinical evaluation more complex than some have supposed, particularly where there is a wish to use so-called 'sensitive panels'. The reality is that each of the end points being separate, the construction of such a panel requires a great deal more than the identification of those who are sensitive to lactic acid stinging in the nasolabial fold (Marriott *et al*., 2003; Peters *et al*., 2006).

5 DERMAL SENSITIZATION

Whereas irritation arises from a direct local response to skin insult, sensitization requires the systemic involvement of the immune system. So, chemicals which can penetrate into the viable epidermis, react with skin protein, cause local trauma and so be perceived by the immune system as foreign are termed skin sensitizers. Such chemicals have the capacity to induce delayed contact hypersensitivity (contact allergy), a T-cell-mediated response. With further skin contact, the same or a closely similar substance can elicit the local inflammation characteristic of this type of allergy, commonly termed allergic contact dermatitis (reviewed in Rustemeyer *et al*., 2006).

Extensive reviews have been written concerning the guinea pig as the *in vivo* model for the identification of skin sensitization hazards, that is of those substances which possess the intrinsic property that they can cause skin sensitization (Andersen and Maibach, 1985). The guinea-pig maximization test (Magnusson and Kligman, 1970) and the Buehler occluded patch test (Buehler, 1965) are the main tests, and they share certain features in common, in that there is a set of procedures with test substances to attempt to induce sensitization, then the extent, if any, of that sensitization is revealed by challenge testing (application of an occluded patch to the skin) and the reading of any reactions during the next 24–72 hours. Details of the regulatory protocols are in the relevant OECD Guidelines (OECD, 1992). Extensive lists of chemicals tested using these procedures have been published (Wahlberg and Boman, 1985; Cronin and Basketter, 1994).

Towards the end of the twentieth century, a mouse test, the local lymph node assay (LLNA) was developed (Kimber and Basketter, 1992; Kimber *et al*., 1994). The animal-welfare advantages, the objective and quantitative nature of the end point, the simple prediction of skin-sensitization hazards and the full independent validation of the assay (NIH, 1999; Gerberick *et al*., 2000; Balls and Hellsten, 2000; Dean *et al*., 2001) led to this method having its own OECD Guideline (OECD, 2002). Most recently, it has become the preferred assay under REACH (Registration, Evaluation, Authorisation and restriction of Chemicals) and in globally harmonized guidelines for the assessment of skin sensitizers (Commission of the European Communities, 2006). Lists of chemicals tested using the LLNA have been published (Gerberick *et al*., 2004; ICCVAM, 2008).

The identification of chemicals with skin-sensitization hazard may satisfy regulatory toxicology, but is rarely

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

adequate for the proper protection of human health, for example for those chemicals used in cosmetics and personal-care products. Rather, it is simply an essential prerequisite on which to build further analysis, particularly the measurement of the relative potency of a skin sensitizer. In combination with potency data, information on exposure permits a risk assessment to be undertaken. The measurement of the relative potency of skin-sensitizing chemicals has been reviewed recently (Kimber *et al*., 2001; Basketter *et al*., 2005a; van Loveren *et al*., 2008). Guinea-pig tests were not designed for potency assessment and have not been proven to be particularly useful in this respect. In contrast, the LLNA has dose–response assessment and the method used for potency measurement has been to estimate the concentration necessary to cause a threshold effect. In the LLNA, this is termed the EC3 value, the concentration necessary to cause a threefold stimulation compared to concurrent vehicle-treated controls (Basketter *et al*., 1999). What is more important is that the EC3 values correlate well with human predictive test thresholds (Basketter *et al*., 2000; 2005a; 2008b; Ryan *et al*., 2000; Gerberick *et al*., 2001b; Griem *et al*., 2003; Schneider and Akkan, 2004). It is critical to note that this correlation uses the available threshold data from published human experiments, and does not relate to either induction or elicitation thresholds associated with consumer and occupational exposure safe limits—for that, exposure information is required.

Of course, an EC3 value, whilst not an absolute measure, is quantitative and has proven to be very reproducible over time and between laboratories (Dearman *et al*., 1998; Warbrick *et al*., 1999; Basketter *et al*., 2007).

Owing to the lack of definition of a measure of a no observed-effect level (NOEL) within guinea-pig testing strategies, the assessment of skin sensitization risk generally was achieved by application of comparative toxicology and use of complementary processes such as the human repeated-insult patch test (HRIPT). These techniques are detailed elsewhere (Basketter *et al*., 1996). With the advent of the LLNA EC3 value, which is able to predict the HRIPT induction threshold (Safford, 2008), then it has been possible to devise an approach to risk assessment similar to that used in many others of repeat-dose toxicity. Quantitative risk assessment (QRA) for skin sensitization now uses the LLNA EC3 value (together with any other available information) to predict what is effectively an NOEL in the HRIPT. This value is then adjusted by a number of uncertainty (i.e. safety) factors to determine a maximum acceptable exposure level (Gerberick *et al*., 2001a; Felter *et al*., 2002; 2003). There are several important issues that must be noted. Firstly, exposure is measured in terms of dose per unit area, this being the key measure for skin sensitization (Kimber *et al*., 2008). Then, the maximum exposure level is calculated for specific product types since the uncertainty factors incorporate elements of the nature of the exposure which may occur (e.g. rinse off vs. leave on), as well as of the vehicle matrix in which exposure occurs. An outline of the QRA process is presented in **Figure 1**. This process has been evaluated for a range of types of allergen, including fragrances (Gerberick *et al*., 2001a; Api *et al*., 2008), transition metals (Basketter *et al*., 2003) and preservatives (Basketter *et al*., 2008a; Basketter, 2009). It has also been adjusted to take into account exposure at mucosal surfaces (Farage *et al*., 2003). Furthermore, by combining the daily doses from multiple (product) exposures, it represents a transparent tool for the completion of a more comprehensive strategy for the establishment of safe exposure levels than has heretofore been available. Ultimately of course, as in all areas of toxicology, this risk assessment contains assumptions and requires elements of expert judgement and thus is most appropriately used to guide a final safety decision rather than being regarded as a precision tool.

The elimination of animals from this area of predictive toxicology seems a more realistic goal than even just a few years ago and has been the subject of recent reviews which discuss the approaches being currently explored (Casati *et al*., 2005; Basketter and Maxwell, 2007). The prospect of predictions on the basis of chemical structure continue to offer limited utility (Patlewicz *et al*., 2007). Nevertheless, these approaches do offer some very specific benefits, not least that it is not necessary to synthesize the chemical in order to test its sensitizing potential. However, the estimation of chemical reactivity by evaluation of peptide binding (Gerberick *et al*., 2004; 2007; Natsch *et al*., 2007), particularly if combined with other information (Natsch *et al*., 2009), does provide confidence that current efforts are proceeding in a potentially fruitful direction. Cell-based assays have also shown some promise, particularly those utilizing dendritic-like cell lines (Ashikaga *et al*., 2002; 2006; Yoshida *et al*., 2003; Sakaguchi *et al*., 2006; 2007; Python *et al*., 2007). These assays have generally been the subject of some degree of interlaboratory evaluation, but much of the data remains unpublished. All of these and other methods suffer from one defining limitation, that they provide data only on one aspect of the sensitization induction mechanism. For example, peptide-binding assays inform on the potential for chemical reactivity, but do not tell us about epidermal bioavailability, the capacity to produce danger signals or the intrinsic antigenicity of the hapten-modified self-protein structure. It seems probable therefore that data from these various elements of the induction process will have to be combined in order to deliver a nonanimal equivalent to the LLNA or guinea-pig methods. An outline of the strategic approach to this has been presented already (Jowsey *et al*., 2006; Basketter and Kimber, 2009). A first attempt to translate this theory into practice has recently been published and already shows considerable promise, with a good degree of accuracy (approximately 85%) in terms of both the identification and potency characterization of skin-sensitizing chemicals (Natsch *et al*., 2008).

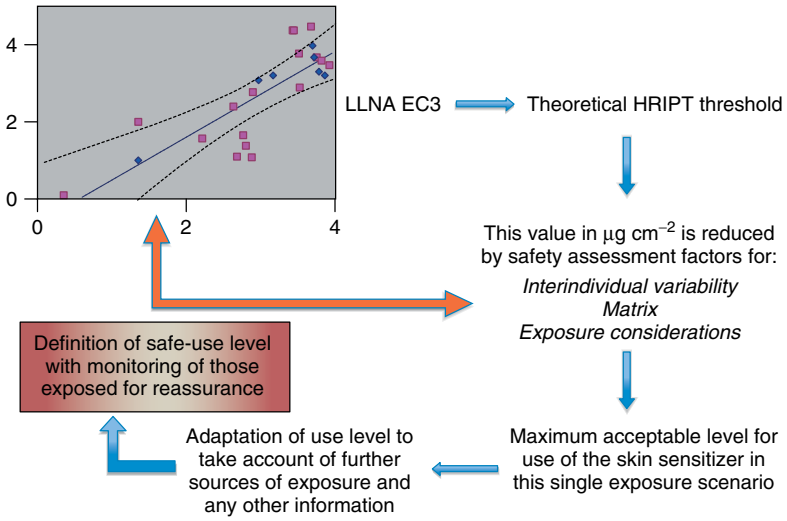

Figure 1 Outline of skin sensitization quantitative risk-assessment process. For a new substance, the definition of the LLNA EC3 value (or its estimation using *in vitro* techniques) permits the prediction of the threshold for the induction of skin sensitization in the human repeated-insult patch test. This latter threshold is then adjusted by the consideration of three safety-assessment factors, each from 1 to 10× (normally, human variability is always taken as 10×, complementing the assumed 100 subject variation in the HRIPT). The calculation yields a maximum acceptable exposure level, expressed in $\mu g\,cm^{-2}$ per day. However, this is associated with the individual sensitizer and exposure scenario under consideration, so the safety assessor must also take account of other potential exposures to the particular substance. Finally, the ultimate test, safety in use, should be followed and any clinical feedback on the success or failure of the safety assessment can be used to refine the critical variables and assumptions implicit in the QRA process.

6 GENOTOXICITY

An assessment of genotoxicity is required for all cosmetic ingredient products with the three main end points under evaluation being:

- Mutagenicity at the gene level
- Clastogenicity (chromosome damage and/or rearrangements)
- Aneugenicity (numerical chromosome aberrations).

Currently there is no single test method that is capable of detecting all these end points and it is usual for a battery of tests to be employed to assess genotoxicity. Previously, it was considered sufficient for a battery of at least two *in vitro* tests, normally a bacteria gene-mutation test (OECD, 1997a) and an *in vitro* mammalian cell chromosome-aberration test (OECD, 1997b) to be carried out (SCCNFP, 2003) and indeed this type of assessment has been widely used for many years. It has now been suggested that the *in vitro* micronucleus test (OECD, 2004a) should be used for the detection of chromosomal effects as it is able to detect both clastogens and aneugens (Kirsch-Volders *et al.*, 1997; 2004). Moreover, in the sixth revision of the notes of guidance for the testing of cosmetic ingredients, the Scientific Committee on Consumer Products (SCCP) now recommends that the first stage of genotoxicity testing should comprise two gene-mutation tests, a bacterial test and a mammalian cell test (OECD, 1997c), along with an *in vitro* micronucleus test to assess clastogenicity and aneugenicity (SCCP, 2006). Other genotoxicity-testing strategies for chemicals have been proposed (Cimino, 2006; WHO, 2008; Pfuhler *et al.*, 2007), as well as that defined in the European Union (EU) Technical Guidance Document (Technical Guidance Document, 2003). This is an area of ongoing discussion and the reader is referred to other chapters (see **Mutagenesis**; **Cytogenetics**; **Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation**) in this book for a more detailed discussion of this subject. In practice, any *in vitro* testing strategy undertaken for a new ingredient should be justified scientifically.

As part of an initial screen, a (Q)SAR ((quantitative) structure–activity relationship) evaluation of new chemicals is now common practice before embarking on any *in vitro* testing. There are a number of commercial and noncommercial software packages available for the prediction of genotoxicity end points, for example TOPKAT, DEREK, MCASE, OECD Toolbox. Whilst a (Q)SAR is unlikely to replace the need for *in vitro* testing, it can provide a useful adjunct to *in vitro* tests.

If the battery of *in vitro* screening tests and any associated SARs analysis are negative then the ingredient can be considered as acceptable for use as a cosmetic ingredient. However, if any of the tests give a positive result, further investigations are required. The nature and extent of the additional testing will be dependant on

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat143
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the positive results in the *in vitro* assays so needs to be considered on a case-by-case basis. It may involve additional *in vitro* tests or there may be a need for *in vivo* tests to be carried out, but a thorough review of all the available toxicology data on the ingredient and, if available, data on structurally related materials should be carried before defining any *in vivo* testing strategy. The most common *in vivo* assays used are the *in vivo* micronucleus and/or the unscheduled DNA synthesis (UDS) assay (OECD, 1997d; 1997e), but before undertaking any testing it needs to be established that the there is adequate exposure to the target tissue to ensure the validity of a negative *in vivo* result.

One of the main issues with current *in vitro* testing batteries is the number of false positives generated. Kirkland *et al*. (2005) evaluated the ability of a battery of three *in vitro* genotoxicity tests to discriminate rodent carcinogens and noncarcinogens and found that the specificity of the mammalian cell tests was low (45%). This can present a problem for evaluating new cosmetic ingredients as a positive result in an *in vitro* mammalian cell test may well define the need for *in vivo* testing, which, under the provisions on the Seventh Amendment to the Cosmetics Directive 76/768/EEC (2003/15/EC), may not be possible. There is also the question as to whether it is economically viable to pursue testing of an ingredient that has given a positive result *in vitro*, as the testing requirements to negate the positive test can be significant and also there is no guarantee that the outcome will be favourable.

For existing chemicals being considered for use as cosmetic ingredients, genotoxicity data should already be available. However, many different test methods both *in vitro* and *in vivo* have been used over the years to make this assessment, not all complying with current testing guidelines and the toxicologist can sometimes find themselves presented with a large number of conflicting results for evaluation. In such cases each study should be evaluated carefully in terms of its quality compared to standard testing guidelines and GLP compliance, as well as scientifically. A weight-of-evidence approach should then be taken to make an assessment of the overall genotoxic potential of the ingredient. Genotoxicity and/or carcinogenicity data from structurally related materials can also be relevant to this evaluation, as well as (Q)SAR predictions.

7 SYSTEMIC TOXICITY

It is the responsibility of the manufacturer of cosmetic products to carry out an appropriate risk assessment to ensure that the products they place on the market will not cause harm to human health, and this includes an assessment of systemic toxicity. This is normally considered in terms of the individual components contained in the product and not on the finished formulation.

The general principles of the risk-assessment process have been well documented by others (WHO/UNEP/ILO, 2001; European Commission, DG Health and Consumer Protection, 2000). The safety assessment process as applied to chemicals used as cosmetic ingredients is the same as for any other chemical. This can be summarized as follows:

- Hazard identification: this is the identification of the intrinsic toxicological properties of the chemical as determined by *in vitro* or *in vivo* toxicological tests. It may also include quantitative structure–activity relationship (QSAR) evaluations.
- Dose–response assessment: this establishes the relationship between the observed toxic effect and the dose. For effects with thresholds it is usually defined as a no observed adverse-effect level (NOAEL) or in cases where no such level can be established a lowest observed adverse-effect level (LOAEL) is sometimes used.
- Exposure assessment: this defines the expected human exposure to the chemical from its intended use.
- Risk characterization: this calculates the likelihood that the chemical could cause damage to human health. For an effect with a threshold, the margin of safety (MOS) is calculated, the MOS being defined as the NOAEL/exposure. For systemic toxicity, an MOS greater than 100 is usually considered acceptable. For other end points, a different MOS may be appropriate. For nonthresholded carcinogens, a slightly different approach is applied, but these chemicals should not be used in cosmetic products, so will not be considered further.

The final stages in the process are risk management and risk communication, which are the responsibility of the regulatory authorities and not considered further here.

7.1 Hazard Assessment/Dose–Response Assessment

The most appropriate hazard study to assess systemic toxicity is a repeat-dose (28 or 90 day) dermal toxicity study. This design of this study closely follows that of a repeat-dose oral toxicity study in that three dose groups and a control group of a minimum of five male and five female rats are used. The maximum dose level is normally $1000\,\mathrm{mg\,(kg\,bw)^{-1}\,day^{-1}}$. The dose is applied to an area of clipped and shaved skin, which should not be less than 10% of the body surface area of the animal, daily for a period of 28 days. The treated area is covered with a fixed dressing to ensure that the animal does not ingest any of the test chemical. Clinical observations are made daily to check for signs of toxicity, and body

DOI: 10.1002/9780470744307.gat143
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

weights and food intakes recorded throughout the study. At the end of the study blood is taken for the measurement of a range of biochemical and haematological parameters. At termination, selected organs are weighed and any gross pathological changes recorded. Histopathological examination of a range of selected tissues is also carried out. After evaluation of all the recorded data an NO(A)EL, expressed in $\mathrm{mg\,(kg\,bw)^{-1}\,day^{-1}}$, is established, which is the maximum dose used in the test producing no adverse effect. If adverse effects are recorded at all dose levels then an LOAEL is established. Full details of the test methodologies can be found in the relevant testing guidelines (OECD, 1981a; 1981b).

In reality, most chemicals are evaluated for the purposes of general chemical use and not specifically for dermal application and in many cases a repeat-dose dermal toxicity study may not be available. However, a repeat-dose oral toxicity study may have been conducted on the chemical and an NOAEL derived from oral exposure is often used to calculate the MOS for dermal exposure.

For some chemicals, particularly chemicals that have been used for many years, more than one repeat-dose study may be available. Some studies may have been conducted more than 30 years ago and may not have evaluated the same end points as more recent studies. The dose levels, species and strains of animals, animal numbers, duration of study and route of administration may differ between the studies. This leaves the safety evaluator with the dilemma of which study to use to calculate the MOS as NOAELs/NOELs can vary between studies.

A more recent study conducted to current testing guidelines that is compliant with GLP standards will normally take precedence over an older, nonstandard, non-GLP study. However, it is fair to say that 20 or 30 years ago many chemical and end-product manufacturers had their own in-house animal testing facilities and so had the opportunity to conduct investigative studies for their own purposes; these studies are often now in the public domain. These studies, whilst not complying with current testing guidelines, can sometimes provide valuable information. There was also less concern over the number of animals used for safety assessments. This is in contrast to the current situation, where many manufactures now contract out their toxicity testing, which, combined with the increasing pressure to reduce animal testing, means that studies on newer chemicals tend to be the more standard toxicity tests required for chemical registration.

There are no hard and fast rules on which study to select for calculating the MOS and each study should be evaluated on its merit. It may be the case that a repeat-dose oral toxicity study is chosen over a repeat-dose dermal toxicity study if the former is considered to be more scientifically valid. The NOAEL could also from a longer-term chronic toxicity test, carcinogenicity study or reproduction toxicity test. It is usual practice to take the lowest NOAEL from the scientifically valid studies reviewed to the safety evaluation. Whichever study is chosen as the pivotal study for the safety evaluation, a justification for the selection should be documented.

Given that oral toxicity studies are often used for the safety evaluation of products applied dermally, there is a need to understand the percutaneous absorption of the chemical across the skin, so an accurate estimate of the systemic exposure can be made. Taking a pragmatic approach before any testing is carried out, it is worth considering calculating the MOS assuming 100% dermal absorption (DA), that is, systemic exposure is equal to dermal exposure. If taking this worst-case approach there is an adequate MOS, then testing may not be necessary. If however, the MOS is not acceptable, then there is a need to generate specific data on DA. This can be determined through either *in vivo* or *in vitro* DA assays such as those outlined in OECD Guidelines 427 and 428 (OECD, 2004b; 2004c). Given the restrictions outlined for animal testing in the Seventh Amendment to the Cosmetics Directive 76/768/EEC (2003/15/EC), in Europe the *in vivo* test option will no longer be available after March 2009 for the assessment of new cosmetic ingredients.

The *in vitro* skin absorption test is described fully in OECD 428 (OECD, 2004b), but in summary consists of applying the chemical to excised skin in a specially developed diffusion cell, which consists of a donor chamber and a receptor chamber between which the skin sample is positioned. The amount applied should be representative of the human exposure expected, typically in the range $1-5\,\mathrm{mg\,cm^{-2}}$ for solids and up to $10\,\mu\mathrm{l\,cm^{-2}}$ for liquids. Although human skin is the obvious choice, availability can sometimes be a problem, in which case pig is the preferred alternative, as it has similar characteristics to human skin. Rodent skin is not normally used, as it is not representative of human skin (ECETOC, 1993). The skin integrity should be verified before the start of the study and afterwards a full mass balance should be carried out.

DA can be affected by a number of factors, such as the physical and chemical properties of the skin, the composition of the formulation, the concentration in the formulation, the site of exposure and whether occlusion occurs (Schaffer and Redelmeier, 1996; ECETOC, 1993). Some cosmetic products are formulated specifically to enhance penetration of other ingredients through the skin. For this reason the full formulation of the cosmetic product needs to be assessed and where such penetration enhancers are present it should be assumed that the systemic exposure is 100% of the dermal exposure. Similarly for ingredients used in cosmetic products intended to come into contact with mucous membranes, the systemic exposure should be considered to be equivalent to the dermal exposure.

7.2 Exposure Assessments

It is standard risk-assessment practice to consider exposure scenarios resulting from intended use or foreseeable misuse of the product, but not abuse. For cosmetic products, exposure is primarily via the skin, although for some lip and dental-care products, ingestion should also be considered; this is outside the scope of this chapter, but in general the same principles apply as for other ingested products. The main considerations for exposure to cosmetic products are as follows:

- Frequency of exposure. The product may be intended for multiple applications daily, such as a hand cream, daily use, such as a shower gel, or intermittent use, such as hair colouring products.
- Duration of exposure. Products such as skin creams are intended to be left on the skin, whereas products such as shampoo or shower gel are rinsed off the skin.
- The concentration of the ingredient in the finished product. Some ingredients, such as the 'actives', preservatives, colours and fragrance ingredients, are used at low levels in the formulation, whereas others that form the base of the formulation can be present as high concentrations. Possible cumulative exposure should also be taken into consideration, as many ingredients are used in many different product types.
- The area of skin exposed. In some cases, such as a body lotion, a large surface area is exposed, whereas for a make-up product only the face will be exposed.
- The quantity of product used at each application. Again this will vary considerably according to product type. Also, some products, such as soaps, are applied in a fairly dilute solution, which will affect the overall exposure.
- Cumulative exposure. Many ingredients are common to different types of cosmetic products, so an estimation of the cumulative exposure from a range of products should also be considered.
- Other factors. There may be a number of other special considerations that can affect exposure. These include: skin integrity—some products are specifically designed for damaged skin and here the skin barrier may be compromised increasing skin penetration; products intended for babies and small children, as these have a high surface area to body weight ratio; oxidative hair dyes, where the ingredients react on the hair and exposure to the reaction products not present in the formulation occurs; products intended to come into contact with mucous membranes where the thin epithelial skin layer is minimal.

This list is not meant to be exhaustive, but gives an indication of the factors to be considered for the exposure assessment. Each new product needs to be considered on a case-by-case basis to ensure all aspects have been covered.

Many companies have their own habits and data practices for particular product types. But there are also a number of published sources of typical exposure data for a large number of cosmetic products, such as those from the Cosmetics, Toiletry and Fragrance Association (CTFA) and the SCCP notes of guidance for the testing of cosmetic ingredients and their safety evaluation (Loretz *et al.*, 2005; 2006; Hall *et al.*, 2007; SCCP, 2006). Using the above, exposure scenarios can be developed that reflect the use of the substance in various applications and can be used to calculate the systemic exposure dosage (SED) in $\mathrm{mg\,(kg\,bw)^{-1}\,day^{-1}}$. For example:

$$\mathrm{SED} = \frac{\mathrm{DA}\left(\frac{\mu g}{cm^2}\right) \times 10^{-3}\frac{\mathrm{mg}}{\mu g} \times \mathrm{SSA(cm^2)} \times F(\mathrm{day^{-1}}) \times R}{60\mathrm{kg}} \quad (1)$$

where

DA—dermal absorption in $\mu g\,cm^{-2}$
SSA—skin surface area in cm^2
F—frequency of application of finished product per day
R—retention factor, for example, 100% for leave on products to 1% for rinse off products
60 kg—typical default human body weight.

There will be considerable variation in the exposure between individuals, so in many instances it may not be possible to measure the exposure accurately and a conservative approach is taken to the exposure assessment. The gathering of exposure data is an ongoing activity and as more data becomes available, the default figures may be refined and updated. It should also be noted that the use of cosmetic products can be very susceptible to changes in fashion and trends in the marketplace.

7.3 Risk Characterization

The final stage in the safety assessment of a cosmetic ingredient is the calculation of the MOS. The MOS is the NOAEL divided by the SED. For a cosmetic ingredient to be considered safe for use, a default value of 100 for the MOS is considered acceptable (SCCP, 2006). It allows a factor of 10 for the interspecies differences between experimental animals and man, and a factor of 10 for human variability. This value is used generally in toxicological risk assessment and is not specific to cosmetic ingredients. An MOS of 100 is not an absolute cut-off and each MOS is considered on a case-by-case basis, as in some circumstances, additional data, for example toxicokinetic, may be available

which suggests that a higher or lower figure may be acceptable.

7.4 Alternative Methodologies for Assessing Systemic Toxicity

Within the EU there is a requirement to develop and validate alternative methods to animal testing to meet the scientific objectives of the 3 R strategy of refinement, reduction and replacement of animal testing. In the Seventh Amendment of the Cosmetics Directive (2003/15/EC) the marketing of finished products containing an ingredient that has been subjected to any animals testing after 2013 is prohibited. At the moment there are no alternative *in vitro* methods or even relevant proposals for alternative methods to evaluate systemic toxicity. This is not surprising given the complexity of evaluating the effects on the whole organism. However, one area that is active is that of developing alternative methodology for carrying out safety evaluations, such as the application of the threshold of toxicological concern (TTC) concept to cosmetic ingredients.

7.5 Use of the TTC

The TTC concept is not new; it is based on a generic exposure threshold that originally formed the basis of the US Food and Drug Administrations Threshold of Regulation for Indirect Food Additives (Food and Drug Administration, 1983; 1993; Threshold of Regulation for Substances used in Food Contact, 1995). Since then, the concept has been continuously developed and undergone many refinements (Munro *et al*., 1996; 1999; Kroes *et al*., 2000; 2004) to its current application in the area of risk assessment (Kroes *et al*., 2005). The basic principle is that a threshold of human exposure can be established below which there is a very low probability of adverse effects on human health. The threshold level is dependant on chemical structure and the known toxicity of a large number of existing chemicals that share similar structural characteristics. Application of the TTC requires the user to work through a decision tree comprising a number of steps which require a yes/no response to progress to the next step. The outcome is that the threshold value is compared to the estimated exposure; where the exposure is lower the chemical is predicted not to be a health concern and where the exposure is higher than a further risk assessment is necessary using compound-specific toxicity data. There is insufficient space here to describe the full history and the methodology, but this can be found in Kroes *et al*. (2005; 2007).

The TTC concept has its origins in food safety and this is where it has been most widely used, particularly in relation to food contact materials and food flavourings. It is also used as a tool in the safety assessment of contaminants in pharmaceutical products (Delaney, 2007). Kroes *et al*. (2005) first suggested the idea that the concept may be suitable for application to nonfood chemicals and many toxicologists have been interested in evaluating whether this approach could be widened to the risk assessment of consumer products. This led to the European Cosmetic Toiletry and Perfumery Association (COLIPA) sponsoring a group of experts to evaluate potential use in the safety evaluation of cosmetics ingredients. The focus of the Expert Group was to evaluate a number of factors related to the use of chemicals as cosmetic ingredients and their exposure. In particular, the similarity of cosmetic ingredients to the chemicals used to establish the thresholds of concern (Cramer classes); differences in metabolism between the oral and dermal route of exposure; default adjustment figures for percutaneous penetration to adjust for systemic exposure via the skin; consideration of the use of adjustment factors to assess the exposure for rinse-off products and products used intermittently; and total exposure to the ingredient. The outcome of this detailed evaluation by the Expert Group has been published by Kroes *et al*. (2007), with an overall conclusion that the TTC approach is suitable for evaluating cosmetic ingredients. Their proposal is for the application of the TTC for cosmetic ingredients to consist of the following steps:

1. Define product type, its intended use and related skin surface area involved
2. Define concentration of ingredient in the product
3. Estimate external exposure per day
4. Estimate skin absorption of the ingredients based on its physical and chemical characteristics
5. If it is a rinse-off product apply retention factor
6. Establish use pattern: for example, daily or intermittent use, if the latter is the case apply the default factor related to the use interval
7. Calculate adjusted internal exposure per person per day
8. Where relevant, calculate total (aggregate) exposure when several cosmetic products contain this target ingredient
9. Use this average aggregate internal dosage in the TTC decision tree.

Using the TTC approach, if the systemic dosage is below the threshold level for the chemical class for the given chemical under consideration, then it is considered not to present a human-health concern and is acceptable for use in cosmetic products. If the level is higher, then the TTC approach cannot be used and ingredient-specific toxicity data is needed for the safety evaluation.

If one compares the steps outlined above with the standard methodology for safety evaluation there is commonality in the process. In particular, both methodologies require a rigorous estimate of exposure, as this is key to providing a reliable safety evaluation. The Expert Group state that the use-related adjustment factors should be regarded as provisional and may need refinement as more data becomes available (Kroes *et al*., 2007). This is also true for any exposure assessment.

Clearly, for some macroconstituents of cosmetic products, a TTC approach is not appropriate, as the exposure will always be above any threshold of no concern. Substances, such as heavy metals, proteins and those with specific structural alerts, that were excluded in the original decision tree developed by Kroes *et al*. (2004) are excluded from inclusion in the TTC approach, as are new chemical ingredients that are suspected to have pharmacological activity (Kroes *et al*., 2007). Furthermore, plant extracts could not be evaluated by the TTC as these are usually complex mixtures of chemicals and the starting point for a TTC evaluation is having a known chemical structure (Kroes *et al*., 2007).

The SCCP was requested to review the proposal put forward by the Expert Group and also address more generally the use of the TTC concept in consumer products and others, where a significant exposure to chemicals is likely to occur through normal-use situations. They also considered whether there was a distinction between intentionally added ingredients and those chemicals that are present as inadvertent contaminants. A draft opinion was published in 2008 (SCCP/1171/08, 19.11.08). Whilst broadly supportive of the TTC approach, the opinion was that the current database of toxicity data used to establish the threshold exposure levels is inadequate for the assessment of chemicals used as cosmetic ingredients. The rationale being that after comparison of the 15 000 cosmetic ingredients listed in the EU database (CosIng) with the chemicals listed in the Munro database (Munro *et al*., 1996), cosmetic ingredients were only covered to a limited extent. A similar conclusion was found for impurities present in cosmetic ingredients. However, at the time of writing, this draft opinion had only just been published and whilst disappointing, the recommendation from the SCCP that the toxicity database needs to be validated and extended before a TTC approach becomes more generally acceptable is one that is likely to be addressed in the near future. The application of the TTC concept in the risk assessment of cosmetic ingredients is still in its infancy and no doubt this is an area where there will be significant focus in the future, as it provides significant opportunity for advancement of alternative methodologies for safety evaluation. As discussed here, the TTC is only being used to consider systemic toxicity, and local end points require separate evaluation, although a proposal for a TTC approach to sensitization risk assessment has already been discussed elsewhere in this chapter.

8 OTHER TOXICOLOGICAL END POINTS

In this review we have focussed on the end points which we consider to be the essential elements of a review of the dermal toxicology of cosmetic and beauty-care products. However, in some instances, further information may be required, such as phototoxicity data, where the cosmetic product is intended for sun-exposed skin (see, for example, Basketter and Jones, 2008). Also, carcinogenicity and/or reproductive toxicity data may be required, due to potential adverse findings in the studies conducted, for example evidence of toxicity to the reproductive system in a repeat-dose toxicity study, or the expected use levels and skin penetration may be high. This has to be evaluated on a case-by-case basis. For high production volume, existing chemical reproductive toxicity and/or carcinogenicity data may already be available, and in such cases any existing data should be taken into account. If there is a need to generate new data this must to be considered carefully, as there will be a requirement for significant animal use with considerable costs and in many cases, unless the ingredient brings significant benefit to the end product, the additional testing requirements may not be justified.

Organic Solvents

Håkon L. Leira, Frode Fonnum and Tore Syversen

CONTENTS

1 GENERAL PRINCIPLES

Organic solvents are a chemically heterogenous group of small lipophilic compounds defined on the basis of their common function, namely the ability to dissolve and disperse solids not soluble in water. Solvents are fluid at room temperature and many of them are highly volatile. These common properties make the number of potential solvents quite large, and several hundred different compounds are in use. However, only a minority of these are used on a regular basis in industry and/or in consumer products. Organic solvents belong to several chemical classes, for example, aliphatic and aromatic hydrocarbons, as well as chlorinated and oxygenated compounds such as alcohols, ketones, aldehydes, esters, glycols and glycol ethers, see **Table 1**.

Solvents are mainly used for metal degreasing and as intermediate chemicals in industry. They are important ingredients in varnishes, paints, lacquers, dyes and adhesives, as well as liquid fuels (gasoline, diesel, jet fuel) and fuel additives (benzene, methyl-*t*-butyl ether). Solvents are also found in the general environment and contamination of drinking water is a growing problem in many parts of the world. Chlorinated solvents, in common with many other halogenated compounds, may deplete stratospheric ozone, thus increasing the amount of incoming solar radiation.

Although exposure to solvents is ubiquitous, the main health challenge results from occupational exposure. The doses encountered in industry may be orders of magnitude greater than in other settings, with one exception. Due to their inebriating properties, various solvents are extensively abused ('glue-sniffing'), particularly among disadvantaged children and adolescents in many countries throughout the world. Part of our knowledge of the potential health effects in humans of organic solvents originate from studies among such abusers.

In industry, single compounds may be used, but exposure to solvent mixtures is the general rule. The literature on health effects of single compounds is extensive, but our understanding of the health effects of solvent mixtures is limited. Thus, toxicological risk evaluations in this field are challenging. In addition to the problem of mixtures, the question of exposed groups further complicates the risk assessment. It is well established that the risk profile of solvent exposure can differ substantially between, for example, neonates, children, pregnant women, diseased people and the elderly, as well as by gender.

In addition to the neurotoxic effects, some solvents have been classified as carcinogens or mutagens. In some cases also the immunological system is affected (Dreiem *et al.*, 2003; Harris *et al.*, 1997). However, except for turpentine, organic solvents are not allergens.

Table 1 The structures, molecular weights and oil/water partition coefficients of selected solvents

Solvent		MW[a]	p.c.[b]
Benzene		78	177
Toluene		92	659
Styrene		104	1168
o-Xylene		106	1318
Ethylbenzene		106	2243
Cyclohexane		84	2754
n-Hexane		86	8710
Carbon tetrachloride		154	631
1,1,1-Trichloroethane		133	309
Trichloroethylene		131	263

[a]Molecular weight.
[b]Oil–water partition coefficients according to Leo *et al*. (1971).

1.1 Exposure and Absorption

Occupational exposure affects a large number of workers in most countries of the world. It is estimated that 10 million workers are exposed in the USA (OSHA (Occupational Safety and Health Administration), 2006). In a representative survey in 1997 by the national bureau of statistics in Norway, 11% of male workers and 7% of female workers stated that they were occupationally exposed to solvents on a daily basis. In many industrialized countries, exposure to organic solvents in industry has decreased over the last decades (Caldwell *et al*., 2000; Burstyn and Kromhut, 2002).

Exposure is particularly common in painters, printers, fibreglass laminators and floor-layers, as well as in petrochemical and refinery workers. Volatility and evaporation surface area are the main determinants of solvent concentrations in air. Spraying procedures lead to high concentrations of solvent vapour as the aerosols represent a vast surface from which the solvents can evaporate. Industrial spray painters are thus among the occupational groups most at risk.

Inhalation and skin absorption represent the most significant routes of solvent uptake. Uptake by inhalation is a simple physical process: the molecules diffuse from the alveolar space into the blood where they dissolve. The solvent molecules will partition between air and blood during the absorptive phase and between blood and other tissues during the distribution phase. The more water soluble a vapour is, the more will be absorbed into the blood during each respiratory cycle. The amount of vapour taken up by various tissues depends on the affinity of the organic solvent for each tissue. Thus, the rate of absorption of organic solvents in the lungs and the distribution to tissues varies considerably and depends on the blood/gas and fat/blood partition coefficients, respectively (Fiserova-Bergerova, 1985; Sato and Nakajima, 1987). Hydrophobic solvents have low blood–gas partition coefficients and their fat–blood partition coefficients are much larger than one. Hydrophilic solvents have blood–gas partition coefficients larger than 200 and fat–blood partition coefficients much smaller than one (Fiserova-Bergerova, 1985). Differences in the uptake and distribution of various organic solvents have been shown predominantly to result from differences in such solubility factors. The pulmonary uptake of many organic

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

solvents in physically active individuals is much larger than in resting individuals, provided that the diffusion of the solvent from the alveolar space into the blood is not rate-limiting (Åstrand, 1983; Fiserova-Bergerova, 1985).

Percutaneous absorption of solvents is generally considered to be of minor importance compared to pulmonary uptake. However, several solvents can be absorbed through the skin, depending on their physical and chemical properties (Nakaaki *et al*., 1980; Kezic *et al*., 1997; Brooke *et al*., 1998). The degree of uptake also depends upon exposure conditions and is proportional to exposure time and the amount of skin surface exposed. Hydrophobic solvents of low molecular weight permeate the skin better than those with high molecular weights or hydrophilic solvents. Solvents that damage the skin will affect the skin integrity and this may enhance the percutaneous absorption of the agent. The glycol ethers 2-methoxyethanol (2-ME) and 2-ethoxyethanol (2-EE) are readily absorbed through the skin, and skin contact of both forearms and hands for 15 minutes may cause a body uptake exceeding inhalation for eight hours at the occupational exposure limit value (Kezic *et al*., 1997). Toluene, xylene, tetrachloroethylene, 1-propanol, methanol, 2-hexanone (methyl butyl ketone (MBK)), 1,4-dioxane and 2-butoxyethanol are examples of other solvents that easily penetrate the skin.

1.2 Metabolism

The metabolism of solvents can be divided into two phases. Phase I is characterized by oxidation, reduction and hydrolysis rendering the molecule more water soluble, while phase II reactions conjugate the metabolite, rendering a product having a molecular weight which is more suited for excretion (through bile or urine). The products of phase I reactions are often more reactive and toxic than the parent compound (metabolic activation), while phase II reactions usually represent a true detoxification reaction. Metabolizing enzymes are widely distributed throughout the body, although the liver is the major metabolic organ.

Several solvents are hepatotoxic due to their conversion to toxic intermediates or metabolites in the liver (Sipes and Gandolfi, 1982). Many of the haloalkanes and haloalkenes appear to have similar toxic effects in liver and kidney (Kitchin and Brown, 1989; Dekant *et al*., 1989). The hepatotoxic and carcinogenic effects of haloalkanes and haloalkenes are generally thought to be due to reactive metabolites rather than the parent molecule. Free-radical intermediates are involved in the toxicity through mechanisms including, for example, lipid peroxidation, covalent binding and cofactor depletion (Cheeseman *et al*., 1985). Ethylene glycol, for example, is metabolized by alcohol dehydrogenase (ADH) to glycolaldehyde and further to glycolic acid. Glycolic acid is oxidized to oxalic acid by glycolic acid oxidase (von Wartburg *et al*., 1964; Liao and Richardson, 1973; Gessner *et al*., 1960). The oxalate may cause acute renal tubular necrosis through the formation of insoluble oxalate crystals in the kidney (Gabow *et al*., 1986; Turk *et al*., 1986). The lethal dose of ethylene glycol is reported to be approximately 100 ml in an adult, but only 5–10 ml in children. ADH catalyses ethanol oxidation, and ethanol can be used as an antidote in ethylene glycol intoxication, as it will reduce the production rate of oxalic acid (Jacobsen and McMartin, 1986). Specific toxic effects of several other solvents such as, for example, benzene, styrene, *n*-hexane, glycol ethers and methanol are also due to production of toxic metabolites, and are discussed elsewhere in this chapter.

1.2.1 Metabolic Interactions of Solvent Mixtures

A thorough review on the toxicology of exposure to mixtures is given in **Toxicology of Chemical Mixtures**. Organic solvents are more commonly used as mixtures than as individual chemicals. Thus the metabolism, and hence the toxicity, of one solvent may be modified by other solvents in the mixture.

The effect of ethanol on metabolism of organic solvents has been shown to be rather complex (Sato *et al*., 1981). At high concentrations, ethanol may act as an inhibitor of solvent metabolism. Thus, concurrent exposure to ethanol and solvents may reduce the clearance of other solvents and the result is increased and sustained internal dose of the solvent (Cherry, 1993). However, an acute dose of ethanol will increase the metabolism of toluene and trichloroethylene (TRI) in rat liver, and ethanol may enhance the hepatic metabolism of these solvents (Sato *et al*., 1981). Ethanol may impair the metabolic clearance of *m*-xylene, causing raised xylene blood concentration and a decrease in the excretion of methylhippuric acid (Riihimäki *et al*., 1982). Some people appear to be more susceptible to combined ethanol–xylene exposure than others, and may develop nausea and dermal flush (Riihimäki *et al*., 1982).

Coexposure of hexane and toluene decreases hexane neurotoxicity and urinary excretion of hexane metabolites in rats (Takeuchi *et al*., 1993). Methyl ethyl ketone inhibits the *in vitro* metabolism of *n*-hexane in a noncompetitive pattern and decreases the levels of the toxic metabolite 2,5-hexanedione (Mortensen *et al*., 1998). Concomitant treatment of rats with a nonhepatotoxic dose of dichloromethane potentiates the hepatotoxicity of carbon tetrachloride (Kim, 1997). Several investigators have demonstrated that coadministration of toluene with benzene protects animals from benzene-induced haematotoxicity (Ikeda *et al*., 1972; Andrews *et al*., 1977; Sato and Nakajima, 1979; Tunek *et al*., 1982). However, such interactions are exhibited only at high concentrations.

Several kinetic studies conducted with volunteers have demonstrated similar metabolic interactions in humans (Engström *et al*., 1984; Wallen *et al*., 1985; Liira *et al*., 1988). In male workers exposed to benzene and toluene, the metabolism of both solvents was depressed, indicating a mutual suppression of metabolism between benzene and toluene (Inoue *et al*., 1988). Coexposure to xylene (100 ppm) and methyl ethyl ketone (200 ppm) in humans has resulted in reduced xylene metabolism (Liira *et al*., 1988). However, the combined exposure did not cause any change in methyl ethyl ketone metabolism. In humans, metabolic interaction took place when the subjects were exposed to a combination of 95 ppm toluene and 80 ppm xylene, whereas no interaction was detected after exposure to a combination of 50 ppm toluene and 40 ppm xylene (Tardif *et al*., 1991). Benzene and toluene competitively inhibit each other's metabolism (Sato, 1993). Male workers exposed to a mixture of solvents, including toluene (18 ppm), methyl ethyl ketone (16 ppm), isopropyl alcohol (7 ppm) and ethyl acetate (9 ppm) (Ukai *et al*., 1994) showed no signs or symptoms that suggested anything other than irritation effects due to toluene exposure. There was no evidence to suggest any modifications of toluene toxicity or metabolism due to coexposure. The results indicate that metabolic interaction depends on the solvents and the level of exposure.

Gasoline (petrol) is a complex mixture of aromatic and aliphatic chemicals. The same enzyme responsible for the metabolism of benzene metabolizes many components of gasoline. Studies at the Chemical Industry Institute of Toxicology (CIIT) have shown that the interactive effect of a complex mixture, such as benzene in gasoline, may only occur at saturating concentrations of these chemical mixtures. At lower and environmentally relevant concentrations, however, these interactions become negligible (Bond *et al*., 1997). 1,2,4-Trimethylbenzene (1,2,4-TMB) occurs mainly in petroleum products, and in man it has been shown that metabolism of 1,2,4-TMB is inhibited after exposure to white spirit compared to exposure to 1,2,4-TMB alone (Järnberg *et al*., 1997). It appears that components in white spirit inhibit the metabolism of 1,2,4-TMB.

1.3 Enzyme Induction

A number of solvents may induce xenobiotic metabolizing enzymes, for example, CYP 2E1 (Conney, 1968; Nebert *et al*., 1978). This enzyme catalyses the metabolism of a large number of solvents, including ethanol. As a socially accepted toxin, ethanol is consumed in large quantities compared to other solvents. Ethanol is known to inhibit drug metabolism acutely, and to stimulate xenobiotic metabolism through enzyme induction when administered repeatedly. Thus the effects of ethanol on the metabolism of other solvents are complex, depending on the timing and frequency of ethanol intake. It has been shown that chronic ethanol administration induces CYP 2E1. Thus, in regular drinkers, elimination of solvent metabolites appears to be faster compared to nondrinkers, presumably caused by enzyme induction (Cherry, 1993). In addition to a faster elimination of solvents, chronic ethanol intake may lead to a faster and increased formation of metabolites, and therefore increased risk of adverse effects due to production of toxic metabolites. It has been shown that alcoholics have an increased susceptibility to solvents such as carbon tetrachloride and benzene (Morimoto *et al*., 1993; Ronis *et al*., 1996; Lindros, 1997). While extinguishing a fire, seven workers were exposed to high concentrations of carbon tetrachloride. However, only the two workers with a high ethanol intake sustained hepatotoxic and nephrotoxic effects (Manno *et al*., 1996).

It has been shown that even a single dose of benzene, toluene or *m*-xylene may induce the activity of CYP 2E1 significantly, and thereby enhance metabolism of other solvents (Kim and Kim, 1996). Methyl ethyl ketone pretreatment induced rat liver cytochrome P450 and increased the formation of the toxic metabolite 2,5-hexanedione in rat liver (Mortensen *et al*., 1998). Exposure to small aromatic hydrocarbons shows that the addition of methyl groups to the aromatic ring affects the inductive capacity of different CYP isoenzymes (Pathiratne *et al*., 1986; Backes *et al*., 1993; Gut *et al*., 1993; Yuan *et al*., 1995; Wang *et al*., 1996). Sex differences in enzyme induction have been observed. Ethylbenzene treatment induced CYP 2B1 and CYP 2B2 to a greater extent in male rats than in females, and CYP 2E1 only in female rats (Sequeira *et al*., 1992). Several studies have indicated no induction of hepatic ADH following treatment with ethanol (Gillion *et al*., 1985; Guthrie *et al*., 1990; Singh and Pandey, 1991; Aasmoe and Aarbakke, 1999). The glycol ethers 2-ME and 2-EE induced liver ADH in male rats only, while no induction was observed in female rats (Aasmoe and Aarbakke, 1999).

However, induction is not always reflected in increased *in vivo* metabolism. If the hepatic blood flow rather than the enzyme activity becomes rate limiting to the metabolism of a solvent, then enzyme induction will not affect the solvent toxicokinetics. In such cases, the blood flow limits the extent of their metabolism and enzyme induction has little effect on metabolism when exposure concentration is low. Examples of such solvents are TRI and xylene. In humans, enzyme induction resulted in increased metabolism of TRI only at high exposure concentrations (Sato, 1993). Ethanol consumption increased the metabolism of xylene about fivefold in rats only at high exposure concentrations (Kaneko *et al*., 1993).

1.4 Toxic Effects of Organic Solvents

The common effects of most solvents include anaesthetic effects on the central nervous system (CNS) and irritation of mucous membranes and tissues. These are the dominant signs of short-term exposure at a high concentration. Distinct from general effects are the specific toxic effects of individual solvents. They are often related to the metabolism of the solvent. The specific toxic effects are often not caused by the parent compound, but rather by the metabolites created by this metabolic activation.

1.4.1 Irritation of Mucous Membranes and Tissues

Irritation is a physiological response to chemical or physical stimuli. Depending on dose, most organic molecules have some irritant properties, such as stinging, burning, prickling or tingling (Cometto-Muñiz and Cain, 1992). Such irritation may damage the skin, lungs or eyes. If certain functional groups are added to an organic molecule, the irritant properties of the chemical will increase. Examples are amines and acids, which will add corrosive properties to the molecule. Aldehydes and ketones can produce narcosis, but this effect is usually avoided because the vapours are irritating to the eyes and respiratory tract at low concentrations (James, 1985). It has been shown that the irritation thresholds decrease logarithmically with carbon-chain length for a homologous series of ketones, secondary and tertiary alcohols, acetates, aldehydes and alkylbenzenes (Cometto-Muñiz and Cain, 1991; 1994; Cometto-Muñiz *et al*., 1998). Eye irritation thresholds and nasal pungency thresholds were well below the odour threshold (Cometto-Muñiz and Cain, 1995). However, irrespective of molecular size or chemical functional group, threshold for nasal pungency is observed at a fairly constant percentage of vapour saturation, which implies an important role for a physical rather than chemical interaction with the nasal mucosa (Cometto-Muñiz and Cain, 1993). Thus, irritation of mucous membranes is probably related to the size as well as to the structure of the molecule.

1.4.2 Clinical Effects on the Central Nervous System

Cross-sectional epidemiological studies have supported the hypothesis that occupational low-level, long-term exposure to solvent mixtures may cause adverse CNS effects (Tähti, 1984; Bleecker *et al*., 1991; Triebig *et al*., 1992; Hakkola, 1994; Hogstedt, 1994). They have demonstrated significant dose-response relations between exposure, mental symptoms and neurobehavioural performance. Occupational solvent exposure may be the cause of mental and cognitive impairment that can become permanent. In complex exposures, the adverse CNS effects seem to occur at exposure levels well below the accepted threshold limit values (Mikkelsen, 1997). Such values are, in most cases, set according to mucus membrane irritation, and in no case according to the risk of chronic CNS effects.

At occupational exposure levels, organic solvents can cause various symptoms and signs of CNS origin: fatigue, anxiety, irritability, headache, weakness, depression, neurobehavioural changes and impairment of cognitive performance (Milanovic *et al*., 1990; Evans and Balster, 1991; Hakkola, 1994; Kishi *et al*., 1995; Mikkelsen, 1997).

Long-term occupational exposure to solvents may cause a neurotoxic syndrome commonly known as chronic toxic encephalopathy. Symptoms and clinical signs typical of chronic toxic encephalopathy are impairment in memory and learning skills, increased irritability, fatigue, sleeping problems and changes in personality (Ng *et al*., 1990; Hein *et al*., 1990; Mikkelsen, 1997). Epidemiological studies on occupational solvent exposures have shown impairment in short-term memory and in psychomotor function (Baker, 1994). In cross-sectional studies, differences between exposed and unexposed workers have been most commonly seen in performance tests of memory function and particularly in short-term memory ability (Moen *et al*., 1990; Bleecker *et al*., 1991; Hänninen *et al*., 1991). Notably the performance in associated learning tasks and in memory span has been reduced in solvent-exposed workers. In many epidemiological studies, a dose–response relationship has been demonstrated. In heavily exposed workers the neurobehavioural deficits are similar to those seen in persons with pronounced neurobehavioural dysfunction due to solvent abuse (Baker, 1994). Follow-up studies have shown that after removal from solvent exposure, persistent deficits can be observed in persons with severe initial impairment, but no progression is seen once exposure is stopped (Gregersen, 1988; Edling *et al*., 1990). Of particular interest is a Swedish follow-up study of floor layers who, as a group, did not show neurobehavioural deterioration compared to controls (carpenters) at evaluations after 5 and 20 years of exposure. During the following 18 years, exposure was low, but the floor layers most heavily exposed during the first 20 years of exposure showed a significant deterioration in visual memory and perceptual speed, relative to the carpenters and to the less-exposed floor layers. The results are consistent with the view that the negative effects of exposure to solvents may interact with the normal ageing process, primarily at heavy exposure (Nilson *et al*., 2002).

Intentional inhalation of volatile organic compounds (VOCs) is well known and the abuse of volatile substances (glue sniffing, inhalant abuse, solvent abuse) in order to achieve intoxication has been reported from most parts of the world (Giovacchini, 1985; Flanagan and Ives, 1994). Small doses can lead to euphoria,

delusions and hallucinations. Higher doses may produce life-threatening effects, such as convulsions and coma. Death may ensue indirectly after aspiration of vomit or from direct cardiac or CNS toxicity. Chronic abuse of toluene-containing products and of chlorinated solvents such as 1,1,1-trichloroethane can produce severe organ damage, especially in the liver, kidneys and brain. Prolonged abuse may be fatal.

The question of solvent-induced toxic encephalopathy is controversial (Fiedler and Lerman, 2007), although the condition is accepted as an occupational disease in many European countries, including the European Union. In the Nordic countries it was recognized as an occupational disease in the 1970 and 1980s, almost reaching epidemic proportions. In parallel with the decline of exposure in industry, there has been a decline in the number of new cases. Thus, the condition is no longer considered to be a major problem in these countries.

In electrophysiological studies on solvent-exposed workers, some changes in electroencephalography consistent with diffuse cortical dysfunction have been found (Orbaek *et al*., 1988). Impairments in posture-control mechanisms (Niklasson *et al*., 1997), colour vision (Mergler and Blain, 1987) and olfactory functions (Schwartz *et al*., 1990) have also been associated with the neurotoxic syndrome caused by chronic exposure to organic solvents. Also, temporal epileptic seizures have been found as a result of occupational exposure to solvents (Jacobsen *et al*., 1994).

1.4.3 Effects on the Peripheral Nervous System (PNS)

Most organic solvents will have a nonspecific effect on the CNS, some leaving chronic effects after high or prolonged exposure. Peripheral polyneuropathy, on the other hand, results from exposure only to certain specific compounds, namely *n*-hexane, *n*-MBK and carbon disulfide (CS_2). Among these, *n*-hexane has been the most studied.

There are various industrial applications of *n*-hexane, including use in solvents and thinners in rubber, food and the pharmaceutical industry. Other uses are in adhesive tape and in glue in shoes, as well in cleaning agents. This hydrocarbon is also used in the production of polypropylene and polyethylene. In most circumstances, *n*-hexane is mixed with other aliphatic hydrocarbons and toluene for its primary industrial uses as a solvent.

About 15% of inhaled *n*-hexane vapour is absorbed. Large quantities (50–60%) of *n*-hexane are expired by the lungs after vapour exposure. The remaining *n*-hexane is biotransformed by the cytochrome P450 mixed-function oxidase system to 2-hexanol. 2-Hexanol is subsequently oxidized to 2,5-hexanediol, 2-hydroxy-5-hexanone, 2-hexanone, 2,5-hexanediol and 2,5-hexanedione (see **Figure 1**). The metabolites

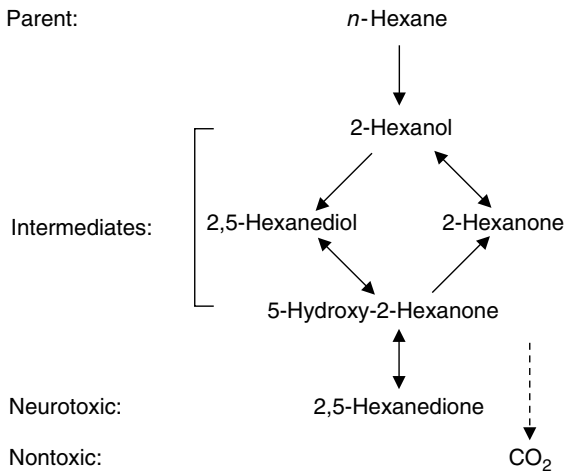

Figure 1 The biotransformation of *n*-hexane. Formation of the neurotoxic metabolite 2,5 hexanedione.

of *n*-hexane are more neurotoxic than the parent compound. The neurotoxic potency of *n*-hexane and some of its metabolites are (in ascending order): *n*-hexane < 2-hexanone < 2,5-hexanediol < 2,5-hexanedione. *n*-Hexane is known to cause peripheral neuropathies following long-term occupational exposures (Scaumburg *et al*., 1983).

Short-term, high-dose *n*-hexane exposure can cause narcotic effects, with headache and nausea at 1500 ppm, and confusion and dizziness at 5000 ppm within some minutes (Jørgensen and Cohr, 1981).

Long-term exposure to *n*-hexane and other liquid aliphatic hydrocarbons that undergo biotransformation to γ-diketone can cause peripheral axonal damage (peripheral axonopathy) (Ruff *et al*., 1981; Cavanagh, 1982; Bachmann *et al*., 1993; Graham *et al*., 1995). This toxic effect of *n*-hexane is based on the biotransformation product 2,5-hexanedione (**Figure 1**). The toxic mechanism appears to be that 2,5-hexanedione can bind and subsequently crosslink neurofilaments (Abou-Donia and Lapadula, 1988; Graham *et al*., 1995). It has been proposed that the γ-diketone, 2,5-hexanedione, reacts with lysine amino groups of neurofilaments to form pyrrole rings, which can interact with other proteins (DeCaprio, 1987). Neurofilaments accumulate above the nodes of Ranvier and form giant axonal swellings characteristic of γ-diketone-induced neurotoxicity (see **Figure 2**). Neurofilament crosslinking has been demonstrated both *in vitro* and *in vivo*. Although more than one mechanism may be operating, the following cascade of events seems to be supported by present knowledge: *n*-hexane is metabolized to 2,5-hexanedione, which causes decreased kinase-mediated phosphorylation of neurofilament proteins. This leads to a breakdown of the cytoskeletal matrix and dissociation of neurofilament proteins. Accumulated neurofilaments can then

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat144
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

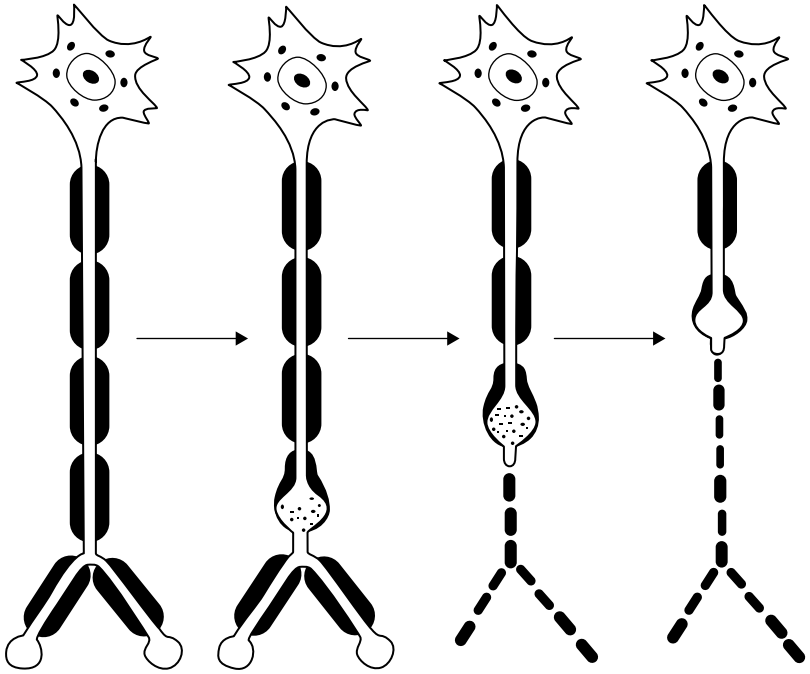

Figure 2 The mechanism of *n*-hexane-induced peripheral neurotoxicity. The axonal swellings are caused by the metabolite 2,5-hexanedione. Because of the axonal swelling there is no transport from the neuronal cell body to the peripheral part behind the swelling, and this part degenerates.

react with 2,5-hexanedione to form crosslinked neurofilaments, which results in the giant axonal swellings and distal axonopathy (**Figure 2**.). Based on studies with specific marker proteins for both the peripheral nervous systems (PNSs) and CNS, long-term *n*-hexane exposure in rats has shown changes in the PNS, but no significant changes in the CNS (Huang *et al*., 1992; 1993). The PNS seems to be the most sensitive target for *n*-hexane, while toluene mainly causes CNS toxicity (Tähti *et al*., 1997). Toluene has been shown to inhibit hexane metabolism and decrease its neurotoxicity (Takeuchi *et al*., 1993).

Although chemically similar to *n*-hexane, *n*-pentane, *n*-heptane and the alkenes, hexene and heptene, do not produce similar toxic metabolites to those of *n*-hexane and they have not been shown to cause peripheral axonopathy.

The polyneuropathy of MBK resembles that of *n*-hexane and is caused by the same toxic metobolite, 2,5-hexanedione. MBK is roughly 12 times more potent than *n*-hexane (Bos *et al*., 1991). In MBK neuropathy, swellings have also been found in the cerebellar white matter in the CNS and in the distal optic nerve, causing spastic gait and impairments of vision and memory (Bos *et al*., 1991). The long ascending and descending tracts of the spinal cord are also particularly vulnerable.

Carbon disulfide also causes polyneuropathy by neurofilament-filled swellings of the distal axons, similar to that produced by the metabolite of *n*-hexane (Graham *et al*., 1995).

1.4.4 Mechanisms of Neurotoxicity

The mechanisms of the CNS toxicity of solvents are not fully understood. Generally it has not been possible to identify specific sites of toxic effects in the CNS. Chronic high exposures to, for example, toluene cause multifocal disorders, including cerebral, cerebellar and brain-stem atrophy (Ikeda and Tsukagoshi, 1990). When inhaled at high concentrations, organic solvents produce CNS depression. The effect is related to the concentration of the solvent in the brain (Papper and Kitz, 1963; Lowe, 1972; Eger, 1974; Tichy, 1983). There is no simple relationship between the partition coefficient and the chemical structure or molecular weight which would help predict the uptake or the effects of the solvent in the nervous system (Sato and Nakajima, 1987). The length of the narcosis induced by organic solvents correlates well with their octanol–water partition coefficients (Wasserkort and Koller, 1997). A linear relationship between the 50% effective dose (ED_{50}) for CNS depression and the olive-oil–water partition coefficients for 20 different narcotics have been reported (Miller *et al*., 1972). As a broad generalization, the CNS depressant activity of an organic compound correlates with the length of its carbon chains and thus its lipid solubility.

Aliphatic, alicyclic and aromatic hydrocarbons have in common the ability to interact with biological membranes (Engelke *et al*., 1996). This interaction has been thought to cause changes in neural membranes, which then

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat144
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cause the CNS-depressant effect. According to the 'lipid theory', the anaesthetic potency of inhalation aesthetics and the CNS-depressant effects of organic solvents are related to their lipophilicity and to their effects on the lipid bilayer (Seeman, 1972). Organic solvents readily pass the blood–brain barrier and distribute into the lipid membranes of the neural cells, where they can affect neural membrane target proteins (Franks and Lieb, 1978; Korpela and Tähti, 1988; Edelfors and Ravn-Jonsen, 1992; Tähti *et al*., 1992; Naskali *et al*., 1993). The CNS depressant effect is greatly enhanced by halogenation, and to a lesser extent by alcoholic functional groups (James, 1985; Sato and Nakajima, 1987). Many organic solvents have effects similar to anaesthetics, and several halogenated solvents are the systemic anaesthetic agents of choice in surgery. In the past, TRI, diethyl ether and chloroform were used in clinical anaesthesia. Today, halogenated solvents such as sevoflurane, isoflurane and halothane are commonly used as anaesthetics.

Solvents with an aromatic structure are thought to localize in hydrophobic pockets in the protein or simply to be concentrated at the protein–lipid interface. The accumulation of organic solvents in neural cell membranes produces bilayer disorder (Engelke *et al*., 1992; 1996). The disorder in the phospholipid bilayer can indirectly affect the function of membrane enzymes (Edelfors and Ravn-Jonsen, 1992; Engelke *et al*., 1992). The physical/chemical activity relationship has been found important for the effects of organic solvents on synaptosomal membrane Na+/K+-ATPase activity and membrane fluidity (Naskali *et al*., 1993; Tanii *et al*., 1994). Both groups reported that partitioning of solvents into the lipid bilayer changes the membrane fluidity and leads to the inhibition of membrane-bound enzymes.

An effect which is seen with many lipophilic substances, such as polychlorinated biphenyls and brominated flame retardants is oxidative stress, or the production of free radicals (Mariussen and Fonnum, 2006). Intraperitoneal injection of toluene caused a significant elevation of the rate of production of reactive oxygen species (ROS) in the mitochondrial fraction of the liver and the synaptosomal fraction of the brain (Mattia *et al*., 1993a). The ROS was assayed with 2,7-dichlorodihydrofluorescein, which can detect hydrogen peroxide alone and in the presence of peroxidase, nitric oxide, peroxynitrite and hydroxyl radical (Myhre *et al*., 2003). Mattia *et al*. (1993a) confirmed the oxidative stress by showing a fall in the antioxidant glutathione. By employing a spin trap they were able to show that the hydroxyl radical was produced. Using the same technique they also showed that injection of toluene (0.5, 1 and 1.5 $mg\,kg^{-1}$) was accompanied by ROS production in the mitochondrial fraction from lung, kidney and liver, and in the synaptosome fraction from cerebellum and hippocampus (Mattia *et al*., 1993b). It was subsequently shown that exposure both to aromatic and dearomatized white spirit (0, 400 and 800 ppm, six hours a day, seven days a week, for three weeks) produced definite oxidative stress in subcellular fractions of brain, kidney and liver tissue of rats. Both a reduction in glutamine synthetase, which is an enzyme marker for oxidative stress, and a decrease in glutathione was found (Lam *et al*., 1994; Bondy *et al*., 1995). After exposure of white spirit to rats at days 7–20 during pregnancy, the rats were killed at day 35 and synaptosomes prepared. The synaptosome fraction from exposed animals showed an increase in calcium concentration (Edelfors *et al*., 1999). Also, synaptosomes exposed *in vitro* to white spirit showed an increase in calcium (Edelfors *et al*., 1999; von Euler *et al*., 1990). This can also be related to oxidative stress.

The studies on oxidative stress have been expanded to compare the effect of C6–C10 aliphatic, naphthenic and aromatic hydrocarbons on synaptosomes and on cerebellar granule cells. The results show that the alicyclic solvents were the most active, followed by the aliphatic hydrocarbons. Since the general feeling was that the aromatic hydrocarbons were the most toxic, it was a surprise to find that aromatic solvents were the least active (Myhre and Fonnum, 2001; Dreiem *et al*., 2002). The alicyclic and the naphthenic hydrocarbons were active in the range 100–800 μM, whereas the aromatic hydrocarbons were active at much higher concentrations (2–6 mM). The most active hydrocarbons in each group were *n*-octane, trimethylcyclohexane and *n*-butylbenzene respectively. When the granule cells were exposed to 200 μM *t*-butylcyclohexane, 1000 μM *n*-decane and 800 μM *n*-butylbenzene, cell death was encountered with the naphthenic and the aromatic compounds, but not with the aliphatic compounds. Both vitamin E and glutathione decreased the amount of cell death (Dreiem *et al*., 2005). Mechanistic studies of ROS production in synaptosomes showed the involvement of the neuronal nitric oxide synthetase, phospholipase A2 and mitochondria (Myhre and Fonnum, 2001). Similar studies were carried out with hydrocarbons on human granulocytes and gave similar results as with granule cells (Dreiem *et al*., 2003) The effect on granulocytes indicates that the immune system may be affected by exposure to hydrocarbon solvents.

As hydrocarbons interact with membranes, one would expect an effect on transporter molecules and receptors. Chronic exposure to styrene did not increase the binding of the dopamine agonist radopride to D2 dopamine receptors, but induced a persistent decrease in affinity of the neostriatal D2-agonist binding sites, possibly mediated by membrane perturbations (von Euler and Bjørnaes, 1990). Further experiments in the rat indicated that subchronic exposure to toluene at low concentrations caused a slight, but persistent deficit in spatial learning and memory, a persistent increase in dopamine-mediated locomotor activity due to an increase in the number of dopamine D2 receptors (von Euler *et al*., 1993). Exposure of rats to white spirit was also accompanied by

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat144
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

an effect on the serotonin transporter and receptor (Lam *et al*., 2001). In conclusion, the lipophilic hydrocarbons affected both ROS formation and neurotransmitter transporters and receptors. Neuronal death is probably in some way linked to ROS formation, although it is surprising that aliphatic hydrocarbons with high ROS-producing activity did not produce cell death *in vitro*. The effects on biogenic amines could be involved in some of the neurobehavioural changes that are observed.

2 TOXICOLOGY AND EFFECTS OF INDIVIDUAL SOLVENTS

2.1 Aliphatic Solvents

Aliphatic hydrocarbons are open-chain carbon-containing chemicals derived from crude oil. The group can be divided into three subgroups. Alkanes or paraffins (C_nH_{2n+2}) are saturated hydrocarbons. Alkenes or olefins (C_nH_{2n}) contain one or more double bonds. Alkynes or acetylenes (C_nH_{2n-2}) contain one or more triple bonds.

Aliphatic hydrocarbons containing four or less carbon atoms are gases (e.g. methane, ethane, propane, butane, 1,3-butadiene and acetylene). Compounds with a 16-carbon atom chain or longer are solids at room temperature. Aliphatic hydrocarbons containing 5–16 carbon atoms are liquids. C_5-C_8 compounds are very volatile solvents.

Aliphatic hydrocarbons are found in fuels (natural gas, gasoline, kerosine), propellants, solvents, dyes, inks, plastics and coatings, dry-cleaning agents and chemical intermediates. Aliphatic volatile alkanes (e.g. pentane, hexane, heptane, octane and nonane) are CNS depressants in high concentrations. They may also irritate mucous membranes, as well as cause defatting of the skin that may develop into dermatitis. *n*-Hexane may cause peripheral polyneuropathy (see Section 1.4.3).

Alkenes, the unsaturated aliphatic solvents, are toxicologically very similar to alkanes. Acetylenes, the aliphatic solvents with triple bonds, are toxicologically inert, but may displace oxygen in confined spaces and thus act as asphyxiants.

2.2 Chlorinated Aliphatic Solvents

Chlorinated aliphatic hydrocarbons have been widely used as solvents, dry-cleaning agents, aerosol propellants and as raw materials in the chemical industry. They may be found as by-products of drinking-water chlorination. Exposure to chlorinated aliphatic solvents can cause CNS depression, and, after chronic exposure, permanent damage such as impaired memory, concentration difficulties and personality changes (Stevens and Forster, 1993). Chlorinated solvents have also been shown to cause CNS depression in experimental animals (Honma, 1990), and chloroform and TRI have been used as inhalation anaesthetics.

TRI and tetrachloroethylene are classified as probable carcinogens (Group 2A) by International Agency for Research on Cancer (IARC) while carbon tetrachloride, chloroform, 1,2-dichloroethane and dichloromethane are classified as possible carcinogens (Group 2B). Most of the chlorinated solvents will sensitize the myocardium to endogenous catecholamines, so acute high exposure may lead to ventricular fibrillation and death. The chlorinated solvents are nonflammable, but upon heating they disintegrate partly into chlorine-containing compounds, which are very irritating to the bronchial and lung mucosa. Among these is phosgene, which may cause lung oedema and death, and was therefore used as a war gas during World War I.

2.2.1 Carbon Tetrachloride (Tetrachloromethane/ Perchloromethane)

Carbon tetrachloride (CCl_4) is a well-known hepatotoxic compound (Kefalas and Stacey, 1991). Its use has been declining as it has been replaced by less toxic chlorinated solvents such as TRI, perchloroethylene (tetrachloroethylene) and methylchloroform (1,1,1-trichloroethane) (see **Table 1**.). However, it is still used, mainly in the synthesis of fluorocarbon refrigerants, solvents and aerosol propellants.

Carbon tetrachloride is well absorbed by the lungs and gastrointestinal tract and percutaneous absorption can also occur. CCl_4 is concentrated in fatty tissues, while the main excretion route (50–80%) is as the unchanged compound via the lungs. Dechlorination occurs in the liver microsomal cytochrome P450 system, and the formation of free radicals may cause lipid peroxidation and subsequent hepatocellular damage. A small part of the dose is excreted as carbon dioxide via the lungs or kidney.

Acute exposure to CCl_4 causes CNS depression followed by hepatic and renal dysfunction. The mechanisms of the CNS effects are not clear. However, it has been demonstrated that acute exposure to high doses of CCl_4 leads to the same kind of CNS effects as acute exposure to other organic solvents, for example headache, dizziness, blurred vision and constricted visual fields (Stevens and Forster, 1993).

The cerebellum is particularly sensitive to the actions of CCl_4. Bilateral visual field constriction, optic atrophy and amblyopia (reduced vision) characterize the effects of CCl_4 on the optic system. Alcoholics are especially sensitive to CNS effects. Death results from respiratory depression or from dysrhythmias (Hyatt and Salmons, 1952).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The liver toxicity is based on the formation of free radicals from the biotransformation reactions. The dechlorination of CCl_4 produces phosgene and the trichloromethyl free radical, which is subsequently metabolized to chloroform and carbon dioxide, as well as hexachloroethane. Free radicals can attack proteins and destroy membranes by affecting membrane lipids and producing lipid peroxidation (Sáez *et al*., 1987). Hepatotoxicity caused by CCl_4 is characterized by acute fatty degeneration of the liver, leading to hepatic necrosis. There are also theories that toxic liver cell death might be associated with alterations of Ca^{2+} homeostasis due to CCl_4 (Rechnagel, 1983). CCl_4 inhibits the ability of microsomes to sequester Ca^{2+}, but does not prevent the influx of extracellular Ca^{2+}. The release of Ca^{2+} into the cytosol will result in a number of regulatory alterations (Rechnagel, 1983), which can lead to triglyceride accumulation in the cell. Calcium-channel blockers have been shown to protect against CCl_4-induced liver toxicity (Romero *et al*., 1994). CCl_4 has been considered a potential carcinogen. It has produced hepatocellular carcinoma in hamsters and hepatomas in mice and rats. The data on humans are inadequate to link CCl_4 to liver cancer. CCl_4 can also produce renal damage via acute tubular necrosis.

2.2.2 Chloroform (Trichloromethane/Methyl Trichloride)

Chloroform ($CHCl_3$) is now restricted to industrial uses as a solvent or a chemical intermediate. In 1847 it was introduced as a general anaesthetic because it was less volatile and not as flammable as ether. The use as an anaesthetic was banned early in the twentieth century. The industrial use of chloroform is also restricted, because it can cause liver and kidney cancer in experimental animals. Chloroform is a potent CNS depressant that produces a variety of acute symptoms, for example, nausea, headache and coma (Schroeder, 1965).

Chloroform is rapidly absorbed via the lungs and gastrointestinal tract, the peak blood concentration is reached in one hour. A considerable amount (17–67%) is expired by the lungs. In the liver, cytochrome P450 enzymes dechlorinate chloroform by oxidation to trichloromethanol, which spontaneously dehydrochlorinates to phosgene. Phosgene can react with water to form carbon dioxide, or bind covalently to cellular macromolecules. It produces hepatotoxicity characterized by fatty infiltration and necrosis (Larson *et al*., 1993).

Chronic oral exposure to chloroform has caused hepatocellular tumours in mice and kidney tumours in rats (Byron *et al*., 1994). However, Jorgenson and coworkers could not find any tumours in the livers of mice after administration of chloroform in drinking water (Jorgenson *et al*., 1985). The studies of Larson and colleagues have shown that chloroform administered in corn oil by gavage causes hyperplasia in mouse liver and in rat kidney (Larson *et al*., 1993). Chloroform-induced mouse liver cancer may be secondary to events associated with induced cytolethality and cell proliferation (Butterworth *et al*., 1998). Chloroform is an example of a nongenotoxic cytotoxic carcinogen. Chloroform-induced cytotoxic effects (necrosis, inflammation and regenerative cell proliferation) can start the carcinogenic process and enhance endogenous and exogenous mutagenic activity (Butterworth *et al*., 1998). The possible carcinogenicity of chloroform has been of particular concern as drinking-water purification using chlorination results in the formation of trace amounts of disinfection by-products such as chloroform. Chloroform is often the most prevalent by-product in the chlorination process.

Chloroform may cause renal toxicity 24–48 hours after exposure characterized by proteinuria. Like most chlorinated hydrocarbons, chloroform sensitizes the myocardium to endogenous catecholamines.

2.2.3 Trichloroethylene

TRI ($CHCl{=}CCl_2$) has been widely used in metal degreasing, dry cleaning and chemical synthesis and as a component in household cleaning agents. It was also used as a nonflammable narcotic during the early 1900s. It occasionally produces euphoria, and consequently it has been abused for that purpose. In cases of sniffing, TRI has caused fatal accidents, perhaps through the induction of ventricular fibrillation.

TRI is readily absorbed into the body through the lung and gastrointestinal mucosa. Elimination involves two major processes: pulmonary excretion of unchanged TRI and relatively rapid hepatic biotransformation to urinary metabolites. The major metabolites of TRI are trichloroethanol, trichloroethanol-glucuronide and trichloroacetic acid. Reactive intermediates can be produced in the biotransformation process: TRI-epoxide, dichloroacetic acid, dichlorovinyl-cysteine, dichloroacetyl chloride and chloroform. The liver toxicity, as studied in animal models, is caused by the metabolism of TRI to trichloroacetic acid and dichloroacetic acid, although a possible role of TRI-epoxide cannot be ruled out.

The acute toxic effects of TRI are CNS depression, visual disturbances, mental confusion, fatigue and nausea. In experimental studies in developing rats, effects on myelin formation in the hippocampus were found (Isaacson and Taylor, 1989). TRI can cause changes in the proportion of the long-chain polyunsaturated fatty acids in rat brain after subchronic and chronic exposure (Kyrklund *et al*., 1986). The changes in membrane fatty acid composition might alter brain function. A reduction in myelin could, in part, be responsible for the behavioural effects observed in TRI exposure (Isaacson and Taylor, 1989). TRI can also cause arrhythmia through sensitizing the heart to catecholamines and also pulmonary oedema if the exposure is severe. Compared

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat144
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

with carbon tetrachloride and chloroform, TRI is a weak hepatotoxin. Hepatocellular carcinoma has been found in mice after high doses of TRI (Kimbrough *et al*., 1985). Epidemiological studies have presented conflicting evidence for the carcinogenicity of TRI in humans (Kaneko *et al*., 1997). A cohort study of 2050 male and 1924 female workers indicated excess of cancers in the CNS and increased risk of multiple myeloma among TRI-exposed workers. However, the overall cancer incidence within the cohort was similar to that of the Finnish population as a whole (Anttila *et al*., 1995). A review from 2000 found the strongest evidence for a causal relationship with cancer of the kidney, liver and non-Hodgkin's lymphoma (Wartenberg *et al*., 2000). The IARC has characterized TRI as a probable human carcinogen causing non-Hodgkin lymphoma and cancer of renal cells, and of the liver and bile ducts (IARC, 1995).

2.2.4 Tetrachloroethylene (Perchloroethylene)

Tetrachloroethylene ($CCl_2{=}CCl_2$) is used particularly in dry cleaning and degreasing. The toxicity of tetrachloroethylene resembles that of TRI. Tetrachloroethylene has caused loss of myelin-enriched lipids, which might indicate a persisting loss of myelin membranes (Kyrklund *et al*., 1990). According to studies with experimental animals, tetrachloroethylene may cause liver cancer (Kyrklund *et al*., 1990). A cohort study of dry-cleaning workers exposed mainly to tetrachloroethylene has shown an increased risk of oesophageal, intestinal, pancreatic and bladder cancers (Ruder *et al*., 1994). IARC has characterized tetrachloroethylene as a probable human carcinogen causing non-Hodgkin's lymphoma.

2.2.5 1,1,1-Trichloroethane (Methylchloroform)

1,1,1-Trichloroethane (CH_3CCl_3) has many industrial and household applications. The relatively low acute toxicity of trichloroethane is mainly a consequence of the low blood–gas partition coefficient compared to other chlorinated solvents. Due to the low blood solubility, the uptake of trichloroethane is low. The principal effect is CNS depression, and high doses can sensitize the heart to the effects of catecholamines and thus cause arrhythmia. In high concentrations, trichloroethane can cause changes in the fatty acid pattern in rat brain (Kyrklund and Haglid, 1991).

2.3 Alicyclic Hydrocarbons

These colourless liquid solvents are saturated or unsaturated hydrocarbons in which three or more carbon atoms join to form rings. They include cycloalkanes, cycloparaffins and naphthenes. They are present in petroleum solvents and are used in the manufacture of organic chemicals. Alicyclic hydrocarbons have similar toxic effects to aliphatic hydrocarbons, but have a greater depressive or anaesthetic effect on the CNS. Alicyclic solvents with small molecular weight, such as cyclopropane, have been used as anaesthetics. The higher-molecular-weight compounds, for example, cyclohexane, cannot be used as narcotics because the safety margin between the narcotic dose and the lethal dose is narrow. Cyclohexane does not change the neural membrane fluidity to the same extent as aromatic hydrocarbons (Engelke *et al*., 1996).

2.4 Aromatic Hydrocarbons

2.4.1 Benzene

Benzene has mainly been used as a raw material in chemical processes and as a solvent in rubbers and glues. It is also used in the synthesis of ethylbenzene, styrene, cumene, phenolic resins, ketones and various dyes. However, in most industrial products, benzene has been substituted by other organic solvents because of its myelotoxicity and since it can cause aplastic anaemia and leukaemia (Vigliani and Forni, 1976; Infante *et al*., 1977). Benzene is a natural constituent of gasoline and can be added as an anti-knocking agent at concentrations of up to 5% and thus is a constituent of gasoline fumes and automobile exhaust. Tobacco smoke also contains benzene. Benzene is one of the VOCs in the city air, and benzene concentrations are monitored in many cities. In industrialized countries workplace exposures to benzene are quite limited, but in the developing world exposure is widespread, especially in artisan work, shoe manufacture and small chemical enterprises. Some of these workplaces may include children in the labour force (Hricko, 1994; Tompa *et al*., 1994; Vermeulen *et al*., 2004).

Benzene is metabolized in the liver to phenols by the cytochrome P450 mixed-function oxidase system (**Figure 3**). Benzene epoxide is the most toxic metabolite of benzene and may be responsible for benzene-induced haematological abnormalities. The conjugation products with glutathione form phenyl mercapturic acid, which is excreted in the urine (Schlosser *et al*., 1998).

Acute exposure to benzene results in CNS depression characterized by euphoria, headache, nausea and ataxia. These symptoms may progress to a change in gait, convulsions and coma. Acute exposure to benzene may

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

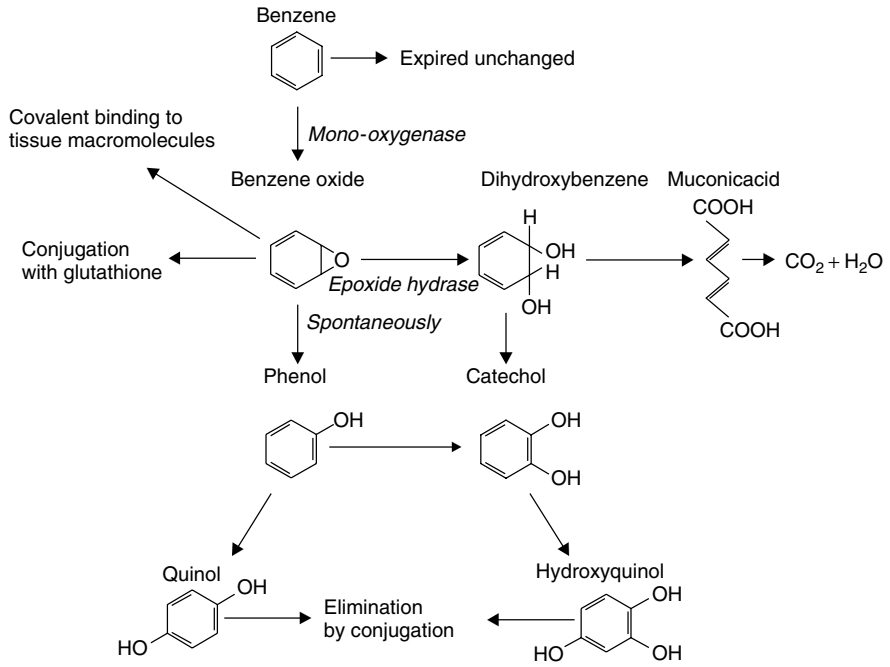

Figure 3 The biotransformation of benzene. The intermediate metabolite benzene oxide (epoxide) is highly reactive and glutathione conjugation removes this metabolite via formation of phenylmercapturic acid.

cause arrhythmia due to myocardial sensitization to endogenous catecholamines (Snyder and Kocsis, 1975).

Chronic occupational exposure of humans to benzene can lead to bone-marrow damage, which may be manifested as anaemia, leukopenia and/or thrombocytopenia. Benzene has been found to induce leukaemia in humans (Snyder and Kalf, 1994). The fact that benzene is carcinogenic is supported by the chromosomal aberrations found in the peripheral blood lymphocytes of exposed workers (Tompa *et al*., 1994). Benzene does not induce leukaemia in rats and mice, although benzene oxide has been shown to induce oxidative microsomal metabolism of benzene in mice and rats, as well as humans (Schlosser *et al*., 1998). Benzene oxide may be an important link between benzene and leukaemia (Snyder *et al*., 1978), but even though it has been shown that metabolism plays a role in benzene toxicity, and that benzene can interfere with DNA, the exact mechanism of benzene-induced leukaemia is not known (Snyder, 2004).

2.4.2 Toluene

Toluene (methylbenzene) is used as a solvent for paints, lacquers, thinners, coatings, glues and cleaning agents. Toluene is also used in the production of other chemicals and in pharmaceutical industries. The important exposure route is by inhalation, but toluene is also absorbed through the skin.

The biological half-life of toluene ranges from several hours for white adipose tissue to a few minutes in highly perfused organs (Pyykkö *et al*., 1977). After inhalation exposure of rats to toluene, the distribution to various tissues is rapid. Toluene accumulates in white adipose tissue, from which the elimination is slow, compared to other tissues (Pyykkö *et al*., 1977). Approximately 18% of the absorbed toluene is expired unchanged via the lungs, and less than 0.1% is eliminated unchanged in the urine. Toluene is metabolized via cytochrome P450 to benzyl alcohol, which is further oxidized via ADH and aldehyde dehydrogenase to benzaldehyde and benzoic acid, respectively (Pyykkö, 1983). Benzoic acid conjugates with glycine to form hippuric acid, which is excreted in the urine (**Figure 4**). Some other solvents (e.g. *n*-hexane, benzene, styrene, xylene and TRI) can inhibit toluene biotransformation (Sato and Nakajima, 1979; Tähti, 1984; Liira *et al*., 1988). Competitive metabolic inhibition is the plausible mechanism of this toxicokinetic interaction between the individual solvents. Toluene causes induction of microsomal liver enzymes at relatively low concentrations (Pyykkö, 1983). Toluene has neither carcinogenic nor mutagenic potency. Kidney damage has been reported in sniffers of glues that may have contained toluene and other solvents.

The CNS is sensitive to the effects of toluene. Acute exposure to toluene causes CNS depression, including the following symptoms: drowsiness, tiredness, headache, dizziness and nausea. The anaesthetic effect of toluene, as with other CNS-depressing solvents, is thought to be based on the ability of toluene to disturb the lipid–protein interaction in neural membranes (Engelke *et al*., 1992; 1996). Due to their lipid solubility, solvents are readily incorporated into neural membranes (**Figure 5**). Solvent molecules can bind to the hydrophobic parts of membrane

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat144
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

integral proteins, and disturb the ion balance in the membrane (Naskali *et al*., 1993). Exposure for a short time to very high concentrations of toluene (10 000–30 000 ppm) produces unconsciousness and anaesthesia. Long-term inhalation of toluene by abusers is known to cause a multifocal neurological disorder called toluene leukoencephalopathy which is characterized by ataxia, tremors and emotional lability as well as cerebral, cerebellar and brain stem atrophy (King *et al*., 1985; Ikeda and Tsukagoshi, 1990; Filley *et al*., 2004). The acute effect of toluene has been described in controlled conditions in exposure chambers at dose levels which are consistent with those seen in the work places. According to such studies, toluene can cause impairment of visual vigilance (Dick *et al*., 1984) and vestibular function (Hydén *et al*., 1983).

Experimental studies have given some evidence that toluene can cause irreversible effects on noradrenaline, dopamine and 5-hydroxytryptamine mechanisms in various brain regions in rats (Ladefoged *et al*., 1991) and in peripheral sympathetic ganglia (Alho *et al*., 1986). Several case histories describe a consistent pattern of neurological damage in individuals repeatedly inhaling toluene at high concentrations because of its euphoric properties (Fornazzari *et al*., 1983; Spencer and Schaumburg, 1985; Rosenberg *et al*., 1988). There is evidence for an increased risk of neuropsychiatric disorders and behavioural disturbances after chronic toluene intoxications (Kishi *et al*., 1995).

2.4.3 Xylene

There are three isomers (*ortho*-, *meta*- and *para*-) of xylene (dimethylbenzene) in the commercial product, *meta*- being the major isomer. Xylene is one of the most common solvents in paints and varnishes, and it commonly also occurs in glues and printing inks. Furthermore, xylene is used as a solvent in the rubber and leather industries and in pathology laboratories. Xylene is also used in the chemical manufacture of synthetic fibres, plastics, and enamel, as well as the formulation of

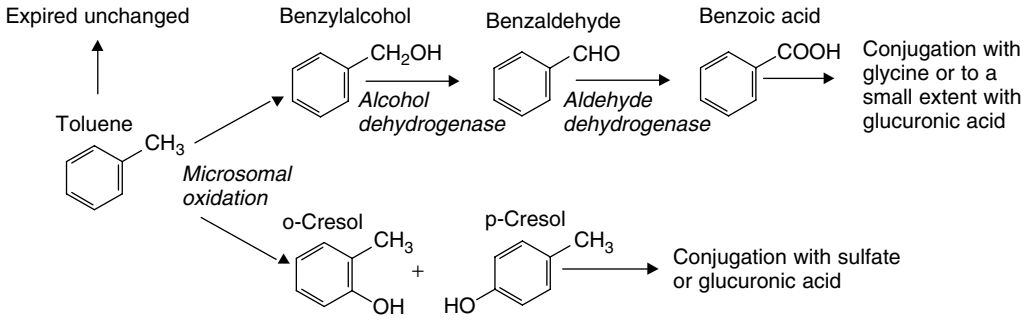

Figure 4 The biotransformation of toluene. The main metabolite in the urine is hippuric acid.

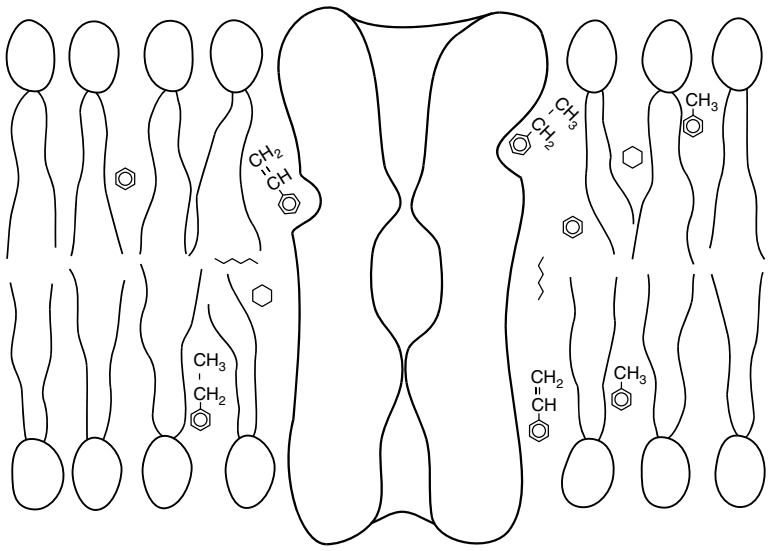

Figure 5 A schematic representation of the incorporation and location of solvent molecules in the neural membrane. Solvent molecules are drawn approximately at the same scale as the membrane molecules. Solvent molecules can bind in the hydrophobic pockets in the integral proteins (enzymes, e.g. Na^+, K^+-ATPase) and disturb the ion balance across the membrane.

DOI: 10.1002/9780470744307.gat144
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

insecticides. Xylenes are often used to replace benzene as a solvent.

Xylene is rapidly absorbed through the lungs and approximately 65% of the inhaled dose is retained by the lungs. Xylene is also absorbed through the gastrointestinal tract and the skin. Only 3–6% of the absorbed xylene is exhaled via the lungs. Most of the remaining xylene is oxidized to methylbenzoic acid, which is conjugated with glycine to form methylhippuric acid. Only 2% of the absorbed xylene is excreted in urine as xylenols (Riihimäki *et al*., 1979).

The acute toxicity of xylene is greater than that of toluene, although the symptoms are quite similar. The major effect of xylene is CNS depression, resulting, at low doses, in lightheadedness, nausea, headache and ataxia. High dose exposure to xylene produces confusion, respiratory depression and coma. Xylene causes conjunctivitis, nasal irritation, sore throat and respiratory irritation. Xylenes have been shown to induce microsomal enzymes in the liver, although their hepatotoxicity is considered to be low. Concentrations as high as 10 000 ppm produce a reversible and minor increase in hepatic aminotransferase activity, and reversible renal failure. Like other aromatic solvents, xylenes may also cause skin and eye irritation.

2.4.4 Styrene (Vinyl Benzene)

More than 50% of the world's production of benzene is used in the manufacture of styrene. Styrene materials account for 20% of all plastic production, for example, polystyrene, resins and polyesters.

Styrene is readily absorbed via the lungs and gastrointestinal tract and also to some extent via the skin. Styrene is metabolized to mandelic acid (70%) and phenylglyoxylic acid (30%), both of which are excreted in the urine. Styrene is also metabolized to styrene oxide, which is more toxic than the parent compound (Mendrala *et al*., 1993). Hippuric acid is also excreted in the urine following exposure to styrene and this metabolite has been used for biological monitoring of occupational exposure.

The major effect of styrene is on the CNS (Pahwa and Kaira, 1993; Naskali *et al*., 1994; Pierce *et al*., 1998). In addition to CNS depression, styrene causes mucosal irritation. Symptoms and clinical signs include those of eye irritation, as well as nasal and respiratory tract irritation.

Styrene is an indirect genotoxic agent, which requires metabolic activation to an epoxide in order to bind covalently to DNA. Styrene 7,8-oxide, the active metabolite of styrene, is a carcinogen in rodents and has been shown to be genotoxic in most *in vitro* test systems. Styrene has been found to be weakly genotoxic in the sister chromatide exchange assay, especially in mice. Cytogenetic damage has been reported in many studies of workers, mainly from the reinforced plastics industry, where ambient concentrations of styrene have been high (Norppa and Sorsa, 1993). Styrene has been characterized as possibly carcinogenic to humans (IARC, 2002)

2.5 Alcohols

2.5.1 Methanol

Methanol (CH_3OH) is used as a solvent, an antifreeze agent and an ingredient of car-windscreen washing fluid. Methanol is also used in the production of stains, enamels and photographic films.

Plans to use methanol as a fuel or as a component in gasoline may widen the probability of exposures to methanol. Inhalation and skin absorption are the most important entry routes of methanol in occupational exposure. Ingested methanol is absorbed from the gastrointestinal tract almost completely (Liesivuori and Savolainen, 1991). The first step in the metabolic pathway of methanol is oxidation to formaldehyde. In humans, ADH is the enzyme that catalyses oxidation. The resultant formaldehyde is spontaneously hydrated to methanediol, which is further metabolized by ADH to formic acid (Liesivuori and Savolainen, 1991). Urinary formic acid can be used for biological monitoring of methanol exposure in the working place (Liesivuori and Savolainen, 1987). The symptoms caused by methanol exposure are dizziness, nausea and vomiting, various types of visual disturbances, headache and metabolic acidosis. At high doses, methanol can cause permanent blindness resulting from retinal damage (Røe, 1946; Liesivuori and Savolainen, 1991; Eells *et al*., 1996). Methanol poisoning is characterized by severe metabolic acidosis which can inhibit cellular respiration and hasten cellular failure. Progressive acidosis will also induce circulatory and respiratory failure. This leads to tissue hypoxia and lactic acid production, both of which further increase the acid load (Jacobsen and McMartin, 1986). The toxic effects of formic acid are due to inhibition of the cytochrome oxidase complex at the terminal end of the respiratory chain in the mitochondria, leading to tissue hypoxia. In addition to the optic nerve and retina, other organs (e.g. brain, heart, kidney) with a high rate of oxygen consumption are possible targets. Oral ingestion of methanol as a single moderate to large dose ($0.4–1\ g\ kg^{-1}$) may cause blindness. Other common clinical manifestations of methanol poisoning in humans include CNS depression, weakness, headache and vomiting (McMartin *et al*., 1980). The symptoms and signs of methanol poisoning may be delayed for up to 24 hours due to the time taken for methanol oxidation to formic acid. The elimination of formic acid from the body is slow. In human methanol poisonings, the half-life of formic acid is about 20 hours (Shahangian

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat144
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

et al., 1984; Shahangian and Ash, 1986). The treatment of methanol poisoning includes administration of ethanol (Røe, 1946) and folic acid. The ethanol will compete for ADH and thus reduce formate production, while the folic acid will enhance formate oxidation to carbon dioxide (Becker, 1983). Dialysis and alkalinization of urine have been used to increase elimination of formic acid (Liesivuori and Savolainen, 1991). In recent experiments with methanol-intoxicated rats, a significant recovery of rod- and cone-mediated function after exposure to light in the red and near-infrared range has been documented. Such exposure also protects the retina from histopathological changes induced by methanol-derived formate (Eells *et al*., 2003)

2.5.2 Ethanol

Ethanol (CH_3CH_2OH) is extensively used in the chemical industry and in the production of cosmetics and drugs. Exposure to low doses of ethanol by inhalation is not uncommon in industry. Chronic alcohol consumption causes significant CNS toxicity characterized by cerebellar atrophy and dilation of cerebral ventricles. Harper and Kril (1990) have proposed a model for alcohol-induced brain damage. The model includes loss of dendritic arbour and shrinkage of the neuronal body. These changes are potentially reversible and occur in many brain regions. The second phase is neuronal death, which is irreversible and has been demonstrated primarily in the frontal cortex.

A serious consequence of ethanol consumption is its multiple effects on the developing embryo and foetus (Pratt, 1982). Foetal alcohol syndrome occurs in the children of approximately 10% of the women drinking heavily during pregnancy (Sokol *et al*., 1986). Recent studies have indicated that a possible explanation for the toxic effects is the enhanced production of acetaldehyde in the placenta and foetus due to induction of CYP 2E1 (Boutelet-Bochan *et al*., 1997; Carpenter *et al*., 1996; 1997; Rasheed *et al*., 1997). One mechanism for the interindividual variations is that induction varies among heavy drinkers, and may be genetically controlled (Rasheed *et al*., 1997).

Ethanol is oxidized to acetaldehyde and on to acetate, mainly through the action of ADH and aldehyde dehydrogenase (ALDH), primarily in the liver, but ADH is found also in the stomach, lungs and eye. Minor amounts are metabolized by catalase and CYP 2E1. Due to its high affinity to ADH, ethanol is effective in the treatment of methanol intoxications (Røe, 1946). It can also be used in the treatment of ethylene glycol and diethylene glycol poisoning. CYP 2E1 can be induced by ethanol consumption, leading to increased toxic effects of other solvents and some drugs that are metabolized by this enzyme.

On average, an adult will metabolize 16 mg $100\,ml^{-1}\,hour^{-1}$, but there are important genetic polymorphisms concerning the ethanol-metabolizing enzymes. Some Asiatic populations have a high frequency of a rapidly acting form of ADH and of a slow acting form of ALDH. After ethanol consumption, such individuals may experience acetaldehyde intoxication with effects such as nausea, flushing and hyperventilation. Disulfiram, which is an ALDH inhibitor used in the treatment of chronic alcoholism, will produce a similar syndrome. Women metabolize ethanol less effectively than men. This may, in part, be due to a less pronounced activity of ADH in the stomach mucosa of females and to a smaller distribution volume, thus increasing blood concentrations of ethanol, making women more prone to negative health effects.

2.5.3 Isopropanol

Isopropanol (isopropyl alcohol, $CH_3CH(OH)CH_3$) is used in industry as a solvent and disinfectant. Isopropanol is metabolized via ADH to acetone, which is eliminated through the kidney and the lung. Acetone is further oxidized to acetic acid, formic acid and CO_2 (Daniel *et al*., 1981).

Exposure to high concentrations of isopropanol causes CNS and cardiovascular depression. Lower concentrations can cause mild irritation of eyes. Isopropanol exerts its primary effect on the CNS in both humans and laboratory animals, showing a more potent narcotic effect than ethanol (Daniel *et al*., 1981). It is the second most ingested alcohol after ethanol (Litovitz *et al*., 1985) and has caused poisonings in connection with heavy drinking (Rich *et al*., 1990)

2.6 Glycol Ethers

The acute toxicity of the glycol ethers is low. Until the mid-1980s, the focus regarding these solvents was on the toxicity towards the CNS and haematopoietic systems, blood, liver, and kidneys. In later years, attention has also been focussed on the effects on reproduction and foetal development. Several animal studies have shown that 2-methoxyethanol (2-ME) and 2-ethoxyethanol (2-EE) have teratogenic and spermatotoxic effects (Lamb *et al*., 1985; Nagano *et al*., 1981). Workers exposed to 2-ME and 2-EE were found to have lower sperm counts compared to nonexposed workers (Ratcliffe *et al*., 1989; Welch *et al*., 1988). A case–control study among patients at a clinic for reproductive disorders showed an association between a diagnosis of impaired fertility and exposure to glycol ethers (Veulemans *et al*., 1993). Several studies of female workers have shown an increased risk of spontaneous abortions, subfertility and congenital malformations due to glycol ether exposure (Beaumont *et al*., 1995; Cordier *et al*., 1997; Correa *et al*., 1996; Swan *et al*., 1995).

The metabolism of glycol ethers is a key factor in understanding the biological interactions and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat144
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

structure–activity relationships of these compounds. The adverse effects have been attributed to the corresponding alkoxyacetic acid metabolites of the glycol ethers, methoxyacetic acid (MAA) and ethoxyacetic acid, respectively (Miller *et al*., 1982; Foster *et al*., 1983; Brown *et al*., 1984; Moss *et al*., 1985). These acids arise after oxidation with ADH and ADHL. A competing metabolic pathway is *O*-dealkylation to ethylene glycol and alkyl aldehyde.

Longer-alkyl-chain glycol ethers are more haematotoxic than those having a shorter chain, while shorter-alkyl-chain glycol ethers are more embryotoxic than those having a longer chain (Nelson *et al*., 1984). Alkoxyacetic acids added to postimplantation rat embryo cultures increase the incidence of abnormalities in a dose- and structure-related manner, MAA being more effective than ethoxyacetic acid (Rawlings *et al*., 1985). Ethoxyacetic acid has been shown to produce less severe testicular toxicity, *in vivo* as well as *in vitro*, in the rat, compared to MAA (Foster *et al*., 1987). On a molar basis, 2-EE produces less severe toxic effects than 2-ME (Wess, 1992).

Little is known about the biochemical mechanisms that induce the embryotoxicity and testicular toxicity of 2-ME and 2-EE, and the possible contribution from the alkoxyacetic acid metabolites. Several studies in rats and mice indicate that MAA undergoes further metabolism, and that these metabolites could be responsible for developmental and testicular toxicity (Welsch *et al*., 1987; Mebus and Welsch, 1989; Mebus *et al*., 1989; 1992; Sumner and Fennell, 1993). Developing embryo and late-stage spermatocytes both undergo rapid nucleic-acid biosynthesis. MAA or a product of its metabolism can influence common biochemical pathways by affecting the availability of one-carbon units, thus causing depression of purine and pyrimidine biosynthesis (Mebus and Welsch, 1989; Mebus *et al*., 1992; Sumner *et al*., 1992). Alterations in the availability of these precursors might be expected to affect DNA and/or RNA synthesis and thereby influence normal cellular proliferation and differentiation. Some studies indicate that 2-ME induces spermatocyte apoptosis in rats and guinea pigs (Brinkworth *et al*., 1995; Ku *et al*., 1995; Wine *et al*., 1997). It has been shown that MAA induces cell death of spermatocytes in both rat and human seminiferous tubules in the same dose ranges (Li *et al*., 1996). MAA has been shown to increase progesterone production in rat and human luteinized granulosa cells, and this would probably result in reduced fertility due to a disturbed menstrual cycle (Almekinder *et al*., 1997).

3 FUTURE CHALLENGES

The wide use of organic solvents in industry will in the future also present an important occupational health risk. In particular, prospective epidemiological studies will be needed to study the effects of long-term exposure to low levels of organic solvents. At least one such study has been underway (Williamson, 1996).

A particular problem that has not been well addressed is the question of exposure assessment. Workers are typically exposed to solvent mixtures and the doses may vary considerably during exposure periods. The usual proxy for exposure, namely the number of years employed in the trade, may lead to serious misclassifications.

The classification of effects is also challenging. Experimental techniques have been developed for studies of CNS functions in experimental animal models (Vorhees, 1987; 1991; Stanton and Freeman, 1994). However, extrapolation of behavioural data from animals to humans may be difficult and possibly misleading. An overview of available test batteries has been presented by Anger who offers a summary of their features, benefits and limitations (Anger, 2003).

Genetic polymorphism may be of importance. It has been shown that polymorphisms of glutathione-S-transferase may influence the risk of solvent-induced toxic encephalopathy (Söderkvist *et al*., 1996; Kezic *et al*., 2006).

Epidemiological studies have shown that long-term exposures to specific solvents, for example, benzene, TRI, tetrachloroethylene and carbon tetrachloride, may increase the cancer risks. Occupational exposure to mixtures of solvents in paints has consistently been associated with a 40% increased risk of lung cancer (Lynge *et al*., 1997). However, addressing these questions is becoming ever more demanding, since most long-term exposures are to mixtures rather than to single chemicals at any one time.

Early health effects of organic solvents may be difficult to detect and in many cases it may be hard to know even what kind of effect to look for.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the authors of the solvent chapter in the previous edition of General and Applied Toxicology, Hanna Tähti and Lisbeth Aasmoe, as much of the text and all tables/figures have been re-used in the present chapter.

Toxicology and Biological Monitoring of Metals

Monica Nordberg and Gunnar F. Nordberg

CONTENTS

1 INTRODUCTION

In total, 111 elements have been identified, 90 occur naturally on earth and 67 are metals. All metals but one of these, that is Hg, are solid. The chemistry of metals represents a major part of inorganic chemistry. Understanding of the toxicology of metal species has advanced substantially during recent decades, thanks to the considerable contributions of bioinorganic chemistry, that is the discovery that some metal species undergo biomethylation and thus can form organometallic compounds. This discipline goes hand in hand with chemical speciation, which is instrumental in understanding metal toxicology and related adverse health effects.

It was pointed out by Duffus (2002) that the oldest scientific use of the term 'heavy metals' to be found in the English literature is cited in Bjerrum's *Inorganic Chemistry* published in 1936. The Bjerrum definition is based upon density of the elemental form of the metal, and he classifies heavy metals as those metals with elemental densities above $7\,g\,cm^{-3}$. Over the years, this definition has been modified by various authors, and there is no consistency—the term is not recommended (Cornelis and Nordberg, 2007). The term 'heavy metals' has sometimes been used to describe metals or metalloids that can give rise to toxicity. Such use should be discouraged. The Scientific Committee on Toxicology of Metals (SCTM) under the International Commission on Occupational Health (ICOH) had already concluded in the 1970s that the term should not be used (Task Group on Metal Accumulation, 1973; Nordberg, 1976).

2 DEFINITION OF METALS AND SOME GENERAL ASPECTS OF METAL TOXICOLOGY

2.1 Definition of Metals and Metalloids

Metals are usually defined on the basis of their physical properties in the solid state. The physical properties of great technological significance are those such as high reflectivity which is responsible for the characteristic metallic luster, high electrical conductivity, decreasing with increasing temperature, high thermal conductivity and mechanical properties, such as strength and ductility.

Metals in the solid state are also characterized by their crystal structure, by the specific chemical bond in which electrons are delocalized and mobile, and by their magnetic properties. These physical properties have only limited value for understanding the systemic toxic effects, although some may be important in understanding the local effects of metal aerosols.

A more useful definition of metals, in order to make it possible to explain the toxic effects, is based on their properties in aqueous solutions. This definition is: 'a metal is an element which, under biological conditions, may react by losing one or more electrons to form a cation'. In the following text the discussion will be based on the behaviour of metals/metal ions in solution and, where applicable, in biological media.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The distinction in metal toxicology between metals and nonmetals, whether based on their physical or on their chemical properties is not sharp. In metal toxicology, some metalloids are included, since they produce adverse health effects in humans, either by themselves or by interaction. They exhibit certain properties that are typical of metals, while other properties make them similar to nonmetals. In general, in some groups of the periodic system, there occurs a gradual transition of properties from nonmetals to metals when descending from the lighter to the heavier elements, for example, C, Si, Ge, Sn, Pb in Group 14. Borderline elements such as As, Ge, Sb, Se and Te are sometimes called metalloids. Metals are persistent and naturally occurring in the environment and show reactivity. Some have long biological half-lives.

2.2 General Aspects of Metal Toxicology and Biological Monitoring

Metals may bioaccumulate and some are toxic at low-level exposure. Even essential elements may cause toxicity at high exposures.

A number of factors influence the toxicity of metals. Such toxicity depends on general factors, such as dose, exposure conditions, bioavailability and species. Essential metals important for life might cause adverse health effects if exposure is excessive or if the chemical species or exposure route is not the physiological one. The toxicology of metals vary with nutritional factors like iron status, intake of protein, calcium and zinc. Elemental speciation is of fundamental importance in human-health risk assessment (WHO/IPCS, 2006a) where 'chemical species' is defined as a 'specific form of an element defined as to isotopic composition, electronic or oxidation state, and/or complex or molecular structure'. In metal toxicology the elements are often classified as essential or toxic metals, and both categories include metals and metalloids. Metalloids are sometimes referred to as semimetals (WHO/IPCS, 2006a).

Most metals display systemic toxicity, which means that the toxic effect is on an organ other than where the metal is taken up. After absorption, transport, metabolism and kinetics, the metal compound under consideration gives rise to an adverse effect in the critical organ, as defined for each metal compound and exposure condition. Methylation of metals generally increases their toxicity by rendering them more lipid soluble and facilitating their crossing lipid barriers, such as the cell membrane or a blood–tissue (e.g. blood–brain) barrier. However, the opposite is seen for the metalloids arsenic and selenium, where methylation can serve as a means of detoxification (WHO/IPCS, 2006a). Some metals may give rise to cancer. The International Agency for Research on Cancer (IARC) is a part of the World Health Organization (WHO) and is located in Lyon, France. This organization has classified a number of metals and their compounds with respect to their carcinogenicity (IARC, 2008). Either a chemical compound or a specified exposure circumstance is classified by its carcinogenicity. IARC have classified beryllium, cadmium, chromium [VI] and nickel compounds, for example, as carcinogenic to humans (Group 1) and a number of other metals and their compounds as probable or possible carcinogens to humans (Group 2A and 2B) (**Table 1**).

Metals can be organized into toxic metals, essential metals and nonessential metals of major concern in metal toxicology. Metals can be listed by increasing number in the periodic system (**Table 2**). However, in this chapter the metals are listed in alphabetical order.

Table 1 Cancer Classification by International Agency for Research on Cancer (IARC, 2008)

Group 1 Carcinogenic to humans	Group 2A Probably carcinogenic to humans	Group 2B Possibly carcinogenic to humans	Group 3 Not classifiable as to carcinogenicity to humans
Beryllium	Cisplatin[a]	Cobalt and cobalt compounds[d]	Mercury and inorganic mercury compounds
Cadmium	Indium phosphide[b]	Cobalt sulfate and other soluble cobalt(II) salts	Selenium and Selenium compounds
Chromium [VI]	Lead compounds, inorganic	Titanium oxide	—
Nickel compounds	Exposure circumstances: cobalt metal with tungsten carbide[c]	Nickel metal and alloys	—
		Methyl mercury

82	Lead	Pb	II/IV
92	Uranium*	U	III/VI
94	Plutonium*	Pu	III/IV/V/VI

[a]Elements marked with an asterisk are taken from Yokel *et al*. (2006). From WHO/IPCS (2006a).

Biological monitoring is defined as continuous or repeated measurement of potentially toxic substances or their metabolites or biochemical effects in tissues, secreta, excreta, expired air, or any combination of these in order to evaluate occupational or environmental exposure and health risk, by comparison with appropriate reference values based on knowledge of the probable relationship between ambient exposure and resultant adverse (health) effects. Biological assessment of exposure is used as a synonym (Nordberg *et al*., 2004).

The most commonly used media in biological monitoring for assessing exposure and risk assessment are blood, urine and hair. Which media is sampled depends on the kinetics of the respective metal and which biomarkers are most feasible (Aitio *et al*., 2007).

3 ALUMINIUM (Al)

Alum was used by the Greeks and Romans as an astringent in medicine. The element was named aluminium, derived from the Latin words *alumen* or *alum*. Aluminium is widely used in modern society for aeroplanes, in building materials, electrical equipment and so on.

The toxicology and biological monitoring of aluminium has been reviewed by WHO/IPCS (1997) and more recently by Sjögren *et al*. (2007).

3.1 Uptake, Metabolism and Excretion

Aluminium is only absorbed to a limited extent in the gastrointestinal tract, and in the lungs to a variable extent, depending on solubility of the Al compound inhaled and its particle size. Excretion is mainly by the kidneys, probably as aluminium citrate.

3.2 Toxic Effects and Dose–Response Relationships

Aluminium is a well-known neurotoxicant. Accumulation in the human body has been related to the presence of aluminium in dialysis fluids and the concomitant intake of aluminium-containing drugs. This accumulation has resulted in dialysis encephalopathy that is often fatal. The occurrence of this disease has decreased dramatically due to the control of aluminium levels in dialysis fluid (see Section 3.5). Neurotoxic effects have been observed in welders with aluminium in urine $>100\,\mu g\,l^{-1}$. The upper reference limit among nonexposed individuals is $16\,\mu g\,l^{-1}$. Aluminium has been suggested to be one of several factors that might contribute to Alzheimer's disease, although this has not been satisfactorily demonstrated. Occupational exposure to aluminium powder has resulted in pulmonary fibrosis. Asthma has been associated with the inhalation of aluminium sulfate, aluminium fluoride, potassium aluminium tetrafluoride and the complex environment in pot rooms during aluminium production (Sjögren *et al*., 2007).

3.3 Carcinogenicity and Genotoxicity

Cancer and coronary heart disease have been observed among aluminium production workers. However, it is unlikely that aluminium *per se* is responsible for these diseases. Simultaneous exposure to other compounds, such as polyaromatic hydrocarbons, is considered important. Aluminium production is classified as a human carcinogen (IARC, 1987).

3.4 Biological Monitoring

Levels of aluminium in biological fluids that are related to adverse health outcomes are given in Section 3.2 and **Table 3**.

3.5 Recommendations

Aluminium is used as a coagulant in water treatment. WHO has set a practical level in drinking-water plants using aluminium-based coagulants, of $0.1\,mg\,l^{-1}$ or less

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 3 Concentration of aluminium in biological fluids and organs

Exposures based on urine levels in different occupations
High aluminium exposure (urine concentrations often $>100\,\mu g\,l^{-1}$)
Intermediate aluminium exposure (urine concentrations sometimes $>100\,\mu g\,l^{-1}$)
Low aluminium exposure (urine concentrations seldom $>100\,\mu g\,l^{-1}$)

From Sjögren *et al*., 2007.

in large water treatment facilities, and $0.2\,mg\,l^{-1}$ or less in small facilities (WHO, 2004). Similarly, Health Canada established an operational guidance value of $<0.1\,mg\,l^{-1}$ for drinking water from treatment plants using aluminium-based coagulants and $<0.2\,mg\,l^{-1}$ for other types of treatment systems.

The occupational exposure limits for aluminium have decreased during the last decade in many countries. Occupational biological exposure limits have been established in some countries. Finland has a urine biological action level (BAL) of $160\,\mu g\,l^{-1}$ ($6\,\mu mol\,l^{-1}$) (Kallio *et al*., 1999). Germany has a biological tolerance value for occupational exposure of $200\,\mu g\,Al\,l^{-1}$ of postshift urine (Deutsche Forschungsgemeinschaft, 2004). Physicians determine dialysate aluminium levels twice a year. It has been recommended that dialysate aluminium should be $<10\,\mu g\,l^{-1}$ and stated that it must be $<20\,\mu g\,l^{-1}$ (Rob *et al*., 2001).

The amount of aluminium in vaccines in the United States is limited to 0.85 mg per dose if the level is assayed or 1.14 mg if determined by calculation on the basis of the amount of aluminium compound added. The daily intravenous intake of more than $4–5\,\mu g\,Al\,kg^{-1}$ from total parenteral nutrition solutions can produce aluminium accumulation and central nervous system (CNS) and bone toxicity. To avoid this problem, the US FDA (Food and Drug Administration) established a labelling requirement that large- and small-volume additives used in parenteral nutrition must state the maximum aluminium concentration (US FDA 2002; Health Canada, 2009) see also **Toxicities Associated with Parenteral Nutrition**.

4 ANTIMONY (Sb)

The use of Sb as the standard chemical symbol for antimony is due to the abbreviation of the name *stibium*. Antimony is a silvery-white brittle metal of medium hardness and exists in four valence states: 0, −3, +3 and +5. The toxicology and biological monitoring of antimony was recently reviewed by Tylenda and Fowler (2007).

4.1 Uptake, Metabolism and Excretion

Most absorbed antimony is excreted rapidly through urine and faeces. Elimination and route of excretion depend on the type of antimony compound. Urinary excretion is higher for pentavalent than for trivalent antimony compounds, whereas the gastrointestinal excretion is higher for trivalent than for pentavalent antimony. Some data on humans, as well as on animals, indicate that a small part of absorbed and retained antimony may have a long biological half-life of years, especially in the lung (Leffler *et al*., 1984). After acute or chronic oral or parenteral exposure to antimony, the highest concentrations are found in the thyroid, adrenals, liver and kidney.

4.2 Toxic Effects and Dose–Response Relationships

Industrial exposure may give rise to symptoms of irritation in the respiratory tract. Pneumoconiosis, occasionally in combination with obstructive lung changes, has been reported after long-term exposure in humans. Focal fibrosis of the lung has been seen in animal trials. Effects on the heart, even fatal, have been related to long-term industrial exposure to antimony trioxide. Secondary cardiovascular effects as a result of treatment of parasitic disease with antimony compounds have also been reported. In addition, cardiovascular effects have been observed in animal experiments.

4.3 Carcinogenicity and Genotoxicity

Rats exposed to antimony trioxide through inhalation for long periods of time showed a high frequency of lung tumours. IARC (1989) classified antimony trioxide a Group 2B and antimony trisulfide a Group 3 carcinogen.

4.4 Biological Monitoring

Antimony levels in human tissues have been summarized by Tylenda and Fowler (2007). Among members of the general population in various countries, levels are $30–100\,\mu g\,g^{-1}$ in lung tissue and $10–30\,\mu g\,g^{-1}$ in liver, wet weight. Blood and serum concentrations of antimony in normal subjects have been reported to be around 3 and $1\,\mu g\,l^{-1}$, respectively. The 24 hour urinary excretion of 16 subjects ranged from 0.5 to 2.6 µg (Wester, 1973). Smith and Griffiths (1982) found a median antimony concentration of less than $1\,\mu g\,l^{-1}$ for persons not occupationally exposed to antimony and $54\,\mu g\,l^{-1}$ for occupationally exposed workers. Determination of urinary antimony is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

considered useful for biological monitoring of exposure. Significant correlation was found between the concentration of antimony in air, and in the blood and urine of workers in a lead battery factory (Kentner *et al*., 1995). Because quality control programmes were not reported in any of the studies cited, the results on normal levels of antimony in biological materials, especially in urine and blood, must be regarded as tentative only. A study of workers in a textile factory that uses antimony-containing flame retardants compared urinary antimony levels in two groups of workers and controls. The 'high' exposure group had a urinary antimony level of $0.39 \pm 0.26\,\mu g\,l^{-1}$ compared with $0.10 \pm 0.06\,\mu g\,l^{-1}$ in the controls (Iavicoli *et al*., 2002). However, increased urinary antimony levels are seen in cases of exposure to even low levels of antimony in air and may be useful for biological monitoring.

5 ARSENIC (As)

The name arsenic is derived from the Latin word *arsenicum* and the Greek word *arsenikon* (yellow orpiment). Arsenic in the environment occurs in both organic and inorganic compounds in its trivalent or pentavalent state. Certain fish and crustaceans contain very high levels of organic arsenic, often as arsenobetaine. In most other foodstuffs, levels of arsenic are low and the form is not known. The total daily intake of arsenic in the general population is reported to be approximately a few tenths of a milligram, but varies to a great extent, depending on the amount of fish consumed.

The literature on toxicology and biological monitoring has been reviewed by Fowler *et al*. (2007), WHO/IPCS (1981b; 2001).

5.1 Uptake, Metabolism and Excretion

Both organic arsenic in seafood and inorganic arsenic in water, beverages and drugs are readily absorbed (70–90%) by the gastrointestinal tract (Fowler *et al*., 2007; WHO/IPCS, 2001). Some reports also indicate a fairly high degree of absorption after inhalation of arsenic. Absorbed arsenic, irrespective of form, is widely distributed in the body. After exposure to inorganic arsenic, clearance of arsenic from the skin, upper gastrointestinal tract, epididymis, thyroid and skeleton is slower than from other organs. The highest levels of arsenic in humans are normally found in hair, nails and skin. The main route of excretion is through the kidneys. After ingestion of arsenite or arsenate, approximately 35% of the dose is excreted within two days. From animal experiments it seems that insoluble inorganic arsenic inhaled through the airway is deposited and retained in lung tissue for a relatively long time. Animal data indicate accumulation of arsenobetaine in cartilage, testes, epididymis and muscle. Of ingested arsenobetaine, 50–80% is excreted by the urine within two days. Biotransformation of inorganic arsenic has been shown to occur in both animals and humans. Methylated compounds, such as monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA), have been detected in urine after ingestion or inhalation of inorganic arsenic. Reduction of arsenate and oxidation of arsenite *in vivo* have been demonstrated in experimental animals. Recently, a human arsenic methyl transferase has been identified. Medications, contaminated food, beverages, and drinking water have given rise to a number of episodes of arsenic poisoning.

Most arsenic that is absorbed from the lungs or the gastrointestinal tract is excreted in the urine within one to two days. Inorganic arsenic can easily pass through the placenta.

5.2 Toxic Effects and Dose–Response Relationships

Inorganic arsenic-induced skin lesions such, as dermatoses, which may include eruption, pigmentation or leukodermal hyperkeratosis, may ultimately lead to the development of skin cancer and Bowen's disease. Effects on the nervous system (e.g. peripheral nervous disturbance), as well as on the heart and circulatory system (e.g. abnormal electrocardiograms, and peripheral vascular disturbances with gangrene of the extremities), have also been reported after chronic exposure to inorganic arsenic. Haematological changes after inorganic arsenic exposure are characterized by anaemia and leukopenia.

Arsenic poisoning among industrial workers is characterized by perforation of the nasal septum, skin changes and peripheral neuritis. Arsine gas is a powerful haemolytic poison encountered under some industrial conditions. Arsine poisoning is characterized by nausea, vomiting, headache, shortness of breath and haemoglobinuria (WHO/IPCS, 2001).

5.3 Carcinogenicity and Genotoxicity

Arsenic is a human carcinogen (IARC, 1987) Group 1. That evaluation applies to the group of compounds as a whole. IARC (2004) classified arsenic in drinking-water as Group 1. They summarized data on cancer in specific organs, that is, skin, lung, liver, bladder and kidney. There is substantial epidemiological evidence of an excessive risk of lung cancer among workers exposed to arsenic

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and experimental data in animals also gives support to carcinogenicity (Pershagen *et al*., 1984).

5.4 Mechanism of Action

Inorganic arsenic undergoes methylation. Monomethylarsonic acid (MMA) and DMA are thus formed and are excreted in the urine. Methylated forms of arsenic undergo demethylation. Methylation of As has previously been regarded a detoxifying process, but has been shown to induce reactive oxygen species (ROS), playing important roles in cellular toxicity.

5.5 Biological Monitoring

Fowler *et al*. 2007 reviewed available information on As in human organs. The highest levels have usually been found in liver, followed by kidney and the other organs.

It is not known to what extent concentrations in human organs represent inorganic or organic arsenic. Concentrations of 0.014–0.21 mg As kg^{-1} wet weight have been observed in the lungs of smelter workers who had retired 2–19 years before death, whereas unexposed controls had 0.001–0.018 mg kg^{-1}, indicating a long retention time for arsenic in the lungs after inhalation, which may occur in certain occupations (Brune *et al*., 1980).

Arsenic was detected in human breast milk at concentrations of 0.13–0.82 µg l^{-1} wet weight (Somogyi and Beck, 1993). In a population of Andean women exposed to high concentrations (approximately 200 µg l^{-1}) of inorganic arsenic in drinking water, concentrations of arsenic in breast milk ranged from about 0.8–8 µg kg^{-1} wet weight (Concha *et al*., 1998).

5.5.1 Urine

Measurement of urinary arsenic levels is generally accepted as the most reliable indicator of recent arsenic exposure. Normal levels of arsenic in the urine of people with no known high exposure are apparently in the range of 5–50 µg As l^{-1} (Buchet *et al*., 1980). Ingestion of seafood may, however, increase the concentrations to more than 1 mg As l^{-1} (review Fowler *et al*., 2007).

Arsenic concentration in urine may be used as an index of exposure, but a number of factors, such as a diet containing mainly seafood and the time between exposure and urine sampling have to be considered. Because 'fish arsenic' arsenobetaine is essentially nontoxic, total urinary arsenic content may overestimate exposures to arsenic species that are of health concerns. Analytical differentiation of the forms of arsenic in the urine is an appropriate way of determining how much and what form of arsenic has been absorbed (Buchet *et al*., 1980). The sum of urinary excretion of inorganic arsenic and its monomethylated and dimethylated metabolites is a good indicator of exposure to inorganic arsenic when there is some fish consumption. Buchet *et al*. (2003) determined such values by means of hydride generation combined with atomic absorption spectroscopy (AAS) or flame atomic absorption spectroscopy (AAF) and reported a mean value of approximately 7 µg g^{-1} creatinine and a 95% cut off of 18 µg g^{-1} creatinine, in a group from the general population of Belgium. In a population group from an area near the sea in China not known to be exposed to inorganic arsenic, there was a mean of approximately 25 µg g^{-1} creatinine and a 95% cut off of 50 µg g^{-1} creatinine (Buchet *et al*., 2003).

5.5.2 Blood

By use of neutron activation analysis (NAA), Brune *et al*. (1966) found a mean concentration of 0.004 mg kg^{-1} in whole blood of normal people. In studies of As-exposed populations, Concha *et al*. (1998) average blood total As levels of 8–10 µg l^{-1} have been reported. The range of blood As concentrations in an unexposed population was 1–2 µg l^{-1}. By use ofhigh-performance liquid chromatography/inductively coupled mass spectrometry (HPLC-ICP-MS), Mandal *et al*. (2004) were able to separate and quantify the As species in the blood of an As-exposed population, with a total As of 10.1 µg l^{-1}. They found arsenobetaine, DMA, MMA, and inorganic As.

The clearance of arsenic from blood is very rapid. The time lapse between exposure and sampling will, therefore, be of importance if the blood levels are being related to the exposure. Furthermore, intake of seafood may greatly influence the (total) blood arsenic levels. For these reasons, blood arsenic cannot be regarded as a useful indicator of exposure.

5.5.3 Hair

Available information about levels of As in hair, as a biomarker of exposure and the internal dose of As has been reviewed by Fowler *et al*. (2007). In the past, somewhat higher levels in hair were reported, for example, an average of 0.81 mg kg^{-1} in the 1960s. More recently, hair As from an unexposed population in the USA was 0.17 µg g^{-1}, with a range of 0.06–0.33 µg g^{-1} (10–90 percentiles), (Pellizzari and Clayton, 2006).

Speciation of hair by HPLC-ICP-MS showed the presence of As(III), As(V), MMA(V), and DMA(V) in hair, but no arsenobetaine; therefore it does not accumulate in hair. The mean concentration of arsenic in hair has been found to reflect the degree of arsenic pollution in community air in areas polluted by airborne As from coal

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

burning (Bencko *et al*., 1971). Among persons with high water exposures to As, Hinwood *et al*. (2003) found a geometric mean of 5.5 $\mu g\,g^{-1}$ As in the hair with a range of 1.2–20 $\mu g\,g^{-1}$.

There are several caveats related to the analysis of hair As that must be taken into consideration when evaluating an individual or population suspected to have chronic or acute As exposure or poisoning. It may not be possible to distinguish between arsenic adsorbed onto hair from external contamination and arsenic incorporated into hair from the internal body burden.

6 BARIUM (Ba)

Barium stems from Greek *barys*, meaning 'heavy'. The toxicology and biological monitoring of barium was reviewed by WHO/IPCS (1990c), Dallas and Williams (2001) and more recently by Oskarsson and Reeves (2007).

6.1 Uptake, Metabolism and Excretion

The free ion is readily absorbed in the lung or gastrointestinal tract, but barium sulfate remains essentially unabsorbed. After absorption, barium accumulates in the skeleton; an accumulation also takes place in the pigmented parts of the eye.

6.2 Toxic Effects and Dose–Response Relationships

The toxicity of barium compounds depends on their solubility. Acute or chronic exposure to barium salts results in a number of disorders, including renal intoxication, hypertension and cardiac malfunction in experimental animals. A higher incidence of hypertension has been observed after occupational barium exposure, but no association was found between blood pressure and barium in drinking water, up to 10 $mg\,l^{-1}$, corresponding to approximately 0.21 mg Ba kg^{-1} day^{-1}. The kidney seems to be the most sensitive target organ in rats and mice exposed repeatedly to barium chloride in drinking water.

Poisoning with soluble barium compounds has resulted from accidental or suicidal ingestion or when barium sulfate, used as an opaque contrast medium for X-ray studies of the gastrointestinal tract, has been contaminated with soluble barium. The Ba^{2+} ion is a muscle poison, causing gastrointestinal, cardiac and skeletomuscular stimulation, followed by paralysis. In the Szechuan province of China, a subacute form of barium poisoning (pa-ping) was endemic because of use of contaminated table salt (Oskarsson and Reeves, 2007).

6.3 Mechanism of Action

Barium seems to act as a potassium antagonist and calcium agonist. The mechanism of action is partly due to blocking of the K^+ channels of the Na–K pump in cell membranes, increasing the active inward transport and inhibiting the passive outward transport of potassium. Cases of barium poisoning are accompanied by severe hypokalemia, and potassium infusion is an effective antidote. If administered promptly, soluble sulfates are also an effective antidote, because they form a precipitate with barium that is not readily absorbed from the gastrointestinal tract or lung. Inhalation of barium sulfate dust causes a benign pneumoconiosis ('baritosis') with conspicuous radiographic manifestations, but no impairment of pulmonary function. The condition has been reproduced in rats.

6.4 Biological Monitoring

Most or all barium in blood is in the plasma fraction. Serum reference values of barium have been reported, varying from 1 (Cornelis *et al*., 1994) to 60 $\mu g\,l^{-1}$ and higher with increasing age, especially in women (Rahil-Khazen *et al*., 2000). A temporary increase occurs after barium absorption, but the excess disappears from the bloodstream practically completely 24 hours after cessation of absorption. Exposure to soluble barium compounds during welding resulted in median plasma levels up to 24.7 $\mu g\,l^{-1}$ and median urinary levels up to 101.7 $\mu g\,l^{-1}$ (Zschiesche *et al*., 1992). Urinary levels of barium were determined by ICP-MS in 1437 samples collected from US patients (Komaromy-Hiller *et al*., 2000). The mean level was 3.5 $\mu g\,l^{-1}$ (standard deviation (SD), 2.2) and the calculated representative ranges 1.0–7.0 $\mu g\,l^{-1}$ (95% confidence interval after exclusion of the top 10% of the results), which was somewhat higher than the reference values, 0.25–5.7 $\mu g\,l^{-1}$ from a control population, as reported by Minoia *et al*. (1990). Rosborg *et al*. (2003) determined 34 elements in hair in females from acid and alkaline regions in southern Sweden. The median hair concentration of barium was 1057 $\mu g\,kg^{-1}$ (range, 10–7150). The concentrations of barium were significantly higher in hair collected in acid compared with alkaline regions ($p < 0.001$). No correlation was found between barium levels in drinking water and in hair.

7 BERYLLIUM (Be)

The name of the element can be derived from the Greek words *beryllos* and *beryl.* Aquamarine and emerald are precious forms of the mineral beryl. Beryllium is a strategic and critical material for many industries. It is widely used, in spite of its relatively high cost. Three primary forms of beryllium are produced. Copper beryllium alloy is the largest, followed by pure beryllium metal and beryllium oxide ceramics. As a result of the increasing industrial use of beryllium, occupational exposure to the metal may be an important issue. At present, the levels in the occupational environment are below the occupational exposure limits of $2\,\mu g\,m^{-3}$, but this exposure level is not protective of pulmonary disease among sensitive persons in a worker population. The toxicology and biological monitoring of beryllium was reviewed by WHO/IPCS (1990b) and more recently by Jakubowski and Palczynski (2007).

7.1 Uptake, Metabolism and Excretion

Beryllium and its compounds are poorly absorbed in the gastrointestinal tract. In general, inhalation exposure to beryllium compounds results in long-term storage of appreciable amounts of beryllium in lung tissue, particularly in pulmonary lymph nodes, and in the skeleton, which is the ultimate site of beryllium storage.

7.2 Toxic Effects and Dose–Response Relationships

Exposure to beryllium compounds has caused dermatitis, acute pulmonary inflammation and chronic beryllium disease (CBD). Exposure to soluble beryllium salts may cause skin reactions such as oedematous, erythematous and papulovesicular dermatitis. Those changes usually disappear after cessation of exposure. Granulomatous necrotic changes and ulcerations due to skin penetration by insoluble beryllium salts were also observed. These pathological changes are based on delayed allergic hypersensitivity. Acute toxicity of beryllium at concentrations usually above $25\,\mu g\,m^{-3}$ is manifested by skin, eye, nose and throat irritation, followed by upper- and lower-airway inflammation, pulmonary oedema and (above $100\,\mu g\,m^{-3}$) chemical pneumonitis.

CBD (chronic pulmonary granulomatosis, berylliosis) is the most common health problem caused by exposure to beryllium. The beryllium blood lymphocyte proliferation test (BLPT) is used as a medical surveillance tool for assessment of persons at risk for developing clinical and subclinical CBD. The LOAEL (lowest observed adverse-effect level) for beryllium sensitization and CBD progression was suggested to be $0.55\,\mu g$ Be m^{-3}. However, recent reports suggest that sensitization and CBD were associated with beryllium air TWA (time-weighted average) levels exceeding $0.2\,\mu g\,m^{-3}$. These results suggest that to avoid sensitization and CBD, the occupational exposure limits should be lower than $0.2\,\mu g\,m^{-3}$.

7.3 Carcinogenicity and Genotoxicity

An excess of lung cancer occurs in persons occupationally exposed to beryllium and its compounds. IARC (1993) have classified beryllium as a Group 1 carcinogen (sufficient evidence for carcinogenicity in humans). In general, it seems that the lung cancer observations related to occupational exposure to beryllium are linked to higher exposure levels, which were associated with acute beryllium pneumonitis and predominated prior to 1950s.

7.4 Mechanism of Action

CBD is a T-cell-mediated disorder. Beryllium, acting as a hapten, interacts with the antigen-presenting cells in the lungs.

7.5 Biological Monitoring

According to Apostoli and Schaller (2001), the 'normal' urinary Be concentrations reported earlier in the literature were too high, mainly as a result of the poor specificity and sensitivity of the adopted analytical methods. In the control groups investigated by Apostoli and Schaller (2001), all results of determinations were below the detection limits of $0.03\,\mu g\,l^{-1}$.

The data for biological monitoring of exposure to beryllium are not available because of the small number of occupational activities involving exposure to this metal and the lack of appropriate analytical methods in the past.

Apostoli and Schaller (2001) examined 65 metallurgic workers in two electric steel plants and two copper alloy foundries. Beryllium concentrations in urine varied from <0.03–$0.54\,\mu g\,l^{-1}$. A significant correlation was found for the relationship between external and internal exposure. Urinary Be levels were in the range 0.12–$0.15\,\mu g\,l^{-1}$ in workers exposed to Be concentrations in respirable dust; below the recommended threshold limit value (TLV) TWA of $0.2\,\mu g\,m^{-3}$.

8 BISMUTH (Bi)

The name originates from the German *Weisse Masse*, (white mass), later transformed to *Wismuth* and *Bisemutum.* There are no reports on occupational exposures.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

For the general population, the total daily intake via food is about 5–20 μg, with much smaller amounts contributed by air and water. An important source of exposure for specific segments of the population in the past was the therapeutic use of bismuth compounds. The cosmetic use of bismuth compounds still continues to be fairly widespread. The toxicology and biological monitoring of bismuth was recently reviewed by Fowler and Sexton (2007a).

8.1 Uptake, Metabolism and Excretion

Bismuth compounds are considered to be poorly to moderately absorbed following inhalation or ingestion, but there are no quantitative data. Absorbed bismuth is distributed throughout the soft tissues and bone, the highest concentrations being found in the kidney and liver. Absorbed bismuth is excreted primarily via the urine. The biological half-life for whole-body retention is about five days, but intranuclear inclusions containing bismuth seem to remain for years in the kidneys of patients treated with bismuth compounds.

8.2 Toxic Effects and Dose–Response Relationships

High-level exposure causes renal failure associated with degeneration and necrosis of the epithelium of the renal proximal tubules, fatty changes and necrosis of the liver, reversible dysfunction of the nervous system, skin eruptions and pigmentation of the gums and intestine. For information on neurotoxic effects in persons taking Bi medicine see Section 8.3, Biological Monitoring.

Bismuth subnitrate has been used to induce metallothionein (MT) in heart tissue and kidneys, and to attenuate the toxicity of adriamycin and cisplatin compounds, respectively.

8.3 Biological Monitoring

Studies in Belgium (Vanhoe *et al*., 1993) on measured bismuth in human serum by ICP-MS showed a range of $<0.007–0.067\,\mu g\,l^{-1}$ in 19 healthy adults. Slikkerveer and de Wolff (1989) reported that the normal concentration of bismuth in blood is in the range of $1–15\,\mu g\,l^{-1}$. Serum concentrations of bismuth of $242\,\mu g\,l^{-1}$ have been reported in patients with bismuth encephalopathy originally diagnosed with Alzheimer's disease (Summers, 1998). Even higher levels are found in those with renal dysfunction.

9 CADMIUM (Cd)

The Latin word *cadmia* and the Greek word *kadmeia* are ancient names for calamine (zinc carbonate) and the element was discovered from an impurity in zinc carbonate. Cadmium is chemically similar to zinc; it occurs naturally with zinc and lead in sulfide ores. Elevated concentrations in air, water and soil may occur close to industrial emission sources, particularly those of nonferrous mining and metal-refining industries.

Cadmium metal has been used as an anticorrosive, electroplated onto steel, and Cd compounds are used as pigments, often in plastics. Cadmium and its compounds are also used in electric batteries, electronic components and nuclear reactors. Because some of the applications of Cd can be performed by other less-toxic materials, the use of Cd has, therefore, been restricted by law in some countries. The toxicology and biological monitoring of cadmium was reviewed by WHO/IPCS (1992), Satarug and Moore (2004) and recently by Nordberg *et al*. (2007a).

9.1 Uptake, Metabolism and Excretion

Absorption of Cd compounds through the skin is negligible. Inhaled Cd will be absorbed, to between 10 and 50% depending on particle size. The absorption is greater for smaller particles and fumes than for larger dust particles. Humans, absorb 5–10% of ingested Cd. A low intake of calcium, zinc or iron increases the degree of absorption; for example, in iron-deficient individuals, the gastrointestinal absorption rate may be as high as 20% (WHO/IPCS, 1992). Experimental studies have indicated that cadmium, following absorption, is bound to albumin and other high-molecular-weight proteins in the blood plasma. Most cadmium in blood is, however, found within the red blood cells. In the liver, cadmium binds to MT, a low-molecular-weight protein (6.5–7.0 kDa) that is induced by cadmium and zinc. Each MT molecule can bind seven atoms of cadmium. Cadmium is transported in plasma when bound to MT and/or to certain high-molecular-weight proteins (Nordberg and Nordberg, 2000; Nordberg and Nordberg, 2009). Cadmium is accumulated in most organs and the half-lives of 10–30 years are reported for humans in muscle, kidney and liver tissue.

9.2 Toxic Effects and Dose–Response Relationships

The average amount of Cd ingested in most European and North American countries is about $10–20\,\mu g\,day^{-1}$.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The corresponding average urinary excretion is about 0.5–1.0 μg day^{-1}. Most of the Cd in blood is located in the cells. The average blood concentration is about 0.5–1.0 μg l^{-1} in nonsmokers; it is twice as high in smokers because of Cd absorption from cigarette smoke. Concentrations of 10–20 μg kg^{-1} are usually found in the kidney cortex of nonsmokers in European countries. Although the intake of Cd through food has been higher in Japan than in Europe, and the reported tissue levels are correspondingly higher, the food intake of Cd has decreased in Japan during the last few decades.

Ingestion of highly contaminated food or drink results in acute gastrointestinal effects with concomitant diarrhoea and vomiting. Acute inhalation of Cd in air—for example, from soldering or welding fumes—may lead to severe chemical pneumonitis. Long-term exposure to low air levels may lead to chronic obstructive lung disease and lung cancer. Long-term excessive exposure from the air or food leads to renal tubular dysfunction. The first sign of damage is a low-molecular-weight proteinuria. This condition is the critical effect of such exposure to Cd and is used in quantitative risk assessment.

Long-term exposure from food, often combined with other means of delivery, may also lead to disturbance of calcium metabolism, osteoporosis and osteomalacia, mainly among postmenopausal women. A disease exhibiting these features—called *Itai-itai* disease—occurred in the 1950s in Cd-polluted areas of Japan; 124 cases were diagnosed up to 1970 and decreasing numbers of clinical cases have been diagnosed later with 66 cases during the period between 1970 and 2006 (WHO/IPCS, 1992; Nordberg *et al*., 2007a).

9.2.1 Exposure–Response Relationships: Treatment of Poisoning

Exposure to Cd in the air at concentrations of 5–10 μg m^{-3} during a working life of 45 years may give rise to renal tubular dysfunction in a small proportion of exposed workers. At about 100 μg m^{-3}, signs of chronic obstructive lung disease may develop, even after exposure for a shorter duration. After a lifetime of exposure from food at an average intake of about 200 μg day^{-1}, adverse effects on the kidney with low-molecular-weight proteinuria have been observed at age 50. There is considerable individual variation in the sensitivity to development of these renal effects. It has been suggested that such effects can be avoided if renal cortex levels are kept below 50 μg kg^{-1} and urine levels below about 2 μg g^{-1} creatinine. Recent reports of low, but statistically significant, increases at even lower levels of urinary Cd are, however, noteworthy. Such increases are observed in the general population, particularly among people with diabetes.

There is no specific treatment for Cd poisoning. When there are signs of osteomalacia, large doses of vitamin D should be given. Because of the long half-life of Cd in the kidneys, which are the critical organs, and the irreversibility of the effect, primary prevention is essential. Prevention can be assisted through environmental and biological monitoring.

9.3 Carcinogenicity and Genotoxicity

In animals exposed to Cd through injection, inhalation or oral exposure, cancer may develop at the injection site, in the lungs and prostate, or in other organs. Although some epidemiological studies have found an increase in the rates of cancer of the lungs and prostate, other studies have not demonstrated such effects. Since 1993, cadmium has been classified as a human carcinogen (Group 1) by the IARC (1993).

9.4 Mechanism of Action

Cadmium stimulates MT production in the same manner as other bivalent metals, such as zinc, copper and mercury. MT-bound Cd in plasma is filtered through the renal glomeruli and reabsorbed in the tubuli, where the metal ion is released following lysosomal degradation of the protein. The unbound Cd stimulates the production of new MT, which binds the Cd in the renal tubular cells. There is a continuous accumulation of Cd in the kidney tubules in long-term cadmium exposures. When not all of this accumulated Cd is bound, toxic effects occur, possibly because of the interference of Cd with zinc-dependent enzymes and/or membrane function.

9.5 Biological Monitoring

9.5.1 Biomarkers of Exposure

The biomarkers of exposure include biomarkers of external and internal doses and accumulation in critical organs. The utility of using the Cd content in blood and urine to indicate these three dose measurements is discussed in the following text.

9.5.1.1 Cd in Blood

Cadmium in blood occurs mainly in the blood cells. Whole-blood levels in nonsmokers from the general population, in areas without Cd pollution, are below 1 μg l^{-1} in most countries. Smokers have higher values. There is a fast and a slow component in the elimination of Cd from blood. The half-life in the fast component is approximately 100 days on average; the slow component

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is 7–16 years. The 'fast' component may reflect the turnover of cells in the blood.

The Cd concentration in blood may be a useful indicator of the degree of exposure in recent months. After long-term Cd exposure, however, an increasing proportion of blood Cd will be related to the body burden, and blood Cd is a good indicator of internal dose and accumulation in the kidney in long-term orally exposed population groups (Nordberg *et al*., 2002). These considerations are in concordance with the general understanding of Cd kinetics and the toxicokinetic multicompartment model for Cd. Because of the 'fast' compartment of blood Cd (Järup *et al*., 1983), high blood Cd values may be found before critical levels are reached in the kidneys. The level of blood Cd is used for occupational biomonitoring (e.g. in Sweden, a level of 50 nmol l^{-1} (5.5 µg l^{-1})) is used as an action level.

9.5.1.2 Cd in Urine

Urine levels of Cd often are adjusted for variations in volume that occur as a result of variable fluid intake. The most common adjustments are for creatinine or specific gravity, the latter usually being preferred to Cd, but the following discussion will focus on creatinine (CR)-adjusted values, because such values are those available in the published literature.

In urine, 'normal' or 'reference' levels will also vary with age, area and smoking habits, but they are generally $<1\,\mu g\,g^{-1}$ CR (or $1\,\mu g\,l^{-1}$ adjusted to specific gravity 1.024), although levels of $1–4\,\mu g\,g^{-1}$ CR have been reported from some nonpolluted areas in Japan (Ezaki *et al*., 2003; Nordberg *et al*., 2007a). Variation with age is seen in Sweden.

The Cd content in urine increases with the body burden of Cd and also after renal damage has occurred and is usually not related to recent exposure.

It was demonstrated in the 1970s (Nordberg, 1972), from animal experiments, that during the early phase of exposure, before renal tubular impairment has occurred, a correlation exists on a group basis between the body burden and the urinary concentration of Cd. Such information has also been reported in humans in several epidemiological studies. Urinary Cd is presently widely accepted as an indicator of body burden and kidney accumulation of Cd (Järup *et al*., 1998; Nordberg *et al*., 2002). Estimated relationships in the general population between the levels of urinary and kidney cortex Cd and the risk for developing tubular dysfunction are given in Section (9.2.1).

9.5.1.3 Cd in Placenta

Cadmium accumulates in the human placenta, and placental samples can be used as an indicator of Cd exposure during pregnancy. Lagerkvist *et al*. (1996) found levels of 2.6 and $5.0\,ng\,g^{-1}$ wet weight in Swedish nonsmokers and smokers, respectively. Placental levels were four times higher than those in the maternal blood.

9.5.1.4 Cd in Hair, Faeces and Other Biological Materials

For people exposed to Cd almost exclusively from food, the average daily Cd content in faeces is a good indicator of the daily intake, because 90% or more of the ingested Cd passes through the gastrointestinal tract unabsorbed and reaches the faeces. The average daily faecal Cd varies with age in a manner similar to the average daily energy intake. Faecal Cd has been used in several studies to estimate the average daily intake from food in Cd-polluted areas and in populations exposed to background levels of Cd.

Cadmium in hair may be used as an indicator of exposure and of the internal dose in oral Cd exposure (Nordberg and Nordberg, 1988). Because Cd levels in hair are fairly low, there is a risk of external contamination; thus, Cd in hair has not been used significantly for biological monitoring.

9.5.1.5 Cd in Kidney and Liver, Measured In vivo, Body Burden

Among adults in Sweden, USA and Germany, concentrations of Cd in the liver is approximately $1–3\,mg\,kg^{-1}$ and in the kidney cortex $15–50\,mg\,kg^{-1}$ (corresponding to approximately $10–30\,mg\,kg^{-1}$ calculated for a whole kidney). Higher values are found among smokers than among nonsmokers.

In vivo NAA or *in vivo* X-ray fluorescence measurements of liver and kidney Cd has made it possible to measure the correlation between the levels of Cd in the indicator media and in the critical organ, the kidney cortex. Roels *et al*. (1981) found no increase in the blood Cd with increased body burden. The generally high blood levels of Cd (5–30 µg l^{-1}) among the workers studied reflected their high daily exposures. The levels of urinary Cd, on the other hand, correlated with the body burden in workers not exhibiting renal damage. Ellis *et al*. (1984) calculated the relationship between the Cd levels in the kidney or liver measured with *in vivo* NAA and the prevalence of renal tubular dysfunction. Other studies have not succeeded in establishing these relationships because of the lower levels measured and the related larger proportion of values falling below the detection limit (for a review, see Järup *et al*., 1998).

10 CHROMIUM (Cr)

Chromium takes its name from the Greek word for colour, *chroma*. Chromium (Cr) is found in nature primarily as chromite ore with Cr in the trivalent (Cr(III)) form. This ore is used for manufacturing monochromates, dichromates, chromic acid and Cr pigments, as well as Cr metal. Chromium chemicals are of great significance to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the health of workers. Chromium is an important component of stainless steel and is widely used in the rust protection of iron.

The toxicology and biological monitoring of chromium was reviewed by WHO/IPCS (1988) and recently Langard and Costa (2007) have reviewed the toxicology and biological monitoring of chromium.

10.1 Uptake, Metabolism and Excretion

The uptake of Cr through the airways and the digestive tract is much quicker in the hexavalent Cr(VI) than in the Cr(III) state. Chromium is found in all human organs of adults and newborns. The Cr concentrations are generally highest in lung tissue, where the concentration tends to increase with age, most likely resulting from inhalation and retention of Cr compounds with low water solubility. Chromium is excreted through the urine and faeces, predominantly through the urine. Chromium excretion in rats has been reported to take place exponentially, with half-lives of 1.5, 5.9 and 83.4 days.

Trivalent Cr seems to be a nutritional supplement for humans and animals and may play a role in the in metabolism of glucose. However, the mechanism still remains to be further explained. The daily diet is the main source of Cr in humans, and minute amounts of the intake come from drinking water and inhalation, but any daily requirement is still not fully defined.

10.2 Toxic Effects and Dose–Response Relationships

Exposure to Cr(VI) compounds is the main source of acute and long-term untoward effects of Cr. Allergic reaction of the skin is the adverse effect for Cr most frequently observed, and Cr(VI)-induced ulcerations of the mucosa of the nasal septum and ulcers of the skin are still seen frequently in developing countries. Long-term inhalation exposure to various Cr(VI) compounds has been shown to result in a high risk of carcinomas of the respiratory organs. Some of the Cr(VI) compounds, when inhaled seem to be among the most potent human carcinogens. Many animal experiments with instillation and injection of different Cr compounds, have resulted in local cancers in the skin and muscle tissue.

The most significant exposure to Cr(III) compounds in the general population is through food, but no untoward effects of Cr have been reported on this basis.

10.3 Carcinogenicity and Genotoxicity

Manufacture, exposure and analyses of Cr compounds have been reviewed by IARC (IARC, 1990) and chromium (VI) has been classified as carcinogenic to humans (Group 1), while chromium (III) compounds and metallic chromium are Group 3.

10.4 Mechanism of Action

Compounds of Cr(VI) are shown to induce mutations, chromosomal aberrations, DNA damage in the form of single-strand breaks, and DNA–protein and DNA–DNA crosslinks. The end reductant product of Cr(VI) in the cell is Cr(III), which is thought to be responsible for much of the DNA damage and mutations induced by Cr(VI).

10.5 Biological Monitoring

The highest concentration of Cr in humans is found in hair, with values from 200 to 2000 $\mu g\,kg^{-1}$ reported (Mertz, 1969). Levels of Cr in various human organs obtained at autopsy from persons in the general population of various countries show the highest levels in lung and lower levels in other tissues (review by Langard and Costa, 2007).

The Cr concentration in all tissues decreases from the moment of birth up to the age of approximately 10. After this time, there is a slight increase in lung concentration, but a continuing fall in all other organs (Schroeder *et al*., 1962). This indicates that Cr in the lungs is a result of deposition from inhaled air, whereas Cr in food is the main source of Cr in other organs.

Previously reported normal levels of Cr in blood up to 3–30 $\mu g\,l^{-1}$ were probably too high. Later the concentration of Cr in plasma was reported to be 0.14 $\mu g\,l^{-1}$ (Veillon *et al*., 1979). Urinary Cr has been used for exposure biomonitoring in welders with levels of 16–58 $\mu g\,g^{-1}$ creatinine in the 1970s and 1980s (Aitio, 1988).

11 COBALT (Co)

Cobalt was isolated by the Swedish chemist Georg Brandt in the middle of the eighteenth century, although compounds containing cobalt were already used in ancient Egypt. *Kobold* was a name applied during the sixteenth century to ores eventually found to be toxic, arsenic-bearing cobalt ores.

Cobalt is a relatively rare element in the earth's crust, which is essential to mammals in the form of cobalamin (vitamin B_{12}). The adult human body contains about 1 mg of cobalt, 85% of which is in the form of vitamin B_{12}. Human dietary intake of cobalt varies between 5 and 50 $\mu g\,day^{-1}$ and most of the cobalt ingested by humans is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

inorganic, vitamin B_{12} representing only a small fraction. The oral bioavailability of inorganic cobalt varies with the solubility of the cobalt compound (5–45%). In occupational settings, workers are exposed to cobalt compounds by inhalation of dust. The main industrial use of cobalt is for the manufacture of alloys and hard metals. The toxicology and biological monitoring of cobalt was recently reviewed by WHO/IPCS (2006b) and Lison (2007).

11.1 Uptake, Metabolism and Excretion

The absorption rate of inhaled cobalt also varies with the species considered. Cobalt does not accumulate in the organism and is rapidly excreted in urine. The concentration of cobalt in urine or in blood may be used as a biomarker of recent exposure to soluble cobalt species (WHO/IPCS, 2006b).

11.2 Toxic Effects and Dose–Response Relationships

The respiratory system is the main target organ (asthma, fibrosing alveolitis, lung cancer) upon inhalation exposure to cobalt, with a higher risk of fibrosing alveolitis (hard-metal disease) and lung cancer in the hard-metal industry, where workers are exposed to cobalt metal mixed with tungsten carbide particles. A physicochemical interaction leading to the formation of ROS may account for the increased toxicity of this mixture of particles. Other target organs include the haematopoietic system, the myocardium, the thyroid gland and possibly the reproductive system.

11.3 Carcinogenicity and Genotoxicity

Cobalt and cobalt compounds (evaluated as a group) were classified by IARC as Group 2B (1991). In 2006, cobalt metal without tungsten carbide was classified as Group 2B and cobalt metal with tungsten carbide as Group 2A; cobalt sulfate and other soluble cobalt(II) salts are Group 2B agents (IARC, 2006a).

11.4 Biological Monitoring

In nonoccupationally exposed subjects, a wide range of cobalt concentrations in urine and blood have been reported, and normal values are probably $<2\,\mu g\,l^{-1}$ (or $\mu g\,g^{-1}$ creatinine) for urine and $0.5\,\mu g\,l^{-1}$ for blood (Lauwerys and Hoet, 2001). Increased urinary cobalt concentrations may be observed in individuals taking multivitamins and patients with a Co-containing prosthesis (Schaffer *et al*., 1999).

Lison (2007) reviewed available data on the relationship between urinary cobalt and exposure in the hard-metal industry. Several studies have demonstrated a good correlation between cumulative exposure via air during the workweek and Co in urine samples on Friday afternoon.

On the basis of the correlation analyses (Ichikawa *et al*., 1985) reported that an airborne exposure to $100\,\mu g\,m^{-3}$ was associated with a cobalt concentration of $5.7–7.9\,\mu g\,l^{-1}$ in blood and $59–78\,\mu g\,l^{-1}$ in urine (95% confidence intervals). The importance of the solubility of cobalt compounds to which workers are exposed is evident from studies by Christensen and Poulsen (1994), who observed increased concentrations of cobalt in blood ($0.2–24\,\mu g\,l^{-1}$) and urine ($0.4–848\,\mu g\,l^{-1}$) of pottery-plate painters who used a soluble cobalt pigment, whereas only slightly increased values were measured in those using an insoluble cobalt pigment (0.05–0.6 and $0.05–7.7\,\mu g\,l^{-1}$ in blood and urine, respectively).

Biological monitoring of workers (Lison *et al*., 1994) exposed to cobalt oxides revealed increased blood and urine levels compared with nonexposed subjects, but parameters poorly reflected recent exposure levels. In contrast, when exposure was to soluble cobalt compounds, urine and/or blood cobalt at the end of the workweek would be recommended for monitoring. It was calculated that an eight hour exposure to 20 or $50\,\mu g\,m^{-3}$ of a soluble form of cobalt would lead to average urinary concentrations of 18.2 and 32.4 μg Co g^{-1} creatinine, respectively (postshift urine sample collected at the end of the workweek). In workers from the hard-metal industry, cobalt in urine rapidly increased in the hours immediately after exposure, with a peak approximately 2–4 hours after exposure, and a subsequent decrease (more rapid for the first 24 hours) in the following days (Apostoli *et al*., 1994).

There is no biological marker of effect that would be specific for cobalt or hard-metal exposure. The determination of the HLA-DP genotype may have some relevance in terms of individual susceptibility to hard-metal disease.

12 COPPER (Cu)

The element was discovered in prehistoric times and takes its name from the island of Cyprus (Latin: *cuprum*). The toxicology and biological monitoring of copper was recently reviewed by Tapiero *et al*. (2003), and Ellingsen *et al*. (2007). Copper is an essential trace element and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is a vital part of several enzymes (e.g. ferroxidases, cytochrome c oxidase, superoxide dismutase (SOD), tyrosinase, lysyl oxidase and dopamine β-hydroxylase).

In the general environment, humans are exposed to copper via food and drinking water which are the most important sources of copper exposure in humans. It is widely used in cooking utensils and water distribution systems as well as in fungicides. Major sources for copper distribution in the environment are mining operations, agriculture, solid waste, and sludge from treatment factories.

12.1 Uptake, Metabolism and Excretion

Absorption depends on the amount ingested, its chemical form and the composition of other dietary components, such as zinc. Drinking water may contribute significantly to the daily copper intake because of the widespread use of copper pipes. Absorption is regulated by homeostatic mechanisms in the liver, and biliary excretion increases when copper is in excess. Copper is found in all organs. The highest concentrations, both in adults and in the newborn, are found in the liver; the brain is also rich in copper.

Excretion is mainly through the bile, and only a small percentage of absorbed copper is found in urine. The total-body biological half-life in groups of healthy humans after oral administration has been calculated in the range of 2–5 weeks.

In people with Wilson's disease, an inherited deficiency of ATP7B, biliary excretion of Cu is impaired and, as a consequence, Cu is accumulated in the liver and other organs. In Menkes disease, there is an uptake of Cu in some organs, and related severe, often fatal, intracellular tissue deficiency due to deficiency in ATP7A.

12.2 Toxic Effects and Dose–Response Relationships

Ingestion of a large amount of copper salts causes gastrointestinal disturbances. The first symptom to occur is nausea, with increased reporting starting at approximately $4\,\mathrm{mg\,l^{-1}}$ of copper in drinking water.

In severe cases, systemic effects, especially haemolysis, and liver and kidney damage, can occur. Indian childhood cirrhosis is a rare liver cirrhosis with increased liver Cu levels. The disease is of unclear aetiology, affecting children from one to six years of age. In Wilson's disease, the impaired excretion of Cu gives rise to tissue accumulation with increasing damage to the liver and brain. In contrast to data obtained after ingestion, comparatively little is known about health effects related to the inhalation of copper and copper fumes in an industrial setting. Copper may cause irritation in the respiratory tract and metal fume fever. Lung changes in vineyard workers have been attributed to copper sulfate, but the role of copper has not been fully explained.

12.3 Mechanism of Action

Crucial for appropriate biliary excretion of copper is the presence of the copper exporter ATP7B. Mutations in the ATP7B gene are responsible for the genetic disorder Wilson's disease.

12.4 Biological Monitoring

Several markers of exposure have been assessed for the purpose of biological monitoring, but none of them have shown clear associations with excessive exposure. Because copper is a highly reactive metal and thus harmful to cells if present as free ions, intracellular copper levels are strictly controlled by a number of integral transmembrane transporters, metallobuffers and metallochaperones.

Ellingsen *et al*. (2007) reviewed data on tissue levels of Cu in humans. In normal humans the highest levels are found in the foetus, decreasing after birth to about $5\,\mu\mathrm{g\,kg^{-1}}$ in liver. In patients with Wilson's disease and in children with Indian childhood cirrhosis considerably higher levels occur.

In the blood, copper is distributed into a plasma pool associated with large proteins, an exchangeable fraction of low-molecular-weight copper complexes and a red cell pool that is partly nonexchangeable. Most of the copper in blood plasma is bound to ceruloplasmin, approximately 15% to albumin, 10% to transcuprein while small amounts are bound to small peptides and amino acids (see review by Ellingsen *et al*., 2007). Transcuprein and albumin represent the bulk of the exchangeable copper pool in plasma. The percentage of plasma copper bound to ceruloplasmin is approximately 60–95%. The copper concentration in red blood cells is about the same as in plasma. Copper is also found in leukocytes. In erythrocytes, approximately 60% of the copper is bound to Cu–Zn–SOD. The normal concentration of copper in plasma is approximately $1\,\mathrm{mg\,l^{-1}}$ ranging up to approximately $1.5\,\mathrm{mg\,l^{-1}}$. Several factors, related to changes in ceruloplasmin levels, make plasma copper an unreliable marker of copper status, except in more severe deficiency states. Increased serum copper levels have been measured in clinically severe cases of copper-sulfate poisoning. The increased concentrations of copper in serum measured in various liver diseases,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

carcinomas, acute and chronic infections, rheumatoid arthritis and other conditions may be related to the increased synthesis of ceruloplasmin as an acute-phase reactant, and thus not related to copper status as such. The half-life of apoceruloplasmin (five hours) is much shorter than the half-life of holoceruloplasmin (5.5 days). Women have generally higher plasma copper levels than men (Milne, 1998). Higher levels have also been measured in women taking oral contraceptives and post-menopausal women receiving oestrogen. Serum copper and serum ceruloplasmin concentration increase during pregnancy.

In healthy adults, the urinary excretion of copper is generally between 30 and 60 μg Cu day^{-1}. An oral intake severalfold higher than the daily recommended intake does not increase the urinary copper excretion over a three week time period. Thus, urinary copper is unsuitable for biological monitoring at moderately elevated oral intakes. However, whether this is true for the occupational setting where exposure occurs by inhalation, has hardly been studied. An increased urinary excretion >100 μg Cu day^{-1} is often observed in patients with Wilson's disease.

13 GALLIUM AND SEMICONDUCTOR COMPOUNDS (Ga)

The name gallium stems from the Latin word *Gallia,* the name for Roman provinces roughly coterminous with modern France. Semiconductors may be elemental materials such as silicon and germanium, or compound semiconductors such as gallium arsenide and indium phosphide, or alloys such as silicon germanium or aluminium gallium arsenide.

Gallium is a member of Group III of the Periodic Table of Elements, and new uses have been found for different chemical forms of this metal over the past two decades in the fields of semiconductor materials, lasers, cancer and malaria chemotherapy, and dental materials. The production of gallium for these uses has increased greatly during this period. Analytical methods for gallium include atomic absorption/emission spectrometry, X-ray fluorescence and, more recently, inductively coupled plasma spectrometry. The toxicology and biological monitoring of gallium and semiconductors was recently reviewed by Fowler and Sexton (2007b).

13.1 Uptake, Metabolism and Excretion

Gallium absorption is independent of exposure route and very limited. After injection it is taken up by bone, kidney and specifically by neoplastic tissue. It is excreted in urine and faeces (Nordberg and Nordberg, 1996).

13.2 Toxic Effects and Dose–Response Relationships

The main health concerns for gallium have been centered on workers in the semiconductor industry engaged in the production of gallium-arsenide-based devices. Toxicity studies in experimental animal systems have shown gallium nitrate and gallium arsenide to produce toxicity to the lungs, immune system, kidneys and haematopoietic systems. Injected gallium compounds may give rise to kidney damage and neuromuscular toxicity.

13.3 Carcinogenicity and Genotoxicity

In 2006, the IARC classified gallium arsenide as a human carcinogen (Group 1). Studies of semiconductor workers are limited, but clinical trials in humans treated with gallium nitrate for various cancers have demonstrated renal toxicity as the primary side effect.

13.4 Mechanism of Action

Gallium is transported in the circulation, bound to transferrin, and competition with iron for transferrin binding seems to be one mechanism by which it may act as an anticancer agent.

13.5 Biological Monitoring

Liao *et al*. (2004) reported gallium concentrations in blood and urine from workers in Taiwan engaged in the production of III–V semiconductors. The gallium blood levels were approximately 0.5 μg l^{-1} for workers in various occupations and office workers (controls). Gallium concentrations in urine were 0.2–0.3 μg l^{-1} among workers and 0.15 μg l^{-1} in controls. Although blood levels were not consistently higher in 'exposed' workers than office workers, urinary gallium was significantly higher ($p < 0.05$) in all other workers compared with the officer workers (controls).

14 GERMANIUM (Ge)

In 1871, Mendeleev predicted the existance of germanium (Latin *Germania* for Germany), as a missing analogue of the silicon group, and called it 'ekasilicon'). Tao and Bolger (1997) reviewed the adverse effects of Ge and more recently Faroon *et al*. (2007) summarized available evidence on toxicity and biological monitoring of Ge.

14.1 Uptake, Metabolism and Excretion

Animal experimental data show that germanium compounds, both inorganic and organic, are rapidly and almost completely absorbed from the lungs and the gastrointestinal tract. The distribution among the organs and tissues is fairly uniform, and there is no evidence of preferential uptake or accumulation. The systemic toxicity is low. Absorbed germanium is rapidly excreted, mainly in urine. Data on biological half-lives are inadequate, but for the rat the whole-body retention half-life has been estimated at about 1.5 days.

14.2 Toxic Effects and Dose–Response Relationships

Germanium tetrachloride is a strong irritant of the respiratory system, the skin and the eye, possibly because it is easily hydrolyzed, producing hydrogen chloride; in mice high-level inhalation exposures caused necrosis of the tracheal mucosa, bronchitis and interstitial pneumonia. Systemic toxicity of germanium compounds is comparatively low. The specific target or critical organs cannot be identified, but nephropathy, neuropathy and hepatotoxicity are usually observed. Trialkylgermanium compounds are less toxic than the corresponding lead or tin alkyls. Germanium compounds do not seem to be carcinogenic. Dimethylgermanium oxide is teratogenic in chickens, but sodium germanate has not produced malformations in hamsters.

There is little information on the toxicity of inorganic germanium compounds to man, except that germanium tetrachloride may produce skin irritation. In clinical trials, spirogermanium, an organogermanium antitumour agent, has been shown to be neurotoxic. Recently, germanium was reported as having anticancer effects. A patient with $175\,\mu g\,g^{-1}$ of germanium in their hair showed a variation in the fibre sizes of the skeletal muscles, with dense cytoplasmic bodies, reduction of cytochrome c oxidase activity, mitochondrial myopathies and vacuolar degeneration; similar findings were observed in rats treated with germanium oxide.

High doses of germanium compounds (taken as supplements) induced remarkable lactic acidosis, hydropic degeneration of the proximal convoluted tubules, with presence of inclusion bodies, and some cellular necrosis and subsequent renal failure; however, the renal glomeruli and the renal interstitial tissue appeared normal. Neurological effects involved negative deep-tendon reflexes in the lower extremities and a persistent tingling sensation in the palms and soles. In addition to severe cardiac dilation, vacuolar degeneration of myocardial cells and interstitial oedema were observed.

Inhalation is the main route of exposure under occupational conditions; the main source of germanium for the general population is food.

14.3 Biological Monitoring

Faroon *et al*. (2007) have recently summarized available data on tissue levels in humans and biological monitoring of Ge. Urinary Ge concentrations can be used for biological monitoring of occupational Ge exposure. Swennen *et al*. (2000) reported urinary concentrations of $<0.25\,\mu g$ Ge g^{-1} creatinine in control workers. In exposed workers, they reported geometric mean urinary concentration ranges from 1.36 (Monday) to 3.6 (Friday) μg Ge g^{-1} creatinine before the working shift to 4.22 (Monday) to 4.34 (Friday) μg Ge g^{-1} creatinine after the working shift. Ranges of individual values before the shift were $0.23–70\,\mu g\,g^{-1}$ creatinine and after the shift $0.16–195\,\mu g\,g^{-1}$ creatinine.

15 INDIUM (In)

The name of the element alludes to the brilliant indigo line in its spectrum. One unusual property of indium is that its most common isotope (^{115}In) is slightly radioactive; it very slowly decays by β-emission to tin. Indium compounds of toxicological interest include indium trichloride, indium oxide, indium sulfate, indium sulfide, indium sesquioxide and colloidal indium hydroxide. Indium also forms organometallic compounds such as trimethylindium, a polymeric solid. Indium phosphide and indium arsenide are used in the manufacture of III–V semiconductors, and indium phosphide is used in the production of nanoparticles, nanowires and dots. Available evidence regarding indium toxicology has been reviewed by Fowler and Sexton (2002) and more recently by Fowler (2007).

15.1 Uptake, Metabolism and Excretion

Indium (In) compounds are poorly absorbed when ingested and moderately so when inhaled. The most

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

common routes of exposure for the general population are inhalation and ingestion; for occupationally exposed persons it is inhalation. The use of In for nanotechnology may increase the possibility of dermal absorption in work environments.

Muscle, skin and bone constitute the main storage sites, but the excretion routes vary depending upon the form. Ionic indium is excreted primarily in urine; faecal elimination is the predominant route for removal of colloidal indium. A biphasic pattern of excretion and a whole-body biological half-life on the order of two weeks have been reported for both forms of indium.

15.2 Toxic Effects and Dose–Response Relationships

Ionic indium is concentrated in the kidneys, producing renal failure; colloidal indium is taken up by the reticuloendothelial system, causing damage to the liver and spleen. Intravenous administration of ionic indium to pregnant hamsters has been reported to produce malformations of the foetal digits.

15.3 Carcinogenicity and Genotoxicity

In 2006, indium phosphide was upgraded from Group 2B to 2A (IARC, 2006a).

15.4 Mechanism of Action

Ionic indium has been shown to produce marked ultrastructural damage in the endoplasmic reticulum of both hepatocytes and renal proximal tubule cells with associated disruption of haem metabolism and haemoprotein function.

15.5 Biological Monitoring

Smith *et al*. (1978) have extensively reviewed the literature concerning reported tissue concentrations of indium in animal and human tissues, and most values have been found to be $<0.05\,\mu g\,g^{-1}$.

16 IRON (Fe)

The name stems from the Latin word *ferrum*. Iron has been known since prehistoric times. It is the fourth most abundant metal in the earth's crust and the most abundant transition metal. Iron can easily change valence and form complexes with oxygen, and iron-mediated reactions support the respiration of nearly all aerobic organisms. An adequate oral intake of iron is thus essential to human life. However, unless appropriately shielded, iron catalyses the formation of radicals that can damage biological molecules, cells, tissues and entire organisms. A review of iron biochemistry and toxicology has recently been presented by Ponka *et al*. (2007).

16.1 Uptake, Metabolism and Excretion

Exposure to excess iron—typically from multiple blood transfusions over many years—can lead to numerous pathological consequences. In contrast, severe iron deficiency may also have serious health consequences. Because of the inherent danger of iron, specialized molecules for the acquisition, transport and storage of iron (ferritin) in a soluble nontoxic form have evolved.

16.2 Toxic Effects and Dose–Response Relationships

Despite these homeostatic mechanisms, organisms can face the threat of either iron deficiency or iron overload. Acute iron poisoning occurs in children as a result of accidental ingestion of medical iron preparations. Such ingestion gives rise to gastrointestinal symptoms with blood vomiting and acidosis; subsequently hepatic and renal damage may develop. Hereditary haemochromatosis is an inherited inability to downregulate intestinal iron absorption. The disease gives rise to gradually increasing excessive iron level with related liver disease. Other forms of haemochromatosis give rise to damage to the heart. In addition, occupational inhalation exposures to iron may give rise to siderosis, a benign condition easily diagnosed by chest X-ray. Emerging knowledge of iron metabolism increasingly emphasizes the simultaneously vital and threatening nature of this most important and abundant metal.

16.3 Carcinogenicity and Genotoxicity

IARC (1987) classified iron-related industrial activities and iron compounds as to their carcinogenicity. Iron and steel founding are Group 1, that is, carcinogenic to humans, iron–dextran complex is Group 2B, while iron–dextrin complex and iron-sorbitol–citric-acid complex is Group 3. It should, however, be noted that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the carcinogenic agent in the occupational environment is most probably not iron, but other compounds generated in the process, such as polyaromatic hydrocarbons.

16.4 Mechanism of Action

Delivery of iron to most cells occurs after the binding of transferrin to transferrin receptors on the cell membrane. The transferrin–receptor complexes are then internalized by endocytosis, and iron is released from transferrin by a process involving endosomal acidification and reduction. Iron is then transported through the endosomal membrane by the Fe(II) transporter DMT1/Nramp2. Importantly, this same transporter is involved in the absorption of inorganic iron in the duodenum, a process facilitated by the ferric reductase, Dcytb, which presumably provides Fe(II) for DMT1/Nramp2. Organisms and cells possess limited ability to excrete excess iron, and only some specialized cells have active mechanisms to export iron. Iron release from these 'donor cells' (primarily enterocytes and macrophages that recycle haemoglobin iron) is mediated by ferroportin 1. The ferroxidase activity of copper-containing proteins, hephaestin and ceruloplasmin, facilitates the movement of iron across the membranes of enterocytes and macrophages, respectively. Cells are also equipped with a regulatory system that controls iron levels in the labile pool. Levels of iron modulate the capacity of iron regulatory proteins (IRPs) to bind to the iron-responsive elements (IREs) present in the untranslated regions of messenger RNAs (mRNAs) for several proteins involved in iron metabolism (e.g. ferritin, transferrin receptor, DMT1); these associations, or lack of them, in turn control the expression of these proteins. In fact, important information about regulation of iron metabolism came from studies of proteins (e.g. HFE (gene encoding for haemoachromatosis), ferroportin and hepcidin) coded by gene mutations that cause different types of hereditary haemochromatoses.

16.5 Biological Monitoring

Iron status can be monitored by measurements of serum iron, transferrin and ferritin. Acute iron poisoning is monitored by measurements of serum iron. Haemochromatosis is evaluated based on serum ferritin levels.

17 LEAD (Pb)

The chemical symbol Pb is derived from the Latin word for lead, *plumbum*. Inorganic lead is certainly the most extensively studied of all toxic agents. Occupational exposure occurs in a wide variety of settings. There is also widespread exposure in the general environment. However, after the ban of lead addition to petrol, the exposure has decreased dramatically in several parts of the world. The toxicology of lead and its compounds has been reviewed by WHO/IPCS (1995), ATSDR (Agency for Toxic Substances and Disease Registry) (2005) and more recently by Skerfving and Bergdahl (2007).

17.1 Uptake, Metabolism and Excretion

Uptake of lead from the gastrointestinal tract is variable: 4–70% may be taken up depending on conditions of ingestion and dietary composition. Absorption via inhalation is dependent on particle size and solubility of the lead compound being inhaled. Inhalation of small particles of water soluble Pb compounds gives higher uptake, up to 60%.

After uptake into the blood, Pb is distributed to blood cells. A major proportion, approximately 99% is in blood cells and only 1% in plasma. From plasma, Pb distributes to other soft tissues and is gradually incorporated into the mineral part of the bone, where it has a long biological half-life, from two years to several decades, related to bone structure. Excretion is mainly via urine and faeces.

17.2 Toxic Effects and Dose–Response Relationships

Heavy exposure to lead causes anaemia and symptoms of the nervous system, involving both the brain and the peripheral nerves with paralysis. Toxic effects of somewhat lower exposure to inorganic lead may occur in the central and peripheral nervous systems, blood (including inhibition of haem synthesis, which also affects other cells), kidney, and cardiovascular, endocrine and immune systems, gastrointestinal tract and male reproduction (sperm quality). Lead causes increase in blood pressure; several studies have reported slight effects, increase by 1 mm Hg, in adults with a mean blood Pb (PbB) of $0.4\,\mu mol\,l^{-1}$ when PbB was doubled. Furthermore, lead passes through the placenta and may cause effects on the nervous system of the foetus. Lead in the skeleton is mobilized during pregnancy and lactation, and is transferred to both the foetus and the lactating infant. Slight (but adverse) effects on the mental development of infants and children in terms of performance in neurobehavioural tests have repeatedly been reported at a mean PbB of $0.5\,\mu mol\,l^{-1}$, about $100\,\mu g\,l^{-1}$ or even less, in the pregnant woman. The most important organolead compounds are tetraethyl and tetramethyl lead, which have been used in enormous quantities in leaded petrol. They are easily

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

absorbed through inhalation and through the skin and may cause acute encephalopathia.

17.3 Carcinogenicity and Genotoxicity

Lead is carcinogenic in animal experiments, but there is only limited evidence for carcinogenicity in humans. Inorganic lead compounds are classified as Group 2A (IARC, 2006b) and organic lead compounds as Group 3 (IARC, 2006b).

17.4 Mechanisms of Action

In the adult, the early effects of lead exposure are effects on the synthesis of haemoglobin. In children a neurotoxic effect is the critical effect. The mechanism for this is not quite fully understood. It is, however, suggested that impairment of haem metabolism might cause interference with cellular energy metabolism.

Lead inhibits enzymes in the haem synthesis pathway, particularly (aminolevulinic acid dehydratase (ALAD) and ferrochelatase. The latter effect means that iron cannot be incorporated into haem and an erroneous metabolite zincprotoporphyrin (ZPP) is formed. These effects are sometimes used for biological monitoring (see Section 17.5). Anaemia in lead-exposed persons may also be partly related to tubular toxicity in the kidney, with decreased production of erythropoietin.

17.5 Biological Monitoring

Most of our knowledge about dose–response relationships of Pb comes from studies using biological monitoring. There are well-established biomarkers of lead exposure and also biomarkers of some of the adverse effects. The level of lead in whole blood (PbB) is the most commonly used biomarker of exposure and internal dose. The PbB reflects both recent exposure and long-term accumulation of Pb. There is a curvilinear relationship between PbB and lead uptake. At low uptakes there is a steady increase of PbB, but at high uptakes the PbB level flattens out. Recently plasma and serum levels of Pb have also been reported. Determination of these levels, which are considerably lower than those in whole blood is now possible as a result of improved chemical analyses. However, experience is still limited from studies using this, possibly improved, biomarker of exposure and internal dose (Bergdahl *et al*., 1997).

Existing levels of PbB vary among populations and are related to the use of lead in petrol. Unleaded petrol is presently used in most countries. For example, in the Swedish town of Trelleborg, PbB levels in children have decreased since the 1990s when there was a switch from leaded to unleaded petrol. The mean level in 2003–2005 was 16–12 $\mu g\,l^{-1}$. Gellein *et al*. (2007) reported Pb levels of 1.32 and 0.2 $\mu g\,l^{-1}$ (arithmetic average and standard error of the mean (SEM)) in the CSF of adults in Norway by high resolution (HR)-ICP-MS. Comparable values for the serum analyses for Pb was below detection limits. In 33 patients with Parkinson's disease, serum concentration, expressed as $\mu g\,l^{-1}$, for Pb, average and SD, was 0.29 and 0.43, respectively (Gellein *et al*. 2008c). Dose–response relationships for PbB and adverse health effects are given in Section 17.2. Urinary lead levels are also used in biological monitoring, particularly as a test of 'chelate lead'. In order to measure 'chelate lead', either ethylenediamine tetraacetic acid (EDTA) or dimercaptosuccinic acid is administered to the patient and subsequently urine is collected and the urinary Pb level determined. It is believed that 'chelate lead' should reflect the total body burden of lead, but several studies have shown that it reflects mainly soft tissue levels of lead (Gerhardsson *et al*., 1998).

Lead interferes with haem synthesis (Section 17.4) and ZPP accumulates in blood with increasing PbB, starting at 1–2 $\mu mol\,l^{-1}$ of PbB, differing among individuals. Increased levels of ALAD in red blood cells are related to PbB levels above 30 $\mu g\,l^{-1}$ (0.15 $\mu mol\,l^{-1}$) and thus ALAD is a very sensitive biomarker of lead effects. Other metabolites in the haem synthesis pathway have also been used as biomarkers for lead, for example aminolevulinic acid (ALA) in blood plasma or urine. There are differences in the effect on ALA depending on the ALAD genotype (Schwartz *et al*., 1997). Lead accumulates in teeth and in the skeleton. Pb in deciduous teeth is a useful biomarker of cumulative exposure in children. Pb in bone may be determined by *in vivo* methods, which reflect long-term uptake.

18 MANGANESE (Mn)

The name manganese stems from two black minerals from Magnesia, in Greece. *Magnes* was later called *magnesia and* in modern times manganese dioxide. The metal isolated from magnesia negra, *Manganesa* was recognized as manganese, from the German, Mangan.

Manganese is ubiquitous in the environment. It occurs in soil, air, water and food. Its concentration in food varies markedly, but on the whole, food is the major source of manganese intake for humans. The toxicology and biological monitoring of Mn has been reviewed by WHO/IPCS (1981a), WHO (2004), ATSDR (2000) and Sarić and Lucchini (2007).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

18.1 Uptake, Metabolism and Excretion

Manganese absorption is by inhalation, ingestion and through the olfactory pathway. The absorption and homeostasis of ingested manganese is regulated by absorption mechanisms, but manganese homeostasis is primarily achieved by excretion. Absorbed manganese is rapidly eliminated from the blood and first concentrates in the liver, where it conjugates with the bile and is excreted into the intestines. Reaching the intestines, most of the element is excreted in the faeces. Urinary excretion is only approximately 0.01% per day of the body burden. The biological half-life in humans is two to five weeks, depending on body stores. Manganese crosses the blood–brain barrier and accumulates in the brain, where the half-life is much longer. Manganese is an essential element for humans and animals. Although many people are likely to be below the estimated safe and adequate daily manganese intake, no large-scale deficiency has been reported.

18.2 Toxic Effects and Dose–Response Relationships

Long-term exposure to increased concentrations of manganese, associated primarily with inhalation in occupational settings, may result in neurological and neurobehavioural effects. On the basis of the cumulative mechanism of neurotoxicity, concerns have been raised regarding the possible long-term effects on the CNS, represented by parkinsonian disturbances. Manganism, a manganese-induced brain disease, is a progressive irreversible impairment. Positron emission tomography (PET) with ^{18}F-dopa or single-photon emission tomography (SPET) afford a differentiation between manganism and parkinsonism, which is marked by neurodegradation in the dopaminergic nigrostriatal pathway, whereas manganism-induced damage occurs postsynaptic to the nigrostriatal system (Racette *et al*., 2005). Lungs are the second target organs affected by exposure to manganese. Inhalation exposure to high concentrations of manganese dioxide (or tetroxide) can cause chemical pneumonitis, an inflammatory response in the lung. Moreover, even at rather low exposure levels, increased incidence of acute respiratory diseases—bronchitis and pneumonia—have been reported, indicating impaired resistance to respiratory infections. There is also some limited evidence of adverse manganese effects on the reproductive, cardiovascular, haematological, endocrine and immunological systems.

18.3 Carcinogenicity and Genotoxicity

Although manganese causes mutations, it is not carcinogenic. As part of an alloy with chromium, increased incidence of tumours has been seen in experimental studies.

18.4 Mechanism of Action

The principal mechanism of manganese neurotoxicity has not yet been found. Manganese may enhance the auto-oxidation or turnover of various intracellular catecholamines, such as dopamine, leading to an increased production of free radicals, ROS and other cytotoxic metabolites. It may also disturb γ-aminobutyric acid (GABA) regulation, as well as glutamatergic transmission. It also seems to impair the cellular antioxidant defence mechanism.

18.5 Biological Monitoring

Manganese can be measured with good sensitivity in biological fluids and tissues, and levels in blood, urine, faeces and hair have been investigated as possible biomarkers of exposure (Sarić and Lucchini 2007).

The average normal level in whole blood is $7–12\,\mu g\,l^{-1}$. Approximately 85% of blood manganese is in the erythrocytes. In serum and plasma, average manganese concentrations are reported to be 0.6–4.3 $\mu g\,l^{-1}$.

The reported normal concentrations of manganese in urine vary to a large extent, but normally less than $1\,\mu g\,l^{-1}$ is found. As a group, workers exposed to a mean concentration of $1\,mg\,Mn\,m^{-3}$ had higher levels of manganese in the blood and urine than unexposed controls (Roels *et al*., 1987). The group average levels in blood seem to be related to manganese body burden, whereas average urinary excretion levels are judged to be most indicative of recent exposures. However, the individual measurements do not correspond to individual exposures.

In a study by Lucchini *et al*. (1995), blood and urine levels were correlated with exposure levels on an individual basis. In this study, a correlation was observed between a cumulative exposure index (CEI) and manganese in blood (MnB), and both MnB and CEI were associated with neurobehavioural outcomes. Workers had been tested during a month of layoff, and all the correlations increased proportionally to the latency from the exposure cessation. Thus the influence of current exposure was decreased. A factor that limits the usefulness of measuring current MnB and urine as a measure of excess manganese exposure is the relatively

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

rapid rate of manganese clearance from the body, with very little excretion in urine.

In a Canadian study by Baldwin *et al*. (1999) on the relationship between the levels of manganese in air and blood manganese, significantly higher levels of blood manganese were correlated with high levels of airborne manganese. Data obtained in this study combined with the occupational studies indicated that there might be a plateau level of homeostatic control of manganese.

At low levels, blood manganese concentrations are related to food, water and air levels of manganese, and large differences in individual blood levels are observed. At high exposure levels, such as in occupational environments, this plateau may be reached or exceeded.

Manganese-dependent superoxide dismutase activity in lymphocytes increases with increased manganese uptake. It has been suggested that this could be used, in conjunction with serum manganese levels, to assess low and moderate levels of exposure to manganese.

Magnetic resonance imaging (MRI) can be useful to track manganese distribution in the brain among industrial workers exposed to airborne manganese, and to identify accumulation of manganese in children exposed to excess manganese.

The use of hair as a possible biomarker of manganese exposure is problematic. In hair, manganese concentrations are reported to be normally $<4\,\mathrm{mg\,kg^{-1}}$. There is no consensus concerning the validity of scalp hair analysis as a biomarker of exposure.

Ethylene thiourea is readily detected in the urine of humans (and animals) exposed to maneb and mancozeb, but there is no clear relationship between dose and urinary levels (Kurttio and Savolainen, 1990; Kurttio *et al*., 1990).

Clara cell protein CC16 in blood serum or urine is a potential biomarker for pulmonary effects from exposure to MMT (Halatek *et al*., 1998). Clara cells are found in the bronchioles. Damage to these cells causes a significant change in the levels of CC16.

Serum PRL (prolactin) has been shown to be a possible biomarker of manganese effects on dopamine neurotransmission. Namely, the tuberoinfundibular dopaminergic system, which exerts tonic inhibition of PRL secretion, is affected by manganese action (Smargiassi and Mutti, 1999). Still, it is not clear whether PRL levels indicate recent or cumulative exposure. It has to be mentioned, also, that in a study by Roels *et al*. (1992) and more recently in a large South African study on ferroalloy workers (Myers *et al*., 2003), serum PRL levels were not increased in workers chronically exposed to airborne manganese.

19 MERCURY (Hg)

Hg, the chemical symbol for mercury, stems from the name of the planet Mercury and is derived from the Latininized Greek word *hydrargyrum* ('liquid silver') 'water' and 'silver'. Mercury occurs as elemental mercury and as inorganic and organic compounds (mercury vapour, mercury liquid, mercury salts, short-chain alkylmercury compounds, alkoxyalkylmercury compounds and phenylmercury compounds), all having different toxicological properties.

Mercury is circulated naturally in the biosphere, with 30 000–50 000 tons being released into the atmosphere by degassing from the earth's crust and the oceans. In addition, 20 000 tons of mercury are released into the environment each year by human activities, such as combustion of fossil fuels and other industrial release. Annually, approximately 2000 tons of mercury is produced for industrial use, a small part of which is used for synthesizing organic mercury compounds. The world production of mercury for commercial uses has been slowly declining over the past 20 years. In nature, methylmercury (MeHg) is produced from inorganic mercury as a consequence of microbial activity. In mammals, oxidative demethylation occurs *in vivo* to produce inorganic mercury. In fish, the major amount of mercury is MeHg. Factors determining the MeHg concentration in fish are the mercury content in the water and bottom sediments, the pH, the redox potential of water, and the species, age, and size of the fish.

The toxicology and biological monitoring of Hg and its compounds has been reviewed by WHO/IPCS (1990a; 1991b) and more recently by Clarkson and Magos (2006) and by Berlin *et al*. (2007).

19.1 Uptake, Metabolism and Excretion

There are considerable differences in toxicokinetics among various mercury compounds. Mercury vapour is efficiently taken up (about 80%) by inhalation. Metallic mercury, if swallowed, passes the gastrointestinal tract almost without uptake. After uptake of mercury vapour, it is initially transported in blood, bound to erythrocytes, but is gradually oxidized to divalent mercury. Because of its lipid solubility, mercury vapour in blood is efficiently taken up by the brain. Higher brain levels and more toxicity to the brain thus occurs from exposure to mercury vapour compared to exposure to other inorganic forms of Hg. Divalent mercury compounds, if inhaled, are taken up to a considerable extent, but there is no specific information on this. When ingested, approximately 2% of these compounds are taken up in adults and probably a larger proportion in infants and children, as indicated by animal experiments. Divalent mercury, regardless of whether it is derived from mercury vapour or directly absorbed, is efficiently taken up in the proximal tubules. The hazards resulting from long-term intake of food containing MeHg and in occupational exposure to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

MeHg are due to the efficient absorption (90%) of MeHg in man and the long retention time (mean half-life of 65 days but up to 190 days in about 10% of a human population). With continuous long-term exposure there is an accumulation of MeHg in the brain. MeHg also crosses the placental barrier.

19.2 Toxic Effects and Dose–Response Relationships

The toxic properties of mercury vapour are due to mercury accumulation in the brain causing neurological signs, involving an unspecific psychoasthenic and vegetative syndrome (micromercurialism). At high exposure levels, mercurial tremor is seen, accompanied by severe behavioural and personality changes, increased excitability, loss of memory and insomnia. Mercurials may also affect other organ systems, such as the kidney. On a group basis, exposure levels are likely to be reflected in mercury concentrations in blood and urine. Occupational exposure to mercury concentrations in air $>0.1\,mg\,m^{-3}$ may produce mercurialism. Micromercurialism has not been reported at concentrations $<0.01\,mg\,m^{-3}$. Exposure to mercury vapour inhibits foetal brain development in primates. The exact dose–response relationship in humans is not known. Inorganic, but not MeHg, has been found to induce and bind to the low-molecular-weight metal-binding protein, MT. The acute and long-term actions of mercuric salts, phenylmercury compounds, and alkoxyalkylmercury compounds are likely to be gastrointestinal disturbance and renal damage, appearing as a tubular dysfunction progressing to tubular necrosis in severe cases. The lethal dose in man is approximately 1 g of mercuric salt. The mercury load on the kidney is best determined by analysis of renal biopsy. Mercury concentrations in the kidney between 10 and $70\,mg\,kg^{-1}$ have been reported in poison cases with renal injury. Levels $<3\,mg\,kg^{-1}$ may be found in normal cases. Occasionally, mercuric compounds may cause idiosyncratic skin symptoms, which may develop into severe exfoliative dermatitis or may cause glomerular nephritis. Animal and clinical observations have shown that mercuric mercury stimulates, and MeHg inhibits, the immune system, in a specific form of idiosyncrasy, called acrodynia or pink disease, seen in children. Most cases are associated with mercury exposure where increased levels of mercury in urine are observed.

Chronic poisoning by MeHg results in degeneration and atrophy of the sensory cerebral cortex, paraesthesia, ataxia, hearing and visual impairment. Prenatal exposure causes cerebral palsy and, in less severe cases, psychomotor retardation. MeHg concentration in blood and hair reflects the body burden and the MeHg concentration in the brain. Intake resulting in body burdens of $<0.5\,mg\,kg^{-1}$ body weight (bw) is not likely to give rise to detectable neurological signs in adults. This intake corresponds to blood values of $<200\,\mu g\,l^{-1}$ and mercury levels in hair of $<50\,mg\,kg^{-1}$. However, this level of MeHg exposure in pregnant women may result in inhibited brain development of the foetus with psychomotor retardation of the child. The highest level of MeHg load in pregnant women, not associated with inhibition of foetal brain development, is not known.

19.3 Carcinogenicity and Genotoxicity

IARC (1993) classified mercury and inorganic mercury compounds as Group 3 and MeHg compounds (evaluated as a group) as Group 2B carcinogens.

19.4 Mechanism of Action

Glomerular injury of the kidney subsequent to inorganic mercury exposure is due to an autoimmune reaction, with formation of an antigen against the glomerular membrane. Uptake of divalent Hg into the proximal kidney tubule takes place via the pathway of the amino acid cystine, because gluthathione complexes with mercury (II) are connected to cysteine complexes that mimic the amino acid cystine. Such uptake leads to tubular necrosis at higher levels of accumulation in the tubules (see Section 19.2). MeHg toxicity to the brain is considered to be related to the inhibition of tubulin polymerization in naive cells.

19.5 Biological Monitoring

Biological monitoring of mercury exposure is possibly by means of determination of Hg levels in blood, urine or hair. For exposures to mercury vapour, urine or whole-blood levels have been used. Relationships between urine Hg and neurological signs, that is, tremor have been described (Chaffin *et al.*, 1973) at urine levels of $10\,\mu g\,l^{-1}$. Urine levels of Hg usually are below $5\,\mu g\,l^{-1}$ among adults without exposure. For exposure to inorganic mercury compounds, urine Hg levels are also used. Dose–response relationships are, however, not well established for this less common exposure.

When there is exposure to MeHg, whole-blood erythrocytes or hair are the most useful indicators, because the highest levels of this mercury compound occur in these media, while serum or plasma and urine levels are low. There is a well-established relationship of 1/250

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

between MeHg levels in human blood and hair. Levels of Hg in hair exceeding 10 mg kg^{-1} in pregnant women have resulted in adverse effects on the foetal brain, with increased occurrence of neurodevelopment deficits in their children (Debes *et al*., 2006).

Gellein *et al*. (2007) found Hg concentrations of 1.87 µg l^{-1} in whole blood and 0.5 µg l^{-1} in plasma and 2.53 µg g^{-1} (Gellein *et al*., 2008b) in hair among persons without excessive exposure, in Norway.

20 MOLYBDENUM (Mo)

Molybdenum comes from the Greek and means 'lead-like'. Molybdenum is an essential element for humans and dietary recommendations have been established. Dietary intakes in humans are usually within the range of the recommendations. The toxicology and biological monitoring were reviewed by Turnlund (2002) and by Turnlund and Friberg (2007).

20.1 Uptake, Metabolism and Excretion

Soluble molybdenum compounds are readily absorbed when ingested. The highest molybdenum concentrations are found in the kidneys, liver and bone. Excretion, primarily via the urine, is rapid. The biological half-life ranges from a few hours to a few days. Turnover is much more rapid when intake is high than when intake is low. The metabolism of molybdenum is affected by copper and sulphur intake in some species. In ruminants, copper generally has a beneficial effect on the symptoms caused by excessive molybdenum, and thiomolybdates increase the excretion of copper. Both positive and negative effects of the interaction between these three elements have been reported. The effects and their magnitude vary between animal species.

20.2 Toxic Effects and Dose–Response Relationships

In livestock, chronic molybdenum poisoning known as 'teart disease' is caused by a diet high in molybdenum and low in copper. Symptoms include anaemia, gastrointestinal disturbances, bone disorders and growth retardation. In laboratory animals, excessive molybdenum may give rise to morphological and functional changes in the liver, kidneys and spleen. It has a growth-depressing action and deformities of bone may occur.

A few cases of pneumoconiosis have been reported among workers exposed to metallic molybdenum and molybdenum trioxide. Increased blood uric acid values and gout-like symptoms have been reported among workers exposed to molybdenum in a copper-molybdenum plant, as well as among the general population living in an area with high molybdenum and low copper contents in soil and vegetables.

20.3 Mechanism of Action

Molybdenum is important for enzymes such as the mammalian molybdoenzymes, which are involved with the catabolism of sulphur amino acids, purines and pyrimidines; defects in these enzymes result in changes in metabolites. *S*-sulfocysteine, taurine, xanthine and hypoxanthine increase and uric acid is low (Turnlund, 2002).

20.4 Biological Monitoring

So far, no biochemical marker for molybdenum status has been identified. Levels in many tissues and excretion reflect dietary intake in animals and humans. However, none of these has yet been directly related to molybdenum status (Turnlund and Friberg, 2007). In normal adults, median values for the liver, kidneys and adrenal glands have been found to be approximately 1, 0.3 and 0.7 mg kg^{-1} wet weight, respectively. Data on daily urinary excretion of molybdenum in 'normal' human subjects have been presented in groups varying between 49 and 71 µg day^{-1}. Urinary excretion is directly related to recent dietary intake (Turnlund *et al*., 1995). However, the values do not necessarily reflect molybdenum status. A wide range of plasma molybdenum concentrations were reported before 1973; however, more recent estimates on the basis of NAA and ICP-MS resulted in concentrations of from 0.3 to 1.1 µg l^{-1} (Versieck and Cornelis, 1980). As with urinary excretion, blood plasma concentrations also reflect recent dietary intake, but not molybdenum status. They are considerably higher, from 2 to 4 µg l^{-1}, when intake is unusually high, from 500 to 1500 µg day^{-1} (Turnlund and Keyes, 2004).

21 NICKEL (Ni)

The German word *Kupfernickel* meaning 'Old Nick's (Satan's) copper' is considered as the origin of the name, nickel. Nickel is widely used in steel and alloy production, electroplating, in coins, household items and so on. It is an essential metal for the growth of bacteria and for lipid metabolism in rats, but its essentiality for humans has not been finally established. Its toxicology and biological monitoring was reviewed by Lu *et al*. (2005) and by Klein and Costa (2007).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

21.1 Uptake, Metabolism and Excretion

Ni is absorbed to a very limited extent from food, approximately 1%, but much more from drinking water. It is taken up via inhalation to an extent of approximately 20%. Ni uptake through the membranes is facilitated by transport proteins like DMT1. It binds to transferrin and competes with iron. Ni is efficiently excreted via urine and is poorly retained in tissues, with a biological half-life of approximately one day. The highest levels are found in the kidneys.

21.2 Toxic Effects and Dose–Response Relationships

Acute nickel poisoning can occur as a result of inhalation of nickelcarbonyl ($NiCO_4$). Initial symptoms are modest, but after two to three days progressive cough, dyspnoea, pneumonia and respiratory distress are seen. There may also be myalgias, delirium and convulsions.

Less severe respiratory symptoms related to long-term inhalation exposures to Ni dust have been reported in workers. Long-term exposures may give rise to pulmonary fibrosis and pneumoconiosis. Perforation of the nasal septum is common in Ni workers. Dermal Ni exposure may give rise to contact allergy. Ni allergy is a very common disorder affecting as much as 30% of the population in industrialized countries, particularly among women who have previously had skin piercing. Nickel crosses the placental barrier and is teratogenic in animals. Limited human evidence indicates an increased rate of spontaneous abortions among women Ni workers.

21.3 Carcinogenicity and Genotoxicity

The IARC concluded, in 1990, that metallic nickel and alloys, were human carcinogens Group 2B, and the majority of animal data *in vivo* and genetic toxicology data *in vitro* prior to that time suggested that the insoluble particulate nickel species were the most carcinogenic; however, more recent human epidemiology and experimental data is pointing to the water-soluble nickel compounds as perhaps of equal hazard. Accumulating molecular and genetic toxicology data show that soluble nickel chloride ($NiCl_2$) can in fact, be mutagenic and genotoxic, especially when cells are chronically exposed for long durations up to several weeks to allow sufficient nickel uptake. Upon reconsideration of the previous experimental studies with shorter 24–48 hour acute exposures to the insoluble nickel compounds *in vitro*, it is likely that the actual nickel exposures were in fact of much longer duration than previously thought, owing to the insufficient removal of adherent nickel particles from the cell surfaces.

21.4 Mechanism of Action

Nickel (Ni(II)) can generate ROS and activates a number of cellular signal-transduction pathways. The newest information on the molecular mechanisms of nickel's action in biological systems has been summarized by Davidson *et al.* (2007).

21.5 Biological Monitoring

Both serum and urinary nickel measurements can be useful monitors of environmental or occupational exposures. Precautions have to be taken in blood sampling to avoid contamination from stainless-steel needles. Normal levels of nickel in unexposed adults are reported to be in the range of 0.05–1.1 μg Ni l^{-1} serum and a mean value of 1.5 μg g^{-1} creatinine in urine (WHO/IPCS, 1991a). In a study of Finnish factory workers (Kiilunen *et al.*, 1997), after-shift urinary concentrations of nickel were 0.1–2 μmol l^{-1} and were still elevated after a two to four week vacation. However, concentrations of nickel in urine in this study showed no correlation with nickel concentrations in the air. In a Norwegian study of potential nickel exposure from nearby Russian refineries, nickel levels in the urine of residents living near the refineries were significantly lower than for urban residents living away from the refineries in areas of high vehicular traffic (Smith-Sivertsen *et al.*, 1997). In flux-core-wire (FCW) stainless-steel welders exposed to workplace air levels of nickel of 50.4 μg m^{-3} (ranging from <2 to 416.7 μg m^{-3}), whole blood and plasma levels were found to be low at 0.84 μg l^{-1} and 0.57 μg Ni l^{-1} and urine levels were also very low at 2.5 μg g^{-1} creatinine (Stridsklev *et al.*, 2004). These values were all near the current detection limit ranges for Ni in whole blood (0.48–1.5 μg Ni l^{-1} whole blood), plasma (0.3–0.9 μg Ni l^{-1}) and urine (0.3 μg g^{-1} creatinine). Although there were no associations between the Ni levels in air and in biological fluids; statistically significant associations between Ni levels in whole blood and plasma before and after work were found. Compared with manual metal arc welding (Stridsklev *et al.*, 1993), the levels of nickel in biological fluids were the same or slightly higher for FCW welders. When measuring blood, plasma and serum levels of nickel, investigators must consider the use of non-stainless-steel needles, because of the potential for unintended Ni contamination of the samples. Nickel measurements in smokers' blood range from 0.01 to 0.42 μg Ni l^{-1}, not much higher than

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in nonsmokers' blood (0.01–0.26 μg Ni l^{-1}), whereas nickel in the urine of smokers (<0.01–8.20 μg l^{-1}, median) is significantly higher than nonsmokers (<0.01–4.60 μg Ni l^{-1}) (Stojanović *et al*., 2004).

22 PALLADIUM (Pd)

Palladium is named after the asteroid Pallas, which had been discovered at the beginning of the 1800s, just before Pd. Palladium is one of the six platinum group metals and possesses strong catalytic activity. Demand for palladium is high for its uses in electrical equipment, dental materials and automobile catalysts. Environmental levels of palladium in water, soil and ambient air are not high, and environmental exposure and intake from food are not significant. However, palladium concentrations are increasing in the general environment because of its increased use in automobile catalysts. Workers in palladium mines and refineries are possibly exposed to palladium, as are dental personnel during the processing of dental alloys containing palladium. The toxicology and biological monitoring were reviewed by WHO/IPCS (2002) and more recently by Satoh (2007).

22.1 Uptake, Metabolism and Excretion

The general population may be exposed to palladium through inhalation of ambient respirable particles from automobile catalytic converters that incorporate palladium, but relevant data are rare. Among the general population, skin exposure may occur through contact with jewellery containing palladium.

Uptake of palladium ions via the gastrointestinal tract ranges from 0.5–4% in animal experiments. Aqueous aerosols of ionic palladium are taken up to a greater extent. After uptake, Pd is distributed to the kidneys, liver, lymph nodes and spleen. Placental transfer is limited. Excretion is via urine to a considerable extent.

22.2 Toxic Effects and Dose–Response Relationships

The oral toxicity of palladium is believed to be low, although it does depend on the water solubility of the palladium compounds. Therefore, similar intravenous LD_{50} values have been reported for several palladium compounds: from 3 to 6.4 mg kg^{-1} bw. From a 28 day toxicity study of tetraamine palladium hydrogen carbonate in rats, performed through gavage, the no observed adverse-effect level (NOAEL) was 1.5 mg (kg bw)$^{-1}$ day^{-1}. Many case reports exist describing palladium sensitivity and recovery after removal of dental restorations. The symptoms that have been observed include swelling of the lips and cheeks, stomatitis, oral lichen planus, itching, dizziness, asthma and chronic urticaria. ^{103}Pd has been used as a radioactive source implanted directly into a malignant tumour; no palladium-related complications have been reported. Although sensitization effects, such as bronchial asthma, can occur among workers exposed to palladium and its compounds, its incidence is extremely low.

22.3 Biological Monitoring

Studies in Germany gave levels of 0.03–0.2 (mean, 0.1) μg l^{-1} for 24 hour urine samples from 14 nonsmokers (Schramel *et al*., 1997), 0.02–0.08 μg l^{-1} (mean, 0.04) for 24 hour urine samples (Begerow *et al*., 1997c), 0.03–0.08 μg l^{-1} (mean, 0.05) for whole blood (Begerow *et al*., 1997a), 0.03–0.22 μg l^{-1} (mean, 0.14) for 24 hour urine samples (Begerow *et al*., 1997b) and slightly lower values of 0.013–0.048 μg l^{-1} (mean, 0.031) for morning urine. Urine levels among groups living in areas having different automobile traffic densities did not display a definite difference.

23 PLATINUM (Pt)

The word *platinum* comes from the Spanish word *platina*, meaning 'little silver'. Commercial sources of platinum are sulfide and arsenide minerals, and, increasingly, recycled platinum. The main source of platinum in the environment is release from vehicle catalysts, and platinum concentrations near highways and urban areas have gradually increased. In occupational exposure, the form of platinum is mainly coordination complexes, most often with chlorine as a ligand, whereas the platinum released from automotive catalysts is metallic or oxidic. Kiilunen and Aitio (2007) have recently reviewed the toxicology and biological monitoring of Pt.

23.1 Uptake, Metabolism and Excretion

Animal experiments with intratracheal instillation of platinum-coated aluminium particles less than 5 μm (a model aerosol for automobile exhaust) showed that 97% of the dose was excreted in faeces the first two days. After day 5 there was also some urinary excretion. Oral dosing of platinum(IV) chloride in rats showed a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

limited systemic uptake (2%). After intravenous administration or administration by other routes, Pt mainly accumulates in the kidneys. Systemically absorbed Pt is excreted in urine and faeces. Distribution and excretion of *cis*-platinum used in chemotherapy is different, with faster initial clearance from blood plasma, but *cis*-platinum also accumulates in kidneys.

23.2 Toxic Effects and Dose–Response Relationships

The acute toxicity of platinum compounds depends mainly on their solubility, soluble platinum salts being more toxic than compounds with lower solubility, such as oxides. Chloroplatinates are irritating to the eye and skin. The main health effect of platinum compounds is sensitization; the symptoms of platinum-salt sensitivity include irritation of the eyes and upper respiratory tract, and asthma. The allergenic potency of platinum compounds seems to be limited to coordination complexes containing halogen ligands as leaving groups, hexa- and tetrachloroplatinates being the most potent sensitizers. Neutral coordination complexes such as diamminedichloroplatinum do not seem to be allergenic. Bromine and iodine analogues of platinates may cause sensitization, but seem to be less potent.

23.3 Carcinogenicity and Genotoxicity

With the exception of platinum-containing chemotherapeutic drugs such as cisplatin (*cis*-diamminedichloroplatinum), no relevant human or experimental data are available on the potential carcinogenicity or teratogenicity of platinum compounds. Cisplatin and other platinum-containing chemotherapeutic drugs are genotoxic in a variety of test systems, and other platinum compounds have induced mutations *in vitro* (but not *in vivo*).

Platinum compounds used as anticancer drugs, such as cisplatin and its analogues, are not covered in detail in this review. However, cisplatin was classified as a Group 2A carcinogen (IARC, 1981; 1987) and in combination with certain agents as a Group 1 carcinogen, according to IARC (2000).

23.4 Mechanism of Action

The mechanism of platinum-salt allergy is likely to be Type 1 (i.e. involves IgE). Atopic constitution is not associated with susceptibility to platinum sensitization. Smokers have a higher risk of platinum sensitization. No health effects from environmental exposure to platinum have been reported.

23.5 Biological Monitoring

Previous studies have reported high concentrations for platinum in biological fluids, but are not considered reliable. Dental gold alloys were found to increase urinary and saliva platinum concentrations (mean age, 35.9 years, 326 urine samples, median 9.3 ng g^{-1} creatinine with dental gold inlays and 5.3 ng g^{-1} creatinine without dental inlays, $p < 0.001$, and 5–2770 pg g^{-1} saliva, median 160 pg g^{-1} and 4.8–26 pg g^{-1} saliva, median 8.1 pg g^{-1} saliva, $p < 0.001$) (Schierl, 2001). Also, the German Environmental Survey (GerES III) from 1998 (Becker *et al*., 2003) found a positive relation between the platinum levels in urine and teeth with dental inlays, crowns and bridge elements, whereas road traffic was related to urinary platinum concentrations. The geometric mean value for all occupationally unexposed persons (age, 18–69 years, $n = 1080$) was 2.18 ng l^{-1} (1–75 ng g^{-1} creatinine) and the 95% CI from the log-normal distribution was 2.01–2.36 ng l^{-1}; (1.60–1.90 ng g^{-1} creatinine). Those with no dental inlays ($n = 509$) had a geometric mean platinum concentration in urine of 1.32 ng l^{-1} (0.99 ng g^{-1} creatinine) with 95% CI of 1.1–1.47 ng l^{-1} (0.89–1.11 ng g^{-1} creatinine). From Italy, Iavicoli *et al*. (2004) reported a mean urinary platinum concentration of 4.56 ng l^{-1} in 58 people. They found a statistical difference between females and males (4.09 vs. 5.77 ng l^{-1}, $p = 0.004$). The subjects older than 40 years of age ($n = 28$) showed statistically significantly higher mean platinum concentrations in urine than those of younger colleagues ($n = 21$, $p = 0.03$). In children, the Pt concentrations were 0.9 ± 1.1 ng g^{-1} creatinine, and they were not associated with traffic density in the area of residence (Caroli *et al*., 2001).

In Budapest and Vienna, platinum concentrations in the urine of adult inhabitants without occupational exposure were on average 10.1 ± 8.8 and 3.7 ± 4.3 ng g^{-1} creatinine ($n = 100$), respectively (Záray *et al*., 2004).

The serum platinum concentration in Germany in nonexposed persons was 6.35 ng l^{-1} (median; range, <5.0–42.1 ng l^{-1}, number of subjects not given) (Merget *et al*., 1999). In Italy, the blood platinum level was 10 ± 2 ng l^{-1}, in urine the level was 5 ± 0.1 ng l^{-1} and in hair 50 ± 8 ng kg^{-1} ($n = 25$) (Petrucci *et al*., 2005).

24 SELENIUM (Se)

The name is derived from the word *selene*, the Greek name for moon. The element was associated with

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

tellurium, named after *Tellus*, the Earth. Selenium is an essential trace element and has been shown to be a natural component in the enzymes glutathione peroxidases (GSH-Pxs 1–5), iodothyrodine deiodinases, thioredoxin reductases, selenoprotein P and other proteins, 25 altogether. The toxicology and biological monitoring of selenium has recently been reviewed by Högberg and Alexander (2007).

24.1 Uptake, Metabolism and Excretion

Most selenium inorganic and low-molecular-weight compounds are water soluble and can efficiently be taken up in the intestine. Soluble, as well as nonsoluble, compounds can be taken up by the lungs. Selenium occurs as cysteine in selenoproteins, whereas selenomethionine can non-specifically substitute for methionine in proteins. The selenium requirement to compensate minimal losses in man is 50–70 μg day^{-1}.

When given in excess, selenium compounds are rapidly distributed to major organs of the body. In the liver, many selenium compounds are biotransformed to excretable metabolites. Identified metabolites include selenosugars in urine and dimethylselenide in breath. Biotransformation seems to be a major mechanism by which selenium homeostasis is maintained during excessive exposure, and there is a rapid phase and a slow phase of elimination. The half-life of the rapid phase is one to three days, depending on the compound ingested, and for the slow phase it is 30–110 days. Blood levels are approximately 0.027 μg ml^{-1} in geographical areas with low selenium intake, and an intake of about 90 μg day^{-1} would correspond to approximately 0.11 μg ml^{-1}.

24.2 Toxic Effects and Dose–Response Relationships

Toxic effects have been seen at blood levels ranging from 0.179 to 7.5 μg ml^{-1}. In most parts of the world, normal urine levels are 0.03 mg l^{-1}. Occupationally exposed workers usually excrete <0.1 μg ml^{-1}.

The LD_{50} ranges between 1.5 and 6 mg (kg bw)$^{-1}$ for many selenium compounds and animal species. The CNS seems to be the target organ at these dose levels, but the liver, heart and lungs may also be affected. Cases of acute selenium poisoning in humans have been described, a few with fatal outcomes. These cases occurred either after consumption of selenium or after exposure through inhalation. Gastrointestinal and neurological symptoms predominated.

Chronic poisoning caused by long-term exposure has been reported in livestock and humans from geographical areas where soil contains high levels of selenium. In rodents, liver cirrhosis is a common effect, whereas typical effects in domestic animals are emaciation, deformation of hooves, loss of hair and joint erosions. In humans consuming 1–5 mg Se day^{-1}, hair and nail problems have been reported, and are very common at 5 mg Se day^{-1}. An intake of approximately 1200 μg day^{-1} is the LOAEL for clinical selenosis, and 850 μg day^{-1} can be taken as a NOAEL for clinical selenosis. However, a clinically insignificant rise of serum alanine aminotransferase (ALAT) has been reported at slightly lower doses. Other adverse effects among a few individuals in larger study cohorts have also been reported at lower doses. Skin lesions and depigmentation are also common signs of intoxication. In more severe cases, neurological and gastrointestinal symptoms predominate. Death, albeit rarely, has been associated with chronic selenium poisoning.

Teratogenicity has been observed, particularly in avian species and fish. Selenite in hamsters and mice and selenomethionine in macaques were essentially negative. Selenium may prevent or alleviate toxic effects of arsenic, cadmium, mercury, platinum and silver. Conversely, some of these metals protect against selenium toxicity.

24.3 Carcinogenicity and Genotoxicity

Selenium and selenium compounds are classified as Group 3 carcinogens (IARC, 1987). Although several selenium compounds have been tested for possible carcinogenic potential, only selenium sulfide in large oral doses has shown convincing carcinogenic effects. Conversely, some of these compounds have been shown to prevent the development of cancer. Some selenium compounds can cause DNA damage, probably by inducing oxidative stress.

24.4 Biological Monitoring

The reference urinary level should not exceed 0.03 μg ml^{-1} (Robberecht and Deelstra, 1984). It is recommended that selenium in urine is measured in 24 hour samples or is related to the creatinine level. This is also a biomarker of exposure.

Urinary levels in workers exposed to 0.2–0.4 mg Se m^{-3} were usually <0.1 mg l^{-1}. At air concentrations as high as 3.6 mg m^{-3} times the urinary level averaged 0.25–0.45 mg l^{-1}. A garlic odour on the breath usually accompanied these higher levels (Glover, 1967).

Toxic effects of selenium are reflected by increased blood, urine and hair levels. In China, people consuming selenium-rich food and exhibiting signs of selenosis had

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

mean levels in blood, urine and hair of 3.2 μg ml^{-1}, 2.7 μg ml^{-1} and 32.2 μg g^{-1}, respectively. The corresponding values in people from a high selenium area without selenosis were 0.44 μg ml^{-1}, 0.14 μg ml^{-1} and 3.7 μg g^{-1} in blood, urine and hair, respectively. In selenium-adequate areas, the levels were 0.095 μg ml^{-1}, 0.026 μg ml^{-1} and 0.36 μg g^{-1} in blood, urine and hair, respectively (Yang *et al*., 1983).

Supplementation of the diet with yeast or wheat, so that 200 μg Se day^{-1} was consumed, resulted in an increased plasma level from 0.07 to 0.17 μg ml^{-1} within 11 weeks (Levander *et al*., 1983). Supplementation with selenate was less efficient. On a low-selenium diet (33 μg day^{-1}), the level in breast milk was 5.8 μg l^{-1}. At a higher dietary level (50 μg day^{-1}), the milk level was 10.0 μg l^{-1} (Kumpulainen *et al*., 1984). Many supplementation studies have been carried out since then.

The highest levels are often achieved on supplementation with selenomethionine, a common form in plants, which is nonspecifically incorporated into proteins. The efficiency of selenium compounds to raise plasma selenium levels also depends on the selenium status (Alexander and Meltzer, 1995; Rayman, 2004). In deficiency, selenium in blood or plasma is decreased.

25 SILVER (Ag)

Silver has been known since ancient times. The symbol 'Ag' is from the Latin for 'silver', *argentum.*

The toxicology and biological monitoring has recently been reviewed by Holler *et al*. (2007).

25.1 Uptake, Metabolism and Excretion

Silver compounds may be absorbed to varying degrees through inhalation. Silver salts are absorbed by up to 10–20% after ingestion. The highest concentrations of silver are usually found in the liver and spleen, and to some extent in the muscles, skin and brain, after ingestion. The biological half-life for silver ranges from a few days for animals up to approximately 50 days for the human liver; it is possible that skin deposits have an even longer half-life, but there are no quantitative data on this for man. Silver binds to high-molecular-weight proteins and MT in tissue cytosol fractions. Excretion of silver from the body is primarily biliary.

25.2 Toxic Effects and Dose–Response Relationships

Water-soluble silver compounds, such as the nitrate have a local corrosive effect and may cause fatal poisoning if swallowed accidentally. Chronic exposure of humans leads to argyria, a clinical entity characterized by grey-blue pigmentation of the skin and other body viscera. Repeated exposure of animals to silver may produce anaemia, cardiac enlargement, growth retardation and degenerative changes in the liver.

25.3 Biological Monitoring

Plasma samples from an unexposed population were all <1 μg l^{-1} (Wan *et al*., 1991). Tipton *et al*. (1966) found between 0.006 and 0.015 mg day^{-1} in urine and between 0.02 and 0.11 mg day^{-1} in faeces. Wester (1971), by use of NAA, found 0.9–1 μg day^{-1} in urine and 0.9–97 μg day^{-1} in faeces of two patients with pancreatic insufficiency. In urine, Bostrom and Wester (1968) found 1 μg day^{-1} in normal persons and 0.7–7.5 μg day^{-1} in patients with untreated hyperthyroidism. Wan *et al*. (1991) observed urinary excretion levels in a control group generally to be <2 μg day^{-1}.

26 TELLURIUM (Te)

Tellurium stems from Latin *tellus* meaning 'earth'. The main source of exposure in the general population is food, for example, meat, dairy products and cereals. The toxicology and biological monitoring was recently reviewed by Gerhardsson (2007).

26.1 Uptake, Metabolism and Excretion

In the work environment, inhalational exposure predominates. Small amounts of organic tellurium compounds can also be absorbed through the skin. There are no quantitative data on absorption of tellurium or tellurium compounds in humans. In animals, the intestinal absorption has been estimated to range between 10 and 25%. The highest tissue concentrations have been observed in the kidneys. Increased levels have also been noted in blood, heart, lungs, liver, spleen, muscle and bone. The main accumulation is in bone, which harbours >90% of the total body burden. Tellurium can pass both the placenta and the blood–brain barrier. Parenterally administered tellurium is predominantly excreted in the urine, whereas orally ingested tellurium salts through biliary secretion are mainly excreted in the faeces. Small amounts, probably approximately 0.1%, of absorbed tellurium are exhaled, presumably as dimethyltelluride. In rat experiments, biological half-lives ranging from nine days in blood to 23 days in kidney have been reported.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The whole-body retention model for man estimates a biological half-life of approximately three weeks. The elimination from bone is slow, with an estimated half-life of approximately 600 days.

26.2 Toxic Effects and Dose–Response Relationships

Acute systemic effects of tellurium toxicity in rats include listlessness, decreased locomotor activity, somnolence, anorexia, weight loss, gastrointestinal disturbances, changes in fur, and, occasionally, epilation and hind-leg paralysis. Long-term studies of chronic effects are sparse. Dominant and critical effects have been reported from the nervous system, including peripheral neuropathy, characterized by segmental demyelination and minor axonal degeneration. In the brain, black changes caused by dark tellurium particles that are localized in lipofuscin granules in neuron cytoplasm have been observed. Other effects have been reported from the liver (fatty degeneration and necrosis), kidney (proximal tubular lesions, oliguria, or anuria) and heart (cell necrosis, oedema and congestion). Reproductive effects, including, for example, hydrocephalus, oedema, exophthalmia and ocular haemorrhage have been described.

Acute exposure to tellurium in occupational settings may cause acute respiratory irritation followed by the development of a garlicky odour on the breath and sweat, drowsiness, headache, malaise, lassitude, weakness and dizziness. Gastrointestinal symptoms such as anorexia, nausea, vomiting, metallic taste, dry mouth and constipation may appear. Dermatitis and blue-black discoloration of the skin may follow from exposure to tellurium hexafluoride. Severe intoxication may lead to depression of the respiratory system and circulatory collapse. No specific antidote for tellurium poisoning has been found.

26.3 Biological Monitoring

Blood and urinary analyses may be used for biological monitoring as biomarkers of exposure, but data are very scanty. Tellurium values for normal subjects have been reported for blood $0.15–0.3\,\mu g\,l^{-1}$ (van Montfort *et al.*, 1979) and urine $<0.1–10\,\mu g\,l^{-1}$ (Fodor and Barnes, 1983; Kobayashi and Imaizumi, 1991). Only few and incomplete data are, however, available from the working environment, regarding the relationship between tellurium in air, blood and urine. Quantitative data on the relationship between internal dose and adverse health effects are still lacking and, thus, risk assessment cannot be carried out. An early and classical sign is the garlicky odour on the breath, which may appear after ingestion of $40\,\mu g$ of soluble tellurium.

27 THALLIUM (Tl)

Thallium originates from Greek, *thallos*, and means a green shoot or twig. The name comes from thallium's bright green spectral emission lines. The toxicology and biological monitoring have been reviewed by WHO/IPCS (1996) and more recently by Kazantzis (2007).

27.1 Uptake, Metabolism and Excretion

After rapid, almost total, absorption from the gastrointestinal tract, soluble thallium compounds are widely distributed in the body, the highest concentration being accumulated initially in the kidneys. Excretion occurs through urine and faeces, the disappearance of thallium from the tissues following first-order kinetics. The biological half-life of ^{204}Tl in the rat has been calculated at three to four days. In man, increased concentrations of thallium may be found in urine and faeces for several weeks after absorption. Excretion also occurs through hair, which, in unexposed subjects, has been shown to contain the highest concentration of thallium in any tissue. In the rat, 21 days after dosing by parenteral or oral routes, up to 60% of the remaining body burden was found in the hair.

27.2 Toxic Effects and Dose–Response Relationships

Thallium has caused acute and often fatal poisoning as a result of unintentional, criminal or suicidal ingestion. Fatalities have also occurred after the now obsolete therapeutic administration of thallium. Gastroenteritis, collapse and later peripheral neuropathy are the principal features in acute poisoning, but, with longer survival, alopecia becomes a characteristic feature after two to three weeks. In chronic poisoning, the main features are vague ill health, paraesthesias and, in some cases, loss of hair; this pattern is seen after low-level occupational exposure. The widespread use of thallium as a rodenticide has been responsible in some countries for the death of domestic and wild animals and their natural predators. Dose–response relationships for symptoms of adverse health effects from thallium exposure in the general environment are discussed in Section 27.4.

27.3 Mechanism of Action

There are similarities between the ionic transport of thallium and of potassium through cell membranes, but

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

once intracellular, thallium is less rapidly released than potassium.

27.4 Biological Monitoring

Thallium intake in polluted areas may exceed the normal dietary intake in the general population, estimated to be $<5\,\mu g\ day^{-1}$, mostly from foodstuffs, which does not constitute a threat to health. Where environmental monitoring shows thallium levels significantly above background, biomonitoring of the population should be carried out and where this reveals evidence of excessive exposure, emissions should be reduced.

Weinig and Zink (1967) determined the thallium concentration in early-morning urine samples in nine subjects to range from 0.13 to $1.69\,\mu g\,l^{-1}$. In three carefully controlled population-based studies involving a total of 686 unexposed subjects, the range of urinary thallium concentrations was $0.06–1.2\,\mu g\,l^{-1}$, with a mean thallium urinary concentration of $0.3–0.4\,\mu g\,l^{-1}$. With a short biological half-life and an assumed steady state in such population-based samples, the urinary excretion value can be considered as an indicator of total dose after inhalation and total dietary intake (WHO/IPCS, 1996). The concentration of thallium in whole blood in a population of 320 children in New Jersey was measured by AAS. Values ranged between nondetectable ($<5\,\mu g\,l^{-1}$) and $80\,\mu g\,l^{-1}$, with a mean concentration of $3.0\,\mu g\,l^{-1}$. Approximately 80% of the children showed no detectable thallium in the blood, whereas 17.5% had between 5 and $20\,\mu g\,l^{-1}$. Five children (1.6% of the total group) had blood thallium levels between 40 and $80\,\mu g\,l^{-1}$, but all were without evidence of thallium toxicity (Singh *et al*., 1975).

In a population sample living in the vicinity of thallium emission into the atmosphere, the mean urinary thallium concentration was $5.2 \pm 8.3\,\mu g\,l^{-1}$, with a range of $0.1–76.5\,\mu g\,l^{-1}$. From a questionnaire, a clear dose–response relationship was identified between thallium concentrations in urine and the prevalence of tiredness, weakness, sleep disorders, headache, nervousness, paraesthesia, and muscle and joint pain, with a similar dose–response relationship when thallium in hair was taken as an indicator of exposure (WHO/IPCS, 1996).

From these limited studies, it has been suggested that an approximately 15-fold increase in urinary thallium excretion above the mean unexposed level of $0.3–0.4\,\mu g\,l^{-1}$ may be related to subjective symptoms that could possibly be considered as early adverse effects. The WHO Task Group (WHO/IPCS, 1996) considered that exposures with urinary thallium concentrations $<5\,\mu g\,l^{-1}$ are unlikely to cause adverse health effects. In the range of $5–500\,\mu g\,l^{-1}$, the magnitude of risk and severity of adverse effects are uncertain, whereas exposures with urinary thallium concentrations $>500\,\mu g\,l^{-1}$ have been associated with clinical poisoning.

Extensive data on thallium levels in persons from the general population is available from the NHANES studies in the United States. Thallium levels in urine, blood and hair are useful biomarkers of exposure to thallium.

28 TIN (Sn)

Tin stems from the Latin *stannum* and is one of the earliest metals known and used as a component of bronze, as early as 3500 BC, even if not used until about 600 BC as just tin. Tin is not an essential metal and is widely used in industry. In nature, it occurs both in inorganic and organic forms. The toxicology and biological monitoring was reviewed by WHO/IPCS (1980; 1990d) and more recently Ostrakhovitch and Cherian (2007).

28.1 Uptake, Metabolism and Excretion

The gastrointestinal absorption of soluble tin salts is only a few % of the ingested dose. In chronic exposures, bone is the major storage organ for tin, and its biological half-life in bone is approximately 100 days. The excretory routes of tin compounds may vary, depending on the type of tin compounds and the mode of exposure.

28.2 Toxic Effects and Dose–Response Relationships

Most of the inorganic tin compounds are nontoxic because of their low solubility and absorption. In workers who inhale tin oxide, it accumulates in the lung and causes ‘stannosis’, a benign pneumoconiosis without any tissue reaction or pulmonary dysfunction. Although insoluble tin compounds are nontoxic, soluble tin compounds can be toxic. Oral administration of $45\,mg\,kg^{-1}$ of stannous chloride can induce vomiting and diarrhoea in cats. In human, high intakes of inorganic tin compounds can cause abdominal pain and anaemia. Inhaled tin hydride gas can cause damage to nerves. Epidemiological study shows a positive relationship of increased tin intake to a decrease in copper status, changes in cholesterol metabolism and ischaemic heart disease. Tin can be converted by chemical and biological reactions in the environment to form more toxic organotin compounds. Short-chain alkyltin compounds, such as trimethyl and triethyl tins are well absorbed from the gastrointestinal tract, whereas long-chain alkyltin compounds are not much absorbed. The toxicity of organotin compounds differs, depending on their physicochemical properties. Alkyl and aromatic tin compounds are neurotoxicants. Triethyltin can cause encephalopathy and cerebral

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

oedema. Severe dermatitis has been described in workers exposed to tributyltin and painters applying formulations. Tributyltin is widely used as an antifoulant in marine paints to prevent any growth on ocean vessels. However, the use of tin-containing paints for smaller marine vessels is restricted in many countries.

28.3 Carcinogenicity and Genotoxicity

Tin as tannic acid and tannins are classified as Group 3 agents by IARC (1987). Organotin compounds can penetrate cell membranes because of their lipophilicity and cause damage to cell membranes, interrupt oxidative phosphorylation and damage mitochondria. They can inhibit synthesis of haem oxygenase and can be immunotoxic and genotoxic. There is no definite evidence that inorganic or organic tin compounds can cause carcinogenic or teratogenic effects, although in a few studies, effects have been reported. Tributyltin and triphenyltin are implicated in endocrine disruptions, and hence cause reproductive failure in marine organisms.

28.4 Biological Monitoring

The average concentration of tin in urine is approximately 4.2–42.2 nmol l^{-1} and in hair is approximately 0.42–3.37 nmol g^{-1}. The average concentration of tin in blood of normal subjects is 0.14 mg l^{-1} and is found mainly in the erythrocytes (Baselt and Cravey, 1989). Tissue analysis has shown that tin is present in lungs, adrenal glands and liver at concentrations of 37, 23 and 23 mg kg^{-1}, respectively. The highest amount of tin (in dry ash) has been found in the cecum (130 mg kg^{-1}), ileum (79 mg kg^{-1}), rectum (57 mg kg^{-1}) and sigmoid colon (45 mg kg^{-1}) (Schroeder *et al*., 1964). Inorganic tin does not accumulate in soft tissues with increasing age (Baselt and Cravey, 1989). Concentrations of organotin compounds in organisms are very high near sources such as ports, pleasure-boat marinas, shipyards and much-travelled shipping routes. The bioconcentration factors for triphenyltin have been found to be 2090 in carp kidney and in the range of 80 000–440 000 in the crab hepatopancreas (Kannan *et al*., 1995b; Tsuda *et al*., 1987). The levels of triphenyltin in mussels and samples of sea birds from coastal areas of Japan are approximately 0.45 and 0.05 μg g^{-1}, respectively. In fish from the same coastal areas, the maximum concentration of triphenyltin has been reported to be 2.6 μg g^{-1} in 1989 and 0.25 μg g^{-1} in 1995. Butyltin compounds in the tissue of mussels from Egremont are in the range 0.217–0.508 mg kg^{-1} dry wt, slightly higher than the range of 0.11–0.201 mg kg dry wt at New Brighton (Harino *et al*., 2005). The concentration of tributyltin reached 1000 ng kg^{-1} in bream muscles from the Elbe estuary (Shawky and Emons, 1998). The concentration of trisubstituted organotins is higher in digestive glands than in other tissues.

Tributyltin concentration in digestive tissue and the gills has been reported to be twice as high as in mantle and muscle (Laughlin *et al*., 1986; Shim *et al*., 1998). The average estimated level of triphenyltins in fish and other marine products ranges from 0.03 to 1.3 mg kg^{-1} (Ishizaka *et al*., 1989). In fish from sampling sites of the North Sea, concentrations of tributyltin range from 27–202 ng g^{-1} in muscles and 54–223 ng g^{-1} in liver (Shawky and Emons, 1998). Concentrations of tributyltin in the muscle of fish from the Gulf of Mexico were from 0.1 to 0.196 mg kg^{-1}, whereas in fish from Switzerland, the concentration reported is 0.17 mg kg^{-1} (Fent and Hunn, 1991). A recent study from Denmark determined the levels of total butyltin in shellfish and fish, and they were approximately 10–440 ng g^{-1} (Nielsen and Strand, 2002). It was shown that concentrations of butyltin compounds in the liver of dolphins from the Italian coast of Mediterranean Sea were in the range of 1.2–2.2 μg g^{-1} (Kannan *et al*., 1995a).

The total butyl content in the liver of mice exposed to tributyltin is approximately 1 mg kg^{-1} and remains unchanged 24 hours after administration. The contents of tin in the liver of rats and guinea pigs are lower at three hours and higher at 24 hours than those of mice (Ueno *et al*., 2003). The main form of butyltin in the liver of rats treated with tributyltin was dibutyltin. After a single oral dose of tributyltin, high levels of tributyltin were seen in the frontal and temporal lobes and in the cerebellum of rabbits. Despite the possibility of human exposure to butyltins, only a few studies have examined butyltins in human tissues. The concentrations of butyltins in the liver of Japanese subjects ranged from 59 to 96 ng g^{-1} wet wt, whereas monobutyltin and dibutyltin, degradation products of tributyltin, were predominant (Takahashi *et al*., 1999). The hepatic deposition of butyltin in a group of Danish men was from 1 to 33 ng g^{-1}, whereas total butyltin concentrations in human liver samples collected from Poland were in the range 2.4–11 ng g^{-1} (Nielsen and Strand, 2002). The variation in concentrations of butyltin among individuals from different countries may probably reflects the differences in dietary intake of fish (Nielsen and Strand, 2002). The concentration of butyltin in blood collected from 32 volunteers during a blood drive organized by the American Red Cross in central Michigan in 1998 ranged from 0 to 101 ng ml^{-1} (Kannan *et al*., 1999). After removing the highest concentration from the data, the average concentration was approximately 4.5 ng ml^{-1}. The occurrence of butyl compounds in human blood suggests the widespread exposure to these compounds from a variety of sources. When tributyltin in a mixture

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat145
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of 3 ml cherry brandy and 7 ml ethanol was given orally to a volunteer, only 5.1–5.4% of the dose was excreted in the urine, mainly as dibutyltin metabolites (Uhl, 1986). In 1999, more than 1000 people were exposed to methyltin contained in cooking oil in Southeast China. The concentration of trimethyltin in blood samples from these people after the incident was approximately 70 ng g^{-1}, whereas the levels of di- and trimethyltin in urine were approximately 80 ng ml^{-1} (Jiang *et al.*, 2000). Analysis of tin in organs showed high concentrations of methyltin in liver (1.93 µg g^{-1} dimethyltin and 1.42 µg g^{-1} trimethyltin), kidney (1.05 µg g^{-1} dimethyltin and 0.47 µg g^{-1} trimethyltin) and heart (0.1 µg g^{-1} dimethyltin and 1.48 µg g^{-1} trimethyltin).

29 TITANIUM (Ti)

Titanium was named after the Titans of Greek mythology. There is no evidence indicating that titanium is an essential element for humans or other animals. Titanium belongs to the first transition group; its chemical behaviour is similar to that of silicon and zirconium. The toxicology and biological monitoring was recently reviewed by Jin and Berlin (2007).

29.1 Uptake, Metabolism and Excretion

Although titanium compounds are, in general, absorbed poorly through ingestion and inhalation, titanium still can be detected in the blood, brain and parenchymatous organs of individuals in the general population, with the highest concentrations being found in the hilar lymph nodes and the lungs. Titanium is excreted in urine; information on other routes of excretion is lacking.

29.2 Toxic Effects and Dose–Response Relationships

Studies on titanium alloys used in implants and titanium compounds—such as its salicylate, oxide and tannate derivatives—used in cosmetics and pharmaceuticals, have not indicated any significant local effects on tissues, but, under certain circumstances, cases of inflammatory reactions and systemic effects have been observed. Thus, titanium cannot always be considered as being inert and biocompatible, as was once believed. Titanium tetrachloride, a strong irritant to mucous membranes and the eyes, can cause skin burns through accidental exposure. A soluble titanate given to rats in their drinking water was found to disturb their reproduction in a three-generation study on rats.

29.3 Carcinogenicity and Genotoxicity

Several epidemiological studies have suggested that TiO_2 dust has no carcinogenic effect on human lungs. IARC has listed titanium dioxide within Group 2B (IARC, 2006c). There is sufficient evidence from experimental animal studies for the carcinogenicity of TiO_2, but no adequate evidence exists for the carcinogenicity of titanium oxide in humans. Intramuscular injections of powdered titanium metal have induced fibrosarcomas and lymphosarcomas in rats; similarly, the organotitanium compound titanocene has induced fibrosarcomas in rats.

29.4 Mechanism of Action

Bronchoalveolar lavage cells from rats instilled intratracheally with TiO_2 particles induce *hrpt* gene mutations in rat alveolar cells *in vitro*. Experimental animal studies, clinical studies and some epidemiological surveys have indicated that titanium dioxide is generally biologically inert, but cases of adverse reactions have been reported. In experimental studies on animals, titanium carbide, hydride, nitride and boride have exhibited slight fibrogenic activity. Artificial fibres—such as potassium octatitanate and titanium phosphate fibres—possess fibrogenic properties.

29.5 Biological Monitoring

It has been reported that the blood concentration of titanium ranges from 0.03 to 0.15 mg kg^{-1} (Hamilton *et al.*, 1973). Titanium concentrations of 0.8 mg kg^{-1} wet weight in the brain, 1.3 mg kg^{-1} in the kidney cortex, 1.3 mg kg^{-1} in the liver, 3.7 mg kg^{-1} in the lungs and 0.2 mg kg^{-1} in muscle have been reported (Hamilton *et al.*, 1973). Titanium tends to accumulate with age in lung tissue, but not in other organs (Schroeder *et al.*, 1964). Titanium concentrations of 33 mg kg^{-1} dry weight in the lungs and 150 mg kg^{-1} in hilar lymph nodes have been reported (Teraoka, 1981). No analytical methods have been described for the measurement of titanium dioxide in urine. It has been observed that serum titanium concentrations were approximately 50 times greater, because of abrasion and wear of the titanium base material, in patients with failed patellar components of titanium-based joint implants (average concentration of serum titanium, 135.57 ng ml^{-1}) compared with those of a control group. There were, however, no significant

differences in the levels of urinary titanium. Elevated serum titanium may, therefore, serve as a marker of failed patellar components in subjects who have undergone total knee replacements with titanium alloy bearings (Jacobs *et al.*, 1999).

30 TUNGSTEN (W)

Tungsten is also known as wolfram. Apart from occupational sources, small quantities of tungsten are present in food and water; trace quantities, related to industrial emissions, have been found in the general atmosphere. Tungsten is also present in trace amounts in human serum and in urine and faeces, elimination approximately balancing the intake of the metal in the few nonindustrially exposed subjects studied. Industrial, medical and military uses of tungsten have been expanding rapidly, as has the potential for the spread of tungsten to the environment (Leggett, 1997). The toxicology and biological monitoring of tungsten was recently reviewed by Kazantzis and Leffler (2007).

30.1 Uptake, Metabolism and Excretion

Almost one-half of an ingested dose of tungsten in the form of a soluble salt, and one-third of a deposited inhaled aerosol of tungstic oxide, were rapidly absorbed in those animal models which have been studied. Most of the absorbed tungsten was rapidly excreted in the urine. The small amount of tungsten retained was transferred in part from plasma to red blood cells and distributed mainly to spleen, kidney and bone. About three months after ingestion and six months following inhalation, the largest proportion of the body burden of tungsten was found in bone, although this was only a very small part of the administered dose. Sodium tungstate resembles molybdate in chemical properties and antagonizes the normal action of molybdate in its role as metal carrier for certain enzymes.

30.2 Toxic Effects and Dose–Response Relationships

Little is known about the toxicity of tungsten compounds, although the LD50 of soluble salts in the rat is relatively high. Following occupational exposure to tungsten carbide dust by inhalation, cases of pulmonary fibrosis have been reported, but this 'hard-metal disease', as it is often called, is more likely to be caused by cobalt, with which tungsten carbide is fused.

30.3 Carcinogenicity and Genotoxicity

Recent studies have shown a risk of cancer induction following exposure to toxic-metal tungsten alloys, which requires further investigation.

30.4 Biological Monitoring

In man, the mean serum concentration of tungsten, estimated by NAA, was found to be 5.8 ng ml^{-1} in eight healthy subjects, with an SD of 3.5. The urinary excretion of tungsten, again measured by NAA, ranged from 2.0 to 13.0 µg per 24 hours in four subjects in eight estimations. Faecal elimination in the same subjects ranged from 1.6 to 5.7 µg W per 24 hours (Wester, 1973).

31 ZINC (Zn)

Zinc was used in alloys centuries before it was identified as an element. Metallic zinc was produced in thirteenth-century India. The pure zinc metal was rediscovered in the eighteenth century. The toxicology and biological monitoring of zinc was recently reviewed by Sandstead and Au (2007).

Zinc (Zn) is environmentally ubiquitous and essential for life. However, Zn serves as a nutrient and as a toxic metal. There is a risk of deficiency or excess. Human Zn deficiency is common throughout the life cycle, especially in populations with diets that infrequently include animal flesh, and thus are limited primarily to plant products, many of which are rich in indigestible Zn-binding ligands. One estimate suggests that 20% of the world's population is at risk of Zn deficiency. The link between Zn, geology and health effects is presented in Nordberg and Cherian (2005).

31.1 Uptake, Metabolism and Excretion

Zn abundance in humans is approximately half that of Fe. A 70 kg adult male contains approximately 2–3 g, and women contain less. Approximately 60% is in muscle, 30% in bone, 8% in skin and hair, 5% in the liver, 3% in the gastrointestinal tract and pancreas, and other organs contain <1% (Wastney *et al.*, 1986). Soft tissue Zn

($\mu g\,g^{-1}$ fresh tissue) ranges from approximately 12 in the adrenal glands to 102 in the prostate (Tipton and Cook, 1963). The body has no readily available Zn store similar to the store of Fe. However, Zn in bone is available to other tissues when bone turns over. When bone turnover is increased, much of the released Zn is excreted (Fell *et al*., 1973), although some is reused (Masters *et al*., 1986).

31.2 Toxic Effects and Dose–Response Relationships

Manifestation in animals given high doses include abortion, teratology and neonatal death. Human Zn toxicity is uncommon. Inhalation of Zn oxide fumes generated by welding and certain other industrial processes causes metal-fume fever, a self-limited flulike illness. In contrast, inhalation of zinc chloride, from smoke bombs, causes severe pulmonary injury and may be fatal. Ingestion of food or drink contaminated by exposure to galvanized surfaces can cause resulting nausea, vomiting, cramps and diarrhoea that is seldom fatal. Uncontrolled consumption of dietary supplements rich in Zn represents a hazard; intestinal absorption of Cu is suppressed, and Cu deficiency can occur. A similar phenomenon can occur when oral intakes of Zn are physiological or near physiological, and intakes are low. Present data suggest the risk of Cu deficiency is increased when the oral intake Zn/Cu molar ratio is >18; however, the critical level is unknown.

31.3 Biological Monitoring

The zinc content of serum/plasma is normally approximately $1\,mg\,l^{-1}$. The lower limit of 'normal' for morning fasting plasma Zn is approximately $700\,\mu g\,l^{-1}$ (Yokoi *et al*., 2003). Plasma Zn is higher in the morning and decreases after meals. Approximately 60–80% of plasma Zn is bound to albumin, and most of the remainder is bound to transferrin and an α2-macroglobulin (Wastney *et al*., 1986). Plasma Zn concentration is relatively insensitive to changes in Zn status; concentrations may be maintained within the accepted normal range for several weeks to months when subjects are fed 2.6–3.6 mg day^{-1} (40–55.5 µmol day^{-1}) (Milne *et al*., 1983; 1987), amounts of Zn that are inadequate for neuropsychological function (Penland, 1991). In addition, plasma Zn may not be reflective of foetal growth and maternal muscle Zn, although maternal leukocyte Zn is closely related to maternal muscle Zn and foetal growth (Meadows *et al*., 1981).

ACKNOWLEDGEMENTS

Toxicology of Substances that Affect Performance and Behaviour

John P. Thompson

CONTENTS

1 INTRODUCTION

The use of drugs to enhance performance has become a matter of increasing concern in recent years. The use of foods containing active substances, for example caffeine, which may be taken to improve perceived levels of concentration, is well known. However, with the advent of a greater range of pharmacologically active substances, and the possibility of psychological or financial reward, the temptation to use drugs in the pursuit of enhanced sporting performance has increased.

Within different sports, drugs are taken for a variety of reasons. Some drugs are taken in the expectation that they will alter physical characteristics which will improve performance. Not only are drugs used to enhance performance in sports, studies have shown their use to improve the perception of body image and their use is prevalent in some sports facilities and gymnasia.

Performance-enhancing drugs of abuse may, or may not, be required to be taken at the time of competition. This has implications for those programmes which aim to detect the unfair use of drugs in sport.

For drugs that have to be present at the time of competition it is a relatively simple process to introduce testing programmes designed to detect banned substances. However, drugs which are intended to increase muscle mass may be used 'out of season' to develop increased muscle mass, which is then maintained by regular exercise and training throughout a competitive season. Since these drugs may be completely metabolized by the time of competition, detecting unfair practice may be much harder and require the use of random testing

throughout the whole year. Similarly, the abuse of substances which are present naturally within the body presents a particular problem for regulatory authorities, as demonstrating that they are present in an unusual amount may be difficult.

Drugs of abuse are not only taken by athletes seeking to improve their performance. They may also be taken to improve the perception of body image, and by those not participating in competitive sport. The prevalence can be difficult to ascertain as studies often rely on self-reporting or the results from screening programmes. A study of people attending fitness centres, using both voluntary questionnaires and direct interviews suggested a high prevalence of doping, 12.5%, and also that use of other illegal substances was common in this group (Simon *et al*., 2006).

2 EPIDEMIOLOGY

In many sports, the absolute limits of performance have been increasing regularly. High-profile cases of very high-performing athletes who have subsequently been found guilty of using performance-enhancing drugs have raised the question as to whether such performances would have been possible without the misuse of drugs. It has also been suggested, that for some sports, the ever-increasing levels of performance are starting to plateau, since the introduction of more vigorous testing regimes.

2.1 Rationale for Banning Particular Substances in Sport

There is a moral and ethical debate to be had about the use of drugs in sport. Arguably, a variety of techniques are used by athletes to improve their performance. Society judges some of these, for example training, to be acceptable, whilst others, including the use of drugs, are largely considered unacceptable. However, there are additional reasons, other than performance enhancement, which should also be considered in determining what is acceptable to society and to those authorities which regulate sport. The use of drugs in sport not only offers the opportunity to obtain better performance, but may also put the individual at increased risk of an adverse event, which may be life-threatening.

Banned substances therefore not only include those which may improve performance, but also include those which may put the athlete or others, at risk, for example alcohol in motor sport.

International regulation of drug abuse for many sports is undertaken by the World Anti Doping Agency (WADA). Not only are particular individually named substances banned under the WADA regulations, but the WADA code of practice also proscribes generic approaches to unfair enhancement of performance (The World Anti-Doping Code, 2009). It is hoped that this will mitigate against the use of small molecular alterations to develop 'designer drugs', which do not appear on a particular static list, with the regulatory authorities always playing 'catch-up'.

Such a generic approach to regulation can also be used against techniques designed to improve oxygen delivery to the tissues. Various approaches to this are possible. Allegations of blood-doping have been made historically. In these techniques, an athlete could, for example, undergo a blood transfusion prior to competition which would transiently increase the oxygen-carrying capacity of the blood. A different approach to increasing oxygen delivery, also banned, is the use of erythropoietin (EPO) to stimulate increased red-cell production.

Categories of drugs and methods prohibited by WADA include (The World Anti-Doping Code, 2009):

- Anabolic agents
  - Anabolic androgenic steroids
  - Other anabolic agents
- Hormones and related substances
- Beta-2 agonists
- Hormone antagonists and modulators
- Diuretics and other masking agents
- WADA-prohibited methods:
  - Enhancement of oxygen transfer
  - Chemical and physical manipulation
  - Gene doping.

Athletes abusing drugs may attempt to hide their use from the regulatory authorities. Numerous techniques have been attempted for this, including substitution of test fluids (e.g. urine) from a nonexposed individual, to the inclusion of substances which would not of themselves enhance performance, but might make the analytical detection of a banned substance difficult or impossible.

2.2 Prevalence

Historically, there have been allegations of organized misuse of drugs in sport. It is reported that following the collapse of the German Democratic Republic, evidence became available that hundreds of physicians and scientists performed doping research and administered prescription drugs, as well as experimental drug preparations. In addition they contributed to the development of methods of drug administration that would evade detection by international doping controls (Franke and Berendonk, 1997). There are numerous examples of high-profile international athletes

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

who have been stripped of medals in international competition. Use outside competitive sport also appears prevalent.

A survey of 12th grade male students in 46 American high schools reported that 6.6% had used anabolic steroids and that over two thirds of the group had initiated their use when aged less than 16 years old; 21% reported that a health professional was their primary source (Buckley *et al*., 1988). In 2003, a study of Indiana high school students suggested that 6.3% had used androgenic anabolic steroids (AASs). The average age of first use was 14, and 15% began taking them before the age of 10. Other athletes, physicians and coaches were listed as sources of AASs (Stiger and Yesalis, 1999). In Sweden, a study of over 5000 males aged 16- or 17-years-old reported that 3.6 and 2.8%, respectively, had misused AASs. Among female adolescents there was no reported use of these drugs (Nilsson *et al*., 2001). This may be due to the side-effect profile of these drugs. It has been suggested that use of anabolic steroids is prevalent more commonly in body-builders and weight-lifters than in other populations (Eklo *et al*., 2003; Thiblin and Petersson, 2005). It is suggested that the use of AASs by females is very much less than in males, but, calls to an antidoping telephone hotline suggest doping may be increasing (Doping Jouren, 2009).

2.3 Prohibited Substances

The WADA produces, each year, a list of substances which are prohibited in particular sports. It also provides useful advice on its web site for athletes and those involved in their training. The particular substances which are prohibited may be specific for particular sports. Similarly, some substances may be banned only at the time of competition, but may be permissible at other times.

2.4 Therapeutic Use Exemption

The use of prescription medicines by athletes poses particular problems. An athlete may have a legitimate medical need for a drug which would otherwise be banned. For example, it would clearly be wrong to ban an asthmatic athlete from using beta-2 agonists, whilst their use by a nonasthmatic competitor for the sole purpose of obtaining an unfair advantage would not be desirable. This issue is addressed by the use of exemptions for therapeutic use.

The principles of therapeutic-use exemptions are defined by the WADA. The antidoping guidelines are updated regularly and copies of current guidelines are held on the WADA web site (*www.wada-ama.org*). General principles for the therapeutic use of medicines are:

- An application for therapeutic-use exemption should be made in advance
- There would be a significant health impairment if the substance were withheld
- No additional performance-enhancement should occur, other than that which might be anticipated by a return to a state of normal health following the treatment of a legitimate medical condition
- Increasing 'low-normal' levels of any endogenous hormone is an unacceptable therapeutic intervention
- No reasonable alternative therapeutic intervention is available (WADA, 2009).

Some of the drugs which appear on lists of prohibited substances have legitimate medical uses. It is accepted that there are occasions when it would be appropriate for an athlete to be taking these and that this should not be a reason to be barred from competing. However the therapeutic use of these substances should not confer an unfair advantage upon an athlete. Generally the use of such drugs should be agreed prospectively, although some athletics associations may agree to *post hoc* agreement. There is a need to demonstrate that the medication is necessary for treatment of a medical condition. In some cases, for example the appropriate use of insulin in an insulin-dependent diabetic, this will be easy to verify and monitor. However, the situation is not always so clear. For example, the use of stimulants in psychiatric conditions may be harder to justify. In any case, the use should confer an improvement in the medical condition, rather than an unfair advantage in performance over an athlete not taking the medicine. With this principle in mind, alternative therapies for the particular condition should be considered which might not confer a performance advantage before other drugs are considered. For illnesses with limited treatment options the case is fairly clear cut, but for others, the situation may be much more complicated. Finally, the therapeutic-use exclusions do not allow the use of an otherwise prohibited substance to treat the consequences of prior misuse of substances on the prohibited list.

3 PERFORMANCE-ENHANCING EFFECTS OF PARTICULAR DRUGS

Whilst it would be unlikely that athletes would use drugs of abuse unless they had a beneficial effect, objective evidence for their efficacy is harder to find. The possible beneficial and adverse effects may be considered by looking at the following illustrative examples.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat147
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.1 Androgenic Anabolic Steroids

AASs are said to have three beneficial effects for an athlete (Calfee and Fedale, 2006). Binding to androgen receptors produces an anabolic state by causing nitrogen to accumulate in muscles, although whether this produces a major effect in males has been questioned. In males, most of the available androgen receptors are already saturated by endogenous testosterone. It is thought that in overtrained individuals, there is an excess of glucocorticoids and that these increase the breakdown of muscle glucogen to release energy. The effect of exogenous steroids in an individual whose androgenic receptors are already saturated is to inhibit, competitively, the binding of other steroids, including those which would have catabolic effects. Another effect of anabolic steroids is that on emotion. In particular it is claimed that they increase aggression. This may be of benefit during a competitive performance, or may allow athletes to trainer harder of for longer (American Academy of paediatrics Committee on Sports Medicine and Fitness, 1997). The use of anabolic steroids increases muscle mass. This is due to both muscle fibre hypertrophy and the formation of new muscle fibres (Kadi *et al*., 1999). Volunteer studies have also shown an increase in muscle pennation following 12 weeks exposure to testosterone (Blazevich and Giorgi, 2001). The increase in muscle mass is associated with an increase in strength. Increases in performance have been demonstrated following abuse of anabolic steroids. In a randomized controlled trial, subjects treated with 3.5 mg kg^{-1} testosterone ethanate and undergoing resistance training were assessed. The ability to perform a one-repetition maximum bench press was increased (Blazevich and Giorgi, 2001). An increase in strength is not, however, necessarily associated with an increase in the aerobic work rate (Haupt and Rovere, 1984).

3.1.1 Adverse Effects of Anabolic Steroids

Anabolic steroids have adverse effects upon the cardiovascular system via several different mechanisms. A study of body-builders using, or not using, AASs, and of matched controls showed that those body-builders using AASs had a greater left ventricular mass, a larger right ventricular diameter and depressed diastolic function of both ventricles than those in other groups (Kasikcioglu *et al*., 2009). Similarly, post-mortem findings have suggested hypertrophy, ventricular dilatation and premature atherosclerosis (Madea and Grellner, 1998). The effects on left ventricular mass may be greater when anabolic steroids are used in association with growth hormone (Karila *et al*., 2003). Male subjects taking 3.5 mg kg^{-1} $week^{-1}$ intramuscular testosterone developed an increase in systolic blood pressure of 10 mmHg (Giorgi *et al*., 1999).

Androgenic steroids have a deleterious effect on lipid profiles. A study of men taking a combination of methandrostenolone, testosterone and nandrolone showed a severe depression of high density lipoprotein cholesterol (HDLC) and an associated rise in low density lipoprotein cholesterol (LDLC) (Webb *et al*., 1984). An eight week course of androgens in power-lifters was associated with a 54% decrease in HDLC (Alen and Rahkila, 1984). Similarly, endogenous testosterone has a strong negative association with HDLC concentrations (Semmens *et al*., 1983).

Numerous hepatic side effects have been reported in association with the use of ASSs. In particular, cholestasis and the production of hepatic tumours are of concern. Although most of the tumours are benign, and may regress once the steroid use is terminated, there is an associated risk of life-threatening haemorrhage (Patil *et al*., 2007) and of malignant transformation (Socas *et al*., 2005).

Numerous reports have suggested that the use of anabolic steroids is associated with aggression. Results of epidemiological studies may be difficult to interpret as use of AASs may be associated with misuse of other drugs. However, a study in Sweden showed that weapons offences were almost twice as common amongst those who tested positive for AASs than in those who did not. However, there were no statistically significant differences between users and nonusers with respect to violence, either in the incidence of convictions or the proportion of individuals convicted (Klotz *et al*., 2006).

3.2 Creatine

Creatine is formed from arginine, methionine and glycine. Once formed, 95% is stored in the muscles. Supplementation with dietary creatine, often using a loading regimen followed by maintenance dosing has been shown to increase muscle creatine and phosphocreatine. Creatine is converted to phosphocreatine by the enzyme creatine kinase. Phosphocreatine, in turn, is a source of energy for the muscle (Calfee and Fedale, 2006). It has been suggested that phosphocreatine is a major source of early energy in anaerobic metabolism, after free adenosine triphosphate is consumed during the first few seconds of activity. Creatine supplementation has been shown to increase the ability to perform anaerobic exercise (Balsom *et al*., 1993) and this ability to increase early exercise performance has been suggested to be due to increased turnover of adenosine triphosphate (ATP) during muscle contraction (Birch *et al*., 1994).

Creatine powder has been shown to improve sprint cycling performance when compared to creatine serum in volunteers supplemented with either 20 g per day of creatine powder or 5 ml per day of serum creatine. The

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat147
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

total work (9.6%) and peak power (3.4%) were both increased (Blazevich *et al*., 2004).

3.3 Beta-2 Agonists

Although the acute inhalation of beta-2 agonists, for example salbutamol, has not been demonstrated to have substantial effects on respiratory function in normal subjects, ingestion of beta-2 agonists such as clenbuterol and salbutamol may increase muscle mass. Clenbuterol has been used in animals as a growth enhancer. It is sometimes taken by body-builders or athletes for its lipolytic and anabolic effects. However it may have serious cardiac side effects. A case report describes a myocardial infarction in a 17-year-old body-builder (Kierzkowska *et al*., 2005).

3.4 Beta Blockers

Beta-blockers reduce tremor and heart rate. These may therefore be beneficial in sports which require accuracy, for example target shooting.

3.5 Peptide Hormones

A number of peptide hormones occur in the WADA list of prohibited substances. These include EPO, growth hormone, insulin-like growth factors, insulin, gonadotrophins and corticotrophins. EPO, a glycoprotein hormone, is discussed in Section 4.3

3.5.1 Gonadotrophins

3.5.1.1 Human Chorionic Gonadotrophin (HCG)

Human chorionic gonadotrophin (HCG) has been used for doping and causes an increase in testosterone levels. This increase in testosterone is associated with an increase in epitestosterone, thereby mitigating the risk of being detected, by calculation of a testosterone to epitestosterone ratio (Barroso *et al*., 2008).

3.5.1.2 Luteinizing Hormone (LH)

In men, luteinizing hormone (LH) is said to increase production of testosterone from the testes, whereas in women it produces changes in progesterone and oestrogen. Detection relies on either the use of immune assays, or on sensitive assays using tandem mass spectrometry. Given that these hormones are present in varying amounts in healthy females, the interpretation of results to determine whether they have been administered exogenously may be challenging.

3.5.2 Human Growth Hormone (HGH)

Historically human growth hormone (GH) was formerly extracted from the pituitary gland. With concern over Creutzfeld–Jacob disease, recombinant growth hormone (rGH) was developed. The degree of similarity between the endogenous and the recombinant forms of growth hormone, its pulsatile secretion and marked interindividual variability makes detection of doping difficult. Similarly, levels of growth hormone increase substantially after periods of exercise, hypoglycaemia and stress, potentially confounding tests for misuse.

The use of growth hormone in sport is said to depend, not only on its anabolic properties, but also on its effect on carbohydrate and fat metabolism (Saugy *et al*., 2006).

That GH can be used as a doping agent is not disputed. GH increases circulating levels of insulin-like growth hormone I (IGF-I), primarily of hepatic origin (Velloso, 2008). However, objective evidence for its effect on strength, rather than on changes in lean body mass is not so clear. Clinically, an excess of endogenous growth hormone in adults results in acromegaly and is associated with raised blood pressure, diabetes and increased mortality.

Detection of doping with growth hormone presents many difficulties. Urine samples contain concentrations of growth hormone that are several orders of magnitude lower than blood samples. rGH consists of a 22 kDa isoform, whereas endogenous GH is present in the blood in several forms. The ratio of rGH to other isoforms will vary when rGH is administered acutely. With chronic use, endogenous secretion of the 22 kDa form may be suppressed, perturbing the ratios. Two approaches have been investigated to detect GH abuse, one detecting different pituitary isoforms and another, the measurement of GH-dependent markers (Holt and Sonksen, 2008).

3.6 Diuretics

Diuretics produce a decrease in body water. Acutely, this is associated with a decrease in weight and therefore may confer advantages in sports which are categorized in terms of weight. Use of a diuretic may allow an athlete the ability to compete in a weight category in which they would otherwise not be able to compete.

3.7 Cofounders and Masking Agents

The use of substances which serve to make the detection or interpretation of the presence of a banned substance is forbidden.

4 ENHANCED OXYGEN DELIVERY

Whilst drugs such as anabolic androgenic steroids may increase power or strength, they would not be expected to enhance aerobic performance. Numerous techniques have been attempted to improve oxygen delivery to the tissues. These include high-altitude living, 'living high'–'training low', experimental hypobaric hypoxia, transfusion of red blood cells or other substances to increase the oxygen-carrying capacity of the blood and administration of EPO.

4.1 Oxygen Deprivation

'Altitude therapy' may be effective. For example, a study of athletes who lived at 2500 m for 27 days and trained at 1250 m, showed that circulating EPO levels 20 hours after ascent were nearly double their initial value at sea level. Haemoglobin increased 1 g dl^{-1} over the course of the trial, maximum oxygen intake increased and one third of athletes achieved personal-best times (Stray-Gundersen *et al*., 2001).

Intermittent hypobaric oxygen has been studied to determine its effects on EPO, red-cell volume and haemoglobin mass. Four weeks of intermittent exposure, three hours per day, five days per week, resulted in an increase in EPO, but not in red-cell volume or haemoglobin mass (Gore *et al*., 2006).

4.2 Blood Doping

The use of blood transfusions to improve sporting performance was suggested decades ago and allowed an increase in haemoglobin greater than that found from altitude training. However, the introduction of synthetic EPO enhanced the opportunity to manipulate the oxygen-carrying capacity of the blood. The ability to synthesize recombinant human EPO as a medicine has enabled its illicit use in sport.

4.3 Erythropoietin

EPO is a 30.4 kDa glycoprotein hormone that is the main synthetic control for red blood cell formation. It consists of isoforms that differ in their patterns of glycosylation and biological activity (Skibeli *et al*., 2001; Sherwood *et al*., 1988). Naturally, it is synthesized largely in the kidneys, but also from other tissues, including liver and brain.

Administration of exogenous EPO results in an increased red-cell mass and haematocrit. A study of exogenous EPO demonstrated an increase in haemoglobin concentration and an associated increase in maximal aerobic power (VO_2 max). The increase in VO_2 max per g dl^{-1} increase of haemoglobin was no different from that which was seen following transfusion (Ekblom and Berglund, 1991).

In otherwise healthy individuals, there is some evidence to suggest that an increased haematocrit is associated with increased cardiovascular risk. Use of EPO is associated with headaches, hypertension and increased risk of thrombotic events, in addition to other effects not directly related to an increase in haemoglobin concentration (Lappin *et al*., 2002). Due to the abuse of several different agents, it is sometimes difficult to ascribe an adverse effect to a particular agent, for example as was the case with a 26-year-old professional cyclist who developed a sagital sinus thrombosis, with a history of using EPO, growth hormone and vitamin A and E supplements (Lage *et al*., 2002).

Suggestions that EPO may be misused in sport date from the late 1980s. As a test that could distinguish recombinant human EPO (rHuEPO) from endogenous EPO was not initially available and early indicators of misuse were indirect.

Indirect evidence for the abuse of Epos may come from comparison of haemoglobin concentrations in athletes competing in different years, which suggested that these were increasing. Analysis of blood samples taken from elite cross-country skiers in World ski championships suggested that half the medal winners and one third of those finishing in 4th–10th place had highly abnormal haematological profiles (Stray-Gundersen *et al*., 2003). Similarly, haemoglobin concentrations were found to rise as time went on, with concentrations in ski teams increasing between 1989 and 1994 and again in 1996. Following the introduction of a rule limiting maximum values, a fall of 1.5 g dl^{-1} in males and 4.2 g dl^{-1} in female skiers was noted (Videman *et al*.). Riders have admitted using EPO in the 1996 Tour de France (Elliott, 2008).

5 DETECTION

5.1 Testing Programmes

Testing programmes are potentially fraught with difficulties. Physicians involved in an athlete's training may also be involved in testing programmes and the prescription of therapeutic drugs to the athlete. They may, in some cases, also be responsible for the supply of illicit substances. This may produce conflicts of interest.

A unified approach to the control of substances is fostered by the WADA, which produces annually a list of prohibited substances. In order for a drug-testing programme to have credibility it must fulfil a number

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat147
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of different criteria. Firstly, it must be possible to obtain samples at a time when they might be being used and have a chance of being detected. As some drugs of abuse are used outside the competition season, for example to produce increased muscle bulk, which is subsequently maintained by training, it is essential that athletes must be prepared to undergo random testing, including testing which occurs outside the competitive season. Similarly, there must be confidence that the sample to be tested comes from the specified individual. Once a sample has been obtained, a chain of custody must be demonstrable throughout the analytical procedure.

For convenience, a noninvasive screening programme, for example using urine samples, would be preferable. However, to detect some proscribed activities, for example those used in blood doping, it may be necessary to take more invasive samples.

Once a sample has been obtained, there should be a robust analytical process available to detect a proscribed substance, or reliable markers to show that it has been present. Once detected, it must be able to be demonstrated that the substance has not occurred naturally, or that if it might be detected as a natural phenomenon, it is present in abnormal quantities. Defining what is 'normal' and what is 'abnormal' may be quite difficult. For some compounds, the decision-making process is relatively easy, as no compound should be detectable at all. For other substances, the process is more complex and a decision-making 'cut-off' concentration or ratio has to be determined.

5.2 Collection

Following the selection of the individual to be tested, and the timing of the test, collection is the first step in the analytical process. This will involve the witnessed collection of the relevant sample from an unambiguously identified athlete. The athlete may be allowed to select the sample container into which the sample is taken. Once obtained, specimen validity checks may be commenced, for example density and pH measurements for urine samples. The sample will be labelled in front of, or by the athlete, and the whole process documented carefully, with signatures being obtained from both the tester and the athlete. Once obtained, the sample will generally be split into two separate sealed samples, one of which is available to be retested in case of an appeal (Green, 2006).

5.3 Analysis

For competition at Olympic level, samples must be analysed by a laboratory which is accredited by WADA. If the sample is negative, the process is terminated. In the event of a positive test, a further sample from the same sample will be tested. If positive, the result may then be reported, with the second sample bottle available for further testing.

It should be remembered that the presence of a negative test does not exclude the use of banned substances, merely that the test did not detect them. This may be due to the presence of a novel compound for which current analytical techniques are inadequate, or, more likely, that the substance is not there. Even the lack of a banned substance for which there are robust analytical techniques does not mean that it has not been abused; merely that it was not detected. For example, AASs used out of season would not be expected to be detected during an in-season test.

For some substances, trace amounts may appear in the urine for several months following a positive test. A repeat positive test does not necessarily mean that further abuse has occurred. If an athlete does not receive a permanent ban having tested positive, it may be required that a negative sample is obtained before return to competition.

Problems associated with testing for drugs of abuse may occur when the prohibited substance occurs as a natural hormone.

5.3.1 Testing for Androgenic Anabolic Steroids (AAS)

Anabolic steroids may occur naturally within the body or may be administered exogenously. Similarly, exogenous steroids may have the same chemical structure as endogenous hormones, or may be artificially synthesized with subtle differences in structure. Recently, 'designer' anabolic steroids have been manufactured and detected, perhaps in the hope that they would not be identified.

Generally, urine testing for anabolic steroids will be undertaken using gas chromatography–mass spectrometry analysis (GC-MS), relying upon the retention time and spectrometry of both parent compounds and metabolites. If a screening test is positive, further tests to identify the specific compound will be undertaken.

Testing for anabolic steroids illustrates some of the generic difficulties in testing for prohibited substances to identify positively which substance may have been abused. For example, when testing for 19-nortestosterone (nandrolone), a 'positive' result may come from the detection of its metabolites, 19-norandrosterone (19-NA) and 19-noretiocholanolone (19-NE), rather than 19-nortestosterone itself. However, these two metabolites may also be formed from the metabolism of 19-norandrostenedione and 19-norandrostenediol. The presence, *per se* of 19-NA does not of itself indicate conclusively that 19-nortestosterone has been abused. However, as these compounds are now also considered as prohibited substances this may be of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat147
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

limited consequence. It is also accepted that small amounts of 19-NA may occur in pregnant women and following the ingestion of norethesterone-containing oral contraceptives. In this case, the detection of other metabolites of norethesterone may clarify the picture. It is also accepted that some males may excrete small amounts of 19-NA. A threshold value is therefore used, albeit with very low concentrations set (Green, 2006).

With improved analytical techniques, it has become possible to detect exogenous and 'designer' steroids more readily and to show that they would not be expected to be found naturally. This has made the use of naturally occurring substances more attractive for abusers, as the defence that they have occurred naturally may then become possible. It becomes necessary to determine whether they are present in unusual concentrations, or in an unusual ratio when compared to other endogenous compounds.

Naturally occurring substances, for example testosterone, administered endogenously will produce the same chromatograph. However, naturally occurring testosterone is found in approximately equal concentrations as epitestosterone, although there can be considerable interindividual variation. It therefore becomes possible to use the ratio of testosterone to epitestosterone to provide a threshold suggestive of exogenous administration. However two potential problems may arise. Firstly, some individuals have a naturally high ratio. However, as the intraindividual ratio is relatively constant, serial measurements may be used to determine what is usual in a particular individual. The second problem is that manipulation of the ratio of testosterone to epitestosterone is possible by abusing epitestosterone to manipulate the ratio. For this reason, both the ratio of testosterone to epitestosterone and the concentration of epitestosterone must be considered. In difficult cases, the use of a ketaconazole challenge (which changes the ratio of testosterone to epitestosterone in different directions, depending upon whether the testosterone is endogenous or exogenous) may be considered. An alternative approach is to use isotope ratio mass spectrometry (IRMS) (Green, 2006).

IRMS is able to compare the prevalence of carbon isotopes ^{12}C and ^{13}C. Different plant groups fix different proportions of the two isotopes of carbon during photosynthesis. As exogenous steroids may be manufactured from plant substrates, the ratio of carbon isotopes from exogenous anabolic steroids may be different from the ratio found in steroids synthesized endogenously by an athlete (Green, 2006).

5.3.2 Detection of Erythropoietin

Direct tests for EPO are available, indicating the presence of exogenous EPO isoforms. Indirect tests are also available, indicating haematological changes induced by exogenous EPO administration, measuring, for example haematocrit, reticulocyte haematocrit, serum soluble transferring receptors and the proportion of macrocytic red cells (Wilber, 2002).

As early as 2000, a technique was reported for distinguishing between EPO forms. Using this technique, 102 frozen urine samples from the 1998 Tour de France cycling competition were analysed. Twenty-eight samples had EPO levels above the normal range. The 14 samples with the highest levels underwent further analysis and gave rise to banding patterns typical of recombinant hormone (Lasne and de Ceaurriz, 2000).

The tests used include those based on a combination of isoelectric focussing and double immunoblotting and distinguish between endogenous and exogenous EPO. However, concerns over interpretation of results have been expressed due to the use of a primary antibody which is not monospecific, although careful pre-analytical care may improve the reliability (Delanghe *et al*., 2008). Some have suggested that false positives may occur occasionally in post-exercise protein-rich urine (Beullens *et al*., 2006), although this view has been challenged (Catlin *et al*., 2006; Lasne, 2006).

6 CONCLUSION

It is clear that xenobiotics are abused, both by individuals seeking to improve their body image and by those who are seeking to gain an improvement in their performance in competitive sports. There is objective evidence that a variety of substances are capable of improving performance and that drugs have been abused, even by those competing at the highest levels, where testing is known to occur. This alteration in performance, however, may be achieved to the detriment of the health of the individual.

It is a matter of concern that pressure, perhaps from peers or coaches, may be brought to bear upon young athletes who may be placing their health and even their lives at risk. It is a societal decision to determine which techniques to improve performance (e.g. diet or training) are acceptable within competitive sport and which are not (e.g. drug abuse). The simplest and most attractive toxicological approach is to ban the use of drugs taken with the intent of improving performance, rather than to treat an underlying medical condition. The concept of a toxicological 'level playing field' is very attractive.

Achieving the level playing field is becoming increasingly difficult, but perhaps more successful. There are huge rewards available to successful sportsmen and women. These rewards provide the temptation to cheat, and the possibility that it might be worth 'investing' heavily to achieve them. This 'investment' could include the development of new or modified xenobiotics, in an attempt either to gain further improvements in performance, or to avoid detection. In order to combat this trend, drug-abuse control schemes have had to develop, both organizationally and analytically.

The introduction of out-of-season and random testing is a prerequisite for a successful antidoping scheme. Merely testing during competition will not catch all those who abuse drugs. For example, drugs may be used out-of-season to gain strength, with muscle bulk retained due to subsequent training. This may also be an issue if a decision is made to allow a banned athlete to return subsequently to competitive sport. Just how long do the effects last?

Those involved in the analytical detection of banned substances need to be constantly vigilant if new substances are to be detected. Considerable advances have been made in recent years. Once a substance has been detected, a decision then has to be made to determine what is 'normal' or 'acceptable' and what is not. The development of synthetic human hormones has been a particular challenge for regulatory authorities. Increasingly, it may become necessary to determine an individual's personal 'profile' to inform the decision-making process. With future developments, increasingly invasive sampling may become necessary, as may diagnostic challenges with test agents, to determine whether a particular biochemical or haematological profile, which represents only a static picture, is due to natural homeostasis or the exogenous administration of banned substances.

The abuse of drugs in sport remains an area which will challenge physiologists, and clinical and analytical toxicologists.

Poisons of Animal Origin

Gregory P. Wedin, Daniel E. Keyler and Elisabeth F. Bilden

CONTENTS

1 INTRODUCTION

Poisons of animal origin is a broad topic that covers a great variety of toxic substances found in thousands of animal species. The scope of the problem that these animals pose throughout the world is presented here through a discussion of representative species whose poisons are significant hazards to humans.

It is important to first distinguish between animals that are poisonous and those that are venomous. Venomous animals, as the name implies, produce venom in specialized glands or cells that can be administered in some way to its enemy or prey. Poisonous animals, on the other hand, possess a toxin(s) within their tissue that can have deleterious effects on those who eat them.

The venom apparatus, mode of envenomation and constituents of venom vary considerably throughout the animal kingdom. Venomous animals can either bite or sting their victims and some are capable of squirting or spitting venom. The venom of most species is a unique, but complex proteinaceous mixture. The biochemical and pharmacologic properties of most venoms are incompletely understood due to their complexity. Interspecies differences, as well as difficulties in obtaining sufficient venom and in extracting individual components further complicate this issue.

An animal may use its venom offensively or defensively. For example, it may be used to subdue or kill its prey and aid in digestion. It also may be used to ward off predators. Most venoms are multipurpose and cannot be narrowly classified. Obviously, the toxic effects that result from envenomation are greatly influenced by these functional properties and the corresponding venom constituents.

Most poisonous animals accumulate toxin through the marine food chain. The most common initial source is unicellular sea algae (dinoflagellates). A number of these dinoflagellates are responsible for the often-publicized 'red tides' which are linked to poisonous shellfish.

Although people who live in regions inhabited by venomous or poisonous animals are at greatest risk for toxic exposure, such encounters can occur virtually anywhere. Venomous animals, for example, are imported by hobbyists and have been shipped inadvertently in produce or other goods. Likewise, poisonous seafood may be shipped to distant markets. This may present a therapeutic dilemma to a practitioner who is unfamiliar with such exposures. Poison Information Centres are staffed with specially trained professionals who can provide expert information and advice on managing such cases. These centres also have access to the Antivenom Index, which was developed to assist with locating the appropriate antivenom for exotic bites and stings. The Index is a joint effort of the American Association of Zoological Parks and Aquariums and the American Association of Poison Control Centers.

2 VENOMOUS SNAKES

Venomous snakes have fascinated mankind for millennia, and continue to be of significant importance, not only to native peoples in the vanishing natural world, but also to scientists, religious groups, and in recent decades, amateur herpetologists (Stocker, 1990; Bates *et al*., 1988; Ivanyi and Altimari, 2004). The encroachment of human beings into once remote habitats is rapidly changing the natural landscape of our world and the ability for venomous species to survive has become more complex and difficult. As a consequence, many venomous snake species exist in quite precarious environments (O'Shea, 2005).

Human encounters with snakes occur across large geographic regions, and are a frequent part of everyday living in many third-world countries and rural areas of more developed countries, with the consequence of snakebite having a significant impact on public health (**Table 1**). All too frequently it is children and the elderly who suffer the greatest mortality (Russell *et al*., 1997). In stark contrast has been the increasing number of exotic snakebites that have occurred to amateur collectors due to a booming interest in the herpetoculture of exotic venomous snakes. Species from nearly every genus listed in **Table 1** are bred in captivity, and available online via the Internet (Trestrail, 1982; Pearn *et al*., 1994; Keyler, 2006). Additionally, with the drive to study snake venoms in biomedical research, even professionals are

Table 1 Venomous snakes frequently responsible for envenomation to humans in nature: taxonomy, geographic distribution and venom effects

Family/*Genus*	Common names	Native country	Chief venom effects
Atractaspididae			
Atractaspis	Burrowing asps	Africa	Vasoconstriction, myocardial effects
Colubridae			
Dispholidus	Boomslang	Africa	Coagulopathy, haemorrhage
Philodryas	Cobra-verde	C, S America	Coagulopathy, haemorrhage
Rhabdophis	Keelbacks	Asia	Coagulopathy, haemorrhage
Elapida			
Acanthophis	Death adders	Australia	Paralysis
Bungarus	Kraits	SE Asia	Paralysis
Dendroaspis	Black/green mamba	Africa	Paralysis
Hemachatus	Rinkhals	Africa	Paralysis, local necrosis
Hoplocephalus	Broad-headed snakes	Australia	Coagulopathy
Micropechis	Small-eyed snake	New Guinea	Paralysis, coagulopathy, myolysis
Micrurus	Coral snakes	N, C, S America	Paralysis
Naja	Cobras/spitting cobra	Africa/Asia	Paralysis/corneal ulceration
Notechis	Tiger snakes	Australia	Paralysis, coagulopathy, myolysis
Ophiophagus	King cobra	Asia	Paralysis
Oxyuranus	Taipan	Australia	Paralysis, coagulopathy, myolysis
Pseudechis	Mulga/black snakes	Australia	Coagulopathy, myolysis
Pseudonaja	Brown snakes	Australia	Coagulopathy, paralysis
Tropidechis	Rough scaled snake	Australia	Coagulopathy, paralysis, myolysis
Hydrophiidae			
Astrotia *and many other genera*	Sea snakes	Indo-Pacific Oceans	Paralysis, myolysis
Viperidae			
Crotalinae (pit vipers)			
Agkistrodon	Cantils, copperheads, moccasins	N, C, S America	Coagulopathy, necrosis
Bothrops	Lanceheads	C, S America	Coagulopathy, necrosis
Calloselasma	Malayan pit viper	Asia	Coagulopathy, necrosis
Crotalus	NA rattlesnakes, tropical rattlesnakes	N America C, S America	Coagulopathy, necrosis Paralysis, myolysis
Hypnale	Hump-nosed vipers	Asia	Local necrosis
Lachesis	Bushmaster	C, S America	Coagulopathy, necrosis
Sistrurus	Massasauga, pigmy rattlesnake	N America	Haemorrhage, local necrosis
Trimeresurus	Bamboo vipers	SE Asia	Coagulopathy, necrosis
Viperinae (true vipers)			
Bitis	Gaboon/puff adder	Africa	Cardiovascular, coagulopathy
Causus	Night adders	Africa	Local necrosis
Cerastes	Horned vipers	Africa/Asia	Coagulopathy, necrosis

not immune to the consequences of envenomation (Ivanyi and Altimari, 2004; Keyler, 2008).

Globally, venomous snakebite has been reported to cause 3 million envenomations annually, resulting in 150 000 fatalities with the greatest morbidity and mortality occurring in tropical regions (White, 2000). In North America, rattlesnakes have been responsible for the greatest number of venomous snakebites, and the greatest number of fatalities (Russell, 1990). In the United States, 2001 data from the Toxic Exposure Surveillance System revealed that 2450 venomous snakebites had occurred, with 47% caused by rattlesnakes, and 5% caused by exotic species. Interestingly, the percentage of bites by exotic snakes was greater than the percentage (3.5%) caused by the native coral snake (*Micrurus fulvius*). Only two fatalities were documented, and both were from rattlesnake bites (Watson *et al*., 2002). However, according to data from 1979 to 1998 in the National Vital Statistics System, 97 deaths ($\approx$5 year^{-1}) were documented by medical examiners. Young white males aged 25–34 years were the most common victims, with the greatest number of bites occurring in Texas, Florida and Georgia, respectively (Morgan *et al*., 2004). Alcohol involvement is not uncommon, and bites frequently result from poor judgment and bare-handling (Gold *et al*., 2002).

Adders, bamboo vipers, cobras, mambas and rattlesnakes are all familiar names, but may leave the medical clinician at a loss with respect to their venom effects, consequences of their envenomation to humans, and what constitutes appropriate medical management. Thus, regardless of where medical professionals practise, it is important to have some basic knowledge of snakebite medical management if a favourable outcome is to be achieved.

2.1 Venomous Snakes, Venoms and Envenomation

2.1.1 Venomous Snakes

The taxonomy of venomous snakes was traditionally based on hierarchal biological classifications, but has been a constantly evolving process in recent years, due to the increasing flow of DNA analysis data used in constructing snake phylogenies (Slowinski and Lawson, 2002). Currently, there are approximately 420 different snake genera representing 2900 species that range geographically over six continents and the Indo-Pacific oceans (Greene, 1997). The venomous snakes that are frequently involved in envenomation to humans are represented in five families, with the family Viperidae divided into two important subfamilies, the true vipers (viperinae) and the pit vipers (crotalinae), which possess infrared heat-sensing pits between the eye and nasal opening (**Table 1**).

Venomous snake species of the different genera are all equipped with fangs, but not all fang structures are the same, as there are evolutionary differences in dentition type for venom delivery (Kardong, 1979). Sea snakes have conical fangs with no grooves (aglyphous), boomslangs and many other colubrids have enlarged rear fangs with a ventral groove (opisthoglyphous), cobras and most elapids have large anterior, fixed-position fangs with deep frontal grooves (proteroglyphous), and vipers and pit vipers, such as rattlesnakes, have the most sophisticated snake dentition with large tubular canaliculated fangs with hinge-like action (solenoglyphus) (Greene, 1997). The larger the fang structure, the greater the ability to penetrate tissues with a bite, and the potential for deep venom-dose delivery. Spitting cobra fangs are unique and capable of ejecting venom for distances of several feet due to a forward-angled venom-exit-orifice modification in their fangs that allows the venom to be sprayed towards their victim.

Venom is delivered to the fangs either by a duct from a venom gland, as found in vipers, pit vipers, most elapids and sea snakes, or from a modified salivary structure of secretory cells that allow the toxins to be elaborated onto the fangs or to grooves in the fangs, such as the case with venomous colubrid snakes. Rear-fanged snakes (i.e. boomslang, *Dispholidus typus*) and many short fixed-fanged elapids (i.e. sea snakes, *Hydrophiidae* spp.) will usually grab their prey, or human victim, and repeatedly chew, while most vipers (i.e. Gaboon viper, *Bitis gabonicas*; Russell's viper, *Daboia russelli*) and pit vipers (i.e. rattlesnakes, *Crotalus* spp.; Fer-de-Lance, *Bothrops lanceolatus*) will rapidly bite and release. Either method can effectively deliver venom in quantities sufficient to subdue prey, or cause envenomation to humans. Interestingly, the fangs of dead snakes are not without potential effect as envenomation has been documented to result from the accidental penetration of fangs into the digits (Griffen and Donovan, 1986; Keyler and Schwitzer, 1987).

2.1.2 Snake Venoms

Venoms are basically biochemical cocktails of greater than 20 different components that are primarily enzymatic and nonenzymatic proteins, such as hyaluronidase, phospholipases, hydrolases and polypeptide toxins (Stocker, 1990; Iyaniwura, 1991). Venom composition has undergone divergent evolution and varies considerably among different snake families and species (Ivanov and Ivanov, 1979). Further complicating our understanding of venom effects associated with a specific species are the findings of intraspecific, subspecific and geographic variations in venom and, consequently, different toxicity profiles (Glenn *et al*., 1994; Chippaux and Goyffon, 1998; Keyler and Van De Voort, 1999). A few venom components,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

like the polypeptide α-neurotoxins, may be quite selective and act like a pharmacological bullet for a specific target (i.e. neuromuscular junction receptors), a feature common to many elapid venoms. In vipers and pit vipers, multiple venom components may function collectively and in concert or synergistically, to produce a staged progression for achieving a net toxic effect or effects on a physiological system or systems. Certain venom components have even been shown to induce apoptosis, a form of programmed cell death (Suhr and Kim, 1996).

The important concept about different snake venoms is that they possess their own library of different venom components, yet quite similar toxic effects may be induced via a multitude of different pharmacologic mechanisms. These venom actions and their associated pathophysiologic effects can be simplified and generalized in order to provide a better basic understanding of venomous snakebite and responsible species (**Table 2**). However, there are exceptions, despite the generalities. For example, several species of spitting cobras (*Naja kaouthia*, *Naja mossambica* and *Naha nigiricollis*), whose venoms contain neurotoxins, are also capable of causing significant localized necrosis, and potentially lethal cardiotoxic events (Blaylock, 1982; Kunkel *et al*., 1983–1984; Minton, 1990). Similarly, the majority of rattlesnake envenomations generally cause local tissue damage and coagulopathies, but rarely true neurotoxicity. However, the bite of the Mojave rattlesnake (*Crotalus scutulatus*) produces less local swelling and pain, and victims can exhibit profound neurotoxic effects (Russell *et al*., 1975; Kunkel *et al*., 1983–1984; Jansen *et al*., 1992).

2.1.3 Envenomation Effects

The effects of envenomation are initially dependent on the pharmacokinetics of the venom, the dose delivered and its route of delivery. The dose of venom a snake delivers can vary widely, especially in cases of human envenomation. Pit vipers will use their heat-sensing pits to size up their prey prior to biting, and then when delivering their bite will meter the dose to conserve venom, as there is no need to use excessive amounts

Table 2 Snake venom toxins: generalized actions, pathophysiology, clinical symptoms and representative species

Toxin actions/pathophysiology	Clinical symptoms	Representative species
Cardiotoxic		
Coronary vasoconstriction/vasodilation, direct myocardial effects	Hypotension, arrhythmias	Mole/stiletto vipers
Cytotoxic/vasculotoxic		
Cell membrane destruction, Inflammation	Ocular ulceration,[a] blebs, erythema, oedema, necrosis, fluid shifts, hypotension, pain	Spitting cobras,[a] N, S American and Asian pit vipers, African vipers
Haemotoxic		
Anticoagulant/procoagulant, fibrinolysis/haemolysis, direct haemorrhagic effects, microangiopathy, platelet aggregation/inhibition	Haemorrhage, thrombi formation, ecchymosis, haematuria, thrombocytopenia	Boomslang, green pit vipers, N, S American pit viper spp., Asian viper spp., African and Asian pit viper spp.
Myotoxic		
Rhabdomyolysis, selective ion channel blockade	Myoglobinaemia, myoglobinuria, pain, renal failure	Sea snakes, tiger snakes, taipans
Necrotoxic		
Direct tissue destruction	Local necrosis, pain	N, S, American and Asian pit vipers, African and Asian vipers, spitting cobras
Nephrotoxic		
Direct nephrotic damage, acute tubular necrosis, renal cortical necrosis	Acute renal failure, anuria/oliguria, haematuria, haemaglobinuria, myoglobinuria	Russell's vipers, N, S, American and Asian pit vipers, African and European vipers
Neurotoxic		
Pre/postsynaptic blockade, neurotransmitter destruction	Flaccid paralysis, respiratory arrest, fasciculations, ptosis, dysphagia	Cobras, coral snakes, kraits, mambas, sea snakes, Mojave and tropical rattlesnakes

[a]Ocular ulceration most commonly associated with spitting cobras.

of venom to subdue a small prey animal. When a human–snake encounter occurs, the snake is biting out of a fear response and may expel venom amounts ranging from none (dry bites) to 90% of its venom gland reserves (Russell, 1990). In fact, 'dry bites' may occur in up to 30% of Crotalidae bites, 50% of Elapidae bites and 75% of Hydrophiidae bites (Kunkel *et al*., 1983–1984). However, vipers or pit vipers may inject potentially large venom doses, due to their sizeable venom gland and fang structure. This is exemplified with the bite of the terciopelo (*Bothrops asper*) as approximately 3 ml of venom can be injected in a single bite (Avila-Aguero *et al*., 2001). This sizeable venom dose can lead to the rapid development of both local and systemic symptoms. At the other extreme is the microlitre quantities injected with sea-snake bites (*Hydrophiidae* spp.); however, even these minute doses have been fatal (Heatwole, 1999). Whatever the dose, it may be delivered subcutaneously, intramuscularly or intravenously. The route of delivery influences the absorption kinetics of the venom and the resulting onset and severity of symptoms. Many bites to humans are superficial and absorption may be incomplete, resulting in only minor medical consequences (Russell, 1990). In contrast, intravenous envenomation, although uncommon, results in instantaneous systemic uptake of the entire venom dose and leads to more rapidly progressing systemic toxicity, causing profound morbidity or death (Davidson, 1988). The anatomical location of the bite may be important. It has been noted for pit-viper envenomation that distal appendage bites are more likely to result in less severe envenomation, but more proximal appendage bites lead to more severe envenomation and complications (Moss *et al*., 1997). Bites to the eye, face and tongue have occurred, and resulted in severe complications due to oedema-related airway obstruction (Gupta *et al*., 1995; Lewis and Portera, 1994; Gerkin *et al*., 1987). Severe bites have also occurred to unusual anatomical sites such as the penis, further complicating treatment (Crane and Irwin, 1985). Additional factors that can affect the venom pharmacokinetics include: the chemical make-up of the venom; the species of snake; the age, size and health of the victim; and an individual's susceptibility to the venom (Gold *et al*., 2002).

A final feature influencing both toxicokinetic (venom distribution and time to target tissues) and toxicodynamic (magnitude of clinical and systemic symptoms) effects from envenomation is the interval between the time of the bite and the time to medical treatment. Increased time to adequate medical care, including antivenom administration, correlates with increased morbidity and mortality from envenomations (Nishioka and Silveira, 1992; Russell *et al*., 1997).

2.2 Venomous Snakebite: Characteristics and Toxic Manifestations

The potential pathophysiological effects to humans having sustained venomous snakebites are wide-ranging, as venoms can affect nearly every tissue and organ system, depending on the species of snake involved. Although most snake venoms have multiple venom-toxin actions, they usually induce one or two predominant clinical effects (**Table 2**). A few generalized broad categories are of major clinical importance: (i) cardiotoxicity; (ii) coagulopathy; (iii) flaccid paralysis; (iv) haemorrhage; (v) renal injury and (vi) localized tissue injury and destruction (White, 2005).

2.2.1 The Snakebite

The bite of a venomous snake can easily be confused with that of a nonvenomous one initially, or in cases of a dry bite. If skin where the bite occurred is not broken there is usually very little risk of toxicity. If the skin is broken then the history of how the bite occurred becomes important. Bites can have the appearance of scratches or defined puncture wounds, and in cases involving front-fanged snakes, the classic two-fang punctures are often seen, but not always.

When an amateur herpetologist tells emergency department staff that a black mamba bit them, then probably they have been bitten by a black mamba! Usually the amateur knows exactly what they were bitten by, though they may know little else. The difficulty in confirming venomous snakebite usually involves individuals bitten in a natural setting, when the offending snake was not clearly seen. Rattlesnakes are usually identified with some reliability, but it is important to confirm that rattlesnakes are indigenous to the geographic locality where the bite occurred. Many nonvenomous snakes are frequently misidentified as venomous, therefore, the resource and consultation of a knowledgeable herpetologist is helpful. If there is any question about the species involved, it is best to keep the patient for observation for a minimum of six hours or longer, especially in paediatric cases (Guisto, 1995; Swindle *et al*., 1992). This leaves the clinician to rely on the observation of objective signs and symptoms of envenomation for the diagnostic confirmation of a venomous snakebite (**Table 2**).

2.2.2 Local Toxic Effects

Envenomation by pit vipers and vipers typically results in significant localized pain, swelling and oedema within 30–60 minutes, and in cases of severe envenomation these intensify and progress rapidly (Russell, 1991; Gold *et al*., 2002). Ecchymosis may develop and spread following the path of lymphatic drainage (Roberts and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Greenberg, 1997). Vesicles or blebs may also appear, which are usually filled with clear fluid or blood in severe cases. Local tissue necrosis also may follow due to local ischemia and direct action of venom enzymes. Pain and swelling are generally more severe following bites by the larger rattlesnake species such as eastern and western diamondbacks, while bites by small *Sistrurus* rattlesnake species (Massasauga and pygmy rattlesnakes) tend to be less locally severe (Russell *et al*., 1975). However, even copperheads can cause significant local pain and tissue destruction (Thorson *et al*., 2003). Pit-viper envenomation-associated pain may persist for days, and there may be long-term sequalae associated with recurrent oedema due to limb activity that lasts for weeks, and poorly healing wounds can fester for months (Spiller and Bosse, 2003). Similar local wound complications have been reported with the bites of African vipers and spitting cobras (Bey *et al*., 1997; Spawls and Branch, 1995).

2.2.3 Coagulopathies

A wide range of coagulopathies, which can be a complex consequence of snakebite, can be difficult to manage, and often cause significant morbidity and mortality (Markland, 1998; White, 2005). A variety of snake species may produce haemostatic disorders including members of the Colubridae, Elapidae and Viperidae (pit viper and vipers) families (White, 2005). Venom constituents will interact at various points of the coagulation cascade, depending on the species involved.

Principal coagulopathic effects are due to procoagulant (Factors V, IX, and X activation, prothrombin activation and fibrinogen clotting) and anticoagulant (protein C activation, Factors IX and X activating protein, thrombin inhibitor and phospholipase A_2) actions, fibrinolytic activity (fibrin degradation and plasminogen activation), platelet activity (platelet aggregation inducers and inhibitors), plasma protein activation and vessel wall disruptors (haemorrhagins) (Hutton and Warrell, 1993; Markland, 1998). Disseminated intravascular coagulation (DIC) may complicate severe cases, and frequently renal failure ensues, as the kidneys are excessively burdened with degradation products (Curry and Kunkel, 1985; White, 2005).

Procoagulant effects result in consumption of coagulation factors. Laboratory data can suggest the potential for profound clinical bleeding, but this may or may not occur, and the resolution of complications may be highly variable. Anticoagulant venoms contain toxins that are indirect or direct in their ability to inhibit clotting mechanisms. The end clinical picture of anticoagulant effect is similar to the end effect of the consumptive route observed with procoagulant venoms, although the risk of pathologic bleeding is less. Haemorrhagic toxins are usually metalloproteinases that disrupt the integrity of the vascular endothelium and are present in numerous viperid snake species (Markland, 1998). Platelet function is compromised by intravascular clotting and consumption of platelets, sequestration of platelets at the site of envenomation or direct destruction of platelets by the venom (Riffer *et al*., 1987). The degree of thrombocytopenia may directly correlate with the severity of envenomation; however, the extent of thrombocytopenia and increased risk of bleeding in cases of snakebite is less clear (La Grange and Russell, 1970; White, 2005).

2.2.4 Cardiotoxic and Haemodynamic Effects

Cardiovascular shock leads to systemic complications and is a common cause of death in humans due to crotalid envenomation (Hardy, 1986). Reduced cardiac output secondary to venom-induced cardiac changes, as well as the release of mediators such as bradykinins, histamine and serotonin may also contribute to haemodynamic compromise (Curry and Kunkel, 1985; Christopher and Rodning, 1986). Electrocardiographic abnormalities, including T-wave inversion and heart block have also occurred following envenomation by a number of snake species (Lalloo *et al*., 1997) (**Table 2**). Tropical rattlesnake (*Croatlus durrissus terrificus*) envenomation has been implicated to cause direct venom-induced changes in myocardial enzymes (Cupo *et al*., 1990). Viper and pit-viper envenomation frequently cause haemodynamic changes that alter membrane permeability of the pulmonary blood vessels, resulting in pulmonary oedema and blood pooling in the vasculature, but almost all organ systems can be affected (Russell, 1991). This sets the stage for shock as a result of third-spacing of fluids and intravascular volume depletion (Schaeffer *et al*., 1979).

2.2.5 Neurotoxicity

Neurotoxicity results from envenomation by elapids such as coral snakes, cobras, mambas and kraits; the hydrophid sea snakes; the South American tropical rattlesnake (*Crotalus durissus terrificus*) and the North American Mojave rattlesnake (*Crotalus scutulatus*) (Ekenback *et al*., 1985; Cupo *et al*., 1988; Jansen *et al*., 1992). Sea snakes have potent venom compared to many other snakes, and their neurotoxin binds postsynaptically on acetylcholine receptors (Tu and Fulde, 1987). The venom of kraits acts presynaptically inhibiting the release of acetylcholine at the myoneural junction (Minton, 1990). Neurotoxic signs and symptoms in general progress as a descending paralysis with ptosis, dysphagia and blurred vision being early signs of envenomation, and respiratory paralysis the most common cause of death (Kitchens and Van Mierop, 1987). The onset of symptoms may occur in minutes or be delayed hours, and symptoms may persist for days (Minton, 1990). Crotalid envenomations from timber rattlesnakes and western diamondback rattlesnakes

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

have also been reported to cause paraesthesias, muscle fasciculations, myokymia (including lingual myokymia) and weakness (Russell, 1980; Brick *et al*., 1987; Clark *et al*., 1997).

2.2.6 Ocular Effects of Venom

Several species of African and Asian cobras are capable of spraying or 'spitting' venom defensively into the eyes of a predator. The venom of these snakes can produce a spectrum of corneal lesions, such as intense conjunctivitis, pain, tearing, corneal oedema, de-epithelialization and opacification (Ismail *et al*., 1993a; Minton, 1990). Corneal opacification syndrome has been attributed to the cardiotoxins in their venom (Ismail *et al*., 1993b). Ocular exposure to the venom of several species of pit vipers (rattlesnakes and cottonmouths) has been reported, but reactions of minimal irritation and burning resolved rapidly (Troutman and Wilson, 1989).

2.2.7 Other Toxic Manifestations

Many potential systemic toxic effects may result from direct actions of venom or as secondary complications of cardiovascular, neuromuscular or coagulation disorders. Renal failure is a frequent complication associated with direct venom toxicity, or haemostatic complications from envenomations by crotalidae, hydrophidae, viperidae and some elapid envenomations, and may be further complicated by DIC or cardiovascular shock (George *et al*., 1987; Nelson, 1989; Vijeth *et al*., 1997). Adult respiratory distress syndrome may develop in severe cases. The aetiology is unclear but shock, DIC, multiple blood-component transfusions and the venom itself are all postulated (Curry and Kunkel, 1985). Pancreatitis and hepatocellular necrosis have also been reported following snakebite, the aetiology of which is unclear (Kjellstrom, 1989; de Silva *et al*., 1992; Narvencar, 2006). Hepatic necrosis has been reported in cases of envenomation by *Crotalus* spp. in South America (Barraviera *et al*., 1989).

2.3 Out-of-Hospital Management

The actions taken prior to a venomous snakebite victim's arrival at a medical facility can have a major influence on the course of envenomation. Initially, providing reassurance to the victim followed by removal of bracelets, watches, rings, or any constrictive jewellery or clothing, including shoes, are important first steps. However, the use of arterial tourniquets, cryotherapy, electric shock, excision and incision have all resulted in various forms of increased morbidity, and in cases of severe envenomation may exacerbate venom-induced toxicity and mortality (Dart and Gustafson, 1991; McKinney, 2001). Negative pressure suction remains controversial, and if used should not involve incision or other invasive techniques (Bush *et al*., 2000; Alberts *et al*., 2004). If the use of a compression bandage or the pressure immobilization technique has been implemented, they are best left in place until arrival at a hospital and comprehensive evaluation (Watt *et al*., 1988; Hardy and Bush, 1998).

It is also beneficial to know if the victim has a prior history of venomous snakebite or treatment with antivenom as both can influence the potential for allergic or anaphylactic complications. If the victim is being transported via emergency medical services (EMS) and venomous snakebite has been confirmed, baseline vital signs should be taken, cardiac monitoring should be initiated, the progression of signs and symptoms should be documented, intravenous access should be established and supportive measures should be performed as needed.

2.4 Medical Management

Effective management of venomous snakebite patients requires an understanding of snakes and their behaviour, envenomation pathophysiology, proper clinical assessment, knowledge of what not to do and the timely implementation of appropriate pharmacotherapies (**Table 2** and **Table 3**). The scope of discussion here will not be to provide specific treatment protocols, but to give a general overview of the important concepts involved in the medical management of the snakebite patient.

2.4.1 Initial Measures

In Australia and some Asian countries, the immunodiagnosis of snakebite can be made using enzyme-linked immunoassay technology (ELISA), which can serve as an aid in the prognosis of symptoms and selection of appropriate antivenoms. However, economic factors have hindered development and use in countries outside of Australia (Ratanabanangkoon *et al*., 1987; Hawdon and Winkel, 1997; Rodriguez-Acosta *et al*., 1998). In addition to confirming the venomous snake involved in the bite history, the patient's medical history should be documented (particularly relating to previous snakebite or antivenom exposure), evaluation of the bite wound performed and tetanus vaccination status determined (Russell, 1991). The bitten limb should be maintained in an immobilized functional position, and blood/urine taken for laboratory analysis. In cases of pit-viper and viper envenomation, circumferential measurements at a point above and below the bite site should be documented, and repeat measurements taken at 15–20 minute intervals (Gold *et al*., 2002). The accepted period of patient observation in a medical facility following snakebite in the United States has been six hours with crotalid envenomation, but caution should be taken, as even crotalid bite victims have had severe symptoms delayed

Table 3 Clinical therapeutic intervention options used in the treatment of snakebite patients

Physiologic system	Pharmacotherapeutic agents	Supportive measures
General	Tetanus Analgesics Antibiotics (aerobic/anaerobic gram negative bacilli primarily)[a] Antivenom?	Reassurance
Cardiocirculatory	Antivenom Epinephrine	Blood replacement products Fluid volume replacement
Dermal tissues	Antibiotics	Wound debridement Wound soaks/baths
Gastrointestinal	H_1, H_2 antihistamines	Fluid
Musculoskeletal	Antivenom	Limb elevation
Nervous (CNS and autonomic)	Antivenom Anticholinesterases	—
Ocular	Antibiotic eye drops Heparin solution Epinephrine drops	Voluminous irrigation
Pulmonary	Antivenom Epinephrine (anaphylaxis cases)	Endotracheal intubation Mechanical ventilation
Renal	Antivenom	Fluids—maintain urine flow Haemodialysis

[a](Jorge *et al*., 1998).

up to 12 hours (Swindle *et al*., 1992; Guisto, 1995). Victims of coral-snake envenomation have been reported to have a delayed development of symptoms, up to 12 hours in some cases (Gold *et al*., 2002). Accordingly, antivenom therapy may be a consideration for all victims of eastern coral snake bite and other neurotoxic snake bites when there is evidence of skin penetration by fangs (Otten, 1983). In general, if there is any question of envenomation and an apparent bite is evident (especially in small children), there is no harm in admitting the patient for 24 hours of close monitoring. Although medical personnel are inclined to administer antibiotics prophylactically, their use in snake-venom poisoning is rarely needed (Talan *et al*., 1991; Clark *et al*., 1993; Kerrigan *et al*., 1997). In some instances this may be due to the antibacterial activity of snake venom itself (Talan *et al*., 1991). Exceptions requiring the use of antibiotics usually result from an extensive delay to medical treatment (common in rural areas), or the use of inappropriate first aid measures, such as tourniquets (Jorge *et al*., 1998).

2.4.2 Laboratory

Laboratory data are of great utility for assessing the severity of toxicity, directing the course of treatment and monitoring the effectiveness of treatment. Initial baseline laboratory values, drawn as soon as possible following the bite for coagulation profile (prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen, fibrin split products) and haematology, should be determined in all cases of confirmed or questionable envenomation, regardless of the species involved. Complete blood count (CBC), creatine kinase and lactate dehydrogenase levels, along with urinalysis (haematuria, haemaglobinuria, myoglobinuria), renal function and hepatic function tests are useful. The typing and crossmatching of patient blood should also be done prior to antivenom administration to avoid potential immuno-induced haemolytic complications (Miwa and Fujii, 1996). Tests should be repeated at regular intervals during the course of antivenom therapy, and particularly following antivenom infusion (Gold *et al*., 2002). Values may not reverse readily, but when adequate doses of antivenom have been administered and venom is neutralized the progressive coagulopathic deterioration should stop.

2.4.3 Antivenom Therapy

Definitive treatment of confirmed envenomation is ideally with species-specific antivenom. Venom differences across a genus may exist, and intraspecific and geographic venom variability occurs, yet some degree of paraspecific coverage is frequently afforded by many polyvalent antivenoms (Minton, 1967; 1990; Chippaux and Goyffon, 1998). However, despite the crossreactivity of snake venom components, a monovalent or monospecific antivenom developed

Antibody structure	$F(ab')_2$	IgG	Fab
Molecular Wt.	102 kDa	150 kDa	50 kDa
Immunizing snake venoms	Tropical rattlesnake common lancehead	Death adder	Eastern diamondback Western diamondback Mojave rattlesnake Water moccasin
Immunized host animal	Horse	Horse	Sheep
Specficity Valency	Polyspecific Polyvalent	Monospecific	Polyspecific Polyvalent
Country of production	Mexico	Australia	United States

Figure 1 Molecular properties and immunological characteristics of three forms of antivenom produced in three different countries. Venom from a single snake species or venoms from several species may be used to immunize a host animal. Antibodies formed against venoms are harvested from sera of host animals and purified to make antivenom. Whole antibody, immunoglobulin G (IgG), is the most common antivenom form. Each mole of IgG has two binding regions, and each binds or neutralizes 1 mol of venom toxin. IgG digestion with pepsin yields a single $F(ab')_2$, two-thirds the size of IgG, that can bind two moles of venom toxins. IgG digestion with papain yields two smaller Fab subunits, each one-third the size of IgG, that can bind a single mole of venom toxin. Each form has its own pharmacokinetic and therapeutic advantages/disadvantages.

for treatment of envenomation from a single species may be ineffective or have limited effectiveness for treating envenomation by related subspecies, or even the same species from a different geographic region (Berger and Bhatti, 1989; Gillesen *et al*., 1994; Chippaux and Goyffon, 1998). As a result, the tendency has been towards the development of numerous polyvalent or polyspecific antivenoms that provide a broader spectrum of coverage (Laloo and Theakston, 2003).

Snake antivenoms are prepared by harvesting antibodies from the sera of horses, sheep or goats that have been hyperimmunized with the venom of a single species of snake, or the venom of multiple snake genera and species, or by pooling venoms for immunization (**Figure 1**). Antibodies are proteins that are usually affinity purified, and may be used as whole immunoglobulin G (IgG), or enzymatically digested into an $F(ab')_2$ subunit that is two thirds, or digested to two subunits that are one-third the parent IgG size, respectively (**Figure 1**). Efforts to make even smaller humanized single-chain antibodies with predefined binding specificities for specific target toxins of South American rattlesnake (*Crotalus durissus terrificus*) venom has been accomplished using phage technology, which may open new avenues for passive immunotherapy in snakebite (Lafaye *et al*., 1997).

The variant antibody forms have different chemical properties, pharmacokinetics and immunogenic characteristics (**Figure 1**). The renal elimination of Fab is possible because of its small molecular size, but IgG and $F(ab')_2$ antivenoms, being larger, have prolonged elimination (Ismail *et al*., 1998). Thus, Fab in excess of the quantity needed to bind and neutralize all the venom toxins, is readily eliminated (Meyer *et al*., 1997; Seifert and Boyer, 2001). This feature is good in one way, but is also a limitation. The larger $F(ab')_2$ and IgG antibody forms remain in the systemic circulation longer due to slower elimination, and, as such, remain available to bind persistent venom toxins that slowly release from tissue depots to the circulation (Seifert and Boyer, 2001; Quesada *et al*., 2006). One must remember that once venom toxins are complexed to antivenom, not only do the pharmacokinetics of the toxin change, but the antivenom pharmacokinetics may change as well (Laloo and Theakston, 2003).

Another feature of different antibody forms stems from the antigenicity they exhibit based on their differing molecular sizes. The small Fab form is less antigenic than IgG, and consequently possesses less risk of allergic side effects following its administration. Both the Fab and $F(ab')_2$ forms have had the Fc region (compliment binding region) digested away, and this also reduces antigenicity (Seifert and Boyer, 2001) (**Figure 1**). Since the antibodies that constitute the make-up of any given

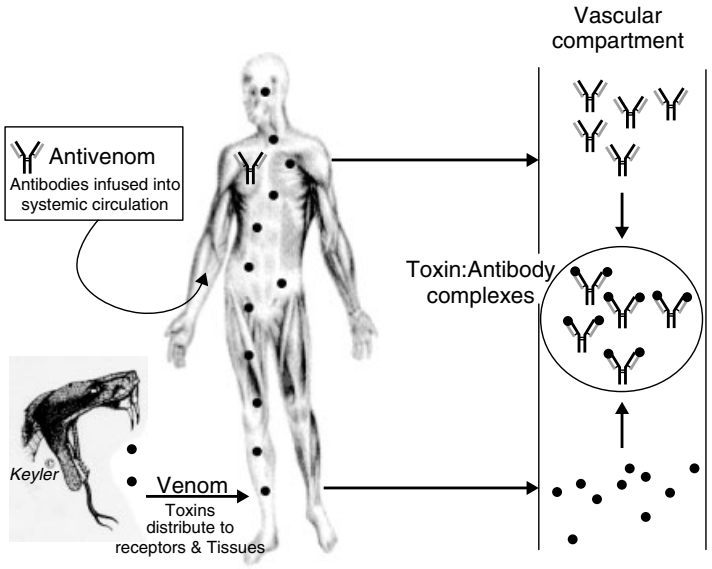

Figure 2 Snakebite can deliver venom subcutaneously, intramuscularly or intravenously. Venom is taken up by the systemic circulation and toxins distributed to target tissues and receptors resulting in toxic effects. Antivenom infused into the vascular compartment results in antibody recognition and binding of venom toxins, forming toxin:antibody complexes that essentially render the toxins pharmacologically inactive. Ideally, antivenom doses should be escalated in increments to achieve a total dose that is sufficient to neutralize all toxins.

antivenom are proteins, derived from other mammalian species, the lack of purity in their pharmaceutical preparation can also contribute to antivenom antigenicity. However, high-quality purified IgG antivenoms can be administered safely to humans (Chippaux and Goyffon, 1998).

Antivenom should be administered intravenously. Antivenom cannot alter the venom dose injected, but does alter distribution and elimination pharmacokinetics of venom and venom components by action of the antibodies binding to venom. Venom or venom components, bound to antibody (toxin:antibody complexes) become inaccessible to target tissues and receptors and are essentially neutralized and rendered pharmacologically inactive (**Figure 2**). Therefore, the total dose of antivenom should be great enough to theoretically bind/neutralize all the venom dose injected. Ideally, antivenom dosing would be based on actual stoichiometric venom:antibody relationships in order to effectively neutralize all venom components. Since the quantity of venom injected with a bite is unknown; clinical signs, symptoms and laboratory analyses are used to guide treatment, and the antivenom dose is empirical. Basically, the larger the quantity of venom injected, the greater the dose of antivenom required. Antivenom administration, preparation, dosing guidelines and other useful information are normally clearly printed and provided in the manufacturer's package insert. Dosing is generally done using a given number of vials or units at intervals and, as such, the total effective dose is accomplished via gradual escalation. On occasion, venom-induced coagulopathy may recur after an initial response to treatment with Fab, $F(ab')_2$ or IgG antivenom, even after lengthy periods, which may require repeated antivenom dosing. This is a result of the pharmacokinetic mismatch between venom components and the antibody make-up of the antivenom, with the most pronounced mismatch occurring with Fab antivenom (Seifert and Boyer, 2001).

The selection of appropriate antivenom will depend on the species of snake, and in many cases this leaves attending medical personnel at a loss as to sources of antivenom and the need for information concerning the management of venomous snakebite, especially in cases of exotic envenomation. Contacting a regional poison centre can be most useful to obtain snakebite toxicology consultation, and to identify sources of antivenom. In the United States there are two antivenoms that are FDA (Food and Drug Administration) approved for use in treating venomous snakebite victims: Crotalidae Polyvalent Immune Fab (Ovine) is available for treating envenomation by all species of North American pit vipers (**Figure 1**) and; coral snake antivenom that is an equine IgG preparation is available for two subspecies of eastern coral snake (*Micrurus fulvius fulvius/tenere*). However, other foreign-produced antivenoms have also been shown to provide significant protection, in animal models, against the effects of envenomation from North American coral snakes, and may become available for human use in the future (Wisniewski *et al*., 2003; de Roodt *et al*., 2004; Sanchez *et al*., 2008).

The rationale for the administration of antivenom early-on following envenomation is based on the pharmacokinetic relationships between venom dose and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

antivenom (antibody) dose, with the timely coordination of these leading to the neutralization of venom toxins and the halting of the progression of venom-induced pathophysiologies and symptoms. However, there may be limitations as to the effectiveness of antivenom in preventing the worsening of local tissue damage. Regional administration of antivenom intramuscularly has been demonstrated to be of no benefit in limiting necrosis following envenomation in animal models (Norris *et al*., 2003). Other studies with pit-viper venoms (i.e. Jararaca, *Bothrops jararaca*) revealed that venom in the microcirculatory complex at the site of fang punctures can significantly alter the microcirculation, resulting in reduced antivenom absorption kinetics, and impaired antivenom-venom neutralization, with any neutralization that does occur being delayed (Battellino *et al*., 2003).

In general, the sustained plateau of laboratory test values, their gradual recovery towards normal and the general clinical stabilization of the patient suggests adequate neutralization of venom by antivenom has been achieved. On occasion, continued absorption of venom from a depot at the bite site may prolong the clinical course. As a result, antivenom may need to be administered over a period of days. Importantly, antivenom therapy should not be ruled out, even if the patient presents for treatment after significant delay, if toxic effects of venom are evident (Rosen *et al*., 2000; Bebarta and Dart, 2004).

In the event of an allergic response, the potential risks and benefits of therapy must be weighed carefully, but if life or limb is at stake, antivenom therapy should commence after taking appropriate precautions. Patients who are treated with antivenom also are likely to develop a delayed immune complex reaction commonly known as serum sickness. This is an IgG- and IgM-mediated process, which results in the formation of antigen–antibody complexes, and the subsequent activation of the complement system (Otten and McKimm, 1983). Lastly, the use of antivenom does not preclude the use of symptomatic and supportive management, as it is the combination of these that will optimize the potential for reducing morbidity and mortality.

2.4.4 Supportive Treatment and Other Therapeutic Measures

Since intravascular volume depletion is a primary cause of cardiovascular shock, adequate fluid replenishment is essential. Oxygen should be administered and appropriate respiratory support provided as needed. Whole blood or blood products may be needed to treat acute blood loss and specific coagulopathies, but should be used judiciously (Burgess and Dart, 1991). Paralysis from elapid venom-induced neurotoxicity has been successfully treated with anticholinesterase agents such as edrophonium and neostigmine (Watt *et al*., 1986; Gold, 1996; Lalloo *et al*., 1996). In the absence of pharmacotherapeutic agents in cases of neurotoxic envenoming, respiratory support has proven life-saving (Deer, 1997; Pochanugool *et al*., 1997).

2.5 Ocular Venom Exposures

Snake venom can be ejected into the eyes of a human by spitting cobras, and resulting complications can be significant (Ismail *et al*., 1993a; Ismail *et al*., 1993b; Cham *et al*., 2006). This risk is obvious to those who live in spitting cobra habitats of various countries, but amateur and professional herpetologists are also at risk when manipulating these snakes. If at all possible, immediate irrigation of affected eyes should be performed prior to reaching medical care, and can be accomplished with water or normal saline solution. Irrigation with an aqueous heparin solution (2500 U ml^{-1} in saline) or tetracycline (1% solution) were effective in limiting the corneal opacification syndrome induced by several African cobras such as Rinkhals (*Hemachatus haemachatus*), forest cobra (*Naja melanoleuca*), black-necked spitting cobra (*Naja nigricollis*) and the Cape cobra (*Naja nivea*) (Ismail *et al*., 1993a). Recent studies of venom-induced epithelial damage, inflammation and scarring effects from the black spitting cobra (*Naja sumatrana*), native to Malaya, Borneo and Sumatra, revealed that topical application of heparin (5000 U ml^{-1}), or topical application of reconstituted antivenom, significantly reduced corneal damage (Cham *et al*., 2006).

2.6 Pregnancy and Snakebite

The pregnant snakebite patient presents a serious and perplexing situation, as treatment must be rendered to two patients concurrently. Depending on the species of snake, the severity of envenomation and time interval to medical care, there can be foetal and maternal mortality in the absence of treatment (Dunnihoo *et al*., 1992; Pantanowitz and Guidozzi, 1996). Data are limited, and although it has been suggested that envenomation in early gestation may have a less favourable prognosis, the outcome is highly variable (Parrish and Khan, 1966; Seneviratne *et al*., 2002). In two large case-series reviews of 30 and 39 cases, a 43% foetal mortality (20% spontaneous abortions), 10% maternal mortality and 30% abortion rate were reported, respectively (Dunnihoo *et al*., 1992; Seneviratne *et al*., 2002). Venom may cross the placenta resulting in systemic foetal poisoning, in the absence of maternal symptoms (James, 1985). The best way to provide any chance of foetal survival is to insure maternal survival. Both foetal and maternal monitoring is essential.

If coagulopathy is evident, the use of blood-component replacement alone will be insufficient, and the use of antivenom should be considered (Pantanowitz and Guidozzi, 1996). Crotalidae Polyvalent Immune Fab (Ovine) antivenom, five vials, has been successfully used in treating a 32-year-old patient (28 weeks gestation) following copperhead envenomation (Kravitz and Gerardo, 2006).

2.7 Surgery and Snakebite

Surgical management of venomous snakebite has been performed for decades, and in recent times has been carefully scrutinized (Glass, 1991; Hall, 2001; Dart, 2004). Surgical procedures, such as incision of the bite site as a first-aid measure, and excision of the bite to remove enough venom in order to avoid the need for antivenom were frequently used interventions (Glass, 1976; Huang *et al*., 1974). These are no longer recommended procedures (Hall, 2001). The main issue prompting surgical intervention is the possibility of compartment syndrome that can cause severe muscle necrosis and permanent nerve damage, with loss of functionality (Dart, 2004). When this process occurs in a digit the possibility of dermotomy is raised, and when it occurs in the larger limbs the question of fasciotomy arises. Justification to perform either should be cautiously approached, as compartment syndrome from snakebite results from a toxin-induced compartment syndrome rather than that caused by physical trauma. Collectively, the data from multiple research studies suggest that surgery does not improve the outcome of venom-induced compartment syndrome; however, it may be considered in carefully selected cases (Hall, 2001; Dart, 2004). Only two out 1257 cases, in case series collectively reported, required fasciotomy (Hall, 2001). Technology now provides for the measurement and monitoring of compartment pressures, which should be used to confirm the diagnosis of true compartment syndrome (Mars *et al*., 1991; Seiler *et al*., 1994). Clinical evaluation is an important adjunct to compartment pressure measurements and is critical in the decision-making process for surgical intervention.

2.8 Allergies, Anaphylaxis, Antivenom and Venom

Acute allergic reactions to snake venom from multiple species from all geographic regions of the world have been documented to occur following repeated venomous bites (Schmutz and Stahel, 1985; Wadee and Rabson, 1987; Domingos *et al*., 1990; Bush and Jansen, 1995; Alonso *et al*., 1995). In regions of the world where native populations encounter indigenous species of snakes on a regular basis, there is evidence of active immunization, with some protection afforded (Theakston *et al*., 1981; 1983). However, this is the exception, as amateur herpetologists have tried self-immunization, resulting in unfavourable effects that further contributed to the complications of their envenomation (Keyler, 1991). Thus, individuals who have routine contact with snakes, and persons who have repeat bites, can present with complex clinical findings of both allergic and toxic manifestations. Active immunization against snake venoms has been formally attempted in man, but the antibody concentrations achieved following immunization have been short-lived, and protection limited and too brief to be practical (Theakston, 1989).

Antivenom therapy has also been frequently associated with systemic allergic reactions, both from single and repeat treatment exposures (Malasit *et al*., 1986; Pugh and Theakston, 1987; Jurkovitch *et al*., 1988; Premawardena *et al*., 1999; Chen *et al*., 2000; LoVecchio *et al*., 2003; Fan *et al*., 2006). In cases of IgE-mediated allergic reactions to snake venom or antivenoms the patient is at immediate increased risk for potential respiratory and shock complications requiring pharmacologic and supportive interventions (Moran *et al*., 1998; Chen *et al*., 2000; Fan *et al*., 2006). Thus, there should be close observation of the patient, both following the actual snakebite and during administration of antivenom, with epinephrine, antihistamines and life support at the ready.

Two useful manoeuvres can be taken to reduce the likelihood of adverse reactions with antivneom administration in patients, with or without allergy history. First, adequate dilution of the antivenom is important. Dilution should be based on manufacturers' guidelines. Second, the rate of antivenom administration can be controlled, and in cases of reaction, the rate can be reduced, or even stopped, and then gradually restarted at a slower rate (Russell, 1983).

3 GILA MONSTER/BEADED LIZARD

The genus *Heloderma* contains the only two species of lizards known to be venomous to humans. The Gila monster (*Heloderma suspectum*) and the beaded lizard (*Heloderma horridum*) are further classified to five subspecies. The banded Gila monster (*Heloderma suspectum cinctum*) is the only subspecies with part of its geographical range in the southwestern United States. The beaded lizard ranges from southern Mexico on down the Pacific coast to Guatemala (Campbell and Lamar, 2004). Because of their unique features and colour patterns, and the fact that they are venomous, they have become quite popular with amateur collectors. Thus, they can be present in virtually any state or country far from their native range.

Both species have a broad head, solid bodies and legs with thick tails, but the forked tongue of the Gila

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

monster is black while that of the beaded lizard is pink (Beck and Lowe, 1991). Their short curved teeth are peg-like and grooved on both the anterior and posterior surfaces. A venom duct opens at the base of the teeth, and when the lizard bites, the muscle contraction of the jaw causes the chanelling of venom along the tooth grooves bidirectionally via capillary action.

3.1 Heloderma Venom

Venoms of helodermids are quite similar between both species, and possess numerous enzymatic properties, including a phospholipase A_2 and kallikrein-like enzymes such as, 'helodermatine', along with an acidic neurotoxin, 'gilatoxin' (Alagon *et al*., 1982; 1986; Mochca-Morales *et al*., 1990). In animal toxicity studies these toxins have induced lethargy, partial paralysis and hypothermia (Mochca-Morales *et al*., 1990). Although Gila monster venom lacks apparent haemolytic or haemorrhagic activity, it does contain vasoactive peptides capable of inducing vasodilation, and a Type III phospholipase A_2 that blocks platelet aggregation (Hendon and Tu, 1981; Huang and Chiang, 1994). These may produce profound systemic effects, such as hypotension, coagulation disorders and a rapid loss of consciousness (Fry *et al*., 2005).

3.2 Heloderma Bites

Heloderma bites that occur naturally are very rare (Hooker and Caravati, 1994). Neither species of lizard attacks humans, despite the stories that are rumoured. It takes considerable provoking to get them to bite, and although they appear sluggish, they can rapidly flex their stumpy body, deliver a substantial clamping bite and they are notorious for remaining attached to their victim. When victims present to the emergency department for treatment the circumstances leading to the visit usually involve prodding and bare handling of the lizards. Their bite can result in considerable mechanical trauma in addition to venom toxicity.

3.3 Toxic Manifestations of Heloderma Envenomation

Reports of human envenomation by the Gila monster and beaded lizard have been sporadic, frequently exaggerated, and documentation is rare (Russell, 1983; Strimple *et al*., 1997; Cantrell, 2003). Although fatalities have been reported, their legitimacy is highly questionable (Russell, 1983). Bites should be treated, however, as medical emergencies, with appropriate evaluation and care.

3.3.1 Local Toxic Effects

Puncture wounds usually result, due to their powerful bite, and occasionally teeth become lodged in the tissue and even break off when trying to disengage the lizard. Bluish discoloration around the bite may be noted, but tissue necrosis is unlikely. Injected venom causes pain that can be intense and may radiate throughout the extremity. Oedema generally develops more slowly and is less severe than that which occurs with snakebite, but in some cases it can become quite marked and tense (Russell and Bogert, 1981; Roller, 1976; Hooker and Caravati, 1994). This may contribute to the pain of envenomation. Lymphadenopathy and lymphadenitis have also been reported (Russell and Bogert, 1981; Bou-Abboud and Kardassakis, 1988).

3.3.2 Systemic Effects

Systemic manifestations include generalized weakness, faintness or dizziness, diaphoresis, nausea and vomiting. Hypotension and tachycardia are complications of significant concern (Hooker and Caravati, 1994; Cantrell, 2003). Profound hypotension has been reported in several cases (Streiffer, 1986; Piacentine *et al*., 1986; Heitschel, 1986; Bou-Abboud and Kardassakis, 1988; Preston, 1989). Additionally, cardiovascular effects have been described, including nonspecific electrocardiographic changes, ventricular arrhythmias and myocardial infarction (Roller, 1976; Streiffer, 1986; Bou-Abboud and Kardassakis, 1988; Preston, 1989). Impaired renal function has also been reported as a possible result of prolonged hypotension (Preston, 1989).

Swelling of the lips and tongue have been noted in two separate reports, as anaphylaxis from Gila monster envenomation, in two patients without a prior bite history (Piacentine *et al*., 1986; Caravati *et al*., 1999). Marked swelling of the tongue and lips has also been reported in a case of beaded lizard envenomation in a patient without previous exposure (Cantrell, 2003). Given these three similar profiles, it may be that symptoms of swelling of the lips and tongue are potentially direct venom effects.

3.3.3 Laboratory

Laboratory abnormalities may include hypokalemia and leukocytosis. Thrombocytopenia has been rarely reported (Russell and Bogert, 1981; Bou-Abboud and Kardassakis, 1988; Preston, 1989). Thrombocytopenia associated with reduced fibrinogen and increased PT, PTT and fibrin split products indicated a consumptive coagulopathy in two cases (Bou-Abboud and Kardassakis, 1988; Preston, 1989).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.4 Management of Heloderma Envenomation

There is no antivenom; therefore the management of toxic manifestations is limited to supportive and symptomatic care. Removal of the offending lizard is commonly a first-aid measure required, and is important, because the longer the lizard is attached the greater the potential envenomation. Approaches that have been tried with mixed success include: (i) prying the jaws apart with a stick; (ii) submersion of the extremity and attached lizard under water or (iii) lighting and holding a match under the Gila monster's jaw. The bite site should be rinsed off to remove venom on the skin and further reduce venom absorption. Keep the patient warm, immobilize the extremity and transport the patient to an appropriate healthcare facility.

The site of the bite should be thoroughly cleansed and examined for remaining teeth. Careful exploration of the wound should be performed and soft-tissue radiography of the site may be helpful (Cantrell, 2003). Elevation of the limb may reduce swelling. Tetanus immunization should be updated, and follow-up wound care is essential. Prophylactic antibiotics are not necessary (Strimple *et al*., 1997). Vital signs, including pulse oximetry, and laboratory values should be regularly monitored. Pain management with opiates is usually beneficial, but should be used with caution in patients experiencing hypotension. Observe for electrocardiogram abnormalities, as transient T-wave anomalies and conduction abnormalities may occur (Bou-Abboud and Kardassakis, 1988). Volume resuscitation usually corrects the hypotension, but vasopressors may be necessary (Strimple *et al*., 1997). Systemic symptoms usually resolve within one to two days with adequate supportive care, depending on the degree of envenomation (Cantrell, 2003).

4 HYMENOPTERA

Flying insects of the order Hymenoptera can be found throughout the world. Only a few of the thousands of known species are significantly hazardous to man. These include honeybees, bumblebees, wasps, hornets and yellow jackets. Honeybees and bumblebees belong to the family Apidae while the others belong to the family Vespidae.

Honeybees, *Apis mellifera*, account for most apidae stings. People are most likely to be stung by honeybees when around flowering plants or if they disturb the bees' colony. The introduction of an African race of honeybee, *Apis mellifera scutellata* or *adansoni*, to South, Central and North America raises some additional concern. Most of the time, their behaviour is the same as other honeybees. However, if disturbed, these hybrid bees attack more quickly, attack in greater numbers, pursue for longer distances and sting continually over longer distances (Kim, 1999).

The vespids are generally more aggressive and attack vigorously if disturbed. Yellow Jackets, *Vespula maculiforma*, are the most common source of Hymenoptera stings (Kemp, 1998; Sigford, 2000). Yellow jackets tend to nest on the ground or in decaying wood. They will scavenge for food and may be pests at picnics or around garbage cans. Hornets build nests in trees or shrubs, while wasps often nest under eaves of buildings. Venom-sensitive patients may be more likely to be stung than nonsensitive individuals. It is postulated that intrinsic attractants may account for this phenomenon (Stone *et al*., 1992).

Their stinging apparatus consists of a modified ovipositor that is connected to a venom sac. They grasp the victim's skin with their claws and then pierce the skin with their stinger. The stinger of honeybees is barbed, so it and the venom sack remain attached to the victim's skin when the bee flies away. This results in the honeybee's demise. Vespids and bumblebees are generally able to withdraw their stingers and are capable of stinging again. Some yellow jackets, however, also may lose their stinger. Hymenoptera venom is composed of various proteins and peptides, some of which can cause vasoactive responses.

4.1 Toxic Manifestations

Stings from these insects may result in manifestations ranging from minor local pain and swelling to life-threatening respiratory and cardiovascular compromise (Ceyhan *et al*., 2001; Wagdi *et al*., 1994). The toxic effects may result from direct local and systemic effects of the venom, as well as anaphylactic reactions to venom proteins.

Up to 50 µl of venom may be injected with each sting. This dose is insufficient to produce systemic toxicity; however, vasoactive constituents of venom will produce local irritation with redness, swelling, tenderness and pain at the site of the sting. If a person is stung repeatedly on one occasion, then sufficient venom may be injected to produce systemic toxicity. Systemic toxicity due to multiple bee stings typically resembles an allergic reaction because of the histamine effects of the large dose of venom. Acute renal tubular necrosis resulting from multiple bee or wasp stings has been reported (Beccari *et al*., 1992; Kim *et al*., 2003). Systemic toxicity and death from a single bee sting is usually due to an anaphylactic reaction in those individuals who have developed specific IgE antibodies from prior stings (Kemp, 1998; Freeman, 2004).

Toxicity due to vespid stings may include an acute allergic-like response, followed by delayed effects such as

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

haemolysis, rhabdomyolysis and renal failure (Bousquet *et al*., 1984).

The normal physiologic response to a hymenoptera sting consists of a small, painful, urticarial lesion that lasts only a few hours. Approximately 10–17% of people may develop a large local reaction that includes swelling and erythema greater than 5 cm in diameter, which may last more than 24 hours (Maguire and Geha, 1986; Reisman, 1989; Lin, 2003; Freeman, 2004). This large local reaction likely represents a cell-mediated, Type IV hypersensitivity reaction.

4.2 Allergic Manifestations

The allergic reactions to hymenoptera stings deserve detailed discussion. The allergic response may range from cutaneous effects of pruritis, urticaria and angioedema, to broader effects including nausea, vomiting, diarrhoea, abdominal cramps, uterine cramps, light-headedness and dizziness. The reactions with greatest risk include dyspnoea, bronchospasm, hypotension, dysrhythmias and cardiovascular collapse (Freeman, 2004). It is estimated that hymenoptera stings account for at least 40–50 deaths annually in the United States, more deaths than result from all other venomous animals (Golden, 1989). The systemic allergic response to hymenoptera stings is an IgE-mediated, Type I hypersensitivity reaction. Indirect complement activation may also play a role in insect sting anaphylaxis (Van Der Linden *et al*., 1990).

Unusual serum-sickness-like reactions have also been reported (Reisman and Livingston, 1989). There is considerable crossreactivity among the various vespids but cross-reactivity between vespid and bee venoms is relatively uncommon (Wright and Lockey, 1990).

The incidence of systemic allergic reactions may be as low as 0.4–0.8% in children, but as high as 4.0% in adults (Settipane *et al*., 1972; Golden *et al*., 1982). Up to 10–15% of the population may be sensitized to hymenoptera venom, but have not had an allergic response (Golden *et al*., 1982; 1997).

There is limited data to characterize which patients may develop none, some or all of these manifestations. Important factors include the insect type, age of the patient, underlying mastocytosis, underlying cardiovascular disease, treatment with β-adrenergic blockers, history of prior stings, time interval between stings, number of stings, venom sensitization, as documented by skin test or RAST (radioallergosorbent tests) and severity of the previous response to hymenoptera stings. Approximately 75% of the population is not sensitized to hymenoptera venom and will develop a normal local response and less than 1% will develop a systemic allergic reaction (Golden, 1989). Those who have previously had normal or large local reactions, but have a positive skin test or RAST have a 10–20% risk of developing a systemic reaction (Golden, 1989). Patients with a previous history of a systemic reaction who have a positive skin test or RAST have a 50% chance of developing another systemic reaction (Golden, 1989; Golden *et al*., 1997).

Individuals with bee-venom allergies are at a greater risk of systemic reactions on subsequent stings than are those with vespid-venom allergies (Bilo *et al*., 2005). It is commonly thought that patients develop more severe reactions with subsequent stings. While it is true that patients who receive repeat stings within a relatively short period (weeks to months) are more likely to develop a systemic reaction, most patients develop more mild or similar reactions with subsequent stings (Golden, 1989; Valentine *et al*., 1990; Bilo *et al*., 2005). Insect-sting allergy, in fact, is a self-limited disease for most people (Reisman, 1989). In other words, the more time between stings, the less likely a person is to have a serious systemic reaction. However, tolerance sometimes develops with very frequent stings, as observed with beekeepers (Bilo *et al*., 2005). Patients with mastocytosis, cardiovascular diseases or who are being treated with β-blocking drugs are associated with more severe sting reactions (Bilo *et al*., 2005).

The typical allergic response in children is very different to that in adults. Children are more likely to have cutaneous manifestations, but less likely to develop hypotension (Golden, 1989). Also, children much less frequently develop recurrent systemic manifestations. In fact, children who have previously had non-life-threatening allergic reactions are unlikely to subsequently develop a life-threatening reaction (Schuberth *et al*., 1983; Valentine *et al*., 1990).

Most fatalities occur within one hour of envenomation and are usually due to airway obstruction, hypotension or both. Almost all fatalities that occur do so within five hours of envenomation (Erickson, 2007).

4.3 Management

First-aid treatment for hymenoptera stings includes removing the stinger, if left behind, as rapidly as possible, by any method. Quick timing of stinger removal seems to be more important than potentially delaying removal by scraping across the site with a blunt edged object, as previously recommended (Visscher *et al*., 1996). The area should be washed well with soap and running water. Local reactions can be managed by applying ice to reduce swelling, oedema and pruritus. An antihistamine such as diphenhydramine may also help relieve pruritus. Large local reactions may improve with elevation of the extremity and administration of an analgesic, as well as a corticosteroid such as prednisone. The combined use of H_1- and H_2-antagonists has

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

been suggested as a means to decrease the severity of late-phase cutaneous reactions (de Shazo *et al*., 1984).

Epinephrine (adrenaline) is the drug of choice for systemic sting reactions. Intramuscular administration is adequate in mild to moderate cases. In the event of hypotension, epinephrine may be administered intravenously. Vasopressin has also been used successfully to treat severe anaphylactic shock due to hymenoptera envenomation (Kill *et al*., 2003). Intravenous fluids and aggressive cardiopulmonary resuscitation should be provided if epinephrine therapy alone is not adequate. Intravenous antihistamines and corticosteroids should be used in addition to epinephrine for systemic reactions. Inhaled β_2-agonists may help relieve bronchospasm.

Patients who are at risk of developing systemic allergic reactions should be prescribed an emergency kit that contains epinephrine for subcutaneous injection. This includes those patients with a previous history of systemic allergic effects, and those who have had large local reactions and have a positive skin test or RAST.

Venom immunotherapy (VIT) may be useful in selected cases. It is presently indicated for those patients who have previously had life-threatening systemic reactions and have a positive skin test or RAST (Maguire and Geha, 1986). Adults are more likely candidates than children, since adults are at greater risk for developing a repeat systemic reaction. However, immunotherapy should be considered in children who have systemic allergic reactions, therefore following the same indications as with adults (Gruchalla, 2004; Golden *et al*., 2004). Other patients with less severe systemic reactions who have positive skin tests or RAST may benefit from VIT, but the cost of therapy and other factors, such as their age, medical history, occupation, outdoor activities or hobbies must be considered.

Conventional VIT consists of administering a gradually increasing dose of venom over 4–12 weeks to a maintenance dose of 50–100 µg. Rush protocols, in which venom doses are administered while the patient is hospitalized, achieve maintenance doses within only four to five days. The incidence of adverse reactions varies greatly among studies, but it seems that 50% or more of patients develop at least mild systemic effects. The variability reported may result from differences in patient populations, dosing regimens and the species of venom used for VIT. Bee venom, for example, is not as well tolerated as vespid venoms (Muller *et al*., 1992; Youlten *et al*., 1995). Both conventional and rush VIT protocols have produced protection rates up to 97% (Golden and Valentine, 1984; Reisman and Livingston, 1992). The protection rate for honeybee venoms, however, is only about 80%.

The issue of when to discontinue VIT is still controversial. Recent evidence, however, suggests that VIT can be safely discontinued after five years in most patients (Graft and Schoenwetter, 1994; Golden *et al*., 1996).

In an animal model, an antivenom has been effectively administered to treat mass bee envenomation. This has not been used in humans and is not commercially available (Jones *et al*., 1999).

5 ANTS

Ants belong to the family Formicidae and comprise the third group of venomous Hymenoptera. Thousands of ant species are found throughout the world, some of which can inflict painful venomous stings. Local or systemic allergic reactions can also occur. Not all venomous ants sting. Some, such as the carpenter ant, *Camponotus atriceps* and weaver ants, genus *Oecophylla*, of the subfamily Formacinae, bite their prey and then spray venom into the wound. Formic acid, which is a potent cytotoxin, is the primary constituent of their venom (Rhoades *et al*., 1977).

Fire ants (*Solenopsis* spp.) are native to both North and South America. Fire-ant envenomation is a significant health hazard in the southern United States (Blum, 1984; Stafford *et al*., 1989a; Tracy *et al*., 1995). In fact, up to 60% of the population in an infested area are stung each year (de Shazo *et al*., 1990). The red imported fire ant (*Solenopsis invicta*) has rapidly spread throughout the southern United States and has overtaken the less aggressive native species (*S. xyloni*), as well as the black imported fire ant (*S. richteri*). The imported fire ants of the United States are so named because they are thought to have been introduced via produce shipped from Brazil to Mobile, Alabama in 1918 (Hung and Vinson, 1978).

Ants sting to subdue their prey and as a means of defense. A fire ant grasps its victim with its mandibles then, using its head as a pivot, it swings its abdominal stinger to inflict multiple stings (Diaz *et al*., 1989). Unlike other Hymenoptera, fire ants sting slowly and may inject venom for seconds to minutes (Stafford *et al*., 1989b). With each sting the ant injects from 0.04 to 0.11 µl of venom (de Shazo *et al*., 1990).

The venom of most ants and other Hymenoptera consists primarily of protein (Blum, 1984). Imported fire-ant venom, on the other hand, is 90–95% piperidine alkaloids, which cause histamine release and skin necrosis. This venom contains only 0.1% protein (Hoffman *et al*., 1988a; Bilo *et al*., 2005). Four proteins have been identified, namely: Sol i I, Sol i II, Sol i III and Sol i IV (Hoffman *et al*., 1988a; Bilo *et al*., 2005). All these proteins are significant allergens.

5.1 Toxic Manifestations

Toxicity associated with fire-ant envenomation is normally limited to the site of the sting. *In vitro* studies

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

indicate that the venom has haemolytic, cytotoxic, bactericidal and insecticidal properties (Rhoades *et al*., 1977; Adrouny *et al*., 1959). Multiple stings (approximately 10 000), however, have not resulted in systemic toxicity (Diaz *et al*., 1989).

The local response to envenomation includes instant pain, an initial wheal and a flare reaction. Superficial vesicles with clear fluid develop at the site of the sting within four hours. This fluid is lost and replaced within 8–10 hours by cloudy fluid, which becomes purulent. A pustule develops within 24 hours, which may be surrounded by a red halo (Car *et al*., 1957). This lesion is pathognomonic in the United States for fire-ant stings (Lockey, 1990). An important complication of fire-ant stings is secondary infection (Parrin *et al*., 1981).

Large local reactions may also occur, which may be immunologically mediated (Diaz *et al*., 1989). These reactions are characteristic of 'late-phase reactions' that occur secondary to ragweed (de Shazo *et al*., 1984). Systemic allergic reactions characteristic of those caused by other Hymenoptera also may occur. The natural history of such responses has not been well studied, but is probably comparable to that for other Hymenoptera. Anaphylaxis may result in up to 1% of stings (de Shazo *et al*., 1990). Anaphylactic deaths due to fire-ant envenomation have occurred (Prahlow and Barnard, 1998).

The prevalence of asymptomatic sensitized people to fire-ant venom is comparable to that which exists for other Hymenoptera, approximately 16% (Hoffman *et al*., 1988b). Crossreactivity may exist between bee or wasp venom and fire-ant venom. Sol i II has been identified as the crossreactive protein (Hoffman *et al*., 1988b; Bilo *et al*., 2005).

Neurologic sequelae, including seizures and mononeuropathy have also been reported (Fox *et al*., 1982; Candiotti and Lamas, 1993). The aetiology of such reactions is not known.

Envenomations by the samsum ant, *Pachycondyla sennaarensis* found in the African tropics and Arabian Peninsula, and Australian bull ants (*Myrmecia* spp.) have caused anaphylactic reactions.

Giant black ants, genus *Paraponera* found from Nicaragua to the Amazon basin cause severe pain and fever, and lymphangitis has also been reported (Dib *et al*., 1995; Erickson, 2007).

5.2 Management

First aid for fire-ant envenomation consists primarily of thorough washing with soap and water. Although a number of therapeutic measures have been evaluated as a means to alter the development of pustules, neither topical nor parenteral therapies had any effect on developing lesions (Parrin *et al*., 1981). A cold compress may help relieve some swelling and discomfort. The pustules should be bandaged to prevent excoriation. Large local reactions and systemic allergic reactions due to fire ant and other ant envenomations should be managed as previously described for other Hymenoptera.

As with other Hymenoptera, the indications for immunotherapy for fire-ant envenomation are not clear. The relatively high risk for stings in sensitized people, however, causes many to undergo such therapy (Stafford *et al*., 1989c). To further confound the issue, only whole-body extracts are available for therapy, which contain variable quantities of venom. Some evidence of its effectiveness, however, has been presented (Hylander *et al*., 1989; Brown *et al*., 2003).

VIT for the Australian bull ant using purified *Mymecia* ant venom has been shown to be effective in individuals with known allergy to these ants (Brown *et al*., 2003).

6 SPIDERS

Spiders are arthropods of the order Arachnidae. Most spiders are venomous; in fact, all but two families of spiders have venom glands. Thousands of venomous spiders exist throughout the world, however, only a few are of significant medical importance. Most notable are spiders of the genus *Latrodectus* and *Loxosceles*. Other spiders of clinical significance include the *Tegenaria*, *Hadronyche*, *Phoneutria* and various genera of tarantulas.

6.1 Widow Spiders

The true black widow spider (*Latrodectus mactans*) is found in temperate zones of North America, including all of the United States except Alaska. Other *Latrodectus* species are found throughout the world (Rauber, 1983–1984) including Australia, Europe, South America, Asia and the Middle East. The major differences between these species are in their body markings and habitats. *L. mactans* has a characteristic shiny black coloration with a red hourglass-shaped marking on its abdomen. Generally these spiders are nonaggressive and bite defensively when threatened or disturbed. They are typically found in undisturbed, protected areas such as storage buildings, wood piles and trash heaps. Female spiders make irregular funnel shaped webs in which to trap prey and suspend their egg sacs.

Only the females of this species are hazardous to man. The male is too small to cause significant envenomation. The black widow has claw-like hollow fangs that are connected to two venom glands in its cephalothorax. The venom glands have striated musculature that controls the injection of venom. While there are some interspecies

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

differences in venom constituents, the toxic fraction affecting vertebrate nerve endings, α-latrotoxin, appears to be the same (Rauber, 1983–1984; Müller, 1993).

The venom of *Latrodectus* spiders, which is one of the most potent of all animal venoms, is primarily neurotoxic. The venom gland of the black widow spider contains just less than 0.2 mg of venom (Binder, 1989). The mean lethal dose ranges from 0.005 to 1.0 mg kg^{-1} in various animal species (Edlich *et al*., 1985). The venom acts at the neuromuscular synaptic junction, causing the release of acetylcholine and norepinephrine from presynaptic vesicles (Rauber, 1983–1984; Binder, 1989). This results in excessive neuromuscular stimulation and, as expected, other cholinergic and adrenergic signs and symptoms. The venom causes local muscle pain initially, which then generalizes to involve primarily large muscle groups (Kobernick, 1984).

6.1.1 Toxic Manifestations

Most bites in humans occur above the waist on the forearm or torso (Moss and Binder, 1987). Bites are more prevalent during late summer and early fall, when there are increased numbers of both young and mature spiders (Moss and Binder, 1987). Although the bite itself is often not initially painful and may go unnoticed, pain at the site is the most common early symptom of envenomation (Moss and Binder, 1987). Other common symptoms include severe abdominal pain and cramping, as well as lower extremity pain and weakness. Hypertension, tachycardia, fever, leukocytosis, vomiting, restlessness, mental status changes, headache, rash, priapism, paraesthesias, albuminuria, ptosis and periorbital oedema also have been reported. Facies latrodectismica, with spasm of facial muscles, blepharitis, lacrimation and rhinitis, has been described (Maretić, 1983). In severe cases shock, coma, respiratory failure and pulmonary oedema may occur (Binder, 1989; LaGrange, 1990). In most cases, resolution of symptoms usually occurs within a few days, however pain may last for over a week. The mortality rate from black widow envenomation is probably less than 1% (Binder, 1989).

6.1.2 Management

There are no specific first-aid measures for black-widow envenomation. The bite site should be thoroughly cleansed and tetanus immunization should be updated if necessary. Medical management is primarily directed at relieving muscle spasms and pain. Opioid analgesics and benzodiazepines appear to be the most effective treatment for mild to moderate envenomations (Clark *et al*., 1992). Calcium gluconate has been used, however, it does not appear to be routinely effective (Clark *et al*., 1992). In addition, centrally acting muscle relaxants, such as methocarbamol, do not appear to be effective (Key, 1981).

Lactrodectus antivenom is available in Argentina, Australia, Mexico, South Africa and the United States. These are all equine-derived antivenoms. Some of these are whole IgG and some are $F(ab')_2$ IgG fragments, the latter having reduced antigenicity. The use of antivenom should be weighed against the potential risk of acute hypersensitivity and delayed serum sickness. In general, antivenom should be reserved for cases of severe *Lactrodectus* envenomation, including those with systemic involvement or severe local symptoms refractory to other treatments. It also can be used in life-threatening situations and in those patients at high risk for severe morbidity, such as the very young or old, and in those with underlying hypertension, cardiac or cerebrovascular disease.

6.2 Brown Spiders

Bites of some spiders result primarily in local tissue destruction. This condition has been referred to as necrotic arachnidism. The most notorious of these spiders are those of the genus *Loxosceles*. Spiders of this genus are found throughout South America, southern North America, Africa, Australia and southern Russia, as well as the Mediterranean and the Orient (Gertsch and Ennik, 1983; Gendron, 1990). *Loxosceles* spiders are fawn to dark brown in colour with relatively long skinny legs and have a characteristic violin-shaped marking on their dorsal carapace (Binder, 1989). The terms brown, violin or fiddleback spider are used to describe these species. The brown recluse spider, *Loxosceles reclusa*, is the most important species in the United States, as it is responsible for the majority of envenomations. It has been extensively studied and exemplifies the toxicity associated with these spiders.

The diagnosis of *Loxosceles* envenomation and its actual incidence are difficult to establish because of other potential causes of necrotic wounds, including bites of other spiders and confusing medical conditions, such as infections or toxic epidermal necrolysis (Russell and Gertsch, 1983). Diagnostic difficulties also have hampered attempts to study various treatment modalities. For example, in one series of 95 cases of presumed brown-recluse-spider bite, only 17 cases could be confirmed and ultimately studied (Rees *et al*., 1987). A venom-specific immunoassay has been used to identify *Loxosceles* envenomation (Berger *et al*., 1973a). Also, a highly specific passive haemagglutin inhibition test has been used for determining entry into controlled treatment trials for brown-recluse-spider bites (Barrett *et al*., 1993). In addition, a *Loxosceles* species venom ELISA has been developed for detection of *Loxosceles* species spider venom (Gomez *et al*., 2002). However, no diagnostic test is readily available to confirm *Loxosceles* venom exposure in a clinical setting.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The brown recluse spider is found primarily in the south-central United States (Majeski and Durst, 1976). Most reported bites have occurred in Arkansas, Kansas, Missouri and Oklahoma. These spiders inhabit primarily warm, dry, secluded places and can be found both indoors and outdoors. The household closet is the most frequently reported site of discovery (Rees and Campbell, 1989). Other potential sites include wood piles, storage buildings, stored clothing, attics, basements and other quiet locations. The brown recluse is nocturnal and, as a result, most bites occur during the night (Rees and Campbell, 1989). These spiders are most active in summer months and hibernate during the winter.

6.2.1 Toxic Manifestations

The venom of *Loxosceles* spiders is both cytotoxic and haemolytic. At least nine proteins have been identified, most notably a hyaluronidase, which accounts for the spreading of injected venom, and sphingomyelinase D, which likely contributes to its haemolytic and cytotoxic properties (Rees and Campbell, 1989; Wasserman, 1988; Hobbs and Harrell, 1989). Sphingomyelinase D activity has been found in a worldwide sampling of *Loxosceles* (Binford and Wells, 2003). It is this component to which dermonecrosis is attributed. The quantity of injected venom is relatively small and by itself is unlikely to cause significant injury. The destructive nature of the venom is apparently facilitated by complement activation and subsequent inflammatory response (Hobbs and Harrell, 1989; Rees *et al*., 1983). This results in endothelial cell damage, haemorrhage, infiltration of polymorphonuclear leukocytes and thrombosis of venules and arterioles, causing necrosis (Berger *et al*., 1973b).

The bite of a brown recluse spider results in little more than a stinging or prick sensation and may go unnoticed by the victim. In contrast to this, the bite of the South American *Loxosceles laeta* can cause severe pain and oedema, but less tissue necrosis. The clinical manifestations following envenomation depends on the amount of venom injected and the site of envenomation, as well as the age, underlying health and immune status of the victim (Wasserman and Anderson, 1983–1984; Majeski and Durst, 1976). Not all patients develop the characteristic necrotic lesion or potentially severe systemic effects. It may be that many bites go unrecognized because only minimal envenomation occurs and victims experience only mild discomfort that resolves uneventfully within a few days (Berger, 1973).

Most patients, even following significant envenomation, do not present for treatment until many hours after the bite, once the initial signs of a necrotic lesion become evident (Gendron, 1990). The most common presenting signs and symptoms include erythema, cellulitis, generalized rash, blister, pain, pruritus, malaise, chills and sweats (Rees *et al*., 1987). The characteristic lesion begins as a blister with surrounding ischaemic discolouration (Wasserman and Anderson, 1983–1984; Hobbs and Harrell, 1989). An erythematous ring may surround this area giving a characteristic 'bulls eye' or 'halo' appearance (Wasserman and Anderson, 1983–1984). The blister subsequently becomes a bluish macule, the centre of which generally sinks below surrounding tissue (Hobbs and Harrell, 1989). Over several days the necrotic lesion may progress, resulting in an area of eschar that sloughs off after 7–14 days. This leaves an area of ulceration from 1 to 30 cm in diameter (Wasserman and Anderson, 1983–1984; Hobbs and Harrell, 1989). Bites in fatty areas of the body tend to become more extensive (Wasserman and Anderson, 1983–1984). It may take weeks to months for this area to heal by secondary intention. A small percentage of patients may develop persistent lesions, which could subsequently progress to the development of pyoderma gangrenosum and pseudoepitheliomatus hyperplasia (Rees *et al*., 1987; Hoover *et al*., 1990). The extent of local bite findings may not correlate with the presence or severity of systemic findings.

Systemic toxicity occurs less commonly and may not develop for 24–72 hours after the bite. Systemic toxic effects may include fever, malaise, arthralgias, myalgias, rash, convulsions, haemolysis, thrombocytopenia, anaemia and DIC (Wasserman and Anderson, 1983–1984; Williams *et al*., 1995). Nephrotoxicity may result as a complication of haemolysis and subsequent haemoglobinuria. Shock without the presence of DIC, possibly due to an endotoxemic-like effect of *Loxosceles* venom, has been reported (Walter *et al*., 1999). Death due to the systemic effects of *Loxosceles* envenomation has occurred.

6.2.2 Management

The treatment of necrotic arachnidism, regardless of the spider involved, should consist of sound local-wound management. This should include thorough cleansing, tetanus prophylaxis as necessary, immobilization, elevation and rest (Wasserman, 1988). Cool compresses may help relieve inflammation and pain (Gendron, 1990). Prophylactic antibiotics generally are not indicated and steroid therapy has not been found to be effective (Wasserman, 1988; Cole *et al*., 1995). Symptomatic relief can be provided with the use of antipruritic, analgesic and antianxiety agents. Other treatments including dapsone, glucocorticoids, diphenhydramine, dermal nitroglycerine and hyperbaric oxygen have been described, but efficacy has not been established (Burton, 1995; King and Rees, 1983; Elston *et al*., 2005; Phillips *et al*., 1995).

Surgical debridement may be needed, but should be delayed until progression of erythema has stopped and eschar margins are defined, usually occurring about one to two weeks after the bite. In cases of systemic involvement, therapy should be directed at specific complications. Platelets and packed red-blood cells may

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be indicated in the presence of thrombocytopenia or anaemia, respectively. Good hydration should be maintained and renal function monitored. Alkalinization of the urine may be considered in the presence of haemoglobinuria or haematuria.

Brown-recluse-spider antivenom has been prepared and has been shown *in vitro* to abolish the dermonecrotic activity of brown-recluse venom (Rees *et al*., 1984). Equine-derived *Loxosceles* antivenom, is available in endemic areas of South America, including Brazil and Peru, for severe dermal and systemic effects of *Loxosceles* envenomation. Results are often disappointing given the delayed presentation and therefore delayed treatment (White *et al*., 1995).

6.3 Hobo Spiders

Hobo spiders, *Tegenaria agrestis*, build their funnel-shaped webs in undisturbed areas. They are found in Europe, west central Asia, British Columbia and areas of the United States, including the Pacific Northwest and Utah (Boyer *et al*., 2007). The components of their venom are not well identified and no necrotic component has been found. The venoms of the European spiders and those in the United States appear to be similar, but no medical problems have been reported following envenomation by the European *T. agrestis* (Binford, 2001; Boyer *et al*., 2007).

6.3.1 Toxic Manifestations

Necrotic arachnidism has been attributed to the Hobo spiders of the Pacific Northwest but often the spider is not identified and further study has been suggested (Vest, 1996; Vetter and Isbister, 2004). Systemic effects are also reported and these include headache, visual changes, hallucinations, weakness and lethargy (Vest, 1996).

6.3.2 Management

Treatment is supportive and includes local wound care with cleaning and debridement as needed and tetanus prophylaxis when indicated.

6.4 Funnel Web Spiders

The clinically significant species *Hadronyche* (or *Atrax*) are found in southeastern Australia, Tasmania, Papua New Guinea and the Solomon Islands (Boyer *et al*., 2007). They live in protected spaces such as silk-lined burrows in the ground or they create shallow, funnel shaped burrows with silk under objects such as rocks or thick vegetation. The venom of these spiders is complex with components that include both high and low-molecular-weight proteins and various acids. The Sydney funnel web spider, *Atrax rorobustus*, is an aggressive spider, which causes widespread neurotransmitter release (Mylecharane *et al*., 1989).

6.4.1 Toxic Manifestations

The clinical result of envenomation includes severe local pain followed by muscle fasciculations, diaphoresis, tachycardia, hypertension, hypotension, agitation and pulmonary oedema (Mylecharane *et al*., 1989; Isbister *et al*., 2005). Although uncommon, death has occurred due to respiratory failure, hypotension or cardiac arrest (Isbister *et al*., 2005).

6.4.2 Management

In addition to local-wound care and tetanus prophylaxis if indicated, treatment is similar to that for Australian snakebite. A compression wrap is placed on the affected extremity and the extremity immobilized. This dressing should only be removed after antivenom administration is started (Isbister, 2006). Antivenom, an IgG product, is produced against *Atrax robustus* and is also effective against the *Hadronyche* spp. It should be reserved for and appears effective in the treatment of severe funnel-web-spider envenomation. The risks of immediate allergic reaction and delayed serum sickness exist but appear to be infrequent (Isbister *et al*., 2005).

6.5 Banana Spiders

Phoneutria spiders of South America are large, nocturnal spiders. *Phoneutria nigriventer* is found in southern Brazil, Argentina and Uruguay. Other lesser-known species are found in Bolivia and Columbia (Boyer *et al*., 2007). Spiders of this genus are aggressive hunters. Their venom contains a mixture of histamine, serotonin, amino acids, hyaluronidase and other peptides (Costa *et al*., 2003). The venom effect is on both the central and peripheral nervous systems (Costa *et al*., 2003).

6.5.1 Toxic Manifestations

Most envenomations by *Phoneutria* are not significant. However, in some cases, severe local pain that radiates proximately occurs. Following this, diaphoresis, salivation, vomiting, priapism, hypothermia, hypertension, tachycardia and death, usually due to respiratory muscle paralysis, may occur (Lucas, 1988).

6.5.2 Management

Little information is available about the treatment of *Phoneutria* envenomation. Cleansing the wound and tetanus prophylaxis, when indicated, should be

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

performed. When pain is present, injecting a local anaesthetic near the bite site often provides relief (Lucas, 1988; White *et al*., 1995). The use of opioid analgesics may potentiate the venom-induced respiratory compromise and suggestions against their use, in the setting of systemic toxicity, have been made (Boyer *et al*., 2007).

Monovalent and polyvalent antivenoms, active against *Phoneutria* species, are available in Brazil. Given the risks of immediate and delayed hypersensitivity reactions, their use should be reserved for cases of severe envenomation.

An ELISA has been developed for rapid detection of venom antigens, but is not readily available (Chávez-Olórtegui *et al*., 2001).

6.6 Tarantulas

Tarantulas belong to the Theraphosidae family and suborder Mygalomorphae. About 800 species have been described worldwide on all continents, with the greatest number in tropical regions. They live in burrows with trip-line threads. The venoms' multiple constituents vary and include hyaluronidase, nucleotides, polyamines and proteins, depending on species. Some genera, including *Haplopelma*, *Lasiodora*, *Grammostola*, *Acanthoscurria* and *Brachypelma*, located in the western hemisphere, are unique in that they have urticating hairs. When threatened, these spiders send these specialized hairs, located on their tarsi (feet), towards a victim by rubbing the hind legs across the dorsal abdomen.

6.6.1 Toxic Manifestations

Most tarantula bites cause mild local symptoms such as immediate pain and redness. Some cause more severe pain, swelling, numbness, lymphangitis, weakness and emesis. No deaths have been reported due to envenomation. The urticating hairs irritate skin and mucous membranes. These barbed hairs can penetrate human skin causing oedematous, pruritic papules; itching may persist for weeks. Ophthalmic complications such as keratoconjunctivitis, and ophthalmia nodosa have been reported (Belyea *et al*., 1998).

6.6.2 Management

Standard wound care, oral analgesics, and, when indicated, tetanus prophylaxis is the treatment for tarantula envenomation. Removal of urticating hairs can be achieved by repeated use of sticky tape and irrigation with water. Oral antihistamines and oral corticosteroids may be of benefit.

7 SCORPIONS

True scorpions are arachnids of the order Scorpionida. It is estimated that up to 1400 species are distributed worldwide, only a few of which are of significant medical importance (Hutt and Houghton, 1998; Lucas and Meier, 1995). Most of these are in the Buthidae family. One, however, belongs to the Scorpionidae family (Radmanesh, 1990; Bush, 2007). Scorpions primarily inhabit deserts and semi-arid regions. While scorpions are native to certain locales, it is important to recognize that they may be inadvertently transported in luggage or other goods to distant areas (Trestrail, 1981).

In the United States, the most significant of all the scorpions is *Centruroides sculpturatus* (bark scorpion), which is found primarily in Arizona, but also inhabits areas within New Mexico, California, Texas and Nevada. *Centruroides exilicauda* is found in Mexico (Likes *et al*., 1984; Curry *et al*., 1983–1984; Bush, 2007). A number of other scorpions that can produce significant envenomation may be found in Central America, South America, the Caribbean, Asia, Africa, India and the Middle East (Banner, 1989; Bush, 2007; Lucas and Meier, 1995).

Scorpions are nocturnal and take shelter during the day under rocks, piles of debris or may hide inside houses in clothing or shoes. The bark scorpion notoriously shelters under the loose bark of trees, and in crevices of dead trees or logs (Likes *et al*., 1984). Scorpions feed primarily on insects, spiders and occasionally on other scorpions (Banner, 1989).

Scorpions have a hard exoskeleton and three primary body parts: the cephalothorax, to which are attached a pair of pincers; the abdomen, which has four pairs of legs; and the tail, which is segmented and ends in a telson which contains the stinging apparatus. The telson contains two venom glands that lead via independent ducts to the stinger. The scorpion uses its pincers to grab its prey and then arches its tail over its body and head to inject venom. Likewise, the scorpion may grab the skin of humans and sting, sometimes repeatedly, in self-defense.

7.1 Toxic Manifestations

The venom of scorpions is primarily neurotoxic. This property appears to result from its effects on voltage-dependent ion channels. The best studied of these are sodium channels. The activation and inactivation of sodium channels ultimately results in the release of catecholamines and acetylcholine (Wang and Strichartz, 1983; Banner, 1989). Other venom fractions exhibit enzymatic, anticholinesterase, coagulopathic, haemolytic, cardiotoxic and pancreatotoxic properties (Banner, 1989). The venom of one genus, *Hemiscorpion lepturus*, belonging to the Scorpionidae family, also has cytotoxic properties (Bush, 2007; Radmanesh, 1990).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Most envenomations occur on the extremities. Adults are most commonly stung, however, children are more likely to develop serious toxicity (Curry *et al*., 1983–1984; Likes *et al*., 1984; Berg and Tarantino, 1991). The sting of *Centruroides* causes local pain, numbness, hyperaesthesia, salivation, agitation, wheezing, tachycardia, hypertension and muscle spasms (Likes *et al*., 1984). Usually, there are no visible findings at the site of envenomation. In severe cases, cranial nerve and somatic motor abnormalities, such as eye movement disorders, blurred vision, tongue fasciculations, difficulty swallowing and jerking of the extremities, may develop (Curry *et al*., 1983–1984). Respiratory failure, pulmonary oedema, multiorgan failure and rhabdomyolysis have been described in severely envenomated children (Berg and Tarantino, 1991).

Tityus scorpions are of significant importance in South America, Central America and the Caribbean. Clinical manifestations are similar to those produced by other scorpions and result from excess neurotransmitter release from the sympathetic and parasympathetic nerve endings and adrenal medulla. Severe envenomation may result in cardiocirculatory failure and pulmonary oedema (Hering *et al*., 1993). *Tityus* scorpion envenomation may also produce significant local pain and erythema. The *Tityus trinitatis* species has also been reported to produce pancreatitis (Bartholomew, 1970).

In South Africa the most important genera of scorpions include *Parabuthus* and *Bothotus.* These scorpions most commonly sting their victims, however, certain species of *Parabuthus* are also capable of squirting venom for up to 1 m (Newlands, 1978). If the venom enters the eye or an open wound it can cause toxicity comparable to that of the spitting cobra. Local effects following envenomation by these South African scorpions includes local burning and possibly swelling. Systemic toxicity may include muscle contractions, convulsions, perspiration, salivation, tachycardia, arrhythmias and irregular respirations (Newlands, 1978). Death may result from respiratory or cardiac failure.

Red scorpion (*Mesobuthus tamulus*) envenomation in India can cause severe toxicity and death. Excessive release of catecholamines can result in myocardial damage, arrhythmias, cardiac failure and pulmonary oedema (Alagesan *et al*., 1977; Rajarajeswari *et al*., 1979; Bawaskar, 1982). Other reported manifestations in both fatal and nonfatal cases include profuse sweating, mydriasis, vomiting and priapism (Bawaskar, 1982).

The yellow scorpion (*Leiurus quinquestriatus*), as well as *Androctonus* and *Buthus* species, inhabit the Middle East and northern Africa. The yellow scorpion also causes excessive release of catecholamines, which can result in myocardial damage and congestive heart failure (Barzilay *et al*., 1982). Arrhythmias and pulmonary oedema have also been reported (Alagesan *et al*., 1977; Rahav and Weiss, 1990). Pancreatitis is a common complication of envenomation by the yellow scorpion and may explain the abdominal pain and vomiting commonly seen following envenomation (Sofer *et al*., 1991).

Hemiscorpion lepturus inhabits southwest Iran, Iraq, Pakistan and Yemen. The cytoxic venom can cause significant tissue destruction. Usually, a 3–4 mm dark blue macule develops and is surrounded by a red halo on the skin. In some cases, this area becomes indurated and inflamed and eventually skin sloughing may occur leaving a disfiguring wound. In severe cases, central nervous system and cardiovascular involvement may occur (Radmanesh, 1990).

7.2 Management

First aid for scorpion envenomation consists of good local-wound care, including thorough cleansing and tetanus prophylaxis, if necessary. Cold compresses can be applied to help relieve pain and inflammation, if present. Opioid analgesics may be needed to treat severe pain, which can sometimes occur. Systemic manifestations of envenomation can generally be managed conservatively with traditional supportive measures. Atropine sulfate may be indicated to control excessive parasympathetic manifestations, however, this is often not necessary (Banner, 1989). Clinical reports describe successful management of the cardiovascular manifestations of scorpion envenomation with β-blockers, calcium-channel blockers, vasodilators, such as hydralazine, and angiotensin-converting enzyme inhibitors (Gueron *et al*., 1992). The selection of specific therapy should be based on the clinical findings and manifestations of the patient. Prazocin is first-line treatment in India for hypertension and pulmonary oedema caused by the red scorpion, *Mesobuthus tamulus* (Bawaskar and Bawaskar, 1997). Sodium nitroprusside is used for severe cases of pulmonary oedema. However, these treatments have not been rigorously studied. For severe symptoms due to *C. sculpturatus* envenomation, a continuous midazolam infusion, administered in an intensive care unit, has been retrospectively evaluated and felt to be safe for the treatment of these symptoms (Gibly *et al*., 1999). This provided an alternative to previously available antivenom.

Antivenom therapy has an important role in therapy for scorpion envenomations in some parts of the world. Twenty-two types of scorpion antivenom are listed in the American Zoo and Aquarium Association Antivenom Index. Scorpion antivenom is available in Brazil, India, Israel, South Africa, North Africa and Mexico (Banner, 1989; Bush, 2007). In the United States, an IgG antivenom for *C. sculpturatus* had been derived from goat serum, but it was not approved by the Food and Drug Administration and is no longer available (Rachesky *et al*., 1984). It had been used

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

safely and successfully to relieve severe signs and symptoms of envenomation (Gateau *et al*., 1994). An $F(ab')_2$ *Centruroides* antivenom, manufactured by Instituto Bioclon in Mexico, is undergoing clinical trials in the United States. One advantage of this antivenom is less antigenicity when compared with the previous whole IgG antivenom. Experience with antivenom in other parts of the world is also limited and issues relative to safety, efficacy and specificity remain to be resolved (Banner, 1989). Given the risks, which include immediate and delayed hypersensitivity reactions, the use of antivenom should be reserved for symptoms consistent with severe scorpion envenomation.

8 JELLYFISH

The phylum Cnidaria includes the class Scyphozoa, the true jellyfish. The Portuguese man-o'-war, although generally considered a jellyfish is actually a Cnidarian of the class Hydrozoa. Because of marked similarities, however, the Portuguese man-o'-war will be discussed here with the true jellyfish.

The most notable of these species are: the box jellyfish (*Chironex fleckeri*), which inhabits the coastal waters of Australia and the Indo-Pacific region; the Irukandji jellyfish (*Carukia barnesi*), found in the northern coastal waters of Australia; the Portuguese man-o'-war (*Physalia physalis*), located in the more tropical waters of the Atlantic; the sea nettle (*Chrysaora quinquecirrha*), which is endemic to the Chesapeake Bay and the mid-Atlantic coastal waters of the United States; and the Pacific Portuguese man-o'-war (*Physalia utriculus*), which is often responsible for stings off the Hawaiian coast. Multitudes of other jellyfish species are also found in these and other waters throughout the world.

The hanging tentacles of jellyfish contain thousands of stinging organelles known as nematocysts. Within the nematocyst is a coiled thread-like structure coated with venom. In response to pressure or changes in osmolarity, the nematocyst fires its thread, which can penetrate the skin to cause envenomation.

The venom of jellyfish contains various polypeptides and enzymes. It is both toxic and allergenic. In animal studies, the venom has been shown to produce dermonecrosis, vasopermeability, haemolysis, cardiotoxicity, neurotoxicity, musculotoxicity and cytotoxicity (Burnett and Calton, 1987a). A kinin-like fraction has also been identified which is believed to account for pain (Burnett and Calton, 1987a). The exact mechanisms by which most jellyfish produce their toxic syndromes remain to be elucidated.

8.1 Toxic Manifestations

The most common manifestations from Cnidaria envenomation are local toxic effects. Severe systemic and allergic reactions also may occur. The severity of envenomation is dependent on a number of factors, including: the species of jellyfish; the extent and duration of contact with tentacles; the resultant number of fired nematocysts; the amount of venom available in the nematocyst at the time of firing; the thickness of the skin at the site of the sting; and the size, age and underlying health of the victim (Burnett *et al*., 1987a; Lumley *et al*., 1988).

Dermal contact with jellyfish tentacles typically results in linear, urticarial and painful eruptions, which result from the direct toxic effects of the venom (Burnett and Calton, 1987a). The sting of the Portuguese man-o'-war is generally considered more painful than that of the sea nettle and the local pain from envenomation by the box jellyfish can be excruciating (Burnett *et al*., 1987a). The resultant lesions produced by jellyfish envenomation may be vesicular, haemorrhagic, necrotizing or ulcerative (Burnett *et al*., 1987a). Subacute or chronic reactions may include localized hyperhidrosis, desquamation, lymphadenopathy, angioedema, urticaria, keloid formation, hyper- or hypopigmentation, local fat atrophy, contractions, vasospasm, gangrene and nerve damage (Burnett *et al*., 1987a; Burnett and Calton, 1987b). Envenomation by the small carybdeid jellyfish *Carukia barnesi*, on the other hand, may result in a relatively minor initial sting followed by the delayed onset of a potentially severe systemic reaction (Little *et al*., 2003).

An allergic response may contribute to the local effects (Burnett *et al*., 1983). In fact, a large local reaction comparable to that seen with hymenoptera stings has been described (Burnett and Calton, 1987a). Delayed, persistent or recurrent eruptions at the site of the initial sting and at distant sites have also been reported (Burnett *et al*., 1983; 1987b; O'Donnell and Tan, 1993). It has been postulated that an antigen depot must exist for this to occur. There is also evidence that individuals may crossreact with different animals of this phylum (Burnett *et al*., 1987b). The potential for an anaphylactic reaction must be considered.

Jellyfish stings to the cornea cause intense pain, tearing and photophobia. The injuries are typically self-limited without long-term sequelae. Unusually severe reactions consisting of iritis, mydriasis, loss of accommodation and increased intraocular pressure have been reported (Glasser *et al*., 1992).

Jellyfish envenomation may result in severe systemic toxic reactions and even death. The most common systemic toxic effects include headache, nausea, vomiting, malaise, weakness, perspiration and lacrimation (Burnett *et al*., 1987a). More severe manifestations include hypotension, cardiac conduction disturbances, arrhythmias, respiratory depression, pulmonary oedema and cardiovascular collapse. Irukandji syndrome,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

resulting from the stings of the Irukandji jellyfish (*Carukia barnesi)* may include the delayed onset (30 minutes) of severe backache, muscle pains, chest and abdominal pain, nausea and vomiting, headache and sweating (Little *et al*., 2003). Patients are often hypertensive on presentation. Pulmonary oedema is also a potential complication.

Death from jellyfish envenomation may result from either allergic or toxic mechanisms. The box jellyfish is the most toxic of all marine animals, and has been implicated in most jellyfish-related fatalities. It is not clear whether death results from cardiotoxicity, respiratory failure or both (Lumley *et al*., 1988; Stein *et al*., 1989). The precise aetiology, in fact, may be dose dependent (Lumley *et al*., 1988).

8.2 Management

Victims of jellyfish envenomation should be kept quiet and the affected limb should be immobilized, because muscle activity may increase the firing of nematocysts. Compression bandages, which are used to impede lymphatic flow following snakebite, have been shown to cause the mechanical expression of additional venom from discharged nematocysts and should be avoided (Pereira *et al*., 2000). The exposed area should be rinsed with seawater. Fresh water is contraindicated, as this too will increase nematocyst firing due to the osmotic change.

The next step is to inactivate the nematocysts. For most species this can be accomplished by flooding the area with household vinegar (5% acetic acid). Vinegar should be applied to a small test area first, since this may aggravate some jellyfish stings by causing nematocysts to fire. Nematocysts can then be removed from the skin by scraping with a blunt edged object such as a seashell, credit card or by shaving with a razor.

Application of a cold pack has traditionally been recommended to help relieve mild to moderate pain (Exton *et al*., 1989). However, hot water (45 °C for 20 minutes) immersion of the affected part has recently been shown to be significantly more effective than ice packs following Portuguese man-o'-war stings (Loten *et al*., 2006). In addition, the pain did not recur, suggesting that hot water immersion deactivates the venom. This theory is supported by data showing that the lethality of *Chironex fleckeri* venom is reduced by exposing the venom to temperatures above 39 °C (Carrette *et al*., 2002). The extent to which this treatment will prove effective for other species of jellyfish remains to be determined. Topical anaesthetics or steroid creams, as well as oral analgesics may benefit some patients. Hyperpigmentation can be treated with a bleaching agent such as topical hydroquinone (Kokolu and Burnett, 1990).

Topical corticosteroids and cycloplegics are recommended as initial treatment for corneal jellyfish stings (Glasser *et al*., 1992). Topical or systemic therapy for increased intraocular pressure should be administered as needed.

Systemic manifestations are managed with traditional supportive measures. The definitive treatment of box jellyfish envenomation is a specific antivenom from the Commonwealth Serum Laboratory in Australia (Holmes, 1996). The calcium-channel antagonist verapamil hydrochloride has been shown to inhibit the action of box jellyfish cardiotoxin and prolong survival in mice (Burnett and Calton, 1983). However, this mode of therapy has become controversial, as more recent data from an investigation using mechanically ventilated piglets demonstrated that verapamil actually exacerbated cardiovascular collapse and increased mortality from box jellyfish venom (Tibballs *et al*., 1998).

Opiate analgesics such as morphine are generally required to treat the intense pain associated with Irukandji syndrome. Early experience with parenteral magnesium sulfate for the management of pain and hypertension associated with Irukandji syndrome is favourable, however, further study is needed before it can be recommended (Corkeron *et al*., 2004).

Antihistamines may be useful if there is evidence of an allergic response to the venom. Anaphylactic reactions should be managed accordingly. In the event of recurrent dermal eruptions, a tapering dose of a corticosteroid may be employed.

In addition to the Portuguese man-o'-war, another important hydrozoan is fire coral. The fire coral, while not a true coral, is so named because of its marked resemblance to these species. Polyps, which contain nematocysts, protrude through pores of its calcareous skeleton. It typically produces only mild dermatitis and burning discomfort (Kizer, 1983–1984). The class Anthozoa includes the sea anemones, which also contain modified nematocysts capable of inflicting stings and local effects as described for other cnidarians.

9 STINGRAYS

Another important costal hazard is the stingray. Approximately 50 marine species and 20 freshwater species have been described (Barbaro *et al*., 2007; Haddad *et al*., 2004). These cartilaginous fish are often found partially buried in the sand and are a significant hazard to beachcombers and to those who swim or play in shallow water. Although normally very docile, if they are stepped on or are otherwise abruptly disturbed, stingrays will lash their tails forward and sting with a spine located near the base of the tail. Some species of stingray contain more than one spine and are capable of inflicting multiple simultaneous stings (Grainger, 1987).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

A venom-containing integumentary sheath covers the stinging spine(s) of stingrays. As the spine enters the victim this sheath may rupture, resulting in the release of venom into the wound. The spines of stingrays vary by species and may range from 2.5 to 12 cm in length (Grainger, 1985). The spine is curved and serrated, enabling it to inflict significant trauma in addition to envenoming the victim. Lethal injury can result if the stinging spine penetrates a vital organ.

9.1 Toxic Manifestations

Most stings are to the lower extremities (Russell *et al*., 1958; Clark *et al*., 2007). The upper extremities, abdomen or thorax may be involved due to careless handling or under extraordinary circumstances. The stingray's venom consists of a heat-labile protein that causes intense pain at the site of the sting, which is out of proportion to the physical trauma. In the event that the wound is not characteristically painful and other toxic manifestations do not occur, it is likely that the integumentary sheath had already been lost or it was not disrupted during the sting.

The venom can produce local tissue necrosis, which complicates the healing process (Fenner *et al*., 1989). Necrosis and inflammation is much more prominent with injuries produced by freshwater stingrays (Barbaro *et al*., 2007; Haddad *et al*., 2004). Freshwater species have been found to have a larger number of secretory cells spread over the entire stinger epidermis, whereas the protein secretory cells in marine species are found only around or inside the ventrolateral grooves (Pedroso *et al*., 2007). The presence of hyaluronidase and other enzymes in the venom of freshwater stingrays may also explain the more severe tissue necrosis caused by these species (Haddad *et al*., 2004; Barbaro *et al*., 2007).

Stingray venom has also been shown in animal models to possess both cardiotoxic and neurotoxic properties (Russell *et al*., 1958). Secondary infection is also possible (Clark *et al*., 2007).

9.2 Management

First aid for stingray envenomation consists of washing the wound with seawater and as soon as possible soaking the site in water which is as hot as the patient can tolerate for 30–90 minutes. This is done to denature the thermolabile venom (Fenner *et al*., 1989; Russell *et al*., 1958). The wound should then be surgically explored to remove any remaining fragments of the sheath or spine. Necrotic tissue should be debrided and an antiseptic should be used to cleanse the wound, which should be left open to heal by natural intention. Tetanus immunization should be updated, if necessary, and prophylactic antibiotics should generally be administered (Fenner *et al*., 1989; Clark *et al*., 2007). Narcotic analgesics may be necessary to control pain. No antivenom is available and systemic manifestations should be managed with traditional symptomatic and supportive care.

10 STINGING FISHES

Other venomous underwater creatures include fresh- and salt-water fishes. Common examples include the lionfish, scorpion fish, stonefish, catfish and weever fish. All these fish sting with venomous spines on their fins. The sting of these fish is much less traumatic than that associated with the stingray, but in other respects their stings are very similar.

Fish stings may result when handling venomous species and by chance encounters in shallow waters. The lionfish is popular with marine aquarists and has been responsible for many stings to the hand and fingers (Kizer *et al*., 1985; Trestrail and Al-Mahasneh, 1989).

10.1 Toxic Manifestations

Fish stings result in an initial sharp stabbing pain when the spine penetrates the skin. In some cases the spine may break free and remain lodged in the wound. Severe pain may ensue, which can radiate to involve the entire extremity. The pain may become excruciating and incapacitating in some cases. Pronounced local swelling occurs commonly, and vesicles may form at the puncture sites (Auerbach *et al*., 1987). The vesicular fluid can itself be harmful and prompt drainage of the fluid is recommended. Delayed onset of Raynaud's phenomenon following a weever fish sting to the finger has been reported (Carducci *et al*., 1996).

Systemic manifestations may occur with significant envenomation resulting from multiple stings, or single stings from certain species such as the stonefish. These toxic effects may include nausea, vomiting, diaphoresis, bradycardia or tachycardia, conduction disturbances, hypotension, myocardial ischemia, respiratory distress, pulmonary oedema, muscle tremor, weakness, delirium, convulsions and death (Kizer *et al*., 1985; Ell and Yates, 1989; Lehmann and Hardy, 1993). Delayed onset of systemic manifestations has been reported following lionfish envenomation (Bangh, 1997).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

10.2 Management

As with the stingray, the venom of these fish consists primarily of heat-labile proteins. Accordingly, first-aid treatment should include immersion of the affected site in water as hot as the patient can tolerate for 30–90 minutes. Afterwards the site should be thoroughly cleaned and in some cases the wound may need to be surgically explored to remove any remaining spine. Tetanus prophylaxis should be updated as necessary. Prophylactic administration of antibiotics is not routinely necessary. Catfish stings may pose a greater risk of infection and should be managed accordingly (Baack *et al*., 1991).

Failure to promptly treat these inflictions may result in significant tissue necrosis, permanent scaring and physical impairment (Kasdan *et al*., 1987; Mann and Werntz, 1991). Systemic manifestations should be managed with traditional supportive and symptomatic measures. An antivenom is available for the management of stonefish envenomation from CSL Ltd. (Parkville, Victoria, Australia). Stonefish antivenom may be useful in treating severe evenomation by other fish species, based on similarities of symptoms resulting from envenomation by the various fish species, similar pharmacological activity between fish venoms and the observed crossreactivity of stonefish venom with the venom of other species (Church and Hodgson, 2003).

11 POISONOUS FISH AND SHELLFISH

In addition to those animals that cause human poisoning by envenomation, a number of toxic syndromes may result from ingestion of various fish and shellfish. In some cases these animals excrete the toxin, but most concentrate toxins that are produced by dinoflagellates or bacteria. Fish can be categorized based on the tissue that contains the toxin (Halstead, 1964). Ichthyosarcotoxic fish, which cause most poisonings, have toxin in muscle, viscera, skin or mucus. Ichthyootoxic fish produce toxin that is concentrated in the gonads. Ichthyohemotoxic fish, which rarely produce poisoning, have toxin in their blood. There are many common characteristics between these syndromes and some distinct differences (**Table 4**). Diagnosis is primarily based on signs and symptoms and a history of ingesting fish or shellfish.

11.1 Ciguatera Fish Poisoning

Ciguatera intoxication is the most common type of ichthyosarcotoxic fish poisoning. The primary responsible toxins, ciguatoxins, are produced by the dinoflagellate *Gambierdiscus toxicus* (Eastaugh and Shepherd, 1989). Ciguatoxins activate voltage-sensitive sodium channels at nanomolar and picamolar concentrations, resulting in spontaneous firing of a variety of nerve types, giving rise to the neurologic signs and symptoms of intoxication (Lewis, 2006). Ciguatoxin is a heat-stable, lipid-soluble compound that is resistant to gastric acid (Eastaugh and Shepherd, 1989).

Ciguatoxins are concentrated up the food chain; as a result, large fish are most likely to cause human poisoning. Hundreds of fish species have been reported to harbour ciguatoxins; common examples include the barracuda, grouper, snapper, amberjack and sea bass (Halstead, 1964).

Most outbreaks of ciguatera intoxication occur in the Caribbean, South Pacific and Indian Oceans. In the United States, most cases have been reported in Hawaii and Florida (Hughes and Merson, 1976). Ciguatera poisoning, however, has also been associated with ingestion of fish caught from the southeastern United States coastal waters as far north as North Carolina (Morris *et al*., 1990). The ability to readily transport fresh fish great distances may result in ciguatera poisoning in virtually any geographic region.

11.1.1 Toxic Manifestations

Ciguatera poisoning is characterized by gastrointestinal, neurological and cardiovascular disturbances. Although signs and symptoms usually develop within six hours, there is considerable variability. Common gastrointestinal effects include diarrhoea, vomiting and abdominal pain (Morris *et al*., 1982). These symptoms generally occur early and resolve within 24 hours. Other initial symptoms may include malaise, and pain and weakness in the lower extremities, as well as pruritus and paraesthesias around the mouth and of the extremities (Hughes and Merson, 1976; Morris *et al*., 1982). A characteristic finding of cold allodynia (dysesthesia when touching cold water or objects) is nearly pathognomic of ciguatera poisoning. This is commonly referred to incorrectly as ‘temperature reversal’ (Isbister and Kiernan, 2005). Neurologic manifestations may persist for weeks or months. Other common findings include rash, dry mouth, metallic taste, myalgias, arthralgia, visual disturbances and a sensation of loose teeth. Bradycardia, hypotension and respiratory paralysis may occur in severe cases (Hughes and Merson, 1976).

11.1.2 Management

Treatment is primarily symptomatic and supportive care. Fluid and electrolyte balance should be maintained. Atropine and intravenous fluids have been effective in the treatment of bradycardia and hypotension. Mannitol was found to dramatically improve neurologic and gastrointestinal toxicity in a group of 24 patients (Palafox *et al*., 1988). Mannitol has also been shown to benefit patients with chronic symptoms, even with delayed administration (Blythe *et al*., 1992; Eastaugh, 1996). It is postulated

Table 4 Characteristics of poisoning by ingestion of marine toxins

Poisoning syndrome	Characteristic symptoms	Toxin	Mechanism of action
Ciguatera fish poisoning	Diarrhoea, abdominal pain, cold allodynia, numbness, paraesthesia, myalgia, arthralgia, headache, pruritis, dizziness, asthenia	Ciguatoxins	Activate sodium channels
Paralytic shellfish poisoning	Paraesthesias, headache, dizziness, nausea, hypersalivation, diaphoresis, weakness, muscle paralysis, respiratory paralysis	Saxitoxins	Block sodium channels
Neurotoxic shellfish poisoning	Nearly identical to ciguatera poisoning, but less severe	Brevitoxins	Activate sodium channels
Amnesic shellfish poisoning	Vomiting, abdominal cramps, diarrhoea, headache, confusion, memory loss	Domoic acid	Excitatory neurotransmitter
Tetrodotoxic fish poisoning	Paraesthesias, nausea, numbness, weakness, ascending paralysis, respiratory impairment, hypotension, bradycardia, (consciousness may be maintained)	Tetrodotoxin	Block sodium channels
Histamine fish poisoning	Urticaria, flushing, hypotension, headache, abdominal cramps, diarrhoea, vomiting, itching	Histamine	Histaminic action
Diarrhetic shellfish poisoning	Nausea, vomiting, diarrhoea, abdominal cramps	Okadaic acid and its analogues	Phosphorylase phosphatase inhibitors

that mannitol may have inactivated the toxin or competitively inhibited its action on the sodium channel (Palafox *et al*., 1988). The possibility that ciguatera may cause oedema in the nervous tissue, which mannitol could reverse, has also been hypothesized (Palafox, 1992). In a recent double-blind randomized trial of mannitol therapy for ciguatera poisoning, however, there was no significant difference between mannitol and normal saline in relieving signs and symptoms (Schnorf *et al*., 2002). The authors postulated that dilution of the toxin or restoration of a volume deficit with normal saline provided therapeutic benefit. The use of mannitol is still a generally accepted practice, but further study is warranted. Gabapentin, an anticonvulsant that has been used successfully to treat neuropathic pain, has recently been shown to also relieve symptoms of ciguatera poisoning (Perez *et al*., 2001).

11.2 Paralytic Shellfish Poisoning

Paralytic shellfish poisoning results from ingestion of contaminated bivalve molluscs, such as clams and oysters. These molluscs concentrate neurotoxins known as saxitoxins, which are produced by a number of dinoflagellates, including those of the *Alexandrium* spp., *Gymnodinium catenatum* and *Pyrodinium bahamense* (Lehane, 2001). The toxin is a water-soluble, heat and acid-stable compound that cannot be destroyed by ordinary cooking (Auerbach and Halstead, 1989). The toxin acts by blocking sodium channels, thereby inhibiting neuromuscular transmission.

11.2.1 Toxic Manifestations

As the name implies, paralytic shellfish poisoning affects primarily the nervous system. The onset of symptoms occurs within 30 minutes of shellfish ingestion (Eastaugh and Shepherd, 1989). Prominent toxic effects include paresthesias of the lips, face and extremities, headache, weakness, dizziness, vertigo and difficulty walking (Hughes and Merson, 1976; Eastaugh and Shepherd, 1989). A sensation of floating has also been described (McCollum *et al*., 1968). In severe cases, muscle paralysis may occur. Death may result due to respiratory arrest if adequate life-support cannot be provided. Some neurologic symptoms such as headaches, memory loss and fatigue may persist for up to two weeks (Rodrigue *et al*., 1990).

11.2.2 Management

The mainstay of therapy is symptomatic and supportive care. Respiratory function should be monitored closely with ventilatory assistance provided as needed.

11.3 Neurotoxic Shellfish Poisoning

A milder intoxication, known as neurotoxic shellfish poisoning, results from ingestion of shellfish contaminated with brevitoxins, produced by the dinoflagellate *Gymnodinium brevis* (Isbister and Kiernan, 2005). The costal waters of western Florida, Texas, North Carolina and New Zealand have been affected by *G. brevis* (Sakamoto *et al*., 1987; Morris *et al*., 1991; Ishida *et al*., 1996). These toxins activate sodium channels, producing

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

a clinical syndrome nearly identical to that produced by ciguatera, but less severe (Daranas *et al*., 2001). Toxic manifestations include nausea, vomiting, diarrhoea and paresthesias. As with ciguatera poisoning, patients may experience cold allodynia or 'temperature reversal' (Sims, 1987; Hughes and Merson, 1976; Isbister and Kiernan, 2005).

11.4 Amnesic Shellfish Poisoning

A unique toxic syndrome has been described that resulted from ingestion of contaminated mussels from Prince Edward Island in Canada (Perl *et al*., 1990). Domoic acid was implicated as the responsible toxin, which was apparently produced by the marine algae *Pseudo-Nitzschia* spp. Domoic acid is an excitatory neurotransmitter structurally similar to glutamic acid and kainic acid (Teitelbaum *et al*., 1990).

The most common acute symptoms of intoxication included nausea, vomiting, abdominal cramps, diarrhoea, headache and memory loss (Perl *et al*., 1990). In severe cases altered mental status, seizures, myoclonus and cardiovascular instability resulted. Death was reported in four cases. The initial widespread neurotoxicity and subsequent chronic residual memory impairment differentiates this syndrome from either paralytic or neurotoxic shellfish poisoning.

Following this outbreak of amnesic shellfish poisoning (ASP) in Canada, an action limit of 20 μg of domoic acid per gram of shellfish was introduced in Canada and subsequently other parts of the world. The thorough study and documentation of this outbreak, and these subsequent action levels, appears to have prevented further large-scale outbreaks of ASP (Jeffery *et al*., 2004).

11.5 Tetrodotoxic Fish Poisoning

Tetrodotoxication is primarily associated with ingestion of the puffer fish and related fish of the order Tetraodontiformes. Other animals may also contain this neurotoxin, for example the Californian newt (*Taricha torosa*), Pacific goby (*Gobius criniger*) and Costa Rican frog (Tibballs, 1988). Two species of gastropod molluscs collected off the southern Taiwan coast have also been implicated in an outbreak of tetrodotoxin poisoning (Yang *et al*., 1995). The bite of the blue-ringed octopus also causes tetrodotoxication due to toxin in the salivary glands (Hwang and Noguchi, 2007).

Tetrodotoxin acts similar to saxitoxin in that it blocks neurotransmission by action on sodium channels (Narahashi, 1972). This results in motor, autonomic and sensory-nerve impairment (Tibballs, 1988). It also has direct action on the medulla, stimulating the chemoreceptor trigger zone and depressing the respiratory centre (Eastaugh and Shepherd, 1989). The type, severity, onset and range of symptoms depend on the amount of toxin ingested (Hwang and Noguchi, 2007).

11.5.1 Toxic Manifestations

Prominent signs and symptoms of intoxication include persistent vomiting, paresthesias, weakness, respiratory impairment, hypotension and bradycardia (Tibballs, 1988; Sims and Ostman, 1986). Hypertension has been reported in patients with pre-existing hypertensive disease (Deng *et al*., 1991; Yang *et al*., 1995). The precise mechanism of the hypertensive response is not understood. Other manifestations may include headache, dilated pupils, salivation, diaphoresis, myalgias, dysarthria, ataxia, muscle fasciculations and seizures (Sims and Ostman, 1986). Severe poisoning rapidly progresses to flaccid paralysis, but consciousness is typically maintained, except in the most severe cases (Isbister and Kiernan, 2005). Death may result in severe cases due to respiratory failure or cardiovascular collapse.

11.5.2 Management

Treatment primarily consists of symptomatic and supportive care. Patients should be admitted for observation until peak effects have occurred and improvement is noted. Paralysed patients should be sedated to minimize psychological stress. Ventilatory assistance may be required in severe cases. Hypotension and bradycardia should be managed with atropine and fluid therapy. Vasopressors, such as dopamine hydrochloride may be required.

11.6 Histamine Fish Poisoning

Histamine fish poisoning (HFP), often referred to as scombroid fish poisoning, is a toxic syndrome that resembles an acute allergic reaction. HFP results from ingestion of spoiled fish that is contaminated with histamine and possibly other toxins. Histamine is formed as a result of bacteria that cause enzymatic decarboxylation of histidine, which is normally present in the flesh of certain fish species (Lerke *et al*., 1978). Fish most commonly involved are those of the families Scombroidae, such as the tuna and mackerel, and Scomberesocidae, such as the saury. Other nonscombroid marine fish such as bluefish, sardines, anchovies and mahi-mahi have also been implicated in outbreaks of HFP (Lehane and Olley, 2000).

Although histamine is an important factor in the pathogenesis of scombroid poisoning, the exact mechanism is still unclear. Histamine has limited activity

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat148

when administered orally, due to rapid metabolism and elimination in the urine (Garrison, 1990). However, markedly elevated urinary histamine concentrations have been measured in symptomatic patients after ingestion of scombrotoxic fish (Morrow *et al*., 1991). This evidence and the effectiveness of antihistamines to relieve symptoms of scombroid intoxication implicate histamine as the causative toxin.

A variety of hypotheses have been put forward to explain the pivotal role of histamine in the pathogenesis of scombroid intoxication, despite the lack of a straightforward dose–response relationship. These include: the toxicity of other biogenic amines, the inhibition of histamine detoxification by histamine potentiators, disruption of the intestinal barrier or the release of endogenous histamine from mast cells by sombroid toxins (Lehane and Olley, 2000). None of these hypotheses has proven totally satisfactory. This is an area that warrants further investigation.

11.6.1 Toxic Manifestations

HFP usually results in a relatively mild, self-limited syndrome, which typically begins within one hour of ingestion and lasts for eight hours or less (Merson *et al*., 1974; Hughes and Merson, 1976). Typical manifestations include nausea, diarrhoea, abdominal cramps, vomiting, throbbing headache, oral blistering or burning sensation, flushing, burning sensation of the skin and urticaria. Tachycardia, palpitations, bronchospasm and respiratory distress may also occur (Merson *et al*., 1974; Hughes and Merson, 1976; Blakesley, 1983).

11.6.2 Management

Treatment is primarily symptomatic and supportive care. Antihistamines, such as diphenhydramine, are the mainstay of therapy. The use of cimetidine in a few cases has been shown to dramatically relieve the signs and symptoms of HFP (Blakesley, 1983; Auerbach, 1990). Bronchodilators may be needed in the event of bronchospasm.

It is important to differentiate between HFP and fish allergy. An incorrect diagnosis of fish allergy will unnecessarily limit the diet of the patient. Considerations include the patient's prior response to ingestion of the implicated fish species and the response in others who consumed the same meal (Taylor *et al*., 1989). The food can be analysed for the presence of histamine, but at this time there are no diagnostic tests that can be performed on the patient (Lerke *et al*., 1978; Taylor *et al*., 1989).

11.7 Diarrhetic Shellfish Poisoning

Several species of the dinoflagellate *Dinophysis* produce okadaic acid and its analogues, dinophysistoxin-1 and dinophysistoxin-2, the primary toxins responsible for diarrhetic shellfish poisoning (DSP) (Daranas *et al*., 2001). DSP is a worldwide public-health problem with documented outbreaks in Japan, Europe, Chile, Thailand, Nova Scotia and New Zealand (Tester, 1994). DSP toxins produce gastroenteritis within 30 minutes to two hours, resulting in diarrhoea, nausea, vomiting and abdominal cramps. These symptoms are self-limiting with recovery occurring within hours to a few days. Treatment should be directed at maintaining fluid and electrolyte balance.

Okadaic acid and some dinophysistoxins are potent protein phosphorylase phosphatase Type 1 and 2A inhibitors, which cause phosphorylation of numerous proteins, resulting in sodium release from intestinal mucosal cells and causing diarrhoea (Sobel and Painter, 2005). These compounds and have also been shown to be potent tumour promoters (Daranas *et al*., 2001). Recently, it has been postulated that the ingestion of shellfish with low levels of DSP toxins is an important risk factor for colorectal cancer (CRC) and is increasing the incidence of CRC in the European Union (Manerio *et al*., 2008).

Other DSP toxins, the yessotoxins and pectenotoxins, do not cause diarrhoea, but more importantly, are hepatotoxic (Daranas *et al*., 2001). The extent to which these or yet other unidentified toxins produce other toxic syndromes remains to be determined.

Poisons of Plant Origin

Deon van der Merwe

CONTENTS

1 INTRODUCTION

We share our world with a vast number of plant species. Species of seed plants alone number around 400 000 (Govaerts, 2001). Plants are adapted to many different environments and growing conditions that, in turn, are related to the production and/or accumulation of a multitude of biologically active compounds, also referred to as phytochemicals, that make it possible for plants to thrive under different environmental and competitive conditions. Examples include compounds produced to deter herbivores of various kinds, from large mammals to insects, compounds to defend against infection by bacteria, fungi and parasites, as well as compounds that increase success in competing for resources against other plants. Some biologically active compounds are accumulated to provide a store of nutrients or to facilitate specialized physiological processes, or may simply reflect the relative abundance of chemicals in the plant's environment. The diversity of biologically active phytochemicals is a valuable resource, both as nutrients and as compounds that have health benefits when consumed in moderate quantities. Many important classes of pharmaceuticals were originally derived from plants, or are extracted directly from plants. Traditional herbal medicines, derived directly from plant tissues or crude extracts, are the mainstay of healthcare in many parts of the world, especially where access to modern healthcare is limited (Kofi, 2005), while persisting to varying degrees in societies with the most advanced healthcare systems (Bent and Ko, 2004).

Since biologically active compounds are so commonly encountered in plants, it is not surprising that some plants, under conditions of sufficient exposure and phytochemical absorption, have the ability to cause toxicity. As with most other toxicants, the dose required to produce toxicity varies tremendously between compounds, routes of exposure and with the susceptibility of the individual.

The relative importance of plant toxicities is illustrated by the fact that human exposures to plants that are perceived as poisonous, and reported to Poison Control Centers in the United States, comprised 2.7% of total reported exposures to toxicants in 2006. This represents over 64 000 incidents (Bronstein *et al*., 2007). The 25 most frequently reported poisonous-plant exposures in the United States from 1987 to 2006 are listed in **Figure 1**. These reports indicate the relative importance of popular, decorative garden and house plants in a predominantly urban, Western society, like the United States. Due to cultivation in nurseries and wide distribution to gardens and homes, where growing conditions can be controlled, exposure to these plants is no longer correlated with their original distributions under natural conditions, and exposures can be expected in almost any urban environment. In societies where naturally occurring, local vegetation is commonly used in traditional medicine and as a food source, the most frequent poisonous-plant exposures are likely to reflect local abundance and use of plants. An ominous development in recent years has been the speed and efficiency of distribution of potentially hazardous food ingredients, which may be contaminated with poisonous plant material (Prakash *et al*., 1999). A recent example is an Australian recall of

vegetarian crackers in January 2008 that were manufactured using cyanogenic glycoside-containing cassava as an ingredient (SADH, 2008). Rapid and massive distribution of processed and poorly recognizable hazardous food ingredients of plant origin presents a difficult challenge.

Fortunately, the majority of poisonous plant exposures do not result in toxicity. Most plant toxins, with some notable exceptions, produce severe toxicity or lethal effects only at relatively high doses, and exposures to highly toxic doses are uncommon under normal conditions. Our interactions with plants are therefore mostly harmless, even when we are exposed to potentially poisonous plants. It is only when exposed to plant species of exceptional toxic potential, or when the route of exposure and dose leads to ample absorption of toxic compounds, that we see toxic effects. This represents a problem in its own right, however, because it may lull us into disregarding as trivial those rare exposures that may lead to severe toxicity or death (Nelson *et al*., 2006). For this reason, it is important that healthcare professionals have a basic knowledge of the most important and harmful poisonous plants.

Correct identification of a poisonous plant may be crucial in the treatment of patients where significant exposure took place and/or the patient is experiencing symptoms of poisoning. One of the common pitfalls when dealing with plant exposures is the incorrect identification of the plant, based on common names and other assumptions made by nonexperts. The identity of a plant should not be based only on a common name, but should at least be consistent with detailed descriptions of the physical characteristics of the plant. Ideally, the plant should be identified by experts, such as botanists familiar with the plant, based on a properly collected and prepared physical example of the plant, or by direct comparison with herbarium specimens. Where timely submission of plant samples to an expert or herbarium is impractical, plant material should be preserved in a plant press or a substitute, such as a large, heavy book. Whenever possible, reproductive parts, including flowers, fruits and seeds should be included, as well as detailed descriptions of the plant's location and growth form. When rapid identification is needed, references on poisonous plants containing detailed descriptions and pictures are available (Frohne and Pfänder, 2005; Nelson *et al*., 2006; Gloster, 2004), and should be consulted when necessary in the absence of expert opinion. Although online sources should be interpreted with caution, searches for plant images using services such as Google Image Search™ often produce multiple images of the most common and important poisonous plants that can be helpful in attempts to rapidly obtain a probable identification based on prominent morphological characteristics. Comprehensive, reliable online sources are available that can be consulted for additional information that are useful for identification. Some sources are more relevant to specific parts of the world, such as the United States Department of Agriculture (USDA) Plants Database in North America (USDA, 2008), while others have a global coverage, such as the electronic Plant Information Centre (Royal Botanic Gardens, Kew, 2008). Poison centres and other poisoning information services are readily available in many parts of the world, and are often able to give sound advice on plant identification, plant poisoning diagnoses and case management.

The information that follows below is mostly limited to poisons of plant origin that are considered to be important because they are associated with common or serious toxicity. However, discussions of some plants are included that are only mildly toxic and very rarely cause poisoning, but which are often perceived as harmful by the general public and result in frequent enquiries to Poison Control Centers and other healthcare professionals. Plants are discussed as groups that share specific or closely related toxic compounds or that share specific toxicity syndromes. Descriptions include the most prominent families and/or genera associated with poisoning, the toxic agents and their mechanisms of action, risk factors, toxicity syndrome descriptions and suggested management strategies. Where available, frequently used common names for families and genera are included, but it should be noted that common names are often regional, the same name may be used to describe more than one plant and a specific plant may be known by various names.

Finally, plant poisoning is a dynamic field. The distribution of potentially poisonous plants and plant products change over time as people make use of distant sources of food ingredients, which may contain unfamiliar contaminants, as new species and varieties become popular as decorative plants, and as biologically active plants and plant products, used as traditional medicines or mind-altering drugs in one part of the world, become known and used/abused in other parts of the world where the traditional knowledge of preparation methods, dosages and risks are unknown. New information on active constituents and mechanisms of action often change how we approach diagnoses and treatment. Healthcare professionals need to keep abreast of new plant-poisoning hazards and developments in treatment to be in the best possible position to give sound advice and intervene successfully in cases of plant poisoning.

2 ANTICHOLINERGIC ALKALOIDS

2.1 Plants

Anticholinergic alkaloids are mostly associated with members of the Solanaceae (potato) family, including

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat149
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Atropa spp. (belladonna), *Brugmansia* spp., *Datura* spp. (Jimsonweed), *Hyoscyamus* spp. (henbane), *Solandra* spp. (chalice vine) and *Solanum* spp. (nightshade). These plants are typically forbs and small shrubs found in most habitats around the world. They are also commonly cultivated for use in gardens.

2.2 Toxic Agent and Mechanism

Anticholinergic alkaloids, also known as tropane alkaloids, include atropine, hyoscyamine, hyoscine and scopolamine. All plant parts are toxic, but alkaloid concentrations are especially high in green plant parts and unripe fruit (Knight and Walter, 2001). Alkaloids are resistant to breakdown and may persist as contaminants in foods, even following extensive processing into secondary products (Perharic, 2005; Lee, 2007). The tropane alkaloids competitively antagonize the effects of acetylcholine on muscarinic receptors in the central and parasympathetic nervous systems.

2.3 Risk Factors

One of the most common sources of anticholinergic alkaloid poisoning is the abuse of *Datura* spp. (Jimsonweed) seeds as mind-altering drugs, either by ingestion or inhalation (Guharoy and Barajas, 1991; Soneral and Connor, 2005). Variations in the alkaloid levels of individual plants make its use as a mind-altering drug hazardous, even for experienced users. Poisoning may also result from mistaken identification when gathering 'edible' wild leafy greens and berries. This is of particular concern where wild leafy greens are common in the diet. Indiscriminate harvesting and consumption of apparently edible berries, such as those on *Atropa belladonna* is associated with poisoning, mostly in children, where these plants are cultivated as garden subjects. Contaminated flour has been associated with mass outbreaks of poisoning (Perharic, 2005). *Atropa belladonna* poisoning is one of only a handful of plant poisonings where secondary poisoning has been described from eating the meat of animals that grazed on the plant, or from ingesting contaminated honey (Lee, 2007).

2.4 Toxicity Syndrome

Suppression of the parasympathetic nervous system leads to an apparent overexpression of the sympathetic system. Classically, the clinical syndrome has been described as 'blind as a bat', due to ciliary body and iris muscle paralysis that leads to mydriasis and cycloplegia, 'dry as a bone', due to suppression of salivation resulting in a profound dry mouth sensation, 'red as a beet', due to flushing of the skin, 'hot as a hare', due to effects on temperature regulation leading to hyperthermia, and 'mad as a hen', due to central nervous system effects that include visual hallucinations, agitation, impaired judgment and risk-taking behaviour, delirium, seizures and coma (Spina and Taddei, 2007; Lee, 2007). Death may result from respiratory or cardiac arrest. Signs appear from 30 minutes to four hours following ingestion and may last from several hours to several days.

2.5 Management

Initiate supportive and symptomatic treatment. Sedation with a benzodiazepine may be of benefit. Physostigmine by slow intravenous injection ($1–2\,mg\,kg^{-1}$ in adults; $0.02\,mg\,kg^{-1}$ in children) is an antidote. Note that the duration of alkaloid activity can be longer than the antidote activity and may require repeated administration of the antidote (Nelson *et al*., 2006).

3 CARDIAC GLYCOSIDES

3.1 Plants

Cardiac glycosides are produced by a wide range of flowering plants including both monocotyledons and dicotyledons, with growth forms ranging from bulbs to shrubs and small trees. Plants include members of the Apocynaceae (dogbane) family, including *Acokanthera spp.* (poison arrow plant), *Adenium* spp. (desert rose), *Nerium oleander* (oleander), *Pentalinon luteum* (hammock viper's tail), *Strophanthus* spp. and *Thevetia* spp.; the Asclepiadaceae (milkweed) family, including *Asclepias* spp. (milkweed), *Calotropis* spp. and *Cryptostegia* spp. (rubbervine); the Crassulaceae (orpine) family, including *Cotyledon* spp. (pig's ear), *Kalanchoe* spp. (neverdie) and *Tylecodon* spp.; the Hyacinthaceae (hyacinth) family, including *Bowiea volubilis* (climbing onion), *Urginea/Drimia* spp. (snake's head) and *Ornithogalum* spp. (star of Bethlehem); the Iridaceae (iris) family, including *Homeria* spp. and *Moraea* spp. (tulip); the Liliaceae (lily) family, including *Convallaria* spp. (lily of the valley) and *Scilla/Merwilla* spp. (squill); the Melianthaceae (melianthus) family, including *Melianthus* spp. (honey flower); the Ranunculaceae (buttercup) family, including *Adonis* spp. (pheasant's eye) and *Helleborus* spp. (hellebore); the Santalaceae (sandalwood) family, including *Thesium* spp. (flaxleaf); and the Scrophulariaceae (figwort)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat149
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

family, including *Digitalis* spp. (foxglove). Although most of these species have specific habitat requirements that restrict their distribution under natural conditions, many produce attractive flowers and foliage that make them popular as garden subjects and contribute to their availability all over the world. Examples of commonly cultivated plants grown for their showy flowers include *Digitalis purpurea* (foxglove) and *Ornithogalum umbellatum* (grass lily). *Nerium oleander* (oleander) and *Thevetia peruviana* (yellow oleander) are popular in many parts of the world as a hardy hedge plants.

3.2 Toxic Agent and Mechanism

Glycosides consist of two parts: sugars, referred to as the glycone portion of the molecules, are bonded via glycosidic bonds to nonsugar moieties, referred to as the aglycone portion. The aglycones of cardiac glycosides are steroid derivatives and are responsible for the toxic effects (Kellerman *et al*., 2005). Generally, all plant parts are considered toxic.

Cardiac glycosides inhibit Na^+/K^+-ATPase, which causes intracellular Na^+ accumulation, followed by Ca^{2+} accumulation (McDonough *et al*., 2002). These changes result in increased cardiac muscle inotropy and bradycardia. Increased vagal tone contributes to a slowing of the heart rate. As the dose increases, the heart muscle becomes more excitable and the heart becomes susceptible to dysrhythmias of various types, including frequent premature ventricular beats, bradycardia, paroxysmal atrial tachycardia with block, junctional tachycardia and bidirectional ventricular tachycardia (Ma *et al*., 2001). Na^+/K^+-ATPase inhibition also affects other smooth muscle tissue, such as the vascular system, where vasoconstriction occurs in the atrial and venous systems, and in the digestive tract smooth muscle, where excessive smooth muscle contraction is induced.

3.3 Risk Factors

Cardiac-glycoside-containing plants and extracts are commonly prescribed in traditional medicine for a variety of indications and as tonics, but in particular for the treatment of heart failure. Toxicity often results from the uncontrolled use of these plants as medicines, especially when the users have limited experience and training in the safe use of these potent medicines (McVann *et al*., 1992; Tracqui *et al*., 1997). The common use of cardiac-glycoside-containing plants as garden subjects places people at risk (Cheung *et al*., 1989). Cardiac-glycoside-containing plants are occasionally used to commit murder and suicide (Tracqui *et al*., 1997; Driggers *et al*., 1989).

3.4 Toxicity Syndrome

Plant-associated cardiac-glycoside poisoning closely resembles poisoning due to digitalis overdose (Tracqui *et al*., 1997). The most obvious initial clinical signs of cardiac-glycoside toxicity are abdominal pain, nausea and vomiting. Headache, dizziness, blurred vision and dyschromatopsia (disturbance of colour vision) may also occur. After an initial bradycardia, the pulse becomes rapid and weak. Various heart dysrhythmias are discernable by electrocardiography. Hyperkalaemia may be seen in severely affected patients. Other typical signs associated with severe toxicity include weakness, muscle tremors, paresis, dyspnoea, cardiogenic shock, convulsions and coma.

3.5 Management

Consider consulting a Poison Control Center. Prompt administration of activated charcoal is of benefit, but standard decontamination and supportive treatment on its own is often not adequate in severe cases involving life-threatening dysrhythmias, cardiogenic shock and hyperkalaemia (Eddleston, 2003). Digoxin-specific antibody fragments (Digibind™) are available as an antidote. Although it was developed specifically for digoxin, there is sufficient crossreaction with other cardiac glycosides for the drug to be useful in the treatment of cardiac-glycoside poisoning in general (McMillin *et al*., 2002). The initial dose in adults and children should be 400 mg intravenously. Additional doses may be needed, depending on the response to treatment.

4 CYANOGENIC GLYCOSIDES

4.1 Plants

Cyanogenic glycosides are produced by a wide variety of flowering plants as a means of defence against herbivores (Gleadow and Woodrow, 2002). Toxic species include members of the Caprifoliaceae (honeysuckle) family, including *Sambucus* spp. (elderberry); the Caricaceae (papaya) family, including *Carica papaya* (papaya); the Euphorbiaceae (spurge) family, including *Manihot esculenta* (cassava); the Fabaceae (legumes), including *Lotus* spp. (trefoil), *Phaseolus* spp. (tepary bean) and *Trifolium* spp. (clover); the Hydrangeaceae (hydrangea) family, including *Hydrangea* spp.; the Juncaginaceae

DOI: 10.1002/9780470744307.gat149
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(arrow-grass) family, including *Triglochin* spp. (arrow-grass); the Poaceae (grasses), including *Sorghum* spp. and *Zea mays* (maize/corn) and the Rosaceae (rose) family, including *Eriobotrya japonica* (loquat), *Malus* spp. (crab apple) and *Prunus* spp. (plums, prunes, cherries, peaches, apricots and almonds).

4.2 Toxic Agent and Mechanism

Cyanogenic glycosides may be found in most plant parts in affected plant species, but concentrations tend to be highest in the seeds of the Rosaceae, while high concentrations in the grasses are mostly found in young or resprouting plants. Intact cyanogenic glycosides are not toxic. Toxicity occurs when cyanide in the form of HCN (hydrocyanic acid), also referred to as prussic acid, is released from its glycoside form by a process of hydrolyses. Enzymes that are able to hydrolyse cyanogenic glycosides are often present in plant tissues, but are sequestered in different cell compartments and only cause HCN release when plant tissues are damaged. HCN release can also be facilitated by digestive-tract enzymes (Knight and Walter, 2001). This may be a rapid or slow process depending on conditions in the digestive tract. After release, HCN is readily absorbed. It inhibits cytochrome oxidase, which blocks cellular respiration and causes tissue anoxia. Rapid death may result from the failure of organs that are dependent on continuous and relatively efficient oxygen-dependent energy production, such as the brain and the heart. Exposure to toxic doses during pregnancy may lead to teratogenic effects (Frakes *et al*., 1985).

4.3 Risk Factors

The cyanogenic glycoside concentrations in certain plant species, especially the grasses such as *Sorghum halepense* (Johnsongrass) and other sorghum species vary depending on their growth stage. Grazing animals are often at risk if the plants are consumed during their early growth phase, or as plants regrow after a severe frost or mowing, when cyanogenic glycoside concentrations are high (Knight and Walter, 2001). High soil nitrogen content tends to promote cyanogenic glycoside accumulation in plant tissues. The flesh of ripe fruits often does not contain cyanogenic glycosides, even if concentrations in the seeds or leaves are hazardous. Human exposure to toxic levels of cyanogenic glycosides is comparatively rare because people typically do not consume large quantities of those plant parts that are hazardous. Food preparation, such as cooking, further reduces the risk. An exception to this general rule is poisoning by varieties of *Manihot esculenta* (cassava), which accumulate high cyanogenic glycoside concentrations. Cassava poisoning is a common occurrence in regions where home-prepared cassava roots and leaves are a staple food, such as rural areas of central Africa. The cyanogenic glycoside content of cassava can be reduced to safe levels by adequate preparation, which should include extended soaking in water and thorough cooking. When these steps are omitted or deficient, poisoning may occur (Ngudi *et al*., 2003; Tylleskar *et al*., 1992). Another occasional source of human poisoning is the ingestion of large quantities of raw apple seeds or pit kernels from *Prunus* species such as *Prunus armeniaca* (apricot). Note that the amount of seeds or kernels that people consume as part of a normal diet is usually not hazardous. Poisoning typically occurs only when unusually large amounts are ingested.

4.4 Toxicity Syndrome

Cyanogenic glycoside toxicity is often delayed for a variable length of time, up to several hours, because of the time required for glycoside breakdown and cyanide release in the digestive tract. Typical early signs of acute toxicity are nausea, vomiting and abdominal pain. The patient may sweat and complain of headache, disorientation, vertigo, faintness or a burning sensation in the mouth and throat. Signs of hypoxia appear and may include exercise intolerance, tachypnoea and tachycardia. The lack of oxygen uptake in tissues leads to oxygen buildup in venous blood, causing venous blood to become highly oxygenated, similar to arterial blood, and bright red in colour. Compensatory anaerobic energy production leads to lactic acidosis. Signs of hypoxia become progressively worse. Terminal signs may include convulsions, respiratory depression, bradycardia, cardiogenic shock, lung oedema, paralysis and coma (Yen *et al*., 1995; Holland and Kozlowski, 1986).

4.5 Management

When poisoning is suspected, the rapid progression of cyanide poisoning makes it imperative that treatment with an appropriate antidote should be given promptly, even when confirmatory tests are unavailable, as antidote therapy is often essential to survival. The antidote of choice in human poisoning is hydrocobalamin, which is typically packaged in concentrated, stable lyophilized powder form and must be reconstituted before use using suitable diluents such as 0.9% NaCl, lactated Ringer's solution or 5% dextrose solution. The adult dose is 5 g hydrocobalamin by slow intravenous injection (over 15 minutes). If needed, the dose may be repeated for a total of 10 g. Alternative treatments include breaking

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat149
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

a nitrite pearl and holding it under the patient's nose for 30 seconds each minute. Sodium nitrite may be administered intravenously (the adult dose is 10 ml of a 3% solution). This should be followed by intravenous administration of sodium thiosulfate (the adult dose is 50 ml of a 25% solution). Although it has been used successfully (Mannaioni *et al*., 2002), the safety of combining hydrocobalamin with other treatments has not been established. Antidote therapy should be combined with appropriate supportive care.

5 PLANT-INDUCED DERMATITIS

5.1 Plants

Skin effects due to contact with plants are commonly reported to poison-control centers (Nelson *et al*., 2006). Among the 25 most reported toxic-plant exposures in the United States (**Figure 1**), eight are associated with dermal toxicity including *Crassula* spp. (jade plant), *Toxicodendron* spp. (poison oak/poison ivy), *Schefflera* spp. (umbrella tree), *Ficus* spp. (fig), *Chrysanthemum morifolium* (florist's daisy), *Hedera helix* (English ivy), *Eucalyptus* spp. (blue gum) and *Taraxacum officinale* (dandelion). Many, if not most, plants have the potential to induce allergic contact dermatitis, usually following repeated exposure. A listing of all the plants that have been associated with contact dermatitis is, therefore, impractical and it is prudent to assume that any plant has the potential to induce allergic contact dermatitis in susceptible individuals.

5.2 Toxic Agent and Mechanism

Phytotoxins may affect the skin through a variety of mechanisms, including physicochemical disruption of specific cellular processes, mechanical and/or chemical irritation, allergies and phototoxicities. Although the aetiologies differ, the skin's response to acute insult from plant toxins or mechanical injury from plant structures is most often an inflammatory response of varying severity and extent. Reactions to allergens, such as urushiol found in *Toxicodendron* spp. and a wide variety of macromolecules found on or in the tissues of most plants, are variable, depending on the degree, frequency and duration of exposure, and on the allergenic potential of the molecule(s) involved. Persistence of the allergen in the skin may also be an important factor. Type IV hypersensitivity, also referred to as allergic contact dermatitis, is the most common allergic reaction in the skin, but other types of hypersensitivities are possible (Nelson *et al*., 2006). Exposure to light is a prerequisite for the development of dermatitis associated with phototoxicity (Greeson *et al*., 2001), because it depends on the absorption of photons by phototoxic compounds, and the release of the absorbed energy to surrounding tissues in the form of higher-energy particles. Mechanical damage to skin resulting from barbs, thorns, calcium oxalate raphides, commonly found in species of the Araceae family, or stinging trichomes, such as those found in nettles (*Urtica* spp.), is often accompanied by the deposition of irritant compounds that may intensify pain and induce pruritis (Nelson *et al*., 2006).

5.3 Risk Factors

Most cases of plant-associated dermatitis are due to allergic reactions and require prior sensitization in susceptible individuals. Plants, however, vary widely in their potential to induce allergic reactions, as well as the severity and duration of reactions. *Toxicodendron* spp., for example, have a relatively high potential for inducing severe reactions with 50–70% of the general population being susceptible (Tanner, 2000), while reactions to other commonly implicated plants, such as species of *Taraxacum, Eucalyptus* and *Hedera* are usually less severe. There is tremendous variability between individuals' general susceptibility to plant allergies and the plants to which they react, which is likely to be influenced by inheritable traits. Minor exposures, such as lightly brushing against leaves, may induce a severe reaction to *Toxicodendron* spp., while repeated, intimate exposure is often required for reactions to be induced by other species, such as *Chrysanthemum morifolium*, which typically induce allergies in nursery workers who handle the plant. Even with intimate, repeated exposure to unprotected skin, however, the incidence of sensitivity is much lower compared to Toxicodendron sensitivity and appears to be variable between different population groups, being less common in Asian populations (Tanner, 2000). The part of the plant and its cooked or raw status can make a difference. Some individuals, for example, experience dermatitis if they handle uncooked, peeled potatoes, while cooked potatoes or other potato plant parts do not induce dermatitis. The importance of repeated exposure is also demonstrated by the increased incidence of sensitivity to onions in some subpopulations. Onions more commonly cause chronic hand eczema in older, frequently exposed women who handle onions during food preparation, compared to other sections of the population (Cabanillas *et al*., 2006). Phototoxic effects may occur with repeated, high-dose use of herbal remedies containing St. John's wort (*Hypericum perforatum*) (Jacobson *et al*., 2001). Ironically, though, topical St. John's wort treatment has also been shown to be of benefit in the treatment of atopic dermatitis (Schempp *et al*., 2003).

5.4 Toxicity Syndrome

The symptoms resulting from different aetiologies most commonly presents as an inflammatory response of varying severity. The overlap between the symptoms associated with various aetiologies makes the differentiation between specific aetiologies, based on lesions and symptoms, challenging. Allergic reactions to plants that result in dermal inflammation is arguably the most common aetiology of plant-associated contact dermatitis, because many different plant species have the potential to induce allergies in susceptible individuals; and because some of the plants that have a high potential for inducing contact allergies, such as *Toxicodendron* spp. are widespread and hard to avoid when entering habitats where the plants are common. Exposures in sensitive individuals typically presents as a rash or eczema on exposed skin, which may include redness, itching, swelling, blistering and pain. The development of lesions related to Type IV hypersensitivity may take hours to days to fully develop, and symptoms may persist for several days up to two weeks. Secondary infection may result in the formation of pustules and purulent exudates. The severity of lesions associated with allergic contact dermatitis is often not proportional to the level of exposure, but rather depends on the level of sensitization in the individual. Pain and dermatitis due to plant-derived chemical and/or mechanical irritants, from exposures to plants such as stinging nettles and capsicum preparations, do not require prior exposure and sensitization. Reactions to these plants and plant-derived products are rapid and the severity is proportional to the level of exposure. Since exposure to light is a prerequisite for phototoxic effects, only sunlight-exposed skin is typically affected. Lesions tend to be more severe on skin surfaces that receive more light exposure, such as the face and hands, and light-skinned individuals are more susceptible. In some instances, photosensitivity may be linked to plant-associated allergic contact dermatitis, a situation that is more commonly encountered in older individuals (Frain-Bell and Johnson, 1979).

5.5 Management

Avoidance is the simplest and most effective approach to allergic dermatitis-inducing plants. Species that are commonly implicated in serious contact dermatitis, such as *Toxicodendron* spp., should be eradicated from areas where contact is expected to be frequent and difficult to avoid. Effective herbicides, registered for this purpose, are available. Hand-pulling by nonsusceptible individuals and repeated grazing by goats and sheep may also be effective. Burning is not an effective control method and urushiol may be carried in smoke, potentially leading to skin and respiratory reactions in smoke-exposed individuals (Nelson, 2000). If avoidance or eradication is not practical, physical protection of exposed skin using clothing or barrier creams is necessary. Barrier creams containing 5% quaternium-18 bentonite are effective in preventing contact dermatitis if properly applied (Scott *et al*., 2002). Sensitive individuals should also be alerted to the fact that second-hand exposure via pets or clothing may be hazardous. Some individuals are allergic to multiple plant species, making identification of particular species that must be avoided challenging. In such cases, attempts should be made to associate the appearance of symptoms with visits to specific areas or habitats. If associations can be made, identified areas or habitats should be avoided or appropriate precautions taken.

Early skin decontamination may be effective in preventing or reducing the symptoms of exposure to plant-associated contact allergens. This can be achieved by gently rinsing the skin with copious amounts of water. The addition of soap or the use of mild solvents, such as isopropyl alcohol, may help in allergen removal from the skin, but care should be taken not to damage the skin surface. Treatment is aimed at symptom alleviation and may involve the use of corticosteroids, analgesics, anti-inflammatory drugs or antihistamines. An important aim in treatment is to prevent itching and scratching, which leads to secondary skin damage and infections. Corticosteroids are the mainstay of the treatment of severe allergic contact dermatitis because they counter lymphocyte proliferation and cytokine production. Topical medications, such as medicated creams and ointments, are preferred if they are effective. Systemic corticosteroids may be needed if topical treatment is ineffective, usually with good results (Mark and Slavin, 2006). Lesions may become infected with bacteria, requiring systemic antibiotic treatment. Pain and dermatitis associated with direct irritants can be controlled with analgesics and anti-inflammatory drugs. If done shortly after exposure, gentle washing with copious amounts of warm, soapy water may be effective in removing irritating substances from the skin. Avoid deep scrubbing that may cause damage to the stratum corneum. Avoidance of sunlight is essential to control symptoms associated with phototoxicity. Additional alleviation of symptoms may be obtained by using analgesics and anti-inflammatory drugs as needed.

6 GASTROINTESTINAL IRRITANTS/STIMULANTS

6.1 Plants

A wide variety of plants affect the gastrointestinal tract (GIT). Commonly implicated genera and their principle toxins include: *Euphorbia* (spurges), containing diterpene esters; *Alocasia*, *Arum*, *Colocasia*, *Philodendron*, *Dieffenbachia*, *Schlefflera*, *Spathiphyllum* and related

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat149
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Araceae genera, as well as *Brassaia* (umbrella tree), *Caryota* (fishtail palm) and *Parthenocissus* (creeper) containing calcium oxalate raphides; *Daphne* (paradise plant) *Senna* and *Wisteria*, containing glycosides; *Phytolacca* (pokeweed), containing triterpenes; and *Ranunculus* (buttercup), containing protoanemonin. Some plants may be associated with GIT upset only when ingested in high quantities or at specific growth stages, while being safe under other conditions. Examples include the ingestion of greening or sprouting potatoes, unripe fruit or large quantities of dried fruit.

6.2 Toxic Agent and Mechanism

The mechanisms of action of most plants that affect the GIT have not been well defined, but can be classified into two broad categories: nonspecific irritant effects and specific receptor activity leading to GIT effects. Irritants are found in many plants and may be associated with specific growth phases or plant parts, such as unripe fruits. Irritants stimulate GIT smooth-muscle contraction directly and/or induce an acute inflammatory response, typically associated with increased fluid secretion into the GIT lumen. Severe irritation may lead to ulceration. calcium oxalate raphides leads to local tissue damage in the upper GIT associated with severe inflammation, enhanced by proinflammatory compounds associated with the raphides. Plants have evolved a variety of specialized strategies for effectively delivering raphides, including the formation of needle-shaped crystals, and pressurized crystal idioblasts that forcibly expel raphides into tissues upon contact (Franceschi and Nakata, 2005). Stimulation of cholinergic receptors appears to be a major specific mechanism of inducing increased GIT smooth-muscle contraction due to plant toxins (Nelson *et al*., 2006). GIT peristaltic and secretory control, however, depends on a complex system of balanced responses and multiple receptor ligands (Grider, 2004), offering many potential toxicity targets.

6.3 Risk Factors

Due to the relatively common occurrence of irritants in plants, indiscriminate ingestion or chewing on unfamiliar plants often leads to GIT upset. This is especially relevant to young children who often chew on indoor plants. Gathering and eating wild plants is a risk when the collectors are unfamiliar with the plants they collect, particularly when plants are gathered in early growth stages before the development of flowers and fruits. Poorly controlled production and use of herbal remedies intended for the treatment of constipation can be hazardous due to lack of consistency in active compound concentrations and dose formulations. Even when herbal remedies are appropriately formulated and produced, popular perceptions of herbal medicines as 'natural, safer' alternatives to other chemical laxatives, occasionally lead to ingestion of large doses that cause severe, long-lasting diarrhoea.

6.4 Toxicity Syndrome

The first signs of GIT irritant exposure are generally nausea and vomiting. Other typical irritant effects include hypersecretion and smooth-muscle contraction, which leads to diarrhoea, and abdominal pain associated with cramping. Severe gastric irritation or ulceration may lead to blood products appearing in the vomitus, which may have a 'coffee-granule' appearance. Diarrhoea can range widely in severity and appearance. Young children are particularly vulnerable to electrolyte loss and dehydration.

6.5 Management

The management of plant poisoning involving gastrointestinal symptoms is nonspecific, and aimed at symptom alleviation and countering the consequences of fluid and electrolyte loss. Vomiting can often be controlled with drugs such as metoclopramide. The treatment of diarrhoea depends on severity and should be aimed at the control of water and electrolyte loss and its replacement. The use of antidiarrhoeal drugs, such as loperamide, is generally not recommended (Nelson *et al*., 2006). Rehydration and electrolyte replacement therapy may include oral rehydration or intravenous fluids, depending on the need. Since GIT upset is often one of the first effects seen in poisoning cases that eventually include systemic toxicity, the potential for the gastrointestinal effects being part of a more widespread, systemic toxicity should always be considered (Nelson *et al*., 2006).

7 ION-CHANNEL ACTIVATORS/INHIBITORS

7.1 Plants

Many members of genera in the Ericaceae (heath) family have effects on ion channels, including *Rhododendron* spp. (azalea), *Kalmia* spp. (laurel), *Lyonia* spp. (staggerbush), *Leucothoe* spp. (doghobble) and *Pieris* spp. (fetterbush). Other affected families are the Ranunculaceae (buttercup) family, including *Aconitum* spp. (monkshood); the Liliaceae (lily) family, including *Zigadenus* spp. (deathcamus), *Schoenocaulon* spp. (feathershank) and *Veratrum* spp. (false hellebore); and the Taxaceae (yew) family, including *Taxus* spp. (yew).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat149
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

7.2 Toxic Agent and Mechanism

Depending on the plant and predominant active compound, various ion channels may be activated or inhibited. One of the most common mechanisms for toxicity is sodium-channel activation, typical of plants in the heath family, containing grayanotoxins. Excessive influx of sodium causes persistent depolarization of neurons and other conductive tissues such as cardiac muscle cells (Nelson *et al*., 2006). Taxine-derived alkaloids, of which several have been identified, are found in *Taxus* spp. (yew) (Wilson *et al*., 2001). Taxines are calcium- and sodium-channel antagonists. Indirect evidence suggests that taxine toxicity is largely attributable to its calcium-channel blocking effects (Wilson *et al*., 2007). Taxine-B induces increased AV (atrioventricular) conduction time and QRS duration in cardiac muscle. Intestinal effects observed in experimental animals included contraction of the duodenum and ileum and inhibition of peristalsis (Wilson *et al*., 2007).

7.3 Risk Factors

Consumption of honey derived from bees harvesting nectar from *Rhododendron* species, sometimes referred to as 'mad honey' is an important risk factor because grayanotoxins are present in nectar and remain active after nectar processing into honey (Koca and Koca, 2007). Consumption of Rhododendron flowers or nectar in other forms, such as wine, juice or as an ingredient in cakes may also be associated with poisoning (Lee *et al*., 2007).

Yew trees and shrubs are hardy, evergreen and produce attractive, bright red fruit. Their widespread and popular use as garden subjects makes them easily accessible for most people. Eating the flesh of the fruit, a bright red aril with a pleasant, sweet taste is, fortunately, not associated with poisoning (Nelson *et al*., 2006; Pietsch *et al*., 2007). Indiscriminate ingestion of seeds with the fruit's flesh, or chewing on twigs and leaves can, however, be hazardous. Yews are also commonly implicated in animal poisoning when animals gain access to garden waste (Wilson *et al*., 2007). A number of web sites dealing with suicides mention yew as a classical method for committing suicide (Pietsch *et al*., 2007). This may partly explain its relatively common use in suicide.

7.4 Toxicity Syndrome

Excessive sodium-channel activation on neurons leads to a variety of effects associated with the central nervous system, including nausea and vomiting, disorientation and seizures. Peripheral effects include paresthesia, excessive perspiration, hypersalivation and muscle weakness, fasciculation and paralysis. Cardiac effects may include hypotension and dysrhythmias ranging from mild bradycardia to complete heart blocks (Gunduz *et al*., 2008; Koca and Koca, 2007; Nelson *et al*., 2006; Lee *et al*., 2007). Taxus poisoning is associated with initial dizziness, dry mouth and mydriasis, followed by nausea and vomiting, abdominal cramping and pain, tachycardia followed by bradycardia, hyperkalaemia, convulsions and respiratory paralysis (Pietsch *et al*., 2007; Nelson *et al*., 2006).

7.5 Management

Life-threatening cardiac effects associated with sodium-channel activation can be countered with rapid saline infusion and atropine (Gunduz *et al*., 2008). Severe hypotension can be counteracted with norepinephrine (noradrenaline). The use of sodium-channel blocking agents, such as lidocaine and amiodarone, makes sense in terms of their mechanism of action, but superior outcomes using these drugs have not been proven (Nelson *et al*., 2006). Specific antidotes for taxus poisoning are not available. Treatment is based on decontamination, such as gastric lavage and activated charcoal, and symptomatic treatment to counteract cardiac dysrhythmias.

8 MICROTUBULE POLYMERIZATION INHIBITORS

8.1 Plants

Plants that inhibit microtubule polymerization include members of the Apocynaceae (dogbane) family, including *Catharanthus* spp. (periwinkle); the Liliaceae (lily) family, including *Colchicum* spp. (crocus) and *Gloriosa* spp. (flame lily); and the Berberidaceae (barberry) family, including *Podophyllum* spp. (mayapple).

8.2 Toxic Agent and Mechanism

Toxic alkaloids that inhibit microtubule polymerization include some of the most well-known antitumour drugs, such as vincristine and related dimeric alkaloids derived from *Catharanthus roseus* (Madagascar periwinkle) (Barnett *et al*., 1978). These compounds destabilize microtubules, which leads to mitotic arrest and, at sufficient exposure levels, cell death (Groth-Pedersen *et al*., 2007). The effects are more pronounced in rapidly dividing cells, which makes it useful for the treatment of tumours, but also affects rapidly dividing normal cells,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat149
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

such as bone marrow, intestinal epithelium and hair follicles. At high doses or following prolonged exposures, organs with relatively rapid cell turnover rates, such as the liver and pancreas can be affected (Brvar *et al*., 2004). It also affects peripheral nerve function and reduces the number of intraepidermal nerve fibres (Siau *et al*., 2006).

8.3 Risk Factors

The leaves of some toxic members of the Liliaceae, such as *Colchicum autumnale* (autumn crocus), may be confused with that of *Allium ursium* (wild garlic) and is a cause of poisoning in individuals that gather wild herbs for use in food (Hermanns-Clausen, 2005).

8.4 Toxicity Syndrome

Initial signs of acute poisoning usually involve the GIT and include nausea, vomiting and diarrhoea (Brvar *et al*., 2004). Ulcerations in the mouth and gastrointestinal necrosis are also possible (Nelson *et al*., 2006). Subsequent effects potentially include failure of various organ systems, including the heart, liver and pancreas. Bone-marrow suppression leads to pancytopenia (Brvar *et al*., 2004). Acute clinical signs may include colic, hepatosplenomegaly and jaundice, while more chronic exposure may lead to cirrhosis or ascitis following hepatic venous occlusion (Nelson *et al*., 2006).

8.5 Management

There are no specific treatments available. Supportive treatments for liver failure, immune suppression and other manifestations of poisoning should be instituted to alleviate symptoms and promote tissue repair. Severe liver failure may be irreversible and successful treatment could require liver transplant (Nelson *et al*., 2006).

9 NICOTINIC ALKALOIDS

9.1 Plants

Nicotinic alkaloids are found in a wide range of plants, including members of the Apiaceae (carrot) family, including *Conium maculatum* (poison hemlock); Berberidaceae (barberry family), including *Caulophyllum* spp. (cohosh); Campanulaceae family, including *Hippobroma* spp. and *Lobelia* spp.; Fabaceae (pea) family, including *Baptisia* spp. (wild indigo), *Gymnocladus* spp. (coffee tree), *Laburnum* spp. and *Sophora* spp. (necklacepod); Ranunculaceae (buttercup family), including *Delphinium* spp. (larkspur), and Solanaceae (potato family), including *Nicotiana* spp. (tobacco).

9.2 Toxic Agent and Mechanism

Nicotinic alkaloids can be found in a variety of alkaloid groups, such as diterpenoids (found in *Delphinium* spp.), piperidines (found in *Conium* spp.) and pyridines (found in *Nicotiana* spp.) (Pfister *et al*., 2001). Nicotinic receptors are pentameric ligand-gated cation channels, with many subtypes, that are activated by acetylcholine (Schmitt, 2000). They are found in the central nervous system, parasympathetic and sympathetic peripheral nervous systems and at neuromuscular junctions. Depending on the ligand-binding characteristics and the specific binding conditions, nicotinic receptors can transition between closed, open and desensitized states, leading to suppression, excitation or nonreactivity of affected central and peripheral neurological or neuromuscular pathways and functions (Giniatullin *et al*., 2005). Nicotine is the classic nicotinic alkaloid. It binds to nicotinic receptor subtypes relatively indiscriminately and tends to induce initial stimulation followed by nonreactivity in affected pathways. Many nicotinic alkaloids derived from plants share this characteristic to some extent, but different nicotinic alkaloids differ in receptor binding characteristics (Dobelis *et al*., 1999).

9.3 Risk Factors

The most problematic and widespread risk factor associated with nicotinic alkaloids is chronic exposure to tobacco smoke and other tobacco products, which is generally considered to be one of the most important preventable health risks in modern society. This is due, in part, to the tremendous addictive potential of nicotine (Bierut *et al*., 2008). Acute toxicity is, however, much less common and is usually associated with accidental exposure following misidentification of nicotinic-alkaloid-containing plants (Durand *et al*., 2008). The infamy of some plants, such as *Conium maculatum* (poison hemlock) that was used in the execution of Socrates, unfortunately contributes to their use in criminal poisoning (Trestrail, 2007).

9.4 Toxicity Syndrome

The acute effects of nicotinic alkaloids are characterized by initial stimulation, followed by loss of reactivity and

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

function in nicotinic pathways in the central and peripheral nervous systems, and at neuromuscular junctions. Typical symptoms include nausea and vomiting, salivation, diaphoresis, trembling, dyskinesia, weakness, bradycardia followed by tachycardia, hypertension, increased respiration rate, urination, convulsions, paralysis, coma and death (Nelson *et al*., 2006; Vetter, 2004).

9.5 Management

Early decontamination, including stomach lavage and activated charcoal, may be effective in reducing toxic effects (Vetter, 2004). Treatment is symptomatic and should be targeted at correcting serious vital sign abnormalities, such as countering hypertension with diltiazem or nitroprusside. Seizures can be treated with intravenous benzodiazepines. Ventilatory support may be necessary in cases of respiratory muscle weakness or paralysis (Nelson *et al*., 2006).

10 PYRROLIZIDINE ALKALOIDS

10.1 Plants

Pyrrolizidine alkaloid toxicity is associated with a wide variety of plants including members of the Asteraceae (aster) family, including *Callilepis* spp. (ox-eye daisy) and *Packera* spp. (ragwort; formerly known as *Senecio* spp.); Boraginaceae (borage) family, including *Echium* spp. (viper's bugloss), *Heliotropium* spp. (heliotrope) and *Symphytum* spp. (comfrey); Fabaceae (bean) family, including *Crotalaria* spp. (rattlebox), *Sesbania* spp. (riverhemp); Lamiaceae (mint) family, including *Teucrium* spp. (germander); and Zygophylaceae (creosote-bush) family, including *Larrea* spp. (creosote bush). Many other plant families also have members that produce pyrrolizidine alkaloids and, although they are not as often associated with poisoning, can be potentially toxic, including the Apocynaceae (dogbane) family, Celastraceae (bittersweet) family, Convolvulaceae (morning-glory) family, Proteaceae (protea) family, Orchidaceae (orchid) family and Ranunculaceae (buttercup) family.

10.2 Toxic Agent and Mechanism

Pyrrolizidine alkaloids and related N-oxides are not directly toxic, but are metabolized by microsomal enzymes to pyrroles, which are dehydro- forms of the alkaloid, in a process that occurs mostly in the liver. Pyrroles are powerful alkylating agents leading to the formation of DNA adducts and crosslinking of proteins, amino acids and glutathione. Exposure is associated with various genotoxic effects including tumorogenicity, mutagenicity and teratogenicity (Fu *et al*., 2004), but a clear link between human cancer and pyrrolizidine alkaloid exposure has not been made (Prakash *et al*., 1999). The most prominent acute lesions occur in the liver, where high doses can cause centrilobular necrosis. Acute endothelial injury can also occur in the pulmonary vasculature in animals associated with the ingestion of *Crotalaria* spp. (Knight and Walter, 2001), but similar lesions have not been described in human pyrrolizidine alkaloid poisoning (Nelson *et al*., 2006). Chronic exposure leads to nonthrombotic veno-occlusive liver disease and, eventually, liver cirrhosis (Stickel and Seitz, 2000).

10.3 Risk Factors

The use of pyrrolizidine-alkaloid-containing plants in herbal medicines and dietary supplements is common in many parts of the world. It is one of the most important health risks associated with the unregulated use of herbal products (Stickel *et al*., 2000; Sheikh *et al*., 1997; Seeff, 2007). Inclusion of pyrrolizidine-alkaloid-containing plants as contaminants in foodstuffs, such as flour, is a potentially massive source of exposure (Prakash *et al*., 1999). Pyrrolizidine alkaloids are excreted through milk (Panter and James, 1990), which may be a potential source of exposure when milk-producing animals consume pyrrolizidine-alkaloid-containing plants and infants may be exposed through mother's milk. Lactation may partially protect lactating mothers, while exposing vulnerable infants (Schoental, 1968). Pyrrolizidine alkaloid exposure in pregnant women may lead to foetal poisoning (Rasenack *et al*., 2003). A particularly tragic example of the risks associated with inappropriate use of pyrrolizidine-alkaloid-containing herbal medicines is the lethal poisoning of young children due to toxic *Packera* spp. in South Africa (Steenkamp *et al*., 2000). The collection of plant material by nonexperts for sale in markets, and the difficulty of differentiating between toxic and nontoxic *Packera* spp., contribute to the problem.

10.4 Toxicity Syndrome

The major target organ in pyrrolizidine alkaloid poisoning is the liver. Hepatic degeneration and necrosis is mostly centrilobular, but panlobular necrosis is possible at massive exposure levels. Chronic liver lesions include fibrotic and cirrhotic changes. The clinical presentation depends on the level and duration of exposure. Massive, acute exposure leads to gastrointestinal

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat149
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

symptoms, abdominal pain, hepatosplenomegaly and icterus (Nelson *et al*., 2006). Biochemical indicators such as aspartate ammotransferase (AST) and bilirubin levels are consistent with liver failure (Nelson *et al*., 2006). Chronic exposure can lead to cumulative effects, including cirrhosis, ascites and, potentially, liver carcinoma (Nelson *et al*., 2006; Prakash *et al*., 1999).

10.5 Management

There are no specific treatments available. Spontaneous repair of liver damage may occur, depending on the level of injury. Severe liver damage or cirrhosis may require liver transplant (Nelson *et al*., 2006).

11 TOXALBUMINS

11.1 Plants

Toxalbumin-containing plants include species of the Cucurbitaceae family (*Momordica*), the Fabaceae family (*Abrus*, *Robinia*), the Euphorbiaceae family (*Hura*, *Jatropha*, *Ricinus*) and the Visacaceae family (*Phoradendron*). The most infamous example of a toxalbumin-producing plant is *Ricinus communis* (castorbean), because it is the source of one of the most potent toxins known, ricin, which has been used for assassination and is of concern as a potential weapon of terrorism. The number of species containing similar toxalbumins shows, however, that toxalbumins are produced by a fairly large number of plant species.

11.2 Toxic Agent and Mechanism

The toxalbumins in plants that cause most concern are members of a large group of glycoproteins, called lectins, that have the ability to specifically bind or crosslink carbohydrates. They may be loosely classified into high-potency lectins, such as ricin (produced by *Ricinus communis*), abrin (produced by *Abrus precatorius*) and curcin (produced by *Jatropha curcas*), and low-potency lectins (present in most undercooked beans). The toxalbumins are typically water soluble and not present in oil extracts, such as castor oil, in significant concentrations. They denature under high temperature and are therefore wet-heat labile. Due to their large size and polar characteristics, the toxalbumins are poorly absorbed from the GIT and the parenteral lethal dose is typically much smaller than the oral lethal dose. The toxalbumins consists of two distinct chains, called the A-chain and the B-chain. The toxic effects are due to the inhibition of protein synthesis through irreversible inactivation of ribosomal subunits by the A-chain, while the B-chain is necessary for toxalbumin binding to glycolipids and glycoproteins on the cell surface, followed by entry into the cell by endocytosis (Doan, 2004). Human poisoning with low-potency lectins has not been well described, but it has been suggested that acute gastrointestinal distress following the ingestion of inadequately cooked legumes is due to inhibition of plasma-membrane repair (Miyake *et al*., 2007).

11.3 Risk Factors

Ricinus communis (castorbean) is a common weed in many parts of the world. Some varieties are also occasionally used as decorative garden plants. The seeds are quite attractive and may be of interest to children coming in contact with the plant. Although the seeds contain hazardous concentrations of ricin, its release requires mastication or maceration. All plant parts, including leaves and roots, may create a hazard when used in traditional medicines (Audi *et al*., 2005). An increase in the production of *Jatropha curcas* (physic nut) for use as a biofuel may create increased risk of poisoning, especially in children who are often interested in the attractive seeds and occasionally ingest seeds out of curiosity (Kulkarni *et al*., 2005; Menezes *et al*., 2006). A similar risk occurs due to the use of seeds from *Abrus precatorius* (precatory bean), which are particularly attractive (bright red with a black patch on one end), to make jewellery.

11.4 Toxicity Syndrome

Oral exposure is the most relevant route of exposure for unintentional poisoning by toxalbumins. Signs typically appear 2–4 hours, and occasionally as much as 10 hours, after ingestion and may include nausea, abdominal cramps, heartburn, vomiting, diarrhoea, hypotension, dehydration and hypovolemic shock. Haematemesis and melaena are possible in severe cases. Hepatotoxic and renal effects have been recorded, but are not typical. Flulike symptoms, including fatigue, headache and muscle pain may also occur. Laboratory findings may include leukocytosis, elevated transaminases and creatinine kinase, hyperbilirubinemia, renal insufficiency and anaemia (Audi *et al*., 2005; Kulkarni *et al*., 2005). Although possible, lethal poisoning with oral toxalbumins is uncommon and appears to follow severe damage to the gastrointestinal mucosa that allows increased toxalbumin absorption followed by effects on the liver, pancreas, muscle and other tissues. Acute exposure to high concentrations of low-potency lectins, such as those found in

undercooked beans, is associated with nausea, vomiting and diarrhoea (Miyake *et al*., 2007).

11.5 Management

Treatment is mainly supportive and symptomatic and could include intravenous fluids, electrolyte correction and vasopressive treatment for hypotension. Gastric evacuation is considered to be of limited value, but can be considered if ingestion occurred within an hour or less. Activated charcoal may be of benefit if the patient is not vomiting (Audi *et al*., 2005).

Mycotoxins with a Special Focus on Aflatoxins, Ochratoxins and Fumonisins

Pieter S. Steyn, Wentzel C.A. Gelderblom, Gordon S. Shephard and Fanie R. van Heerden

CONTENTS

1 INTRODUCTION

Mycotoxins comprise a structurally diverse group of mostly small-molecular-weight compounds, derived from the secondary metabolism of filamentous fungi. Several of the toxins are important environmental and carcinogenic agents and are ubiquitous in a broad range of commodities, causing toxic responses when ingested by mammals (such as man and higher animals), poultry and fish. Initially, mycotoxin production was mainly linked to the so-called storage fungi, growing saprophytically (post-harvest) on stored grains and nuts; however, fungi growing parasitically (preharvest) on plants also have the propensity to produce mycotoxins.

Not all fungal growth on plants and plant products cause mycotoxin production, therefore detection of fungi, even toxigenic fungi, on foods and feeds does not necessarily imply the presence of mycotoxins. Worldwide, an exponential growth in all aspects related to mycotoxin research is occurring. This chapter is directed at updating the review of Steyn and Stander (1999) with a focus on recent findings.

These toxic secondary metabolites are produced by a number of fungi, including members of the *Aspergillus*, *Penicillium*, *Fusarium*, *Claviceps* and *Alternaria* genera. Several explanations may be given for their production, however, it is likely that mycotoxins could play a role in facilitating competition with other micro-organisms for nutrients and space, and the generation of favourable germination conditions for fungal spores (O'Brien and Dietrich, 2005). Bennett and Arnold (2001) reviewed the genomics of fungi and focussed on the *Aspergillus flavus* complex that encompasses a cluster of anamorphic, haploid species involved in *A. flavus* and *A. parasiticus*, the mycotoxin producers, and the koji moulds, *A. oryzae* and *A. sojae*. Several leading research groups are making considerable progress on the genomics of aflatoxigenic species, as well as on ochratoxigenic and other mycotoxigenic species, and it is envisaged that a better understanding of the genomics of fungi could enhance methods of mycotoxin control. The seminal findings of O'Callaghan and Dobson (2006a; 2006b), O'Callaghan *et al*. (2006c), Geisen *et al*. (2006) and Atoui *et al*. (2006) contributed significantly to a better understanding of the polyketide synthase genes from *Aspergillus ochraceus* and the molecular characterization of ochratoxin A (OTA) biosynthesis.

The epoch-making discovery of the aflatoxins in the 1960s, the causal agents of turkey X-disease in the UK (Lancaster *et al*., 1961; Sargeant *et al*., 1961), subsequently led to their classification as human carcinogens and linked them to primary liver cancer (PLC) in humans. This introduced an unabated worldwide interest in mycotoxins and led to the discovery of the ochratoxins, fumonisins, phomopsins and the tremorgenic mycotoxins. (See the reviews by Murphy *et al*. 2006, and the monograph on *Mycotoxins in Food*, edited by Magan and Olsen, 2004). The aflatoxins, such as aflatoxin B_1 (AFB_1), are transformed in mammals, for example, humans, into reactive mutagenic electrophiles through metabolizing processes. These electrophiles react readily with DNA and are thus considered to be the ultimate carcinogens.

In structural complexity, mycotoxins vary from simple C4-compounds, for example moniliformin, produced by *Fusarium moniliforme*, to complex substances such as the phomopsins, fumonisins, sporidesmin and the tremorgenic mycotoxins. See **Figure 1** for the structures of some representative mycotoxins which are associated with specific human and animal mycotoxicoses. Although there are hundreds of mycotoxins, few of these are considered responsible for large-scale losses associated with contaminated agricultural products. There can be significant year-to-year fluctuations in the levels of mycotoxins in foods, due to many factors, such as adverse climatic conditions that favour fungal invasion, growth and mycotoxin formation. Plant toxins cause local problems, mainly affecting livestock; however, mycotoxins put the world food supply under threat due to the worldwide distribution of toxigenic fungi, and the international trade in foods and feeds. Post-harvest losses in the developing world are particularly severe owing to the quality of the produce and inadequate storage facilities. It is claimed that approximately 60% of Africa's grain supplies are at risk, owing to fungal contamination and mycotoxin formation.

The global threat to mankind is based on well-documented human mycotoxicoses, such as ergotism (St Anthony's fire) which occurred frequently in the middle Ages in Europe, alimentary toxic aleukia (ATA) in Russia, acute aflatoxicoses in South and East Asia, and human PLC in Africa and South East Asia. OTA is suspected of playing a role in Balkan endemic nephropathy (BEN) amongst the population living in the former Yugoslavia (Mantle, 2002) and chronic interstitial nephropathy (CIN) in North Africa. The fumonisins are implicated in the aetiology of the high incidence of oesophageal cancer among the inhabitants of the Transkei region of South Africa. Although the role of mycotoxins in diseases among domestic animals is better established, diagnosis of the mycotoxicosis is extremely difficult owing to the numerous pharmacological effects of the causative toxins, for example, aflatoxins (Turkey-X disease), fumonisins (leukoencephalomalacia in horses and pulmonary oedema in swine (Bezuidenhout *et al*., 1988; Gelderblom *et al*., 1988)), ochratoxins (nephropathy in swine (Danish porcine nephropathy (DPN)) (Krogh, 1976; Stoev *et al*., 2002)), phomopsin A (lupinosis in sheep (Culvenor *et al*., 1989)), sporidesmin A (facial eczema in sheep (Mortimer *et al*., 1978)) and zearalenone (hyperoestrogenism, vulvovaginitis and abortion in swine). Outbreaks of diplodiosis amongst farm animals are linked to feeds contaminated with *Diplodia maydis*.

Mycotoxins induce powerful and dissimilar biological effects. Some are carcinogenic (aflatoxins, ochratoxins and fumonisins), mutagenic (aflatoxins and sterigmatocystin), teratogenic (ochratoxins), oestrogenic (zearalenone), haemorrhagic (trichothecenes), immunotoxic (aflatoxins and ochratoxins), nephrotoxic (ochratoxins), hepatotoxic (aflatoxins, ochratoxins and phomopsins), dermotoxic (trichothecenes) and neurotoxic (ergotoxins, penitrems, lolitrems and paxilline), whereas others display antitumour, cytotoxic and antimicrobial properties. The human ingestion of mycotoxins is due to the consumption of the mycotoxins in plant-based foods, such as grains, like maize, barley and rice, coffee, nuts and their residues, and metabolites in

animal-derived foods, for example aflatoxin M_1 (AFM_1) in milk and meat products. In addition, mycotoxins may occur in beer and wine; worldwide, OTA is a frequent contaminant of wines. Some of the toxic effects of mycotoxins observed in experimental animals are consistent with the characteristic symptoms seen in a number of human and animal diseases.

The impact of mycotoxins on health depends on the amount of the mycotoxin consumed, the toxicity of the compound, for example, acute or chronic (e.g. carcinogenic) effects, the body weight of the individual, the presence of other mycotoxins (synergistic effects) and other dietary effects. Hsieh (1990) maintained that all of the following criteria have to be satisfied to link a mycotoxin to a specific human disease: occurrence of the mycotoxin in food supplies; human exposure to the mycotoxin; correlation between exposure and incidence; reproducibility of the characteristic symptoms in experimental animals; similar mode of action in human and animal models.

In nature, most cereal grains, oil seeds, tree nuts, fruits and dehydrated fruits are susceptible to fungus contamination and mycotoxin formation. Under laboratory conditions, at least 300 mycotoxins have been produced by pure cultures of fungi and chemically characterized. Fortunately, only about 20 mycotoxins are known to occur in foodstuffs at significant levels and frequency to be of food-safety concern. These toxins are mainly produced by five genera of fungi: *Aspergillus, Penicillium, Fusarium, Alternaria* and *Claviceps* (O'Brien and Dietrich, 2005). The mycotoxins produced by these fungi are: *Aspergillus* toxins, aflatoxin B_1, G_1, M_1, OTA, sterigmatocystin and cyclopiazonic acid; *Penicillium* toxins, patulin (PAT), OTA, citrinin, penitrem A (PA) and cyclopiazonic acid; *Fusarium* toxins, deoxynivalenol, nivalenol, zearalenone, T-2 toxin, diacetoxyscirpenol, fumonisins and moniliformin; *Alternaria* toxins, tenuazonic acid, alternariol and alternariol methyl ether; *Claviceps* toxins, ergot alkaloids.

The Council for Agricultural Science and Technology (CAST) considered aflatoxins, trichothecenes, fumonisins, zearalenone, OTA and ergot alkaloids as most relevant for human health (see Serra *et al*., 2005), although the extent of harm caused by each toxin is highly species dependant. This chapter mainly focusses on the mycotoxins aflatoxins, OTA and fumonisins, owing to their high priority for control purposes and their frequent and worldwide distribution in agricultural products. Many mycotoxins are highly resistant, and survive food processing to enter the food chain and provide a threat to human health. Reliable and accurate analysis of mycotoxins at the ppb (parts per billion) and ppt (parts per trillion) levels in the various commodities is essential for protecting human and animal health, as well as for conforming to the standards set for national and international trade. The newer methods which involve antibody-based mycotoxin screening techniques, high-performance liquid chromatography (HPLC) and tandem mass spectroscopy impacted positively on several of the techniques. These procedures are described in more detail in later subsections.

Detoxifying contaminated foodstuffs and feedstuffs is of prime importance in protecting consumer health; and each of the subsections contains a part dedicated to this matter. The decontamination processes aim to destroy, inactivate or remove the mycotoxin, and not to produce or leave toxic or carcinogenic/mutagenic residues in the final products or in the food products obtained from animals fed decontaminated feeds. Regulations for the control of mycotoxins in various commodities have received much international attention, and are contained as a subsection of this chapter. In addition, risk assessment is generic to all the mycotoxins, therefore, a subsection is devoted to this matter as well.

2 AFLATOXIN

The aflatoxins comprise a group of hepatocarcinogenic mycotoxins, mainly produced by the filamentous fungi *Aspergillus flavus* and *Aspergillus parasiticus*. Most foods and feeds, particularly high-energy nuts, are at risk of contamination by these fungi and by the notorious aflatoxins. A cause–effect relationship between dietary aflatoxin intake and human hepatocellular carcinoma (HCC) has become internationally recognized, and their role in human and animal mycotoxicoses firmly established. AFM_1 is found in milk of animals that have consumed feeds contaminated with aflatoxins. Aflatoxins B_1, G_1 and M_1 have been recognized to be possibly carcinogenic to humans (Group 2B) by the International Agency for Research on Cancer (2002), and a plausible mechanism for their mode of action has become generally accepted. As a result, acceptable levels of aflatoxins in foods, feeds and milk have been established and enforced worldwide. The importance of aflatoxin is emphasized by a recent outbreak of aflatoxicosis in Kenya in April 2004 in which 125 people died (Lewis *et al*., 2005).

2.1 Producing Organisms for Aflatoxins

The most important aflatoxin-producing organisms in terms of agricultural products remain *Aspergillus flavus* and *A. parasiticus* (Steyn and Stander, 1999). Although *A. flavus* is mostly associated with oilseed crops (maize, peanuts and cottonseed), the fungus is an extremely common soil fungus, and under improper storage conditions aflatoxin production may be a problem with many other crops (Klich, 2007). Other aflatoxin-producing

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

species include *A. flavus* var. *parvisclerotigenus*, *A. toxicarius*, *A. nomius*, *A. pseudotamarii*, *A. zhaoqingensis* and *A. bombycis* (all from *Aspergillus* section *Flavi*), *A. ochraceoroseus* and *A. ambellii* (*Aspergillus* section *Ochraceorosei)* and *Emericella astellata* and *E. venezuelensis* (*Aspergillus* section *Nidulantes)* (Frisvad *et al*., 2005; Cary *et al*., 2005).

The B-type aflatoxins (AFB_1 and AFB_2) are produced by all the organisms whereas the G-type (AFG_1 and AFG_2) aflatoxins are produced by only some of the species in *Aspergillus* section *Flavi.* Species in this subgroup that produce B-type aflatoxins, but not G-type aflatoxins, often produce cyclopiazonic acid. Production of both the G-type aflatoxins and cyclopiazonic acid by a single strain has not yet been observed (Frisvad *et al*., 2005).

Substantial progress has been made on the sequencing of the genome of *A. flavus* and closely related fungi (Machida *et al*., 2005). Information on the genome sequence of aflatoxin-producing organisms will assist in understanding the pathogenicity and regulatory aspects of aflatoxin biosynthesis (Bhatnagar *et al*., 2003; Chang *et al*., 2007; Kim *et al*., 2005; Yu *et al*., 2007). It has been shown that the genes encoding the biosynthesis pathway of aflatoxins are in a 70 kb cluster of the chromosome (Yu *et al*., 2004). To investigate aflatoxin production, gene expression profiles in aflatoxin-supportive media vs. non-aflatoxin-supportive media were evaluated in *A. flavus* and *A. parasiticus* and genes consistently expressed in several aflatoxin-supportive media were identified (Yu *et al*., 2007).

2.2 Analytical Methodology for Aflatoxins

Since their discovery in the early 1960s, numerous analytical methods have been applied to their analysis in a range of contaminated commodities. These have been highlighted in a previous review (Steyn and Stander, 1999). Analytical methods for aflatoxins have advanced along with general advances in analytical chemistry methods and instrumentation. These improvements have involved changes in sample extract purification with the widespread introduction of immunoaffinity columns (IACs), the increasing use of mass spectrometry (MS) as a HPLC detection tool and the further development of antibody-based rapid methods.

2.2.1 Chromatographic Methods for Aflatoxins

Thin-layer chromatography (TLC) remains widely in routine use in many laboratories. To eliminate the need for chlorinated solvents, IAC clean-up was linked with one-dimensional TLC for analysis of various food matrices at levels significantly lower than European Union (EU) limits (Stroka *et al*., 2000a). As a technique related to TLC, overpressured layer chromatography has been used to achieve reproducible determination of aflatoxins in samples of red paprika (Moricz *et al*., 2007).

A number of papers published in the last five years described the optimization of existing methods to achieve specific goals. Vega (2005) described a method to reduce solvent consumption in the extraction of aflatoxins from peanut butter, by reducing sample size and extraction-solvent volume. Möller and Nyberg (2004) investigated the extraction of aflatoxins from defatted peanut-meal reference samples using four different extraction solvent mixtures, and concluded that the widely used methanol–water $(80 + 20)$ may not always be the best for all matrices, as it achieved a result considerably below the certified value of the test material. Post-column derivatization with iodine or bromine is a widely used method to enhance the fluorescence of AFB_1 and AFG_1 in reversed-phase chromatography. A collaborative study of a post-column photochemical derivatization using a reaction coil wound around an ultraviolet (UV) lamp has been successfully performed and accepted by AOAC International (Waltking and Wilson, 2006). Extraction of high-pigment samples, such as chilli powder, green bean and black sesame was achieved by matrix solid-phase dispersion using neutral alumina, followed by elution of aflatoxins through a bed of graphitic carbon black to remove pigments that interfered with the HPLC analysis (Hu *et al*., 2006). The problem of low recoveries on extracts of herbal samples of high acidity was solved by using 0.1 M phosphate buffer for dilution and neutralization (Ip and Che, 2006). For the purpose of analysing very low levels of mycotoxins in a duplicate diet study, a method for AFB_1, AFM_1 and OTA was developed, which involved chloroform extraction and liquid–liquid extraction prior to IAC clean-up and HPLC determination (Sizoo and Van Egmond, 2005). The limits of quantitation for these mycotoxins were 5, 24 and 16 $ng\,kg^{-1}$ (ppt), respectively.

The introduction of lower EU regulatory limits at 2 $\mu g\,kg^{-1}$ for AFB_1 and 4 $\mu g\,kg^{-1}$ total aflatoxins required the validation of a new official method for aflatoxins in peanut butter, pistachio paste, fig paste and paprika powder which involved IAC clean-up of extract and reversed-phase HPLC with fluorescence detection following post-column bromination (Stroka *et al*., 2000b). Similarly, a collaborative study validated an analytical method for AFM_1 in milk at levels above 0.02 $ng\,ml^{-1}$, which was based on IAC clean-up of a centrifuged milk sample followed by reversed-phase HPLC (Dragacci *et al*., 2001). This methodology, involving extraction with nonchlorinated solvent mixtures, dilution of the filtered extract, clean-up on IAC and reversed-phase HPLC quantification with post-column derivatization has been extended

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to a number of commodities. Thus, methods have been developed for the determination of aflatoxins in medicinal herbs (Ali *et al*., 2005; Arranz *et al*., 2006a; Braga *et al*., 2005; Gomez-Catalan *et al*., 2005), in tiger-nut-based soft drinks (Arranz *et al*., 2006b), in maize (Brera *et al*., 2007), in hazelnut paste (Senyuva and Gilbert, 2005) and in pig liver (Chiavaro *et al*., 2005). The commercial availability of IACs containing antibodies specific to more than one mycotoxin has resulted in the development of methods for aflatoxins and OTA in foods (Chan *et al*., 2004) and in botanical roots (Trucksess *et al*., 2006; Trucksess *et al*., 2007), and for aflatoxins, OTA and zearalenone in rice, rye and pig feed (Göbel and Lusky, 2004).

MS as an HPLC detection system has made rapid advances in the last decade. Methods have been developed in which the conventional fluorescence detectors used for aflatoxins have been replaced by bench-top mass spectrometers operating with various atmospheric pressure ionization (API) sources. The application of these new techniques to a range of mycotoxins has been comprehensively reviewed (Zöllner and Mayer-Helm, 2006). The ability to combine quantification with confirmation from specific fragmentation patterns has distinct advantages. Although some authors have used atmospheric pressure chemical ionization (APCI) (Abbas *et al*., 2006; Liau *et al*., 2007), the majority of methods developed employ electrospray ionization (ESI) in the positive ion mode to yield protonated molecular ions (Cavaliere *et al*., 2007a; 2007b; Lattanzio *et al*., 2007; Spanjer *et al*., 2008; Sulyok *et al*., 2006; Ventura *et al*., 2004). The use of atmospheric pressure photoionization (APPI) has found limited application, although it has been shown to reduce chemical noise (Cavaliere *et al*., 2006; Takino *et al*., 2004). Confirmation of analysis can be achieved by use of time-of-flight mass spectrometry (TOF-MS) (Tanaka *et al*., 2006) or the use of multiple reaction monitoring (MRM), in which one fragment ion is used for quantification and a second for confirmation purposes (Spanjer *et al*., 2008). In many cases, the MS detector has been confined to the detection of the four main aflatoxin analogues. For example, methods have been developed for the determination of aflatoxins in maize (Abbas *et al*., 2006; Cavaliere *et al*., 2007a), olive oil (Cavaliere *et al*., 2007b), hazelnuts (Bacaloni *et al*., 2008), medicinal herbs (Ventura *et al*., 2004) and traditional medicines (Liau *et al*., 2007). In contrast to the above, a few groups have exploited the versatility of MS to develop multimycotoxin methods. This approach can be restricted to mycotoxins for which multitoxin immunoaffinity clean-up columns are available (aflatoxins, OTA, fumonisins, deoxynivalenol, zearalenone, T-2 toxin and HT-2 toxin)(Lattanzio *et al*., 2007) or it can encompass a much larger number of toxins (Delmulle *et al*., 2006; Spanjer *et al*., 2008; Sulyok *et al*., 2006; Tanaka *et al*., 2006). A recent publication allows detection of 90 mycotoxins, secondary fungal metabolites and plant-derived metabolites of mycotoxins (Berthiller *et al*., 2007). Due to the multiplicity of toxin chemistries, no clean-up is available for such mixtures. In these cases, the extracts are diluted and then injected. Matrix effects are monitored and for quantitation, matrix-matched standards are used (Sulyok *et al*., 2007).

2.2.2 Immunological Methods for Aflatoxins

Immunological methods in a number of different formats continue to be developed for aflatoxins. Lateral flow devices have been prepared which incorporate colloidal gold particles to produce the visible end point, the design of the assay being such as to provide a visible line at aflatoxin levels below a designated level. This level is set by adjusting the amounts of reagents used in the assay. The presence of a control line ensures the good performance of the kit in that it indicates that antibodies have migrated past the test line. Such kits have been developed for rapid detection of aflatoxins in pig feed (Delmulle *et al*., 2005), grain and animal feed (Shim *et al*., 2007), and rice, maize and wheat flours (Xiulan *et al*., 2006). In its most popular format, the assay provides a single visible cut-off level, although it can be combined with a photometric strip reader for semiquantitative determinations over a limited range (Xiulan *et al*., 2006). Although the majority of immunological methods utilize a colour reaction (generated by enzyme action or by the use of colloidal gold particles) for the end point, some researchers have developed electrochemical detection systems. These are based on enzyme-linked immunosorbent assay (ELISA) principles using disposable screen-printed electrodes on which the relevant antibodies are coated and the end point is measured by a suitable voltametric or amperometric electrochemical method (Ammida *et al*., 2004). Immunological methods such as ELISA have generally been confined to determination of single mycotoxins. However, a few methods have emerged which allow the simultaneous determination of both aflatoxin and OTA. Using a membrane-based method involving the separate spotting of specific antibodies, good agreement was found with individual ELISA measurements for the toxins in chilli samples (Saha *et al*., 2007). A method for the detection of both AFB_1 and OTA with specific cut-off levels was incorporated in a sorbent tube, which was packed with a clean-up layer at the base and separate detection immunolayers for the two mycotoxins above (Goryacheva *et al*., 2007a). Extracts of spice samples were drawn through the tube from the base, allowing on-tube clean-up prior to the extract solution passing through the immunolayers containing mycotoxin antibodies. The flow through the tube was reversed, and after washing and developing the colour, the presence

or absence of the individual mycotoxins determined by the absence or presence of colour, respectively.

2.3 Occurrence of Aflatoxins

Contamination of groundnuts in the UK by aflatoxins was first reported by Lancaster *et al*. (1961) and Sargeant *et al*. (1961) as a result of the death of turkey poults that were fed contaminated groundnut meal. The highly carcinogenic toxic compounds became known as aflatoxins B_1, B_2, G_1 and G_2. Aflatoxins have been found in a variety of agricultural commodities of which the most important are groundnuts, tree nuts, maize and other oil seeds, such as cottonseed.

The levels of aflatoxins occurring in groundnuts, grown in tropical climatic conditions are generally high, as found in Brazil, Cambodia, India, Jordan, Malaya, Kenya, Nigeria, Uganda, and warm regions of the USA and Australia (Strange, 1991). The EU has established the maximum tolerated level (MTL) of AFB_1 in groundnuts for direct consumption as $2\,\mu g\,kg^{-1}$. Many reports of AFB_1 in ground nuts have appeared over the years. For example, Dos Santos *et al*. (2001) reported contamination of 28 out of 77 samples of raw peanuts with AFB_1 and AFG_1 in Brazil 24 samples had contamination $>30\,\mu g\,kg^{-1}$. A total of 145 raw shelled peanut samples from Malaysia were analysed for the contamination of AFB_1, AFB_2, AFG_1 and AFG_2 (Sulaiman *et al*., 2007). The percentage, along with the range of incidence of the AFB_1 (50%, $0.85–548\,\mu g\,kg^{-1}$) and AFG_1 (37%, $1.37–376\,\mu g\,kg^{-1}$) in raw shelled peanut samples were very high, whereas AFB_2 and AFG_2 were not detected in the samples. In a survey of the occurrence of aflatoxins, OTA and fumonisins in retail foods in Japan, aflatoxin contamination was determined in 10 of 21 peanut-butter samples, while aflatoxins could not be quantified in other foods. The average concentrations for AFB_1, AFB_2, AFG_1 and AFG_2 were 1.07, 0.27, 0.40 and $0.21\,\mu g\,kg^{-1}$, respectively (Sugita-Konishi *et al*., 2006b). In a survey that was aimed at the occurrence of mycotoxins relevant to the feed industry in various parts of the world, eight peanut-meal samples out of nine from Asia and Oceania were contaminated with AFB_1, for which an average concentration of $184\,\mu g\,kg^{-1}$ was calculated (Binder *et al*., 2007). The EU maximum limit of AFB_1 in all feed materials for cattle, sheep, goats, pigs and poultry is $20\,\mu g\,kg^{-1}$.

Levels of aflatoxin contamination of maize is a worldwide problem. It may vary from region to region within a country due to environmental factors, high temperature and humidity that favour its production. For example, the problem of contaminated maize in the southeast of the USA is far greater than in other parts of the USA (Shotwell, 1991). Aflatoxin formation in Australian maize is uncommon (Pitt and Hocking, 2004). Due to maize processing, the consumer is often not exposed directly to mycotoxins in raw maize, but rather in derived products of maize. Thus, the amounts of mycotoxins in raw maize are unlikely to reflect the concentrations in the finished product. Maize is often processed with other feedstuffs for animal feed. A three-year surveillance programme assessed the extent of mycotoxin contamination of key foods and feeds grown in Bangladesh (Dawlatana *et al*., 2002). Of the foods and feeds tested, the levels of contamination of maize, roasted and raw groundnuts, and poultry feed were highest, with average total AFB_1 contents of 33, 13, 65 and $7\,\mu g\,kg^{-1}$, respectively. In Morocco, 58 samples of cereals for human consumption (20 corn flour, 17 wheat flour) and poultry feeds (21) purchased from local markets were analysed (Zinedine *et al*., 2007a). The incidence of aflatoxin in corn flour, wheat flour and poultry feeds was about 80, 17.6 and 66.6%, respectively. Levels of contamination of analysed samples with AFB_1 ranged from 0.23 to 11.2, 0.03 to 0.15 and 0.05 to $5.38\,ng\,g^{-1}$ for corn flour, wheat flour and poultry feeds, respectively. Results showed also that the contamination of 10% of samples of corn flour was higher than the limit set by EU regulations for AFB_1 and total aflatoxins. In Brazil, aflatoxins were found to co-occur with fumonisins on freshly harvested maize kernels (Ono *et al*., 2001). Aflatoxins were detected in 11.3% of the total samples and all the aflatoxin-positive samples (range $38.0–460.0\,ng\,g^{-1}$) were cocontaminated with fumonisins. The co-occurrence of AFB_1 and fumonisins was previously reported in Indian maize and poultry feeds by Shetty and Bhat (1997). Co-occurrence of aflatoxin and OTA seems to be rarer. Maize and barley samples intended for animal feed in northern Iran were analysed for aflatoxin and OTA. AFB_1 and AFB_2 were detected in 88.8 and 66.6% of the corn samples, at a mean level of 15.83 and $2.99\,\mu g\,kg^{-1}$, respectively (Yazdanpanah *et al*., 2001). Only one of the AF-contaminated maize samples was cocontaminated with OTA at a concentration of $0.35\,\mu g\,kg^{-1}$. Neither aflatoxin nor OTA was found in any of the barley samples. In India (Thirumala-Devi *et al*., 2002) ingredients intended for incorporation into chicken feed, which included groundnut cake, maize, millet, rice bran, sorghum, soybean, sunflower and mixed feeds, were assayed for aflatoxins and OTA contamination. Of the samples, 38% were contaminated with aflatoxins and 6% with OTA. AFB_1 has been reported in conserved hay and in maize silage used as animal feed (Lacey, 1991).

Although reported in more than 20 countries, the incidence and levels of aflatoxins in small grains such as wheat, barley, rye, oats, sorghum, millet and rice are relatively low (Yoshisawa, 1991). Ayalew *et al*. (2006) recently reported the occurrence of mycotoxins in the Ethiopian staple cereals, barley, sorghum, teff (*Eragrostis tef*) and wheat. AFB_1 and OTA were detected in samples of all the four crops. AFB_1 was detected in 8.8%

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of the 352 samples analysed at concentrations ranging from trace amounts to concentrations of $26\,\mu g\,kg^{-1}$. The results indicated higher mycotoxin contamination in sorghum, which could be related to the widespread storage of sorghum grain in underground pits. AFB_1 was found in 58.3% of *menu* (crushed fermented soybean cake) samples in Korea, with an average concentration of $7.3\,ng\,g^{-1}$ (Kim *et al*., 2001).

The occurrence of aflatoxin in cottonseed is of great concern in the USA due to its wide usage in feedstuffs. The oil from cotton kernels is used for manufacturing of margarine and soap, and the remaining press cake is used for animal feed. The occurrence of aflatoxin in cottonseed is uncommon in Australia (Pitt and Hocking, 2004). The occurrence of AFB_1 in other oil seeds such as soya has received attention as a potential health risk. A total of 694 food samples collected from six different regions of South Korea were analysed for their AFB_1 content (Ok *et al*., 2007). Thirty-two samples, including three soybean products, were found to be contaminated with AFB_1 up to $48.6\,\mu g\,kg^{-1}$. The level of AFB_1 contamination in 28 of the 32 food products was below $10\,\mu g\,kg^{-1}$, which is the legal tolerance limit in Korea. The major contributors to the dietary intake of AFB_1 were soybean paste and soy sauce, which composed 91% of the total exposure to AFB_1. Sunflower is an important ingredient of animal feedstuff and is a source of concern. For example, in the study of Thirumala-Devi *et al*. (2002) (see above), the following incidence scores of aflatoxin contamination in excess of $10\,\mu g\,kg^{-1}$ were found in poultry feed: 41 of 95 for maize, 18 of 30 for mixed feeds, 10 of 37 for groundnut, 6 of 29 for sorghum, 5 of 10 for sunflower, 3 of 14 for rice bran and one of eight for millet.

Zinedine *et al*. (2006) reported the analysis of 55 samples of spices (14 of paprika, 12 of ginger, 14 of cumin and 15 of pepper) purchased from markets in Morocco. Spice samples were analysed for aflatoxins and the average contamination found for AFB_1 was 0.09, 0.63, 2.88 and $0.03\,\mu g\,kg^{-1}$ for black pepper, ginger, red paprika and cumin, respectively.

AFM_1 and AFM_2, the hydroxylated metabolites of AFB_1 and AFB_2 (Holzapfel *et al*., 1966), are found in milk products obtained from livestock that have ingested contaminated feed, such as peanut, maize and cottonseed meal. About 1–2% of AFB_1 in animal feed is transformed to AFM_1 in milk (Van Egmond, 1989). The European Commission has set a maximum tolerated level of $0.05\,\mu g\,kg^{-1}$ for AFM_1 in milk, whereas the maximum level set by Codex Alimentarius is $0.5\,\mu g\,kg^{-1}$. In a study in Egypt, Salem (2002) reported that all feedstuff samples from six farms and two from feedstuff factories were found to contain total aflatoxin levels ranging between 2 and $60\,\mu g\,kg^{-1}$, with four samples exceeding the Egyptian maximum levels ($20\,\mu g\,kg^{-1}$). AFM_1 was found in 58.8% of the investigated milk samples with concentrations not reaching the MTL of the EU countries. Kim *et al*. (2000) showed that, the incidence of AFM_1 in milk was 76%, with a mean concentration of $18\,pg\,g^{-1}$ in Korea. Rastogi *et al*. (2004) showed that the incidence of contamination of AFM_1 in milk was 33%, with a concentration range of $28–164\,ng\,l^{-1}$ in Indian markets. In Brazil, Sassahara *et al*. (2005) analysed 42 samples of milk: 10 (24%) were contaminated by AFM_1 and three (7%) were above $0.5\,\mu g\,l^{-1}$. Aflatoxin contamination was investigated in 48 raw milk and 48 feed samples in Turkey (Ayar *et al*., 2007). Altogether, 20 raw milk samples (41.67%) and 15 feed samples (31.25%) exceeded the relevant legal limits established by the Turkish Food Codex (TFC) and the EU. Similarly, Unusan (2006) reported a mean value of $108.17\,ng\,l^{-1}$ for AFM_1 in 129 samples of commercial UHT (ultra-high temperature) whole milk from Turkey and an incidence rate of 58%. Of the contaminated samples, 47% were well above the limit permitted by the EU. Kamkar (2005) found that in 76.6% of samples from Iran the presence of AFM_1 was detected in a range between 0.015 and $0.28\,\mu g\,l^{-1}$. Of positive samples, 40% exceeded the concentration limit permitted by the EU. Similarly, 64% of 186 milk samples from different dairy farms in Iran were contaminated (Ghiasian *et al*., 2007), having a mean concentration of AFM_1 in contaminated samples of $43.4\,ng\,l^{-1}$. Fourteen (11.76%) contaminated samples had AFM_1 in concentrations in excess of the maximum levels specified in EU regulations. In a study on Feta cheese Kamkar (2006) reported an 82.5% incidence of AFM_1 in the range $0.15–2.41\,\mu g\,l^{-1}$. In Italy, a total of 332 samples were collected from dairy farms delivering milk to factories for Parmigiano Reggiano cheese production over a six year period (Pietri *et al*., 2003). While AFM_1 was present in 95.5% of the samples, with 8.4% exceeding the limit set by the EU, it was reported that in later years there was a general trend towards lower AFM_1 levels in dairy products. In a study in Brazil, Iha *et al*. (2007) found that 18% of UHT and pasteurized frozen goat-milk samples contained between 20 and $98\,ng\,l^{-1}$ AFM_1. However, Oliveira and Ferraz (2007) found the incidence in Brazil to be as high as 69% with mean concentrations of 0.58, 0.56 and $0.72\,\mu g\,l^{-1}$ for UHT, powder and pasteurized goat milk, respectively. Virdis *et al*. (2006) found 17.3% of bulk goat milk at a cheese factory in Sardinia, Italy, to contain between 5 and $40\,ng\,l^{-1}$ AFM_1, whereas ripened tank cheese had an incidence of 9.8%, with concentration values between 79 and $389\,ng\,kg^{-1}$.

The staple food in many African countries is frequently contaminated by aflatoxins. Prenatal exposure of the foetus to AFB_1 in Ghana, Kenya and Nigeria was revealed by analysis of cord blood (Shephard, 2004). Exposure of infants to aflatoxins in human breast milk has been reported in Egypt (El-Sayed *et al*., 2000), Gambia, Ghana, Kenya, Sierra Leone, Sudan and Zimbabwe (Shephard, 2004). Aflatoxins are common contaminants of staple foods in sub-Saharan Africa and are associated with increased risk of liver cancer and impaired

growth in young children (Wild, 2007). In an intervention study of exposure to infected groundnuts from 20 African farms, the concentrations of blood aflatoxin–albumin adducts from 600 people immediately after harvest and at three and five months post-harvest were monitored. In control villages mean aflatoxin–albumin concentration increased from 5.5 pg mg^{-1}, immediately after harvest, to 18.7 pg mg^{-1} five months later (Turner *et al*., 2005).

2.4 Biological Activity of Aflatoxins

As mentioned by Steyn and Stander (1999), the aflatoxins, particularly AFB_1, can be regarded as potent toxins, carcinogens, teratogens and mutagens. Of the four naturally occurring aflatoxins (B_1, B_2, G_1 and G_2), AFB_1 is the most toxic and carcinogenic. AFM_1, a metabolite of AFB_1 present in milk, is considered to be as toxic, but less carcinogenic than AFB_1 (Bailey *et al*., 1998; Wogan and Paglialunga, 1974). Different animal species have different oral LD_{50} values for AFB_1, as is quoted by Leung *et al*. (2006): rabbits (0.3 mg (kg body weight)$^{-1}$), mink (0.5–0.6 mg (kg body weight)$^{-1}$), cats (0.55 mg (kg body weight)$^{-1}$), dogs (1.0 mg (kg body weight)$^{-1}$) and guinea pigs (1.4–2.0 mg (kg body weight)$^{-1}$), being more sensitive than mice (9.0 mg (kg body weight)$^{-1}$) or hamsters (10.2 mg (kg body weight)$^{-1}$).

AFB_1, the most potent natural carcinogen (Bennett and Klich, 2003), is converted in human liver to the 8,9-epoxide, which can bind to both DNA and proteins (**Scheme 1**). Although Essigmann *et al*. (1977) were the first to postulate that the AFB_1 epoxide was the active intermediate in the hepatocarcinogenicity of AFB_1, it was only after the availability of the epoxide by chemical synthesis (Baertschi *et al*., 1988) that the mechanism was unravelled. In the human liver, AFB_1 is metabolized by cytochrome P450 (Guengerich, 2003) to yield the highly reactive 8,9-epoxyaflatoxin B_1 (Kelly *et al*., 1997). In chemical synthesis (Baertschi *et al*., 1988) and enzymatic reactions (Ueng *et al*., 1995), both the *exo*- and *endo*- epoxides are formed in varying ratios. However, it has been proven that the *exo*-stereoisomer is the carcinogenic metabolite and that the *endo*-epoxide is 1000-fold less active than the *exo*-isomer. It is postulated that furocoumarin intercalates between the bases of DNA and that with the *exo*-epoxide, an S_N2 reaction between the N^7 of guanine and the epoxide is possible, whereas with the *endo*-epoxide, attack is blocked by the epoxide group (Iyer *et al*., 1994). However, Bren *et al*. (2007) have proved by calculations that the higher activity of the *exo*-epoxide already exists in aqueous solution and that it is only further enhanced by DNA intercalation.

AFB_1 epoxide undergoes hydrolysis to form a diol, which under slightly basic conditions, is transformed into a dialdehyde. The dialdehyde can form a Schiff base with the primary amine group of lysine to form protein adducts (**Scheme 1**). AFB_1 *exo*-epoxide also reacts with DNA after intercalation to form a *trans*-8,9-dihydro-8-(N^7-guanyl)-9-hydroxyaflatoxin adduct (Croy *et al*., 1978; Brown *et al*., 2006; Johnson and Guengerich, 1997). The cationic DNA adduct promotes depurination, resulting in an apurinic site or, under basic conditions, the imidazole ring opens to form the stable AFB_1 formamidopyrimidine. The initial cationic DNA adduct and the two secondary DNA lesions promote GC → TA transversions (Bailey *et al*., 1996). A characteristic G to T mutation is observed at the third position of codon 249 of the p53 tumour suppressor gene in more than 50% of human HCC cases associated with AFB_1 exposure (Smela *et al*., 2002).

In the human liver, at least four different cytochrome P450 enzymes can metabolize AFB_1 to the more carcinogenic epoxide, but Kamdem *et al*. (2006) have shown that cytochrome P450 3A4 plays the most important role and should be targeted for the development of inhibitors. Although AFB_1 is mostly associated with liver cancer, there is also the risk of lung cancer, either by inhalation of grain dust or by dietary exposure (Kelly *et al*., 1997; Van Vleet *et al*., 2002). He *et al*. (2006) have shown that AFB_1 can also be activated by cytochrome P450 2A13, an enzyme predominantly expressed in the human respiratory tract (Zhu *et al*., 2006).

PLC is the fifth most common cancer in the world and the third most common cause of cancer-related deaths (Lau and Lai, 2008). The incidence of liver cancer is much higher in developing countries than in developed countries, with a very high incidence in sub-Saharan Africa and Asia. The risk factors for liver cancer include exposure to hepatitis B or C and aflatoxin-contaminated food (Lau and Lai, 2008; Henry *et al*., 1999; Wang and Tang, 2004). An extensive study by Qian *et al*. (1994) on human HCC patients has shown that although aflatoxin exposure as detected by urinary aflatoxin (relative risk = 3.4), and hepatitis B infection as detected by hepatitis B surface antigen (relative risk = 7.3), play a role in the development of HCC, a significant increase in the relative risk was observed for people who tested positive for both (relative risk = 59).

Poultry, and especially turkeys, are extremely sensitive towards the toxic effects of AFB_1 and small amounts of AFB_1 cause reduction in growth rate, feed efficiency, hatchability and increased susceptibility to disease. Klein *et al*. (2000) have shown that turkey livers are more efficient in the epoxidation of AFB_1 than rodent livers and that turkeys are deficient in the glutathione S-transferase (GST) isoform that efficiently detoxifies AFB_1. This information was crucial in the development of dietary

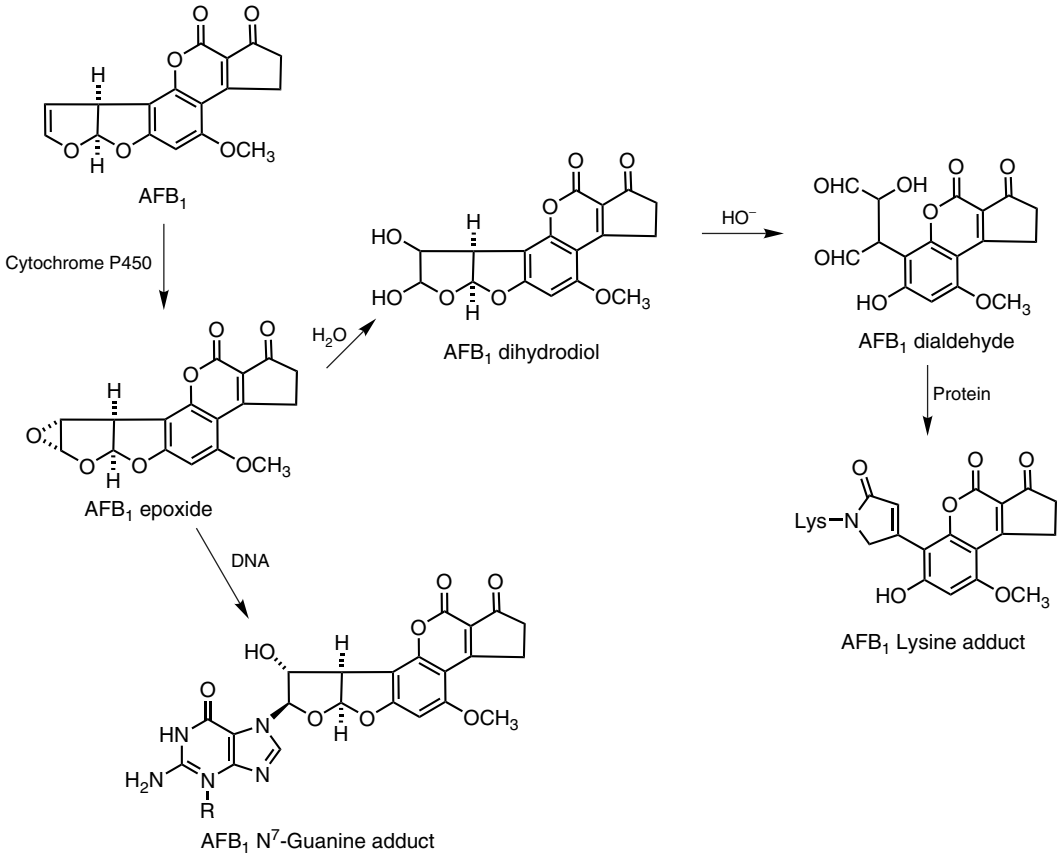

Scheme 1 Metabolism of aflatoxin B_1 in humans. (Based on Guengerich, 2008; Bedard and Massey, 2006.)

antioxidants for the protection of turkeys against AFB_1 toxicosis (Coulombe *et al*., 2005). Yip and Coulombe (2006) have cloned and expressed a cytochrome P450 from turkey livers which can transform AFB_1 to the AFB_1-8,9-oxide and AFM_1.

2.5 Control and Decontamination of Aflatoxins

Approaches to decontaminate aflatoxin-containing food or feedstuffs, or to minimize the effect thereof, include treatment with ammonia or ozone and addition of a sorbent (e.g. activated charcoal, montmorillonite or bentonite clay), microbial degradation, or the addition of antioxidant dietary supplements to the food or feedstuff.

Treatment of plant-derived material with ammonia in the gaseous phase or in solution is a well-known process and has been discussed by Piva *et al*. (1995) and Steyn and Stander (1999). The efficacy and safety of any decontamination process need constant scrutiny. Allameh *et al*. (2005) have done a comparative study on one-day-old broiler chickens fed on uncontaminated, ammonia-treated uncontaminated, aflatoxin-contaminated and ammonia-treated aflatoxin-contaminated maize and found that aflatoxin-contaminated maize led to a suppression of dietary intake, body-weight gain and feed conversion ratio in chickens, but that ammonia-treated maize (both with or without aflatoxin) did not affect any of these parameters and that treatment of aflatoxin-containing maize with ammonia can significantly suppress aflatoxicosis. Hoogenboom *et al*. (2001) investigated the absorption, distribution and excretion of aflatoxin-derived ammoniation products in lactating cows by feeding the cows naturally contaminated peanut-meal spiked with radiolabelled aflatoxin. It was observed that the reduction of aflatoxin levels by ammoniation of contaminated peanut meal resulted in a strong reduction of aflatoxin-related residues in milk and meat of cows.

Treatment with ozone has also been investigated as a method for the decontamination of aflatoxin. McKenzie *et al*. (1998) have shown that turkey poults fed on aflatoxin-contaminated whole-kernel corn treated with ozone did not exhibit any of the negative symptoms of aflatoxicosis. Inan *et al*. (2007) found that the AFB_1 content of red pepper (*Capsicum annuum*) could be reduced by 80 and 93% by exposing it to 33 and $66\,mg\,l^{-1}$ ozone, respectively, for 60 minutes. Akbas and Ozdemir (2006) investigated the effect of ozone on aflatoxin-containing pistachio kernels and ground pistachios, and found that with pistachio kernels the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

AFB_1 levels could be reduced by 23% (9 mg l^{-1} ozone, 420 minutes, 20 °C), whereas only a 5% reduction was observed for ground pistachios under the same conditions. Furthermore, although no change in the fatty acid composition of both the kernels and ground pistachios was observed, significant changes in the organoleptic properties of the ground pistachios were detected. Proctor *et al*. (2004) observed degradation of aflatoxins in peanut kernels and flour by gaseous ozonation and mild heat treatment. In a study on the safety and efficacy of ozonation by Prudente and King (2002), it was found that although ozonation (10–12 wt%) reduced aflatoxin levels by 92% and had a minimal effect on the fatty acids of the uncontaminated corn, it had an effect on the fatty acids of the contaminated corn and that extracts of the treated contaminated corn showed mutagenic effects in the Ames assay. It is clear that the safety of ozonation as a decontamination method for aflatoxins needs further investigation.

Clay additives are used to pelletize animal feeds and as an anticaking agents to improve the flow characteristics thereof. It was also found that certain clays can reduce the toxic effects of certain mycotoxins, especially the aflatoxins. The clays are added to dry feeds and, therefore, absorption of the mycotoxins must occur after ingestion. Several studies have shown the benefits of different clays against aflatoxicosis (Piva *et al*., 1995). For instance, Bailey *et al*. (2006) have investigated the effect of montmorillonite clay (NovaSil PLUS) on the performance of full-term broiler chickens fed on a diet containing 4000 μg kg^{-1} aflatoxin. The birds fed with the clay received a considerable protection against aflatoxicosis for most parameters measured (tissue analyses of blood serum, relative liver, spleen and kidney weight, and histological examination of sampled organs). However, it was clear that at exposure of this high level of aflatoxin, full protection was not received, since the performance of the chickens was not as good as the control group. In a short-term study, Wang *et al*. (2005) investigated the safety of this montmorillonite clay (NovaSil) on humans. Upon ingesting either 1.5 or 3.0 g per day for 14 days, no negative symptoms were observed. In a study among residents of Qidong, People's Republic of China, who are at high risk of developing of PLC, partly from aflatoxin ingestion, treatment with chlorophyllin, water-soluble derivatives of chlorophyll (100 mg per day, three times per day for four months) reduced the level of biomarkers associated with aflatoxin-induced liver cancer by 55% (Egner *et al*., 2001).

Extensive research has also been done on compounds/extracts that will inhibit aflatoxin biosynthesis. Many of the active inhibitors are plant-derived compounds. A review article by Holmes *et al*. (2008) summarizes a large number of such products.

Teniola *et al*. (2005) studied the biological degradation of AFB_1 by *Rhodococcus erythropolis* in liquid cultures and in cell-free extracts. A dramatic reduction of AFB was observed, and after 72 hours only 3–6% of residual AFB_1 remained. Similar results were obtained by employing *Mycobacterium fluoranthenivorans*. The high degradation rate and wide temperature range for degradation by *R. erythropolis* and *M. fluoranthenivorans* indicated the potential for application in the food and feed industries.

3 OCHRATOXIN

The ochratoxins, metabolites of several *Aspergillus* and *Penicillium* species, described by Van der Merwe *et al*. (1965), comprised the first major group of mycotoxins discovered subsequent to the aflatoxins. The ubiquitous ochratoxins formed the substance of many reviews (Steyn, 1993; Steyn and Stander, 1999; Blank *et al*., 1999; Gareis, 2000; Varga *et al*., 2001; Frank, 2001; Mantle, 2002; Belli *et al*., 2002; Aish *et al*., 2004; Huijbregts *et al*., 2005; Ringot *et al*., 2006; Clark and Snedeker, 2006; Pardo *et al*., 2006; Murphy *et al*., 2006; Pfohl-Leszkowicz and Manderville, 2007). The production of OTA by the black *Aspergilli* on grape berries, leading to the contamination of wines, established OTA as the most important mycotoxin in wine (Serra *et al*., 2005). These findings led to a renewed interest in ochratoxigenic micro-organisms, and the toxicology of OTA (Battilani *et al*., 2006; Leong *et al*., 2006a).

OTA comprises a pentaketide-derived (R)-3,4-dihydro-3-methylisocoumarin moiety linked via its 12-carboxy group to L-β-phenylalanine, as verified by X-ray crystallography (Bredenkamp *et al*., 1989) (See **Figure 1**). De Jesus *et al*. (1980), employing stable isotopes, verified the biosynthetic origin of OTA, its 12-carboxy group being derived from a C1 unit, such as methyl-methionine. The physical data for OTA and ochratoxin B (OTB) were described by Van der Merwe *et al*. (1965) and Bredenkamp *et al*. (1989). OTB, the dechloro derivative of OTA is essentially non-toxic.

3.1 Ochratoxin A-Producing Micro-Organisms

A. ochraceus, *A. carbonarius* and *Penicillium verrucosum* are the three major ochratoxigenic fungi. These fungi grow in atmospheres with a relatively high moisture content. Therefore, harvesting crops at high moisture contents and storage of contaminated commodities under damp conditions favour the production of OTA (Birzele *et al*., 2000; Esteban *et al*., 2006a; 2006b; Leong *et al*., 2006b; 2006c). However, many fungal species have the propensity to produce OTA. Frisvad *et al*. (2004) described new species of *Aspergillus* section *Circumdati*, namely *A. cretensis*, *A. flocculosus*, *A. neobridgeri*,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

A. pseudoelegans, *A. roseoglobulosus*, *A. steynii* and *A. westerdijkiae*. Except for *A. neobridgeri*, all of these species are producers of OTA. *A. ochraceus, A. westerdijkiae* and *A. steynii* were reported by Frisvad *et al*. (2004) as the most important species regarding OTA production in coffee, rice, beverages and feedstuffs. Vega *et al*. (2006) described four potent *Penicillium* species as OTA producers, namely *P. brevicompactum*, *P. crustosum*, *P. olsonii* and *P. oxalicum*. Rizzo *et al*. (2002) reported that *Aspergillus* and *Penicillium* fungi contaminate cereals and foodstuffs, and found five new isolates of *Aspergillus* which produce OTA namely: *A. albertensis*, *A. auricomus*, *A. wentii*, *A. fumigatus* and *A. versicolor*. Al-Julaifi (2003) found that *Eurotium amstelodami*, *E. herbariorum* and *Euortium* spp. isolated from barley all produced OTA.

3.1.1 Producers of OTA from Grapes

Although OTA was first detected in wine during 1996, the role of the black *Aspergilli* in OTA production was only discovered in 1999. The black *Aspergilli*, namely *Aspergillus* section *Nigri* are the producers of OTA on grape berries/vines with *A. carbonarius* as the main producer (Battilani *et al*., 2003; 2004; 2006; Serra *et al*., 2003; 2005; Bau *et al*., 2005; Medina *et al*., 2005; Belli *et al*., 2006; 2007; Leong *et al*., 2006a; Chulze *et al*., 2006; Bejaoui *et al*., 2006b; Gomez *et al*., 2006; Martinez-Culebras and Ramon, 2007; Ponsone *et al*., 2007; Hocking *et al*., 2007; 2008). Esteban *et al*. (2006b) observed that *A. carbonarius* is able to grow and produce OTA in a wide range of water activities (a_w) and temperatures. Leong *et al*. (2006b) investigated the effects of a_w and temperature on the survival of *A. carbonarius* spores *in vitro* and concluded that increased incidence of black *Aspergillus* spp. in dry soils and from grapes in dry conditions may result partly from prolonged survival of spores. In fact, *A. carbonarius* grows optimally at 32–35 °C and is resistant to sunlight. In a related study, employing a simulated grape-juice medium, Leong *et al*. (2006b) observed that maximum growth for *A. carbonarius* occurred at about 0.965 a_w and 30 °C, and for *A. niger*, at about 0.98 a_w and 35 °C. In Spain, Belli *et al*. (2004a) found that the fungal infection in grape berries increased with time, reaching a maximum at harvest. A total of 386 isolates of *Aspergillus* section *Nigri* and 10 of *Aspergillus* section *Circumdati* were isolated and tested for their ability to produce OTA. Twenty-one strains produced OTA (18 *Aspergillus* section *Nigri* and three *Aspergillus* section *Circumdati).*

To monitor and quantify *A. carbonarius,* a specific primer pair Ac12RL_OTAF/Ac12RL_OTAR, was designed from the acyltransferase (AT) domain of the polyketide synthase sequence Ac12RL3 to amplify 141 bp by polymerase chain reaction (PCR) (Atoui *et al*., 2007). Among the toxigenic fungi tested, only *A. carbonarius* gave a positive result. This specific primer pair was successfully employed in real-time PCR conjugated with SYBR Green I dye for the direct quantification of this fungus in grape samples. A positive correlation was found between *A. carbonarius* DNA content and OTA concentration in 72 grape samples, allowing for the estimation of the potential risk from OTA contamination.

Bau *et al*. (2006) developed RFLP (restriction fragment length polymorphism) characterization of *A. niger* aggregate species on grapes from Europe and Israel. All of the strains belonging to the *A. niger* aggregate were classified into the two RFLP types previously defined: type N (43%) and type T (57%). Out of the 173 strains of *A. niger* aggregate, 20 produced OTA ($0.1–10.5\,\mu g\,g^{-1}$). All the OTA-producing species belonged to the N-RFLP type.

3.1.2 Producers of OTA from Cereal Grain

OTA was initially obtained from cultures of *A. ochraceus*, isolated from grain sorghum (Van der Merwe *et al*., 1965). In Poland, Czerwiecki *et al*. (2002a; 2002b) studied 200 samples of cereal grain for the presence of OTA and contamination by microscopic fungi. These fungi were classified as *P. cyclopium*, *P. viridicatum*, *A. ochraceus* group, *A. glaucus* and *A. versicolor*. OTA-producing *Penicillium* strains were isolated from 71% of the samples; in 28% of samples, only *Aspergillus* strains (species known to be OTA producers) were noted.

Czaban *et al*. (2006) studied the production of OTA by *P. verrucosum* on wheat grain and wheat-grain barley, respectively. *P. verrucosum* occurs in the cool and temperate climates of Northern Europe and Canada, and is the cause of the formation of OTA in cereal products. Gareis and Gareis (2007) reported that toxigenic *P. nordicum* and *P. verrucosum* produced guttation droplets containing high amounts of OTA and OTB when grown on Czapek yeast extract.

Bogs *et al*. (2006) developed a PCR method for differentiation and detection of the two known OTA-producing species, *P. verrucosum* and *P. nordicum.* It is based upon two genes of the OTA biosynthesis, namely the OTA polyketide synthase gene (otapksPN) and a nonribosomal peptide synthetase gene (otanpsPN) from *P. nordicum.* Both OTA-producing *Penicillia* differ characteristically in the PCR result, making a taxonomic differentiation possible.

3.1.3 Producers of OTA from Coffee

Frank (2001) found *A. niger, A. carbonarius* and *A. ochraceus* (and other *Circumdati* species) on coffee. *A. ochraceus* is the source of OTA contamination in coffee, whereas the commonly occurring *A. niger*, with a low capacity for OTA production, is an important quality

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

degrader. Related findings were reported by Bucheli *et al*. (2001), Urbano *et al*. (2001), Suarez-Quiroz *et al*. (2004), Pardo *et al*. (2004) and Kouadio *et al*. (2007a). Recently *Aspergillus westerdijkiae* was also described as a potent OTA producer in coffee beans (Mata *et al*., 2007; Morello *et al*., 2007).

Leong *et al*. (2007) studied the biota of green Vietnamese coffee beans: *A. niger* infected 89% of Robusta beans, whereas *A. carbonarius* and yellow *Aspergilli* each infected 12–14% of beans. OTA was not produced by *A. niger* or *A. ochraceus*, but was detected in 110 of 113 isolates of *A. carbonarius*, 10 isolates of *A. westerdijkiae* and one isolate of *A. steynii*.

Sartori *et al*. (2006) developed a multiplex-PCR for detection of *A. carbonarius, A. niger* and *A. ochraceus* in coffee-bean samples, and succeeded in developing specific primers for *A. niger* detection. The primer designed (OPX7372) provided an amplicon of 372 pb in all *A. niger stricto sensu* isolates. Subsequently a multiplex-PCR method for detection of *A. carbonarius, A. niger* and *A. ochraceus* species in coffee beans was developed.

3.1.4 Producers of OTA from Nuts and Olives

In studies on OTA and the occurrence of ochratoxigenic black *Aspergilli* in stored peanut seeds from Argentina, 43 isolates (27%) of *Aspergillus* section *Nigri,* were found to be ochratoxigenic. The highest percentage of ochratoxigenic strains (57%) was found within the *A. carbonarius* spp. (Magnoli *et al*., 2006). Moroccan olives and olive cake contained strains of *A. niger* which produced OTA (Roussos *et al*., 2006).

3.2 Analytical Methodology for Ochratoxin A

3.2.1 Chromatographic Methods for Ochratoxin A

The present trend in the analysis of mycotoxins is to use IAC as a clean-up and enrichment technique. The OTA in the resulting purified extract is determined by HPLC linked to fluorescence detection or, more recently, to mass spectrometric detection. This methodology has been used for establishing analytical methods for OTA in various matrices at levels consistent with intended EU regulatory limits. Interlaboratory collaborative studies have successfully been completed for OTA in baby food (Burdaspal *et al*., 2001), OTA in currants, raisins, sultanas, mixed dried fruit and dried figs (MacDonald *et al*., 2003) and OTA in green coffee (Vargas *et al*., 2005). Determination of OTA in roasted coffee was achieved with a sequential clean-up of the extract, using first a phenyl silane solid-phase extraction cartridge and then an IAC specific for OTA (Entwisle *et al*., 2001). In a study of three wine samples distributed to 24 laboratories from 17 countries in five continents, 75% of the laboratories used IAC clean-up and HPLC with fluorescence detection (Pascale *et al*., 2000). Only three outliers were found over all the analyses performed, demonstrating the reproducibility of methods for OTA determination in wine. IAC clean-up with HPLC determination has also been used for the determination of OTA in physiological samples, such as urine and blood serum (Yordanova *et al*., 2005). All the above methods have used fluorescence detection, although the purified extracts can also be quantitated by liquid chromatography-mass spectrometry (LC-MS). Chung and Kwong (2007) reported the determination of OTA at ppt levels in cereal products by IAC clean-up and LC-MS. OTA was extracted from cereal products with acetonitrile–water, the extract was diluted with a buffer and cleaned up on an IAC before LC-MS analysis. Two multiple-reaction monitoring (MRM) transitions were used, one for quantification of OTA and one for confirmation of identity. A recent report described the simultaneous determination of OTA, together with aflatoxins, deoxynivalenol, zearalenone, and T-2 and HT-2 toxins in maize by LC-MS/MS after multitoxin IAC clean-up with a new multitoxin IAC containing antibodies for all these mycotoxins (Lattanzio *et al*., 2007). Detection and quantification of the 11 mycotoxins were performed by reversed-phase liquid chromatography coupled with electrospray ionization triple quadrupole mass spectrometry (LC-ESI-MS/MS) using, as chromatographic mobile phase, a linear gradient of methanol/water containing 0.5% acetic acid and 1 mM ammonium acetate. Method performances were quite satisfactory for all tested mycotoxins at contamination levels close to or below the relevant EU maximum permitted or recommended levels. Trucksess *et al*. (2006; 2007) used an IAC with antibodies against OTA and aflatoxin to determine these toxins in ginseng, ginger and other botanical roots, by fluorescence detection with LC-MS confirmation.

Apart from the IAC clean-up methods reviewed above, other extract purification methods are still being investigated. Sugita-Konishi *et al*. (2006a) compared two clean-up procedures, namely a multifunctional column and an IAC, for HPLC determination of OTA in cereals, raisins and green coffee beans. The results suggest that a multifunctional column could be used to detect OTA in wheat and corn grits at a concentration as low as $0.5\,\mu g\,kg^{-1}$; however, it was difficult to detect OTA in green coffee beans and raisins at such a low level. Although an IAC could be used for all the test samples in this study, from a low level to a high level, the recovery rates were lower than with a multifunctional column. In a related study, employing ultra-performance liquid chromatography-MS/MS (UPLC-MS/MS), Ren *et al*. (2007) described the simultaneous determination of multicomponent mycotoxin contaminants in foods

and feeds. The treatment of the homogenized samples involved extraction, followed by clean-up with multifunctional cartridges, filtration, concentration and secondary filtration. The limit of quatitation (LOQ) of selected analytes ranged from 0.01 to 0.70 $\mu g\,kg^{-1}$. Reinsch *et al*. (2005) reported the use of anion exchange/reversed-phase clean-up for the determination of OTA in mulled and red wine. The substances were analysed by LC-MS/MS. The method was validated with naturally contaminated and spiked wine samples with OTA contents from 1.34 to 3.48 $\mu g\,kg^{-1}$. A clean-up method for beer, which involved zinc acetate and silica solid-phase extraction cartridges, was developed (Medina *et al*., 2006). Another method developed for beer involved clean-up on a polymeric sorbent and determination of both aflatoxins and OTA by UPLC-MS/MS (Aresta *et al*., 2006).

Apart from the above methods, which all involve sample extract clean-up prior to chromatography, certain laboratories have developed methods which utilize the sensitivity of MS detection to avoid clean-up altogether. Timperio *et al*. (2006) developed a rapid and highly sensitive method for detection of OTA in grapes by using nano-reversed-phase high-performance liquid chromatography with electrospray ionization mass spectrometry (nano-RP-HPLC-ESI-MS). This method gives a detection limit in the fg ml^{-1} range, without resorting to IAC clean-up or concentration. The advantage of coupling a direct-injection technique with LC-MS analysis lies in its ability to undertake multitoxin determination of a wide range of toxins. This has been achieved for OTA and other toxins in maize and wheat matrices (Sulyok *et al*., 2006; 2007; Spanjer *et al*., 2008).

3.2.2 Capillary Electrophoresis Methods for Ochratoxin A

Apart from the analytical separation achieved by chromatography, a few papers have described the application of capillary electrophoresis (CE) to the determination of OTA. Koeller *et al*. (2006) compared ELISA and CE with laser-induced fluorescence (LIF) detection in the analysis of OTA in low volumes of human blood serum. Both methods showed an LOD of 0.5 ng ml^{-1}. However, comparing the precisions of both methods, the data show that the quantified concentrations in ELISA are higher than the corresponding concentrations in the CE-LIF method. Hong and Chen (2007) achieved the selective enrichment of OTA using human serum albumin (HSA)-bound magnetic beads as the concentrating probes for OTA in aqueous solutions or in wine. Sensitive detection was achieved using CE coupled with electrospray ionization mass spectrometric (ESI-MS) analysis. This method features speed and cost-effectiveness, making it suitable for the purpose of rapid screening. The lowest detection limit for OTA was approximately 4 $\mu g\,l^{-1}$.

3.2.3 Immunological Methods for Ochratoxin A

Apart from conventional commercial ELISA methods, a number advances have been made in the area of antibody-based rapid techniques for OTA. Sibanda *et al*. (2001) developed a flow-through enzyme immunoassay for the fast screening of green coffee for OTA contamination. Saha *et al*. (2006) applied membrane-based dot immunoassays to mycotoxin analyses and developed a method for homogeneous spotting of antibodies on membranes. This method gave twofold increased sensitivity in a competitive assay of the toxin compared to conventional spotting methods. The detection limit of OTA obtained in wine (1 $\mu g\,l^{-1}$) and coffee (2.5 $\mu g\,kg^{-1}$) is superior to values reported recently. De Saeger *et al*. (2006) developed a rapid antibody-based mycotoxin screening technique incorporating microporous membranes for use at the place of sampling. When using this clean-up tandem-assay column for the detection of OTA in roasted coffee, a cut-off value of 6 $\mu g\,kg^{-1}$ was reached. No false positive results were obtained, however the false negative rate was 8%. An immunosensor based on an optical waveguide lightmode spectroscopy (OWLS) technique was developed for the measurement of AFB_1 and OTA in barley and wheat flour, and the results were in good correlation with those measured by ELISA (Adanyi *et al*., 2007).

A novel quartz crystal microbalance (QCM)-based immunosensor was developed by immobilizing anti-OTA antibodies onto the surface of the 16-mercaptohexadecanoic acid (MHDA)-modified electrode, and allowing competition between free OTA and that conjugated with BSA to occur (Tsai and Hsieh, 2007). The OTA-specific assay exhibited a working range of 50–1000 ng ml^{-1} and a detection limit of 16.1 ng ml^{-1}. Goryacheva *et al*. (2007b) used a rapid all-in-one three-step immunoassay for noninstrumental detection of OTA in high-coloured herbs and spices. The same research group developed a simultaneous detection of AFB_1 and OTA using a clean-up tandem immunoassay column (Goryacheva *et al*., 2007a). The described method was applied to the simultaneous detection of AFB_1 and OTA in spices with cut-off levels at 5 and 10 $\mu g\,kg^{-1}$, respectively. Results were confirmed by LC-MS/MS with IAC clean-up.

3.3 Occurrence of Ochratoxins

Although OTA was discovered in 1964, it was only found in nature in the late 1960s by Shotwell *et al*.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(1969). OTA is regarded as one of the most commonly occurring mycotoxins, found, not only in cereals (Czerwiecki *et al*., 2002a; Beretta *et al*., 2002), grapes, raisins and wines (Zimmerli and Dick, 1996), in nuts (Magnoli *et al*., 2006; 2007), in beers (Mateo *et al*., 2007), in coffee (Jørgensen, 1998; Pardo *et al*., 2004), in cocoa (Bonvehi, 2004), in spices (Aziz *et al*., 1998), in dried figs (Senyuva *et al*., 2005), in mouldy fruit (Engelhardt *et al*., 1999) and in dairy and meat products of animals (Aish *et al*., 2004; Jørgensen, 1998), but also in human blood and milk. Cereals are considered the major source of human OTA intake, with wine as the second most important source (Miraglia and Brera, 2002). The main regions of concern are Europe and, for some foods, Africa. Occurrence data may vary in a region due to year-to-year variation in climatic conditions, and variation in agricultural and processing practices. A plethora of papers and reviews have appeared on the occurrence of OTA. A selection of the most recent findings will be discussed in this section.

3.3.1 OTA in Human Food

Wheat, barley, oats, maize and rye are highly susceptible to fungal infection and mycotoxin contamination. The EU laid down an MTL of $5.0\,\mu g\,kg^{-1}$ for raw cereals (European Commission, 2006; Food and Agriculture Organization, 2004). In the BEN areas, investigations revealed the mean concentration in maize of positive samples to be $73.4\,\mu g\,kg^{-1}$ (50% incidence) in 1997 (Jurjevic *et al*., 1999). In Spain and Portugal (83 samples including rice, wheat, barley, rye, oats and maize) OTA was detected in 22% of cereal samples, with mean concentrations of 0.93 and $0.64\,\mu g\,kg^{-1}$, respectively, for each country (Juan *et al*., 2008). In Poland, rye from the conventional farms showed a 5.8% OTA contamination and a mean concentration of $1.38\,\mu g\,kg^{-1}$, while rye from ecological farms was contaminated over six times as frequently (37.5%), with a mean concentration of $3.17\,\mu g\,kg^{-1}$ (Czerwiecki *et al*., 2002a). Yet, a study by Biffi *et al*. (2004) of commercial cereal products in the Italian market revealed that all products contained OTA in concentrations below the Italian legal limit of $3\,\mu g\,kg^{-1}$, except four samples of baby food that exceeded the Italian permitted level of $0.5\,\mu g\,kg^{-1}$. Analyses of 338 samples of baby food indicated that 16.8% contained detectable quantities of OTA and 3.4% contained OTA above the Italian permitted value (Beretta *et al*., 2002). OTA was present in 60% of semolina-based baby foods ($0.14–0.65\,\mu g\,kg^{-1}$) and in 80% of multicereal formulas (up to $0.4\,\mu g\,kg^{-1}$).

A survey of the occurrence of aflatoxins, OTA and fumonisins in retail foods in Japan revealed that OTA was present in low levels ($<0.8\,\mu g\,kg^{-1}$) in oatmeal, wheat-flour, rye, buckwheat flour, green and roasted coffee beans, raisins, beer and wine, but not in rice or corn products (Sugita-Konishi *et al*., 2006b). Similarly in Brazil, no OTA could be detected in rice (68 samples analysed) (Simionato *et al*., 2003). However, the incidence of occurrence of OTA in rice was found to be 90%, with an average value of $4.15\,\mu g\,kg^{-1}$ in Morocco (Zinedine *et al*., 2007b). In Korea, where rice is the major contributor (>90%) to the Korean dietary intake, it was found to contain $2.1–6.0\,\mu g\,kg^{-1}$, presenting no considerable risk to the consumer (Park *et al*., 2005).

OTA in beer has its origin mainly from malting barley. OTA occurs in beer with high frequency, but in low levels all over the world (Scott and Kanhere, 1995). In a study in Denmark, a 100% incidence was achieved for 21 samples of beer, with an average concentration of $0.049\,\mu g\,l^{-1}$ (Jørgensen, 1998). Similar results of high incidence, but low levels of OTA were obtained for Belgian beers (Tangni *et al*., 2002). This was again confirmed by a recent survey in which more than 50% of analysed samples do not show detectable levels, that is, $<0.2\,\mu g\,l^{-1}$ by Mateo *et al*. (2007). Yet, in the case of some traditionally brewed beers in South Africa, 34% of traditional beers prepared from the raw ingredients maize and sorghum, contained OTA concentrations of $1.5–2340\,\mu g\,l^{-1}$ (Odhav and Naicker, 2002).

OTA in red wine was first reported in 1995 (Zimmerli and Dick, 1996), followed by numerous surveys throughout the world (Belli *et al*., 2002; Battilani *et al*., 2006; Serra *et al*., 2006). The occurrence of OTA in grapes is normally higher than in wine, since some OTA is removed with the removal of spent fractions during the winemaking (Fernandes *et al*., 2007). Generally there is an increase in occurrence for wines from warmer climates. Levels as high as $15.6\,\mu g\,l^{-1}$ have been reported in Southern Europe (Miraglia and Brera, 2002). Yet, El Khoury *et al*. (2006) reported low values (maximum $0.126\,\mu g\,l^{-1}$) for higher-lying areas along the Mediterranean, such as the Bekaa valley in the Lebanon. Stander and Steyn (2002) reported on a comprehensive study on the occurrence of OTA in South African wines. The levels of OTA of most red and white wines were substantially lower than the permissible levels, however, high levels of OTA were detected in a few noble late harvest wines. For the USA, no quantifiable levels of OTA in wine were reported in some investigations (Ng *et al*., 2004); in general North American wines have lower levels of OTA contamination than European wines (Otteneder and Majerus, 2000). Likewise, in Brazil, a mean concentration of $0.0344\,\mu g\,l^{-1}$ was detected in 28.75% of positive samples from 80 samples analysed (Rosa *et al*., 2004) and in Argentina and Chile no OTA could be detected on the 2002 and 2003 markets (Pacin *et al*., 2005). OTA levels generally decrease in the order red wine, rosé and white wine, and usually dessert wines have higher levels than dry wines (Shephard *et al*., 2003; Finoli *et al*., 2004; Rosa *et al*., 2004). OTA has also been detected in low levels in Australian wines (concentration range $<0.05–0.62\,\mu g\,l^{-1}$), but here no significant difference was observed between red and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

white wines (Hocking *et al*., 2003). Similarly Stefanaki *et al*. (2003) found that the OTA concentration in red dry wines did not differ significantly from that found in white and rosé wines in Greece. A survey of the presence of OTA in sweet wines produced in Spain and other countries showed the highest levels for Spain, France and Greece with mean concentrations of 0.645, 0.212 and 0.833 $\mu g\,l^{-1}$, respectively (Burdaspal and Legarda, 2007). The highest OTA concentration reported for dessert wine was 15.25 $\mu g\,l^{-1}$ (Belli *et al*., 2004b). In a study of wine and grape juice on the Polish market, it was found that 92% of the red wine samples contained 0.0022–6.710 $\mu g\,l^{-1}$ OTA, while 100% of the juice samples contained 0.0016–0.0647 $\mu g\,l^{-1}$ (Czerwiecki *et al*., 2005). The EU laid down an MTL of 2.0 $\mu g\,l^{-1}$ for wine, but no levels are set for wines with alcohol strength of more than 15% vol.

Dried fruit is a further source of OTA in human diets (Engelhardt *et al*., 1999; MacDonald *et al*., 2003). OTA has been found in much higher concentrations in Europe (50–70 $\mu g\,kg^{-1}$) in dried vine fruit than in wine or grape juice (Battilani *et al*., 2006; Miraglia and Brera, 2002). Yet, the average OTA contamination of dried vine fruits in the USA during 1998–1999 was reported as 1.27 $\mu g\,kg^{-1}$. It was reported that 79% of samples of raisins and 59% of sultanas from the Canadian retail market had OTA levels above the limit of quantification (Lombaert *et al*., 2004), which was comparable with incidence rates reported in a Greek survey (Stefanaki *et al*., 2003). The incidence of OTA on unprocessed sultanas from Turkey was reported as 68% with a mean concentration of 3.4 $\mu g\,kg^{-1}$ (Meyvaci *et al*., 2005), while an incidence of 90.7% and a mean concentration of 1.36 $\mu g\,kg^{-1}$ were reported for processed sultanas in Turkey (Aksoy *et al*., 2007). In Morocco, the incidence of occurrence of OTA in raisins and dried figs was found to be 30% and 65% with average values for positive samples of 0.96 and 0.33 $\mu g\,kg^{-1}$, respectively (Zinedine *et al*., 2007b). In a study over two years an incidence of 14–15% (>0.5 $\mu g\,kg^{-1}$) of occurrence of OTA was found in dried figs in Turkey (Senyuva *et al*., 2005). The incidence of contamination of dried fruit is influenced by factors such as the suitability of the fruit as a substrate and the possibility of fungal infection of the fruit, as well as the harvesting and drying conditions (Drusch and Ragab, 2003).

OTA contamination of green and processed coffee has been documented since the 1970s (Levi *et al*., 1974). Romani *et al*. (2000) showed that 65% of samples of green coffee beans from various countries tested positive for OTA, with concentrations up to 48 $\mu g\,kg^{-1}$. In a recent study, coffee and corresponding byproducts from seven different geographic regions were investigated (Napolitano *et al*., 2007). Costa Rica and Indian green coffees were the most contaminated samples, with mean concentrations of 13 and 11 $\mu g\,kg^{-1}$, respectively, while Ethiopian coffee was the least contaminated, with 3.8 $\mu g\,kg^{-1}$ of OTA. No significant differences in OTA occurrence between the two main varieties Arabica and Robusta could be observed. The hypothesis is that roasting and processing of coffee reduce the levels of OTA in the final product (Bayman and Baker, 2006).

Only a few studies have evaluated OTA in cocoa products. The highest levels of OTA in 170 samples from different geographical origins were detected in roasted cocoa shell, raw cocoa shell, cocoa cake and cocoa powder with mean concentrations of 11, 2.79, 2.60 and 2.41 $\mu g\,kg^{-1}$, respectively (Bonvehi, 2004). The occurrence of OTA in 18 pure cocoa powder samples purchased from supermarkets, organic product shops and retail shops in Italy was investigated (Tafuri *et al*., 2004). Nine samples were positive and had concentrations ranging between 0.22 and 0.77 $\mu g\,kg^{-1}$ with a mean of 0.43 $\mu g\,kg^{-1}$. Of 14 conventional samples analysed, four samples were above the suggested legal limit (0.5 $\mu g\,kg^{-1}$); this provided a cause for concern, as cocoa is widely used as an ingredient in children's snack foods.

Few surveys of the natural occurrence of OTA in stored peanuts have been reported. In a recent study in Argentina, OTA was found in 60% of the peanut samples, with mean levels ranging from 5.6 to 130 $\mu g\,kg^{-1}$ (Magnoli *et al*., 2006; 2007). In Morocco, the incidence of occurrence of OTA in walnuts and peanuts was found to be 35% and 25%, respectively, with average values for positive samples of 0.11 and 0.68 $\mu g\,kg^{-1}$ (Zinedine *et al*., 2007b).

The occurrence of OTA in olive oil has drawn attention due to its importance as a fat source in the Mediterranean diet. Preliminary data on the presence of OTA in black table olives from Moroccan origin revealed a mean of 0.60 $\mu g\,kg^{-1}$ for seven contaminated olive samples from 10 samples taken from supermarkets and retailers (El Adlouni *et al*., 2006). It was claimed that contaminated black olives could contribute significantly to the total daily intake of OTA. In another study, the occurrence of aflatoxins and OTA was determined in 28 samples of Sicilian extra virgin olive oil produced from olives from traditional and biological agriculture, as well as in 45 samples of green and black olives. (Finoli *et al*., 2005). The OTA levels were 0.052–0.244 $\mu g\,kg^{-1}$ for oil and 0.101–8.391 $\mu g\,kg^{-1}$ for olives. Ferracane *et al*. (2007) found labelled olive oil to be less contaminated by OTA than unlabelled olive oil (mean values of 0.66 $\mu g\,kg^{-1}$ and 2.47 $\mu g\,kg^{-1}$, respectively).

OTA is a frequent contaminant in spices, as reported by Scheuer and Gareis (2002) in a survey of 681 samples of 50 different spice commodities from the German retail market. On comparing the regions of origin of these spices, higher levels of contamination were found in spices from Southeast Asia than from America, Africa, Europe and Near Asia. The highest frequency of occurrence was found for chilli (100%) and pepper (23%) from Southeast Asia and India, and for paprika (23%) from Israel.

3.3.2 OTA in Animal Feed and Animal Products

The presence of OTA in animal feeds raised concern for the livestock industry. The occurrence of mycotoxins in animal feeds and feed ingredients in relation to the regions of their sourcing has been reported by Binder *et al*. (2007). Of the 1507 samples from European and Mediterranean markets and 1291 samples from the Asia-Pacific region, 52% and 30%, respectively, tested positive for *Fusarium* mycotoxins and the non-*Fusarium* toxins, OTA and AFB_1. OTA was found to be a minor contaminant when compared with deoxynivalenol, zearalenone, T-2 toxin, fumonisins and aflatoxins.

OTA is found in dairy products and the meat of animals consuming OTA-contaminated grains, that is, cow's milk, pork and poultry (Boudra *et al*., 2007). In a survey in Denmark of pork and poultry meat and liver, the mean values ranged from 0.02 to 0.11 $\mu g\,kg^{-1}$ (Jørgensen, 1998). Compared to cereal and cereal products the contribution from pork and poultry by the Danish population is considered of less importance. Samples of organic cow's milk, conventional cow's milk and cow's milk-based infant formulas were analysed for the occurrence of OTA (Skaug, 1999). OTA was detected in 6 of 40 conventional cow's milk samples (11–58 $ng\,l^{-1}$), and in 5 out of 47 organic milk samples (15–28 $ng\,l^{-1}$). No OTA was detected in any of the 20 infant formula samples. The OTA levels in cow's milk found in this investigation are sufficient to cause a higher intake of OTA than the suggested tolerable daily intake (TDI).

3.3.3 OTA in Human Blood and Milk

The possibility for maternal milk to be contaminated exists when mothers are exposed to OTA in food. A study was carried out on lactating women in Northern Italy in which OTA was detected in 85.7% of the milk samples with a mean value of 6.01 $ng\,l^{-1}$ (Turconi *et al*., 2004). The results of this work indicated that a high percentage of babies on maternal milk were found to be exposed to mycotoxin levels greater than the TDI value of 0.2 ng (kg body weight)$^{-1}$. Elevated concentrations of OTA are often found in the sera of people exposed to this mycotoxin. In a study of patients affected with renal diseases Grosso *et al*. (2003) found that the average OTA concentration for patients with urinary tract disease (excluding cancer patients) was $0.99 \pm 1.28\,\mu g\,l^{-1}$, while that for the non-nephropathic patients was $0.53 \pm 1.00\,\mu g\,l^{-1}$.

3.4 Biological Activity of Ochratoxins

OTA exhibits many adverse toxicological effects, including renal and hepatic toxicity, mutagenicity, carcinogenicity, teratogenicity, immunotoxicity and neurotoxicity. It is linked to the aetiology of DPN and poultry mycotoxicoses. OTA is relevant to human health and implied in BEN and urinary system tumours in North Africa (Golian, 2000; Mantle, 2002; Gekle *et al*., 2002; Fuchs and Peraica, 2005; O'Brien and Dietrich, 2005; Castegnaro *et al*., 2006a; Ringot *et al*., 2006; Tanaka and Yoshizawa, 2006; Voice *et al*., 2006; Pfohl-Leszkowicz and Manderville, 2007; Pfohl-Leszkowicz *et al*., 2007). Based on the ground-breaking research of Krogh and coworkers, OTA became accepted as the cause of DPN (Krogh, 1978). These findings strongly influenced the association of OTA with BEN.

In a study of German food and its exposure to consumers, OTA was found in 57.2% of the food samples and in 98% of the blood samples of consumers (Gareis *et al*., 2001). Contamination of food by OTA occurs primarily during preharvest periods (Al-Anati and Petzinger, 2006). (see Section 3.3 for the worldwide occurrence of OTA in commodities). Studies on the effect of OTA in human proximal tubule cells and human fibroblasts in primary culture (Schwerdt *et al*., 2007) suggested that consumption of OTA is almost unavoidable, leading to the detection of low blood concentrations, previously considered harmless, which impacted on the reassessment of the risk of OTA consumption. OTA has a half-life of about 35.5 days in humans, 21 days in monkeys, 72–120 hours in pigs and 40 hours in mice (O'Brien and Dietrich, 2005). Mantle (2008) interpreted the pharmacokinetics of OTA in blood plasma of rats, during and after acute or chronic ingestion. Based on animal and epidemiological studies, OTA has been classified by the International Agency for Research on Cancer (2002) as a Group 2 B carcinogen (possibly carcinogenic to humans). Maximum permissible OTA concentrations of 5 and 3 $\mu g\,kg^{-1}$ in raw cereals and processed cereal products, respectively, were reported by O'Brien and Dietrich (2005). Although carcinogenic effects of OTA have been demonstrated only in laboratory animals until now, several European countries have enacted or proposed regulations for levels of OTA in food. This has prompted adoption of regulatory limits in several countries (Monaci and Palmisano, 2004).

3.4.1 Toxicological Effects

In monogastric species, OTA is highly bioavailable with 40–60% of an oral dose being absorbed from the gastrointestinal tract. Due to extraordinary high plasma-protein binding, elimination of OTA is a rather slow process and high concentrations are found in blood, kidneys and the liver. Different from monogastric species, ruminants may tolerate larger amounts of OTA due to hydrolysis to the less toxic metabolite ochratoxin α by micro-organisms within the forestomach contents (Blank *et al*., 1999).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Several mechanisms have been proposed to be involved in the toxicity of OTA: inhibition of protein synthesis, promotion of membrane peroxidation, disruption of calcium homeostasis, inhibition of mitochondrial respiration, apoptosis and DNA damage (O'Brien and Dietrich, 2005; Ringot *et al*., 2006). The contribution of metabolites of OTA in its genotoxicity and carcinogenicity is still unclear (See Section 3.4.4). More recent studies are focussed on the OTA ability to disrupt cellular signalling pathways thereby influencing cell viability and cell growth parameters. The effects of OTA in the nanomolar range and its interactions with cellular signalling networks in different renal cells proposing OTA to act as a signal modulator have been recently reviewed (Gekle *et al*., 2005). Several nephrotoxicants and renal carcinogens have been shown to alter cell–cell signalling by interference with gap junction intercellular communication (GJIC) and/or cell adhesion. It was therefore important to investigate if the disruption of cell–cell interactions occurs in kidney epithelial cells in response to OTA treatment. A study in kidney epithelial cells (MDCK) utilizing the scrape-load/dye-transfer assay suggested that altered cell adhesion and GJIC and cell–cell signalling may contribute to OTA toxicity and carcinogenicity (Mally *et al*., 2006).

When exposed to different concentrations of OTA for 24 hours, apoptotic and necrotic renal cell death was induced in MDCK, porcine renal epithelial cells (LLC-PK1) and RK-13 renal cells in a cell type- and concentration-dependent manner (Petrik *et al*., 2005). Apparently, MDCK and LLC-PK1 cells are more sensitive to OTA than RK-13 cells. Repeated exposure of renal epithelial cells to OTA or OTB provided a subpopulation of cells with reduced ochratoxin-sensitivity and alterations in growth characteristics (Heussner *et al*., 2007).

Investigations of the biotransformation and nephrotoxicity of OTB in rats showed that, in contrast to OTA, no tissue-specific retention of OTB was evident after single and repeated administration (Mally *et al*., 2005). These data suggest that OTA and OTB have a similar potential to induce cytotoxicity *in vitro*, but large differences occur in their potential to induce nephrotoxicity in rodents. OTB is also more extensively metabolized and more rapidly eliminated than OTA, which could explain differences in toxicokinetics and lower nephrotoxicity. The synergistic effects of OTA, OTB, citrinin (CIT) and PAT were investigated *in vitro*, using the well-established porcine renal cell line LLC-PK1 and the MTT reduction test as a cytotoxicity end point (Heussner *et al*., 2006). The results confirmed a potential for interactive effects of CIT and OTA and possibly other mycotoxins in cells of renal origin. The combined treatment with fumonisin B_1 (FB_1), beauvericin and OTA resulted mostly in additive effects, especially after a 24-hour exposure, although synergistic, as well as antagonistic interactions, could not be excluded, depending on toxin concentrations and time of exposure (Klaric *et al*., 2007).

The immunomodulatory effects of OTA and OTC on the human monocyte/macrophage line THP-1 were investigated (Muller *et al*., 2003). Metabolic activity, cell proliferation, cell membrane integrity, cell differentiation, phagocytic behaviour, nitrogen-oxide synthesis and cell surface markers were largely suppressed by OTA and OTC at concentrations ranging between 10 and 1000 ng ml^{-1}.

3.4.2 OTA as a Liver Toxin

Although no hepatic disease is correlated with OTA consumption, the adverse toxic effects in the liver of experimental animals are highly relevant. The overall early effects of chronic OTA treatment on rat liver, analysing different aspects related to: (i) fibrosis; (ii) oxidative stress and stress response and (iii) a possible tumour-promoting effect have been investigated (Gagliano *et al*., 2006). These *in vivo* results showed that OTA-induced liver injury involved a reduction in the ability to counterbalance oxidative stress, presumably leading to altered GJIC and loss of cell adhesion and polarity. These findings suggest that mild oxidative damage might be a key factor, in combination with other cytotoxic effects, in triggering the promotion of liver tumours after exposure to OTA.

The underlying mechanisms of OTA-induced cellular toxicity in liver (HepG2) cells were investigated by determining the impact of serum concentration, dietary antioxidants and glutathione-modulating compounds (Bosch-Saadatmandi *et al*., 2006). It has been suggested that oxidative damage contributes to its cytotoxic effects, therefore, dietary antioxidants, such as vitamin E and polyphenols, may counteract OTA-induced cell death. The effects of serum concentrations, as well as different dietary antioxidants on the viability of OTA-exposed liver (HepG2) cells showed that the cytotoxicity was strongly dependent on the protein concentration in the cell culture medium and was not prevented by preincubation with dietary antioxidants (Bosch-Saadatmandi *et al*., 2006). Although cellular GSH levels are influenced by OTA incubation, mechanisms other than oxidative stress are likely to be involved in OTA-induced cell death in HepG2 cells.

3.4.3 OTA as a Teratogenic Toxin

OTA is teratogenic in the rat, mouse, hamster and chick, with reduced birth weight and craniofacial abnormalities being the most commonly observed malformations (O'Brien *et al*., 2005). Neither the potential of OTA to cause malformations in humans nor its teratogenic mode of action is known. Using the standard American Society for Testing and Materials (ASTM) 96 h exposure protocol and the FETAX (Frog Embryo Teratogenesis Assay Xenopus) system, an embryotoxicity assay

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

system, with a high correlation to animal models and epidemiological data, the effect of OTA and OTB on the *in vitro* development of *Xenopus laevis* embryos was assessed. Both OTA and OTB caused craniofacial malformations, while OTA also caused reduced embryo growth. As expected, OTA was far more potent in inducing these effects than OTB, presumably, as discussed above, owing to greater accumulation of OTA. The critical gestation period for inducing teratogenicity in pregnant Wistar rats is between six and seven days and the minimum single oral dose of OTA was 2.75 mg (kg body weight)$^{-1}$ (Patil *et al*., 2006).

The teratogenic effects of the simultaneous prenatal oral exposure of Wistar rats on days 6–15 of gestation to OTA and AFB_1 were investigated (Wangikar *et al*., 2004). OTA and AFB_1 alone and in combination caused various gross skeletal and visceral anomalies. The occurrence was considerably less pronounced in foetuses of AFB_1 and combination groups as compared with those of OTA group foetuses. However, new manifestations, such as gastroschisis and syndactyly were observed and the incidence of cardiac defects was increased in foetuses due to the combined treatment. The results indicated reduced teratogenic activity of OTA in the presence of AFB_1.

3.4.4 OTA Nephrotoxicity and Its Role in Balkan Endemic Nephropathy

OTA is nephrotoxic to all animal species tested, therefore, it is not surprising that the kidneys are most susceptible to OTA-induced toxicity. The renal lesions associated with the diseases include degeneration of the proximal tubules, interstitial fibrosis in the renal cortex, hyalinization of the glomeruli and atrophy in the tubular epithelium (Steyn and Stander, 1999).

In 1964, the WHO provided a description of Balkan endemic nephropathy (BEN), and the endemic kidney disease became recognized as a new nosological entity. BEN is geographically linked to rural villages in Bosnia, Bulgaria, Croatia, Romania and Serbia, and is considered by several authors to be associated with OTA, the environmental mycotoxin. The clinical features and pathomorphological changes of BEN have been described (Pfohl-Leszkowicz and Manderville, 2007 and references cited therein). Early histopathological changes of BEN are characterized by tubular and degenerative and regenerative processes of epithelial cells, without reduction in organ size. In chronic cases, the size of the kidneys is considerably reduced and diffuse interstitial fibrosis without inflammatory cells is the most prominent finding. The three affected countries are Bulgaria, Croatia and Romania and the association between BEN and urinary tract tumours (UTT) has been highlighted. The clustering of BEN to specific families living in these rural areas suggests that a genetic predisposition may be involved. Such a genetic factor for BEN could be due to genes located in the region between 3q25 and 3q26 (Toncheva *et al*., 1998).

In countries such as Bulgaria, a much higher prevalence of OTA, exceeding 2 μg l^{-1} in the blood of affected population, was observed (Castegnaro *et al*., 2006a). To quantify human exposure to OTA in the Vratza district, Bulgaria, OTA intake was monitored for one month by examining the OTA in blood and urine from healthy volunteers, from two villages with high risk for BEN (Pfohl-Leszkowicz *et al*., 2007). Food samples were collected daily, blood and urine at the beginning of each week. The average weekly intake of OTA varied from 1.9 to 206 ng (kg body weight)$^{-1}$, twice the tolerable weekly intake recommended by the Joint FAO/WHO Expert Committee on Food Additives (JECFA), with OTA blood concentrations reaching 10 μg l^{-1}. Biomarkers of biological effects such as DNA adducts were detected in patients affected by UTT, similarly detected in rat studies. It was concluded that all these data support a causative role of OTA in BEN and UTT. DNA adduct formation and persistence of OTA/CIT and aristolochic acids (AA) adducts in human kidney cell culture were compared to DNA adducts in several tumours from human kidney suspected to be exposed to either OTA and CIT, or AA. In kidney cell cultures, the formation of specific OTA–DNA and AA–DNA adducts was detected in the same range (around 10 adducts/109 nucleotides) and were time- and dose-dependent. DNA adducts related to the mycotoxins, OTA and CIT were found in human kidney tissues from the Balkans, France and Belgium, whereas no DNA adducts related to AA could be found in any tumours of BEN patients from Croatia, Bulgaria or Serbia. OTA and CIT were more frequently found in rural areas, whereas AA was never detected. The findings of this study were in support of those reported previously (Castegnaro *et al*., 2006a). Providing further evidence for the involvement of mycotoxins, especially OTA, in BEN and UTT.

However, it was recently reported that the pathologic lesions in kidneys of rats treated with OTA appear rather differently from the clinical and pathologic characteristics of endemic nephropathy (Mally *et al*., 2007). Moreover, increasing evidence suggests that OTA does not bind to DNA, but induces tumours by an epigenetic route, implying a threshold mechanism by which doses below a certain level will induce no adverse health effects. Based on food consumption data and OTA serum concentrations, it appears that human exposure, even in areas with relatively high dietary exposure to OTA, is several orders of magnitude below doses known to cause nephrotoxicity and tumour formation in laboratory animals. These observations suggest that OTA is not likely to be an aetiologic factor involved in BEN and indicate a need to search for new clues towards the aetiology of this endemic kidney disease.

Worldwide, several studies have been conducted to assess the potential role of OTA in the aetiology of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

BEN and CIN. The occurrence of OTA in human sera from patients in Tunisia was reported (Grosso *et al*., 2003). In cases where the high incidence of CIN of unknown aetiology were pointed out, the involvement of OTA was suspected, but findings on the rather low degree of exposure failed to provide sufficient proof for its causative role. In Portugal, the levels of OTA in haemodialysis patients in Coimbra were higher than in Aveiro (Dinis *et al*., 2007). In the Pomeranian region in Poland, OTA was determined in human serum and kidney samples from a healthy group and from patients after nephrectomy. The mean concentration of OTA in the healthy group was $0.37\,\mathrm{ng\,ml^{-1}}$. In patients subjected to nephrectomy it reached $1.06\,\mathrm{ng\,ml^{-1}}$ in men and $0.94\,\mathrm{ng\,ml^{-1}}$ in women. These results support the role of OTA in kidney diseases (Grajewski *et al*., 2007).

3.4.5 Mechanisms in OTA Genotoxicity and Carcinogenicity

The genotoxic status of OTA is still controversial because contradictory results were obtained in various microbial and mammalian tests, notably regarding the formation of DNA adducts. It is of importance to note that the genotoxicity of OTA was originally established (Knasmueller *et al*., 2004), whereas under identical conditions OTB was devoid of genotoxic activity, although it caused pronounced inhibition of cell division, even at doses lower than OTA. Evidence of OTA genotoxicity was derived from the sensitive ^{32}P-labelling assay. OTA facilitates guanine-specific DNA adducts *in vitro*, and in rat and pig kidney when dosed orally. One adduct comigrates with a synthetic C-bonded C8-dG OTA-adduct standard. Like other chlorinated phenols, OTA undergoes an oxidative dechlorination process to generate a quinone (OTQ)/hydroquinone (OTHQ) redox couple that may play a role in OTA-mediated genotoxicity. To determine whether the OTQ/OTHQ redox couple of OTA contributes to genotoxicity, the DNA adduction properties of OTHQ were compared to OTA in the absence and presence of metabolic activation (pig kidney microsomes) utilizing human bronchial epithelial (WI26) and human kidney (HK2) cells (Tozlovanu *et al*., 2006). OTHQ generates DNA-adduct spots in the absence of metabolic activation. These results establish structure–activity relationships for OTA-mediated DNA adduction and provide new evidence for the potential role of the OTQ/OTHQ redox couple in OTA-induced genotoxicity.

The genotoxicity of OTA was investigated in primary human urothelial cells by means of alkaline single-cell gel electrophoresis (Comet assay), indicating great interindividual differences (Lebrun *et al*., 2006). To evaluate these differences, the influence of the genotype of the isoenzymes of GST, namely GSTT1, GSTM1 and GSTP1 on the genotoxic potential of OTA was examined. It was concluded that genetic predisposition has the potential to influence OTA genotoxicity. The genotoxic potential of OTA in the kidney of adult female Wistar rats was studied using the Comet assay, monitoring the tail length, tail intensity and tail moment. Changes in the kidney tissue in all the OTA treated groups were significantly higher than in controls ($p < 0.05$) thereby confirming the genotoxic potential of OTA (Zeljezic *et al*., 2006). The severity of DNA lesions in kidneys also correlated with OTA concentration. These results were in agreement with the findings on the genotoxicity of OTA in primary human urothelial cells (Lebrun *et al*., 2006). In the leading review, the current understanding of OTA toxicity and carcinogenicity (Pfohl-Leszkowicz *et al*., 2007) is debated. The genotoxic activity could play a central role in OTA-mediated carcinogenesis and may be divided into direct (covalent DNA adduction) and indirect (oxidative DNA damage) mechanisms of action. The available evidence suggests that OTA is a genotoxic carcinogen by induction of oxidative DNA lesions coupled with direct DNA adducts via OTQ formation. In an earlier paper the molecular details of the binding of OTA to HSA, and the affect on the transport across epithelial cell membranes by organic anion transport proteins, the oxidative activation of OTA and the formation of OTA adducts with biological molecules were investigated (Dai *et al*., 2004). These studies contributed to a better understanding of a detailed chemical model for the transport, accumulation, and genotoxic and carcinogenic effects of OTA.

A recent study showed that OTA inhibits cell proliferation, strongly reduces protein synthesis and induces a decrease of GSH in a concentration-dependent manner in both HepG2 and Vero cells (Hassen *et al*., 2007). In a subsequent study, the reduction of Nrf2-regulated gene expression resulting in oxidative DNA damage was evidenced by formation of abasic sites *in vitro* and confirmed in kidney *in vivo* (Cavin *et al*., 2007). All OTA-mediated effects observed were prevented by pretreatment of cell cultures with inducers of Nrf2 activity. These data suggest that reduction of cellular defence against oxidative stress by Nrf2 inhibition may be a plausible mechanism of OTA nephrotoxicity and carcinogenicity.

Although the mechanisms of the genotoxicity and carcinogenicity of OTA have been thoroughly studied, many controversial findings have been reported. The ability of OTA to produce single-strand DNA breaks and oxidative DNA damage in the human renal proximal tubular epithelial cell line (HK2) was evaluated (Arbillaga *et al*., 2007). The authors also attempted to determine if biotransformation processes mediate OTA genotoxicity. Single-cell gel electrophoresis assays were performed after three and six hour treatments using different OTA concentrations, both cytotoxic and noncytotoxic doses, in order to distinguish the apparent genotoxic effect from an indirect effect derived from its general cellular toxicity. No effect was shown in the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

absence of cytotoxicity, both in the presence and in the absence of metabolic activation, suggesting that OTA is not acting as a direct genotoxic carcinogen and that oxidative stress is likely to be responsible for the genotoxicity and cytotoxicity observed in human renal cells. A similar study involving single-cell gel electrophoresis investigated the genotoxic potency of OTA and its metabolites in NIH/3 T3 cells stably expressing the human cytochrome P450 isoenzymes CYP 2C9 and CYP 3A4 (Simarro *et al*., 2006). Their results confirmed the hypothesis that biotransformation processes mediated OTA toxicity and affected the genotoxicity. Measurement of the production of reactive oxygen species (ROS) showed that the OTA-induced ROS production corresponded to the OTA-induced genotoxicity.

The DNA ploidy distribution, measured in experimental renal tumours, that occurred in 12 ageing male Fischer rats in response to chronic dietary OTA exposure, was diploid in all renal adenomas and aneuploid in all carcinomas, correlating with their typical organized and disorganized histopathology, respectively (Brown *et al*., 2007). Thus, an experimental rat renal carcinoma could arise within an adenoma directly from certain persistent karyomegalic tubular epithelial cells, long after their particular genetic damage has been caused during a protracted period of OTA insult. A marked change in DNA ploidy over the adenoma–carcinoma continuum in OTA-generated rat renal tumours was observed. No case of testicular cancer occurred in over 250 male rats given dietary OTA at renal tumourigenic doses; these findings refuted the suggestion by (Schwartz, 2002) that OTA could be the cause of testicular cancer in young men.

A study using a toxicogenomics approach to identify new plausible epigenetic mechanisms of OTA carcinogenicity was conducted in male Fischer rats for two years (Marin-Kuan *et al*., 2007). Renal tumours were discovered during the last six months of the study, and the total tumour incidence reached 25% at the end of the study while gene expression profile was analysed in groups of animals taken in intervals from 7 days to 12 months. Tissue-specific responses were observed in kidney versus liver. In the kidney, several genes known as markers of kidney injury and cell regeneration were significantly modulated by OTA. The expression of genes known to be involved in DNA synthesis and repair, or genes induced as a result of DNA damage, was only marginally modulated. Another study found very little or no effect amongst genes associated with apoptosis (Marin-Kuan *et al*., 2007). The depletion of these genes is likely to impair the defence potential of the cells, resulting in chronic elevation of oxidative stress in the kidney. The inhibition of the defence mechanism appears to be a highly plausible new mechanism which could contribute to OTA carcinogenicity. OTA-induced mutagenesis was also investigated in mammalian cells and mutations characterized as point mutations (48%) and a lack of a detectable reverse-transcription polymerase chain reaction product (52%) (Palma *et al*., 2007). The pattern of OTA-induced point mutations was similar to that of spontaneous mutants, suggesting that OTA induced an increase of the endogenous oxidative metabolites, but not covalent DNA adducts. These data support a model where OTA is mutagenic via oxidative DNA damage induction.

3.5 Decontamination of Ochratoxins

OTA, the dangerous and ubiquitous mycotoxin, is frequently found in different foods, as well as in beverages such as grape juices, and wines; see Section 3.3 in this chapter. The inactivation of mycotoxins by enzymes or by selected micro-organisms is an attractive strategy for the decontamination of agricultural commodities without significant losses in nutritive value and the palatability of the detoxified feed or food (Bata and Lasztity, 1999). Several of these approaches are described in this section.

The ochratoxins contain an amide bond, therefore, it should be prone to hydrolysis by hydrolases to its nontoxic components OTα and β-phenylalanine. Stander *et al*. (2000) screened 23 lipases and esterases for their ability to hydrolyse OTA and found that only a lipase preparation from *A. niger* degraded OTA. It is very likely that proteases or amidases are responsible for the hydrolytic activity observed with the crude lipase preparation. Stander *et al*. (2001) subsequently undertook a kinetic study into the hydrolysis of the ochratoxins and their analogues by carboxypeptidase and found that the halogen-containing toxins were much slower to hydrolyse than the analogues without the halogen group, such as OTB. Abrunhosa *et al*. (2006) reported the ability of several commercial proteases to hydrolyse OTA into OTα. Upon an incubation period of 25 hours at pH 7.5, significant hydrolytic activities for protease A (87.3%) and for pancreatin (43.4%) were detected.

Bejaoui *et al*. (2006a) studied the biodegradation of OTA by *A*. section *nigri* species isolated from French grapes in order to reduce OTA in grape juices and musts. Forty isolates of the *Aspergilli* species from French grapes, namely, *A. carbonarius, A. niger aggregate* and *A. japonicus* were assessed for their capacity to degrade OTA in Czapek yeast extract broth (CYB) and in a synthetic grape juice medium (SGM) contaminated with OTA at $2\,mg\,l^{-1}$ (5 µM). In both media these fungi had the ability to degrade OTA to OTα. In SGM and CYB, 77 and 45% of the isolates, respectively, were able to degrade more than 80% of the OTA. *A. niger* was regarded as the most effective species for OTA detoxification processes, followed by *A. japonicus*. These results are consistent with the findings of Stander *et al*. (2000). Abrunhosa and Venancio (2007) isolated and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

purified a metalloenzyme hydrolysing OTA from *A. niger* leading to OTα and L-β-phenylalanine, based on the known capacity of *A. niger* to hydrolyse OTA. The OTA hydrolytic enzyme presented a V_{max} of 0.44 μM min^{-1} and a K_m of 0.5 mM when the reaction was carried out at pH 7.5 and 37 °C. The 33.9 megabase genome of *A. niger* CBS 513.88, the ancestor of currently used enzyme production strains was recently reported in *Nature* by Pel *et al*. (2007). Noteworthy are the large number of major facilitator superfamily transporters and fungal zinc binuclear cluster transcription factors, and the presence of putative gene clusters for fumonisin and OTA synthesis. A reconstructed metabolic network comprising 1069 unique reactions illustrates the versatile metabolism of *A. niger* (Pel *et al*., 2007).

Varga *et al*. (2005) examined several filamentous fungi representing the genera Rhizopus and Mucor for their ability to degrade OTA, AFB1, zearalenone and PAT in a liquid medium. OTA was successfully degraded by *Rhizopus stolonifer*, *R. microsporus*, *R. homothallicus* and two *R. oryzae* isolates, and by four unidentified *Rhizopus* isolates. The *Rhizopus* isolates were able to degrade more than 95% of OTA within 16 days, furthermore an isolate of *Rhizopus stolonifer* effectively decomposed OTA on moistened wheat.

In their studies on the fate of OTA during vinification of grapes, Leong *et al*. (2006d) observed a reduction in the amount of OTA in juice and wine at every solid–liquid separation stage. The OTA concentration (μg kg^{-1}) in white and red wine after racking was 4 and 9%, respectively, of that in crushed grapes. The OTA content was divided between solid and liquid phases at each stage of vinification. OTA did not appear to be transformed either chemically or biologically by yeast during fermentation. However, it was discarded with the marc, juice lees and gross lees. Fernandes *et al*. (2007) similarly investigated changes in OTA levels during the making of the Portuguese wine, Vinho Verde. It was found that vinification consistently reduced the levels of OTA, independent of the initial OTA concentrations in the grapes used. The reduction in OTA was associated with the removal of spent fractions during the wine making rather than degradation by yeasts or bacteria. The findings of Fernandes *et al*. (2007) were confirmed by Del Prete *et al*. (2007) who observed that OTA was not degraded by cell-free extracts of wine lactic acid bacteria (LAB). In fact, no degradation products of OTA were detected in the bacterial pellets, therefore the removal of OTA by wine LAB was a cell-binding phenomenon. Shetty and Jespersen (2006) reviewed the mycotoxin-binding capacity of *S. cerevisiae* and LAB, and concluded that their strains have prospects as mycotoxin-binding organisms. More importantly, *S. cerevisiae* and LAB are the major micro-organisms involved in food fermentations in tropical countries with high levels of mycotoxin contamination.

Angioni *et al*. (2007) reported the *in vitro* interaction during alcoholic fermentation between OTA and 20 different strains of *S. cerevisiae* and *Kloeckera apiculata*. The yeast cells do not adsorb OTA and, for all yeasts, OTA levels did not affect the alcoholic fermentation. Only some yeast strains reduced the levels of OTA, thereby demonstrating that the reduction of OTA levels to genus or species characteristic, but a strain trait. Cecchini *et al*. (2006) studied the influence of the yeast strains on OTA content during the fermentation of red and white wines. Depending on the yeast strain involved in the fermentation, there was a difference in the OTA levels in the wines. The absence of degradation products indicated an adsorption mechanism.

Bejaoui *et al*. (2004) assessed the efficiency of removing OTA from yeast peptone glucose (YPG), SGM and natural grape juice by viable and dead (heat and acid-treated) oenological *Saccharomyces* strains (five *S. cerevisiae* and one *S. bayanus*) compared with a commercial yeast-cell-wall additive. A significant decrease of OTA levels in YPG medium and SGM was observed for many of the growing strains reaching a maximum of 45%, but no degradation products were detected. With both heat- and acid-pretreated yeasts, OTA removal was enhanced, indicating that adsorption, not catabolism, is the mechanism to reduce OTA concentrations. Approximately 90% of OTA was bound rapidly within five minutes and up to 72 hours of incubation with heat-treated cells of either *S. cerevisiae* or *S. bayanus.*

Steyn *et al*. (2000) reported that certain yeasts, such as *Rhodotorula*, *Cryptococcus* and *Pichia* species have the ability to hydrolyse OTA to OTα and phenylalanine. Peteri *et al*. (2007) observed OTA degradation and adsorption by astaxanthin-producing yeasts, namely *Phaffia rhodozyma*. This yeast is able to convert OTA to OTα, by a conversion possibly mediated by carboxypeptidases. In addition, viable and dead *P. rhodozyma* cells have the ability to absorb significant amounts of OTA. Schatzmayr *et al*. (2006) isolated a novel yeast strain, *Trichosporon mycotoxinivorans*, from bovine rumen fluid capable of degrading OTA and zearalenone.

OTA is mainly produced by the black *Aspergilli*, namely *A. carbonarius and A. niger.* Therefore, Bleve *et al*. (2006) isolated a total of 144 antagonistic yeasts from the epiphytic flora associated with grape berries and tested these isolates for a killer activity against the two black *Aspergilli*. Of 28 yeast isolates selected, two isolates of *Issatchenkia orientalis* and one each of *Metschnikowia pulcherrima*, *Kluyveromyces thermotolerans*, *Issatchenkia terricola* and *Candida incommunis* were finally selected and screened on wounded grape berries for their ability to inhibit infection by ochratoxigenic moulds. The best antagonistic activity was shown by the two *I. orientalis* isolates. Results suggest that antagonist yeasts with the potential to control *A. carbonarius* and *A. niger* on grapes can be found among the microflora associated with the berries.

Valero *et al*. (2006) observed that maintaining the temperature at or above 30 °C during dehydration of grapes may provide some control against OTA accumulation by *A. carbonarius.* Savino *et al*. (2007) reduced OTA contamination in red wines by adding oak-wood fragments. The effectiveness of the treatment depended upon the quantity of the oak fragments used; the best results were obtained by using the oak powder. During the roasting of Arabica coffee at 190 °C (mild roast) and 210 °C (dark roast) 63 and 82%, respectively, of the OTA was degraded (Santos *et al*., 2006).

4 FUMONISINS

Fumonisins are mycotoxins mainly produced by fungi of the genus *Fusarium* and predominantly associated with maize. The high concentrations found on maize worldwide and particularly on maize produced by subsistence farmers are of great concern. FB_1 is the major structural analogue produced on maize, whereas FB_2 and FB_3 are produced to a lesser extent. The toxicological profiles of the different analogues are similar and have been reviewed in detail; they provide the scientific base of certain regulations and guidelines (WHO, 2001). Fumonisins are regarded to be possibly carcinogenic to humans (Group 2B) by the International Agency for Research on Cancer (2002).

4.1 Fumonisin-Producing Organisms

Owing to the widespread occurrence of the fumonisins in feed and foods, numerous studies focussed on the ability of different fungal spieces to produce these mycotoxins. High levels of fumonisins are generally produced in hot and dry weather followed by periods of high humidity. Environmental factors, such as temperature, humidity, drought stress, insect damage and rainfall during preharvest and harvest periods could result in the formation of extremely high levels of the fumonisins. Although 28 analogues of fumonisin have been characterized, which include the fumonisin A, B, C and P series, specific studies reported on the production of FB_1, FB_2 and FB_3, of which FB_1 predominates as the main fumonisin produced in nature. Fifteen *Fusarium* species are known to produce fumonisins, which belong to sections *Liseola*, *Dlamini*, *Elegans* and *Arthroporiella* (Rheeder *et al*., 2002), although the verification of fumonisin production of certain strains needs confirmation. The two main fumonisins producing strains of *Fusarium,* occurring on maize worldwide, are *F. verticillioides* and *F. proliferatum*. Two other fungal species known to produce the fumonisins are *Alternaria alternata* (Fr.) Keissler f. sp. *lycopersici* (Mirocha *et al*., 1996) and *Aspergillus niger* (Frisvad *et al*., 2007).

Maize and maize products are known to contain high levels of the fumonisins, which pose a health risk to humans and animals. Other agricultural important crops such as sorghum and millet, colonized by certain *Fusarium* spp. are also contaminated with the fumonisins (Marasas *et al*., 2001; Nirenberg and O'Donnel, 1998). Certain traditional herbal medicines that enter the human food chain in developing countries via muthi markets have been shown to contain the fumonisins, although the specific fungal species responsible for the production are not known (Sewram *et al*., 2006). The relative stability and accumulation of the fumonisins in the soil (Williams *et al*., 2006) could also be responsible for its widespread contamination of plant products utilized for human consumption.

4.2 Analysis of Fumonisins

Since the discovery of FB_1 and FB_2 in 1988 (Gelderblom *et al*., 1988), 28 individual analogues have been reported (Rheeder *et al*., 2002), as well as a number of reaction products with sugars (Poling *et al*., 2002). In addition, the fumonisin chemical structure containing two ester functional moieties implies the potential occurrence of partially and fully hydrolysed forms of each analogue. Despite this multiplicity of forms, the majority of analytical methods have focussed on the determination of FB_1, FB_2 and FB_3, which are the most abundant naturally occurring members of this group of mycotoxins (Shephard *et al*., 1996). A wide range of analytical techniques have been applied to the fumonisins. The majority of the literature on natural occurrence of fumonisins is based on their determination by HPLC with fluorescence detection of appropriate derivatives. More recently, the coupling of HPLC with mass spectrometry (LC-MS) via ESI has allowed both sensitive quantification and confirmation of fumonisins. Apart from these techniques, both TLC and ELISA methods are available. Other methods that have been used to a limited extent for the determination of fumonisins include gas chromatography (GC) (Plattner *et al*., 1990), CE (Maragos, 1998), fluorescence polarization (FP) (Maragos *et al*., 2001) and biosensor techniques (Mullett *et al*., 1998). The fumonisins occur primarily in maize and hence the analytical methods have been predominantly developed for their determination in maize and its food and feed products. For this reason, the following subheadings relate mainly to analytical techniques.

4.2.1 *Thin-Layer Chromatographic Methods for Fumonisins*

TLC has found limited application in fumonisin analysis. A method with a detection limit of 1 mg kg^{-1} was developed, which included reversed-phase and strong anion exchange clean-up of the extract. The reversed-phase

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

TLC plate was developed with ethanol–water–acetic acid (65:35:1) and FB_1 was visualized by a fluorescamine spray technique (Schaafsma *et al*., 1998). Comparison with HPLC results over a range of FB_1 contamination levels up to 250 mg kg^{-1} demonstrated a significant positive correlation. Further improvements in sample extract purification can be achieved by using IACs. These have been combined with reversed-phase TLC separation, followed by fluorescamine spray and fluorodensitometry for quantification of FB_1 in corn with a published detection limit of 0.1 mg kg^{-1} (Preis and Vargas, 2000). In order to separate FB_1 from a cochromatographing impurity, Shephard and Sewram (2004) reacted a cleaned-up maize extract with fluorescamine and separated the FB_1 derivative by reversed-phase TLC, using a developing solution of methanol–aqueous 4% potassium chloride (70:30). Based on visual comparison, the quantification limit of the method in maize was estimated to be 0.5 mg kg^{-1}.

4.2.2 High-Performance Liquid Chromatographic Methods for Fumonisins

Fumonisins are widely determined by HPLC and methods for their determination in maize have been validated by international collaborative study (Sydenham *et al*., 1996; Visconti *et al*., 2001). Typically, these methods or their modifications involve extraction of the sample with methanol–water or methanol–acetonitrile–water mixtures by shaking or homogenization, and clean-up on reversed-phase (C18) or strong anion-exchange solid-phase extraction cartridges or on IACs containing specific fumonisin antibodies, prior to derivatization and subsequent separation on reversed-phase HPLC with fluorescence detection. Nevertheless, a number of issues continue to be studied and reported. Extraction of fumonisins from processed foods, such as maize-based infant foods, was investigated and the optimum extraction solvent found to be acidified 70% aqueous methanol (Sewram *et al*., 2003). However, recovery studies still showed that some products, especially those containing a high proportion of maize starch, gave poor recoveries of spiked standards. Similar problems with extraction recoveries from spiked samples of rice flour have been reported, in that recovery of the spike can decrease over time (Kim *et al*., 2002a). IACs have been used extensively in mycotoxin analysis and a study has reported the possible regeneration and reuse of these columns for fumonisin analysis (Fazekas *et al*., 1999), whereas other authors have highlighted the problems that can arise if extracted impurities interfere with the antibodies, leading to under-reporting of the analyte levels (Castegnaro *et al*., 2006b). Existing methods for fumonisins in maize have been adapted to determine fumonisins in corn silage and swine liver. In the former, fumonisins were extracted with 0.1 M EDTA (ethylenediaminetetraacetic acid), cleaned-up on IAC and finally determined by HPLC with fluorescence detection after derivatization with naphthalene-2,3-dicarboxaldehyde (Kim *et al*., 2004). The method for swine liver involved clean-up on a hydrophilic–lipophilic balance cartridge, which retained both the FB_1 and its fully hydrolysed analogue (Pagliuca *et al*., 2005). Thereafter, the extract was derivatized with *o*-phthaldialdehyde and determined by HPLC on a phenylhexyl column with fluorescence detection.

A large number of authors have described the use of LC-MS or LC-MS/MS, mostly with ESI in the positive ion mode, for the detection, quantitation and confirmation of fumonisins in a number of matrices. These methods have been the subject of reviews (Musser *et al*., 2002; Zöllner and Mayer-Helm, 2006). Confirmation of fumonisins is readily achieved in MS/MS mode as, apart from loss of water during fragmentation, the fumonisin molecule readily fragments with the loss of one or both of the tricarballylic acid side chains, leading to a characteristic pattern of product ions (Musser *et al*., 2002). As in the case of aflatoxins, some authors have confined their work to fumonisin analogues (Faberi *et al*., 2005; Seefelder *et al*., 2003a; Sewram *et al*., 2001; Paepens *et al*., 2005a), whereas others have used the versatility of MS to develop multimycotoxin methods. These latter methods utilize extract dilution and direct injection (Spanjer *et al*., 2008; Sulyok *et al*., 2006; 2007) or extract clean-up with multimycotoxin IAC (Lattanzio *et al*., 2007) or with conventional solid-phase extraction cartridges (Cavaliere *et al*., 2005; Royer *et al*., 2004). A LC-MS/MS method for the determination of fumonisins in maize-based foods, which involved reversed-phase and graphitized carbon solid-phase clean-up, achieved detection limits for fumonisins of the order 1–2 μg kg^{-1} (Faberi *et al*., 2005). A method for fumonisins in cornflakes, which involved IAC clean-up of an acidified methanol–water extraction solution, was successfully validated in-house (Paepens *et al*., 2005b). Many of the developed methods use matrix-matched standards to overcome potential matrix effects in the ionization process (Sulyok *et al*., 2007). Apart from its use to determine fumonisins in food, Sewram *et al*. (2001) used LC-MS/MS to measure fumonisins in hair as a suitable biomarker of exposure. Following methanol extraction, the sample extract was cleaned-up on strong anion exchange (for fumonisin analogues) and on reversed-phase C18 (for hydrolysed analogues) solid-phase extraction cartridges prior to injection on the LC-MS/MS. Quantitation limits were of the order of 60–80 pg on column.

4.2.3 Immunological Methods for Fumonisins

In common with the other major mycotoxins, a number of immunological methods have been developed for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the determination of fumonisins. A commercial competitive direct ELISA with colorimetric end point was studied collaboratively for determination of total fumonisins in maize and achieved AOAC official status (Bird *et al*., 2002). Greater sensitivity and shorter assay times were obtained in a direct competitive ELISA developed with polyclonal antibodies and enhanced chemiluminescence detection for FB_1 (Quan *et al*., 2006). Although IACs are widely used for clean-up of sample extracts prior to further chromatographic separation and analysis, under suitable conditions and with suitable matrices, the resulting purified extract has itself been used, after derivatization, for quantitation of total fumonisins by direct fluorescence measurement (Duncan *et al*., 1998). However, such methods must be carefully validated for the analytical matrix, as incorrect reports of fumonisin contamination are possible if used outside their area of validation (Shephard *et al*., 2005a).

For rapid screening of samples at a set level of contamination, lateral flow and flow-through enzyme immunoassays have been introduced. Wang *et al*. (2006) developed both flow-through and lateral flow formats which utilized colloidal gold as the visual component in test and control lines. Paepens *et al*. (2004) developed a flow-through immunoassay with a colorimetric end point. The method was successfully applied to maize, maize flour, maize grits and to an evaluation of fumonisin levels in cornflakes on the Belgian market (Paepens *et al*., 2005b).

4.3 Occurrence of Fumonisins

The main producing fungi of fumonisins are *Fusarium verticillioides* (Sacc.) Nirenberg (formerly *F. moniliforme* Sheldon) and *F. proliferatum* (Matsushima) Nirenberg, which are associated with maize in most areas of the world (Marasas, 1996). As a consequence, fumonisins are ubiquitously found in maize and the vast majority of publications on natural occurrence of fumonisins deal with either maize or maize products. The first comprehensive survey of fumonisin occurrence was published by Shephard *et al*. (1996), and this was followed by a comprehensive compilation of published data undertaken by the JECFA (Bolger *et al*., 2001). Subsequently, other reviews of fumonisin occurrence have also been published (Soriano and Dragacci, 2004; Weidenbörner, 2001).

The natural occurrence of fumonisins in unprocessed maize has been investigated by numerous researchers in many countries of the world. The contamination levels found vary greatly and are influenced by a number of factors, such as weather, temperature and plant stress induced by drought or insect herbivory (Miller, 2001). Consequently, contamination frequency and levels can vary greatly between geographic areas, seasons, years and climate zones. Typically, contamination levels vary from detection limits of $10–20\,\mu g\,kg^{-1}$ up to a level of some several thousands or tens of thousands of $\mu g\,kg^{-1}$. Studies in four regions of Iran have shown how levels can vary in different climate zones in that maize harvested in Mazandaran had mean total fumonisin levels of $10674\,\mu g\,kg^{-1}$, whereas samples from Fars, Kermanshah and Khuzestan had mean levels of 215, 71 and $174\,\mu g\,kg^{-1}$, respectively (Ghiasian *et al*., 2006). Relative to the other growing areas, Mazandaran is an area of relatively high rainfall, higher relatively humidity and the lowest minimum altitude. Another study in Mazandaran demonstrated how contamination levels can vary between harvest seasons in that mean FB_1 levels were shown to vary from 2.27 to 3.18 to $6.14\,mg\,kg^{-1}$ over three consecutive years (Yazdanpanah *et al*., 2006). Depending on the region, maize can be infected with more than one fungal species and the resulting crop contaminated with multiple mycotoxins. Of particular concern is the co-occurrence with fumonisin of another carcinogenic mycotoxin, aflatoxin. This situation has been studied in various countries, such as Brazil, where analysis of 214 unprocessed maize samples showed 212 fumonisin-contaminated samples (mean FB_1 of $2200\,\mu g\,kg^{-1}$), of which 82 samples were co-contaminated with a mean aflatoxin level of $9.4\,\mu g\,kg^{-1}$ and a maximum level of $129\,\mu g\,kg^{-1}$ (Vargas *et al*., 2001). A multiyear study in Arkansas, USA, showed that cocontamination is common among a large number of commercial hybrids, that it varies from year to year and that natural infection with *Fusarium* spp. does not protect against aflatoxin production (Abbas *et al*., 2006). The association of fumonisins with high incidence of oesophageal cancer has increased interest in studying contamination of maize grown in these specific areas. In the affected areas of Asia, studies in Mazandaran have shown high levels of fumonisin in maize (Ghiasian *et al*., 2006). A comparison of maize samples from three areas of China (one of high oesophageal cancer, one of high liver cancer and one of low incidence of both cancers) showed a significantly higher fumonisin contamination in the high cancer-incidence areas (mean FB_1 of 2.84 and $1.27\,mg\,kg^{-1}$ vs. mean FB_1 of $0.65\,mg\,kg^{-1}$, respectively) (Sun *et al*., 2007). Results of an extensive field study comparing maize kernels from Bt maize hybrids (containing the Cry1Ab protein from *Bacillus thuringiensis* (Bt) that controls European stalk borer infestation) with near isogenic controls confirmed that in a significant number of locations, kernels of the Bt maize varieties showed considerably lower fumonisin contamination than their conventional controls due to reduced insect herbivory (Hammond *et al*., 2004). A comparison carried out in Spain between maize samples collected from conventional and nearby organic farms showed very low levels of fumonisin (mean $FB_1 < 50\,\mu g\,kg^{-1}$) in both sets of samples, with no significant difference between the two farming systems (Arino *et al*., 2007).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Industrially processed maize products intended for human consumption and derived from contaminated unprocessed maize will generally retain, at a lower level, some fumonisin contamination. Industrial milling processes, which generate a number of maize milling fractions, result in the fumonisin being reduced in fractions intended for human consumption (grits, flour, maize meal, polenta and starch) and to be concentrated in fractions intended for animal feed (bran and germ fractions) (Brera *et al*., 2004; Saunders *et al*., 2001). Cooking of maize either as home porridge or polenta, or industrial canning and baking produce zero to low levels of fumonisin reduction, whereas the higher temperatures and pressures associated with extrusion products can result in higher losses depending on the processing time and temperature (Brera *et al*., 2004; Bullerman *et al*., 2002; Shephard *et al*., 2002). Market surveys of commercial maize-based foods confirm the widespread presence of fumonisins. Corn flour, corn snacks and corn flakes collected in Spain had mean levels of FB_1 of 363, 46 and 17 $\mu g\,kg^{-1}$, respectively (Velluti *et al*., 2001). Analysis of breakfast cereals in France showed that 94% of samples containing maize, oats or rice contained FB_1 at levels between 1 and 1110 $\mu g\,kg^{-1}$ (Molinie *et al*., 2005). A survey of 196 samples of infant food in Campinas, Brazil showed fumonisin contamination depended on the ingredients (De Castro *et al*., 2004). Infant cereals containing corn starch or wheat as main ingredients were free of fumonisins, whereas those containing corn flour or corn meal contained mean total fumonisins of 664 and 2242 $\mu g\,kg^{-1}$, respectively. Other surveys in countries such Canada (infant cereal foods), Japan (frozen corn, corn flakes and corn grits) and Korea (various corn products) have all shown that fumonisin contamination of maize-based foods at levels ranging up to several 100 $\mu g\,kg^{-1}$ is a universal occurrence (Kim *et al*., 2002b; Lombaert *et al*., 2003; Sugita-Konishi *et al*., 2006b). The possible binding of fumonisins to the food matrix during processing has been investigated. For a range of Canadian samples, including corn flakes, maize-based breakfast cereals, tortilla chips and corn chips, it was shown that there was an average of about 30% more FB_1 in a bound form than was determined by conventional extraction techniques (Park *et al*., 2004).

The process of nixtamalization, in which maize is treated with lime as the first stage of tortilla production by Hispanic groups in America, is known to reduce fumonisin levels. Reductions of over 80% were measured in a study of the operation of four small tortilla plants in southern Texas (De la Campa *et al*., 2004). A laboratory study in which contaminated maize was processed into tortilla chips also achieved a measured FB_1 reduction of over 80% and also determined a similar decrease in biological activity measured by *in vitro* inhibition of ceramide synthase (Voss *et al*., 2006a). The presence of fumonisins has been demonstrated in a number of traditional African foods. Of 75 samples of kenkey (a Ghanaian fermented maize product), 55 were found to contain total fumonisins ranging from 15 to 1035 $\mu g\,kg^{-1}$ (Kpodo *et al*., 2006). Eighteen maize beer samples collected in the former Transkei region of South Africa were all positive for FB_1, with a mean level of 281 $\mu g\,l^{-1}$ and a range of 38–1066 $\mu g\,l^{-1}$ (Shephard *et al*., 2005b).

Apart from their ubiquitous presence in human food, fumonisins are widely found in a variety of animal feeds, frequently in conjunction with other mycotoxins. Poultry feed in Kuwait was found by ELISA to be contaminated with fumonisin levels between 1.4 and 3.2 $mg\,kg^{-1}$, in addition to aflatoxin (maximum 3.26 $\mu g\,kg^{-1}$), deoxynivalenol (maximum 0.29 $mg\,kg^{-1}$), OTA (maximum 9.6 $\mu g\,kg^{-1}$) and zearalenone (maximum 67.6 $\mu g\,kg^{-1}$) (Beg *et al*., 2006). Poultry feeds in Rio de Janeiro State, Brazil contained up to 5.5 $mg\,kg^{-1}$ (Oliveira *et al*., 2006), whereas a survey in Portugal reported much lower levels of fumonisin contamination in mixed-feed for laying hens (FB_1 maximum level 110 $\mu g\,kg^{-1}$) (Martins *et al*., 2006). A major survey of animal feed and feed ingredients was performed with samples drawn from Europe, Asia and Oceania (Binder *et al*., 2007). Fumonisins were frequent contaminants in Asia and southern Europe and the Mediterranean. Mean and maximum total fumonisins were 432 and 530 $\mu g\,kg^{-1}$ in northern Europe, 757 and 3120 $\mu g\,kg^{-1}$ in southern Europe, 612 and 1090 $\mu g\,kg^{-1}$ in Oceania, 1011 and 14 714 $\mu g\,kg^{-1}$ in northern Asia, 491 and 4866 $\mu g\,kg^{-1}$ southeast Asia, and 397 and 2217 $\mu g\,kg^{-1}$ in southern Asia. In addition to the above studies, fumonisins have also been determined in corn silage samples collected in the midwestern USA at contamination frequencies of 97% and with mean FB_1 levels of 615 $\mu g\,kg^{-1}$ (maximum 1824 $\mu g\,kg^{-1}$) (Kim *et al*., 2004).

Apart from their association as a universal contaminant of maize and maize-based food and feed, fumonisins have been found in a number of other commodities. Low levels of FB_1 (up to 70 $\mu g\,kg^{-1}$) have been reported in stored einkorn, emmer and spelt wheat (collectively referred to as farro in Italy) (Castoria *et al*., 2005) and pearl millet in Georgia, USA (mean 121 $\mu g\,kg^{-1}$ in one cultivar) (Wilson *et al*., 2006). Limited data is available on the occurrence of fumonisins in sorghum. Of 39 sorghum grain samples from Ethiopia, analysed by ELISA, three showed fumonisin levels ranging from 1370 to 2117 $\mu g\,kg^{-1}$ (Ayalew *et al*., 2006). Three of 46 sorghum malt samples collected in Botswana had FB_1 levels ranging from 47 to 1316 $\mu g\,kg^{-1}$, but no fumonisin was detected in corresponding sorghum wort or beer samples (Nkwe *et al*., 2005). Of 30 samples of healthy asparagus spears collected in Shandong province, China, 24 were shown by LC-MS to contain FB_1 and FB_2 at levels ranging from 24 to 670 $\mu g\,kg^{-1}$ (mean 123 $\mu g\,kg^{-1}$) for FB_1 and 17 to 138 $\mu g\,kg^{-1}$ (mean 35 $\mu g\,kg^{-1}$) for FB_2 (Liu *et al*., 2005). Also, analysis of asparagus spears from Germany, naturally infected with *F. proliferatum*, showed nine of ten samples to contain FB_1 at levels between 36

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and 4514 $\mu g\,kg^{-1}$ (Seefelder *et al*., 2004). Lower levels of FB_2 and FB_3 were also detected. Investigations have also revealed that FB_1 can occur in tea and medicinal plants. Of 87 samples of black teas and medicinal plants collected in Lisbon, Portugal, 55 contained FB_1 at levels as high as 700 $\mu g\,kg^{-1}$ (Martins *et al*., 2001). A low incidence of FB_1 contamination of medicinal plants collected in Istanbul, Turkey (Omurtag and Yazicioglu, 2004) and in the Eastern Province of South Africa (Sewram *et al*., 2006) was reported, although individual levels could be as high as 1487 $\mu g\,kg^{-1}$ in Turkey (two samples of 115 were contaminated) and 1553 $\mu g\,kg^{-1}$ in South Africa (eight samples of 49 were contaminated). Four samples of South African cowpeas were found to contain FB_1 at levels between 0.12 and 0.61 $mg\,kg^{-1}$ (Kritzinger *et al*., 2003).

4.4 Toxicology of Fumonisins

4.4.1 Studies in Domestic Animals

4.4.1.1 Equine Leukoencephalomalcia (ELEM)

Natural outbreaks of leukoencephalomalcia (LEM) in donkeys and horses have been recorded in the USA since the early 1900s, and sporadically occurred during the 1930s, 1980s, specifically 1989 and during mid 1990s (Marasas, 1995; Voss *et al*., 2007). Horses are the most sensitive species to fumonisin toxicity, which is associated with prominent brain lesions associated with liquefactive necrosis of the white matter, oedema and haemorrhage. Clinical signs associated with these changes are decreased feed intake, depression, ataxia, blindness and hysteria. Anorexia occurs as a result of glossopharyngeal paralysis associated with the loss of ability to grasp and chew feed. High exposure, however, is normally associated with hepatotoxicity with an increase of serum bilirubin and liver enzyme activities with lower doses favouring the neurotoxic syndrome. The main liver lesions following high-dose exposure include centrilobular necrosis and perilobular fibrosis. These two forms of the disease may develop concurrently with the one that dominates depending on different factors including the dosage used, length of exposure and individual susceptibility. The first reports on the causative role of FB_1 in LEM resulted from intravenous application by Marasas *et al*. (1988) and Laurent *et al*. (1989), and oral dosing by Kellerman *et al*. (1990). A recent study showed that the clinical signs for the neurological disease are induced after intravenous application (Foreman *et al*., 2004). Cardiovascular effects were also present during the development of the neurological disease, which provide interesting mechanistic perspectives regarding the kinetics of the disease (Smith *et al*., 2002).

4.4.1.2 Pulmonary Oedema Syndrome (PES) in Pigs

Following the first report of the causative role of FB_1 in pulmonary oedema syndrome (PES) by Harrison *et al*. (1990), several studies were conducted to investigate the progression of the disease to elucidate relevant mechanisms. In general, respiratory distress and acute cyanosis, occur in the four to seven days preceding the acute pulmonary oedema and hydrothorax. Perivascular oedema and dilatation of lymphatics occur in the interstitium in the lung, and are regarded as early features of the disease. A reduced cardiac contractility and output, with a concomitant increase in pulmonary artery pressure were observed, implying acute left-side heart failure (Smith *et al*., 2000; Hasheck *et al*., 2001; Constable *et al*., 2000; 2003). Inhibition of L-type calcium channels of cardiac myocytes and the decrease in Ca^{2+} release and resultant cardiac contractility are proposed as a possible mechanism. Hepatic injury is always present, and depending on the dose of exposure, varies from mild to acute effects, including hepatocellular necrosis and apoptosis, with a resultant increase in cell proliferation A dose–response study showed that a FB_1 dosage of 10 ppm in the diet revealed two mild cases of pulmonary oedema which were associated with an increase in serum aspartate aminotransferase activity, indicating pathological changes in the liver (Zomborszky *et al*., 2002). Exposure to even lower dietary levels, up to 1 ppm FB_1, revealed pathological alterations in the lung associated with proliferation of connective tissue fibres in the subpleural and interlobular connective tissue (Zomborszky-Kovacs *et al*., 2002). A study in three-week-old weaned pigs showed that an average dose of 0.5 mg $FB_1\,kg^{-1}$ for six days significantly increased the colonization of the small and large intestine with *Escherichia coli*, suggesting a predisposition to infectious diseases (Oswald *et al*., 2003). A gavage treatment of piglets with a crude extract of FB_1 (0.5 mg kg body weight)$^{-1}$ also predisposes pigs to lung inflammation caused by *Pasteurella multocida*, which was associated with an increased expression of tumour necrosis factor (TNF)-α, interferon (IFN)-γ, interleukin (IL)-18 (Halloy *et al*., 2005). A study in male weanling pigs fed a diet of 8 mg $FB_1\,kg^{-1}$ fed for 28 days led to an immunosuppressive effect after immunization with *Mycoplasma agalactiae*. The specific antibody levels, and the expression of Type 2 T-helper cell (Th2) cytokines, IL-10, IL-4 and IL-6 were decreased (Marin *et al*., 2006). Female weanlings were more resistant.

4.4.2 Studies in Ruminants

FB_1 induces hepatotoxic and nephrotoxic effects in calves after an intravenous dose of 1 mg (kg body weight)$^{-1}$ for 7–14 days. Hepatic lesions consisted of disorganized hepatic cords associated with apoptosis, hepatocyte and bile ductular proliferation. Renal lesions include

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

apoptosis, karyomegaly and proliferation of proximal renal tubular cells (Mathur *et al*., 2001). Feeding studies in lambs and goats also showed renal and mild hepatic injury (See review by Voss *et al*., 2007).

4.4.3 Miscellaneous Studies

FB_1 was also found to be hepato- and nephrotoxic to rabbits after receiving multiple intravenous doses for four to five days ranging from 0.15 to 1 mg (kg body weight)$^{-1}$ (Bucci *et al*., 1998). Studies in vervet monkeys showed that single dosages of FB_1 and FB_2, as well as repeated dosages of FB_1 increased the levels of the liver function enzymes in a reversible time-dependent manner (Van der Westhuizen *et al*., 2001a; 2001b). No effects were noticed when considering the serum markers for urinary functions in any of the studies. Serum parameters and liver pathological alterations in the liver were also reported in a 13-year study of culture material of *F. verticillioides* in vervet monkeys (Gelderblom *et al*., 2001d). Studies in ducks showed that FB_1 and/or crude preparations containing FB_1, FB_2 and FB_3 failed to induced necrotic lesions in the liver and kidneys while the serum enzyme markers showed an increase at the highest dose level of 128 mg FB_1 kg^{-1} feed (Bailly *et al*., 2001; Tran *et al*., 2005; Tradieu *et al*., 2006). Apoptosis, a key toxic parameter induced by the fumonisins also seems not to be important in the liver. The mechanisms involved in the resistance of ducks to the toxic effects of the fumonisins are not known at present. FB_1 increased the activities of drug-metabolizing enzymes in duck liver, of which the Phase 1 enzyme activities are the most sensitive while the Phase 2 enzymes are weakly affected (Raynal *et al*., 2001). The activities of different isozymes of cytochrome P450 are increased, this reaction may affect the metabolism of other carcinogens, steroids, numerous drugs and chemicals. Chickens and minks were also found to be relatively resistant to FB-induced toxic effects (see review by Voss *et al*., 2007). Hepatic necrosis and biliary hyperplasia were noticed in chicks with 200 to 300 ppm, while hepatic enzymes were elevated with a dietary dose of 80 mg FB_1 kg^{-1}. A study in mink showed no clinical evidence of disease at dietary levels between 118 and 254 ppm. Quail chicks showed an increased susceptibility to *Salmonella gallinarum* infection after feeding culture material containing 150 mg FB_1 kg^{-1} (Deshmukh *et al*., 2005). Consumption of pellets to obtain a dosage of 0.5 and 5 mg FB_1 (kg body weight)$^{-1}$ increased liver and kidney function enzymes of one-year old carp fish after 42 days (Pepeljnjak *et al*., 2003).

4.4.4 Studies in Rats and Mice

The effects of the fumonisins in rats and mice have been reviewed extensively (Bolger *et al*., 2001; Voss *et al*., 2001; 2007).

4.4.4.1 Toxicological Effects

Dose-dependent effects in the liver include the appearance of apoptotic and necrotic hepatocytes resulting in mitosis as initial events. Hepatotoxic effects are associated with an increase in serum chemical indicators for liver injury, including alanine and aspartate transaminases, alkaline phosphatase and lactate dehydrogenase. Other serum parameters included an increase in cholesterol and triglyceride levels. Advance liver lesions following long-term chronic exposure include a toxic hepatitis that eventually developed into cirrhosis, cholangiomatous lesions, fibrosis and eventually in nodular regeneration and cirrhosis. This was also associated with bile duct and oval cell proliferation resulting in the formation of cholangiofibromas (Lemmer *et al*., 1999a; 2004). Kidney lesions include apoptosis in the proximal tubules as an initial event, characterized by sloughing of the cells into the lumen, resulting in an increased number of mitoses and foci of tubular hyperplasia, and interstitial fibrosis and inflammation during severe injury. These changes are associated with an increased serum creatinine levels. Although the liver and kidneys are the main target organs in rats, strain and sex differences exist, as the kidney is the most sensitive organ in Sprague-Dawley and Fischer 344 rats, while in BD IX rats, the liver is the main target organ (Voss *et al*., 2007). The liver was also found to be the most sensitive organ in mice, whereas the kidneys were more resistant, even when mice were exposed to dietary levels of 484 ppm FB_1 for 28 days (Voss *et al*., 2001).

4.4.4.2 Reproductive Toxicology

Foetotoxicity has been reported in rats which also exhibited maternal toxicity, with no evidence that FB_1 crosses the placenta (See review by Voss *et al*., 2007; International Agency for Research on Cancer, 2002). The first evidence that FB_1 crossed the placenta was obtained in LM/Bc and CD 1 mice, showing teratogenic effects by inducing neural-tube defects (Gelineau-van Waes *et al*., 2005; Voss *et al*., 2006a). The FB1-induced effects were reduced by folate and the sphingolipid GM_1, colocalized with the folate-binding protein in the mouse yolk-sac membrane.

4.4.4.3 Carcinogenesis Studies

Hepatocarcinogenicity of naturally infected maize and *F. verticillioides* culture material has been demonstrated in Fischer 344 and BD IX male rats, respectively (Wilson *et al*., 1985; Marasas *et al*., 1984). Retrospective analyses of the total fumonisin content of the samples showed that a daily total fumonisin intake of between 2.3 and 3.2 mg affects a carcinogenic response in male Fischer 344 rats (Gelderblom *et al*., 2004). In male BD IX rats, a daily exposure of 3.2 and 6.9 mg FB resulted in 66% of the rats developing liver cancer (Gelderblom *et al*., 2001a; 2004). Varying doses of between 0.4 and 1.3 mg

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

FB_1 (kg body weight)$^{-1}$ per day yielded a far lower carcinogenic response in the liver (Jaskiewicz *et al*., 1987). A no observed effect level (NOEL) of 0.8 and $<$0.3 mg (kg body weight)$^{-1}$ per day was determined using pure FB_1 for the induction of liver cancer and hepatocyte nodules in male BD IX rats, respectively (Gelderblom *et al*., 1996; 2001b). These studies are in contrast with the two year study in male Fischer 344 rats, showing that an exposure of between 2.2 and 6.6 mg (kg body weight)$^{-1}$ did not cause any pathological lesions in the liver (Howard *et al*., 2001a). As different diets were used in the studies, the role of certain dietary constituents, such as the protein content and deficiencies in certain micronutrients could be responsible for differences in the organ-specific responses. A long-term study in Fischer 344 rats showed that female rats are more resistant than male rats in developing a rare variant of kidney tumours that locally invade and metastasize to the lungs (Howard *et al*., 2001a; Hard *et al*., 2001). In B6C3F1 mice FB_1 increased the development of adenomas, and carcinomas developed spontaneously in the liver of female mice, whereas no effect was noticed in males (Howard *et al*., 2001a).

4.5 Synergistic Interactions

The interaction between different mycotoxins that simultaneously occur in feed and food is of importance in order to elucidate possible additive and/or synergistic effects. This synergy is of relevance, as different mycotoxins have been shown to co-occur, which could increase their individual risks in the development of certain human and animal diseases. The studies, which mainly focussed on the interactions of FB_1 and AFB_1 utilized different experimental models including rats (Gelderblom *et al*., 2002; Theumer *et al*., 2003; 2008), weaned piglets (Dilkin *et al*., 2003), broiler chickens (Bianchi *et al*., 2005), male Fischer 344 rats (McKean *et al*., 2006), rabbits (Orsi *et al*., 2007) and rainbow trout (Carlson *et al*., 2001). Sequential treatment of rats with AFB_1 and FB_1 synergistically increased the hepatotoxic effects in the liver and also rendered the liver more susceptible to the cancer-promoting and initiating properties of FB_1 (Gelderblom *et al*., 2002). Coexposure of FB_1-containing maize culture material and AFB_1 enhanced the decrease in body-weight gain while the coexposure increased the toxic effects in the liver and kidney (Theumer *et al*., 2008). A synergistic increase in the Sa/So (sphinganine to sphingosine) ratio in the kidneys was noticed with the combined treatment. A study in weaned piglets showed that feed consumption and feed conversion were the only parameters affected, due to the joint effects of the toxins. Although the highest dose of FB_1 (30 mg (kg feed)$^{-1}$) induced the typical signs of pulmonary oedema, no combined and/or additive toxicological effects were noticed in the lung, liver and kidneys (Dilkin *et al*., 2003). In broiler chicks, the combined effects of FB_1 and AFB_1 did not alter the haematological and serological parameters, although certain changes in the liver and kidneys may be of relevance (Bianchi *et al*., 2005). Coadministration of AFB_1 and FB_1 in male Fischer rats showed that the latter additively increased the mortality caused by the acute toxicity of AFB_1 (McKean *et al*., 2006). Combined OTA and FB_1 treatment of male Wistar rats showed a significant increase in the tail intensity in kidney cells using the Comet assay (Domijan *et al*., 2006). A study in New Zealand using white rabbits showed synergistic liver and kidney toxicological effects when considering the serum biochemical and histology analyses after coadministration of AFB_1 and FB_1 (Orsi *et al*., 2007).

4.6 Fumonisin Biomarker Studies

Studies in animals showed that the disruption of sphingolipid biosynthesis via inhibition of ceramide synthase with the resultant accumulation of Sa, and the Sa/So ratio could be utilized as a biomarker for fumonisin exposure. These studies included investigations in horses (Wang *et al*., 1992), pigs (Riley *et al*., 1993), ducks (Tran *et al*., 2006) and rodents (Wang *et al*., 1999; Enongene *et al*., 2002). The validation of fumonisin biomarkers, including free FB_1 excretion in the faeces, Sa/So and SaP/SoP (sphinganine phosphate to sphingosine phosphate) alteration in the plasma and urine was recently investigated in male mice (Kim *et al*., 2006) and male Fischer rats (Garren *et al*., 2001; Cai *et al*., 2007). Treatment of ICR mice with FB_1 (10 mg kg^{-1}, intraperitoneal (ip)) for five days indicated that the SaP/SoP ratio in the serum was the most sensitive marker of exposure. A time-course study in the Fischer rats over a period of five weeks showed that the urinary SaP/SoP ratio was also the most sensitive biomarker for FB_1 exposure. Free faecal and urine FB_1 levels were strongly correlated with urinary sphingolipid metabolites and also were suggested as possible biomarkers for exposure in humans.

4.7 Studies in Humans

The impact of fumonisin exposure to humans and its involvement in certain human diseases are not known at present. A detailed review of the possible involvement of fumonisins, other fungal toxins and risk factors in human diseases, including oesophageal and liver cancer, and neural-tube defects has been conducted (Bolger *et al*., 2001). Most of these associations have been linked to poor socioeconomic populations using maize and/or maize products as a staple diet. More recent studies focussed on the development of valid biomarkers for fumonisin exposure in human populations consuming

contaminated maize. A study in three different regions, including the former Transkei region of the Eastern Cape, the Madadeni distract in Kwazulu-Natal in South Africa and the Bomet district in western Kenia showed that that no differences exist in the Sa/So ratios in the plasma and urine between males and females, between the different regions or as a function of the home-grown maize collected (Van der Westhuizen *et al*., 1999). These areas are known to have high prevalence of oesophageal cancer, with the populations utilizing maize as the main dietary staple. It was suggested that the Sa/So biomarker was not sensitive enough to monitor fumonisin exposure in humans. Two independent studies conducted in China showed contradictory findings regarding the use of the Sa/So ratio as a biomarker for oesophageal cancer and FB exposure. Randomly selected cases from a prospective control study in Linxian showed no association between the serum Sa/So ratio and the development of oesophageal squamous cell carcinoma (Abnet *et al*., 2001). In another study, the urine Sa/So ratio was suggested to be useful marker to assess FB_1 exposure in northern China (Qiu and Liu, 2001). A study conducted in high maize-consuming populations in northern Argentina and southern Brazil showed that, despite similar FB_1 intake profiles, the urinary Sa/So ratio was significantly higher in the residents from northern Argentina (Solfrizzo *et al*., 2004). Although a significant increase in the ratio was noticed when compared to residents in central Argentina and southern Italy, with low or no maize consumption, changes in the Sa/So values could not be associated with high fumonisin exposure. It would appear that the specific study design and the biomarker used are important when validating the sphingolipid biomarker in humans. A recent study showed that urinary FB_1 appear to be a more sensitive marker for fumonisin exposure and was correlated with tortilla consumption in a Mexican population (Gong *et al*., 2008).

Studies related to the possible role of fumonisins in the development of neural-tube defects (NTD) have been reviewed by Marasas *et al*. (2004). A recent study showed that the consumption of tortillas during the first trimester was associated with an increased risk of developing neural-tube defects (Missmer *et al*., 2006). Based on the Sa/So ratio in postpartum blood, increasing levels of fumonisins exposure were associated with increasing odds ratios for NTD incidence. Estimated fumonisin exposure in Guatemala, based on the consumption of nixtamalized maize products in the form of tortillas, was found to exceed the recommended provisional maximal TDI of 2 μg (kg body weight)$^{-1}$ per day, especially in the rural areas (Torres *et al*., 2007). The association of the high FB exposure and the development of NTD in this region are not known at present.

4.8 Biochemical Mechanisms of Action

4.8.1 Studies Utilizing Cell Cultures

Details of the FB_1-induced cytotoxic effects and possible mechanisms involved in different cell culture systems have been reviewed by Bolger *et al*. (2001). Some of the most recent studies, addressing important aspects regarding the mechanisms involved in FB_1-induced biological effects in different cell culture systems are summarized in **Table 1**. The studies utilized different cell culture systems including kidney, immune and inflammatory cells, cardiomyocytes, intestinal epithelial cells, oesophageal cells and gliomal cells to name a few. Most of the studies implied the disruption of sphingolipid metabolism and the accumulation of sphingoid bases and their phosphate metabolites in the modulation of cytotoxicity, inhibition of cell proliferation and induction of apoptosis. Another mechanism has been proposed implying mitochondrial damage and induction of lipid peroxidation. Irrespective of the mechanism involved, the fumonisins influenced a variety of cells and apart from selective cytotoxicity and the modulation of cell growth parameters, a number of immune cells are also affected, indicating potential immunosuppressive effects.

The comparative and interactive effects of FB_1 and other mycotoxins, including AFB_1, the tricothecenes, nivalenol and deoxynivalenol, and zearalenone have been conducted *in vitro* utilizing different cell lines (**Table 1**). Although differences exist in the specific mechanisms involved, most of the studies showed synergistic and/or additive effects when considering different toxic parameters.

4.8.2 Toxicological Effects in Experimental Animals

Initial studies on the possible mechanisms involved in fumonisin-induced toxic effects were based on the finding that the fumonisins disrupt the *de novo* biosynthesis of sphingolipids by inhibiting ceramide synthase (reviews by Merrill *et al*., 2001; Voss *et al*., 2001). The immediate response of ceramide synthase inhibition is the accumulation of sphinganine and, to a lesser extent, sphingosine, resulting in an increased Sa/So ratio in the blood, urine, kidney and liver, while the more complex sphingolipids are depleted. The sphingoid bases are catabolized by phosphorylation and lytic cleavage resulting in increased levels of sphingoid base 1-phosphate and ethanolamine phosphate, which are incorporated in the phospholipid phosphatidylethanolamine, affecting membrane integrity and fluidity. The sphingoid bases are also substrates for the *N*-acetyltransferase, resulting in the accumulation of *N*-acetylsphinganine metabolites. Apart from the accumulation of the sphingoid bases, the synthesis

Table 1 (*continued*)

Model	Biological effects/end points	Biochemical alterations	Reference
Human SCLC cells (Ms-1)	Regulation of apoptosis	FB_1 inhibits inostamycin-induced apoptosis by preventing cytochrome c release and caspase-3 (like) activation. Apoptosis mediated by PKC-regulated ceramide generation	Kawatani *et al*. (2000)
Human embryonic kidney (HEK-293)	Resistant to cytotoxic effects	Resistance related to the rapid formation of Sa-1-phosphate via sphingosine kinase.	Sharma *et al*. (2004a)
Human proximal tubule-derived cells (IHEK)	Ceramide synthesis, apoptosis.	Fumonisin derivatives increase sphinganine. Only FB_1-induced apoptosis.	Seefelder *et al*. (2003b)
Porcine intestinal epithelial cells (IEPC-1) LLC-PK_1	Cell proliferation	FB_1 blocks proliferation of IPEC-1 and LLC-PK_1 cells in G0/G1 phase. Barrier function of intestinal cells was decreased.	Bouhet *et al*. (2004)
Intestinal cells (Caco-2)	Absorption and toxicity	HFB_1 is more bioavailable than FB_1 and the partial hydrolized FB_1.	Caloni *et al*. (2002)
Caco-2 cells	Absorption of FB_1 and HFB_1 into cells	FB_1 not absorbed by Caco cells. HFB_1 absorption is limited by a P-glycoprotein efflux mechanism	Caloni *et al*. (2005)
NIH 3T3 fibroblasts	Glycosphingolipid synthesis	Ceramide inhibition results in the up-regulation of the activities of enzymes in the synthesis of the neutral glycosphingolipids (Gb_3)	Meivar-Levy and Futerman (1999)
Rat splenic macrophage and lymphocytes cells	Nitric oxide (NO) production; T-cell activation	FB_1 stimulates and potentiates TNF-γ-induced NO production in macrophages. FB_1 potentiates proliferation of splenic cells in the presence of a NO synthase inhibitor.	Dombrink-Kurtzman *et al*. (2000)
Murine macrophages (J774A.1)	NO and PGE_2 production	Increased NO and prostaglandin E_2 production related to increased iNOS and COX-2 expression	Meli *et al*. (2000)
J774A.1	Cytotoxicity; lipid peroxidation	FB_1 enhances susceptibility to oxidative damage; increased membrane microviscosity; enhanced horseradish peroxidase endocytosis, which is reverted by IFN-γ	Ferrante *et al*. (2002)
S-59 $\gamma\delta$ T lymphocytes	Growth arrest in IL-2-dependent proliferation	WCI-induced growth arrest via the accumulation of ceramide. FB_1 blocked WCI-induced growth arrest.	Kirkham *et al*. (2000)
Mouse cytotoxic T-cells (CTLL-2)	Regulation of CD95-induced apoptosis	FB_1 does not block activation-induced cell death (AICD); myriocin, inhibitor of serine palmitoyl-CoA transferase, blocks AICD; sphinganine counteracts the inhibition of myriocin.	Solomon *et al*. (2003)

DOI: 10.1002/9780470744307.gat150

Table 1 (*continued*)

Model	Biological effects/end points	Biochemical alterations	Reference
Avian immune cells peripheral blood lymphocytes (PBL), splenocytes and thymocytes)	Cell viability and proliferative response after mitogen stimulation	FB_1 lacks any effect on PBL; increase number of viable thymic cells with no effect on mitogenic response; secreased spleen viability and mitogenic response	Keck and Bodine (2006)
Swine peripheral blood mononuclear cells	Lymphocytes proliferation and IL-2 production	FB_1 decreases cell proliferation in G0/G1 phase. IL-2 production is decreased by FB_1 in ConA-stimulated cells.	Marin *et al*. (2007)
Murine macrophages (J774A.1) cocultured with liver epithelial cells (NMuLi)	Cytotoxicity measurements and cytokine production	Cocultures exhibit cytotoxic effects against FB_1 while separate cultures show no effect; sphinganine accumulates to a similar extent, while cocultures express TNFα and IL-12; media of FB_1-treated macrophages induce IFNγ expression in NMuLi cells. Cytokine expression potentiated FB_1-induced cytotoxic effects	Sharma *et al*. (2004b)
Neonatal mouse cardiomyocytes	Cell viability (MTT assay)	FB_1 prevented nitrosoglutathione-induced cell death via the reduction of ceramide accumulation	Rabkin (2002)
Rat brain glioma cells (line C6)	Cell viability; cell cycle arrest	FB_1 arrest cells in G2/M phase; induced hypermethylation of DNA; inhibition of protein synthesis	Mobio *et al*. (2000)
Astrocytes and oligodendrocytes of rat cerebrum	Sphingosine accumulation; proliferation	Modify proliferation and differentiation of glial cells	Kwon *et al*. (2000)
C6 gliomal and mouse embryonic fibroblasts (MEF)	Cytotoxicity, protein and DNA synthesis	Induction of lipid peroxidation that was inhibited with antioxidants; oxidative DNA damage in both cell lines; gliomal cells undergo apoptosis while embryonic cells were resistant; MEF cells lost protective effects mediated by p53.	Mobio *et al*. (2003)
Glioblastoma cells (U-118 MG)	Toxicity and oxidative damage	FB_1 increase lipid peroxidation and production of ROS; depletion of GSH associated with decreased cell viability; increased caspase-3 and DNA fragmentation; oxidative stress and apoptosis key determinants for neurotoxicity	Stockmann-Juvala *et al*. (2004)
Oesophageal cancer cells (SNO)	Cytotoxicity	FB_1 predisposes cells for cytotoxicity of diethylnitrosamine. Inhibited cytotoxicity induced by dietary catechol, a constituent of cigarette smoke	Myburg *et al*. (2002)
Comparative and interactive effects between different mycotoxins in cell culture models			
Swine alveolar macrophages	Cytotoxicity and DNA fragmentation	FB_1 and AFB_1 immunotoxic to swine via independent mechanisms; FB_1 decreases the expression of IL-1β and TNF-α; FB_1 induces apoptosis and AFB_1 not; both induce the expression of apoptosis-related heat shock protein.	Liu *et al*. (2002)

Table 1 (*continued*)

Model	Biological effects/end points	Biochemical alterations	Reference
Insect pupal ovary cells (SF-9)	Cytotoxicity and apoptosis	Nivalenol (NIV) and deoxynivalenol (DON) more cytotoxic than FB_1; cell arrest in G0/G1 phase; mycotoxins induce apoptosis	Fornelli *et al*. (2004)
Human erythroleukaemia cells (K562)	Cytotoxicity, proliferation and apoptosis	NIV and DON more cytotoxic than FB_1; cytotoxicity not related to membrane damage. NIV and DON induce more late stage apoptotic events.	Minervini *et al*. (2004)
Rat brain glioma (C6); human colon cancer (Caco-2); green monkey kidney (Vero) cells	Cytotoxicity	Synergistic effect of FB_1 and ochratoxin A	Creppy *et al*. (2004)
Human colon cancer (Caco-2)	Cell viability; DNA and protein synthesis; lipid peroxidation	FB_1 more cytotoxic when using the MTT assay than DON and zearalenone (ZEN); toxicity related to disruption of the mitochondria; DON more effective in the inhibition of protein and DNA synthesis; FB_1 more effective in inducing lipid peroxidation; DON and ZEN more effective in disruption of lysosomes.	Kouadio *et al*. (2005)
Human hepatoma cells (HepG2); human bronchial epithelial cells (BEAS-2B)	Cell cytotoxicty	IC_{50} values show that AFB_1 is more cytotoxic; combined effects showed an antagonistic effect in HepG2 cells and an additive effect in BEAS-2B.	McKean *et al*. (2006)
Human lymphoblastoid cells (Jurkat T)	Cytotoxicity, cell proliferation and apoptosis	ZEN reduces cytokines IL-2 and IFNγ and not FB_1; FB_1 increases cell proliferation, while ZEN shows inhibition; combined effects enhance ZEN inhibitory effects indicating interactive effects.	Luongo *et al*. (2006)
Porcine kidney epithelial cells (PK15)	Cell viability, GSH and thiobarbituric acid reactive substances (TBARS) levels	FB_1, ochratoxin A, beauvericin, increased TBARS, and decrease GSH. Combined effects is additive. Synergistic and antagonistic effects depending on time of exposure and dose.	Klarić *et al*. (2007)
Caco-2	Lipid peroxidation, protein and DNA synthesis, DNA fragmentation and methylation	ZEN, DON and FB_1 additive effects on DNA damage. Increase methylation of DNA with no additive effects. Less than additive effects on DNA synthesis. Synergistic effects on lipid peroxidation.	Kouadio *et al*. (2007b)

of complex sphingolipids from ceramide is reduced. These sphingolipids include sphingomyelin and gangliosides, which are important structural components of the cell membrane and growth-factor receptors, respectively. Ceramide synthase disruption appears to be a critical step as it normally precedes FB-induced toxic effects in different organs of many animal species. The disruption of this pathway and the effect on TNF-α and Fas ligand-induced apoptosis still need to be elucidated. The binding of TNF-a to Fas activates sphingomyelinase, yielding ceramide from sphingomyelin, may be linked to the biological action of IFN-γ and arachidonic acid release (Soriano *et al*., 2005). Modulation of protein kinase Cα, an internal acceptor for tumour promoters, may be related to FB_1 involvement during multistage carcinogenesis. Studies in TNFα (TNFR1 and TNFR2) knockout mice showed reduced hepatotoxic effects associated with the reduction in sphinganine accumulation (Voss *et al*., 2002; Sharma *et al*., 2001; 2002).

However, double knockout mouse showed increased apoptosis compared to the wild-type, indicating the complexity of the mechanism involved in FB_1 toxicity (Sharma *et al*., 2002). FB_1 caused the expression of oncogenic transcription factors and apoptotic genes, as well as activation of the cytokine network in the liver of mice, which was suggested to play a role in cancer promotion (Bhandari and Sharma, 2002; Sharma *et al*., 2003). A different cytotoxic pathway, associated with sphingolipid deregulation seem to exist when considering hepatotoxic effects in mice (Sharma *et al*., 2006). A recent study showed that the induction of nitric oxide (iNOS) gene also plays an important role in sensitivity to the hepatotoxic effect of FB_1 via the regulation of sphingosine kinase and the generation of sphingosine 1-phosphate (Suzuki *et al*., 2007). Changes in the disruption of signalling pathways related to sphingolipid metabolism and subsequent defects in the apoptotic and cytokine expression have been associated with the resistant of hepatocytes in a specific mice strain (Sharma *et al*., 2005). Depletion of the T cells by antibodies against mature peripheral T lymphocytes abolished FB_1-induced hepatotoxic effects in mice by inhibiting the formation of proinflammatory cytokines (Sharma *et al*., 2006). Upregulation of proinflammatory cytokines was also associated with neurodegeneration in murine brain after intraventricular infusion with FB_1 (Osuchowski *et al*., 2005). The hepatotoxic effects were also shown to be independent of the peroxisome proliferator-activated receptor (Voss *et al*., 2006b).

The relative sensitivity of different organs such as rat liver and kidneys was suggested due to differences in fumonisin accumulation and clearance, as well as sphingolipid metabolism into their phosphate metabolites (Soriano *et al*., 2005; Riley and Voss, 2006). The rapid turnover of sphinganine in the liver and intestine and the persistent accumulation in the kidneys is likely to explain the sensitivity of the latter to FB_1-induced toxic effects. Differences, however, exist in mice where the liver appears to be the more sensitive organ, as compare to the kidneys. The accumulation of sphingoid base 1-phosphate due to the induction of sphingosine kinase and inhibition of sphingosine 1-phosphate lyase are key determinants in FB_1-induced apoptosis (Kim *et al*., 2007). The exact role of the sphingolipid mediators in fumonisin toxicity is, however, not known at present and other mechanisms also should be considered.

The induction of oxidative stress and the resulting oxidative damage to membranal and subcellular organelles and macromolecules, such as DNA, should also be considered (Abel and Gelderblom, 1998). Recent reviews have indicated the involvement of sphingolipid turnover in regulating the cellular redox status (Won and Singh, 2006; Kitatani *et al*., 2008). The role of sphingomyelinase activation and cellular glutathione in the regulation of reactive oxygen and nitrogen species has been suggested. Downstream effects of ceramide are also important in the regulation of NADPH oxidase, mitochondrial integrity and antioxidant enzymes. TNF-α, an inducer of oxidative stress and stimulated by FB_1, enhances the generation of long-chain ceramide through a sphingosine recycling pathway, while other studies have reported on the ability of TNF-α to stimulate ceramide formation through sphingomyelinase. It was shown that FB_1 alters cellular redox balance in the liver and kidneys, leading to changes in the glutathione cycle and the activation and expression of redox-sensitive signalling molecules such as mitogen-activated protein kinases (MAPKs) (ERK and p38) and heat-shock proteins (Rumora *et al*., 2007). The interaction of changes in sphingolipid metabolism and the cellular redox balance could be important in clarifying the cytotoxic effects of the fumonisins.

4.8.3 Carcinogenic Effect in Rats and Mice

The fumonisins are regarded as nongenotoxic carcinogens as they lack mutagenic and genotoxic effects in many *in vitro* assays. Although characterized as liver-cancer promoters, they also exhibit cancer-initiating properties in the liver. The *in vivo* genotoxic effects were therefore the topic of many investigations, with the induction of oxidative cell damage as one of the possibilities of being important in the genesis of DNA damage.

4.8.3.1 Genotoxicity of Fumonisins

In vitro mutagenesis assays and *in vivo* DNA repair assays failed to indicate any direct interaction of the fumonisins with DNA. Indirect evidence of interaction with DNA resulted from studies conducted under conditions where toxic effects prevail, implying the interaction of reactive oxygen species with macromolecules, including DNA (see Bolger *et al*., 2001 for review). A study in C6 glioma and mouse embryonic fibroblast (MEC) cells showed that FB_1 induced lipid peroxidation, which was associated with a dose-related increase in 8-OH-deoxyguanine and DNA fragmentation (Mobio *et al*., 2000). However, studies in human fibroblasts and rat astrocytes showed that apoptotic-type DNA damage occurred without increased ROS production (Galvano *et al*., 2002a; 2002b), indicating that lipid peroxidation is an end result rather than a cause of FB_1-induced injury, as suggested previously (Abel and Gelderblom, 1998; Lemmer *et al*., 1999b). In human-derived hepatoma cells, FB_1 affected clastogenic changes, suggested that the mycotoxins may act as a genotoxic carcinogen in humans (Ehrlich *et al*., 2002). The genotoxic effects are exerted in the absence of cell cytotoxicity and induced early by modulating the expression of some genes (Galvano *et al*., 2002a). An *in vivo* study showed that FB_1 induced DNA damage in the kidney and liver prior to inducing oxidative damage, suggesting that changes in sphingolipid metabolism may play a role in DNA damage (Domijan *et al*., 2007). In the liver, however, the oxidative markers

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and changes to the sphingolipid levels coincided with DNA damage.

4.8.3.2 Cancer Initiation

Studies in rat liver showed that FB_1 exhibited cancer-initiating activity (Gelderblom *et al*., 1991; 1994; 1996; 2001b; 2008a). Based on the role of cell proliferation and the irreversible nature thereof, cancer initiation of FB_1 mimics that of genotoxic carcinogens, although the kinetics differ depending on the dose and time of exposure. The fact that different cancer-promoting stimuli selectively promote the development of FB_1-induced initiated hepatocytes into nodules further emphasizes the cancer-initiating potency. A hepatotoxic threshold exists for cancer initiation in the liver, with high doses fed over a short-time period of exposure. The irreversible nature of the cancer-initiating effect was demonstrated by a five-week exposure to FB_1 that resulted in the development of adenomas after one year (Lemmer *et al*., 2004). A long-term study, feeding low dose levels also initiated cancer, which emphasized the complexicity of FB_1–tissue interactions. A specific role for spontaneously initiated cells in the development of FB_1-induced liver carcinogenesis could not be demonstrated in older rats when utilizing a short-term cancer initiating/promoting model (Gelderblom *et al*., 2008a). Although the exact nature of the initiating step is not known, a possible role of oxidative DNA damage has been suggested (Abel and Gelderblom, 1998; Mobio *et al*., 2003).

4.8.3.3 Cancer Promotion

Two major mechanisms of FB_1-induced carcinogenesis, both involving lipid metabolism, have been proposed: (i) the role of FB_1-induced apoptosis due to the disruption of ceramide synthase in the development of hepato- and nephrocarcinogenesis in rats and mice and (ii) the disruption of phospholipid and, mainly, fatty-acid metabolic pathways as important events in the development of hepatocarcinogenesis in rats (Burger *et al*., 2007; Gelderblom *et al*., 2001c; 2008b).

4.8.3.3.1 FB_1 Apoptosis Hypothesis

The induction of apoptosis and necrosis, resulting in a compensatory regenerative response could theoretically increase the likelihood of cancer development (Dragan *et al*., 2001; Howard *et al*., 2001b; Riley *et al*., 2001; Voss *et al*., 2002). In rat kidneys, cell death is exclusively of an apoptotic nature followed by regeneration of the renal tubule epithelial cells. Another possibility is the development of a subpopulation of cells that are resistant to FB_1-induced apoptosis accumulating heritable genetic changes during their increased lifespan. The balance between effectors, which either induce apoptosis (increased ceramide or free sphingoid bases) or stimulate proliferation (decreased ceramide and increased sphingoid 1-phosphate) could eventually determine the outcome regarding the tumourigenic response (Riley *et al*., 2001). Cells sensitive to the proliferative effect of decreased ceramide and increased sphingoid 1-phosphates will survive, thereby creating a proliferative or mitogenic response, eventually leading to cancer. On the other hand, cells sensitive to sphingoid-base-induced growth arrest, due to the accumulation of free sphingoid bases, will die, while the resistant cells will survive, thereby increasing the risk of developing cancer specifically if they are genetically altered. At present the phases of cancer development have not been characterized in the kidneys. Possible precursor lesions were the atypical tubule regenerative lesions which were noticed in the proximal tubules 24 months after chronic treatment with FB_1 (Hard *et al*., 2001). No information regarding the kinetics of lesion development or information regarding the disruption of sphingoid metabolism and the levels of sphingoid metabolites in these and/or the cancerous lesions has been reported in an attempt to clarify the role of sphingolipids.

4.8.3.3.2 Resistant Hepatocyte Hypothesis

Several studies have shown that FB_1 affects both cancer initiation and promotion in the liver and as such mimics genotoxic carcinogens. The mechanism involved during the induction of resistant hepatocytes is not known at present, but a chronic toxic effect resulting in oxidative stress is likely to be involved. The genesis of the resistant hepatocytes induced by FB_1 has been characterized and found to be similar to that induced by genotoxic hepatocarcinogens with respect to its dependence on hepatocyte proliferation of the regenerative type. Proliferation of the mitogenic type failed to support initiation by FB_1 (Gelderblom *et al*., 2001b). A recent study showed that the initiated hepatocytes were selectively stimulated to grow by phenobarbital, a known cancer promoter (Gelderblom *et al*., 2008a). It was also shown that spontaneous initiated hepatocytes, normally present in the liver of older animals, could not explain the cancer-initiating properties of FB_1 in rat liver. The mechanism of promotion by FB_1 was based on the principle of differential inhibition, whereby FB_1 inhibits the proliferation of normal cells, while the resistant hepatocytes are allowed to proliferate. The apparent mechanism involved the inhibition of δ-6 desaturase, a key enzyme in the fatty acid metabolic pathway, resulting in the reduction in the long-chain polyunsaturated fatty content. In hepatocyte nodules, the reduction in long-chain polyunsaturated fatty acids (LCPUFAs) rendered them more resistant to oxidative stress, while normal cells will undergo apoptosis (Abel *et al*., 2001). In addition, the increased levels of arachidonic acid due to an enhanced level of phosphatydylethanolamine provide the nodules with a selective growth advantage due to an increased formation of prostaglandin E2. Interaction of AA with ceramide via sphingomylinase also

links the fatty-acid metabolic pathway with the sphingolipid pathway affecting different cell-survival parameters. These interactive pathways and secondary responses, involving different cell-cycle signalling pathways have been reviewed in detail (Gelderblom *et al*., 2001c; 2008b; Van der Westhuizen *et al*., 2004; Burger *et al*., 2007).

4.9 Reduction, Decontamination and Inactivation Procedures

Several detoxification processes of fumonisins have been investigated. Ammoniation, effectively used in the decontamination of aflatoxins, destroyed only 50% of the FB_1, when applying similar conditions (Chourasia, 2001). As the primary amino group in FB_1 is a prerequisite for cytotoxicity, many attempts have been focussed on either blocking it, thorough diazotation (Lemke *et al*., 2001), or removing this moiety by reaction with glucose (Liu *et al*., 2001; Fernandez-Surumay *et al*., 2004; 2005). These studies showed that the modification of the primary amine significantly reduced the toxic effects of the fumonisins. Other treatments included the use of bentonite clay, fermentative bacteria, clinoptilolite-rich zeolite tuff containing octadecyldimethylbenzyl ammonium ions at different pH values (Miazzo *et al*., 2005; Dakovic *et al*., 2007; Niderkorn *et al*., 2007) and activated carbon (Piva *et al*., 2005). Bentonite and activated carbon failed to reduce the toxic effects of FB_1, while *Lactobacillus* and the organozeolites significantly bound the fumonisins in a pH-dependent manner. Conflicting findings were reported on the effect of gamma irradiation. Application of a radiation dose of 5 kGy completely destroyed FB_1 in wheat, maize and barley (Aziz *et al*., 2007). The viability of *Fusarium* in seeds also decreased with increased radiation dose levels. Conversely, a study in maize showed that a radiation dose of 30–100 kGy totally eliminated *Fusarium* spp. in ground and whole maize (D'Ovidio *et al*., 2007). No reduction, however, was noticed in the level of FB_1 in corn samples irradiated under similar conditions. Nixtamlization of maize and the reduction of the fumonisins in maize have been extensively reviewed (Bolger *et al*., 2001). FB_1 and hydrolysed FB_1 (HFB_1) were found to account for 50% in tortillas prepared in a traditional way (Palencia *et al*., 2003). The effect of shelling and heating were also investigated recently. Mechanical dehulling of maize reduced the fumonisin levels by approximately 60%, depending on the method used (Fandohan *et al*., 2006). Temperatures above 150–200 °C reduced the fumonisin content of different products; the reduction depended on many factors, including the type of sugar present, cooking time, pH, moisture content and the specific recipe used (Humpf and Voss, 2004). Traditional African cooking of maize reduces the FB_1 levels by 23% (Shephard *et al*., 2002).

Reduction of fumonisin contamination via genetic modification or transgenic approaches, resulted in the development of *Bacillus thuringiensis* (Bt) maize (Duvick, 2001). Field studies using Bt maize have been widely applied and showed a significant reduction in fumonisin contamination. Alternative detoxification and/or inhibitory effects on fumonisin production were investigated *in vitro* by utilizing essential oils, cyclic terpenes and naturally occurring phenols. Although certain oils inhibited the growth of *F. verticillioides*, and therefore fumonisin production, they adversely affected kernel germination (Fandohan *et al*., 2004). In contrast, oil from neem seeds accelerated the growth of the fungus. Of the cyclic terpenes, limonene and thymol showed the highest inhibitory effect on FB_1 production (Dambolena *et al*., 2008). Of the plant phenols, chlorophorin was the most active phenol in reducing FB_1 production in culture, followed by caffeic acid and ferulic acid (Beekrum *et al*., 2003).

5 RISK ASSESSMENT OF AFLATOXINS, OCHRATOXINS AND FUMONISINS

5.1 Aflatoxins

When considering the epidemiological data, studies in animals, and different metabolic studies *in vivo* and *in vitro*, aflatoxin is treated as a human carcinogen (Group I). In such cases, the exposure must be kept as low as reasonably achievable (WHO, 2008a; International Agency for Research on Cancer, 2002), and a hypothetical standard ($20\,\mu g\,kg^{-1}$) was therefore set for aflatoxin exposure by the WHO (2008a). However, the risk of liver cancer attributable to aflatoxin and other factors is up to 30-fold higher in populations chronically infected with the hepatitis B and hepatitis C viruses. It was concluded that for populations from western Europe and the USA with a low hepatitis B surface antigen (HbsAg)-positive prevalence, aflatoxin levels below $20\,\mu g\,kg^{-1}$ in maize would be unlikely to decrease the incidence of liver cancer. Similar results were obtained for aflatoxin in groundnuts. Reducing the hypothetical standard from 20 to $10\,\mu g\,kg^{-1}$ would reduce the estimated population risk of liver cancer to two additional cancer cases per year per 10^9 people, as compared to an estimated 300 cases of cancer in people that are carriers of hepatitis B. Populations with a high HBsAg-positive prevalence and a high aflatoxin intake would thus benefit from such reductions, except in cases where there is increased risk of malnutrition or starvation. However, if the EU regulation of $4\,\mu g\,kg^{-1}$ of aflatoxins is adopted, this would encourage the export of the better-quality crops, with

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the poor quality crops being left for domestic consumption, which in turn could increase the risk of liver cancer among hepatitis-infected populations (Wu, 2004).

As a result of consecutive outbreaks of acute aflatoxicosis in Kenya in 2004 and 2005, which resulted in more than 150 deaths, a workgroup of international experts and health officials was convened by the Centers for Disease Control and Prevention and the World Health Organization. They identified gaps in current knowledge about acute and chronic human-health effects of aflatoxins, surveillance and food monitoring, analytic methods and the efficacy of intervention strategies (Strosnider *et al*., 2006).

5.2 Ochratoxins

Both genotoxic and nongenotoxic mechanisms have been suggested to play a role in the development of renal tumours by OTA, although the presence of DNA adducts containing OTA has not yet been confirmed. Consequently, different approaches to the risk assessment of OTA have been adopted by regulatory bodies in different countries, depending on whether the carcinogenicity arises through a threshold or a nonthreshold mechanism. Currently, risk assessment of increased tumour formation induced by OTA is based on a nongenotoxic mode of action exhibiting a threshold. Evaluation by JECFA, both in 2001 and 2007, retained the previously established provisional tolerable weekly intake (PTWI) of 100 ng (kg body weight)$^{-1}$ per week (WHO, 2001; 2008b). Current dietary exposure levels of humans to OTA of 8–17 (kg body weight)$^{-1}$ per week is well below the PTWI, particularly when one considers the consumption of processed cereals in Europe. As contamination levels of raw cereals are below 5 μg kg^{-1}, with only a small number of samples reaching 20 μg kg^{-1}, MTLs of this order will have little impact on dietary exposure to OTA. The situation in developing countries, however, is not clear, as very little data is available on contamination levels and dietary exposure.

5.3 Fumonisins

The NOEL for cancer induction in the liver has been estimated to be in the order of 0.8 mg FB_1 (kg body weight)$^{-1}$ per day, which represents a dietary level of 25 mg FB_1 kg^{-1} over a period of two years (Gelderblom *et al*., 2001a). When using the safety factor approach, a TDI of 0.8 μg (kg body weight)$^{-1}$ per day was calculated for humans, using a safety factor of 1000 (Gelderblom *et al*., 1996). The probable daily intake (PDI) levels for humans will depend on the level of fumonisin contamination and the maize intake profiles, which differ between countries and specific population groups within the same country. In South Africa, urban blacks consume less maize than rural blacks (250 vs. 500 g per person per day, respectively) while the European community consumes extremely low levels of maize (approximately 5 g per person per day). The health risk as a result of fumonisin exposure will therefore differ.

When using the NOEL for kidney toxicity, a provisional maximum tolerable daily intake (PMTDI) of 2 μg (kg body weight)$^{-1}$ per day was calculated, using a safety factor of 100 (WHO, 2002). The MTL established using the exposure and hazard assessments are levels of about 2 and 4 mg kg^{-1} for maize products and whole maize kernels, respectively (FDA, 2001). However, using the risk parameters developed from the NOEL for liver-cancer development, Marasas (1997), proposed levels 10–20 times lower, between 0.1 and 0.2 mg kg^{-1}. These MTL levels however, would seriously affect the food supply and the maize chain between producer and consumer (Viljoen and Marasas, 2003). In developed countries, the PDI levels are well below the PMTDI level proposed by JECFA (WHO, 2002), due to the consumption of small amounts of maize with the lowest contamination levels. However, certain subpopulations in developed countries that consume high quantities are still at risk (De Nijs *et al*., 1997). With respect to subsistence farmers in developing countries, it was suggested that large amounts of maize are consumed, often contaminated with high levels of fumonisins, which provide PDI levels between 10 and 50 times higher that the PMTDI. Another subpopulation that could be adversely affected, when using maize as a monocereal diet in rural areas, is children. As control of fumonisin levels in rural areas is critical, importation of maize with fairly high contamination levels from developed countries could also pose a problem, and specific control measures need to be implemented. However, details of these concerns have already been raised and were recently debated (Shephard *et al*., 2007; Marasas *et al*., 2008; Gelderblom *et al*., 2008b).

6 REGULATIONS FOR AFLATOXINS, OCHRATOXINS AND FUMONISINS

Since the discovery of aflatoxins in the 1960s, an increasing number of countries have legislated MTLs for an increasing number of mycotoxins with the aim of protecting both human and animal populations from the harmful effects of mycotoxin exposure. The most recent international effort to collate these regulations was undertaken under a Food and Agriculture Organization (FAO) project during 2002 and 2003, and a comprehensive compilation has been published as an FAO Food and Nutrition paper (Food and Agriculture Organization,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat150
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2004). These have also been reviewed in the literature (Van Egmond *et al*., 2007).

Aflatoxin remains the most widely legislated mycotoxin. At least 99 countries have regulatory limits for AFB_1 or the sum of AFB_1, AFB_2, AFG_1 and AFG_2 in food and/or feed. The MTLs themselves and the details of the regulations vary widely between countries. In general, limits for AFB_1 in food in different countries range from 1 to 20 $\mu g\,kg^{-1}$, with the limits in the EU for AFB_1 and for total aflatoxins now set at 2 and 4 $\mu g\,kg^{-1}$, respectively, for human food. These MTLs legislated in the EU have elicited considerable international comment concerning the potential effect they may have on exports from developing countries, especially those in Africa. Based on economic modelling of the exportation of edible groundnuts from nine African countries, it was postulated that these MTLs would lead to a 36% reduction in trade and a loss of exports of US$670 million (Otsuki *et al*., 2001). A subsequent World Bank Policy Research Working Paper put the actual loss at hundreds of thousands, rather than hundreds of millions (Jaffee and Henson, 2004). An empirical economic model was developed to further quantify expected export losses for a range of groundnut-exporting countries, including Argentina, China, USA and Africa, if the EU model was internationally adopted. This model predicted total losses would be of the order of US$446 million (Wu, 2006).

OTA is regulated in cereals and/or cereal products in over 30 countries, mainly in Europe. MTLs generally fall in the range 3–50 $\mu g\,kg^{-1}$. For example, within the EU, two limits have been set, namely 5 $\mu g\,kg^{-1}$ for raw cereals and 3 $\mu g\,kg^{-1}$ for processed cereal products intended for direct human consumption. In some countries, other sources of OTA may also be regulated. In the EU, dried vine fruit (raisins, sultanas and currants) have a MTL for OTA of 10 $\mu g\,kg^{-1}$, roasted coffee beans 5.0 $\mu g\,kg^{-1}$, instant coffee 10.0 $\mu g\,kg^{-1}$, wine and grape juice 2.0 $\mu g\,kg^{-1}$, and foods for infants and young children 0.50 $\mu g\,kg^{-1}$ (European Commission, 2006; Food and Agriculture Organization, 2004).

As a relatively recently discovered mycotoxin, only six countries in the FAO survey reported regulations for fumonisin ranging between 1000 and 3000 $\mu g\,kg^{-1}$ (Food and Agriculture Organization, 2004). However, with new EU regulations coming into force, this number has increased significantly. These regulations specify regulatory levels between 4000 $\mu g\,kg^{-1}$ for unprocessed maize (unless intended for wet milling), to 1000 $\mu g\,kg^{-1}$ for maize intended for direct human consumption and down to 200 $\mu g\,kg^{-1}$ for baby foods for infants and young children (European Commission, 2007).

7 CONCLUSION

Although the discovery of the aflatoxins as the causal agents of turkey X-disease in the UK happened 50 years ago, there is still an unabated worldwide concern about mycotoxins, as evidenced by the explosive growth in mycotoxin literature, particularly on the fumonisins and ochratoxins. Sterling progress on the genetics and genome sequence of the some of the filamentous fungi has been achieved, as well as a molecular understanding of the genomics of the toxicity of mycotoxins. Advances in immuno-based and physicochemical techniques have enabled the detection of mycotoxins at ppb levels in food and feeds. Based on these considerations, several countries and international organizations have introduced legislation to control mycotoxin contamination. The prevention of mycotoxin contamination of commodities remains a daunting challenge. In future, the focus should be on better agricultural practice, breeding of mycotoxin-resistant cereal and nut-producing cultivars, storage of crops under hygienic conditions and inactivation of mycotoxins by employing enzymes and micro-organisms.

ACKNOWLEDGEMENTS

We thank Dr. Margot Steyn for her outstanding contribution in the content and compilation of this chapter.

Botulism

Davide Lonati, Ornella Rossetto, Lucia Fenicia and Carlo Locatelli

CONTENTS

1 INTRODUCTION

Botulinum neurotoxins (BoNTs) produced by *Clostridia* species are among the most potent identified toxins. These toxins cause the potentially fatal paralysis known as 'botulism'; this serious intoxication can be a medical and public health emergency for which prompt diagnosis and early treatment are essential. Five well-defined forms of botulism are identified in relation to the route of exposure: foodborne, infant and adult intestinal, wound, iatrogenic and inhalation botulism; some authors add a sixth form as botulism of unknown source (Johnson and Montecucco, 2008). All these forms are finally characterized by the same clinical syndrome, which is caused by toxin-induced neuromuscular paralysis. Among the seven known neurotoxins (types A–G), the types A, B and E (rarely F) are toxic in humans, whereas the other mainly cause disease in animals.

1.1 Definitions

In all its forms, botulism is a poisoning related to the toxic effects of specific xenobiotics, the BoNTs. The

disease in not contagious and patients do not require isolation: only a hypothetical exposure originating from an aerial dispersion (e.g. terrorist attack) could potentially contaminate the nonexposed rescuers. The following 'clinical description, laboratory criteria for diagnosis and case classification' refer to the USA CDC (Centers for Disease Control and Prevention), (1997) and EU European Union (EU) (2002).

1.1.1 Foodborne Botulism

Foodborne botulism results from consumption of preformed BoNT complexes in food:

1. **Clinical description**: Ingestion of BoNTs results in an illness of variable severity. Common symptoms are diplopia, blurred vision and bulbar weakness. Symmetrical paralysis (descending) may progress rapidly
2. **Laboratory criteria for diagnosis**: Detection of BoNTs in serum, stool or patient's food or isolation of *Clostridium botulinum* from stools
3. **Case classification**:
   - **Confirmed**: A clinically compatible case that is laboratory confirmed or that occurs among persons who ate the same food as persons who have laboratory-confirmed botulism
   - **Probable**: A clinically compatible case with an epidemiological link (e.g. ingestion of home-canned or other potentially suspect products within the previous 48 hours).

1.1.2 Wound Botulism

Wound botulism, as with tetanus, occurs when spores of *Clostridium* sp. contaminate and colonize a wound in anaerobic conditions with a subsequent *in situ* multiplication of the organism and production of BoNTs that finally enter into the bloodstream. However, the frequency of wound botulism is much lower than tetanus, despite the fact that the population is not immunized against botulism, whereas many Western populations are immunized against tetanus:

1. **Clinical description**: An illness resulting from toxin produced by *C. botulinum* that has infected a wound. Common symptoms are diplopia, blurred vision and bulbar weakness. Symmetric paralysis may progress rapidly
2. **Laboratory criteria for diagnosis**: Detection of botulinum toxin in serum or isolation of *C. botulinum* from wound
3. **Case classification**:
   - **Confirmed**: A clinically compatible case that is laboratory confirmed in a patient who has no suspected exposure to contaminated food (i.e. has been ruled out as a food-borne botulism case) and who has a history of a fresh, contaminated wound during the two weeks before onset of symptoms.

1.1.3 Intestinal Toxaemia (Adult Intestinal and Infant Botulism)

Botulism can occur as a result of *Clostridium* sp. colonization of the intestinal lumen with subsequently production *in vivo* of BoNTs causing the form of botulism poisoning defined as 'intestinal toxaemia' (Arnon, 1995). The colonization of the intestinal tract by *Clostridium* sp. in an infant under one year of age is defined as 'infant botulism', while in children older than one year or adults cases are defined as 'adult intestinal botulism' (also referred as 'hidden botulism' or 'other botulism').

1.1.3.1 Adult Intestinal Botulism

Adult intestinal botulism is rare and resembles infant botulism in its pathogenesis and clinical status. People with altered intestinal flora are particularly vulnerable; also anatomical or functional bowel abnormalities may permit neurotoxigenic Clostridia colonization:

1. **Case classification**:
   - **Confirmed**: A clinically compatible case that is laboratory confirmed in a patient aged greater than or equal to one year who has no history of ingestion of suspect food and has no wounds.

1.1.3.2 Infant Botulism

Infant botulism results from absorption of BoNTs produced *in situ* by neurotoxigenic Clostridia colonizing the intestinal lumen (large intestine) in infants aged less than one year, who have ingested the spores.

Infant botulism is a disease that affects infants between one and 52 weeks of age, and not later. Infant botulism, first recognized in 1976 (Midura and Arnon, 1976), is the most common form of human botulism in the USA, where it is already included in the National Organization for Rare Disorders:

1. **Clinical description**: An illness of infants, characterized by constipation, poor feeding and 'failure to thrive' that may be followed by progressive weakness, impaired respiration and death
2. **Laboratory criteria for diagnosis**: Detection of BoNTs in stool or serum or isolation of *C. botulinum* from stools
3. **Case classification**:
   - **Confirmed**: A clinically compatible case that is laboratory confirmed, occurring in a child aged less one year.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1.1.4 Iatrogenic Botulism

Iatrogenic botulism, sometimes referred as 'inadvertent botulism' is caused by injection of BoNTs for cosmetic or therapeutic purposes.

1.1.5 Inhalation Botulism

Inhalational botulism, a disease resulting from aerosolized toxin, has been produced experimentally in primates (Franz *et al*., 1993), has been attempted by terrorists (Zilinskas, 1997; WuDunn *et al*., 1998; Tucker, 2000; Arnon *et al*., 2001) and has occurred accidentally in humans (Holzer, 1962).

1.1.6 Botulism from Unknown Source

This form should be considered in cases one year of age or older in whom no plausible food vehicle, or intestinal or wound colonization can be demonstrated:

1. **Clinical description**: See foodborne botulism
2. **Laboratory criteria for diagnosis**: Detection of BoNTs or isolation of *Clostridium botulinum* from clinical specimens
3. **Case classification**:
   - **Confirmed**. A clinically compatible case that is laboratory confirmed in a patient aged greater than or equal to one year who has no history of ingestion of suspect food and has no wounds.

1.2 History

The recorded history of botulism begins in 1735, when minor outbreaks were described. Later, the first well-recognized outbreak occurred in Wildbad in the state of Baden-Württemberg, Germany in 1793, when six people over 13 died after eating a popular blutwurst (blood sausage, black pudding). Following this, the number of reported cases of sausage poisoning rapidly increased, prompting a study of the disease in southern Germany by Kerner, who described 230 cases, as well as the clinical syndrome (Kerner, 1817). He also performed animal and clinical experiments, and hypothesized the possible therapeutic use of botulinum toxin. At approximately the same time, some Russian physicians identified a disease with similar clinical manifestations termed 'fish poisoning' (Young, 1976). In 1870, the German physician Muller derived the name botulism from the Latin term *botulus*, which means 'sausage' (Torrens, 1998). The isolation of the clostridial organism responsible for botulism was made in the nineteenth century by the microbiologist Emilie Pierre Van Ermengem, who conducted a meticulous investigation as a response to an extraordinary outbreak in Ellezelles (Belgium) in December 1895, involving 34 musicians who had consumed raw-salted ham after a funeral meal. During the next two days, 23 of the musicians became ill with increasing neuromuscular paralysis (mydriasis, diplopia, dysphagia, dysartria and progressive muscle paralysis): three of them died. In the investigation of this outbreak, Van Ermengem established that botulism was an intoxication, not an infection, and that the toxin was produced by a spore-forming obligate anaerobic bacterium, called '*Bacillus botulinus*' (Van Ermengen, 1897). The pathogen was later renamed *Clostridium botulinum* to acknowledge both its spindle shape (*kloster* is Greek for spindle) and its anaerobic metabolism (Erbguth, 2008).

A later outbreak in Darmstadt (in the German state of Hesse) associated with canned white beans showed a second type of botulism: the new strain was Type A, while the Van Ermengem strain probably was Type B. In 1922, Type C botulism was identified as causing disease in chickens in USA by Bengston and in Australian cattle by Seddon. Meyer and Gunisson identified the type-D in the USA, and Bier the type-E in Ukraine. Type-F was first described by Moller and Scheibel from a Danish outbreak of botulism involving homemade liver pâté. Finally, type-G botulism was identified in soil from cornfields in Argentina by Giménez and Ciccarelli (Gunn, 1979; Kriek and Odendaal, 1994; Geiges, 2002; Erbguth, 2008).

2 CLOSTRIDIA PRODUCING BOTULINUM NEUROTOXINS

BoNT-producing Clostridia display heterogeneous bacteriological characters and are divided into several species and groups. The taxonomic position of the *C. botulinum* species was originally based on the production of a BoNT, and nontoxic variant strains, although genetically related to *C. botulinum,* were assigned to different species. Moreover, some of the seven different serologically distinct BoNTs (termed with letters from A to G) can be further divided into subserotypes; for example, there are four subserotypes of BoNT/A (termed A1–A4), which are approximately 90% identical in their amino-acid sequences (Arndt *et al*., 2006).

BoNT can be produced by other *Clostridium* species such as *C. butyricum* and *C. baratii*, which have been implicated in human botulism (Hall *et al*., 1985). The toxinogenic property of the *Clostridium* strains remain an important characteristic, mainly in clinical aspects, but this single property is not sufficient to define a bacterial species. Moreover, toxigenicity is unstable, and it appears to be transferable to a wide variety of *Clostridium* species.

C. botulinum strains are divided into four physiological groups:

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat151
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Group I includes *C. botulinum* A, and proteolytic stains of Types B and F, and it is characterized by proteolytic activity and by the nonacidification of carbohydrates. The optimal temperature of growth is 37 °C. The thermoresistance of the spores is usually high (above 120 °C).
- Group II (*C. botulinum* E, and glucidolytic strains of types B and F) acidifies many carbohydrates and produce mainly butyric and acetic acids from trypticase–yeast-extract–glucose broth. They hydrolyse gelatin, but they are nonproteolytic. They have a lower optimal temperature of growth (around 25–30 °C), and they can grow and produce toxins at very low temperature. Spores are only moderately resistant to heat, not withstanding 10 minutes at 90 °C.
- Group III (*C. botulinum* C and D) is poorly proteolytic, and is rather heterogeneous with respect to sugar fermentation and production of indol and hydrogen sulfide. These bacteria grow at higher temperature than the other *C. botulinum* strains (30–37 °C optimal range), with most strains growing well up to 45 °C. Heat resistance of spores is intermediate.
- Group IV (*C. argentinense*). This group includes *C. botulinum* G strains, which have been assigned to a different species termed *C. argentinense*. These bacteria are proteolytic, hydrolyse gelatin and do not ferment any of the usual carbohydrates. Contrary to the other strains of the *C. botulinum* groups, *C. argentinense* strains do not produce a lipase. The optimum temperature of growth is 30–37 °C.

C. butyricum toxigenic strains are nonproteolytic, do not hydrolyse gelatin and acidify strongly various carbohydrates, but they do not produce lipase or lecithinase. Toxigenic and nontoxigenic *C. baratii* strains display similar morphological and biochemical characteristics and are phenotypically related to *C. perfringens*. They produce a lecithinase, but not a lipase.

BoNT-producing *Clostridia* are usually straight to slightly curved rods, 0.6–2 µm wide and 2–22 µm long. They are usually motile and peritrichous, except *C. baratii*, which is nonmotile. Spores are oval and swell one terminus of the cell. These bacteria grow well in usual anaerobic liquid media, with production of gas. Surface colonies can be grown on blood agar plates, incubated under anaerobic conditions.

All the BoNTs producing *Clostridium* belong to Group I of 23 S rRNA homology, which also includes *C. butyricum.* The genome sequence of *C. botulinum* A strain Hall has been completed (Sebaihia *et al*., 2007). It consists of a chromosome (3 886 916 bp) and a plasmid (16 344 bp), which carry 3650 and 19 predicted genes, respectively.

The genes encoding for the different types of BoNT are present on different genetic elements, including phages, plasmids or chromosomes, depending on the species and strain of Clostridia (Minton, 1995). These genes are associated with genetically mobile elements allowing for a loss or acquisition of neurotoxigenicity. In *C. argentinense,* the neurotoxin gene is present within a large plasmid, and in *C. botulinum* A, B, E and F, the toxin genes are located on the chromosome. BoNT/C and BoNT/D are present within bacteriophages and their genes can be transferred in different *Clostridium* host strains, determining their toxinotypes; indeed, transposable elements have been identified in *C. botulinum* C and D (Marvaud *et al*., 2000).

2.1 Ecology of Botulinum-Neurotoxin-Producing Clostridia

C. botulinum is widespread in soils and in sediments of lakes and seas in most parts of the world, and quantitative information on the presence of spores was summarized by Dodds (1994). BoNT-producing Clostridia, as the other Clostridia, are present in the environment, mainly in the form of spores, which are able to survive for very long periods under extreme conditions (including heat, dryness, radiation, chemicals and oxygen). Spore germination and cell division occur only under anaerobic conditions and in the presence of the appropriate nutritional requirements. This restricts the habitat of the *Clostridium* to anaerobic (low oxygen) milieux containing adequate amounts of organic materials. Based on their physiological properties (tolerance or extreme sensitivity to oxygen, requirement of particular pH, temperature and substrate for growth or spore germination), the distribution of the different *Clostridium* species in nature is not uniform. Saccharolytic *Clostridia* such as *C. butyricum* are able to grow on carbohydrates and are mainly found in decomposing vegetables and fruits. Proteolytic and gelatinolytic *C. botulinum* are preferentially associated with animal cadavers, and soils or sediments rich in organic material. They can also be found in the digestive tract of healthy humans and animals, and, after death, they participate in the process of cadaver decomposition.

3 TOXIN STRUCTURE AND MODE OF ACTION OF BOTULINUM NEUROTOXINS

BoNTs bind to and enter inside peripheral cholinergic terminals and cause a sustained block of acetylcholine release, with ensuing flaccid paralysis and loss of function of autonomic glands. These neurotoxins are metalloproteases which exert their enzymatic action in the cell cytosol on selected proteins, which form the core of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat151
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the neuroexocytosis machinery. As a net result of such double specificity of binding (presynaptic membrane and substrate) and of their catalytic activity, these neurotoxins are the most potent toxins known, with a mouse LD_{50} (median lethal dose) between 0.4 and 1.2 ng ip of toxin per kilogram of body weight (Gill, 1982). Such extremely low values are expected to be even lower in the wild, where even a very small deficit in mobility may be sufficient to impair the survival of intoxicated animals.

3.1 Toxin Structure

BoNTs are synthesized in the bacterial cytosol as a 150 kDa polypeptide chain without a leader sequence, and are released in the culture medium after bacterial autolysis as a noncovalent assembly with a set of nontoxic proteins (Minton, 1995; Sakaguchi, 1982). The neurotoxin moiety interacts with a large nontoxic, nonhaemagglutinin protein (NTNH) via its C-terminal domain. This dimeric complex (12 S, MW 300 kDa) serves as scaffold for the assembly of larger complexes formed by the incorporation of three types of additional proteins with haemagglutinin activity: HA of 17 kDa (HA17), HA of 34 kDa (HA34) and HA of 70 kDa (HA70).These additional forms are the large (16 S, MW 500 kDa) and the extra-large (19 S, MW 900 kDa) progenitor toxins. Complexed BoNTs are more stable than isolated BoNTs to proteolysis and denaturation induced by temperature, solvent removal or acid pH (Sakaguchi, 1982). It has been found that the HA component binds to the microvilli of the small intestine through interactions with cell-surface glycoconjugates (Nakamura *et al*., 2008). Whether accessory proteins do promote the toxin uptake from the intestinal lumen into general body-fluid circulations, however, is not known. *In vitro,* small amounts of purified BoNT in the absence of HA proteins can pass through polarized epithelial monolayers by trancytosis (Maksymowych and Simpson, 1998). It has been recently reported that the HA of a 16 S BoNT/B complex was able to disrupt the intercellular junctions of the intestinal epithelium so as to allow passive protein transport via a paracellular pathway (Matsumura *et al*., 2008). The BoNTs transcytose from the apical to the basolateral side of intestinal epithelial cells (Maksymowych and Simpson, 1998) and the toxin form appearing in the lymph is the 150 kDa 'naked' protein (Heckly *et al*., 1960). Once in the tissue fluids, they then reach their specific targets, which are the peripheral cholinergic nerve terminals (Rossetto *et al*., 2006; Montecucco *et al*., 2004). The single-chain 150 kDa neurotoxins are inactive and are activated by specific proteolysis within a surface-exposed loop subtended by a highly conserved disulfide bridge. Several bacterial and tissue proteinases are able to generate the active dichain neurotoxin. The heavy chain (H, 100 kDa) and the light chain (L, 50 kDa) remain associated via noncovalent interactions and via the conserved interchain S–S bond, whose integrity is essential for neurotoxicity (Schiavo *et al*., 1990).

The lengths of the polypeptide chains of BoNTs vary from the 1251 amino-acid residues of *C. butyricum* BoNT/E to the 1297 residues of BoNT/G. Since the first molecular glimpse of BoNT/A in 1998 (Lacy *et al*., 1998), there has been a profusion of X-ray crystal structures, including the BoNT/A and BoNT/B holotoxins, the BoNT/B binding domain and the LC structures of BoNT/A–/G (structures are available at the protein data bank: *http://www.rcsb.org/pdb/*). BoNTs are organized in three distinct 50 kDa domains: an N-terminal metalloprotease domain (light chain, LC), disulfide linked to the first half of the heavy chain (H_N), which is essential for the entry into the cell and the C-terminal domain H_C responsible for the neurospecific binding (Lacy *et al*., 1998; Swaminathan and Eswaramoorthy, 2000).

The H_C binding domain consists of two functionally distinct subdomains of ~25 kDa each, the N-terminal half (H_CN) and the C-terminal half (H_CC), with little protein–protein contacts among them. H_CN is similar to some legume lectins, which are carbohydrate-binding proteins. The amino-acid sequence of this subdomain is highly conserved among BoNTs, suggesting a closely similar folding. On the other hand, the sequence of the H_CC subdomain is overall poorly conserved, but folds similarly to protein of the Kunitz-type trypsin inhibitor family. H_CC harbours one binding site for the oligosaccharide portion of polysialogangliosides in BoNT/A and /B (Rummel *et al*., 2004a). The crystalline structures of the complex between BoNT/B and the luminal domain of synaptotagmin II show that H_CC of BoNT/B also harbours a cleft which fits in segment 44–60 of this synaptic vesicle protein (Jin *et al*., 2006; Chai *et al*., 2006). The translocation domain H_N features a cylindrical shape determined by the presence of a pair of unusually long and twisted 10 nm long antiparallel α-helices (Lacy *et al*., 1998; Swaminathan and Eswaramoorthy, 2000). The overall structure of H_N resembles that of membrane-interacting viral colicin and influenza haemagglutinin proteins, which undergo an acid-driven conformational change.

The metalloprotease domain LC is disulfide bridged to the H_N and has little similarity with related enzymes of known structure, apart from the α-helix segment, including the zinc-binding motif. The active site zinc atom is coordinated by the imidazole rings of the two histidines of the motif, a water molecule bound to the glutamic acid of the motif and a distant glutamic residue (Glu262 in BoNT/A), which is conserved among clostridial neurotoxins. The Glu residue of the motif is particularly important because it coordinates the water molecule directly implicated in the hydrolytic reaction

of proteolysis. The loss of the Glu residue by mutation leads to complete inactivation of these neurotoxins (Li *et al*., 2000). The active site is similar to that of thermolysin and identifies a primary sphere of residues essential to the catalytic function, which coincides with the zinc-coordinating residues. In addition, there is a secondary layer of residues, further from the zinc centre, including Arg362 and Tyr365 (numbering of BoNT/A), which appear to be directly involved in catalysis by providing transition-state stabilization (Rigoni *et al*., 2001; Binz *et al*., 2002). The active site of BoNTs is long and deep, and shielded by the H chain; it becomes accessible to the substrate upon reduction of the interchain disulfide bridge and it appears to be capable of accommodating a 16 residue-long segment of the substrate.

Such structural organization is functionally related to the fact that BoNTs intoxicate neurons via a four-step mechanism consisting of: (i) binding, (ii) internalization, (iii) membrane translocation and (iv) enzymatic target modification (Rossetto and Montecucco, 2008).

3.2 Mode of Action of Clostridial Neurotoxins

3.2.1 Neurospecific Binding

From the site of production or adsorption, BoNTs diffuse in the body fluids and eventually bind with high affinity and specificity to the presynaptic membrane of skeletal and autonomic cholinergic nerve terminals. The H_C domain plays the major role in the neurospecific binding (Jin *et al*., 2006; Chai *et al*., 2006). Polysialogangliosides are involved in BoNT binding (Schiavo *et al*., 2000; Rossetto and Montecucco, 2008). In fact, the H_CC subdomain of BoNT bind polysialogangliosides, particularly GD1a, GT1b and GQ1b, via the conserved peptide motif H . . . SXWY . . . G (Rummel *et al*., 2004a). More recently, polysialogangliosides GD1b and GT1b and phosphatidylethanolamine were reported to be the functional receptors of BoNT/C and BoNT/D, respectively (Tsukamoto *et al*., 2005). However, a double receptor model resulted from the existence of two classes of binding sites distinguished by different affinities and from the discovery of protease-sensitive binding to neurons (Montecucco, 1986). Indeed, the identification of synaptic vesicle proteins synaptotagmin I and II as protein receptors for BoNT/B and /G (Rummel *et al*., 2004b; Nishiki *et al*., 1996; Dong *et al*., 2003) and of SV2 for BoNT/A (Mahrhold *et al*., 2006; Dong *et al*., 2006) confirmed this model. The crystal structures of the complex between BoNT/B and the luminal domain of synaptotagmin II show that H_CC of BoNT/B also harbours a cleft which fits in segment 44–60 of this synaptic vesicle protein (Jin *et al*., 2006; Chai *et al*., 2006). The synaptotagmin-binding cleft and polysialoganglioside-binding pocket are located in the H_CC subdomain and double mutants at the two binding sites abolish neurotoxicity. Therefore, this opens the question of the role of the H_CN subdomain, which still remains unknown (Rossetto and Montecucco, 2007).

3.2.2 Internalization

BoNT binding is followed by endocytosis via a temperature- and energy-dependent process (Dolly *et al*., 1984). The binding of BoNT/B to the luminal portion of synaptotagmin I and II and of BoNT/A to the luminal domain of SV2 suggest that they are endocytosed within synaptic vesicles. This would provide a simple explanation for the accelerated intoxication brought about by increasing the nerve activity (Hughes and Whaler, 1962), because there is a tight coupling between neuroexocytosis and synaptic vesicle retrieval (Cremona and De Camilli, 1997). The protein receptors only become exposed to the external medium for a short time, between the times when the vesicle fuses with the presynaptic membrane and the times when the fission event allows vesicle endocytosis and recycling. Therefore the synaptic vesicle cycling is the cellular event that brings the toxin inside the nerve terminal; synaptic vesicles, hence, act as neuronal Trojan horses for BoNTs. BoNTs are known to act within the peripheric nerve terminal. On the other hand, a closely related clostridial neurotoxin, the tetanus toxin is retrogradely transported and acts at the central nervous system. It is not known if, and to what extent, BoNTs migrate retroaxonally. Direct measurements of retroaxonal transport indicate that 125I-BoNT/A does not reach the central nervous system (Habermann and Dreyer, 1986). However, it was recently reported that BoNT/A was retrogradely transported by central neurons and motoneurons in mice and was then transcytosed to afferent synapses, in which it cleaved SNAP-25 (synaptosome-associated protein of 25 kDa) (Antonucci *et al*., 2008).

3.2.3 Membrane Translocation

To reach the cytosol, the L chain must cross the hydrophobic barrier of the vesicle membrane, and the acidity of the lumen is essential for such a movement. BoNTs have to go through a low-pH step for nerve intoxication to occur (Schiavo *et al*., 2000). This causes a conformational change from a water-soluble 'neutral' structure to an 'acid' structure, with the surface exposure of hydrophobic patches, which mediate the interaction of the H and L chains with the hydrocarbon core of the lipid bilayer (Montecucco *et al*., 1989). Following this low-pH-induced membrane insertion, BoNTs form transmembrane ion channels in planar lipid bilayers (Koriazova and Montal, 2003) and in cell membranes (Sheridan, 1998). Membrane translocation of BoNTs is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the least understood step of their mechanism of action. For BoNT/A, the following translocation mechanism has been envisioned: an acid-pH-induced membrane insertion step is coupled to L-chain unfolding and entry into the H-chain chaperone/channel; then the L chain is conducted through the H-chain channel in an N- to C-terminal orientation, is subsequently released from the chaperone by reduction of the disulfide bridge and is concomitantly refolded at the cytosol (Koriazova and Montal, 2003; Brunger *et al*., 2007).

3.2.4 Proteolysis of SNARE Proteins

Once in the cytosol, BoNT L chains display their catalytic activity. BoNTs are remarkably specific proteases that recognize and cleave only three proteins: VAMP (vesicle-associated membrane protein), SNAP-25 and syntaxin, which form the core of the neuroexocytosis machinery (Schiavo *et al*., 2000; Rossetto and Montecucco, 2008). VAMP, SNAP-25 and syntaxin form a heterotrimeric coiled-coil complex which juxtaposes the vesicle to the target membrane and is involved in their fusion (Chen and Scheller, 2001). VAMP is a synaptic vesicle transmembrane protein. Syntaxin is anchored to target membranes via a C-terminal hydrophobic tail and SNAP-25 is a 25 kDa protein bound to the cytosolic face of the presynaptic membrane.

BoNT/B, /D, /F and /G cleave the VAMP at different single peptide bonds; BoNT/C cleaves both syntaxin and SNAP-25, two proteins of the presynaptic membrane, whilst BoNT/A and /E cleave SNAP-25 at different sites within the COOH terminus (Schiavo *et al*., 2000). Proteolysis of one SNARE protein prevents the fusion complex formation or it may result in a nonfunctional complex (Humeau *et al*., 2000).

The biochemical basis of the BoNT specificity for the three SNAREs is only partially known. Experimental evidence clearly indicates that they recognize a nine-residue-long motif characterized by the presence of three carboxylate residues alternated with hydrophobic and hydrophilic residues (Rossetto *et al*., 1994; Pellizzari *et al*., 1996; Evans *et al*., 2005). A recent cocrystal structure of LC/A and SNAP-25 (146–204) defined additional regions of interaction external to the cleavage site and to the motif (Breidenbach and Brunger, 2004; Breidenbach and Brunger, 2005). More recently, the fitting of an extended region of the substrate (residues 189–203) within the long active-site cleft was defined, following extensive mutagenesis of LC/A and SNAP-25 (Chen *et al*., 2007).

The cleavage of the SNARE proteins by the BoNTs within the nerve cells does not cause cell death, as with other bacterial toxins (diphtheria toxin, shiga toxins, etc.). Within a time period that varies with the type of nerve, the animal species and the type of BoNT, the toxin is inactivated within the nerve and the new SNARE protein is synthesized, leading to full functional recovery.

Such recovery is the end result of a series of events, which include, not only the lifetime of the L chain, but also the replacement rate of the nonfunctional SNARE protein, which depends on several factors. This replenishment tends to be rapid, if the SNARE protein is nonfunctional, but it is slower in the case of the limited modification caused by BoNT/A and /C because these truncated SNAP-25 molecules are still capable of forming SNARE complexes (Meunier *et al*., 2003). Experimental evidence supports the proposal that an important role is also played by the dominant negative effect on neurotransmission exerted by the BoNT/A- or /C-truncated SNAP-25 (Rossetto *et al*., 2006; Montecucco *et al*., 2005). The time required for a full recovery of nerve function varies with the amount and type of L chain, the type of nerve and muscle involved, the animal species and other factors. In general, recovery from BoNT/A and /C intoxication is slower (two to four months in humans), in agreement with the slower recovery from botulism caused by these neurotoxins, whilst recovery from BoNT/B, /E and /F is shorter (one to two months in humans) (Montecucco and Molgó, 2005; Eleopra *et al*., 2006). The recovery from BoNT intoxication in mice is much shorter than in humans for all BoNTs (Morbiato *et al*., 2007).

4 CLINICAL USE OF BOTULINUM NEUROTOXINS

The finding that BoNTs cause only a transient impairment of neuroexocytosis with complete functional recovery provides the scientific basis of the booming growth of the use of BoNTs in the therapy of a variety of human diseases caused by hyperfunction of cholinergic terminals (Scott *et al*., 1989; Jankovic, 2006). Injection of BoNT is currently recognized as the best available treatment for dystonias and for certain types of strabismus, and new uses are continually being found (Montecucco and Molgó, 2005). In addition, BoNT/A inhibits acetylcholine (ACh) release at autonomic nerve terminals, which innervate the glands and smooth muscle, and it is currently used to treat diseases such as hypersalivation and hypersudoration (Naumann and Jost, 2004). Injections of minute amounts of BoNT into the muscle(s) or the gland to be paralysed lead to a depression of the symptoms, lasting months. The duration of the beneficial effect varies according to the type of toxin used and to the type of cholinergic terminals. Autonomic terminals are affected for many months, in certain cases for more than one year.

The use of BoNT/A has been increasingly reported in many conditions of pathological pain, including migraine and other headache disorders, musculoskeletal pain, such as myofascial pain, low back pain and other chronic

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

pain syndromes (Jeynes and Gauci, 2008). On the basis of the differential effect of BoNT on glutamatergic and γ-aminobutyric acid (GABA)-ergic nerve terminals in hippocampal neurons (Verderio *et al*., 2004), BoNT/E was tested as a potential therapeutic for epilepsy, and it was found to effectively decrease the symptoms induced in mice by the epileptogenic, kainic acid (Costantin *et al*., 2005).

There are comparatively few side effects of the treatment with BoNT/A, the most important one is the production of antibodies, which make the patient resistant to the toxin. In general, this occurs with the large doses of toxin necessary for the treatment of spasmodic torticollis; here the aim is to weaken certain powerful muscles in areas rich in lymph nodes, primarily in the neck. If there are neutralizing anti-BoNT/A antibodies, one has to switch to a different type. BoNT/B has been introduced for the treatment of cervical dystonias, and other types of BoNT are undergoing clinical tests, with very encouraging results having been obtained with BoNT/C (Morbiato *et al*., 2007; Eleopra *et al*., 2006).

5 OUTLINE OF EPIDEMIOLOGY OF HUMAN BOTULISM

The worldwide incidence of botulism is still unknown, especially in developing countries. Moreover, some differences regarding the commonest botulism form are present; infant botulism is the prevalent form in USA, whereas foodborne botulism is more common in the EU. Botulism remains underdiagnosed because clinicians are unfamiliar with the signs of presentation, and the first symptoms can be mistaken for several more common clinical entities. In recent years, increased surveillance by *ad hoc* surveillance systems established by health authorities in several countries has contributed to an increase in the number of cases identified.

5.1 Foodborne Botulism

Epidemiological studies have indicated that the home-prepared foods causing the highest incidence of botulism included home-canned vegetables and meat, and garlic, mushrooms and other vegetables packed in oil or brine not suitable because it is not salty enough. Since the beginning of industrial canning (1920s), commercial products have generally had a good safety profile. Few outbreaks due to commercial foods are reported worldwide, and some of them are shown in **Table 1**.

The majority of incidents of foodborne botulism have been caused by Clostridia producing BoNT/A, BoNT/B and BoNT/E. Type A is predominant in the western USA, Argentina and China, most frequently related to vegetables and fruits. Type B is prevalent in Europe (excluding northern countries) and meat has been recognized as the main involved source; only in Italy and Spain are vegetables more frequently incriminated. Type E botulism is found mainly in the colder regions of the northern hemisphere (Alaska, Canada, Greenland, Scandinavia, Japan). Type E due to neurotoxigenic *C. butyricum,* has been reported only in China, India and Italy (Anniballi *et al*., 2002). Type F foodborne botulism is very rare, and only a few poisonings have been

Table 1 Foodborne botulism cases/outbreaks due to commercial food occurred worldwide in the last 25 years

Year	Country	Incriminated food	BoNT type	No. of cases
1983	Canada	Garlic in oil	B	36
1986	Taiwan	Unsalted peanuts in water	A	9
1987	USA and Israel	Uneviscerated salted airdried fish (‘kapchunka’)	E	8
1989	United Kingdom	Hazelnut yoghurt	B	27
1989	Italy	Black olives	B	5
1991	Egypt	Uneviscerated salted fish (‘faseikh’)	E	91
1992	US—Alaska	Uneviscerated salted fish (‘moloha’)	E	8
1993	US—Georgia	Cheese sauce	A	8
1993	Italy	Roasted eggplant in oil	B	7
1996	Italy	Mascarpone cheese	A	8
1997	Germany	Hot-smoked vacuum packed fish	E	2
1998	Iran	Cheese in oil	A	27
2001	USA—Texas	Chili sauce	A	16
2006	USA—Georgia and Florida	Carrot juice	A	4
2007	USA—Texas and Indiana	Canned chili sauce	A	2

recognized; they were in Langeland Island (Denmark), California, Norway and Italy.

The first European Communicable Disease Epidemiological Report (European Centre for Disease prevention and Control, 2007), included data reported from 20 EU member States and Norway from 1995 to 2004. A total of 2388 human cases of botulism were included; Poland reported the highest number (850 cases), accounting for 35% of the total. In 2005, a total of 152 cases were reported by 22 EU countries, with an overall estimated incidence of 0.03 per 100 000.

In the UK, only 37 cases of foodborne botulism, confirmed in the laboratory, were reported to the Health Protection Agency Centre for Infections between 1980 and 2006. In France, a total of 56 incidents (96 patients) of botulism have been notified from 2003 to 2006; 50 of them, involving 64 patients, were laboratory confirmed. In Italy, a total of 283 cases (177 incidents) were confirmed between 1984 and 2007 by the National Reference Centre for Botulism, with an annual incidence of 0.02 per 100 000. The most frequent confirmed vehicle of intoxication (76.3% of confirmed) was home-preserved food, whereas commercially canned foods more rarely caused foodborne botulism. No restaurant-prepared foods were involved. Only two cases of BoNT/F were observed, and *C. butyricum* Type E was isolated from a patient who had consumed a noncanned homemade pasta. The republic of Georgia has the highest rate of foodborne botulism in the world, with 879 cases from 1980 to 2002 (80% attributed to BoNT/B).

In USA, 2757 cases of foodborne botulism were reported by Centers for Disease Control and Prevention (CDC) from 1899 to 2006. Until the 1950s, nearly all outbreaks of botulism were caused by BoNT/A or /B. From 1950 to 1996, 289 outbreaks (65.1%) have been traced to home-processed food and 31 (7%) to commercially processed foods, including food served in restaurants. Type E botulism associated with Alaskan native food has increased in recent decades because traditional practices have been altered in an unsafe manner. In Canada, about 90% of incidents are associated with marine products and due to BoNT/E. Native people are mostly involved, primarily Inuits for whom the risk of botulism is over 1000 greater than for other Canadians.

Argentina reported the highest number of cases in South America. From 1922 to 2006, 695 cases (114 deaths) of foodborne botulism were registered. Type A botulism occurred in 71.6%, while Type B in 9.0%, Type E in 3.0%, Type F in 1.5% and Type Af in 1.5%. In Brazil, 15 cases of confirmed foodborne botulism (BoNT/A identified in 10 cases) were reported in 1997–2007.

Since 1989, 2861 cases of botulism have been reported in China, while in Thailand, an isolated outbreak in 2006 caused 203 cases. From 1955 to 1998, 351 cases (68 fatal) were reported in Japan (mostly BoNT/E).

5.2 Infant Botulism

Several neurotoxigenic Clostridia can cause infant botulism: BoNT/A/B/E and /F can be involved. Most cases are due to BoNT/A or proteolytic BoNT/B produced by *C. botulinum.* A BoNT/F case, produced by *C. baratii,* was first reported in New Mexico in 1979, whereas the first two cases of Type E occurred in Italy in 1984.

Since its first recognition in 1976, infant botulism has become the most common form of human botulism diagnosed in the Western Countries. A total of more than 3100 cases of infant botulism were globally identified from 1976 to 2007 (**Table 2**): the highest incidence of cases is reported in the USA, followed by Argentina, Australia, Canada and Italy. In the USA, approximately 80–110 cases are annually recorded, mostly recognized in California. In Europe, a total of 67 cases were diagnosed in 14 countries from 1978 to 2007.

5.3 Adult Intestinal Colonization

Few cases have been reported worldwide: adult intestinal botulism was reported only in the USA (15 cases of BoNT/A or /F from 1981 to 2003), Italy (three cases of BoNT/E and /A from 1994 to 1997) and Japan. Cases have been related to *C. botulinum* Types A, B, Ab and F. *C. baratii* Type F and *C. butyricum* Type E have also been involved (Fenicia *et al.*, 1999; Gupta *et al.*, 2005).

5.4 Wound Botulism

First recognized in 1943, until 1985, 33 cases were reported in the USA. Among the 25 laboratory-confirmed cases, 17 were due to BoNT/A, seven to BoNT/B and one to BoNT/AB (CDC (Centers for Disease Control and Prevention), 1998). The most affected population is composed of young men, almost exclusively with traumatic or surgical wounds.

From 1979, only five cases of wound botulism were diagnosed in Italy. Four of these were laboratory-confirmed and BoNT/B or *C. botulinum* Type B was detected in serum or tissue samples. Two cases of BoNT/A were reported in 2001 in Ecuador.

Since 1982, there has been a change in the epidemiology of wound botulism: the number of cases has increased dramatically due to a growth in the number of users of injectable drugs, where wound botulism is associated with needle-puncture sites, and, less frequently, in chronic cocaine sniffing via nasal/sinus lesions. About 1000 cases have been reported worldwide so far.

Switzerland	1987	1	1	—	—	—	—
Finland	2002	1	—	1	—	—	—
Greece	2007	1	1	—	—	—	—

Seventy-eight cases were reported in drug users (mostly using injectable drugs) in the USA between 1986 and 1996, and 178 cases (mostly BoNT/A, two fatal) from 2001 to 2006 (Werner *et al*., 2000).

The first European case of wound botulism in illicit drugs users was reported in Norway in 1997, followed by at least three further cases. Subsequently, another nine cases have been identified in Switzerland and one in the Netherlands. From 2000 to 2007, a total of 136 wound botulism cases were reported in UK in those using injectable drugs. In 2007, the first wound case in a user of injectable drugs was reported in Sweden, and in 2008 an outbreak of six patients was reported in Ireland. Simultaneous wound botulism in two brothers addicted to cocaine was reported in Spain in 2007.

6 CLINICAL SYNDROME OF HUMAN BOTULISM AND PATHOPHYSIOLOGY OF THE DIFFERENT FORMS

Human botulism is a 'typical' toxicological syndrome characterized by neurological symptoms and signs resulting from a toxin-induced blockade of the voluntary motor and autonomic cholinergic junctions; it is quite similar for each type of BoNT and route of exposure (foodborne, wound, intestinal colonization—infant or adult, iatrogenic or other less frequent forms).

The route of exposure influences the delay from exposure to the appearance of the typical syndrome. Depending on the route of exposure, the causal 'agent' entering the body may be the *Clostridium* organism itself (e.g. intestinal, wound) or the preformed BoNT (foodborne), whilst in all cases the clinical syndrome of intoxication is due to the preformed neurotoxins or those produced *in situ.* Consequently, the specific treatment is aimed at preventing the binding between BoNTs and the neuromuscular junctions, although in some forms (wound and intestinal forms), additional treatment modalities can be added to prevent or limit the *in situ* production of toxins.

The rapidity of onset and the severity of botulism depend on the rate and amount of toxin absorbed. Generally, BoNT/A is more severe than the other BoNTs; however, patients with Type E botulism have the shortest incubation periods, while patients with Type B botulism show the longest incubation periods. Cases of Type A botulism will most likely require intubation (Woodruff *et al*., 1992).

The typical clinical syndrome of botulism described in medical literature refers to the foodborne form, which historically has been the commonest. This is characterized by an acute or subacute afebrile, symmetric descending flaccid paralysis that always begins in the bulbar musculature, which is the most densely innervated and well supplied with blood (IX, X, XI and XII cranial nerves). Related main symptoms are dysphagia, dysarthria and dysphonia, frequently associated with autonomic dysfunction (i.e. dry or sore mouth and throat) and preceded by gastrointestinal discomfort (such as diarrhoea followed by constipation) in patients with normal mental status, sensation and reflexes (Gomez, 2005; Goldfrank and Flomenbaum, 2006; Schwartz and Morgan, 2007). These complaints are often underestimated, while the first signs observed on clinical examination are those involving cranial abducens (VI) or oculomotor (III) nerves, with diplopia, blurred vision, mydriasis (often fixed), bilateral ptosis, lateral rectus palsy, external ophthalmoplegia. Pupillary reactions may remain abnormal for months after motor recovery (Friedman *et al*., 1990). Nystagmus is only occasionally noted. The clinical picture is completed by progressive respiratory weakness progressing to respiratory failure, as well as urinary retention (Simcock *et al*., 1994; Gomez, 2005).

A neurological syndrome due to cholinergic blockade may be present at first evaluation; visual disturbances, dysarthria, dysphagia and dry or sore mouth and throat are the four most specific neurological symptoms (Hughes *et al*., 1981; CDC (Centers for Disease Control and Prevention), 1998). If the disease is mild, no other symptoms develop and the initial picture will gradually resolve.

Early gastrointestinal signs and symptoms consist of nausea, vomiting, abdominal discomfort, pain and diarrhoea. The presence and ingestion of other bacteria or their toxins in improperly preserved food, or changes in bowel motility are linked to gastrointestinal symptoms, such as pain, nausea, vomiting and diarrhoea that often precede or accompany the typical neurological syndrome; constipation occurs in subsequent days in about 70% of patients (Schwartz and Morgan, 2007). Although gastrointestinal disturbances are common, about 30% of patients may not present any abdominal/gastrointestinal signs or symptoms (CDC (Centers for Disease Control and Prevention), 1998).

The clinical syndrome of botulism usually presents within 12 to 36–48 hours after ingestion of contaminated food (Hughes *et al*., 1981); in some cases, however, onset of initial symptoms can be delayed as long as 10–15 days after ingestion. Variability in the time of onset of symptoms depends on patient, type and quantity of toxin ingested, route of exposure and may make the diagnosis difficult. Generally, Type A botulism is significantly associated with neurological signs and symptoms while Type B seems to produce more autonomic dysfunctions and is characterized by a late and slow progression; Type E is related more to gastrointestinal symptoms than neurological signs (St Louis *et al*., 1988). In these last cases, the suspicion of botulism poisoning is more difficult. Nonspecific neurological symptoms such as malaise, weakness, headache, dizziness and paresthesias may be present, but rarely (CDC (Centers for Disease Control and Prevention), 1998).

In severe cases, the prolonged extensive flaccid paralysis causes life-threatening complications; respiratory dysfunction may result from either upper airway obstruction (the weakened glottis tending to close during attempted inspiration) or diaphragmatic weakness. The most common complication in the first period of botulism poisoning is aspiration pneumonia (Gomez, 2005).

The period requiring mechanical ventilatory support ranges from one to eight weeks, but patients can remain ventilator-dependent for seven to eight months; the mean period for ventilatory support is 58 days for toxin Type A and 26 days for Type B (Hughes *et al*., 1981). After this, most patients have residual symptoms, including easy fatigability and exertional dyspnoea at one year follow-up (Schmidt-Nowara *et al*., 1983), loss of responsiveness to postural change (orthostatic hypotension), hypothermia, alterations in the resting heart rate and urinary retention (Vita *et al*., 1987). Secondary medical complications from prolonged ventilator use, such as nosocomial infection can occur. Recovery results from new motor axon twigs that sprout and reinnervate paralysed muscle tissue in a process that may take months to complete (Duchen, 1972).

The case:fatality ratio was high (approximately 60%) in the fist half of the twentieth century, and has gradually decreased in the second half to 15.5%; at present the mortality rate of foodborne botulism is around 5–15 % of cases (Hughes, *et al*., 1981; Shapiro *et al*., 1998). Early death results from a failure to identify the severity of the disease, or from acute pulmonary or infectious complications. The decline in mortality rate (for all toxin types) is due primarily to improvement in supportive and respiratory intensive care and perhaps to prompt administration of antitoxin.

6.1 Wound Botulism

The clinical syndrome is similar to other forms of botulism, except for the lack of gastrointestinal symptoms and the possible presence of fever. The incubation period may be longer (from 7 to 14 days) than with foodborne botulism (Merson and Dowell, 1973). In nearly 30–50% of cases, toxins are not detected in sera and *Clostridium* sp. are not isolated from the wound.

6.2 Intestinal Toxaemia (Adult Intestinal Botulism and Infant Botulism)

6.2.1 Adult Intestinal Botulism

Rarely, cases of adult botulism have been reported with no known contaminated food, no wound present and no history of drug abuse, and, for these reasons, such cases were defined as 'hidden botulism'. Most of these patients represent adult variations of infant botulism and often have a history of abdominal surgery, gastrointestinal tract abnormalities following inflammatory intestinal disease, recent use of antibiotics that may have altered the natural gastrointestinal flora (which acts as barrier to intestinal colonization), and surgically or pharmacologically induced achlorhydria (Goldfrank and Flomenbaum, 2006; Fenicia *et al*., 2007a).

Cases due to colonization of *C. botulinum* producing toxin Type A and B, *C. baratii* producing toxin Type F and *C. butyricum* producing toxin Type E have been described (McCroskey *et al*., 1991; Fenicia *et al*., 1999). In some cases, a relationship with Meckel's diverticula and *C. butyricum* producing toxin Type E has been hypothesized (Fenicia *et al*., 1999). McCroskey and Hatheway (1988) documented the detection of the toxin in serum 47 days after ingestion of a suspected food, which was contaminated with organisms, but did not test positive for preformed toxin, suggesting continued production of toxin by organisms colonizing the gut. In other cases, organisms were cultured from the stool 119 days after the onset of illness. The production of endogenous antibody to botulinum toxin has been described in a single case report (Griffin *et al*., 1997). The finding of *C. botulinum* in faeces of adult patients is almost always associated with clinical botulism (Dowell *et al*., 1977). The clinical picture is similar to that of foodborne botulism, but the onset is generally gradual and less dramatic.

6.2.2 Infant Botulism

The onset of infant botulism can only be detected by careful observation; in mild cases or in the early stages of illness, the physical signs may be subtle and easily overlooked. On initial presentation, the typical patient has some or all of the following findings: lethargy, listlessness, ptosis, weak cry, diminished suck and gag, drooling and/or pooling of saliva, dysphagia, dilated and/or sluggishly reactive pupils, disconjugate gaze, blunted facial expression, poor head control, decreased anal sphincter tone, hypotonia and generalized weakness, and difficulty in breathing (Arnon *et al*., 2006). Infant botulism is also considered a possible occult cause of the sudden infant death syndrome (Bartram and Singer, 2004). However, in the absence of complications, patients recover completely from the disease.

Certain factors can predispose to infant botulism. Botulism spores are unable to germinate in the presence of high acidity, a mature gastrointestinal immune system or in the copresence of aerobic and anaerobic bacteria. The gastrointestinal tract of infants (up to four to six months) does meet these conditions; in fact the infantile gut is characterized by a more alkaline gastric environment, a paucity of normal flora and a lack of mature mucosal immunological defences including lysozyme, complement and secretory IgA (Arnon, 2004; Istre *et al*., 1986). The difference in pH of faeces may play a role in multiplication of *C. botulinum* and in the production of toxins (Brook, 2007).

Honey (Fenicia *et al*., 1993; Aureli *et al*., 2002), household dust (Nevas *et al*., 2005) and chamomile (Bianco *et al*., 2008) may be considered as known sources of neurotoxigenic *Clostridia* spores, but in about 85% of patients the source remains unknown (Brook, 2007). Another predisposing factor for infant botulism seems to be concomitant enteroviral infection, which may facilitate the colonization with *C. botulinum* (Fenicia *et al*., 2004).

7 DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnosis of botulism is essentially clinical in the first stage: the role of the laboratory is mandatory to confirm the clinical diagnosis, to identify the different BoNTs involved and the source of poisoning.

Foodborne botulism poisoning is often underdiagnosed or misdiagnosed because physicians rarely encounter this disease; the initial symptoms can be confused with more common clinical conditions, such as stroke or the autoimmune acute demyelinating polyneuropathy known as Guillain–Barré syndrome (Miller–Fisher variant) (Shapiro *et al*., 1998). Some cases are undoubtedly entirely unrecognized (CDC (Centers for Disease Control and Prevention), 1998). When the gastrointestinal syndrome is prevalent, such as with BoNT/E-related poisoning, the suspicion of botulism is more difficult. The diagnosis can be easy when the index of suspicion is high, as in the setting of a large outbreak, but often cases occur singly and in most of them patients are referred first to an oculist, otolaryngologist or neurologist and only subsequently to an emergency department because of worsening of clinical features. Indeed, the results from many outbreaks have suggested that early cases are commonly misdiagnosed; in other situations an outbreak was recognized only after a second cluster of cases was associated with the same food vehicle (St Louis *et al*., 1988). In some cases the diagnosis has been made retrospectively (after death),

Table 3 Key signs and symptoms for the diagnosis of foodborne botulism

Recent medical history	Negative for infectious diseases
First evaluation	Dry mouth/sore throat and/or dysphagia
	Anxiety
	Normal mental status
	Afebrile
	Absence of cardiac dysfunction (rarely bradycardia)
	Gastrointestinal discomfort
	Weak
Physical examination	Symmetric oculobulbar symptoms
	Symmetric descending neurological abnormalities

when a cluster of cases finally alerted the public-health authorities to an outbreak of botulism. Therefore, correct diagnosis of the first case of poisoning is very important to ensure the planning of appropriate clinical management of subsequent cases and particularly to avoid serious delay.

Various constellations of features have been suggested to consider diagnosis of botulism early in its presentation (**Table 3**) (CDC (Centers for Disease Control and Prevention), 1998). Botulism must be suspected whenever a patient presents with any kind of weakness: generalized, ocular or oropharyngeal, sometimes associated with a history of acute onset of gastrointestinal dysfunction (Schwartz and Morgan, 2007). Bilateral cranial nerve abnormalities and progression of descending paralyses should raise the suspicion of botulism. Epidemiological criteria may be useful in formulating a correct diagnosis in some cases.

The differential diagnosis of human botulism includes myasthenia gravis, stroke, Guillain–Barré syndrome, bacterial and chemical food poisoning, paralysic tick diseases, chemical intoxication (e.g. methyl alcohol, atropine, magnesium), adverse drug reactions, poliomyelitis, diphtheria and psychiatric illness. About 10.5% of patients with suspected botulism reported to the CDC are finally diagnosed as having Guillain–Barré syndrome, and 3.4, 3.2 and 3% as having carbon monoxide poisoning, food poisoning of unknown aetiology and staphylococcal food poisoning, respectively (CDC (Centers for Disease Control and Prevention), 1998).

Routine laboratory tests are not useful in confirming the clinical suspicion of botulism because they will all be normal, if secondary complications are absent. Some laboratory studies are helpful to differentiate botulism from other diseases; thus, normal cerebrospinal fluid (CSF) may discriminate botulism from Guillain–Barré syndrome, although a slightly elevated CSF protein level is occasionally observed with botulism, and the protein level may be initially normal in Guillain–Barré syndrome (Hughes *et al*., 1981). A negative tensilon test helps to differentiate botulism from myasthenia gravis; also neuroradiological studies may be useful to rule out stroke (St Louis *et al*., 1988).

7.1 Diagnosis and Differential Diagnosis of Infant Botulism

The diagnosis of infant botulism should be based on clinical symptoms; assays for toxin in the serum rarely yield positive results, and a definitive diagnosis may be confirmed by isolation of toxin or organism from the stool (CDC (Centers for Disease Control and Prevention), 1998). Because of constipation, an enema with sterile, nonbacteriostatic water (not saline) commonly is needed to obtain a faecal specimen for diagnostic examination. Electromyography (EMG) may play an important role in instrumental confirmation of the diagnosis, even if normal findings do not rule out the disease. The differential diagnosis of infant botulism includes: sepsis, myopathies, Guillain–Barré syndrome, familial infantile myasthenia gravis, spinal muscular atrophy and poliomyelitis. Approximately the 5% of the 681 patients who were treated (antidote or placebo) in a randomized, controlled clinical trial were not affected by infant botulism; in most of these cases an alternative diagnosis was established as spinal muscular atrophy Type I, metabolic disorders, infectious diseases, miscellaneous and probable infant botulism (Francisco and Arnon, 2007).

7.1.1 Electrophysiological Studies

In all forms of botulism, the EMG pattern is characterized by low amplitude, short-duration and abundant motor-unit action potentials (BSAPs) (Engel, 1975). The most consistent electrophysiological abnormality is a small evoked muscle action potential (MAP) in response to a single supramaximal nerve stimulus in a clinically affected muscle (Cherington, 1998). The EMG findings alone should never be used to differentiate other diseases from botulism. In fact, as many as 15% of patient with botulism may have normal findings on EMG, improvement with edrophonium may be noted in 25% of patients with proven cases of botulism and low-frequency findings supporting myasthenia gravis may be observed in 20% of patients who suffer from botulism (St Louis *et al*., 1988). Anticholinesterase drugs, such as edrophonium, have no effects on the mechanism of action of the botulism toxin; in rare cases, in the first stage of the disease, limited improvement in strength can occur, but is not comparable with the rapid response in patients with myasthenia gravis (Pickett, 1988).

7.1.2 Laboratory Methods to Detect Clostridium Botulinum and Botulinum Toxins

The laboratory diagnosis of botulism is based on the detection of BoNTs in clinical or food samples and the isolation of BoNT-producing Clostridia from stools (CDC (Centers for Disease Control and Prevention), 1997). The most direct way to confirm the diagnosis is to demonstrate the BoNTs in the patient's serum or stools by injecting serum or stools into mice and looking for signs of botulism. The bacteria can also be isolated from the stools of subjects with foodborne and infant botulism. Since other Clostridia can produce human cases of botulism, the presence of other BoNT-producing Clostridia, such as *C. butyricum* and *C. baratii,* will have to be included in the criteria for laboratory diagnosis (Fenicia *et al*., 2007a).

7.1.2.1 Laboratory Safety

The United States Centers for Disease Control and Prevention include BoNTs in the Category A infectious agents. Botulinum toxins may be present in food, serum, gastric contents, faeces and environmental samples. Absorption is possible by accidental ingestion and through damaged skin and mucous membranes, including the respiratory tract. Appropriate Biosafety Level 2 containment facilities, including gloves and a face shield, and trained personnel are therefore the minimum required. A Biosafety Level 3 is required when manipulations producing aerosols or droplet formation from toxic materials are expected. Sentinel Laboratories (Level A) should collect appropriate specimens and, after consultation, ship the specimens to a Reference Laboratory. Restricted entry to the laboratory dealing with the manipulation of presumptive BoNT-contaminated materials has to be secured.

7.1.2.2 Detection and Typing of BoNTs: Mouse Lethality Bioassay

The mouse bioassay (intraperitoneal injections of white mice unprotected and protected with polyvalent botulinum antitoxin) is currently the only accepted method to confirm the presence of BoNTs. Mouse type-specific botulinum antitoxin is used to define the type (typing) of the toxins produced from different strains. Typical botulism symptoms in mice sequentially consist of ruffled fur, 'wasp-like' aspect, hind-limb paralysis, laboured breathing and, finally, death due to respiratory failure.

Mouse bioassay is the only standard validated method for the detection of BoNT in food: the method shows a high degree of repeatability and reproducibility (Kautter and Solomon, 1977), with one intraperitoneal mouse LD_{50} dose corresponding to 5–10 pg and the detection limit being 0.01 ng ml^{-1} of sample. False positive results due to *in vivo* toxin formation from a high number of *C. botulinum* spores, endotoxins from Gram-negative bacteria and tetanus toxins have been reported.

7.1.2.3 Detection and Typing of Neurotoxigenic Clostridia

7.1.2.3.1 Culture Methods

Six phenotypically distinct groups of Clostridia are known to be capable of producing BoNTs. Conventional detection and isolation of *C. botulinum* are based on culturing in liquid medium and subsequent detection of BoNTs in the culture supernatant by the mouse bioassay. Positive samples are streaked on solid media, and the toxin formation by colonies is traditionally further confirmed by the mouse test. Clinical samples, such as serum and faeces, can be cultivated directly or pretreated with ethanol to eliminate vegetative bacteria while recovering bacterial spores. Alternatively, heating may be used to eliminate non-spore-formers, but care should be taken in selecting the temperature; 80 °C for 10 minutes for Group I spores and at 60 °C for 10–20 minutes for Group II spores has been recommended. An enrichment step in a non-selective medium trypticase peptone glucose yeast extract (TPGY) broth followed to isolation in egg yolk agar is used for detecting the suspected BoNT-producing strains of Clostridia. In the isolation step of the neurotoxigenic strains on egg yolk gar, lipase-negative colonies (*C. butyricum* and *C. baratii*), as well as lipase-positive colonies have to be examined (Fenicia *et al*., 2007a). Mouse bioassay is used to confirm BoNT production in subcultured colonies.

7.1.2.3.2 Molecular Method

Nucleic-acid techniques, especially the polymerase chain reaction (PCR), have emerged rapidly as method of choice allowing rapid, specific and sensitive detection of pathogen in clinical, food and environmental samples. In the case of *C. botulinum,* as well as for other toxigenic bacteria, PCR-based methods detect merely the presence of botulinum DNA, but they do not detect the activity of the different DNA genes, nor the presence of the toxins. PCR is a suitable tool for confirming the presence of BoNT-producing Clostridia in enrichment broth and in isolated strains, or for typing isolated strains. A different conventional (gel-based electrophoresis) PCR method has been proposed, based on single PCR reactions for specific detection of the different toxin genes. The use of a general primer pair able to amplify the four toxin genes, while specific internal probes are then used to identify the toxin types of strains is also suggested. An improvement has been the development of a multiplex PCR assay that enables the detection of BoNT/A, BoNT/B, BoNT/E and BoNT/F genes simultaneously (Lindstrom *et al*., 2001).

More recently, realtime PCR has been used to detect pathogenic micro-organisms in food, environmental and clinical samples. Several fluorescent-probe-based real-time PCR studies have been carried out to detect BoNTs using TaqMan probes (Akbulut *et al*., 2004; Yoon *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat151
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2005) and the simple and less expensive double-stranded DNA-binding dye SYBR green (Fenicia *et al*., 2007b). While the majority of the PCR methods are based on the specific detection of BoNT genes, the use of the NTNH gene as a target for PCR has been successfully proposed as a single target to identify human and animal BoNT-producing Clostridia (Raphael and Andreadis, 2007). The use of PCR could reduce dramatically the use of animals in laboratories dealing with surveillance and research into botulism (De Medici *et al*., 2006).

7.1.3 Role of the Laboratory Tests in the Diagnosis and Management of Poisoned Patients

BoNTs and/or *Clostridium* sp. toxigenic strains may be detected in patients' specimens (serum, gastric contents, stool and wound) and in suspected foods. Early sample collection (stools and/or gastric content) before antitoxin administration may increase the likelihood of obtaining positive results. In the cases of foodborne botulism reported in the USA from 1975 to 1988, the toxin was present in 37% of sera (126/240 cases), 23% of stools (65/288) and 5% of gastric aspirate (3/63) (Woodruff *et al*., 1992). Tests in sera were positive in more than 60% of specimens, if collected within two days, in 44% of specimens collected within three days after toxin ingestion and in only 23% of that obtained by day 4 or later. The positivity of toxin assays of sera was much higher for BoNT/A compared to Types B and E. Stools were positive in 50% of specimens collected within one day following the ingestion, in 39% collected within three days and 20% of specimens obtained at day 5 or later. Cultures of stools and gastric aspirates for *Clostridium* sp. from cases of foodborne botulism showed the presence of toxins in 45% of gastric aspirate and 80% of stools at day 2 after ingestion, 40% of specimens remaining positive seven to nine days after ingestion. However, laboratory confirmation of botulism poisoning by either toxin assay or culture could not be obtained in 32% of cases, primarily due to reduced sensitivity of diagnostic testing if undertaken more than three days after toxin ingestion. False-negative results are common when sample collection is made late in the course of the poisoning. Post-mortem diagnosis may be made by identification of toxins or organisms in autopsy specimens of the small or large intestines, the or liver (Dodds, 1994). Laboratory confirmation of botulism may require days before results are available. Since antidotal treatment with botulinum antitoxin is thought to be more effective when given early after poisoning, usually the treatment is applied before the analytical confirmation. BoNTs detection and *Clostridium* sp. isolation from the sera and wounds confirmed most cases of wound botulism (Werner *et al*., 2000).

In cases of botulism due to inhalation of the toxin, the identification of the toxin in typical human specimens, such as serum, stools and gastric contents, may be difficult (Franz *et al*., 1997; Arnon *et al*., 2001). Toxin may be detectable in the nares for up to 24 hours after the contact and a nasal mucosal swab may be useful to help the diagnosis, using an enzyme-linked immunosorbent assay or PCR techniques that are in the course of validation (Chao *et al*., 2004; Akbulut *et al*., 2005; Dembek *et al*., 2007).

8 TREATMENT

The treatment of botulism includes procedures for decontamination, administration of antidotes and, when required, support of respiratory function; only few differences are related to the route of exposure.

8.1 Foodborne Botulism

8.1.1 Gastrointestinal Decontamination

All cases of foodborne botulism, if no contraindications are present, should be evaluated for gastrointestinal decontamination, with the aim of removing the spores and toxin from the gut. Gastric lavage or induced emesis is indicated only in asymptomatic patients that have very recently ingested a possible contaminated food.

Most of the patients present symptoms some days after ingestion; in these cases gastrointestinal decontamination must be applied because of the permanence of contaminated food (and spores and toxins) in the gastrointestinal tract due to the anticholinergic effects. Then, upper and lower decontamination with an orogastric tube and cathartics, or whole-bowel irrigation could be performed, even if the efficacy in suspected and confirmed cases of botulism poisoning are not assessed. Sorbitol is better than magnesium salts to obtain cathartic effects because the latter may exacerbate neuromuscular blockade. Effective whole-bowel irrigation may be difficult in the presence of drug- or toxin-induced ileus; in some cases neostigmine, which inhibits the enzymatic degradation of acetylcholine, appears to be useful in reversing ileus (Isbister *et al*., 2001). Activated charcoal administration must be considered in poisoned patients because it absorbs BoNT/A *in vitro* (Gomez *et al*., 1995).

8.1.2 Antidotes

The aim of the antidotal treatment consists in neutralizing the circulating toxin molecules still unbound to the nerve endings. This mechanism of action was shown to be effective many years ago in experimental studies (Oberst *et al*., 1968). But the specific treatment with

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat151
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

antitoxin limits the involvement of new nerve endings, but cannot reverse the paralysis nor neutralize the toxins already bound to the nerve receptors. Symptoms often progress for up to 12 hours after antitoxin administration before an effect is observed (Dembek *et al*., 2007). The type-specific antitoxins are ineffective against any other antigen. Botulism antitoxin should be administered as soon as botulism poisoning is suspected. The antitoxin is most often used for foodborne botulism, although it would also be an effective antidote in the inhalation form. Animal studies showed that early administration, after an aerosolized release of lethal concentration of botulinum toxin, may be effective (Arnon *et al*., 2001).

Equine-derived antitoxin, available since 1970, is the unique and specific antidotal treatment available for botulism poisoning. Before 1950, the mortality rate for botulism was approximately 60%, even when equine antitoxin was administered in heroic doses (Shapiro *et al*., 1998). During the late 1950s the fatality rate decreased precipitously until it reached the current rate of 3–5%, due, mainly, to the improvement of intensive-care support, quality of respiratory assistance (including the application of tracheotomy) and the introduction of procedures for the prevention of secondary infection (Sobel, 2005).

Although there is evidence of efficacy in experimental studies in animals, no controlled studies have been done in humans to evaluate the usefulness of antitoxin therapy: the clinical evidence for the efficacy of antitoxin use in humans is today supported only by case reports and retrospective analyses of small numbers of patients. Morbidity and mortality studies are difficult to perform because of the rarity of the poisoning and the usual delay in diagnosis, which means that the toxin is already permanently fixed to the neuromuscular junction.

Tacket *et al*. (1984) analysed 132 cases of BoNT/A foodborne botulism reported to the CDC from 1973 to 1980, to evaluate primarily the effect of the trivalent equine antitoxin therapy on the outcome of patients. Patients who had received antitoxin within 24 hours after the onset of symptoms had a lower fatality rate (10%) than those who had received antitoxin after more than 24 hours (15%) and than those who did not receive antitoxin (46%). In addition, survivors that received the antitoxin early had a median hospital stay of only 10 days, compared with 41 days for those who received antitoxin late and 56 days for those who did not receive antitoxin.

In the USA more than 80% of patients with botulism poisoning are treated with antitoxin. In the remaining cases, the diagnosis was delayed, the treatment was considered to be of no benefit and, therefore, antitoxin was not administered (Shapiro *et al*., 1998).

Some evidence shows that the early administration of antitoxin, especially within 24 hours, is more effective in preventing the progression of paralysis and in shortening the duration of mechanical ventilation and intensive-care stay (Tacket *et al*., 1984; Chang and Ganguly, 2003). Nonetheless, respiratory support may be necessary for long time, usually two to six weeks and in some cases may be longer: 58 days for botulism due to BoNT/A and 26 days for BoNT/ B (Hughes *et al*., 1981).

At the present time, only limited data are available on the relationship between dose (intravenous/intramuscular administration) and the amount of circulating antitoxin found in treated patients, their half-life and the toxin-neutralizing capacity. The half-life of circulating antitoxin was evaluated at 6.5, 7.6 and 5.3 days for antitoxin Types A, B and E, respectively. Peak serum concentrations of antitoxin are 10–1000 times higher than the concentrations estimated to be necessary to achieve toxin neutralization (Hatheway *et al*., 1984). Furthermore, 90% of the activity of the antitoxin administered was detected when all the circulating toxin was neutralized (Metzger and Lewis, 1979). The half-life of five to eight days and the exceedingly small quantities of toxin measured explain the limited decrease in antitoxin titres following toxin–antitoxin binding (Goldfrank and Flomenbaum, 2006). Published and unpublished clinical data support, as a correct approach in the USA, the administration of one vial of botulism antitoxin, which produces a high level of toxin type-specific antibodies (100-fold greater than that needed to neutralize the largest amount of circulating toxin ever measured at the CDC) (Hatheway *et al*., 1984).

As with other heterologous proteins, administration of horse-serum-derived preparations can result in adverse effects. During 1967–1977, the overall rate of adverse effects (including hypersensitivity and serum sickness) was 9–17% with an incidence of anaphylaxis of 1.9% (Black and Gunn, 1980). However, in previous decades, the recommended dose was two- to fourfold higher than those currently used in the USA. After changing to single-vial dosing, the incidence of hypersensitivity may be smaller than previously reported; at present, the risk of serum sickness may be approximately 1–4% (Sobel, 2005).

Throughout the world different formulations containing different quantities and combinations of specific types of antitoxins are available.

Currently there is only one product available in the USA, obtainable through the CDC, licensed and FDA-approved for adults (Type-AB-bivalent antitoxin), and containing in each 10 ml vial, 7500 and 5500 IU of Type A and B antitoxins, respectively. The recommended dose is one vial intravenously. Also, a monovalent antitoxin Type E (containing 5000 IU) is available in USA through an investigational new drug (IND) protocol: one vial of antitoxin Type E should be administered consecutively with bivalent (Types A and B) antitoxin if the type of botulism is not known or suspected to be E. Trivalent equine antitoxin (containing in each vial 7500 IU Type A, 5500 IU Type B, 8500 IU Type E of antitoxin), is no

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

longer available from the CDC because of its declining antitoxin titres to antitoxin Type E (Dembek *et al*., 2007).

In addition, two other equine antitoxin preparations (investigational use) against all the seven toxins serotypes have been developed by the US Army Medical Research Institute of Infectious Diseases (USAMRIID) for treating botulism: botulism antitoxin, heptavalent, equine types A, B, C, D, E, F, G, named HE-BAT and botulism antitoxin $F(ab')_2$ heptavalent, equine toxin-neutralizating activity types A, B, C, D, E, F, G, named Hfab-BAT. The purification of the product resulting in Fab fragments potentially reduces the risk for serum sickness and hypersensitivity reactions. Both investigational products are available for botulism due to terrorism events, which may involve the use of any of the seven toxin serotypes (Dembek *et al*., 2007).

In Europe, the formulations currently available are trivalent and contain a different amount of total antitoxin (**Table 4**). The quantity of antitoxin per ml of antidote is quite similar in all the EU and USA formulations, while an important difference is related to the total amount of antitoxin that must be administered following the registered indications. The EU product marketed in Western Europe is recommended by the producer at a dose approximately 50-fold greater than the US formulation. Considering that acute or delayed hypersensitivity reactions have been reported significantly more frequently in patients treated with more than four USA vials of antitoxin, suggesting a dose-related phenomenon (Black and Gunn, 1980), a critical analysis of the minimal optimal dose to administer is needed. It must be considered that, generally, products derived from horse globulin may contain an extra amount of 10–20% of bulk antitoxin.

8.1.3 Supportive Airway Treatment

The mainstay of treatment for severe cases of botulism poisonings is early and advanced medical and nursing supportive care, with particular attention to respiratory status. Because of the high risk of rapid respiratory failure and because respiratory compromise is the usual cause of early death from botulism, close monitoring of respiration is needed throughout the disease.

The patient with suspected botulism poisoning not yet ventilated should be put in the reverse Trendelenburg position at 20–25° with cervical support; this seems to be useful to enhance diaphragmatic function, decreasing the pressure of abdominal viscera and to reduce the risk of aspiration, but the application in moderate to severe cases has not been validated (Arnon *et al*., 2001).

8.1.4 Antibiotic Therapy

Antibiotic therapy is ineffective on the toxin mechanism of action, even if it can be useful when secondary infections are present. Also, in wound botulism, the antibiotic therapy alone is inadequate. In any case, aminoglycoside antibiotics and clyndamicin should not be used because they may exacerbate the neuromuscular blockade (Santos *et al*., 1981).

8.1.5 Experimental Treatments

Guanidine has been used in the past to promote acetylcholine release, but its use, also evaluated in placebo-controlled studies, failed to ameliorate the clinical course of the disease (Roblot *et al*., 1994). Other studies including 4-aminopyridine, a potassium channel-blocking agent, which increases the release

Table 4 Comparison among principal marketed botulinum antitoxin products

Antitoxin product	Available from	Formulation	Total amount of antitoxin (IU)		Antitoxin per ml (IU)	Recommended dosage
Bivalent (A/B) equine	Aventis Pasteur CDC	Vial 10 ml	Type-A	7500	750	1 vial
			Type-B	5500	550	
Monovalent (E) equine	Aventis Pasteur CDC	Vial 10 ml	Type-E	5000	500	1 vial
Trivalent (A/B/E) equine	Biomed (Poland)	Vial 10 ml	Type-A	5000	500	1–5 vials
			Type-B	5000	500	
			Type-E	1000	100

of acetylcholine in the nerve terminations have been proposed (Qiao *et al*., 1997). 3,4-Diaminopyridine does not cross the blood–brian barrier to a substantial extent, and this limits central nervous system adverse reactions, such as seizures, potentially induced by 4-aminopyridine (Goldfrank and Flomenbaum, 2006). However, although some improvement has been reported in moderate cases, its efficacy has not been established (Dock *et al*., 2002). The only benefit observed regards an improvement in ocular and limb muscle strength in some patients, but there has been no benefit on respiratory paralysis (Neal and Dunbar, 1990). Steroids, immunoglobulins, chloroquine and plasmapheresis, have been tried in a few patients, with dubious benefits.

8.2 Wound Botulism

Treatment of wound botulism requires surgical debridement with extensive wound irrigation, preferably, if possible, after administration of the antitoxin and antibiotic therapy. Aerobic and anaerobic cultures of the wound should be performed. In some cases, aggressive surgical wound debridement is needed to remove the source of the toxin (Werner *et al*., 2000). The use of antibiotics is controversial, most likely because of the minimal delivery of drug that reaches the hypoperfused anaerobic wound site where *Clostridium* sp. proliferates. Penicillin G seems to be the first-line antibiotic, even if its clinical efficacy has not been firmly established; high-dose penicillin with other broad-spectrum antibiotics is appropriate, however, until a definitive diagnosis can be made (Mechem and Walter, 1994).

8.3 Intestinal Toxaemia: Infant Botulism

No specific indications are available regarding the treatment of adult intestinal botulism. Conversely, several studies support some different approaches to infant botulism. Supportive care, including respiratory assistance and nutritional support through parenteral feeding, is the mainstay of therapy for infant botulism.

Clostridiocidal antibiotics, such as penicillin, have not been demonstrated to be useful and should be administered with care, according with the clinical conditions, because of the possibility of rupture of the cells of the botulinal agent, causing additional toxin to be released; the use of nalidixic acid or trimethoprim-sulfamethoxazole antibiotics, to which *C. botulinum* is resistant, should be avoided (Swenson *et al*., 1980).

In infant botulism, circulating toxins are believed to be present at very low concentrations, and antitoxin has no effect on toxin-producing organisms in the gut. Therefore, antitoxin is not expected to halt syndrome progression (Goldfrank and Flomenbaum, 2006).

Equine antitoxin used for adult patients, theoretically has a limited role, mainly because of the short half-life (five to seven days) and the known side effects.

The Infant Botulism Treatment and Prevention Program in California, in collaboration with the US Food and Drug Administration and the CDC, produces and distributes the orphan drug botulism immune globulin intravenous (Human) (BIG-IV), a human-derived botulism antitoxin that neutralizes botulinum toxin (Arnon *et al*., 2006). The purified immunoglobulin is derived from pooled adult plasma from persons immunized with pentavalent botulinum toxoid, who were selected for their high titers of neutralizing antibody against BoNT/A and /B.

The treatment of patients with infant botulism Type A or Type B with BIG-IV reduced the mean length of the hospital stay for all patients to 3.1 weeks, and the mean length of stay in the intensive-care unit, the mean duration of mechanical ventilation, the mean duration of tube or intravenous feeding, and the mean hospital charges per patient were also significantly reduced. The only adverse effect perhaps related to treatment with BIG-IV was a transient, blush-like erythematous rash (Arnon *et al*., 2006).

9 INHALATION BOTULISM

Primate experiments designed to study treatment for inhaled botulism toxin showed that doses of 5–10 LD_{50} cause death in 24–96 hours in animals neither immunized nor treated with antitoxin (Franz *et al*., 1993). The syndrome in humans was first described in three German veterinary workers after conducting post-mortem examinations on laboratory animals. With a delay of three to four days, the patients presented with sore throat, dysphagia, mydriasis, mental numbness and extreme weakness; they were treated with antitoxin on the fourth to fifth day after the incident and fully recovered in two weeks. BoNT/A was detected in a serum sample from all three affected patients (Holzer, 1962). Monkeys showed signs of botulism 12–80 hours after aerosol exposure to four to seven multiples of the monkey median lethal dose. The time to onset of inhalational botulism cannot be stated with certainty because so few cases are known. Any outbreak of a large number of simultaneous cases with a common geographic factor, but without a common dietary exposure and, possibly, with an unusual botulinum toxin type (e.g. Types C, D, F, G) may suggest a deliberate release of botulinum toxin as an aerosol attack (Arnon *et al*., 2001). Botulism is at least 5000 times more lethal than sarin and 1800 times more lethal than VX nerve agent.

Botulinum toxin was developed as a biological weapon at least 60 years ago, especially during World War II, by state-sponsored programmes in the USA, Soviet Union, Japan, Germany and Iraq. Although the 1972 Biological and Toxin Weapons Convention prohibited offensive research and production of biological weapons, some signatories, such as Iraq and Soviet Union, continued to produce botulinum toxin to use as a weapon. During the last decade, countries suspected to sponsor terrorism are believed to be still developing botulinum toxin as a weapon. Botulinum toxin has already been used as a biological weapon: aerosols were used in at least three occasions between 1990 and 1995 in Japan by the Japanese Cult Aum Shinrikyo, but these attacks failed.

A deliberate release of botulism either by aerosol or contaminated food would be able to cause a large number of casualties in a civilian population. Predicting the consequences of environmental dissemination is difficult and problematic, since data about the stability of the toxin in water or sunlight are lacking; it has been estimated that an aerosol release of toxin could intoxicate 10% of people within 500 m. The decay rate of the toxin in air is estimated at 1–4% per minute and models of aerosol exposure show that inactivation may take up to two days, and would be accelerated in extreme conditions of temperature and humidity (Arnon *et al*., 2001).

A mass casualty attack with botulinum toxin could likely overwhelm the healthcare system and drastically involve the medical service and response to victims; the medical support required for poisoned patients includes mechanical ventilation as well as urgent attendant medical care, together with the activation of hospital emergency plans, including actions for additional respiratory and intensive-care unit support for mass poisoning. Furthermore, when an outbreak happens, involving a large number of patients, there may be a problem to have an adequate quantity of antitoxin to administer. A recent experience of a massive outbreak of botulism in northern Thailand tested the international capacity to respond to a public-health emergency. An outbreak due to contaminated home-canned bamboo shoots has caused illness in 209 patients, of whom 134 were hospitalized and 42 required mechanical ventilation (Ungchusak *et al*., 2007). A global search for antitoxin has been applied, involving international agencies, embassies, national laboratories, airlines and commercial organizations in seven countries. Sufficient antitoxin was obtained from four sources for treatment of 90 patients, but with delays in treatment of five to nine days from time of exposure. This suggests that a stronger commitment through formal international agreements is urgently needed, including creation of global and regional stockpiles of critical medicines and supplies. Modelling for bioterrorism incidents have been used and analysed in order to plan all the action to counteract the phenomenon.

10 IATROGENIC BOTULISM

The most recent form of botulism described is iatrogenic botulism, which can result mostly from erroneous injection of botulinum toxin (toxin Types A and B) for cosmetic or therapeutic purposes. A distant effect from the site of injection of toxin is also hypothesized: experimentally, the catalytically active BoNT/A is transported in a retrograde manner along microtubules, transcytosed and taken up by afferent terminals (Antonucci *et al*., 2008).

The dose usually administered to obtain local muscle paralysis is not, theoretically, able to cause severe systemic effects. A typical clinical application varies from 4 to 20 units for cosmetic purposes up to 300 units for therapeutic use (Chertow *et al*., 2006). The human lethal dose of crystalline BoNT/A is unknown: data on primates suggests an approximate intravenous or intramuscular human lethal dose of 40 U kg^{-1} (Scott and Suzuki, 1988), each unit being the estimated LD_{50} for mice (CDC (Centers for Disease Control and Prevention), 1998). When used in therapeutic doses, BoNT/A is considered to be safe and effective, and only systemic minor adverse effects are described, such as flu-like symptoms, transient fatigue, nausea, ptosis and generalized weakness. Subclinical effects of the toxin on neuromuscular transmission distant from the site of injection have also been reported, even for doses of 23 U kg^{-1} of BoNT/A (Olney *et al*., 1988; Goldstein, 2006). The analysis of all adverse events suggests that patients receiving more than 1000 U of BoNT/A were more likely to have adverse effects (Crowner *et al*., 2007).

Nonetheless, the reports of adverse effects or electrophysiological abnormalities following therapeutic and erroneous cosmetic use of toxin Type A have increased in recent years.

The first laboratory-confirmed cases of iatrogenic botulism were a cluster of four adult patients who may have each been injected with a highly concentrated (2857 times the estimated human lethal dose by injection), unlicensed preparation of botulinum toxin Type A, for cosmetic treatment (Chertow *et al*., 2006). The serum toxin levels (collected before antitoxin treatment) were equivalent to 21–43 times the estimated human lethal dose. The typical syndrome of botulism poisoning (extreme weakness, vertigo and initial cranial neuropathies) presented two to three days after injection; subsequently the patients presented with dry mouth, diplopia, blurred vision, ptosis, mydriasis, dysphagia, dysarthria, dyspnoea, tachypnoea and respiratory failure. All patients received bivalent anti-AB equine antitoxin; three patients received antidote on day 4 and one patient on day 10. After prolonged mechanical ventilation (from 36 to 171 days), physical rehabilitation and hospital stay, all patients were discharged from the hospital.

The EU has posted a series of warnings concerning botulinum toxin on its web site, the latest in March

2007, alerting physicians in its 27 member states to the need to monitor for signs of botulinum toxin adverse events (European Medicines Agency (EMEA), 2007). Contemporarily, the Danish Medicines Agency published an analysis of adverse reactions from the four products marketed in the EU. The results showed that, since the entry of the product on the market, more than 600 reports of adverse events related to botulinum toxin have been registered, and approximately half of all serious adverse reactions were caused by spread of toxin. These adverse events are substantially under-reported and connected with cosmetic, as well as therapeutic, uses (The Danish Medicines Agency, 2007). Recently, serious adverse effects arising from approved medications (botulinum toxin Types A and B) have been reported by US nonprofit public organizations and also by the FDA, and warnings have been diffused (Med Watch, 2008).

11 NOTIFICATION OF THE DISEASE

As foodborne botulism results from ingestion of preformed BoNTs in foods that still may be available to cause illness in others, a single case of foodborne botulism represents a public-health emergency that might herald a larger outbreak (Shapiro *et al*., 1998). Prompt diagnosis and epidemiological investigation for rapid indentification of the food vehicle is essential, especially for commercial foods. For this purpose, the prompt activation of the Rapid Alert System for Food and Feed, and the withdrawal of goods from the commercial network, could prevent the onset of international outbreaks.

Botulism is a statutory disease and it is mandatory to notify the State Health Department/Officers of cases of suspected poisoning. Serum and stool samples should be obtained (if possible, always before antitoxin administration), and a call to a Poison Control Centre or a National/Regional Reference Centre may be helpful for appropriate clinical management and possible laboratory support.

12 BOTULISM AND PREGNANCY

Clinical experience and experimental data confirm that the large molecular weight of the toxin (150 kDa) blocks passive diffusion through the placenta (Polo *et al*., 1996; Magri *et al*. 2006); no cases of clinical or serum evidence of botulism in infants born from mothers poisoned were observed. Adequate care and preparation for maternal complications of delivery seems to offer the best potential outcome for a normal infant. The use of botulinum toxin Type A in pregnant women appears to be relatively safe for both the expectant mother and the foetus (de Oliveira Monteiro, 2006; Morgan *et al*., 2006). Pregnancy is not considered a contraindication to antitoxin administration, which has been used successfully (Robin *et al*., 1996).

ACKNOWLEDGEMENTS

The authors wishes to thank: Dario De Medici PhD and Fabrizio Anniballi PhD for support in laboratory methods analysis, and Valeria Petrolini, MD, Andrea Giampreti, MD, Stefania Bigi, MD and Sarah Vecchio, MD, who significantly participated in the realization of this manuscript.

Ricin: Chemistry, Sources, Exposures, Toxicology and Medical Aspects

J. Michael Lord and Gareth D. Griffiths

CONTENTS

1 INTRODUCTION

Ricin is a potently toxic protein that occurs in the seeds of the castor oil plant, *Ricinus communis*. This plant thrives in tropical and subtropical regions of the world, but also grows well in Europe including the United Kingdom. It is extensively cultivated in warmer climates for the extraction of castor oil. Approximately 1.3 million metric tonnes of castor oil seeds, grown mainly in India, but also Brazil and China, are processed annually to extract castor oil. This product is used widely in the manufacture of many commodities, including lubricants (oils and greases), polishes, paints and varnishes plasticizers and cosmetics. Ricinus plants exist in a many different forms known as cultivars and, broadly speaking, have green leaves and stems, or red leaves and stems, and the seeds may also vary considerably in size and colour, but the outer husk always bears a characteristic lighter pattern on a darker background (**Figure 1**).

Ricin toxin (also referred to as RCA_{60}, *Ricinus communis* agglutinin with molecular weight of 60 kDa) is abundantly present in the seeds of all cultivars where, together with the closely related lectin (RCA_{120}, *Ricinus communis* agglutinin with molecular weight of 120 kDa), it can account for up to 5% of the total seed protein. Ricin is synthesized during seed development, and is stably stored in mature seeds in an organelle termed the vacuole, together with several other abundant seed proteins. Collectively these proteins are called storage proteins: they are rapidly hydrolysed during the early stages of seed germination to provide a source of amino acids for the synthesis of proteins encoded by genes that are expressed at this stage of development. After a few days of post-germinative growth, the storage proteins, including ricin, have disappeared entirely as

the developing seedling is increasingly able to synthesize the amino acids it needs via photosynthesis. The biological function of ricin, therefore, seems to be as a seed-storage protein, with the added advantage that its potent toxicity deters herbivores from eating the seeds.

Although the toxicity of *Ricinus* seeds had been known from antiquity, the active principle was first described as a toxic lectin in 1888, in the inaugural thesis of Hermann Stillmark. Stillmark worked at the University of Dorpat in what was then Estonia, as a student of Robert Kobert. In one of his *in vitro* experiments, he mixed an extract of the seeds with blood and observed that the erythrocytes rapidly became agglutinated. He found that the agent responsible was a protein which he termed 'ricin', the first lectin to be identified (Stillmark, 1888). Lectins were initially designated as 'haemagglutinins', or 'phytohaemagglutinins' because the first examples of lectins came from plants (Etzler, 1985). We now know that the haemagglutination observed by Stillmark was largely due to RCA_{120} rather than ricin, but in 1888 he reasonably concluded that the toxicity of *Ricinus* seeds was caused by their ability to agglutinate red blood cells. Shortly afterwards, another student of Kobert's, H. Hellin, found that the toxic extracts of the jequirity bean (*Abrus precatorius*) also caused red blood cells to agglutinate, and the second haemagglutinin to be described was called 'abrin'.

Ricin gained considerable notoriety as the likely poison in the small pellet used to kill the Bulgarian journalist Georgi Markov in the so-called 'umbrella-tip' assassination in London in 1978 (Knight, 1979). A more recent concern focusses on the potential use of ricin as a weapon of bioterrorism. *Ricinus* seeds are readily available from the extensive cultivation of the plant for commercial and now, horticultural purposes around Asia, Europe and the Americas. Ricin can be easily isolated from the seeds using uncomplicated and low-cost procedures that require neither complex laboratory facilities nor scientific expertise, thereby making the toxin a desirable biological agent for terrorist organizations. Indeed, descriptions on how to isolate this toxin in an active state have been found in several terrorist manuals. As such, both the UK and US Governments list ricin as a category B agent for bioterrorism.

2 STRUCTURE AND BIOGENESIS

Ricin is the best-characterized member of a family of plant proteins collectively known as ribosome-inactivating proteins (RIPs) (Lord *et al*., 1994). It is a heterodimeric protein (**Figure 2A**) composed of a ribosome-inactivating enzyme (32 kDa, designated the A chain or RTA) linked to a galactose/*N*-acetyl-galactosamine-binding lectin (34 kDa, the B chain or RTB; Figure **2A**) (Lord *et al*., 2004). RCA_{120}, in contrast, is tetrameric, composed of two ricin-like heterodimers (**Figure 2B**), each of which contains an A chain (32 kDa) and a galactose-binding B chain (34 kDa). In addition to their structural differences, these two proteins also differ in their biological properties. Ricin is a potent cytotoxin, but a weak haemagglutinin, RCA_{120} is only weakly toxic to intact cells, but is a strong haemagglutinin. However, although RCA_{120} is only weakly toxic to intact cells *in vivo,* its isolated A chain is an RIP of comparable activity to the ricin A chain in terms of its ability to modify ribosomes *in vitro* (O'Hare *et al*., 1992). The sugar-binding specificities are also similar, but not identical. Overall, however, ricin and RCA_{120} are closely related proteins, and antisera raised against individual ricin A or B chains cross-react strongly with the corresponding RCA_{120} subunits and vice versa. The complete primary structures of the ricin and RCA_{120} subunits are known. Overall the A chains differ in 18 of their 267 residues and are thus 93% homologous at the amino-acid level, whereas the B chains differ in 41 of 262 residues, giving 84% homology (Roberts *et al*., 1985).

The ricin gene encodes a preproprotein containing both the RTA and RTB sequences. Preproricin consists of 576 amino acid residues, the first 35 of which include a 26 residue N-terminal signal sequence and a nine residue propeptide, followed by the mature A chain sequence (267 residues) joined by a 12 residue linker peptide to the mature B chain sequence (262 residues). The 12 residue linker sequence contains a targeting signal that directs the ricin precursor to the vacuole (Frigerio *et al*., 2001).

During ricin biosynthesis, the N-terminal signal sequence directs the transport of the nascent polypeptide across the endoplasmic reticulum (ER) membrane

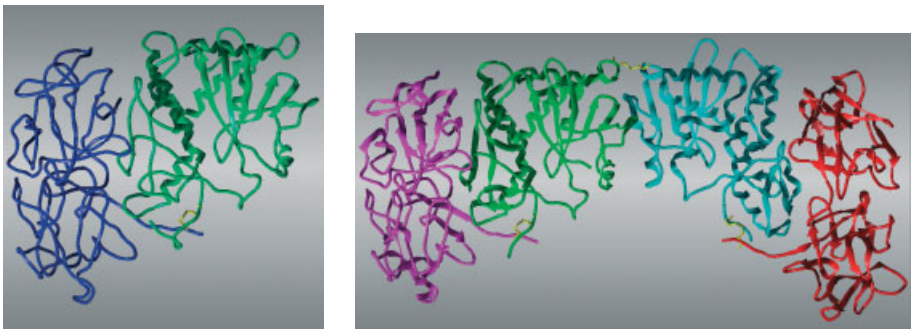

Figure 2 (A,B) Representations of the RCA_{60} and RCA_{120} structures, respectively. (A) Ricin (RCA_{60}) is a heterodimer in which the catalytically active A chain (green) is covalently linked to the galactose-binding B chain (blue) by a single disulfide bond (yellow). (B) *Ricinus communis* agglutinin (RCA_{120}) is a tetramer containing two A chains (green and light blue) and two B chains (pink and red), which are highly homologous to their ricin counterparts. The RCA_{120} A chain contains an extra cysteine residue, not present in the ricin A chain, which forms a disulfide bond linking the A chains of two ricin-like heterodimers (yellow) to give the tetramer.

of the seed endosperm cells and into the ER lumen. Translocation across the ER membrane is accompanied by three major modifications (Lord and Roberts, 1993). First, the N-terminal signal peptide is cleaved by ER luminal signal peptidase. Second, proricin is N-glycosylated as it enters the ER lumen. Proricin contains four N-glycosylation sites, two within the A chain sequence and two within the B chain. Third, protein disulfide isomerize catalyses the formation of five disulfide bonds in the folding proricin. In mature ricin, four of these disulfide bonds are in the B chain, while the fifth one is the disulfide bond linking RTA and RTB. Proricin is transported from the ER, via the Golgi complex, to the vacuole. The attached glycans are modified during intracellular transport (Lord, 1985) and, upon reaching the vacuole, proricin is processed by an endopeptidase that removes the 12 residue linker sequence between RTA and RTB, and the nine residue N-terminal propeptide. The two subunits are still covalently joined by a disulfide bond because cleavage of the linker occurs within a disulfide loop connecting the A and the B chain sequences (Lord and Harley, 1985).

The three-dimensional structure of ricin has been solved by X-ray crystallography (Montfort *et al*., 1987). RTA is a globular protein with a pronounced active site cleft, while RTB is a dumbbell shaped, two-domain protein, the two domains apparently the result of a gene duplication event (Villafranca and Robertus, 1981).

3 RIBOSOME MODIFICATION BY THE RICIN A CHAIN

RTA, in common with other RIPs, is an enzyme that removes a specific adenine residue from the ribosomal 28 S RNA of the large subunit of eukaryotic ribosomes (Endo *et al*., 1987a). The adenine removed, adenine 4324 in the case of rat liver 28 S ribosomal RNA (rRNA), is located in a region of the rRNA that contains one of the longest universally conserved rRNA sequences. This highly conserved region of rRNA functions in the ribosomal elongation cycle, and the adenine residue removed as a result of RTA-catalysed depurination is the binding site for elongation factors 1 and 2. Since RTA-modified ribosomes are rendered unable to bind elongation factors, they are unable to achieve protein synthesis, leading eventually to cell death. Because it is an enzyme, a very small amount of RTA inside a cell can inactivate numerous ribosomes, making ricin one of the most cytotoxic compounds in nature.

4 INTOXICATION OF INTACT CELLS BY RICIN

Because RTA's ribosomal substrate is in the cell cytosol, RTA must enter this compartment in an active conformation in order to intoxicate the cell. In common with other members of the so-called A-B toxin superfamily, ricin's bipartite structure is crucial in the regard. Ricin binds, via its B chain lectin activity, to any cell surface glycoprotein or glycolipid having a terminal β-1-4-linked galactose residues. Such potential ricin binding sites are plentiful on mammalian cells: each HeLa cell, for example, can bind 3×10^7 molecules of ricin (Sandvig *et al*., 1976). Surface-bound ricin enters the cell by endocytic uptake, and is initially delivered into early endosomes. Much of the ricin that enters the cell is returned to the cell surface in recycling endosomes, or is transported via late endosomes to the lysosomes, where it is destroyed. Some of

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the ricin in early endosomes follows an intracellular transport route that is productive for cellular intoxication. This intracellular trafficking entails retrograde transport to the ER via the Golgi complex (Spooner *et al*., 2006), the ricin holotoxin reaches the lumen of the ER, from where RTA crosses the ER membrane to reach the cytosol. The molecular details of this retrotranslocation step from the ER lumen to the cytosol are not yet completely established, but it is thought that RTA and other toxin subunits do so by exploiting the quality-control system known as endoplasmic reticulum-associated protein degradation (ERAD) (Lord *et al*., 2006). The ER lumen is a major protein-folding compartment. Newly synthesized proteins in the ER that fail to fold or assemble correctly are disposed of by ERAD. This entails their retrotranslocation from the ER to the cytosol, where they are degraded by the proteasome, facilitated normally by polyubiquitination (Romisch, 2005). The emerging explanation for RTA retrotranslocation is as follows. After its arrival in the ER lumen, ricin is reductively separated into the A and B subunits by the action of ER protein disulfide isomerase (Spooner *et al*., 2004). Free RTA contains a sequence of hydrophobic amino acids that is covered by RTB in the ricin holotoxin. This exposed hydrophobic stretch inserts into the luminal surface of the ER membrane, which triggers the partial unfolding of RTA (Day *et al*., 2002). RTA is perceived by the ER quality-control system as a misfolded membrane protein and therefore a substrate for ERAD. This results in RTA retrotranslocation, but in order to intoxicate the cell, at least some of the retrotranslocated RTA avoids the normal fate of ERAD substrates, namely proteasomal degradation. The low lysine content of RTA and other protein toxins that retrotranslocate from the ER facilitates this uncoupling from a degradative fate (Deeks *et al*., 2002; Rodighiero *et al*., 2002). The fate of RTA in the cytosol is influenced by molecular chaperones and cochaperones, which assist in regaining the native conformation (Spooner *et al*., 2008).

Earlier studies *in vitro* (Hughes *et al*., 1996) demonstrated that ricin induced apoptosis in bovine pulmonary endothelial cells. Subsequently, ricin-induced apoptosis has been demonstrated in many other cell lines, and studies have been undertaken to further elucidate the mechanism of this form of cell death (e.g. MDCK cells, Oda *et al*., 1999; HeLa cells, Gan *et al*., 2000; U937 cells, Kageyama *et al*., 2002; RAW 264.7 cells, Higuchi *et al*., 2003; human cervical cancer cells, Rao *et al*., 2005; primary human macrophages, Korcheva *et al*., 2007).

5 EXPOSURES TO RICIN

Considerable information has been published on the intoxication of various cell types by ricin. As touched upon above, this *in vitro* approach offers great potential for understanding the mechanism of action of toxins like ricin, but the likely consequences of poisoning in man, and the development of medical countermeasures and therapies, our ultimate concern, can only fully be understood and developed through the use of animal models.

Ricin has been of concern as a possible warfare weapon for some time, but is now also considered a feasible terrorist weapon because of the abundance of the castor oil seeds and the relative ease with which a crude ricin toxin may be extracted. This is further supported by the internet publications describing simple extraction and preparation of extracts from *Ricinus* seeds using low technology.

From a military perspective, the primary route of concern for intoxication by ricin is by inhalation, although poisoning is also possible by other routes, including access to the bloodstream across broken skin or by ingestion. Clearly, these potential routes of intoxication could also be relevant to civilian casualties in a terrorist situation. The inhalation toxicology of ricin will be examined first, before going on to consider the other possible routes of intoxication.

6 INHALATION TOXICOLOGY OF RICIN

There is probably more toxicological information available from laboratory studies of experimental ricin poisoning by inhalation than for the other possible routes of intoxication. The inhalation toxicology of ricin in rodents, both mice and rats, has been examined in the UK at the Defence Science and Technology Laboratory (Dstl), while the US Army Medical Research Institute of Infectious Diseases has examined this route of ricin exposure in rodents and nonhuman primate species (Wannemacher and Anderson, 2006). A number of factors must be considered when designing inhalation toxicological experiments, including, not least, the choice of animal model, its airway physiology and anatomy, the respiratory properties of the species and the size of the aerosol particles produced by the aerosol generator.

6.1 Aerosol Generation

Ricin and other protein toxins could theoretically be produced as aerosols from liquid solutions or from powdered material, using a variety of aerosol generators. In studying inhalation toxicology, key issues to be satisfied include the delivery of sufficient material of the appropriate particle size, its mass median aerodynamic diameter (MMAD), to reach the desired target site.

DOI: 10.1002/9780470744307.gat152
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Inhalation toxicological studies with ricin at Dstl have been conducted using solutions of ricin, generated as respirable aerosols for the rodent models (rats and mice), using a Liu–Lee nebulizer (Liu and Lee, 1975), with modifications to enable a constant output (Leong *et al*., 1982). The ricin solutions were made in phosphate-buffered saline, which was tagged with sodium fluorescein, to enable an estimate to be made of aerosol concentrations achieved during each exposure. The generator produced aerosol particles which, when dry, had a MMAD of between 0.89 and 0.91 μm, with a geometric standard deviation of 1.6. This means that the range of particle sizes produced was very small and largely homodisperse. Rodents were exposed to aerosol by nose only, rather than whole body, being held in metal plethysmography tubes sealed at the 'tail end' with a rubber bung and around the neck of each animal using a latex collar. This enabled respiratory parameters to be measured during the experimental period (online pneumotachography), which, in conjunction with calculated aerosol concentration (from fluorescein tagging) allowed for more accurate determination of the quantities of toxin inhaled.

The inhaled quantities of a challenge agent are usually expressed in terms of aerosol concentration (C; mg m^{-3}) and the time (t) for which exposure was maintained (minutes) giving a composite value (Ct) of mg min m^{-3}. While the likely quantity of toxin inhaled over a period of time can be derived from the information gathered during the experiment, it is far more difficult to estimate the actual quantity of the toxin retained in the respiratory tract. An approximation of retained material is usually made on the basis of the aerosol inhaled during the exposure time and may be expressed as μg or mg per kg bodyweight. Although LD_{50} (median lethal dose) or LCt_{50} (median lethal concentration and time) are normally quoted as single values, there is usually a fairly wide margin of error. In the case of inhalation toxicology, this variation may be between 10 and 20% either side of the quoted mean value (95% confidence limits). There may be several reasons for such variation, one of which is that the lethal Ct is usually determined from relatively few animals, each of which may have different susceptibilities or resistance to the challenge agent.

6.2 Inhalation Toxicity of Ricin

Following observation of the health status and survival of the experimental rodents, it was possible to express aerosol toxicity in terms of lethal Ct_{50} (LCt_{50}), the product of aerosol concentration and the exposure time producing death of 50% of the recipient animals. Alternatively, information may estimate an approximate lethal dose 50 (LD_{50}).

Solutions of different concentrations of pure ricin were made for aerosolization from two different seed cultivars of *Ricinus communis,* Hale Queen (a commercial preparation from Sigma) and *Ricinus zanzibariensis*. Adult rats (approx. 250 g bodyweight) were exposed to aerosols of either material for 10 minute time periods and, following a period of observation lasting 14 days, lethality data were derived. It was interesting to find that the LCt_{50} values determined for the toxicity of the two preparations were different, being between 4.54 and 5.96 mg min m^{-3} (estimated LD_{50} 3.7 μg kg^{-1}) for Hale Queen and 12.7 mg min m^{-3} (estimated LD_{50} 9.8 μg kg^{-1}) for *Ricinus zanzibariensis.* Times to death were related to dose received, varying from about 36 hours at higher Cts to between 66 and 138 hours at lower Cts. Details of these studies have been published (Griffiths *et al*., 1994). The inhalation toxicology of pure ricin extracted from *Ricinus zanzibariensis* in the Balb/c mouse was also examined in our laboratory using the same exposure system, and the LCt_{50} was found to be 6.52 mg min m^{-3} (95% confidence limits: lower 6.153, upper 7.038). This approximated to an LD_{50} of 6 μg kg^{-1}.

Inhalation toxicity studies of ricin have been undertaken by other laboratories using the mouse as the small-animal model. For example, Balb/c mice were challenged by inhalation of pure ricin using a whole-body exposure method (Wannemacher and Anderson, 2006) and an LD_{50} of 11.2 μg kg^{-1} was determined. Differential susceptibilities to inhaled ricin were also mentioned in relation to mouse strain and the LD_{50} for inhaled ricin in the most sensitive strain, BXSB, was approximately 2.8 μg kg^{-1}. It was also intimated by these authors that the toxicities of ricin prepared from different *Ricinus* plant cultivars can vary, an observation supported by our own studies on inhaled ricin purified from two cultivars of the plant.

6.3 Histopathology and Symptoms of Inhalation Intoxication

The pathogenesis of damage resulting from the inhalation of pure ricin aerosol particles (from *R. zanzibariensis*) in the rat, at an approximate LCt_{30} challenge dose (i.e. a quantity of ricin which would kill approximately 30% of recipients) was found to be confined to the lungs (Griffiths *et al*., 1994). Using light microscopy it was evident that ricin had reached the deep lung, since, by 24 hours, lung tissue sections showed acute inflammatory cell infiltration into the alveolar walls with frequent flooding of air spaces by protein-rich oedema (Oe) fluid. By 48 hours (**Figures 3B** and **C**) lung sections clearly illustrated florid intra-alveolar Oe and large numbers of darkly stained migratory inflammatory cells within the alveolar septae. This damage was limited to the lung and other organs examined remained normal in appearance. Using

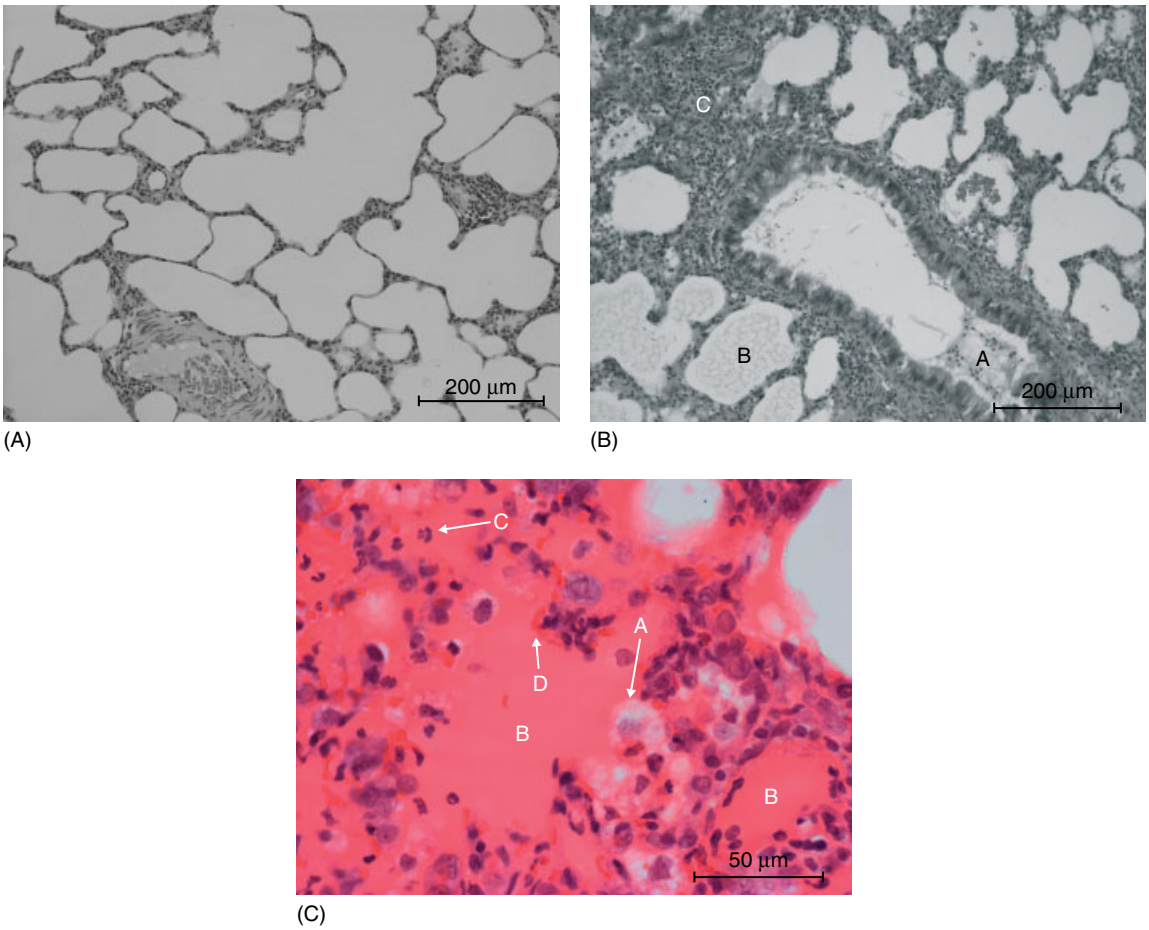

Figure 3 (A–C) Sections from lungs of rats, focusing on the alveolar region. (A) Normal rat lung, showing open, clear alveolar spaces bordered by thin epithelial membranes. (B) Section through alveolar region of lung of rat taken 48 hours after inhalation exposure to ricin toxin (LCt_{30}). The picture shows: A, residual proteinaceous oedema fluid containing inflammatory cells within the lumen of a bronchiole; B, residual proteinaceous oedema fluid within the airspace of an alveolus and C, congestion of the interstitial tissue, between alveolae, with inflammatory cells. (C) A section through the alveolar region of the lung of a rat taken 48 hours after inhalation exposure to ricin toxin (LCt_{30}). The picture shows: A, an example of macrophage next to other cells around what appears to be an alveolus (B); other macrophages may be seen throughout the section. The alveolar epithelial boundary is no longer clear, as a result of damage. An alveolus with epithelium partially intact features on the bottom right of this figure. In another alveolar region, a neutrophil is indicated (C); further neutrophils are evident elsewhere in this section. Red blood cells can be seen (stained bright red) within the alveolar spaces and also amongst interstitial cells as a result of haemorrhage through damage to capillary endothelia. An example is indicated (D).

the higher resolution afforded by electron microscopy, Brown and White (1997) observed the initiation of Oe formation, initially perivascular, from 12 hours following inhaled ricin aerosol (LCt_{30}). The situation progressed from 15–36 hours to include interstitial and intra-alveolar regions. Additionally, inflammatory cell infiltration was evident from 12 hours post challenge and the greatest numbers of macrophages and polymorphonuclear leucocytes were noted between 24 and 48 hours.

Aerosolized ricin particles penetrating the deep lung of the rats induced tissue pathology and the epithelia of both the lower respiratory tract and the alveoli were subject to destructive inflammatory damage, with evidence of necrotic and apparently apoptotic processes. Apoptosis was identified purely on cell morphology, including rounding up, cytoplasmic contraction and frequent appearance of discrete particles of apparently nuclear material. The same picture was maintained at 96 hours when signs of repair were also noted in the form of hyperplasia of Type II epithelial cells. Beyond this time, a gradual clearing of Oe fluid was observed although complete resolution of damage was not achieved until 14 days post exposure. This progressive pathogenesis was also reproduced in studies conducted in mice in our laboratory.

The major problem caused by the inhalation of ricin seems to be pulmonary flooding of the lungs resulting from primary damage to epithelia and presumably underlying blood-vessel endothelia. Damage is probably exacerbated by the massive inflammatory response mounted by the host to the presence of the toxin and the primary damage caused. Together, these events lead to respiratory insufficiency which, in severe cases, leads to death.

There is some debate as to whether inhaled ricin gains access to tissues beyond the lung. In our studies at Dstl we have not found evidence of inhaled ricin causing damage to other tissues. In an earlier inhalation study using ^{125}I-labelled ricin (Doebler *et al*., 1995), mice were exposed nose-only to the aerosol and radiolabel was found in the lungs, but also in the gastrointestinal tract and minimally in the circulation. Some inhaled aerosol is likely to be swallowed, although it is unlikely that it would contribute significantly to the lethality of the total dose received, since the oral toxicity of ricin is orders of magnitude lower than that of the inhaled toxin. It is also difficult, when tracing molecules carrying a radioactive label, to be clear whether one is measuring the intact molecule or a fragment of the molecule. In a more recent study the intrapulmonary instillation of a lethal dose of ricin was found to cause an accumulation of proinflammatory messenger RNA (mRNA) transcripts, primarily in the lungs, but also in other body tissues including the liver, spleen and blood, as well as elevated levels of proinflammatory cytokines. This challenge dose also produced pathology in the kidney, including tubular fibrosis and impaired renal function. The LD_{50} quoted by the authors (Wong *et al*., 2007) for the ricin administered by this method was 10 µg (100 g bodyweight)$^{-1}$ which is equivalent to 100 µg kg^{-1}. In our experience in the rat, the LD_{50} of ricin by instillation was very close to the inhaled LD_{50} and within the range of 1–10 µg kg^{-1} bodyweight. If this is true for the mouse, the lethal dose derived in this study was very high. This might suggest that a significant quantity of the ricin instilled was being delivered to the stomach and intestine, although the lungs were also clearly receiving damaging amounts of the toxin.

7 OTHER ROUTES OF INTOXICATION AND TOXICOLOGY

7.1 Ingestion of Ricin

The toxicity of ricin when delivered by the oral route is much lower than by inhalation and parenteral delivery routes. In the mouse, the LD_{50} for orally administered ricin is quoted by Franz and Jaax (1997) as 20 mg kg^{-1} bodyweight with a time to death of approximately 85 hours. The lower toxicity by this route is probably a reflection of the poor absorption of ricin from the intestine. Another review by Audi *et al*. (2005) reported the LD_{50} of ricin by the oral route to be 30 mg kg^{-1} and a human LD_{50} estimate was given as 1–20 mg ricin kg^{-1} bodyweight. A probable human oral lethal dose given in the TOXNET Hazardous Substances Database for ricin is less than 5 mg kg^{-1}.

While there have been many reported suicide attempts through the ingestion of castor oil seeds, there is great difficulty in the interpretation of the toxic dose because of variables, including differences in ricin content of seed types (e.g. geographic region of plant growth, time of harvesting seeds, degree of hydration of seeds) size and weight of seeds ingested, as well as the degree of mastication to release the seed contents, including the water-soluble ricin.

7.2 Histopathology and Symptoms of Oral Intoxication

Victims of oral ricin poisoning feature prominent gastrointestinal symptoms, which may include colicky abdominal pain, vomiting, diarrhoea, heartburn and oropharyngeal pain. In addition, haematemesis and melena are less commonly-reported symptoms. Fluid loss may result in electrolyte imbalance, dehydration, hypotension and circulatory collapse (Audi *et al*., 2005), and associated symptoms may include tachycardia, tachypnoea, sweating and peripheral cyanosis (Bradberry *et al*., 2003). Histopathology of lethal cases of oral ricin intoxication includes multifocal, often severe, ulceration and haemorrhage of the gastric and small intestinal mucosa. Also necrosis of the draining mesenteric lymph nodes, gut associated lymphoid tissue and spleen. Necrosis is observed in liver tissue, especially the reticulendothelial Kupffer cells and diffuse inflammation of renal tubules (nephritis) and the spleen (Franz and Jaax, 1997). Apoptotic cell death is also cited in the histopathology of ricin toxicity by ingestion (Audi *et al*., 2005).

At Dstl we have limited experience of oral ingestion of ricin in Balb/c mice. Three mice were administered (by gavage) 10 or 20 mg kg^{-1} of ricin purified from *Ricinus zanzibariensis* seeds. Animals appeared normal over a seven day period following oral dosing with 10 mg kg^{-1}. Forty-eight hours after dosing with 20 mg kg^{-1} ricin, however, all mice were relatively inactive, they had lost the inquisitive habit typical of rodents and their fur was piloerected. One animal died on the fourth day and a photograph (**Figure 4**) of the stomach and small intestine shows evidence of inflammatory reddening of the small intestinal wall, close to its point of exit from the stomach. From this very limited study it appears that in

Figure 4 Inflammation of the duodenum proximal to the stomach in the gastrointestinal tract removed from a female Balb/c mouse, four days after oral dosing with ricin (20 mg kg^{-1}).

this species, the LD_{50} of pure ricin (from *Ricinus zanzibariensis*) probably lies around 20 mg kg^{-1} (unreported observations). This concurs well with other reported data (Franz and Jaax, 1997).

7.3 Parenteral Intoxication with Ricin

Routes of intoxication under the 'parenteral' category include intravenous (iv), intraperitoneal (ip) and intramuscular (im). Gill (1982) gives a figure (LD_{50}) for ricin by the iv route in the mouse of 2.7 μg kg^{-1}. This compares fairly closely with the value quoted by Franz and Jaax (1997) of 5 μg kg^{-1} (90 hours to death) for the iv route in the mouse, but 22 μg kg^{-1} (100 hours to death) if ricin is administered by the ip route. The im route is not given by these authors, but they do quote a value for a subcutaneous route of 24 μg kg^{-1} (100 hours to death).

7.4 Histopathology and Symptoms of Parenteral Intoxication

Studies on im dosing of rodents with ricin have used immunocytochemical methods to demonstrate the presence of the toxin in a lymph node draining the injection site (Griffiths *et al*., 1989b). Closer examination of the draining process suggested that ricin reached the lymph node an hour or so after injection and was bound to different cell types, including lymphocytes, by a mechanism which could be inhibited, *in vitro,* by lactose (Griffiths *et al*., 1989a). Damage to the small intestine was a feature following im poisoning with ricin, with the infiltration of plasma cells and activated macrophages into the lamina propria and apoptotic deletion of these and structural cells in the ileum (Leek *et al*., 1989). The most notorious case of alleged ricin poisoning by im injection was that of the murder of Georgi Markov in London in 1978, in which approximately 0.5 mg of ricin may have been delivered in a hollow pellet (Crompton and Gall, 1980; Knight, 1979).

Symptoms included pain at the injection site of the pellet followed by nausea, vomiting, fatigue and fever developing over the 24 hours after injection. Gastrointestinal haemorrhage, hypovolaemic shock and renal failure developed subsequently and Markov died three days after being 'injected' with the pellet. Histopathology subsequently revealed the wide distribution of ricin around the body, including the presence of pulmonary oedema, haemorrhagic necrosis of the small intestine and damage to the lymph nodes draining the original injection site, but also to the myocardium, pancreas and testes.

The fate of iv administered ^{125}I-labelled ricin was examined in the rat (Ramsden *et al*., 1989) and indicated that some 46% of the injected dose reached the liver within 30 minutes of administration, followed by the spleen (9.9%) and muscle (13%). Greatest tissue concentration of labelled ricin was in the spleen (33% of original dose g^{-1} of tissue) while some entered the intestine (10–12% at between 3–12 hours and <5% at 24 hours).

There is little information on ricin administered by the ip route, although the LD_{50} for this route is given as 22 μg kg^{-1} with death at around 100 hours later (Franz and Jaax, 1997).

8 A CONSIDERATION OF ANIMAL MODELS OF HUMAN TOXICITY, FOCUSSING ON INHALATIONAL TOXICITY

Toxicological studies are ultimately concerned with the implications of observations gained in animal species to humans. In many situations there may be human exposure data to help corroborate or refute animal-derived data, but such information is unavailable for inhaled ricin. It is extremely important that the limitations of animal models and the experimental conditions used must be understood for such extrapolations to be appropriately made, even more so when there are no human data to compare.

Modelling inhalation toxicity requires special consideration because, in addition to species' relative sensitivity to the toxin, which affects all routes of intoxication, several other factors must be considered which could lead to misinterpretation of data.

In studies of inhalation of aerosol particles, the aerosol particle size (MMAD) is most important in governing the penetration of the material through the respiratory airways into the deep lung. Other key factors influencing depth of aerosol penetration are the airway diameter and breathing patterns of the animal species studied. Generally, the smaller the species, the lower the MMAD

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat152
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

required for deep-lung penetration, especially if the animals are obligate nasal breathers and have a highly efficient nasal filtration system.

Humans may breathe both nasally or orally and the nose and upper airways (laryngeal, in particular) quite efficiently adsorb aerosol particles larger than about 2 μm aerodynamic diameter, In nasal breathing, particles larger than approximately 0.5 μm MMAD are effectively removed by inertial impaction in the nose, but also the larynx. Smaller particles (e.g. ~1 μm) will reach the deep lung, but may not deposit there, while larger particles (e.g. between 1 and 5 μm), which actually reach the alveoli, stand a better chance of depositing there (Heyder *et al*., 1986). In rats and mice, species commonly employed in inhalation toxicology, the smaller dimensions of the airways and the fact that these species are obligate nasal breathers, requires a lower MMAD in the region of ideally 1–2 μm for penetration of particles through the nasal turbinates and airways down to the deep lung. It has been shown experimentally that in small species, particles of aerodynamic diameter less than 3 μm are required (Raabe *et al*., 1988) in order to study deep-lung penetration. Roy *et al*. (2003) examined the comparative distribution of inhaled aerosolized ricin particles of different size ranges of 1 μm and 5–12 μm MMAD. In general terms, this study showed that, in mice exposed nose-only to aerosol, approximately 60% of the 1 μm ricin particles were deposited in the lungs, followed by the trachea, with very small amounts being measured (using enzyme-linked immunosorbent assay (ELISA)) in the nares and stomach (~1–2%). In the case of the 5–12 μm particles, most ricin was found to be in the trachea, with less in the lungs and very little in the nares and stomach. No animal deaths were noted following the exposure to the 5–12 μm particles at a Ct which, for 1 μm particles would have been $4LD_{50}$.

In terms of species' relative sensitivity to ricin, it was established during World War II that a range of susceptibilities to ricin by inhalational exposure was apparent between animal species (Cope *et al*., 1946). Using an impure sample of ricin, animals were exposed by inhalation to atomized aqueous samples of crude ricin droplets (MMAD 1.4 μm), and the order of sensitivity was established (based on derived LCt_{50}s). In decreasing sensitivity species were: mouse, rabbit, guinea pig, cat, rat and monkey. It has since been shown that such differences may be found, even between strains of the same species, by comparative toxicology studies undertaken in the mouse (Wannemacher and Anderson, 2006).

Thus, care must be taken in the selection of animal models for such studies and in the interpretation of information gained with reference to man, as discussed by Paddle (2003).

9 MEDICAL COUNTERMEASURES

There are two potential approaches to the development of medical countermeasures for ricin. A pretreatment strategy could be adopted, involving vaccination or, alternatively, a post-exposure therapeutic strategy might be considered. Here, for example, a passive immune approach through the timely administration of preformed anti-ricin antibodies (antitoxin) might be employed or, alternatively, the administration of inhibitors of the *N*-glycosidase enzyme activity of ricin or of compounds to prevent ricin attachment to tissues might be considered. The potential for both pre- and postexposure strategies has been explored by several laboratories in the UK and in the USA and key points arising from these studies will be identified below.

9.1 Pretreatment Approaches: Vaccines

When pretreating against poisoning by protein toxins, the key feature is to engender sufficient quantities of neutralizing antibodies, which are available in the right place at the critical time. The vaccine antigens must be as closely preserved as possible to the native protein, in this case, ricin, in order to ensure that antibodies having the appropriate qualities are produced in the vaccinee. Early studies in our laboratory investigated the efficacy of the long-standing toxoiding method, where the protein is incubated with formaldehyde, to produce a nontoxic vaccine candidate. This approach has been used for the preparation of vaccines currently in use, including diphtheria/tetanus toxoids with adsorbed acellular pertussis, as produced by Wyerth–Ayerst and GlaxoSmithKline (Informed Choice, 2009).

At Dstl we examined the efficacy of a formaldehyde-treated ricin (toxoid) vaccine in Porton Wistar rats. Animals were vaccinated with toxoid by three subcutaneous injections at three-week intervals, in the absence of an adjuvant, before challenge by inhalation to two LCt_{50}s of ricin. All vaccinated animals survived aerosol challenge and had mounted strong ricin-specific antibody responses, which, in a blood sample taken just before challenge, included predominantly IgG but also IgA and IgM isotypes with ricin specificity. Although the rats had been protected against toxin challenge, their lungs still showed abnormal histopathology consistent with ricin poisoning, but the study indicated that the toxoid showed promise as a basis for pretreatment against mortality from inhaled ricin toxin (Griffiths *et al*., 1995).

In order to attempt to achieve better protection of the lungs, ricin toxoid was liposomally encapsulated and administered by intratracheal (it) instillation to rats. After challenge ($3LD_{50}$ ricin, it) animals were found to be well

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat152
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

protected, with mild signs of intoxication, producing high titres of ricin-specific antibody with IgA isotype in serum and lung washes. One cause for concern, however, was that ricin-specific IgE was measured in both sera and in lung fluid washes (Griffiths *et al*., 1997). An alternative RTA-based vaccine candidate was compared in rats with ricin toxoid, and each antigen was administered it in liposomal formulations. Protection is believed to depend upon the production of protective, ricin-neutralizing antibodies. One week after vaccine boosts, ricin-specific antibody titres were similar with each antigen, but antibody levels in lung fluid post challenge ($3LD_{50}$, it) with ricin were lower in the RTA-vaccinated group. Once again, ricin-specific IgE levels were measured in rats which had been vaccinated with the toxoid preparation (Griffiths *et al*., 1998).

This quality of protection offered by it vaccination with liposomal ricin toxoid or RTA was compared by analysis of markers of inflammation in lung-fluid protein over several days following challenge with ricin ($3LD_{50}$, it). Rats which had been protected with toxoid had very low levels of protein or inflammatory neutrophils compared with the RTA group. When liposomal RTA had been administered subcutaneously instead of it, lower levels of inflammatory markers were noted after ricin challenge (Griffiths *et al*., 1999).

Overall, therefore, studies indicated that ricin holotoxoid vaccine produced a better quality of protection than the A-chain-based vaccines. One potential problem over formaldehyde-toxoided ricin was that the preparation could revert to active toxin. However, investigation of established formaldehyde-toxoid vaccines in clinical use revealed that residual formaldehyde is included in the formulation in order to prevent the reversion of toxic activity.

Other laboratories have explored the utility of a formalin-inactivated ricin toxoid as a vaccine candidate. Yan *et al*. (1996) demonstrated protective immunity against a supralethal challenge of ricin aerosol, one year after intranasal (in) immunization of mice using ricin toxoid microencapsulated in poly(lactide-coglycolide) (PLG) or polylactide (PLA) microspheres. Kende *et al*. (2002) demonstrated the production of serum antibodies (IgG2a and IgA classes) following oral administration of PLG-encapsulated ricin toxoid in mice. Seven administrations of 25 μg toxoid in PLG over a period of 30 days protected 50% of the immunized mice. For direct comparison, a single subcutaneous dose of microencapsulated ricin toxoid was fully protective. The protection of mice produced against ricin has also been examined by in administration of deglycosylated ricin A chain (Kende *et al*., 2006) or recombinant A chain (Kende *et al*., 2007) in the presence of mucosal adjuvants prepared by mutations of *Escherichia coli* heat-labile enterotoxin. The adjuvants were shown to substantially improve ricin-specific antibody titres in serum and lung lavage. Full protection against death was produced following subsequent inhalation challenge with supralethal amounts of ricin toxin aerosol, although lung damage was still evident.

Growing interest in the use of RTA-chain vaccine candidates is evident over the past 10–15 years. The A chain of ricin and other RIPs, have been used for a long time to produce immunotoxins, by coupling them with antibodies against tumour cell surface-specific antigens (Stirpe and Battelli, 2006). In this connection, it was found that the A chains had adverse effects on human umbilical vein endothelial cells and could cause vascular leak syndrome in Phase I/II clinical trials, so potentially limiting the quantity of immunotoxin which may be administered to patients (Soler-Rodriguez *et al*., 1993). This property would also be undesirable in an RTA-chain-based vaccine.

Further studies by Baluna *et al*. (1999) identified a tripeptide sequence in the A chain of two-chain or single-chain RIPs, with a common aspartic acid residue, flanked by several variable residues, which for ricin were leucine and valine (leucine, aspartic acid, valine tripeptide). This tripeptide enabled binding to and damage of endothelial cells. Engineered recombinant ricin A-chain molecules with mutations in the sequence, or in flanking regions, produced an RTA which behaved like the ricin A chain as an immunotoxin, but did not cause vascular leak in mice (Smallshaw *et al*., 2003). It is important to note that for use as an immunotoxin, the toxic activity of the A chain should be preserved, while the ability to cause vascular leak should ideally be removed. For RTA-based vaccines, however, it is desirable to engineer out the sequence causing vascular leak, but also achieve inhibition of toxic *N*-glycosidase activity.

Mutant recombinant ricin A chains prepared by Smallshaw *et al*. (2002), having a single mutations in the enzyme active site and another in the vascular leak tripeptide, were made. These mutants did not produce pulmonary vascular leak in mice, were immunogenic and protected the animals from an ip challenge with a supralethal quantity of ricin. One successful mutant vaccine candidate named RiVax, has been taken forward as a potential human ricin vaccine candidate. It has been shown to be safe, immunogenic and protective in mice and rabbits (Smallshaw *et al*., 2005). RiVax has passed human clinical trials involving three im dose levels, where antibody titres with neutralizing antibody levels were detected (Vitetta *et al*., 2006).

The vaccine has been shown to prevent lethality of mice when challenged orally (gavage) or by inhalation with ricin (10 LD_{50}), when administered at doses of 1, 3.3 and 10 μg, although minimal pulmonary damage was present even in the highest vaccine dose tested (Smallshaw *et al*., 2007). Future studies will investigate whether higher vaccine doses or the inclusion of an adjuvant will induce more robust, longer-duration immunity with even less lung pathology. The efficacy of this vaccine is currently being evaluated in nonhuman primates (Rhesus

macaque) at Tulane National Primate Research Center in Louisiana (Dor BioPharma, 2008).

Another mutant recombinant RTA vaccine candidate, RTA1-33/44-198, lacks hydrophobic residues implicated in the aggregation and precipitation of recombinant A chain molecules (Olson *et al*., 2004). The molecule is very stable to freezing and thawing, has substantially reduced toxicity compared with the wild-type molecule and has a higher thermal stability. Although the vascular leak tripeptide was not modified, animal studies did not reveal signs of this problem and the candidate protected mice against 5–10 lethal doses of ricin by inhalation.

A novel approach to the preparation of a recombinant ricin A-chain candidate (Marsden *et al*., 2004) involved the incorporation of a natural inhibitory 25 residue peptide from an inactive maize RIP into ricin A chain to produce a recombinant protein, RTA-MPP (maize propeptide). The construct had approximately 300-fold reduced *N*-glycosidase activity, compared with wild-type A chain. RTA-MPP was re-associated with ricin B chain to produce ricin-MPP. This reconstituted mutant holotoxoid was nontoxic to cells in culture. When given to rats with adjuvant it protected them against $5LD_{50}$ of ricin when administered by it instillation. This might be a viable candidate ricin vaccine, but further work would be required to completely eliminate *N*-glycosidase activity.

In summary, studies on vaccinations to protect against intoxication by inhaled ricin indicated that a holotoxoid approach gave a better quality of protection than the subunit approach, although both types of candidate could prevent lethality (Griffiths *et al*., 1998; 1999).

9.2 Postexposure Approaches: Ricin Antitoxin

There are few reports in the open literature on the therapy of ricin intoxication (systemic or inhaled) in animal models. A rabbit affinity-purified polyclonal IgG raised against ricin formaldehyde toxoid (Foxwell *et al*., 1985), and a monoclonal antibody (IgG) raised against the B-chain of ricin (Guo *et al*., 2005) have been shown to be effective when administered 40 and 20 minutes, respectively, following systemic ricin challenge.

Protection against inhaled ricin by prophylactic and postexposure use of an affinity-purified mouse antiricin IgG has been reported in a review article of otherwise unpublished results (Wannemacher and Anderson, 2006). Aerosolized antibodies have also been reported as effective when administered prior to an aerosolized ricin challenge (Poli *et al*., 1996). Instilled antibody was not effective, indicating that pulmonary deposition patterns are important for the toxicity and therapy of inhaled ricin.

The production of antitoxins suitable for use in humans exposed to ricin by inhalation are being developed at Dstl. Antibodies raised in sheep against RTA-chain, RTB-chain and the formaldehyde toxoid of whole ricin (using Alhydrogel adjuvant) have been examined for the postexposure therapy of ricin poisoning in mice. IgG raised against the formaldehyde ricin holotoxoid gave the best protection in mice (ip ricin challenge) when antitoxin was administered intravenously, 60 minutes following challenge (Poole *et al*., personal communication; Holley *et al*. 2006). While the time to death was delayed, actual survival was not achieved. Subsequent studies to prepare formaldehyde ricin holotoxoid in sheep used Freund's incomplete adjuvant. This IgG antitoxin produced was more effective achieving 100% survival when administered two hours after an ip challenge with ricin in mice. Further investigation of this antitoxin to develop a treatment for humans exposed to ricin has involved the production of antibody ($F(ab')_2$ and Fab') fragments. The rationale was that the removal of the reactogenic Fc portion of the antibody should make these fragments more suitable for eventual human use. The antitoxin IgG was marginally more effective than $F(ab')_2$ for the postexposure therapy of a systemic ricin challenge in mice, where the latter complete protection was accompanied by some weight loss, while there was no weight loss in the IgG treated mice. The smaller Fab' fragment was unable to prevent death. Of particular significance was the observation that IgG and $F(ab')_2$ were both able to protect mice against a lethal inhaled challenge ($3LCt_{50}$ ricin) when administered two hours after the challenge. Again the quality of protection was slightly better for IgG than the $F(ab')_2$. It is believed that good protection requires the maintenance of a critical level of antitoxin in the blood to access and neutralize the ricin. For equivalent doses of IgG and $F(ab')_2$ our pharmacokinetic studies have shown that plasma levels of IgG are higher than those for $F(ab')_2$, following iv injection of the antitoxins in mice. Continuing studies show greater promise, with a longer therapeutic window to administer antitoxin against inhaled ricin.

Other interest in an antitoxin approach has been reported, involving a novel single domain antibody to the A-chain of ricin. This was developed using a computer-guided molecular design approach and has demonstrated a remarkable ability to neutralize the *in vitro* toxicity of ricin (Wang *et al*., 2006). This highlights the potential of human V_H (the hypervariable region of the immunoglobulin molecule which recognizes antigen epitopes) to display biostructure and biofunction of peptides designed on the ricin A-chain functional domain and could be useful in developing new antidotes to ricin.

Both vaccination (prophylaxis) and antitoxin (therapeutic) approaches bring positive and negative aspects in terms of giving protection against intoxication by ricin. It is unlikely that a vaccination strategy would be adopted for the population of a whole country, when the likelihood of mass exposure to ricin toxin is improbable. On the other hand, it would be reasonable to vaccinate

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

the Armed Forces and key personnel in a vulnerable organization. It is likely that policy would dictate that a therapeutic approach would be adopted on a needs basis. Such an approach would ideally require robust indication that ricin had been deployed, but also reliable and timely identification of victims of ricin exposure. Since the administration of large quantities of foreign protein (antitoxin molecules) may well not be without side effects, the antitoxin would not be given unless necessary.

9.3 Other Possible Postexposure Approaches

A number of lines of research have recently been explored, which aimed to interfere with the process of intoxication by ricin using a number of approaches. Studies have attempted to identify strategies which may interfere with the binding of toxic lectins, including ricin, with cell-surface glycoconjugates, or have looked at molecules interfering with the cellular uptake of ricin or through the production of inhibitors of the *N*-glycosidase activity of RTA. Examples of these approaches will be examined in more detail.

One novel approach for the potential therapy of ricin intoxication was the investigation of mono- or polyvalent carbohydrate inhibitors (galactose and lactose analogues) to inhibit ricin binding to cell surface receptors. These molecules were less effective than galactose and lactose themselves. However, promising results were obtained for a self-assembled lyotropic mesophase gel containing novel synthetic galactose-based surfactants, which sequestered ricin from aqueous solution (Dawson *et al*., 2006). Another group investigated the potential for synthetic glycoclusters based on calixarenes with thiourea-linked galactose or lactose moieties to bind the ricin-related ribotoxin viscumin. Calyx[6,8]arenes were reported to be very effective in this respect (André *et al*., 2008). Potential inhibitors of the *N*-glycosidase enzyme, which is the toxic activity attributed to the RTA chain, have been explored by Sturm *et al*. (2007). Synthetic circular DNA or DNA/RNA hybrid nucleotide sequences were characterized as substrates for RTA *N*-glycosidase and as potential inhibitor scaffolds. Small circular DNA and DNA/RNA tetramers were found to be promising scaffolds for RTA inhibitor design. A nanomolar inhibition constant was determined for the circular oligonucleotide containing the RTA transition state analogue diazabutadiene methyl (DADMe)-*N*-benzyl (*N*-Bn). The best inhibitor was cyclic G(*N*-Bn)GA with a K_i of 70 nM, making it the lowest-molecular-weight nanomolar inhibitor of RTA. Various modifications to the structures of potential inhibitor sequences may improve performance, but these compounds hold promise as potential inhibitors of RTA.

A further research study has targeted the retrograde transfer of ribotoxin A chain through the trans-Golgi network from the ER to the cytosol, where they gain access to their ribosomal RNA substrate. Two novel compounds which interfere with this process and prevent shiga toxin and ricin-mediated inhibition of protein synthesis have been identified (Saenz *et al*., 2007).

In summary, a vaccination approach is very feasible against fatal intoxication by ricin, but development and licensing is time-consuming and expensive. A therapeutic approach using, for example, antitoxin, is also feasible and cheaper, but adds the requirement for specific and timely knowledge of exposure in order to implement treatment. Several novel lines of research are currently investigating the potential to protect against ricin poisoning through interfering with toxin binding, toxin *N*-glycosidase activity or the retrospective transfer of ricin A chain to the cytosol via the trans-Golgi network. Such inhibitor studies are only at the developmental stage and have yet to be tested *in vivo.*

Research using cultured primary epithelial cells has demonstrated that the addition of ricin induces them to express multiple proinflammatory molecules through the activation of stress-activated protein kinases (SAPKs) and nuclear factor (NF)-$\kappa\beta$ (Wong *et al*., 2007). Studies *in vivo,* covered above, demonstrate that ricin administration leads to tissue inflammation. Using a chemical inhibitor or short, interfering RNA, the inhibition of p38 MAPK or NF-$\kappa\beta$, respectively, reduced the expression of proinflammatory genes. The authors have speculated that these would be good targets to consider for the modulation of ricin-induced inflammation to ameliorate the consequences following a ricin poisoning.

ACKNOWLEDGEMENT

The authors are most grateful to Mr. Bryan Lingard (BL), (Detection), Mr. Christopher Taylor (CT) and Mrs. Jan Platt (JP), (both Biomedical Sciences), all of Dstl, for providing photographic images for this chapter. BL prepared images of representations or RCA_{60} and RCA_{120} molecules (**Figure 2A,B**). CT and JP provided images of *Ricinus* seeds (**Figure 1**), histopathological sections (**Figure 3A–C**) and stomach and intestine from mouse dosed orally with ricin (**Figure 4**).

Occupation, Toxic Exposures and Health Effects

Hilton C. Lewinsohn

CONTENTS

1 INTRODUCTION

It is impossible to discuss a topic such as 'Occupation, toxic exposures and health effects' without referring to Bernardino Ramazzini's unique treatise *De morbitus artificum* ('Diseases of Workers') first published in Modena in 1700 and rewritten in 1713 (Wright, 1993). Nobody before this had written a comprehensive treatise on occupational diseases and their possible prevention. Ramazzini stated that 'Various and manifold is the harvest of diseases reaped by certain workers from the crafts and trades that they pursue'. His major literary contribution to the study of occupational and environmental illness is in these two treatises, and the importance of a physician's medical history is outlined by him as follows:

> *When you come to a patient's house, you should ask him what sort of pains he has, what caused them, how many days he has been ill, whether the bowels are working and what sort of food he eats. So says Hippocrates in his work Affections. I may venture to add one more question: What occupation does he follow?*

The recognition of clinical findings and disease, related to occupation and industry, resulted in great strides occurring towards the development of a systematic classification of this subject. The recognition of occupational medicine can be attributed to Hippocrates and his followers and he advised them 'to observe the environment of their patients' (Ellenbog, 1524). As a result of this practical approach, the basis of curative occupational medicine was developed. In mining towns silicosis was diagnosed, as were lead poisoning and other lung diseases (Ellenbog, 1524).

Another important physician, Georgius Agricola (1494–1555) observed the mining of gold and silver.

In *De Re Metallica* he described 'consumption', which caused early deaths among miners, and which today would probably be considered to be due to silicosis or some other pneumoconiosis (Hunter, 1955).

Paracelsus (1493–1541) studied the diseases of metallurgists and wrote about 'acute and chronic forms of mercurialism'. He also described diseases affecting miners (Hunter, 1955). But, it was obviously Ramazzini who added the significant question regarding occupation, and then went on to describe diseases which he attributed to the various work types involved. Hunter (1955) states that

> *In the course of carrying out his resolve Ramazzini inquired into the conditions of work and the occupational diseases of the following types of workers: miners of metals, healers by inunction, chemists, potters, tinsmiths, glass workers and mirror makers, painters, sulphur workers, blacksmiths, workers with gypsum and lime, apothecaries, cleaners of privies and cesspits, fullers, oil pressers, tanners, cheese makers and other workers at dirty trades, tobacco workers, corpse carriers, midwives, wetnurses, vintners and brewers, bakers and millers, starch makers, sifters and measurers of grain, stone cutters, laundresses, workers who handle flux, hemp and silk, bathmen, salt makers, workers who stand, sedentary workers, runners, grooms, porters, athletes, those who strain their eyes over fine work, voice trainers, singers, farmers, fishermen, soldiers, learned men, nuns, printers, scribes and notaries, confectioners, weavers, coppersmiths, carpenters, grinders of razors and lancets, brick makers, well diggers, sailors and rowers, hunters and soap makers.*

Ulrich Ellenbog (1440–1499) wrote the first work on an occupational disease in 1473, but it was not published until 1524. This pamphlet described the miners' diseases and is said to be the first known work on industrial hygiene and toxicology (Ellenbog, 1524). The study of occupational hazards apparently lay dormant with regard to making specific medical investigations of diseases they caused. The physicians following Ramazzini did not concentrate on industrial illnesses as a whole, but described individual cases which they attributed to isolated tasks.

Hunter (1978) points out that the changes which took place in England between the years 1760 and 1830 are comparable to a revolution in industry, and the term *die industrielle Revolution* was used as early as 1845 by Friedrich Engels in his *Die Lage der arbeitenden Klasse in England.* Hunter states that the credit for originating the comparison is generally ascribed to Arnold Toynbee, whose book, unfinished when he died, was published in 1884 under the title *Lectures on the Industrial Revolution in England.*

As a result there were no significant advances in the study of occupational medicine until Sir Thomas Legge (1863–1932) began to study public-health matters in Europe (Harrington, 1998). Based in the United Kingdom, while serving as medical inspector, he promoted the investigation of occupational diseases and measures to be taken to prevent them. Among the subjects he studied were lead poisoning, anthrax, toxic jaundice and brass-founders' ague. He visited workplaces, examined workers, undertook statistical analysis, risk assessments and, finally, proposed preventive measures. He pointed out that there was widespread ignorance of occupational diseases in the medical profession and recommended that a detailed curriculum on occupational medicine be developed for medical students.

> *As a result of his close contact with the worker he was able to show that lead poisoning resulted from the inhalation of lead and he could then propose preventive measures to decrease the incidence of cases.*
>
> (Harrington, 1998)

The subject of occupation, toxic exposure and health effects, dealt with in this chapter, will review processes involving chemicals, used in various forms, in the manufacture of products in common use by the populations of industrialized countries. It has to be understood that the time lapsed since reports on occupational toxicology in the past century, and the present requirements for the manufacture and modern day usage of industrial chemicals, the hazards and environments presently described are very different from those studied by Legge and others. In this chapter, an attempt will be made to discuss the toxicity and health problems associated with the use of chemicals in the workplace in the twenty-first century. The workplace includes, not only the factory using the raw chemicals and producing finished products, but the source of origin of the materials, the uses of the manufactured products and the disposal of waste generated. The entire course of manufacture and usage will be discussed. Industry standards and government regulations educate workers and their employers in the safe handling of toxic materials, and industrial hygiene standards, which establish exposure levels and regulations for their control. The composition of factory work populations and the life standards they now enjoy, will be taken into consideration when examining the toxicity of the chemicals with which they are in contact.

2 TOXICOLOGY

Toxicology is the science which studies toxic substances, how to detect them and their chemical actions in exposed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat153
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

individuals. The development of control standards, exposure monitoring and the treatment of toxic health effects is the practical outcome of such findings.

Peter S. Thorne has stated that:

> *Occupational toxicology is the application of the principles and methodology of toxicology toward chemical and biological hazards encountered at work.* (Thorne, 2001)

In order to understand occupational toxic hazards likely to influence the twenty-first century work environment, it is necessary to study modern processes and compare them to those originally responsible for occupational toxicological illnesses. The study of occupational toxicology requires that a systematic approach is used to identify workplaces and the types found in the global environment. Employment, which is characteristic of the twenty-first century, requires documentation of materials in use, their handling and the work safety procedures in use. The introduction of modern safety and health standards is developed from knowledge of the exposure quantities involved, confirmatory data derived from human, experimental animal and cell studies, and research presenting evidence of engineering controls eliminating harmful effects.

A leading proponent of change in approach to toxicity definition and toxicity testing is the National Research Council (NRC) of the National Academies, and this is dealt with in the recent publication *Toxicity Testing in the 21st Century –A Vision and a Strategy* (NRC, 2007). The National Academies are advisers to the US Government on science, engineering and medicine, and the four academies are listed in the abovementioned publication (*http://www.national-academies.org/*). They consist of the National Academy of Sciences, The National Academy of Engineering, The Institute of Medicine and the NRC. Three committees work as agents of the groups. They are the Committee on Toxicity Testing and Assessment of Environmental Agents, the Board on Environmental Studies and Toxicology and the Institute for Laboratory Animal Research Council. Other reports of the Board on Environmental Studies and Toxicology, and the Institute for Laboratory Animal Research publications are listed in that publication (*see also* **Regulatory Toxicology**).

This chapter's focus is on occupational toxicity, on better understanding of the health effects and their prevention, by modification of hazardous existing standards. It is important to understand why an individual or group of workers develops disease when employed in a specific occupational circumstance. To do so, the work environment, and the materials handled in the various processes in manufacture of a product, must be studied. In addition, disease processes studied must be considered in the light of exposure types, and manufacturing techniques encountered. The nature of hazardous materials must be characterized and defined, depending on quantitative exposure measurements, types of materials used and human body defences studied.

Natural body defences will be dependent upon the type of material in use and the dose of exposure encountered. It is important to recognize the various portals of bodily entry, and the human tissues in particular, and organ systems in general, which react to the toxic substances encountered. Studies of the materials involved have to be conducted to determine the physical and chemical agents which are likely to cause specific effects. Occupational toxicology is concerned with the workplace environment, and occupational physicians are uniquely placed to study the effects of industrial toxins on the persons in it. Occupational toxicity is studied for the influence of societal factors, such as the general availability of healthcare, the level of cultural and technologic development of the population, and the degree of government and industry regulatory control exercised. In the USA, the National Toxicology Programme (NTP), which is in the Department of Health and Human Services (DHHS), relies on its Office of Chemical Nomination and Selection for public comments on toxicological studies to be considered by the NTP. The agency which is involved is the National Institute of Environmental Health Sciences (NIEHS), National Institutes of Health (NIH). The requirements are published by NIEHS in the *Federal Register* (FR) specifying how NTP solicits and accepts nominations for toxicological studies to be undertaken by the programme. Nominations of substances of potential human-health concern are received from federal agencies, the public and other interested parties. These nominations are subject to several levels of review before selections for testing are made and toxicological studies are designed and implemented. Brief background information and preliminary study recommendations regarding nominations for study by the NTP are provided, public comment and study recommendations on nominations are solicited, and the submission of additional relevant information for consideration by the NTP in its continued review of these nominations is requested.

The NTP actively seeks to identify and select for study chemicals and other substances for which sufficient information is not available to adequately evaluate potential human-health hazards. The NTP accomplishes this goal through a formal open nomination and selection process.

Our environment, in which we work and live, must be kept under surveillance for illnesses, to detect hazardous chemicals, and other workplace factors, which could account for them. For example, cancer research scientists have shown in many studies of our work environment, and our living circumstances, how they contribute to the development of cancer.

> *The scope of toxicology is enormous, since virtually every known chemical, if present in sufficient amount,*

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

has the potential to produce injury or death. In our modern society, toxicologic tests are used to evaluate the potential health hazards that may result from exposure to environmental pollutants, food additives, pharmacologic agents, and occupational exposures among others.

(Logan, 1994)

3 WORKPLACE HAZARD RECOGNITION

Recognition of workplace hazards has been discussed in many different publications in the occupational health literature since at least 1700 AD. In the opening remarks in this chapter this has been pointed out already. Over time, the science of toxicology has evolved and the study of industrial chemical and physical hazards has been developed. The recognition of workplace toxic hazards is now an important factor in the development of safety and health-control-management processes in the work environment. The toxic effects threat is not only confined to the chemical manufacturing industry, but general industry must also be aware of it, since the chemicals will be used in many processes. In addition, it must be recognized that in some instances the hazard spreads beyond the factory fence and exposes the local population to its ill effects. The general industrial population may be exposed in many processes, such as painting, packaging products, cleaning plant machinery, using adhesives for purposes of assembly and many other similar tasks. Modern industrial processes have changed extensively, and, in the twenty-first century, potential exposures are now covered by the term 'occupational and environmental health'. Modern production processes have dramatically changed and are now responsible for 'atmospheric pollution, carcinogenesis, biological monitoring, ergonomics, epidemiology, product safety and health promotion' (Groneberg and Fischer, 2006). The Occupational Safety and Health Act (OSH Act) of the United States Department of Labor Occupational Safety and Health Administration (OSHA) has defined toxic industrial chemicals (TICs). The OSH Act defines toxic industrial TICs as 'industrial chemicals that are manufactured, stored, transported and used throughout the world'. TICs may be gases, liquids or in the solid state. Chemical hazards may be carcinogenic, reproductive toxins, corrosives or pulmonary or haematotoxic hazards. Physical agents may be flammable, combustible, explosive or reactive. **Table 1** is published by the OSHA and lists the most common TICs by their hazard index. It is interesting to note in the twenty-first century, that the OSHA feels that, because of terrorist events, concern has been expressed by some about the possibility of an attack using TICs or toxic industrial materials (TIMs). The OSHA notes that these agents can be highly toxic and are produced in large quantities. It is necessary for industrial workers to understand what TICs are and how they may affect their health. The occupational physician has to be aware of the toxic effects attributable to materials and products present in the workplace, and the possibility of extending their exposure to the outside world. The physician has to be able to determine the risk to factory workers, and to users of the finished products, as well as the general population exposure to waste dusts, gasses and other environmental contaminants. The magnitude of the risk will determine how to safely control the environment for the populations potentially exposed. The physician and other occupational-health workers, such as engineers and industrial hygienists, must maintain records to enable them to eliminate risks. It is important to correctly identify suspected hazardous materials. One example of such a procedure is for an occupational hygienist, personally protected by suitable safety equipment, to collect samples of suspected harmful materials and have them analysed by a laboratory specializing in such work. In the USA, users of known hazardous materials must maintain material safety data sheets (MSDSs) prepared by the manufacturer. These sheets are found to give reasonable information on safety hazards, but describe incompletely toxic effects of compounds.

Toxic dose is measured in milligrams per kilogram body weight ($mg\,kg^{-1}$) or, in the case of fluids, milligrams per litre ($mg\,l^{-1}$). The amount of chemical present is expressed in milligrams (mg); the weight of the exposed subject (human or animal) is expressed in kilograms (kg) and l stands for litre of air. The lethal toxicity of a substance may be expressed according to the dose that causes death in half the test animals exposed and is called an LD_{50} (lethal dose) or LC_{50} (lethal concentration). Tests are usually performed using rats or mice. The higher the LD_{50} or LC_{50}, the lower the toxic fatal dose, therefore indicating that more chemical exposure is needed to result in death. The opposite finding, of a low LD_{50} or LC_{50}, means that there is a higher toxicity, and a lesser amount of the chemical causes death in 50% of the population being tested. These results are due to acute exposure effects, but cannot provide data to allow determination of chronic health effects.

In product manufacture, in the twenty-first century, exposure of factory workers is probably negligible, as processes are largely carried out in enclosed equipment, at least in well-developed countries. Mixing and formulation may not be as easily controlled and packaging, warehousing and distribution are still likely sources of exposure to workers. Workers who repair, maintain and clean factory production equipment in which the products are manufactured are still at risk of being exposed. Potential for exposure exists in handling the raw materials which may be delivered by pipeline, rail, ship or barge, or in tank-trucks.

Table 1 Toxic industrial chemicals (TICs) listed by hazard index

High	Medium	Low
Ammonia (CAS# 7664-417)	Acetone cyanohydrins (CAS# 75-86-5)	Allyl isothiocyanate (CAS# 57-06-7)
Arsine (CAS# 7784-42-1)	Acrolein (CAS# 107-02-8)	Arsenic trichloride (CAS# 7784-34-1)
Boron trifluoride (CAS# 10294-34-5)	Acrylonitrile (CAS# 107-13-1)	Bromine (CAS# 7726-95-6)
Boron trifluoride (CAS 7637-07-2)	Allyl alcohol (CAS# 107-18-6)	Bromine chloride (CAS# 13863-41-7)
Carbon disulfide (CAS# 75-15-0)	Allylamine (CAS# 107-11-9)	Bromine pentafluoride (CAS# 7789-30-2)
Chlorine (CAS# 7782-50-5)	Allyl chlorocarbonate (CAS# 2937-50-0)	Bromine trifluoride (CAS# 7787-71-5)
Diborane (CAS# 19287-45-7)	Boron tribromide (CAS# 10294-33-4)	Carbonyl fluoride (CAS# 353-50-4)
Ethylene oxide (CAS# 75-21-8)	Carbon monoxide (CAS# 630-08-0)	Chlorine pentafluoride (CAS# 13637-63-3)
Fluorine (CAS# 7782-41-4)	Carbon sulfide (CAS# 463-58-1)	Chlorine trifluoride (CAS# 7790-91-2)
Formaldehyde (CAS# 50-00-0)	Chloroacetone (CAS# 78-95-5)	Chloroacetaldehyde (CAS# 107-20-0)
Hydrogen bromide (CAS# 10035-10-6)	Chloroacetonitrile (CAS# 7790-84-5)	Chloroacetyl chloride (CAS# 79-04-9)
Hydrogen chloride (CAS# 7647-01-0)	Chlorosulfonic acid (CAS# 7790-94-5)	Crotonaldehyde (CAS# 123-73-9)
Hydrogen cyanide (CAS# 74-90-8)	Diketene (CAS# 674-82-8)	Cyanogen chloride (CAS# 506-77-4)
Hydrogen fluoride (CAS# 7664-39-3)	1-2-Dimethylhydrazine (CAS# 540-73-8)	Dimethyl sulfate (CAS# 77-78-1)
Hydrogen sulfide (CAS# 7783-0604)	Ethylene dibromide (CAS# 106-93-4)	Diphenylmethane-4.4′-diisocyannate (CAS# 101-68-8
Nitric acid, fuming (CAS# 7697-37-2)	Hydrogen selenide (CAS# 7783-07-5)	Ethyl chloroformate (CAS# 101-68-8)
Phosgene (CAS# 75-44-5)	Methanesulfonyl chloride (CAS# 124-63-0)	Ethyl chlorothioformate (CAS# 2941-64-2)
Phosphorus trichloride (CAS# 7719-12-2)	Methyl bromide (CAS# 74-83-9)	Ethyl phosphonothioic dichloride (CAS# 993-43-1
Sulphur dioxide (CAS# 7446-09-5)	Methyl chloroformate (CAS# 79-22-1)	Ethyl phosphonic dichloride (CAS# 1066-50-8)
Sulfuric acid (CAS# 7664-93-9)	Methyl chlorosilane (CAS# 993-00-0)	Ethyleneimine (CAS# 151-56-4)
Tungsten hexafluoride CAS# 7783-82-6)	Methyl hydrazine (CAS# 60-34-4)	Hexachlorocyclopentadiene (CAS# 77-47-4)
	Methyl isocyanate (CAS# 624-83-9)	Hydrogen iodide (CAS# 10034-85-2)
	Methyl mercaptan (CAS# 74-93-1)	Iron pentacarbonyl (CAS# 13463-40-6)
	Nitrogen dioxide (CAS# 10102-44-0)	Isobutyl chloroformate (CAS# 543-27-1)
	Phosphine (CAS# 7803-51-2)	Isopropyl chloroformate (CAS# 108-23-6)
	Phosphorus oxychloride (CAS# 1795-48-8)	Isopropyl isocyanate (CAS# 1795-48-8)
	Phosphorus pentafluoride (CAS# 7647-19-0)	n-Butyl chloroformate (CAS# 592-34-7)
	Selenium hexafluoride (CAS# 7783-79-1)	n-Butyl isocyanate (CAS# 111-36-4)
	Silicon tetrafluoride (CAS# 7783-16-1)	Nitric oxide (CAS# 10102-43-9)
	Stibine (CAS# 7803-52-3)	n-Propyl chloroformate (CAS# 109-61-5)
	Sulphur trioxide (CAS# 7446-11-9)	Parathion (CAS# 56-38-2)
	Sulfuryl fluoride (CAS# 2699-79-8)	Perchloromethyl mercaptan (CAS# 594-42-3)
	Tellurium hexafluoride (CAS# 7783-80-4)	sec-Butyl chloroformate (CAS# 17462-58-7)
	n-Octyl mercaptan (CAS# 111-88-6)	tert-Butyl isocyanate (CAS# 1609-86-5)
	Titanium tetrachloride (CAS# 7550-45-0	Tetraethyl lead (CAS# 78-00-2)
	Trichloroacetyl chloride (CAS# 76-02-8)	Tetraethyl pyrophosphate (CAS# 107-49-3)
	Trifluoroacetyl chloride (CAS# 354-32-5)	Tetramethyl lead (CAS# 75-74-1)
		Toluene 2,4-diisocyanate (CAS# 584-84-9)
		Toluene 2,6-diisocyanate (CAS# 91-08-7)

The table, prepared by OSHA, lists the most common TICs by their hazard index.

DOI: 10.1002/9780470744307.gat153
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Methyl isocyanate (MIC), used in the manufacture of aldicarb, is a hazardous material and its effect on the general population of Bhopal in India is an example of one of the worst industrial accidents known, resulting in the loss of thousands of lives due to exposure to it.

There is now a great need for the redevelopment of the technology used in estimating toxic hazards in exposed humans, either occupational or environmental, because there is a great difference in the types of hazards in the workplace from those first recognized. The potentially toxic materials now in use are found in industrial situations which vary and in concentrations which differ greatly. It is necessary, therefore, to recognize, not only the *presence of exposure*, but also the variations in *amounts (dose)*.

> *Exposure is the amount of a given agent presented by the immediate environment, whereas dose is the amount of an agent absorbed by the individual. Thus, dose has an implicit time component, which depends on the duration of exposure. Individuals in the same environment for the same amount of time may experience different doses of a given compound because of differences in absorption or metabolism.*

4 IDENTIFIED ROUTES OF EXPOSURE AND POSSIBLE TARGET ORGANS

Occupational health depends on avoiding exposure to toxic substances present in the workplace and to products from which they may escape into the general environment.

Table 2 is an example of the incidence of occupational illnesses and injuries, and in this instance, by using an example from the Bureau of Labor Statistics (BLS) statistics published for the United States; the characteristics can be compared for a particular industry, for example chemical manufacturing, with those for private industry in general. It is important to determine how often exposure occurs, the number of times an individual or group of individuals is exposed and the timeframe of exposure occurrence. Exposure may be acute, when the actual time of exposure may be seconds or minutes and may occur at frequent or long intervals, possibly even up to a week. Chronic exposure occurs over many years or may even be regarded as lifetime in some instances. Chronic exposure is thought to be determined as spanning at least 10% of a lifetime and represents seven or more years in humans. Exposure which is between acute and chronic, as described above, and extends from more than a week to less than seven years, is labelled subchronic exposure.

5 POTENTIAL HEALTH EFFECTS IN TARGET ORGANS AND ON GENERAL BODY FUNCTION

> *Toxicity testing… is poised to take advantage of the revolutions in biology and biotechnology. Advances in toxicogenomics, bioinformatics, systems biology, epigenetics, and computational toxicology could transform toxicity testing from a system based on whole animal testing to one founded primarily on in vitro methods that evaluate changes in biologic processes using cells, cell lines, or cellular components, preferably of human origin. Anticipating the impact of recent scientific advances, the U.S. Environmental Protection Agency (EPA) asked the National Research Council (NRC) to develop a long-range vision for toxicity testing and a strategic plan for implementing the vision.*
>
> (NRC, 2007)

The occupational health hazards encountered in this early part of the twenty-first century are beginning to reflect the need for more accurate methods of detection and product composition in the light of modern engineering controls. Future progress in this field may depend upon the ability to use the knowledge and science developed by the Human Genome Project, one of the greatest biological research efforts ever made (*see also* **Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation**).

The project began to be considered in the late 1980s and, because of the efforts exerted, it fostered the development of rapid DNA sequencing technologies. The genomic sequence of the bacterium *Haemophilus influenzae* was determined in 1995, since when genomes of dozens of organisms have been defined and, above all, the human genome sequence became known by the year 2000. Scientists, clinicians, engineers and information scientists have developed new molecular and bioinformatic tools that make it possible to collect and analyse biologic datasets of unprecedented magnitude and detail. The new analytical techniques are called genomic technologies that allow sequence analyses on a genome-wide scale. The NIEHS of the US DHHS is collaborating with the National Academies' investigative arm, the NRC, to examine the toxicogenomic technologies on predictive toxicology.

The NRC's panel has clarified its task by defining the terms 'toxicogenomics' and 'predictive toxicology' as follows:

- **Toxicogenomics** is defined as the application of genomic technologies (e.g. genetics, genome sequence analysis, gene expression profiling, proteomics, metabolomics and related approaches) to study the adverse effects of environmental and

Table 2 Number and rate[a] of nonfatal occupational injuries and illnesses by selected industry, all USA, private industry, 2006 (Numbers in thousands)

Characteristic	Private industry[b,c,d]		Chemical manufacturing	
	Number	Rate	Number	Rate
Injuries and illnesses				
Total cases	4085.4	4.4	25.6	2.9
Cases with days away from work, job transfer or restriction	2114.6	2.3	15.3	1.7
Cases with days away from work[e]	1183.5	1.3	6.6	0.8
Cases with job transfer or restriction	932.1	1.0	8.7	1.0
Other recordable cases	—	2.1	10.3	1.2
Injuries				
Total cases	3857.4	4.2	22.6	2.6
Illnesses				
Total cases	228.0	24.6	3.1	35.0
Illness categories				
Skin disorders	41.4	4.5	0.7	7.4
Respiratory conditions	17.7	1.9	0.2	2.3
Poisoning	3.4	0.4	—	—
Hearing loss	24.4	2.6	0.4	4.2
All other illness cases	141.1	15.2	1.7	19.6

[a]Incidence rates represent the number of injuries and illnesses per 100 full-time workers (10 000 full-time workers for illness rates) and were calculated as: (N/EH)×200 000 (20 000 000 for illness rates) where N is the number of injuries and illnesses; EH is the total hours worked by all employees during the calendar year; 200 000, base for 100 full-time equivalent workers (working 40 hours per week, 50 weeks per year); 20 000 000, base for 10 000 full-time equivalent workers (working 40 hours per week, 50 weeks per year).
[b]Excludes farms with fewer than 11 employees.
[c]Data for Mining (Sector 21 in the North American Industry Classification System—United States, 2002) include establishments not governed by the Mine Safety and Health Administration (MSHA) rules and reporting, such as those in oil and gas extraction and related support activities. Data for mining operators in coal, metal and nonmetal mining are provided to BLS by the Mine Safety and Health Administration, US Department of Labor. Independent mining contractors are excluded from the coal, metal and nonmetal mining industries. These data do not reflect the changes the Occupational Safety and Health Administration made to its recordkeeping requirements effective 1 January 2002; therefore estimates for these industries are not comparable to estimates in other industries.
[d]Data for employees in railroad transportation are provided to BLS by the Federal Railroad Administration, US Department of Transportation. These data do not reflect the changes the Occupational Safety and Health Administration made to its recordkeeping requirements 1 January 2002; therefore estimates for these industries are not comparable with estimates for other industries.
[e]Days-away-from-work cases include those that result in days away from work with or without job transfer or restriction.
Note: Dashes indicate data that do not meet publication guidelines.
Reproduced from U.S. Department of Labor, 2008.

pharmaceutical chemicals on human health and the environment. Toxicogenomics combines toxicology with information-dense genomic technologies to integrate toxicant specific alterations in gene, protein and metabolite expression patterns with phenotypic responses of cells, tissues and organisms. Toxicogenomics can provide insight into gene–environment interactions and the response of biologic pathways and networks to perturbations. Toxicogenomics may lead to information that is more discriminating, predictive and sensitive than that currently used to evaluate exposures to toxicants or to predict effects on human health.

- **Predictive toxicology** is used (in this report) to describe the study of how toxic effects observed in model systems or humans can be used to predict pathogenesis, assess risk and prevent human disease.

At present, applying toxicogenomic technologies to risk assessment and regulatory decision-making are still mainly exploratory. The ability to enhance the measurements of risk assessments, by introducing toxicogenomic techniques, is not yet available. Toxicogenomics is not practical at present to replace existing industrial hygiene testing abilities needed for determining regulatory toxicology needs or developing practical risk assessments.

DOI: 10.1002/9780470744307.gat153
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

This subject is progressing rapidly, however, and should be carefully considered when health hazards occur in the workplace and they need to be studied by toxicological and toxicogenomic means.

Occupational toxicology studies the harmful health effects which workers may develop from employment in their industrial environment, and also includes the study of effects which can be seen in experimental animals and other researches being conducted to determine the mechanism of action of specific agents. The composition of workforces will differ according to industry, geographic location of manufacturing sites and government regulations in effect.

Industrial hygiene is the science of anticipating, recognizing, evaluating and controlling workplace conditions that may cause workers' injury or illness. Industrial hygienists have to have training in production methods, company management, toxicology, occupational medicine, epidemiology, government regulations and safety standards (legal and corporate). Industrial hygiene includes knowledge of harmful noise levels, effects of radiation, control of hazardous heat levels and heat stress, and increasingly the presence of biohazards in the workplace and its surroundings (*see also* **Occupational Toxicology and Occupational Hygiene within the European Union (EU) Chemicals Regulation**).

The information collected in the workplace and its environment will determine the programme to be developed in order to ensure the health and safety of workers and, if necessary, the population living in the neighbourhood of the manufacturing facility. In this chapter, the general workplace health programme will be discussed as determined by the industrial findings and the government-regulated materials and processes in use. The effects of chemicals may vary in different organs or body tissue exposed to them. The responses may be designated as *target organ toxicity* or *systemic toxicity*. These effects must be distinguished from *local toxicity*.

The importance of determining in-plant exposures and the various groups who handle materials as they pass through stages of manufacture, packaging and waste disposal, is necessary in subsequently implementing health controls. It is important to consider that an indirect toxic risk may be present for the population residing in the neighbourhood of a plant which contaminates their environment. The target-organ toxicity, systemic toxicity and local toxicity of chemicals used in the plant will develop the methods used for medical surveillance of exposed workers and other populations. The health and biological effects to be kept under surveillance are usually determined from either experimental animal or other studies.

The study of the toxic effects of various materials to which the population is exposed is directly related to the means of being exposed and the organs involved. The routes of exposure determine the nature of the harmful effects from the materials encountered. Toxic responses may affect target organs or biological systems (systemic toxicity). Local toxicity directly affects the site of exposure or immediate site contact, such as may occur due to acidic or corrosive action on exposed skin, inhalation damage or exposed eye surface.

Systemic toxicity requires the absorption of the harmful agent which may result in immediate damage to the organ involved, as well as expression of the harmful effect at a distant site. The organ directly affected by the harmful agent is known as the primary target organ and those less directly or seriously affected are referred to as secondary target organs.

> *The scope of toxicology is enormous, since virtually every known chemical, if present in sufficient amount, has the potential to produce injury or death. In our modern society, toxicological tests are used to evaluate the potential health hazards that may result from exposure to environmental pollutants, food additives, pharmacologic agents, and occupational exposures among others.*
>
> (Logan, 1994)

It is well recognized that chemicals in the workplace may readily affect the skin surface if it is not protected. Many chemicals occur in the nature of fine dusts which become airborne and can enter the respiratory tract, where they produce harmful diseases, or as chemicals in a gaseous state which is readily inhalable and damaging to the respiratory system organs.

Toxic effects from exposure to various chemicals may affect:

1. The liver
2. The kidney
3. The nervous system
4. The haematopoietic system
5. The immune system
6. The cardiovascular system
7. The gastrointestinal (GI) system
8. The respiratory system.

Chemicals may be present in the workplace, with reproductive and developmental toxicity. Developmental toxicity leads to foetal death (foetotoxicity) or to birth defects (teratogenicity). Exposure to chemicals and dust products may be responsible for exerting carcinogenic effects in the human body. These effects include:

1. Lung cancer
2. Skin cancer
3. Leukaemia
4. Breast cancer
5. Prostate cancer.

The following organs are known to have been studied epidemiologically and related to occupational exposures.

Table 3 Histological classification of liver injury

Lesion type	Examples
Necrosis (type of cell death)	Carbon tetrachloride Beryllium
Steatosis (intracellular fat accumulation)	Carbon tetrachloride Ethanol
Cholestasis (cessation/flowing of bile flow)	Organic arsenicals
Fibrosis/cirrhosis (end-result of injury)	Carbon tetrachloride Trinitrotoluene
Neoplasia (development of cancer)	Carbon tetrachloride Vinyl chloride

5.1 The Liver

The liver is an important organ, and chemicals which are absorbed by the digestive tract can reach it directly via the portal blood circulation. Toxic materials may also reach the liver via the hepatic artery or portal vein, even when they arise from other routes of exposure and can be concentrated, biotransformed and excreted. Employees in the workplace may suffer liver injury following exposure to a number of materials they may encounter, which can cause either acute, possibly reversible effects or chronic cell damage leading to such conditions as cirrhosis or carcinoma. **Table 3** is an outline of the histological classification of liver injury due to exposure to toxic materials (*see also* **Hepatotoxicity**).

Liver injuries, including cancer, have been described in many workers and attributed to chemicals found in their workplace or present in the environment where their factory is located. Modern methods of workplace improvement and exposure control are reducing the occurrence of liver disease and carcinoma in employees, and also in persons exposed to environmental hazards in the atmosphere in the neighbourhood. Hepatic lesions have been attributed to workplace exposure to a number of chemicals by various patterns of exposure, ranging from acute (various organic solvents) to short-term (tetrachloroethane and trinitrotoluene) and chronic exposure (arsenicals, vinyl chloride and some organic solvents) (Stacey *et al*., 1993).

5.2 The Kidney

Occupational exposure to chemicals, such as lead and cadmium, may be involved in causing renal failure (Bernard and Lauwerys, 1992). Coke-oven workers, exposed to emissions from this process, are at risk of developing malignant neoplasm of the kidney, and unspecified urinary organs (Goldham, 1994). Occupational exposure in the work environment that may be associated with renal disease include metals (e.g. mercury, lead, cadmium, etc.), organic solvents (e.g. carbon tetrachloride, trichloroethylene), glycols, chemicals involved in plastics manufacture and resins (acrylonitrile, styrene, etc.) and herbicides such as diquat and paraquat (Haschek, 1993a) (*see also* **Responses of the Kidney to Toxic Compounds**).

5.3 The Nervous System

> *… no precise figures are available on the total number of chemicals in existence that are potentially neurotoxic to humans.*
>
> (US Congress, 1990)

The nervous system consists of the brain, spinal cord and many nerves that control most important body functions. Neurological disorders may develop in workers in various occupations as the result of exposure to specific chemicals, which result in pathological lesions. Nerve cells affected by specific toxic substances are usually unable to recover, with the exception of the peripheral nervous system. Effects of neurotoxicity may be classified as follows:

- Immediate: Almost instant effect which may continue for several hours
  - *Examples*:
    - Antiseizure preventive agents
    - Alcoholic beverages
    - Fumes from a can of paint
- Repeated: Over weeks or years
  - *Examples*:
    - Regularly breathing solvent fumes in the workplace
    - Eating food or drinking water contaminated with lead.

Some chemicals have the ability to permanently damage the nervous system after only one exposure. It should also be recognized that substances, which individually are not toxic, may become hazardous if combined with certain other chemicals. It must also be recognized that some chemicals may be regarded as safe at one concentration, but then become neurotoxic in larger doses. It is not possible to present an exhaustive section of this chapter to deal with the nervous system and neurotoxicity. In an attempt to describe neurotoxicity briefly and include this in the overall subject heading for this chapter, 'Occupation, toxic exposure and health effects', tables from literature on occupational toxicology and texts from occupational and environmental medicine have been abstracted and are presented (**Tables 4**, **5** and **6**).

It is important to recognize that the diagnosis of neurotoxicity depends on demonstrating suspected substances in the workplace or general environment to which the work population or neighbourhood population has been exposed. The effects of such exposure may be associated

Table 4 Occupational diseases: brain and spinal cord

Neurological effect	Agent(s)
Toxic encephalopathy	
Acute	Organochlorine pesticides
	Arsenic (and arsine)
Damage to basal ganglion	Carbon monoxide
	Manganese
	Carbon disulfide
Damage to cerebellum	Organic mercury
Damage to occipital cortex	Organic mercury
Intracranial pressure	Lead
	Organotins
Chronic	Carbon disulfide
	Organic solvents
	Lead
	Inorganic mercury
	Arsenic
	Manganese
Encephalic syndromes	
Parkinsonism movement disorders	Carbon monoxide
	Manganese
	Carbon disulfide
	Methylphenyltetrahydropyridine
Dyskinesia and tremors	Methyl bromide
Toxic tremors	Mercury
	Organophosphorus compounds
	Tetrachloroethane
	Hexachlorocyclohexane
Isolated convulsive crises	Organochlorine pesticides
	Carbon tetrachloride
	Nitrophenols
	Nitrocresols
	Lead
Bulbar (brain stem) syndromes	Hydrocyanic acid
Spinal cord syndromes	
Polyneuritis	Thallium; triorthocresol phosphate

Adapted from Chapter 3, 'Systemic Toxicology', Occupational Toxicology pages 51–52, Edited by Neill H. Stacey, published by Taylor & Francis, 1993.

with findings demonstrated by various examination techniques during clinical examination and the use of supplemental tests such as electroencephalography and electromyography (*see also* **Neurotoxicology**; **The Role of Behavioural Toxicity in Risk Assessment**).

More than 65 000 chemicals are in the US Environmental Protection Agency's (EPA's) inventory of toxic chemicals, and each year the EPA receives approximately 1500 notices of intent to manufacture new substances (NAS, 1984). Greater exposure to some toxic substances can affect workers in industry and agriculture than occurs in the general population. The US National Institute for Occupational Safety and Health (NIOSH) has recognized neurotoxicity as one of the United Nations' 10 leading causes of work-related disease and injury. Neurotoxic substances include metals, such as lead and mercury, organic solvents, pesticides, such as organophosphates, thallium and chlorinated phenol derivatives, gases, such as methyl bromide and carbon dioxide, and other organic compounds.

It has been noted that an increase in some brain cancers has been reported in a number of occupations involving exposure to chemicals. Ionizing radiation is an established environmental cause of brain tumours (Preston-Martin, 1996). Occupational exposure to radiation has been consistently linked to adult brain tumours (Alexander and DiMarco, 2001) and has also been linked to childhood brain tumours in the offspring of people exposed to radiation at work. It has been suggested that there is an increased risk of brain cancer in farmers than in the general population (Blair *et al*., 1985) which may be due to pesticide exposure (Viel *et al*., 1998). Solomon (2003) summarizes this problem as follows:

> *... brain tumors may be caused, at least partially, by environmental factors. Although living on a farm*

is clearly associated with an increased risk of this disease, it is not clear whether the causal factor is related to pesticides, microorganisms, petroleum products, or other farm exposures.

She goes on to state:

The data on other factors, such as solvents, industrial chemicals, EMF (electromagnetic field), and cell phones are conflicting, and it is not clear to what degree these links are important in the disease.

5.4 The Haematopoietic System

The haematopoietic system has two components, blood and bone marrow. Blood cells are produced in the bone marrow, which keeps their content at a normal level in the circulating system and allows them to function in the body. Bone-marrow function and development may be suppressed or bone-marrow carcinogenesis may result from toxic exposures. When the red-cell development is suppressed it will be manifested as anaemia and examples are those caused by overexposure to lead or arsenic. Cytopenia may result in some instances, and, depending on the nature of exposure, all cell types may be affected. Pancytopenia and aplastic anaemia are two examples of this being attributable to such chemical exposures as benzene or trinitrotoluene. Bone marrow may also be harmed by chemical therapeutic drugs or radiation. Benzene exposure has also been associated with leukaemia.

Direct toxicity can be found to lead to red cells or white cells which have already entered the blood stream being reduced in number. Arsine may cause harmful toxicity to red cells and produce hemolytic anaemia. Chemicals which are toxic to white cells in the circulation cause cytopenia. Certain chemicals may cause methaemoglobinaemia (e.g. aniline, nitrobenzene) or carboxyhaemoglobinaemia due to exposure to carbon monoxide. Platelets may aggregate when exposed to toxins and white cells may be phagocytosed. In view of the possible effect of chemicals on the haematopoietic system it is important to maintain a medical surveillance programme for workers where exposure to such substances may occur. It is advised that a routine blood count be done, as well as a haematological examination. Workers should also be subjected to a periodic clinical medical examination with particular emphasis on the haematopoietic system. If any abnormal findings are present, the worker affected should be kept under surveillance after removal from exposure, and appropriate treatment performed. As an example of a substance affecting a worker over time, lead exposure may induce chronic effects, of which anaemia is one. These ill effects usually resolve on removal from exposure. The reader is advised to study the literature and be aware of other chemicals or industrial circumstances which may be toxic to the haematopoietic system.

5.5 The Immune System

Immunotoxicology is the study of toxic effects of xenobiotics on the cellular and humoral components

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat153

> *of the immune system. The multiplicity of chemical and biologic agents in the home and workplace and their complex interactions within the immune system make this field confusing and difficult to assess.*
>
> (Donald and Faenham, 1994)

The immune system includes a circulatory component, as well as a presence in other tissues. T-lymphocytes arise in the neonatal thymus, while others are processed into B-lymphocytes in the bone marrow, lymph nodes, appendix and other GI-tract-associated lymphoid tissues. Some lymphoid stem cells become natural killer (NK) cells without direct involvement of the thymus and bursal tissue. The major cell types and their functions are shown in **Table 7** published by N.H. Stacey in Chapter 3, Systemic Toxicology, page 62 (*Occupational Toxicology,* Edited by Neill H. Stacey, published by Taylor & Francis, 1993).

Peter S. Thorne states:

> *Injury affecting the immune system may arise from the immune-suppressive effects of chemicals such as dioxins or toxic metals. Many occupational diseases of the immune system occur due to hypersensitivity leading to respiratory or dermal allergy or systemic hypersensitivity reactions. Autoimmune syndromes have been associated with occupational exposures to crystalline silica and vinyl chloride.*
>
> (Thorne, 2001)

John E. Salvaggio writes:

> *Symptoms allegedly resulting from chronic exposure to low levels of synthetic and natural organic and inorganic environmental chemicals have led to the coining of terms such as 'environmental illness', 'ecologic illness', 'twentieth century disease', 'multiple chemical hypersensitivity syndrome' and 'chemical AIDS.*
>
> (Salvaggio, 1994)

Salvaggio goes on to indicate that these effects are from exposure to many industrial and domestic chemicals, atmospheric pollutants, exhaust fumes, insecticides, preservatives, cigarette smoke and related environmental contaminants (Salvaggio, 1994).

It is now recognized that the immune system may be affected by toxicity as a result of exposure to industrial hazards, environmental pollutants from chemical manufacture and from the manufacture of pharmaceutical products. Immunotoxicity of materials to which humans may be exposed is not well defined as yet, but is now becoming a subject of evaluation and concern. Three subsections of immunotoxicity have been identified (Luster, 1994), namely:

- Direct immunotoxicity
- Hypersensitivity
- Autoimmunity.

Jacques Descotes *et al*. state that 'little is actually known of the immunotoxic effects of chemicals in humans' (Descotes *et al*., 1996).

The US Congress, Office of Technology Assessment has published *Identifying & Controlling Immunotoxic Substances-Background Paper, OTA-BP-BA-75* (Washington, DC: US Government Printing Office, April 1991), which is a valuable resource and 'examines a field of study rife with jargon' (OTA, 1991). In this paper, 'immunotoxicity, or an immunotoxic effect, is defined as an adverse or inappropriate change in the structure or function of the immune system after exposure to a foreign substance'.

The study examines industrial, transportation, agricultural and household chemicals, as well as drugs and food additives. Antigens are substances that provoke an immune response. The reader is referred to the International Programme on Chemical Safety (IPCS), which is a joint venture of the United Nations Environmental Programme, the International Labor Organization and the World Health Organization (WHO). The document is found in the WHO Library Cataloguing-in-Publication Data (WHO, 1996). The subject of the immune system, its functions and testing workers for the effects of exposure to various agents, is a matter for this chapter to discuss in detail. **Table 8** is equivalent to US Congress Office of Technology Assessment (Table 1-1) referred to previously. When copied into this section of this Chapter it is valuable in studying the common immunotoxicological tests which can be used (*see also* **Toxicology of the Endocrine System**).

5.6 The Cardiovascular System

Occupational hazards in the workplace which cause cardiovascular injuries or disease are difficult to recognize and are relatively uncommon. Many chemicals

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 8 Common immunotoxicological tests

Category	Test
Pathology	Haematology
	Organ weights
	Histology
	Cellularity
Humoral immunity	Antibody plaque forming cell (PFC) response
	B cell litogen response
	Immunoglobulin levels in serum
	Quantitation of splenic and/or peripheral blood T cells
Cell-mediated immunity	T-cell mitogen response
	Cytotoxic T lymphocyte (CTL) cytolysis
	Delayed hypersensitivity response
	Mixed leucocyte response (MLR)
	Quantitation of splenic and/or peripheral blood T cells
Nonspecific immunity	Natural killer cell activity
	Macrophage counts
	Neutrophil counts
Host-resistance	Syngeneic tumour cells:
	PYB6 sarcoma (tumour incidence)
	B16F10 melanoma (lung burden)
	Bacterial models:
	Listeria monocytogenes (mortality)
	Streptococcus species (mortality)
	Viral models:
	Influenza (mortality)
	Mouse cytomegalovirus (mortality)
	Parasite models:
	Plasmodium yoelii (parasitaemia)
Hypersensitivity	Draize test
	Open epicutaneous test
	Buehler test
	Freund's complete adjuvant test
	Optimization test
	Split adjuvant test
	Guinea pig maximization test
	Mouse ear swelling test
	Respiratory rate measurement
	Serum IgE measurement
	Local lymphnode proliferation assay

Note: Immunotoxicologists seldom perform each test or type of test for a particular substance. They often divide the tests into tiers, using tests that indicate immune system damage at a fairly gross level to screen for potential immunotoxicants, and applying more sensitive and specific tests only to those substances that indicate possible toxicity in the primary screen. These tests are described in Chapter 1 of the Background Paper 'Identifying and controlling Immunotoxic Substances'.
Reproduced from Congress of the United States, Office of Technology Assessment, 1991.

studied experimentally in animals may be found to be cardiotoxins, but in low levels in the workplace, their ability to produce cardiovascular lesions in workers has not been proven. W. M. Haschek has tabulated some of the many ways of classifying types of cardiovascular injury with illustrative examples in **Table 9** (Haschek, 1993b).

There are many sources in industry for exposure to carbon monoxide, such as furnaces and exhaust fumes from in-plant automotive trolleys. The symptoms from exposure to carbon monoxide may be headaches, dizziness and chest pain from myocardial ischaemia. On electrocardiography (ECG), where overexposure to carbon monoxide has occurred, abnormalities may be seen, such as extrasystoles or atrial fibrillation.

Other toxic materials which may be encountered by workers are those used as solvent and cleaning materials. Materials which can contain such agents are paint thinners and degreasing products, such as trichloroethylene or methylene chloride. Again, arrhythmias may be

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

caused by these solvents and sudden death may occur in some cases. According to Haschek (1993c), 'Many chemicals are known to be potentially cardiotoxic; however few have been shown to be of unequivocal importance in the workplace'. He goes on to state: 'Those workplace chemicals which have been identified as significant include: substituted aliphatic hydrocarbons, such as chloroform, fluorocarbons and propylene glycol; heavy metals such as cadmium, lead and nickel and carbon monoxide and carbon disulphide'.

Table 10 (published as Table 14.6) lists agents associated with work-related cardiovascular disease (McCunney and Schmitz, 1994) (*see also* **Cardiac Toxicology**).

5.7 The Gastrointestinal System

> *... the most important examples of occupational gastrointestinal disease, in terms of numbers and impact, are toxic hepatitis and liver and gastric cancers.*
>
> (Flemming and Beckett, 1992)

This statement indicates that persons occupationally exposed can develop gastric and liver disease as a result.

> *Toxicity is the degree to which something is able to produce illness or damage to an exposed organism. Toxicity can refer to the effect on a whole organism, such as a human or a bacterium or a plant, or to a substructure, such as a cell (cytotoxicity) or an organ (organotoxicity) such as the liver (hepatotoxicity).*
>
> (Wikipedia, 2008)

This section will summarize GI occupational diseases, and effects on the liver, from exposure to toxic chemicals encountered by persons in the industrial workplace. It is important that manufacturers and importers of chemicals identify the risks involved and keep exposed workers under medical surveillance. There are numerous chemicals used in industry, and not all have been fully classified or studied as yet. It is noted in this chapter that there may be three types of toxic entities, namely chemicals, biological toxins and physically toxic entities. The scope of this chapter is further decreased and only devoted to brief discussions of specific substances already well studied and evaluated.

The GI tract can be directly exposed to a toxic material after eating or drinking it in the workplace or it may be exposed by oral contact with a hand which handled a toxic chemical (Kemple, 2002). The following are examples of toxic effects of industrial materials to which the GI tract, or the hepatic system, are exposed and will be used for the purposes of this chapter.

5.7.1 Inorganic Lead

The history of toxicity of lead has been known for more than 2000 years. In the twenty-first century, lead toxicity is still occurring and being described, and research is being carried out on it throughout the world. Lead overexposure is still widely occurring in industry and causing illnesses. Overexposure results in impairment and disease of various forms, and may occur after varying timeframes ranging from days (acute exposure) to, in some cases, years of exposure (chronic exposure). Lead is used in some storage batteries, may be found in paint, can be incorporated into ceramic materials and can be found in explosives and bullets. Lead is of no physiological significance in the human body, but if exposure to it and absorption of it occur, it can mimic the effects of metals such as calcium, iron and zinc (see *http://en.wikipedia.org/wiki/Lead_poisoning*). There may be a history of severe GI problems such as constipation, diarrhoea, vomiting, poor appetite and weight loss associated with acute poisoning. Long-term lead exposure or overexposure to its inorganic compounds can result in severe GI disturbances and anaemia.

It is not intended to enter into prolonged discussion on lead poisoning, but merely to bring the GI system's involvement in lead toxicity to the reader's notice. There is extensive literature available on lead and its effects. It is interesting to note that most cases of lead

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat153
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

poisoning probably involve young children and are from ingestion of lead dust or flakes from deteriorating lead-based paints. It must now be remembered that fuel used in automobiles does not contain lead any longer, thus removing an environmental exposure.

The US OSHA has responsibility for the OSHA Lead Standard which 'specifies the permissible exposure limit (PEL) of lead in the workplace, the frequency and extent of medical monitoring, and other responsibilities of the employer. OSHA has set a PEL (enforceable) of lead in workplace air at 50 μ/mg^3 averaged over an 8-hour workday for workers in general industry' (*see also* **Toxicology and Biological Monitoring of Metals**).

5.7.2 Vinyl Chloride Monomer

This chemical is included here as it has been shown to be a human carcinogen which causes occupational cancer of the liver when exposed to it. A study of the mortality of vinyl chloride monomer workers employed in the United Kingdom in 1940–1974 was published and discussed this problem (Jones *et al*., 1988). These workers found that in a cohort of 5498 male workers employed for at least one year during 1940–1974 in the vinyl chloride industry in the United Kingdom and followed to December 1984, there was a significant excess of nonsecondary liver tumours with 11 deaths, of which seven were angiosarcomas. The authors found that all these deaths occurred in autoclave workers with a median latency of 25 years from the date of first exposure. In 2003, mortality from neoplasms in 10 109 men employed in a job exposed to vinyl chloride for at least one year between 1942 and 1972 at any of 37 North American factories was updated and assessed (Mundt *et al*., 2000). The authors state that previous analyses indicated associations between employment in vinyl production and increased mortality risk of cancers of the liver and biliary tract, due to increased mortality from angiosarcoma of the liver and brain cancer. Their study concluded that excess mortality from cancer of the liver and biliary tract, largely due to angiosarcoma, continued. The risk of mortality from brain cancer has attenuated, 'but its relation with exposure to vinyl chloride remains unclear'.

The above two examples of GI and liver disease, due to occupational exposure to workplace agents, are a reminder of the importance of keeping employees under surveillance and investigating any unusual health issues noted (*see also* **Organic Solvents**).

5.8 Respiratory System Toxicology

The respiratory system consists of:

- The nasal pharyngeal compartment (nares to vocal cords)
- The tracheobronchial compartment (vocal cords to respiratory bronchioles)
- The parenchymal compartment (respiratory bronchioles to alveoli)
- The pleural space.

Each component of the respiratory system has specific functions to perform and the reader should study the anatomy and known functions thereof in the abovementioned compartments. In brief, workers in industry should be protected from harmful materials which they can inspire, and in designing pulmonary defences, the type of exposure should be studied, so that inhaled toxicants are avoided, the toxicants are deactivated if possible, the employees are encouraged to clear toxicants by means of coughing and their lungs remain able to discharge toxins up the mucociliary pulmonary escalator, while also using phagocytosis (Baker, 1993).

Some diagnostic features involved in the study of respiratory toxicology will now be mentioned. Exposure to inhalable agents determines the type of effect seen, based on the anatomic areas involved or the protective systems which are affected. Exposure to respirable toxicants may produce pulmonary fibrosis, lung cancer and such conditions as occupational asthma. Occupational lung diseases are well documented and there is an extensive scientific literature database for the interested reader to study. Specific conditions which have been described and discussed over many years include coal workers' pneumoconiosis, silicosis, asbestosis, byssinosis and occupational asthma. To illustrate the means which should be utilized to prevent occupational respiratory illness, an initial medical examination should be performed and then followed on a regular basis with a periodic evaluation. The interval between initial and periodic tests, and physical exams will depend on the symptoms and signs which develop. In addition, an industrial hygiene programme should be developed to coordinate medical examination findings with exposure measurements and develop safe working conditions based on these findings. **Table 11**, published by Baker (1993) summarizes methods for detecting respiratory disease (*see also* **Inhalation Toxicity**).

6 CONTROL OF HAZARDS IN INDUSTRY

6.1 Occupational and Environmental Hazards

In the United States of America, and other countries in the industrialized world, organizations exist to regulate and control hazards in the workplace, and those which may spread in to the general environment. Illnesses, which have been discussed briefly in preceding sections of this

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

chapter are, in addition to providing care to workers, studied by various experts for developing safety standards and methods of controlling such hazards. Workplaces are sampled for hazardous materials, which have previously been studied and shown to cause occupational disease, and industrial hygienists run programmes which measure the levels of exposure in the work environment. Epidemiological studies are of value in developing preventive industrial hygiene standards, based upon the exposure levels in the workplace, and the medical findings associated with them. Engineers are trained in the design and development of workplace machinery which control air contaminants or processes which may cause direct contact with solids or fluids. It is important to develop an overall occupational programme, which includes occupational medical examinations, industrial hygiene monitoring, chemical-control engineering and routinely calculated epidemiological results, to study deviation from normal, thus indicating development of health dangers (*see also* **Occupational Toxicology and Occupational Hygiene within the European Union (EU) Chemicals Regulation**).

6.2 Basic Factors in Industrial Exposure Standards

It is the main task of the industrial hygiene specialist to develop a programme which will recognize and assess exposure levels to chemicals, physical agents or noise in the work environment. Another issue to be taken into account may be biological abnormalities caused by exposure to a harmful agent in the workplace. It is not a subject for discussion in this chapter, but ergonomic factors in industry fall within the field of industrial hygiene.

In modern industrial plants, because of strict standards imposed, most chemicals encountered at work are not hazardous at the levels found there. In some chemical manufacturing plants, exposure levels may be significantly increased, and the need arises for industrial hygiene monitoring programmes there and constant surveillance of the health of exposed employees. If the worksite is not completely isolatable, exposed workers will need to be protected by specifically designed clothes, by skin protection and by respiratory protection using appropriate breathing apparatus. It goes without saying, that a medical surveillance programme must be in effect to follow the health of such workers, and if indicated remove them from any exposure likely to be toxic to them. Employees must be aware of the hazards in the workplace by reading warning labels on materials used by them, by being warned by supervisors to read MSDSs, and by being thoroughly familiar with the Occupational Safety and Health Act requirements for preventing exposures above the OSHA Standard set, and equivalent regulations in other countries. Chemical suppliers are required by the OSHA to provide users with an MSDS for chemicals they use (known as the 'Hazard Communications Standard'). As mentioned previously, workplaces must be checked for physical hazards, biological hazards and ergonomic hazards.

6.3 Recognition and Control of Hazardous Substances

'Industrial hygiene is the science of anticipating, recognizing, evaluating and controlling workplace conditions that may cause workers injury or illness. Industrial hygienists use environmental monitoring and analytical methods to detect the extent of worker exposure and employ engineering, work place controls and other methods to control potential health hazards' (OSHA, 1998). It is stated that material contained in this publication is in the public domain and may be reproduced, fully or partially, without permission of the Federal Government.

Developing and setting occupational health standards requires determination of employee exposures to hazards and deciding how to control them. Training provided to industrial hygienists lets them anticipate, recognize, evaluate and recommend controls of the hazards detected. Their goal is to protect the health of workers and thereby prevent the contamination of their homes and communities.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat153
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Their method of achieving their task is to study the workplace for contamination and evaluate the possible routes of exposure which can be studied and controlled.

The main routes of exposure are inhalation, ingestion, skin contact and accidental injection. The role of an industrial hygienist is to evaluate the magnitude of exposure. This may be done by measuring air levels or levels in other media in use in the factory. Exposure may be calculated in parts per million (ppm), milligrams per metre cubed ($mg\,m^{-3}$) or fibres per cubic centimetre ($f\,cm^{-3}$). It is important to know how long such exposure occurs, ranging from minutes to a lifetime. The frequency with which exposure occurs may range from hours to days to longer, such as weekly, and may take place over a working lifetime.

It is not the subject of this chapter to go into great depth regarding industrial hygiene, but it is important to know that engineering, work practices and administrative controls are the primary means of reducing exposure to industrial health hazards.

- Engineering controls:
  - Replacing known toxic materials with nonhazardous ones
  - Enclosing work processes
  - Confining operations
  - Installing general and local ventilation systems
- Work-practice controls:
  - Follow required procedures to minimize exposure while operating production and control equipment
  - Regular inspection and maintenance of equipment
  - Implementing good housekeeping
  - Good supervision
  - Prohibition of eating, drinking, smoking, chewing tobacco or gum and applying cosmetics in regulated areas
- Administrative controls:
  - Schedule production and workers' tasks to minimize exposure levels.

When all the above controls cannot be implemented then it may be necessary to provide exposed workers with appropriate personal protective equipment, such as safety goggles, gloves, shoes and protective clothing, as well as appropriate respiratory equipment.

7 MEDICAL EVALUATION OF HEALTH IN INDUSTRY

7.1 Principles of Medical Surveillance and Hazardous Substances

The recognition that hazardous materials may be found in industry, and the finding of potential ill-health of workers exposed to them, has resulted in the development of surveillance programmes which follow up both the exposure findings and the health of the exposed population. The implementation of such a programme requires intimate collaboration between company management, industrial hygienists, employees and the corporate medical services. The management involved will observe employees throughout their period of work in an environment suspected of being associated with an occupational hazard. A surveillance programme notes any medical abnormality occurring in individuals in the workplace, and develops an industrial hygiene surveillance programme which will allow potential hazards to be documented. A work programme has to be developed which will intervene and lead to disease reversal or prevention. A programme established to follow the health of employees is known as medical surveillance.

7.2 Medical Surveillance

7.2.1 Work History

The new employee provides an occupational history. Details of potential exposures encountered in previous occupations will be recorded. Attention will be paid to the answers in case the content of the medical examination indicated, and special tests required, need to be modified.

7.2.2 Medical Examination

The medical history is relevant to the industry involved and known hazards in the particular workplace to which the individual is being assigned. There are two types of examination involved, namely the initial medical examination and the periodic medical examination.

7.2.2.1 Initial Medical Examination

It is important to record the applicant's past medical history and establish what previous toxic materials may have been encountered elsewhere. This may influence the initial examination and tests required for potential disease which may already be established; an example would be exposure to asbestos, which does not necessarily exhibit findings for many years.

A complete medical examination will consist of:

- Medical history
- Occupational history
- Physical examination
- Special examination such as, for example:
  - Radiology, for example chest X-rays
  - Haematology, for example blood lead counts
  - Urine analysis, for example proteins and so on
  - Pulmonary function tests, for example spirometry.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat153
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

In asbestos workers, the medical surveillance programme data records must be kept for at least 30 years and for the employee's lifetime, if possible. Similarly, such records should also be retained for 30 years in silica-exposed workers. These requirements are laid down in the USA by the OSHA Standard on Access to Employee Exposure and Medical Records (29 CFR 1910.1020).

7.2.2.2 Periodic Medical Examination

The object of the periodic medical examination is to re-evaluate the medical history and the findings which have been specifically designed for the workplace hazard involved. The periodicity of the examination will depend upon the type of hazard occurring and the timeframe for development of the effects. It may be necessary to examine the workers involved frequently, such as a matter of months, annually or even at an interval of five years. It may be decided to reduce the time between such periodic examinations when it has been determined that the longer the exposure, or time since first exposure, the more ill-effects will become recognizable. For example, since the ill-effects from exposure to asbestos dust may not manifest themselves for 15–20 years (or longer!) the periodic examination of workers exposed will be initially at five yearly instances and then reduced to annually later.

The medical examination will essentially use the same history and physical findings to determine whether the worker can continue the job, be temporarily removed from it and then reinstated on return to physical normality, or be permanently removed from further exposure. The medical examination results must be part of the overall study of the workplace, in conjunction with employers, industrial hygienists and workers.

In summary therefore, a baseline evaluation should be done for each worker potentially exposed to a workplace hazard, the workers should be followed-up at an appropriate interval, and when leaving the job should have an exit evaluation. The periodicity of the examination depends upon the exposure and the epidemiological history findings, which will suggest the time between initial and periodic examinations.

8 SUMMARY

A brief presentation of the history and evaluation of occupation, toxic exposures and health effects has been attempted in this chapter. The history of occupational medicine, as it applies to evaluation of the materials used in the manufacture and use of chemicals in various sectors of industry, is briefly outlined and famous scientists over time are mentioned.

Toxicology is the science which studies toxic substances. This chapter briefly presents the findings of studies which are involved in methods of detecting chemical actions in manufacturing units affecting exposed individuals. Occupational toxicology can be studied by occupational physicians, chemical engineers, industrial hygienists and workplace management, allowing protective controls to be developed. Toxic effects from exposure to various toxic chemicals is briefly reviewed. The review studies the effect of hazardous chemicals and presents a brief outline section for each. Included in the chapter for study of their effects are the liver, the kidney, the nervous system, the haematopoietic system, the immune system, the cardiovascular system, the GI system and the respiratory system. The control of occupational and environmental hazards is briefly discussed. The object is to mention that an overall programme must include occupational medical examinations, industrial hygiene monitoring, chemical-control engineering and routinely calculated epidemiological results. Studying the deviation from normal will allow evaluation of the results the health dangers present.

A brief outline is presented to allow familiarity with engineering controls, work practice controls and administrative controls.

Medical surveillance is briefly discussed and outlines the content of initial and periodic medical examinations.

Biotechnology: Safety Assessment of Biotherapeutics and Agribiotechnology-Derived Foods

John A. Thomas

CONTENTS

1 INTRODUCTION

1.1 History

Biotechnology has been used for centuries, but only recently has it taken on more molecular complexities in terms of the genetic manipulation of both plant and animal cells. Classically, biotechnology refers to any technique that uses living organisms (or components of these organisms) to modify or create, to improve plants or animals or to develop micro-organisms for specific uses. Biotechnology has been used for centuries in making wine, cheese, yogurt, bread and in the selective crossbreeding of both animals and plants, all leading to an enhancement of specific desirable traits. The term 'biotechnology' was first coined by a Hungarian, Karl Ereky, towards the end of WorldWar I. Ereky purportedly used the term to refer to intensive agricultural methods (Thomas, 1998). Unfortunately, the term genetically modified organisms (i.e. GMOs) is a somewhat erroneous term with regard to issues of safety or risk pertaining to foods. GMO is an old term that was coined nearly two decades ago, and by those seeking to give it a negative connotation. In retrospect, many other terms could have been adopted, included that of selective crossbreeding. Genetic engineering involves the ability to manipulate, modify or otherwise 'engineer' genetic material to produce desired characteristics. This has been the integral part of biotechnology (Liberman *et al*., 1991). Genetic engineering also encompasses recombinant DNA technology. The contemporary era of biotechnology began about three decades ago with the discovery of endonucleases or 'restriction enzymes', and their ability to selectively cut-and-paste segments of DNA. Such enzymes act as highly specific chemical scalpels and can be used to obtain specific sequences within genetic material. Thus, restriction enzymes recognize and cut DNA at precise locations. Recombinant DNA and similar genetic engineering procedures led to the transfer of genetic material across species barriers. Actually, cell biology has become another overlapping core discipline of modern

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat154
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

biology, along with genetics and biochemistry. Of course the sequencing of the human genome will undoubtedly lead to significant advances in other areas of biotechnology and to a better understanding of genetic-related diseases.

There are many uses of these new biotechnologies, such as hormone substitutes, nutritional supplements and improved crop yields, but a few examples of how this new biotechnology will impact on the quality of life. The biotechnology industry encompasses several segments, including therapeutics, vaccines, diagnostics (e.g. monoclonal antibodies (mAb)), single nucleotide polymorphisms (SNPs), agriculture and the environment. There is the potential to discover many new drug entities for the treatment of various diseases.

1.2 Transgene Technology

The introduction of transgene technologies involving the transfer of a gene from one species to another species. Genetic manipulation of laboratory mouse models for biomedical research has progressed rapidly, with so-called 'designer mice' (i.e. transgenics) being used to study immune deficiencies, cancer and developmental biology (Grosveld and Kollias, 1992; Goodnow, 1992; Thomas, 1997) (**Table 1**). Over a decade has elapsed since the development of a transgenic mouse model and its introduction into biomedical research. Transgenic animals are produced by inserting a foreign gene into an embryo, with this foreign gene subsequently becoming an integral part of the host animal's genetic material. Increasingly, there have been improvements in the techniques used for gene introduction into animals. There are several techniques that have been used, including microinjections of DNA into the pronucleus, retrovirus infection and embryonic stem cells, which can be grown *in vitro* from explanted blastocysts. All of these techniques have been employed to create chimeric animals. Transgenic animal models are only one type of at least four other classes of models that can be used to study specific disease states (Thomas, 1997).

Generally speaking, progress has been slower in developing transgene species in the plant cell than in the animal cell. Plant breeding techniques have evolved over the millennium with the purpose of improving crops. Artificially induced mutations and selection have hastened the improvements in major cereal crops. Initially, improvements in plant biotechnology have been directed at enhancing agronomic traits, including pest resistance, herbicide tolerance and disease resistance (e.g. viruses, fungi). Significant progress has been made in improving the nutritional value of many cereal grains.

1.3 Regulatory Considerations

The regulatory approval of genetically engineered products has varied widely from country to country and from product to product. The safety and regulatory-approval process for therapeutic proteins has generally proceeded without any major impediments. The approval processes for what are usually considered as 'biologics' have long been established. Alternate sources of insulin for the treatment of diabetes mellitus and of growth hormone for treating children with deficiencies have not been controversial and posed no significant risk. Other more novel therapeutic proteins have undergone more rigorous testing to insure safety and efficacy prior to any regulatory approval. Agribiotechnology involving improvements in food quality, however, has not been universally accepted by the public nor in every instance by regulatory agencies. Generally, the somewhat slower progress in the regulatory approval of genetically modified (GM) foods has not been an issue of human safety, but of environmental impact on wildlife and nontarget species.

Several countries have well-established regulatory committees or groups for biotechnology-derived drugs or biopharmaceuticals (**Table 2**). In the United States, the Food and Drug Administration (FDA), through the Center for Biologic Evaluation and Research (CBER), has oversight responsibilities for insuring safety and efficacy of biopharmaceuticals.

Regulatory responsibility for biotechnology-derived foods may involve several US agencies, including the United States Department of Agriculture (USDA), the Environmental Protection Agency (EPA) and the FDA. The FDA again has oversight on food safety (like drug safety), as it related to new plant varieties (e.g. dairy products, food-processing aids, etc.). The USDA regulates poultry products and meats and has the oversight of field tests for genetically modified crop plants. The EPA, through its regulatory responsibility for pesticides, oversees aspects of genetically altered plants with traits such as herbicide tolerance, pest resistant and potential effects on nontarget wildlife species.

Globalization of commerce has seen many agencies worldwide become involved in the regulation of GMOs (**Table 3**). GMOs involve both plant and animal biotechnologies. Several of these organizations dealing

with GMOs have been identified (**Table 3**). Some of these organizations have no regulatory authority, yet have proposed various guidelines for the use of GMOs. Harmonization and standardization of safety protocols for both biotherapeutic agents and agribiotechnology products has become well established.

Regulatory guidelines offer both advantages and disadvantages to regulatory guidelines (**Table 4**). Importantly, the advantages outweigh the disadvantages. Harmonization or adoption of consistent review protocols is imperative and will lead to better overall assessment of safety and efficacy of new biotechnology-derived products. Importantly, the review must be science-based, and it continues to evolve and keep abreast of the latest breakthroughs in technologies and food processing.

2 BIOTHERAPEUTICS

2.1 Introduction

The development of recombinant DNA technologies has enabled the pharmaceutical-related industries to manufacture large quantities of macromolecules in relatively pure forms. This has led to the production of such therapeutic proteins as human insulin, human growth hormone (hGH), human recombinant plasminogen activator (rtPA) and human erythropoietin (EPO) (Thomas, 1998). While hormone substitutes (e.g. insulin, hGH, etc.) represented an early entry in biopharmaceuticals, many other classes of therapeutic agents have been produced and are undergoing development or clinical trials. Most of the early biopharmaceuticals were represented by simple hormone replacement therapies (e.g. insulin), they did not undergo the same extensive preclinical safety and efficacy studies, such as those that would be required for

Table 4 Advantages and disadvantages of establishing regulatory guidelines[a]

Advantages

- Formalization of a consensus scientific opinion
- Promotion of consistency of review
- Improvement of quality of studies performed
- Assistance to industry

Disadvantages

- Nonuniformity in study designs
- Retreat to 'check-the-box' approach due to uncertainties
- Disincentive to industry to be creative
- Failure to appropriately incorporate new and evolving technologies

[a]Reproduced from Henck *et al*., 1996. © John Wiley & Sons Ltd.

interferon(s) (Vial and Descotes, 1994) and other drugs. Biopharmaceutical products have been approved for a variety of clinical indications (**Table 5**). New clinical indications have been approved for the interferon(s) and for other immunomodulating agents. Blood factor(s) deficiencies or disorders have benefited from these biotechnological advances as have blood-clot dissolution proteins. There has also been an increasing number of regulatory approvals for mAb. It is noteworthy that the regulatory approval of rhGH (recombinant hGH) was expedited by the discovery that some cadaveric hGH was possibly contaminated with latent neural viruses responsible for Creutzfeldt–Jacob disease.

Uses of SNPs can yield information about promising drug targets for a host of diseases. Gene-based medicine, known also as functional genomics, may hold the key to understanding and treating various diseases (e.g. Alzheimer's, diabetes mellitus, etc.).

The preclinical safety assessment of new biotherapeutic agents for human medical therapies has highlighted the issue of immunogenicity between species (Cavagnaro, 1997; Thomas, 1999). Macromolecules derived through biotechnology expectedly will challenge the immune system of the laboratory animal used for toxicological testing protocols. Despite some of these unique and early concerns, guidelines for the preclinical testing of large-molecular-weight biopharmaceuticals has proceeded, and has generally been adopted by regulatory agencies. Macromolecules represent a challenge to the design of toxicological protocols, and have also led to challenges in the formulation and delivery of biopharmaceuticals (Panchagnula and Thomas, 2000). Macromolecules also represent a challenge in noninvasive drug-delivery systems, and the use of supercritical fluid technology may produce dry powder formulations suitable for inhalation or needle-free administrations (Tservistas *et al*., 2001).

2.2 The New Biologies

The scientific disciplines of genetics, immunology and molecular biology have provided a strong impetus for advances in biotechnology, and particularly in biopharmaceuticals (Tomlinson, 1992). Certainly, biotechnology-derived products could not have progressed to their current state had it not been for the coincidental and independently developed technology of monoclonal antibody production. Certainly, recombinant DNA technologies and monoclonal antibody production are two areas that are inseparably important to the development of new biopharmaceuticals. mAb are essential in the identification, extraction and purification of most macromolecules. The term molecular biology has come to signify the biochemical study of nucleic acids, advanced by the discovery of a series of enzymes (e.g. restriction enzymes or endonucleases) that allows for specific manipulation of RNA and DNA. There are several techniques or approaches used in molecular biology (**Table 6**) (Ausubel *et al*., 1995). These technologies are advancing at a very rapid pace. The ability to manipulate the genetic material of a cell in order to modify gene expression has utilized a variety of new techniques, thus facilitating the discovery of new biopharmaceuticals. Using the appropriate mammalian expression system for the development of biopharmaceuticals is very important (Werner *et al*., 1998). New advances in the development of highly sensitive and highly specific analytical methods (e.g. high-performance liquid chromatography–tandem mass spectrometry (HPLC-MS-MS)) and caco-2 cell techniques will facilitate the entry of new biopharmaceuticals into the market (Panchagnula and Thomas, 2000).

2.3 Therapeutic Proteins

Developments in recombinant DNA technologies have focussed upon mammalian macromolecules, often peptides, for discovering therapeutically active entities (Kelley, 1996). Mammalian biotechnology has advanced more rapidly than agribiotechnology, although the latter field promises to be very fast moving. Early successes witnessed the use of prokaryotic cell systems (e.g. *E. coli*) capable of producing rather complex mammalian proteins. Subsequently, and with more advances in techniques employed in molecular biology (**Table 7**), prokaryotic cell systems were found to be able to secrete even more complex proteins and glycoproteins. Improved methods of molecular characterization made it possible to create more complex and more highly purified therapeutic entities. Mammalian organisms possess a plethora of proteins that modulate intricate physiological systems and, through biotechnology, some of these will be discovered for their therapeutic usefulness.

Generic name	Trade name	Classification	Indication(s)
Alteplase (rTPA)	Activase	Recombinant protein	Acute myocardial infarction
Tenectaplase	TNKase	Recombinant protein	Pulmonary embolism Acute mycardial infarction
Epoetin alfa (EPO)	Epogen Procrit	Recombinant protein	Anaemia of chronic renal failure Anaemia secondary to zidovudine treatment in HIV-infected patients
Antihaemophilic factor	Recombinate, Humate-P, Refacto	Recombinant protein	Haemophilia A
Factor VIII	KoGENAteFS, Helix-ate FS	Recombinant protein	Haemophilia A
Factor VIIIc	Monoclate-P	Recombinant protein	Haemophilia A
Factor IX	L-Nine SC	Recombinant protein	Haemophilia B
Tumour necrosis factor	Embrel	Recombinant protein	Active rheumatoid arthritis
Filgrastim (G-CSF)	Neupogen	Recombinant protein	Neutropenia following chemotherapy
Sargramostim	Leukine	Recombinant protein	Myeloid reconstitution after bone marrow transplantation
Interferon-α-2a	Roferon A	Recombinant protein	Hairy cell leukaemia AIDS-related Kaposi's sarcoma
Interferon-α-2b	Intron A	Recombinant protein	Hairy cell leukaemia AIDS-related Kaposi's sarcoma Hepatitis, non-A, non-B/C Condylomata acuminata
Interferon-alpha	Wellferon	Recombinant protein	Chronic hepatitis C
Interferon-α-n3	Alferon N	Human	Genital warts
Interferon-β-1a	Avonex	Recombinant protein	Multiple sclerosis
Interferon-β-1b	Betaseron	Recombinant protein	Multiple sclerosis
Interferon-γ-1b	Actimmune	Recombinant protein	Chronic granulomatous disease
I-IGF-1	Myotropin	Recombinant protein	Amyotrophic lateral sclerosis (ALS)
Aldesleukin (IL-2)	Proleukin	Recombinant protein	Kidney cancer
Dornase-α	Pulmozyme	Recombinant protein	Cystic fibrosis
Human insulin	Humulin	Recombinant protein	Diabetes mellitus
Somatrem (recombinant methionyl-hGH)	Protropin	Recombinant protein	Growth hormone deficiency
Somatropin (rhGH)	Humatrope Saizen Nutrotropin	Recombinant protein	Growth hormone deficiency
Follicle stimulating hormone	Puregon	Recombinant protein	Induce ovulation
Somatotropin (recombinant bovine GH)[a]	Posilac	Recombinant protein	Increases bovine lactation
Pegaspargase (polyethylene glycol-1-asparaginase)	Oncaspar	Polyethylene glycol modified protein	Acute lymphocytic leukaemia
Haemophilus B conjugate vaccine	HibTITER	Recombinant protein	Prophylaxis against haemophilus influenza
Hepatitis B vaccine	Engeridx-B Recombivax HB	Recombinant protein	Prophylaxis against hepatitis B infection
Satumomab	OncoScint CR103	Monoclonal antibody	Colorectal cancer imaging
Satumomab	OncoScint OV103	Monoclonal antibody	Ovarian cancer imaging
Muromonab CD3	Orthoceone (OKT3)	Monoclonal antibody	Acute allograft rejection in renal
Alemtuzumab	Compath	Monoclonal antibody	Chronic lymphocytic leukaemia

[a]From Demain, 1991; Davis, 1996.

Modern molecular biology, particularly through the use of polymerase chain reactions (PCRs), has become exceedingly important in the discovery and production of recombinant proteins. Acting as a molecular 'photocopier', PCR has been employed extensively to amplify DNA sequences. Subsequently, the design of new biopharmaceuticals has proceeded with sufficient quantities of purified material in order to fulfill the amounts required to undertake both preclinical and clinical studies. Nowadays, robot gene sequencers (e.g. ABI Prism 3700) and high-speed computers have greatly facilitated the discoveries associated with the human-genome project.

The majority of new biopharmaceuticals usually must be administered parenterally. Proteins or large peptides are vulnerable to gastric degradation and experience a loss of biological activity. There is considerable interest and need to develop drug-delivery systems for these macromolecules (cf. Tservistas *et al*., 2001). Selective drug targeting is a characteristic that is highly desirable. Progress has been made with some biotherapeutic agents by modifying their biologic dispersion characteristics (**Table 8**). Such approaches have included site-directed mutagenesis, hybrid site-specific proteins and supercritical fluid technologies. In addition, significant progress has been made towards the development of site-specific drug-delivery systems for protein and peptide biopharmaceuticals (Pettit and Gombotz, 1998)

2.4 Safety Assessment

2.4.1 General Considerations

Assessing the 'safety' of drugs produced by biotechnology resembles the assessment of conventional new chemical entities (NCE), but with certain major differences in testing protocols (Zbinden, 1990; Dayan, 1995; Cavagnaro, 1997). Several safety considerations must be incorporated into the preclinical testing protocol (**Table 9**) (Tomlinson, 1992). The quality of each biotechnology-derived product necessitates careful control because of the concern about immunogenic proteins or peptides, endotoxins released by the harvesting of prokaryotic cell systems that secrete the product, and other possible chemical contaminants emanating from processing procedures. There are at least three areas of concern regarding biotechnology-derived products: (i) toxicology issues pertaining to differences in pharmacodynamic properties, (ii) 'intrinsic' toxicity, that is, adverse effects due to the molecule itself and not directly related to pharmacological actions and

Table 7 Methodological advances in the characterization of biological products[a]

Method	Examples
In vitro bioassays	Cell culture techniques for hormones and cytokines
Gene analysis	PCR analysis (viral contaminations of blood products)
Immunological tests	Enzyme-linked immunosorbent assay (ELISA)
	Epitope mapping by panels of monoclonal antibodies
	Immunoblotting of gels (western blots)
	Testing for process-related impurities
Advanced chromatographic techniques	Size-exclusion and reversed-phase HPLC
	Capillary zone electrophoresis
Analysis of 3-D structure	Circular dichroism
	Nuclear magnetic resonance
Protein analysis by mass spectrometry	Fast atom bombardment (Fab)-mass spectrometry (antigen binding)
	Electrospray mass spectrometry
Analysis of glycosylation isoforms	Detailed structure–function studies required

(iii) 'biological' toxicity, responses resulting from the activation of a physiological mechanism (e.g. antigen–antibody reactions) (Zbinden, 1990). There are safety issues that form the basis for toxicity testing. There are safety issues pertaining to the intrinsic actions of the product itself, and there are safety issues pertaining to the cellular systems or processes that lead to the production or secretion of the macromolecule (Thomas and Thomas, 1993; Dayan, 1995; Thomas, 1995; Cavagnaro, 1997) (**Table 10**). Product-related impurities or variants might include mutants, aggregated forms and aberrant glycosylation. Process-related impurities might include pyrogens, host-cell-derived proteins, viruses and possibly prions (Jeffcoate, 1992). Reliable cell systems, expressing the correct gene and insuring its proper insertion along with any promoter is of fundamental importance. The secretion or presence of other bioactive moieties must always be considered, and needs to be addressed through proper extraction and purification processes. Protein or peptide contaminants can produce both unwanted immunologic and nonimmunologic actions. Clinical or conventional toxicologic protocols may not be relevant in attempting to characterize the phrmacodynamics of a macromolecule. Nonimmunologic testing is dependent upon the product's potential therapeutic use, and, at a minimum testing, should include biodistribution, developmental and reproductive and mutagenic/oncogenicity assessments. Protocols that define the kinetics and safety of infused recombinant proteins include bolus delivery, continuous infusion and other physiological parameters (Yaksh *et al*., 1997). It is very important that a panel for detecting possible immune alterations be an integral component of the toxicology testing protocol (**Table 11**). The first tier consists of a screening panel that evaluates immunopathology, cell-mediated immunity and humoral immunity. Tier 1 should also identify any agents that may elicit an immune response. Those agents testing positive in Tier 1 must undergo further evaluation. Tier 2 seeks to evaluate the presence of any immunopathological effects.

Table 8 Approaches for modifying the biological dispersion of therapeutic proteins[a]

Approach	Therapeutic protein
Site-directed mutagenesis	α_1-Antitrypsin

2.4.2 Antisense Drugs

The use of antisense oligonucleotides is probably the most mature in the development of macromolecular drugs (cf. Crooke, 1992; Juliano *et al*., 2001). Base pairing between relatively short oligonucleotides (12–18 residues) and complementary sequences in messenger RNA (mRNA) provide highly selective recognition that can affect gene expression.

The completion of the sequencing of the human genome was one of the early applications of antisense technology in which the primary sequencing information can be used to design short oligonucleotides to hybridize to a specific mRNA (Bennett *et al*., 1998). Once bound to the targeted mRNA in a cell, the antisense oligonucleotide prevents expression of the protein product encoded by the targeted RNA. Antisense oligonucleotides can interrupt gene expression. Antisense molecules are highly selective, and when inserted into a cell can bind particular mRNA molecules and prevent them from being translated into proteins.

Antisense drug therapy may affect pathophysiological processes at the genetic level (Harvey, 1998). Such therapies involve using modified oligonucleotides that bind specifically to target sequences of RNA to affect translational arrest or to sections of DNA to block transcription. It is noteworthy that there are naturally occurring antisense RNAs (Dolnick, 1997). Naturally occurring antisense RNAs may act as mediators of alterations in gene expression.

Some technical issues need to be overcome in order to fully exploit antisense drug development. Such issues include the size of the molecule in order to insure specificity, the chemical stability often needs to be enhanced and control of the agent's uptake and tissue distribution. Unmodified oligonucleotides are negatively charged and do not readily enter cells. However, modification of the internucleoside phosphate linkages to uncharged

[a]Condensed from Luster *et al.*, 1992.

methylphosphonates enables the oligonucleotides to gain access to the cell's interior (cf. Persaud and Jones, 1994).

Oligonucleotides may inhibit target gene expression by several mechanisms (cf. Gibson, 1994; Bennett *et al.*, 1998; Toulme, 2001). Oligonucleotides can induce degradation of the target DNA by the cellular enzyme RNase. Other mechanisms proposed to explain how protein synthesis might be inhibited include the steric blocking of ribosome assembly and splicing, and capping—all events involved in mRNA production. Also suggested is the maturation of mRNA or its translation into protein.

First-generation oligonucleotides have met with limited success due primarily to the rapid degradation of natural DNA by serum and cellular nucleases. Chemical modifications, including oligonucleotides that are resistant to nuclease degradation, have had some limited therapeutic effectiveness. The most commonly used modified oligonucleotides are the phosphorothioate oligonucleotides, in which one of the nonbridging oxygen atoms in the phosphate backbone is replaced with sulphur (cf. Bennett *et al.*, 1998).

Modified oligonucleotides have half-lives that range from 30 to 60 minutes following intravenous administration. Oral bioavailability is low due principally to nucleases present in the gastrointestinal (GI) tract. Biodistribution reveals relatively high concentrations in the liver and kidney.

The pharmacologic implications for antisense therapy may encompass virology, oncology and the cardiovascular system. Pulmonary, immuno- and neuropharmacology are also potential targets. Cancer-related targets such as Bcl-2, Raf-1, the protein kinase C (PKC) isoenzymes, and BCR-Abl have attracted considerable attention. Members of the Bcl-2 family are important regulators of apoptosis and represent attractive targets for the development of anticancer drugs. Targets involved in inflammation (e.g. ICAM-1) and viral diseases are also being developed (Juliano *et al.*, 2001). Most emphasis has been placed on the development of antiviral therapy, cancer therapy and anti-inflammatory therapy. Forevirsen (ISIS 2922) is an agent indicated for cytomegalovirus (CMV) retinitis; vitravene is an antisense agent used for the topical treatment of CMV retinitis in AIDS patients.

Antisense phosphorothioate nucleotides exhibit four distinct types of toxicity (Bennett *et al.*, 1998):

1. Sequence-specific toxicity due to exaggerated pharmacological actions
2. Sequence-specific toxicity due to serendipitous hybridization to nontarget RNA
3. Sequence-specific toxicity due to nonantisense effects
4. Sequence-independent toxicity; nonantisense effects.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat154
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The major toxicological concerns associated with antisense drugs are related to their interaction with non-nucleic-acid targets. Expectedly, species differences play a role in the toxicity of the antisense drugs. In rodents, immune-cell activation appears to be a dose-limiting toxicity. In primates, acute effects on the complement system and anticoagulation effects have been observed. Transient fluctuations in blood pressure occurring during preclinical toxicology assessment may be due to the activation of the complement system.

Emerging technologies will allow the effective intracellular delivery of large molecules including antisense oligonucleotides. Despite early failures, antisense technology will likely play an important role in the development of new biotherapeutics.

2.4.3 Gene Products

Gene therapy has been defined as the transfer of exogenous genes to somatic cells of a patient in an effort to correct an inherited or acquired gene defect or to introduce a new function or characteristic. Gene-therapy products can be considered biotherapeutic agents. Human gene-therapy products include naked DNA, and viral and nonviral vectors containing nucleic acids (cf. Verdier and Descotes, 1999). Notwithstanding some disappointing preliminary clinical results, gene therapy has become an established concept in medicine. The future success of gene therapy depends upon further development of the basic sciences in the discovery of new disease-related genes, as well as identifying suitable animal models (Barzon *et al*., 2000). It has been estimated that nearly 400 gene-therapy clinical trials are ongoing.

By the insertion of plasmid DNA into target cells it may be possible to rectify genetic disorders, and to produce therapeutic agents in the form of peptides and proteins or antigens *in situ* to stimulate the immune system (cf. Davis, 1997). Advances in gene therapy may also allow for controlling pain, and could even be used to block the production of pronociceptive molecules (Yang and Wu, 2001). Other attractive targets for gene therapy include the epithelial surfaces of the lungs and GI tract, endothelial cells lining the blood vessels, muscles, myoblasts and skin fibroblasts. Three principle means of gene-delivery systems include:

1. Viral vectors
2. Nonviral vectors (e.g. particles, polymers)
3. Direct injection (e.g. ‘gene guns’).

Generally, nonviral-vector systems have been favoured, but they too possess certain disadvantages. In order for nonviral vectors to be effective it is essential that the negatively charged plasmid DNA be condensed into a nanoparticulate structure. This can be accomplished by the use of cationic lipids and cationic polymers, in which the interaction between the selected cationic materials and the anionic DNA results in a condensed/compacted structure. Such complexes provide increased stability of the genetic material as well as improved uptake into target cells (cf. Davis, 1997). Safety evaluation of gene therapy products entails a number of toxicological issues (cf. Harris and Dayan, 1998; Verdier and Descotes, 1999). While some of these issues are common to all biological products, there are others that are specific to gene-therapy products. Specific preclinical safety issues for gene-therapy products are depicted on **Table 12**. Of course, all test materials must be in compliance with current good manufacturing practices (cGMPs). Both *in vivo* and *in vitro* assays for adventitious viral contaminants must be undertaken. Human cells employed in the production of adenovirus vectors may be assayed for tumorigenicity in nude mice. Establishing the absence of replication-competent viruses is essential. Modification of the gene-expression construct may potentially alter the product’s biodistribution and/or gene expression, thus necessitating additional toxicologic testing.

Table 12 Pre-clinical safety issues for gene therapy[a]

Characteristics of gene-therapy product

Safety evaluation of the vector
Toxicity of expressed protein (s)
Selection of animal species
Dose selection
Selection of route of administration

[a]Reproduced from Verdier and Descotes, 1999. © Oxford University Press.

No general test is available to predict the virulence or pathogenicity of recombinant viral vectors (cf. Smith *et al*., 1996). Some viral vectors may induce toxic shock and possess other specific cytotoxic properties.

In considering the toxicity of the expressed protein(s), the amount of protein equivalent to the expected total gene expression is compared to the dose of protein used in the safety evaluation (cf. Verdier and Descotes, 1999). The selection of the animal species is critical, and generally only nonhuman primates provide the most relevant model. Dose selection is often based on preliminary dose-ranging studies in animals, but should take into consideration the proposed dose used in human clinical trials. Similarly, the selection of the route of administration should be the same in both the preclinical and clinical studies.

2.4.4 Monoclonal Antibodies (Mab)

Monoclonal antibody technology has revealed that immunoglobulins (Igs) exhibit a wide range of biological activities—they are very specific. Antigen-combining sites on antibody molecules have great potential for developing bioactive peptides. Earlier, technical problems arose in Mab production because

Septic shock	HA-IA	Lipid A region-Gram(-)

[a]Modified and condensed from Vaswani and Hamilton, 1998.

of host-anti-antibody immune responses. Subsequently, 'humanized' antibodies were developed by inserting the rodent hypervariable regions into human framework regions. In addition, Mab have been obtained by selecting antibodies from recombinatorial-phage-display libraries (cf. Dougall *et al*., 1994). Mab have been used for both diagnostic and therapeutic indications. There are a number of clinically approved Mab (see **Table 13**). Mab have been used diagnostically in colorectal cancer and ovarian cancer imaging. Antibodies (e.g. hMN-14) are under development for the treatment of ovarian, breast and medullary thyroid cancers. Still other antibody-targeted chemotherapeutic agents represent a new class of anticancer therapies (e.g. CMA-676-Mylotarg). This recombinant humanized antibody is linked with a cytotoxic antitumour antibiotic (e.g. calicheamicin), and may be indicated in the treatment of acute myelogenous leukaemia (AML).

2.5 Regulatory Considerations

Pharmaceutical companies and regulatory agencies responsible for public health must establish relevant and meaningful guidelines for the preclinical and clinical evaluation of new biopharmaceutical agents. There have been some difficulties in conceiving and applying guidelines for the safety evaluation of biotechnology-derived products (Claude, 1992; Cohen-Haguenauer, 1996; Cavagnaro, 1997). Safety is highly dependent upon the particular industrial process and its quality control. When possible, there should be efforts to compare the new biopharmaceutical to a natural biologic entity. Study designs often use a case-by-case approach (Cavagnaro, 1997). Regulatory guidelines must be mindful of the importance of selecting the appropriate animal model.

Good manufacturing practice (GMP) for biopharmaceuticals is an integral part of the safety and regulatory process (Jeffcoate, 1992; Federici, 1994). Other steps in the manufacturing process that convert the new biologies into biopharmaceuticals require due diligence throughout the entire process (**Table 14**).

Lyophilization
End-product quality:
Accurate and precise methods
Rigorous specifications

[a]Modified from Jeffcoate, 1992.

Biopharmaceuticals are generally classified as 'biologicals' by regulatory agencies. This classification would ordinarily include 'any virus, therapeutic serum, toxin, antitoxin or analogous product applicable to the prevention, treatment or cure of diseases or injuries to man'. The quality-control process of biopharmaceuticals engenders essentially the same as those applied to the analysis of conventional or low-molecular-weight pharmaceutical products or drugs.

3 AGRIBIOTECHNOLOGY

3.1 Genetically Modified Foods

Plants are one of many novel hosts that can be used, not only in the production of more nutritious foods, but also in the production of biopharmaceuticals. Since

Nutrient modification

the early discoveries by Mendel, geneticists have been interested in the prospects of directed genetic change. Genetic modification of crop plants, in order to improve many of their qualities or traits, has led to a proliferation of recombinant products.

Modern-day biotechnology techniques are more precise and more rapid. Agribiotechnology has many potential benefits, including increased crop yields and livestock productivity, enhanced micronutrient composition and improved pest control through the development of herbicide-resistant crops. This technology may also improve food processing and even provide diagnostic tools for detecting plant pathogens. Still another important dimension of transgenic plants is the development and production of edible vaccines and other biotherapeutic agents. Genetic engineering of plants is not unlike the types of modifications that have been used by previous generations of plant breeders, but the techniques are more complex and diverse.

Several agronomic traits can be enhanced through agribiotechnology (Stark *et al*., 1993) (**Table 15**). Transgenically-introduced traits which have received considerable attention include herbicide tolerance (e.g. glyphosate), virus resistance and insect resistance. Other traits include resistance to fungal and bacterial infections, and tolerance to different stresses such as extremes of salt concentrations, heavy metals, temperature, nitrogen levels and phytohormones.

Some agribiotechnology-derived products have been introduced as having altered traits, including both food and vaccines (**Table 16**). Canola can be modified using an acyl carrier-protein thioesterase gene. A glufosinate-tolerant canola can be made using a phosphinothricin acetyltransferase gene obtained from *Streptomyces viridochromogenes*. A glyphosate-tolerant cotton can be made using the enolpyruvylshikimate-3-phosphate gene from *Agrobacterium* sp. strain CP4. Likewise, canola and soybeans can be rendered glyphosate tolerant. Insect-protected potatoes and corn can be made using the CryIIIA gene from *Bacillus thuringiensis*. Squash can be rendered virus resistant by using coat-protein genes from the watermelon mosaic viruses or the zucchini yellow mosaic virus. Viral resistant GM papayas and viral resistant sweet potatoes have flourished locally, but regulatory and cultural issues from other countries have precluded their usefulness and distribution. A modified fruit-ripening tomato has been achieved using several different gene-modification approaches. The insertion of several genes into a plant, often referred to as 'gene stacking' can lead to several new species with enhanced levels of various micronutrients. For example, rice can be nutritional enhanced, with both increased levels of iron and β-carotene (i.e. vitamin A). Genes from the daffodil (a yellow flower containing high levels of endogenous β-carotene) can be transfected into rice to, not only give rise to a 'golden' colour, but, more importantly, a crop plant with enhanced vitamin A. It should be noted that there are several areas involved in food biotechnology, and not just the alteration of plant traits and other forms of resistance. Actually, food biotechnology constitutes several areas:

- Processing aids (e.g. enzymes) and additives produced by fermentation with GM micro-organisms
- GM microbial starter cultures for the production of fermented foods (e.g. dairy products, cereals, vegetables, etc.)
- GM crops for fresh and processed food
- GM animals (e.g. husbandry of lean or less fatty animals).

All these areas of food technology are important advancements, but the public focus has been on GM-crop alterations that relate to human safety and perceptions of environmental risk.

Methods to establish food safety of GM foods (or components) are to determine whether or not it is 'substantially equivalent' to a conventional food product. Equivalency takes into account the biochemical and

Table 16 Selected biotechnology products[a]

Product	Altered trait	Source of gene(s)
Canola	High lauric acid	Turnip, oilseed rape, and so on.
Cotton	Herbicide resistance	Bacteria, virus
Potato	Resistance to beetles	Bacteria
Soybean	Herbicide resistance	Bacteria, virus
Squash	Viral resistance	Virus
Tomato	Delayed ripening	Tomato, bacteria, virus
Vaccinia virus	Vaccine	Rabies virus

chemical composition, the nutritional value comparisons and several other factors (e.g. antinutritional components). In order to demonstrate 'substantial equivalence', several criteria need to be considered:

- The composition and characteristics of the conventional food to which the GM food is being compared
- A knowledge of any new components (i.e. introduced genes) either expressed or otherwise present in the GM food.

Additionally, various food-processing techniques can affect a new GM food. During the entire process of ensuring similar composition and characteristics, it is necessary to establish its safety (e.g. allergenicity). Establishing the concept of 'substantial equivalency' between a conventional food and a GM food has provided the basis for regulatory approval in the US and other countries (Constable *et al*., 2007).

3.2 Altering Genetic Traits

3.2.1 Herbicide Tolerance

A herbicide is a chemical agent that kills or significantly interrupts plant growth and development. Every year, US growers use an estimated 971 million pounds of pesticides, mostly to kill insects, weeds and fungi (Brown, 2001). These chemicals interfere with metabolic processes that are essential for plant growth and vitality. Their phytotoxicity is due to their adverse actions on normal enzyme activity. Crops and weeds are naturally resistant to many herbicides. This resistance can be due to metabolic detoxification, prevention of the herbicide from reaching its site of action, or resistance at its site of action. Glyphosate-based weed-control products are among the most widely used broad-spectrum herbicides in the world (Giesy *et al*., 1996). The herbicidal properties of glyphosate were discovered over three decades ago. Glyphosate-based herbicides are used in agriculture, in industry, in ornamental gardening and in residential weed management. In agriculture, they are used in applications involving genetically modified plant varieties selected for their capacity to withstand glyphosate treatment.

Glyphosate (e.g. Roundup™) is a nonselective broad-spectrum herbicide that ordinarily cannot be used on crops without severe plant injury. Once glyphosate enters the plant, it inhibits the enzyme, 5-enolpyruvolylshikimate-3-phosphate synthase (EPSPS), thereby preventing the plant from producing aromatic amino acids essential for protein synthesis. EPSPS is the only physiological target of glyphosate.

Glyphosate-resistant (glyphosate-tolerant) crops employ a target-site modification wherein a glyphosate-resistant EPSPS is introduced into the plant by genetic engineering. Upon exposure to glyphosate, the plant is now unaffected, because the continued action of the glyphosate-resistant EPSPS enzyme provides for the plant's needs for amino-acid synthesis. An adjacent weed, for example, would not be protected from the glyphosate and hence would die because of the inhibition of amino-acid synthesis.

A number of herbicide-tolerant crops now available commercially (e.g. glufosinate/bialaphos, bromoxynil, etc.), but glyphosate was one of the first to be marketed. It has also undergone extensive safety testing and therefore is a representative prototype. The development of glyphosate-resistant (glyphosate-tolerant) crops has withstood two decades of safety testing and field trials.

Glyphosphate's mechanism of action is through its binding and blockade of EPSPS, an important enzyme necessary in the synthesis of aromatic amino acids both in crops and in weeds. Glyphosate's inhibition of EPSPS prevents a plant's ability to produce aromatic amino acids that are essential for protein synthesis. EPSPS can be found in all plants, in bacteria and in fungi. EPSPS is not found in animals, and therefore aromatic amino acids must be present in the diet.

Herbicide-tolerant crops are more environmentally friendly since they effectively lower the usage of conventional chemical herbicides. Glyphosate is readily degraded to metabolites that are nontoxic and nonresidual. Glyphosate in the environment tends to bind tightly to soil and to particulate matter. It is essentially not available to plants and other soil organisms (Giesy *et al*., 1996).

3.2.2 Bt (Bacillus Thuringiensis) Crops

The gene for the Bt toxin (*Bacillus thuringiensis*) was discovered over a 100 years ago. This soil bacterium has been used extensively in so-called organic farming. Since 1991, the Bt gene has been inserted into more than 50 plant crops (cf. Paoletti and Pimentel, 1996). There have been some concerns about the development of resistance to Bt toxin both in field and laboratory tests (Lambert and Peferoen, 1992; Stone *et al*., 1991; Tabashnik *et al*., 1992). Despite some of these early concerns, and now with the benefit of another decade of evaluation, Bt crops have been approved by US regulatory agencies and other agencies throughout the world. The use of Bt crops requires less chemical pesticide to be sprayed on the crops. Insect resistance can be provided by a gene from the soil bacterium Bt. This gene (*crylAB*) directs cells to synthesize a crystalline protein that is toxic to selected insects, particularly caterpillars and beetles that destroy food crops. The toxin gene in various strains of Bt can affect different insects, and hence a seed can be tailor-made to provide the best protection.

Bt-protected plants provide a safe and highly effective method of insect control (Betz *et al*., 2000). Bt-protected

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

corn, cotton and potatoes were introduced into US agriculture nearly 10 years ago. Not only do they produce higher yields to the farmer, but they also reduce levels of fungal toxins (e.g. fumonisin in corn). Non-Bt corn and other species do not take up the toxin released into the soil in root exudates of Bt-corn. The persistence of the toxin in soil for up to 180 days after its release indicates that the pesticide remains bound to surface-active particles which protect the toxin from biodegradation.

Safety-evaluation tests, including acute, subacute and chronic exposures, have been undertaken with Bt-protected plants. All have been fully approved by US regulatory agencies, including the FDA, EPA and the USDA. These Bt-protected crops have been determined to be 'substantially equivalent' in both food and animal feeds derived from non-GM or from conventional foods.

3.3 Safety Assessment

Safety issues concerning GM plants have involved both foods for human consumption and animal feeds. Toxicological studies have been aimed at ensuring their safety and to establish compositional equivalency. 'Substantial equivalence' establishes important safety criteria for GM foods and animal feeds (Delaney, 2007).

Safety concerns also involve wildlife species and possible adverse effects upon the environment and ecosystems. Concerns for nontarget species (e.g. monarch butterflies) have been raised by environmentalists. Will innocent nontarget species be affected by insecticides that are incorporated into GM crops? The risk appears to be very small, yet continued surveillance and additional research is necessary. Thus far, no 'superweeds' arising from genes inserted into crops have migrated or jumped to nonGM plants.

3.3.1 Allergenicity and Digestible Proteins

In order to assess allergy-inducing potential, it is necessary to examine the chemical composition of each novel protein produced by the GM plant against a known allergen. It is estimated that there are 500 or more known allergens. Several food-allergen sequences can be retrieved from public-domain databases for proteins and nucleic acids (cf. Metcalfe *et al*., 1996).

There are thousands of different proteins in the body. Only a few proteins are capable of causing food allergies. Because genetically engineered crop plants introduce new proteins, there is always the possibility that the protein encoded into this new genetic material might produce an allergic response. Many foods, not genetically modified, including milk, eggs, tree nuts, shellfish and certain legumes (e.g. peanuts, soybeans) are commonly allergenic. Food allergies/intolerances differ significantly across multiple countries (Woods *et al*., 2001). A food crop (e.g. legume) that is genetically modified is apt to be just as allergenic in a sensitive person as in the sensitive person consuming the same legume from a non-GM version of the same crop.

There is no evidence that recombinant proteins in newly developed foods are more allergenic than naturally occurring proteins. In fact, evidence suggests that the vast majority of these proteins are safe to consume (Lehrer *et al*., 1996). The stability (or lack of) of food allergens to gastric digestion can determine their potential immunogenicity (Astwood *et al*., 1996). Moreover, often overlooked are the temperature extremes that might be used in the processing of the final food product and the effect it may have on allergenicity. A decision tree for evaluating recombinant food proteins for immunogenicity can be very useful (Lehrer *et al*., 1996; see also **Table 11**). Recombinant proteins from known allergens can be readily tested using a tier of *in vitro* immunochemical assays. Many biochemical and immunotoxicity tests can be used to evaluate allergenicity. Unfortunately, recombinant proteins from unknown allergenic sources are not easily recognized nor necessarily anticipated. Hence, it may be difficult to assay recombinant proteins from sources with undetermined allergenic activity. Importantly, there is no evidence that recombinant proteins are more allergenic than naturally occurring proteins. In fact, the vast majority of proteins present in new food products are safe for consumption. Nevertheless, it is important that new food products, regardless of source, be prudently developed and tested for any potential immunogenicity.

Food allergens that cross the mucosal membranes of the GI tract are generally a prerequisite for allergenicity. High temperatures associated with food processing and the acidity of the stomach do not necessarily result in their being digested. A protein that is stable under such environmental conditions (i.e. proteolysis) has an increased probability of reaching the intestinal mucosa intact. Many allergens exhibit stability despite such conditions (cf. Metcalfe *et al*., 1996). It is possible to compare the relative stability of proteins engineered into plants with a number of commonly known allergenic food proteins. There are several major classes of food allergens, including egg-white allergens, milk allergens, soybean allergens, peanut allergens and mustard allergens. The toxicologic assessment of many of these allergens can be carried out using simulated gastric and digestive models of mammalian digestion, as described in the US Pharmacopeia. It is possible to compare the relative stability of proteins engineered into plants (e.g. Bt insecticidal protein, CP4 EPSPS synthase, etc.) with a number of commonly known allergenic food proteins. The *in vitro* digestibility of Bt Cry proteins in simulated gastric fluid ranges from 30 to 60 seconds (Betz *et al*., 2000). These *in vitro* models can be used to evaluate the digestibility of both plant and animal proteins, as

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat154
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

well as certain food additives. Not surprisingly, many of the known food allergens are stable to digestion in these simulated GI digestive models. The allergen (or a protein fragment) may be stable for at least two minutes; major allergens are typically stable for as long as one hour. Common food proteins with no history of allergenicity undergo rapid degradation in these simulated gastric and intestinal models. Thus, it is possible to add this *in vitro* battery to safety testing for evaluating new GM foods.

3.3.2 Feeding Studies

Feeding studies are an integral part of the overall safety assessment of GM foods and/or animal feeds. Animal feeding studies, whether using laboratory animals or domestic animals, provide insight into the nutritional status of the new GM product. It also allows for the monitoring of growth rates of the test animals. Daily dietary regimens using several different intake levels and durations (e.g. 4–10 weeks depending upon the species) aid in establishing normal growth patterns and nutritional balance studies. From such studies, it may be possible to set safety margins. Often, several different species can be used to determine nutritional parameters, and might include laboratory rats, as well as domestic animals commonly found in the human food chain. Feeding studies involving invertebrates (e.g. catfish) may also be undertaken, not only for assessing another food-chain component, but also for any potential ecological effect(s).

The chicken is an excellent animal feeding model since it can be easily studied through its lifespan. It also undergoes a severalfold increase in body weight in just over six weeks, and provides additional information about the nutrient value of the new GM food/feed. To accommodate such a rapid body-weight increase during this time period, the chicken's protein requirements are significant, and hence it is a very sensitive model for assessing nutritional equivalency.

3.3.3 Nontarget Species

In the overall safety assessment of GM foods and the safety of animal feeds that are derived from GM plants, is necessity to evaluate the effects of such crops on nontarget species (e.g. monarch butterflies, swallowtail butterfly larvae, honeybees, etc.). Field studies that include any potential harmful effect on nontarget species should be conducted as a routine evaluation of a GM food/feed. If studies are conducted in a laboratory setting, they must closely approximate those conditions found in the natural setting. The environmental risks that GM crops might pose to nontarget species is not completely known, but experiments to date have not revealed any adverse effects. Further, the cultivation of GM food crops (e.g. Bt-protected plants) may result in fewer adverse impacts on nontarget organisms than would be incurred from the use of chemical pesticides. Glyphosate formulations do not affect honeybees nor do they affect nontarget terrestrial plants (Giesy *et al*., 1996). Glyphosate does not bioaccumulate in fish or other animals. There must be continued vigilance to determine any possible ecological consequences arising that might harm nontarget species of wildlife. The weight of evidence indicates no unreasonable adverse effects of Bt Cry proteins expressed into plants on nontarget wildlife or beneficial invertebrates (e.g. earthworms, soil microbials or flora).

3.4 Nutritional Improvement

The nutritional health and wellbeing of humans is dependent on plant foods that are either directly or indirectly consumed by certain domestic animals. Crop foods provide most essential vitamins and minerals along with a host of other nutritionally related phytochemicals. Oftentimes, micronutrients are found only in low concentrations in staple food crops. Essential micronutrients in the human diet consist of about 17 minerals and 13 vitamins. Unfortunately, there are many developing or underdeveloped countries in the world that are unable to provide proper or adequate nutrition. GM foods, particularly those that increase yield and productivity, may allay malnutrition. It has been estimated that about 800 million people, mostly children, have some degree of malnourishment.

Modern agriculture, particularly in the last few decades, has witnessed advances in crop breeding leading to increases in productivity and yields. While efforts have been focussed upon attaining caloric needs, genetically engineered crops now afford the opportunity to enhance the micronutrient composition of crop foods (cf. Comaci, 1993). Through nutritional genomics, it is now possible to increase plant micronutrients leading to an improvement in human health (DellaPenna, 1999). By inserting foreign genes into various crop foods, it is possible to achieve nutritional enhancement of certain micronutrients. Initial efforts to attain GM foods with traits that endow them with herbicidal resistance, ordinarily involve the insertion of one or two foreign genes. Multiple gene insertions, sometimes referred to as 'gene stacking', may involve over a half dozen gene insertions and utilize more than one of the plant's metabolic pathways.

Nutritional genomics using multiple gene insertions is exemplified by rice (e.g. 'golden rice'). Millions of people depend upon rice as a staple food. Through nutritional genomics it is possible to enhance rice with increased levels of micronutrients, namely, β-carotene (vitamin A) and iron. 'Golden mustard oil', much like 'golden rice' can be made with high levels of β-carotene, a precursor to vitamin A. Four encoded enzymes that provide rice with the ability to synthesize β-carotene, and three other encoded enzymes, allow the kernals to accumulate additional iron. Both vitamin A deficiency

Table 17 Production of biopharmaceuticals in transgenic plants[a]

Potential application/indication	Plant	Protein
Anticoagulants:		
Protein C pathway	Tobacco	Human protein C (serum)
Indirect thrombin inhibitors	Tobacco, oilseed Ethiopian mustard	Human hirudin variant 2
Recombinant hormones/proteins:		
Neutropenia	Tobacco	Human granulocyte-CSF
Anaemia	Tobacco	Human erythropoietin
Antihyperanalgesic (opiate)	Thale cress, oilseed	Human enkephalins
Wound repair	Tobacco	Human epidermal growth factor (EGF)
Hepatitis C and B	Rice, turnip	Human interferon-α
Liver cirrhosis	Potato, tobacco	Human serum albumin
Blood substitute	Tobacco	Human haemoglobin
Collagen	Tobacco	Human collagen
Protein/peptide inhibitors:		
Cystic fibrosis	Tobacco	Human α-l-antitrypsin
Trypsin inhibitor	Maize	Human aprotinin
Hypertension	Tobacco, tomato	Angiotensin-converting enzyme (ACE) Inhibitors
HIV	*Nicotiana bethamiana*	α-trichosanthin (TMV-UI)
Recombinant enzymes:		
Gaucher's disease	Tobacco	Glucocerebrosidases

[a]Modified and condensed from Giddings *et al*., 1996, see also Goldstein and Thomas, 2004.

and iron deficiency, particularly in children, can potentially benefit from this novel form of GM rice. Efforts are currently underway to even further increase the levels of these micronutrients in this GM rice, as well as in other food crops. By enhancing the levels of carotenoids and the glucosinolates in GM foods, it might be possible to reduce the risk of certain forms of cancer. Likewise, the enhancement of phyto-oestrogens, as well as selected phytophenolic compounds might reduce the risk of other diseases, including cardiovascular diseases, osteoporosis and certain hormone-related cancers. Aqua farming using GM salmon may prove to be an important alternate source of protein. Commercial 'fish farms' growing GM salmon transfected with a growth hormone from other fish species', that have a four times greater growth than the salmon have been produced and will soon be reviewed for regulatory approval. By inserting the growth hormone gene into the fish's egg, the gene will be present in every cell in the fish's body. Fish with this integrated gene can then be used to create a breeding stock of a newer and faster-growing variety.

3.5 Agribiotechnology and Medicines

Biotherapeutics, which involves the genetic manipulation of mammalian cells, is more focussed upon the discovery of new medicines and other therapeutic products for the treatment of various diseases. Early successes in developing alternate sources of often scarce or animal-origin hormones through recombinant technologies led to recombinant human insulin and human growth hormone. These were indeed scientific breakthroughs enjoyed by the then new biotechnologies. Progress in developing new medicinal therapies through agribiotechnology has not been as rapid nor successful, yet there are many potential indications (Giddings 1996) (**Table 17**). Many of the expression systems used in the production of biopharmaceuticals have employed agrobacterium mediated transformations (AMTs). Finally, the production of nutraceuticals using potato or rice plants may be useful in the eventual treatment of provitamin A deficiencies and amino-acid deficiencies (Giddings *et al*., 1996). Improved crop traits have produced healthier foods such as 'trans'-free margarines, and improved protein and vitamin levels. Agribiotechnology can use GM crop foods as a vector for the delivery of edible vaccines (Richter, 1997; Richter and Kipp, 1999) (**Table 18**). When plants genetically engineered to produce bacterial or viral proteins are consumed as food, they can trigger an immune response (Arntzen, 1998). Oral immunizations using transgenic crops could provide a low-cost approach to protecting against several different diseases. Cholera vaccines, using the potato as a vehicle, could provide

Table 18 Production of vaccines from plants[a]

Potential application/indication	Plant	Protein
Hepatitis B	Tobacco	rHBsAg (recombinant hepatitis B surface antigen)
	Tobacco	Marine hepatitis epitope
Dental caries	Tobacco	*Streptococcus mutans*
Autoimmune diabetes	Potato	*Vibrio cholerae* toxin B
	Potato	Glutamic acid decarboxylase
Cholera and E. coli Diarrhoea	Tobacco, potato	*E. coli* enterotoxin LT-B
Oral vaccine (cholera)	Potato	*V. cholerae* toxin CtoxA/Ctox-B
Mucosal vaccines	Cow-pea	D2 peptide (fibronectin-B) *Staph. aureus*
Diarrhoea (Norwalk virus)	Tobacco, potato	Coat protein (Norwalk virus)
Rabies	Tobacco, spinach	Rabies virus glycoprotein
HIV	Tobacco, blackeyed pea	HIV epitope (gp 120)
	Cow-pea	HIV epitope (gp 41)
Rhinovirus	Blackeyed pea	Human rhinovirus epitope (HR14)
Foot and mouth	Blackeyed pea	Foot and mouth virus epitope (VPl)
Malaria	Tobacco	Malarial B-cell epitope
Influenza	Tobacco	Haemagglutinin

[a]Modified and condensed from Giddings *et al.*, 1996.

immunity to this disease. Likewise, a GM potato could be used as a vehicle for developing vaccines against enterogenic *E. coli* (ETEC) infections. Transgenic bananas, since they can be eaten raw and where cooking might destroy a vaccine, might provide the necessary vehicle for a hepatitis B vaccine. In an effort to control dosage, the transgenic banana could be homogenized into a measured baby food to ensure the effectiveness of the vaccine. Thus, pharmaceutical foodstuffs through oral immunization using a transgenic plant may provide the basis for new immunomodulating drugs and vaccines.

1 INTRODUCTION

The immune system functions to establish and maintain homeostasis by distinguishing endogenous ('self') from exogenous ('nonself') components, thus protecting the body from infectious agents (bacteria, viruses, fungi, parasites) and certain tumours. Perturbation of this homeostasis by interaction with some xenobiotics can result in adverse events. These include immune responses to otherwise innocuous nonself agents (generally proteins) leading to hypersensitivity development. Although most proteins are capable of eliciting immune responses, not all proteins are allergens (Viana *et al.*, 2002). Hypersensitivity reactions can significantly impact patient quality of life (discomfort, lack of activity participation, inability to concentrate at work or school) and produce economic difficulties (medical costs, lost productivity).

Most hypersensitivity responses develop in genetically predisposed individuals. Generally, no symptoms are experienced during the sensitization phase (induction). Instead, disease symptoms appear upon subsequent re-exposure/challenge (elicitation) in previously sensitized individuals.

Hypersensitivity reactions are divided into four types, as originally proposed by Gell and Coombs (**Table 1**). Although these divisions are based upon differences in the underlying immune mechanisms, the four groups are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat155

Table 1 Gell and Coombs classification of hypersensitivity reactions

Hypersensitivity	Mechanism	Examples
Type I Immediate type hypersensitivity	Th2-mediated induction of cytophilic antibody (IgE)	Allergic rhinitis, asthma, systemic anaphylaxis
	Cross-linking of mast cell receptor bound IgE results in mediator release (e.g. histamine)	—
Type II	IgM, IgG antibodies (Ab) react with cell- or matrix-associated antigen (Ag) results in cell cytolysis	Some drug allergies, for example, penicillin
	IgG reacts with cell-surface receptors alters signalling	Chronic urticaria (Ab to FcεR1α)
Type III	IgM, IgG complexed with Ag (immune complexes) activates complement and phagocytes leading to inflammation	Serum sickness, Arthus reaction
Type IV delayed-type hypersensitivity (DTH)	Th1 cells react with soluble Ag resulting in macrophage activation	Contact dermatitis, tuberculin Rx
	Th2 cells react with soluble Ag resulting in eosinophil activation	Chronic asthma, chronic allergic rhinitis
	Cytotoxic T cells react with cell-associated Ag resulting cytotoxicity	Contact dermatitis

not mutually exclusive and hypersensitivity responses are often mixed. In some cases the pathology appears to be similar, suggesting some overlap. Mechanistically, hypersensitivity Types I–III are antibody-mediated and Type IV is cell-mediated.

The incidence of Type I hypersensitivities (atopy or immediate-type hypersensitivity), has increased dramatically over the last several decades in the USA and other industrialized nations, particularly for allergic asthma. This trend has been noted in both the general population and in occupational settings (Petsonk, 2002). It is assumed that changes in environment, lifestyle and/or medical practices have contributed to the increase, as the change is more dramatic than would be expected for a simple population genetic shift (Mannino *et al*., 1998; Pew, 2000).

During the induction of Type I hypersensitivity, cytokines produced by T helper 2 (Th2) subset CD4+ T cells induce B cells to undergo immunoglobulin isotype switching and produce antigen-specific cytophilic IgE or IgG1 antibodies. Subsequent re-exposure induces crosslinking of antigen-specific mast cell/basophile-bound antibodies. This crosslinking induces the immediate release of preformed mediators (including histamine and prostaglandins), which produce bronchoconstriction, increased vascular permeability and inflammation. The resulting allergic reactions may have a variety of clinical manifestations, ranging from skin rashes and rhinitis to life-threatening asthmatic and anaphylactic reactions. In the case of asthma, a late-phase response may also be seen between 2 and 12 hours after challenge. This prolonged response is driven by leukotrienes, chemokines and cytokines synthesized by activated mast cells and CD4+ Th2 lymphocyte cells. It is characterized by mucus hypersecretion, bronchoconstriction, airway hyper-responsiveness (AHR) to nonspecific stimuli (e.g. histamine, methacholine (Mch)) and eosinophilic airway inflammation. The early and late phases of allergic asthma are predominantly a Type I hypersensitivity. However, some late phase and chronic components are Type IV.

Type IV or delayed-type hypersensitivity (DTH) reactions are mediated by CD4+ Th1 and cytolytic CD8+ T cells, not antibodies. Activated T cells may induce cell damage and death directly (CD8+ cells) or indirectly, by recruiting and activating macrophages and other T cells (Th1 cells). An example of a Type IV response is the classic tuberculin reaction, in which antigen-specific Th1 cells induce local accumulation of inflammatory cells and vascular dilation and leakage. An example of Type IV pulmonary hypersensitivity is hypersensitivity pneumonitis (HP; extrinsic allergic alveolitis). This inflammatory lung disease, a mix of Type IV and Type III (circulating antigen–antibody complexes) responses, results from the inhalation of organic dusts, including bioaerosols (containing fungi/bacteria), food ingredients (baker's lung) and certain metals (e.g. beryllium). Although HP is usually induced by occupational exposure, residential mould exposures have recently also been associated with the syndrome. HP is characterized by a predominantly mononuclear inflammation, as well as granuloma formation. In addition to hypersensitivity, development of chronic HP may also require immunomodulatory factors such as viral infections and/or microbial components (endotoxin, fungal glucans).

Human studies of hypersensitivity are frequently impossible for ethical or logistical reasons. Therefore, alternate methods are required to help elucidate mechanisms of pathology. This chapter focuses on the laboratory methods used in hazard identification and the assessment of the health risks associated with xenobiotic exposures that might induce respiratory hypersensitivities.

2 ANIMAL MODELS

Animal models have been developed to assess the risk of hypersensitivity induction and/or elicitation associated with inhalation exposure. These models have been used to identify causal agents (generally proteins) and to assess the relative allergenic potency of various proteins/extracts such as dust mites, moulds and cockroaches in residential environments and detergent enzymes, biotechnology products and latex in occupational settings. These models have also been used to assess the adjuvant activity of common air pollutants (ozone, diesel, NO_2) in respiratory hypersensitivity (Selgrade *et al*., 2000), and to elucidate the mechanism(s) involved in disease pathology.

A good animal model should mimic all or most of the responses characteristic of the human condition under study. Samples and assessments can be tailored to evaluate end points relevant to the hypersensitivity disorder under investigation. For Type I hypersensitivities, these end points include the identification of Th2 cytokines and cytophilic antibodies (IgE and IgG1) in serum and bronchoalveolar lavage fluid (BALF), BALF inflammatory cells (particularly eosinophils), and the induction of antigen-specific lymphocyte proliferation. Whole-body plethysmography can be used to assess both early- and late-phase airway responses.

Unfortunately, animal models are less successful in mimicking the inflammatory changes characteristic of chronic asthma (such as airway remodelling) or HP. Early HP models used rabbits and required extensive exposure protocols. More recent HP mouse models utilize both aerosolized antigen administration and adjuvant co-stimulation to produce lung pathology. End points of interest include demonstration of the presence of Th1 cytokines (interferon γ (IFNγ), interleukin-12 (IL-12)), and BALF inflammatory cells (neutrophils, lymphocytes).

Animals used in hypersensitivity models are primarily mice, rats or guinea pigs, although rabbits, monkeys and dogs are occasionally used. The predominance of murine models largely stems from the availability of inbred and transgenic mouse strains, providing opportunities to address research questions regarding disease susceptibility in sensitive subpopulations. The popularity of these models is further enhanced by the wide spectrum of commercially available murine-specific immunological reagents. Mice and humans share similar mechanisms of sensitization and recognize many of the same allergenic epitopes. Mouse strains relevant to the study of respiratory hypersensitivity include the Th2-biased high IgE responders BALB/c, DBA/2 and A/J mice, and the Th1-biased C57BL/6, B10.D2 and SJL/J mice.

In addition to choosing a model that displays relevant disease characteristics, the experimental design must also allow sufficient time for the adaptive response involved in respiratory sensitization to develop. Furthermore, the experimental design must include controls that distinguish adaptive immune responses from those induced by the antigen delivery vehicle, adjuvants or nonspecific inflammatory or irritant responses. Methods for exposures, sample collection and subsequent analysis are provided below.

2.1 Exposure Methods

Sensitization can be initiated by systemic or local exposures, or by cell transfer. Systemic exposure can be accomplished by intraperitoneal (IP) injection, generally in the presence of an aluminium-based adjuvant, by subcutaneous injection or by dermal exposure. Following systemic sensitization, one or more respiratory challenges are required for airway responses to become evident (Saloga *et al*., 1994).

Respiratory sensitization and challenges can be accomplished using local exposure techniques (inhalation, intranasal, intratracheal (IT) and IT aspiration). Inhalation exposures using whole-body or nose-only systems expose the entire respiratory tract to the aerosolized test agent. However, determination of total inhaled dose in whole-body exposures can be complicated by concurrent dermal, ingestion (grooming), and mucosal exposures, as well as by individual variability in respiration rates. Nose-only exposures limit exposure by nonrespiratory routes, but are more stressful to the animals. Animal stress can be reduced by chamber acclimatization prior to study initiation.

Intranasal exposures may be performed with or without short-term anaesthesia (e.g. isoflurane). The animal is restrained in a supine position with nose pointed upward. The agent is placed at the nostril opening and inhaled by the animal. This method exposes the upper airways, while the amount of agent reaching the lower airways is directly proportional to the volume instilled. However, there is the potential for ingestion of the agent.

IT exposure can be performed under general anaesthesia using a tracheal cannula. This method ensures precise dose delivery to the lower respiratory tract, but requires considerable skill to perform and may produce trauma to the animal.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat155
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Another method of lower airway exposure is aspiration, sometimes called intratracheal aspiration (IA) or oropharyngeal aspiration. Aspiration requires a short period of anaesthesia (~one minute isoflurane). The anaesthetized animal is vertically suspended by the incisors. The oesophagus is occluded and swallowing prevented by gently pulling the tongue out of the mouth in an upward direction. The agent is then placed in the oropharynx while the nose is briefly occluded, inducing aspiration of the agent.

3 SAMPLE COLLECTION

Samples may be collected at various times during the sensitization and challenge process to evaluate end points characteristic of allergic asthma or other respiratory hypersensitivities. Samples include blood, BALF and tissues such as lungs, lymph nodes and spleen. Most of these samples can only be acquired during terminal procedures, although some blood sampling and respiratory physiology assessments can be made in intact animals.

3.1 Blood Collection

To determine if the exposure regime is producing an IgE or IgG1 response (or other end point), it may be useful to periodically collect small blood samples (100–200 µl). Blood collection is survivable if the volume collected is <10% of blood volume (~8% body weight). Some techniques permit repeated sampling of individual subjects. One of these methods is blood collection via the lateral tail vein either by using a needle and syringe (easier in rats than mice) or by nicking the vein.

Small blood samples may be obtained from the retro-orbital plexus/sinus in both mice and rats, although this is not the method of choice for rats. This method requires the use of an ophthalmic anaesthetic or general anaesthesia and a skilled technician to minimize pain and distress. Briefly, the tip of a glass capillary tube is placed at the medial canthus and rotated until the sinus is penetrated and blood is collected. Care should be taken to ensure haemostasis following the procedure. Each orbit should not be sampled more than once every two to three weeks.

Blood may be obtained from the saphenous vein in both rats and mice. Mice are restrained by placing them head-first into a 50 ml conical centrifuge tube (perforated to permit air flow). The mouse is gently held in the tube with the rear legs extended. The fur on the side(s) of one rear leg can then be shaved. Coating the skin surface with silicone grease prior to puncturing the saphenous vein with a needle (e.g. 23 g) optimizes blood flow by minimizing blood loss onto the surrounding skin. Following blood sample collection (~100 µl total), gentle pressure is applied to the area to stop bleeding. This procedure requires more skill and time than either tail bleeding or retro-orbital sampling, but repeated samples can be obtained by removing the scab at the venipuncture site.

A minimally stressful blood sampling method is submandibular venous puncture. The mice are restrained by grasping the dorsal neck skin (the 'scruff') and cradling the mouse's body in the palm of the hand. The submandibular venous sinus can then be punctured using a 5 mm lancet. A maximum of eight drops of blood (~25 µl each; total 200 µl) can be collected at each sampling. Following the sampling, gentle pressure should be applied to ensure that bleeding has stopped.

Collection methods for larger blood volumes are nonsurvival procedures, and require lethal or surgical planes of anaesthesia. Blood collection by intracardiac bleeding is appropriate for both mice and rats (~1 ml from an adult mouse; 4–8 ml from an adult rat) while abdominal aorta puncture can be performed in rats. Abdominal aorta puncture is performed by opening the abdominal cavity, exposing the descending aorta (located on the animal's left side), separating the mesentery covering the vessel and withdrawing blood using a Vacutainer or syringe.

Blood samples are usually processed to provide plasma or serum and possibly a blood smear (see below). Blood collected in the presence of an anticoagulant (e.g. heparin, Alsever's solution) may be centrifuged to separate blood cells from the fluid portion (plasma). Allowing blood to clot also removes cells (and certain other factors) from the fluid portion (now called serum).

3.2 Bronchoalveolar Lavage (BAL)

Bronchoalveolar lavage (BAL) allows assessment of pulmonary inflammation. BAL fluid (BALF) contains cells, cytokines and antibodies that can be assayed to determine an animal's allergic status. It is accomplished in lethally anaesthetized animals or following sacrifice by cannulating the trachea and washing the airway one or more times with a saline solution such as Hank's balanced salt solution (HBSS) or phosphate-buffered saline. Lavage volumes may be determined based on animal body weight or a fixed volume may be used (0.75–1 ml for mice). This volume may be adjusted if some lung tissue will be removed before lavage.

3.3 Organ Tissue

Organs such as lung, lymph nodes, spleen and liver can be collected at necropsy. Differences in tissue

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat155
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

wet weights between treated and control animals may suggest responses such as oedema, cellular influx or cell proliferation. Harvested organs may be frozen or fixed in formaldehyde for histopathologic analysis. Tissues may also be snap-frozen or placed in RNase-inhibitor for RNA isolation and gene expression analysis. Alternately, single cell suspensions may be prepared from the tissue and cultured to provide insight into the disease status or mechanism (see Section 5 on Cell Culture).

3.4 Airway Reactivity Assessment

An important feature of allergic asthma is airway reactivity, which includes both antigen-specific immediate airway responses and antigen nonspecific AHR after experimental exposure to cholinergic agents (e.g. Mch) or histamine. Commonly used methods for AHR assessment include pulmonary function monitoring and whole-body plethysmography.

Pulmonary function monitoring allows measurement of airway responses in anaesthetized animals, but is a terminal procedure. Systems may be built in-house or commercially available monitoring systems may be used. Generally, heart rate and waveform are monitored throughout the experiment. Flow and pressure measurements for each breath are averaged to calculate airway compliance and resistance. A baseline is recorded prior to challenge with increasing doses of Mch, each delivered over one second via a jugular cannula and electronic syringe pump. A brief recovery period is allowed between doses. Airway opening pressure is monitored directly, while total respiratory system resistance and compliance are calculated using software such as that described by Gavett *et al*. (1999). Data may be expressed as the effective dose of Mch causing a percentage increase in airway pressure and airway resistance over baseline values, or a percentage decrease in compliance.

Whole-body plethysmography is a nonterminal method of assessing immediate responses to agent challenge or AHR. Airway responses are measured in unrestrained mice or rats with or without anaesthesia. The results are expressed as enhanced pause (PenH), a unitless parameter derived from whole body flow measurements (respiratory rate, tidal volume, inspiratory and expiratory times, peak inspiratory and expiratory flows and relaxation time). Although PenH has been correlated with airway resistance (Hamelmann *et al*., 1997), some authors (Adler *et al*., 2004; Bates *et al*., 2004) have criticized its use because it is partially based on measurements not related to airway resistance. However, this parameter does reflect changes in airflow, as illustrated in **Figure 1**.

Our laboratory has used plethysmography to follow the progression of immediate airway responses to allergen sensitization/challenge. Baseline measurements were recorded for each animal. Subsequently, mice were administered fungal extracts or HBSS control by aspiration and placed back in the plethysmograph chambers. PenH measurements were collected and averaged over a one hour postinstillation period (Viana *et al*., 2002; Chung *et al*., 2005). A similar approach has been used to assess immediate responses to house dust mite (HDM) in rats (Lambert *et al*., 2001).

An *in vitro* method for assessing airway responses is to measure tracheal tissue smooth-muscle contractions

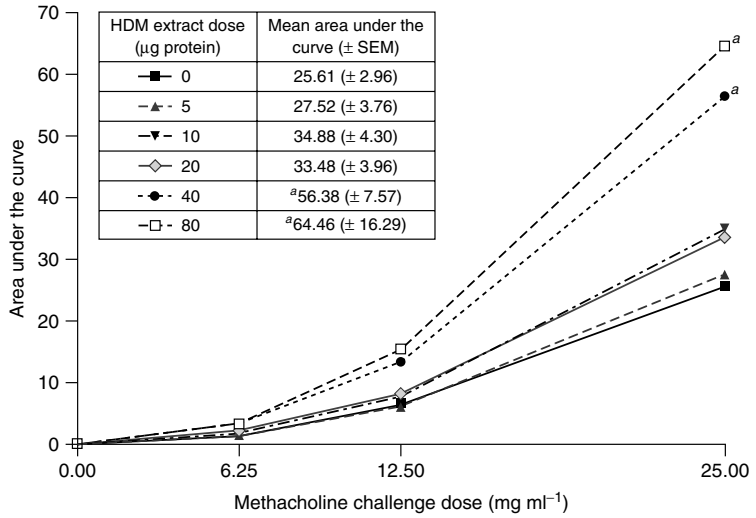

Figure 1 Airway hyper-responsiveness. BALB/c mice were exposed four times over four weeks to house dust mite (HDM) extract at doses ranging from 0 to 80 µg protein. Three days after the final HDM exposure the mice were placed in a whole-body plethysmograph and challenged with doubling doses of Mch (6.25–25.00 mg ml^{-1}). Mice that had received multiple 40 or 80 µg HDM exposures had significantly higher responses to Mch challenge at $p < 0.05$, indicated by *a*. The responses are presented as area under the curve. $n = 5–10$.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat155
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in response to cholinergic stimuli (Mch, carbachol) (Garssen *et al*., 1990). At selected time points following allergen challenge, the trachea is resected, cleaned of extraneous tissue and sectioned. The tracheal sections are fixed to a strain gauge in an organ bath and then suspended in a temperature-controlled chamber filled with Krebs–Ringer solution. After equilibration, cholinergic-induced contractility is recorded with a force (isometric) transducer. Typically, cholinergic stimulant dose–response curves are generated from both allergen-challenged and naive/control animal tracheas for comparison.

4 SAMPLE ANALYSIS/ASSESSMENT

4.1 Blood-Smear Analysis

Blood smears can be used to evaluate circulating blood-cell populations. A small drop of fresh blood is placed near the end of a slide. After bringing the edge of a second slide (at 30–40°) into contact with the blood, the drop is allowed to bank evenly along the slide edge and push the 'spreader' in a smooth, quick motion. The blood cells will be distributed in a thickness gradient and somewhere along that gradient should be a satisfactory distribution of cells. If the blood drop is too large, the red blood cells may obscure the leukocytes. The smear is air-dried and stained, then examined under a microscope for cell evaluation.

4.2 BALF Analysis

BALF can provide information regarding the quantity and quality of the pulmonary cellular influx following allergen sensitization and challenge. Following centrifugation, the supernatant may be submitted for biochemical (e.g. total protein (oedema), lactate dehydrogenase activity (cell damage)) and immunologic (e.g. antibodies, cytokines) analysis. The cell pellet is resuspended in an isotonic solution. The total cell concentration of the suspension can be determined by microscopic examination using a haemocytometer or by counting cell nuclei spectrophotometrically using instruments such as a Coulter Counter (Coulter Corp., Miami, FL). Cell viability can be determined with trypan blue exclusion staining using the microscopic, but not the spectrophotometric, method.

For differential cell counts, another portion of the cell suspension, usually 100–150 µl, is adhered to glass slides by centrifugation. Wright–Giemsa staining allows the cell populations to be identified by differential staining and morphological discrimination. **Figure 2A** shows an example of BALF total and differential cell counts from a HDM dose–response study conducted in our laboratory.

4.3 Lung Histopathology

Although BALF assessments provide some insight into lung inflammation, fixed lung samples provide direct evidence of lung pathology. For our laboratory, lungs are sectioned along the mainstem bronchus and embedded in paraffin. Sections are stained with haematoxylin–eosin solution prior to histopathologic examination. The severity of inflammatory, degenerative and proliferative changes can be graded on a numeric scale. Pathology scores may be expressed as *incidence* (the number of mice in a group exhibiting a particular pathology) and *severity* (the average of the pathology scores for a particular lesion per treatment group).

Fixed lung sections can also be stained immunohistochemically to identify the presence, source and location of molecules of interest. A study in our laboratory demonstrated that certain neurotrophins (NGF (nerve growth factor), NT-3, NT-4) are elevated in the BALF of mould extract-exposed mice, as is seen in human asthmatics. Subsequent immunohistochemical analysis identified mononuclear and epithelial cells as the source of NGF (Chung *et al*., 2007).

4.4 Immunologic Assays

The serum, plasma or BALF from experimental animals can be assayed for proteins of interest in allergy models. These proteins include cytophilic antibodies, such as IgE (mice and rats) and IgG1 (guinea pigs and mice), which arm mast cells/basophiles for allergic responsiveness. Both antigen-specific and total antibody isotype concentrations can be evaluated. Other proteins of interest in allergy models include Th2-relevant and inflammatory cytokines (IL-4, IL-13, IL-5, IL-10, TNFγ) and chemokines (Eotaxin, RANTES, IL-8).

4.4.1 Enzyme-Linked Immunosorbant Assay (ELISA)

The enzyme-linked immunosorbant assay (ELISA) is a method for the quantification of proteins such as antibodies, cytokines or chemokines. Two common assay designs are the antibody-capture ELISA and the two-antibody sandwich ELISA. In the antibody-capture ELISA, the test agent is immobilized on a solid matrix (microtitre plate). Agent-specific antibodies in the sample (serum, BALF) are then allowed to bind to the immobilized agent. Bound sample antibodies may be detected either directly (labelled primary antibody) or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat155
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

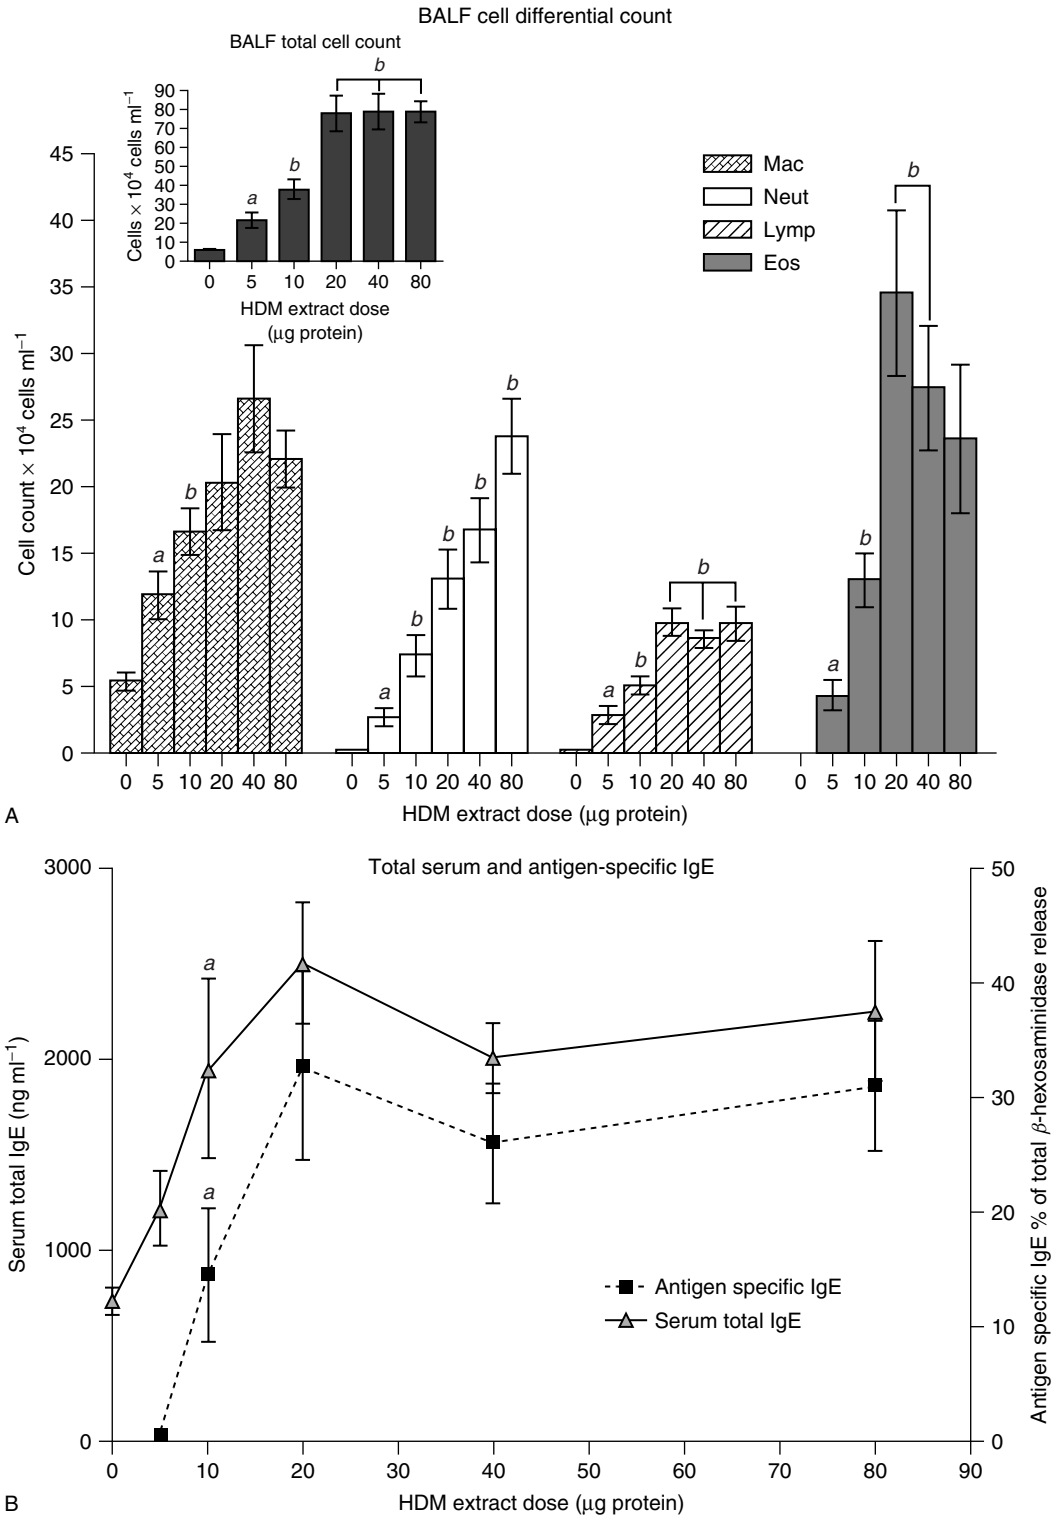

Figure 2 Three days after the fourth HDM (0–80 μg protein) exposure BALF and blood were collected from BALB/c mice. (A) BALF total and differential cell counts are shown. (B) Serum total IgE (ng ml^{-1}) and antigen-specific IgE (% of total mast cell mediator release) are shown. *a* indicates lowest significant dose compared to 0 μg dose; *b* significantly higher than lower doses at $p < 0.05$. $n = 5–10$.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat155
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

indirectly (labelled secondary antibody, e.g. biotinylated anti-IgE). In the two-antibody sandwich ELISA, an antigen-specific antibody is bound to the matrix. These antibodies then bind the target antigen (e.g. serum IgE, cytokines) in the test sample. Subsequently, a second antigen-specific antibody is allowed to bind. The two antibodies are often referred to as paired antibodies because both bind the target antigen but do not hinder the binding of each other. Many kits and paired-antibody sets are commercially available, particularly for mouse samples. **Figure 2B** shows serum total IgE ELISA data from the HDM dose–response.

4.4.2 Measurements of Functional IgE

Other methods may be used to evaluate the functional status of sample IgE. The passive cutaneous anaphylaxis (PCA) assay may be used for detection and quantification of even small quantities of cytophilic antibodies. PCA assays may be homologous (serum donor and recipient animals are the same species) or heterologous (donor and recipient animals are different species). In either case, serum from an allergen-sensitized animal (guinea pig, rat or mouse) is serially diluted and injected intradermally into a nonsensitized animal. Subsequently the test allergen, mixed with Evans blue dye, is injected intravenously. Allergen-specific antibodies from the donor serum bind the allergen and induce mast-cell degranulation, producing a localized cutaneous reaction (wheal and flare) called the Prausnitz-Kustner reaction. This appears as a dark blue area of dye extravasation due to local capillary dilation and leakage. The inverse of the highest dilution factor at which the dye is visible determines the IgE (IgG1) antibody titre.

An alternate measure of functional antigen-specific IgE is the rat basophile leukaemia (RBL) assay (Hoffmann *et al*., 1997). RBL cells (RBL-2H3) are passively sensitized with rat or mouse serum samples. Subsequently, an empirically derived amount of antigen sufficient to provide IgE crosslinking is added, resulting in mediator release (histamine, ß-hexosaminidase or serotonin). Mediator release measurement data are expressed as percent of total mediator release, thus providing an indirect measurement of antigen-specific IgE. In our laboratory, we measure ß-hexosaminidase release (Chung *et al*., 2005). In addition to spontaneous (no serum added) and total release (cells lysed with Triton X100), we measure an adjusted spontaneous release by treating cells with antigen alone to identify any direct effects of the extract. **Figure 2B** shows antigen-specific IgE data from the HDM dose–response study conducted in our laboratory.

4.5 Protein-Expression Analysis

In addition to traditional methods for protein(s) detection, multiplexing techniques have been developed to permit the simultaneous characterization and quantification of multiple proteins. Generally, these multiplexing platforms are variations of either sandwich or antibody-capture ELISAs. With a relatively small sample volume, these techniques can assay for the presence of cytokines, chemokines, growth factors, other plasma proteins and antigen-specific antibodies.

4.5.1 Multiplex Fluorescent Bead Assays

In fluorescent bead assays, polystyrene beads are loaded with a mixture of red and infrared fluorophores in defined proportions. Each mixture generates a unique fluorescent signature, which is reserved for a single target analyte. The fluorescent beads are then bound to agent-specific capture antibodies. Following incubation with the sample and an orange-fluorescing detection antibody, the beads are drawn past two lasers to identify (red laser) and quantify (green laser (orange fluorescence)) the analytes of interest. Advantages of this technology include the wide variety of sample types (including BALF, serum and tissue or cell culture lysates) that can be analysed, and the ability to assay multiple analytes in a small sample volume (Farraj *et al*., 2007). In some cases, this technology can be used to discriminate between protein variants, such as total and phosphorylated forms of cell signalling factors (Rhyne *et al*., 2003). In addition to bead sets that detect preselected protein targets (cytokines, soluble receptors, etc.) custom bead sets can be produced in-house or purchased.

However, many bead-based assays are intolerant of even minor changes in assay conditions, resulting in a tendency for bead ‘clumping’, thus producing a greater degree of variability than that seen with plate-based ELISAs. As a result, at this time, these assays may be better suited for demonstrating qualitative, rather than quantitative differences in protein expression.

4.5.2 Protein Microarrays

Protein microarray platforms employ a solid substrate, such as a glass slide coated with nitrocellulose. This substrate can then be dotted with a pre-defined arrangement of antibodies specific for the proteins of interest. Sample protein binding to these antibodies can be detected and quantified using fluorescently-labelled detection antibodies. Alternately, array substrates can be dotted with sample proteins for subsequent detection using labelled antibodies of known specificities or modified to facilitate the study of protein–protein interactions. Additionally, proteins of known identity can also be spotted on to slides and used to probe for the presence of antigen-specific antibodies in the sample. A brief overview of this technology has recently been published in the journal *Nature* (Eisenstein, 2006).

4.6 Gene-Expression Analysis

Gene-expression analysis can identify differentially up-regulated or down-regulated genes following exposure to the test agent compared to control samples. This technology is very useful when direct detection of target proteins is not possible or when the proteins of interest are unknown. Additionally, the data can be used to identify biomarkers of sensitization or elicitation thus suggesting immune mechanisms as well as targets for disease intervention. Several analytical options are available, from whole-genome-transcript evaluation to more targeted assays evaluating the expression of one to a few dozen genes. Further information on the use of gene-expression analyses in toxicology screening may be found elsewhere in this text (see **Toxicogenomics and the Evolution of Systems Toxicology**).

Gene-expression analysis avoids some of the technical difficulties associated with protein detection (e.g. the need for species-specific reagents), but it must be remembered that the presence of a messenger RNA (mRNA) transcript does not necessarily mean that the protein product is also present. Furthermore, mRNA transcripts provide no information regarding the post-translation processing or activation state of the protein product.

4.6.1 Microarray Gene-Expression Analysis

Microarray (or 'gene chip') analyses allow simultaneous identification and relative quantification of thousands of mRNA transcripts on a single sample. They can provide excellent whole-genome screening for differentially expressed genes or gene families. Depending upon the study goals, data derived from microarray experiments can be used to identify differentially affected pathways for later study, to identify targets/actions for new drugs, or for discovery of 'biomarkers' of sensitization, exposure or overt toxicity.

Gene-expression microarray assays are similar in design to other nucleotide hybridization-based techniques. Briefly, DNA oligonucleotides are arranged (by spotting or synthesis *in situ*) at specific locations on a solid surface, such as a glass slide. Fluorescently labelled RNA fragments from the test sample are added and allowed to hybridize to complementary DNA sequences. Subsequent evaluation of the treated chip allows determination of the presence or absence of specific RNA transcripts, with fluorescence intensity at each site proportional to the quantity of sample RNA bound there.

Array analyses can be performed on RNA obtained from whole-tissue homogenates, from cell culture lysates, or from cell populations separated *ex vivo* by centrifugation or laser capture microdissection. Whole-genome analysis microarrays are available for humans, mice, rats, zebrafish, *Xenopus*, *Caenorhabditis elegans* and other species.

A major limitation to the use of microarrays is their expense. Ideally, only one subject sample is used per chip. However, studies designed in this manner become costly if dose–response evaluations or large numbers of replicates are required. Some researchers economize by pooling RNA samples to allow the use of fewer chips. Unfortunately, expression results derived from pooled samples cannot be correlated with other biological parameters for individual animals, making phenotypic validation of array results difficult or impossible (Jolly *et al*., 2005).

Another constraint in microarray analysis is the requirement for extremely high quality RNA, since the amplification and hybridization steps are very sensitive to RNA degradation and genomic DNA contamination (Medeiros *et al*., 2007). Finally, compared to polymerase chain reaction (PCR)-based methods (see below), microarrays suffer from a lack of detection sensitivity for low abundance RNA transcripts, as well as from limited quantification abilities. For these reasons, it is recommended that 'key' gene targets obtained by microarray analysis be confirmed using an alternate method, such as the quantitative real-time polymerase chain reaction (qPCR). In addition, demonstration of the presence of the protein products of gene targets identified by expression analyses should be performed whenever possible.

The volume of data generated during a microarray experiment can make interpretation of the results very difficult. Whole-genome transcript analyses require the use of powerful computer programmes and statistical tools to make valid determinations of differential gene expression profiles between individuals and groups (**Table 2**). Differentially expressed gene sets may then be superimposed upon known biological pathways or networks ('pathway analysis') to determine relevant relationships, as well as in the context of annotated gene databases (**Table 2**).

The annotated gene databases include detailed information on known biological functions, tissue expression and species-specific homologous gene orthologues. Several of these programmes include their own literature-based, independently curated annotation databases. Other programmes use 'meta-search' type algorithms to compile and cross-reference information from other databases, including pathway databases, tissue expression databases, protein-interaction databases, and disease-association databases.

4.6.2 Real-Time PCR-based Assays

Although gene-expression arrays offer an unmatched ability to rapidly 'screen' for genes or pathways of interest, they do have significant limitations, as mentioned above. Since the mid 1990s qPCR has been used to evaluate gene expression. This technology provides amplification and quantification of mRNA

transcript concentrations over time, thus permitting more accurate quantitation of gene expression than is possible with a microarray. Additionally, because qPCR produces exponential amplification of transcript numbers, it is better suited for the detection of low-abundance transcripts than microarray analyses. Although the sensitivity and precision of qPCR technology makes it well-suited for detailed evaluation of a small number of gene transcripts, multiple targets in a large sample size can quickly consume valuable samples.

Recently PCR technology has expanded with the development of qRT-PCR-based 'arrays', such as the TaqMan Gene Signature Array (Applied Biosystems). In these arrays, individual wells of a 384 well microfluidic card are preloaded with gene-specific primers and probes. Sample and reaction master mix is added to the card through 'ports' and distributed to the wells by centrifugation, after which the plate is processed in the usual manner. Different plate configurations allow for simultaneous evaluation of up to 384 analytes per sample, or up to 24 analytes in eight samples.

5 CELL CULTURE

Animal studies provide logistical challenges. Animals must be bred, housed, exposed and sacrificed under controlled conditions to minimize confounding factors. Due to the complexity of sensitization development requiring tightly regulated interactions between multiple cell types, including lymphoid cells, innate immune system cells (e.g. dendritic cells, mast cells) and epithelial cells (e.g. keratinocytes, alveolar epithelial cells), animal studies have been considered essential for hypersensitivity hazard screening and understanding disease pathogenesis. Although *in vitro* cell culture techniques have been adapted for overt cytotoxicity screening, adaptive immune responses are difficult to model *in vitro*

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and their use thus far has been limited. However, *in vitro* cell culture can provide a homogenous system to dissect out pathways and mechanisms, leading to a better understanding of disease pathology and possibly targets for disease intervention. It is currently feasible to model some early cellular responses in culture systems. Therefore, *in vitro* methods for hazard screening are increasingly being employed in support of or as alternatives to traditional *in vivo* assessments.

Despite the limitations, there are several important reasons to include selected *in vitro* techniques in the sensitization screening process. Cell-culture systems may be developed to evaluate several agents at multiple concentrations simultaneously for known or putative biomarkers. Also, the validity of nonhuman test-subject data used in interspecies extrapolation can be partially addressed by human-derived cell-assay systems.

Culture supernatants or lysates can be harvested following exposure and evaluated for protein or gene expression using methods such as ELISA, and protein- or gene-expression microarrays. Alternately, putative sensitizers could be evaluated for their effects on surface phenotype, cell function or cellular proliferation.

5.1 Primary Cell Cultures

Culture systems involving *ex vivo* exposure of target cells to potential sensitizers avoid many of the difficulties associated with immortalized cell lines. In general, these cells exhibit minimal changes in phenotype and function when compared to the same cell types *in situ*, but have a limited lifespan. Historically, acquisition of sufficient quantities of the desired cell type could be difficult, especially for human-derived cells. However, several commercial sources for both animal- and human-derived primary cells now exist.

Primary cell cultures may display a significant donor-related variability in function. These differences may be exploited in studies comparing cellular responses to an agent in cells from allergic and nonallergic subjects. Both airway epithelial cells and peripheral blood-derived dendritic cells have been demonstrated to behave differently, depending upon the atopic status of the donors (Lordan *et al*., 2002; De Smedt *et al*., 2002). The most frequently used *ex vivo* cell types in exposure studies include exfoliated tracheobronchial epithelial cells and bone marrow or peripheral blood monocyte-derived dendritic cells. Some commercial sources of primary bronchial epithelial cells offer cells categorized by donor type, including nonallergics, asthmatics and smokers.

Ex vivo cultures of dendritic cells may be obtained by selective culture of either $CD34^+$ bone-marrow-derived dendritic cells (BMDCs) or peripheral blood monocytes (monocyte-derived dendritic cells; MoDC). BMDCs are more difficult and costly to obtain than MoDC. However, donor-related differences in response may be greater in MoDC (De Smedt *et al*., 2002).

5.2 Cell Lines

Immortalized cell cultures from a variety of species have been used to study biological phenomena such as cell signalling and apoptosis, and to investigate cytotoxicity. Established culture techniques and the high degree of phenotypic stability demonstrated by many of these cell lines permits some flexibility in protocol optimization and exposure synchronization. However, phenotypic stability, particularly in prolonged culture, does not necessarily imply that the responses are predictive of 'normal' cell behaviour. Additionally, immortalized cell lines may lack features considered characteristic of the parent cell type (e.g. lack of IgE receptor on the human mast cell line HMC-1 (Love *et al*., 1996)). Furthermore, well-established lines may develop sudden alterations in phenotype or function (e.g. prolonged culture of the canine C2 mast cell line results in the loss of IgE receptor function (Brazis *et al*., 2002)). It is also important to remember that there is significant variability in response between cell lines, even those derived from the same species and parent cell type.

Epithelial-derived cells are frequently used in the modelling of respiratory-tract responses. Alveolar epithelial cells represent the largest respiratory-tract cell population and are responsible for many innate defence responses against inhaled xenobiotics, such as surfactant production. One widely used respiratory epithelial cell line is the human alveolar epithelial cell line A549, which displays characteristics analogous to Type II alveolar cells. Other frequently used cell lines are derived from tracheobronchial epithelium and include the human-derived BEAS-2B, 16HBE14o- and Calu-3 cell lines. These lines form polarized cell layers with intercellular tight junctions (physical barrier (Wan *et al*., 2000)), and may retain some secretory properties (e.g. epithelial-derived mucous). Both characteristics are critical components of the airway barrier *in vivo*. Therefore, these cell culture systems can provide insight into agents or other substances that are transported across or cause damage to the airway epithelium.

Dendritic cells represent a far smaller cell population than epithelial cells, but are known to play a vital role in the development of both allergic and nonallergic airway inflammation. Immortalized 'dendritic cell' lines are frequently myeloid-derived cells that have been cultured under conditions that induce the phenotypic development of mature or immature dendritic cells. Commonly used lines include the human KG-1, THP-1 and MUTZ-3 cell lines, as well as the mouse XS52 cell line.

5.3 Three-Dimensional/Coculture Systems

Recent advances in cell-culture techniques have enabled the development of three-dimensional and coculture models. Although first developed as models for screening of contact irritants and sensitizers, modifications of these culture systems permit the study of respiratory immunotoxicity and sensitization.

Cocultures provide a simulated airway environment to evaluate interactions between epithelial and immune-system cells. Commonly, epithelial cells or fibroblasts are cultured on a porous surface, such as a synthetic or organic transwell membrane. This facilitates the development of a polarized monolayer, and permits the subsequent removal and histological/immunochemical examination of the layer *in toto* (Blank *et al*., 2006). Once the monolayer is established, other cell types or agents can be added to the culture. These systems are especially well suited for direct or indirect measurements of epithelial permeability, such as transepithelial resistance or mannitol permeability. Although increased epithelial permeability is not necessarily predictive of sensitization potential, the induction of significant epithelial disruption may increase the systemic availability of other substances, potentially facilitating sensitization (Wan *et al*., 2001)

Coculture experiments can be performed using primary cells, established cell lines or a mixture of both. Bronchial or alveolar epithelial cells are frequently cultured with antigen-presenting cells such as *ex-vivo*-derived macrophages or dendritic cells. One particularly detailed triple coculture includes all three cell types, with peripheral-blood-derived macrophages and dendritic cells seeded apically and basally to A549 epithelial cells (Rothen-Rutishauser *et al*., 2005). Alternately, epithelial cells may be cultured with endothelial cells or fibroblasts to model epithelial–stromal interactions.

This type of culture system is labour intensive and requires a high degree of technical proficiency. In addition to the coordination of the epithelial monolayer culture with the preparation of another cell type for addition to the system, sufficient time must be allotted for the monolayer development and acclimation of the additional cell types before the test compound is added. Despite the technical complexities of these multicell systems they can provide insight into intercellular interactions.

6 SUMMARY

Allergic diseases, particularly asthma, have been increasing in prevalence in Western societies over the past several decades (Pew, 2000). One possible explanation for this phenomenon is increased exposure to environmental sensitizers. Recent advances in industry and biotechnology have produced an unprecedented expansion of novel items, including nanoparticles and bioengineered foods. The sensitization risk represented by these items remains to be determined. This chapter provides an overview of selected laboratory methods used in hazard identification and health-risk assessment of potential respiratory sensitizers.

Animal models of hypersensitivity have been used to elucidate disease pathogenesis, for hazard identification and for the determination of occupational exposure limits. Our laboratory has not only used BALB/c mice to evaluate the allergic potential of several mould extracts (Ward *et al*., 2000; Viana *et al*., 2002; Chung *et al*., 2005), but also to identify IgE-inducing mould proteins (Ward *et al*., in press) and to demonstrate that not all proteins can induce allergic responses (Viana *et al*., 2002). Additionally, the dose–response induced by exposure to mould extract (Chung *et al*., 2005) suggests that this model has utility in assessing the relative allergenicity of various indoor allergens. Other rodent models of allergy have been used to elucidate mechanisms associated with HDM hypersensitivity (Lambert *et al*., 2001) and to demonstrate adjuvant effects of air pollutants, such as NO_2 (Gilmour *et al*., 1996), residual oil fly ash and its metal components (Lambert *et al*., 1999; 2000). Additionally, mouse models have demonstrated that HP severity is modulated by viral infections (Gudmundsson *et al*., 1999) and cytokines (Gudmundsson *et al*., 1998a; 1998b).

Of particular relevance, the detergent industry has demonstrated that animal models can be used to set safe human exposure levels for detergent enzymes (Sarlo *et al*., 1997; Robinson *et al*., 1998). Following the establishment of occupational exposure guidelines for the detergent enzyme, *Bacillus subtilis* subtilisin A (Alcalase), <20% of the manufacturing population has been sensitized (developed IgE) to enzymes in a 10 year period, with no new cases of occupational asthma since 1994 (Sarlo, 2003). Determination of the relative allergenicity of new detergent enzymes compared to Alcalase has been predictive of human health outcomes and has provided a method to ensure the protection of these industrial workers.

In addition to traditional *in vivo* models of hazard screening, promising *in vitro* screening techniques are being developed, enabled by recent advances in cell-culture technology. Multiple-cell-type cocultures allow the evaluation of interactions between airway epithelial cells and extracellular stroma, endothelium and/or cells of the immune system, and provide an approximation of the complex airway environment. The use of cell cultures in toxicity screening has also been facilitated by the increased commercial availability of both established cell lines and primary cells from a variety of species. These techniques are particularly

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

well-suited for high-throughput screening assays, and may eventually be used for first-tier new product evaluation.

In conclusion, several models have been developed for the screening of potential respiratory sensitizing agents. Early identification of potential allergens can facilitate reduction or elimination of environmental exposure and may reduce the risk of asthma development. The methods and models discussed in this chapter have been used in our laboratory and others as a means of determining the risks associated with bioaerosol exposure. However, they could be applied to other putative sensitizing agents and could be used to address a number of issues related to environmental exposures and respiratory hypersensitivity diseases.

National and International Aspects on Bioterrorism and Biosecurity

Philippe Bossi

CONTENTS

1 INTRODUCTION

Bioterrorism is defined as the intentional use or threatened use of micro-organisms or toxins derived from living organisms to cause death or diseases in humans, animals or plants on which we depend. The other major point is to generate fear in the general population.

The deliberate use of micro-organisms as weapons has been attempted throughout history. One of the first major biological warfare attacks was reported during the fourteenth century, in 1346, during the siege of Kaffa, with *Yersinia pestis* The attacking Tatar force catapulted the bodies of their plague-infected soldiers over the city walls. This attack initiated the second major outbreak of plague, the Black Death that decimated one third of people living in Europa, and probably millions of people in Asia. The last biological warfare attack was the deliberate release of *Bacillus anthracis* in the United States shortly after the terrorist attacks of 11 September 2001 and this terrorist act, due to an unknown criminal group, caused 22 cases of anthrax, including five deaths.

More than 150 pathogens have been reported to be potential agents for bioterrorism (**Table 1**). These agents are classified by the Centers for Disease Control and Prevention (CDC) into three different categories, according to the infectiousness, virulence, public perception, impact, cost and sophistication in fighting against the agents. Category A includes agents that can be easily disseminated or transmitted person-to-person, cause high mortality, with potential for major public-health impact, might cause public panic and social disruption, and require special action for public-health preparedness. Category B includes agents that are moderately easy to disseminate, cause moderate morbidity and low mortality, and require specific enhancements of diagnostic capacity and enhanced disease surveillance. Category C includes emerging infectious agents that could be engineered for mass dissemination in the future because of availability and because of ease of production and dissemination, and potential for high morbidity and mortality and major health impact. In biological warfare, these agents would most likely be disseminated by aerosols, which are invisible, silent, odourless, tasteless and, theoretically, easily dispersed without detection. Infective doses for agents commonly considered to be potential biological warfare agents are reported in **Table 2**. In 1970 the World Health Organization (WHO) predicted that a city of 500 000 people would be devastated following an aerosol release of 50 kg of biological warfare agent, if deployed under ideal meteorological conditions; for example, an aerosol of anthrax spores could be associated with 125 000 incapacitated, including 95 000 deaths, and an aerosol of plague with 85 000 incapacitated, including 19 000 deaths (WHO, 1970).

In 1973, the Convention on the Prohibition of the Development, Production and Stockpiling of Biological and Toxin Weapons and on their Destruction, also known as the Biological and Toxin Weapons Convention or BWC, prohibited the development, production, stockpiling and acquisition of these weapons. Despite the international agreements to ban such weapons, there is no effective international mechanism for controlling either the development of biological weapons or their use. It has been reported that the number of countries

Table 1 Biological terrorism agents

Category	Bacteria	Viruses/toxins
A	*Bacillus anthracis* (anthrax) *Yersinia pestis* (plague) *Francisella tularensis* (tularemia)	Variola major (smallpox) Haemorrhagic fever viruses (Ebola, Marburg, Lassa viruses . . .) *Clostridium botulinum* toxin
B	*Burkholderia mallei* (glanders) *Brucella* species (brucellosis) *Coxiella burnetii* (Q fever) Food and waterborne pathogens	Encephalomyelitis viruses (Venezuelan equine encephalitis (VEE), extracellular enveloped vaccinia (EEV), western encephalomyelitis virus (WEV)) *Ricinus communis* toxin (ricin)
C	Mutidrug-resistant *M. tuberculosis*, etc.	Encephalomyelitis viruses (tick-borne encephalitis (TBE), etc.)

Table 2 Infective aerosolized doses for common biological agents (3)

Agents	Infective dose
Bacillus anthracis	8000–50 000 spores
Brucella spp.	10–100 bacteria
Burkholderia mallei	Low
Yersinia pestis	100–500
Francisella tularensis	10–50
Coxiella burnetii	1–10
Encephalitis viruses	10–100 viruses
Haemorrhagic fever viruses	1–10
Smallpox	10–100
Clostridium botulinum toxin	0.001 μg kg^{-1}

known or suspected of having biological-weapons capability has doubled since the convention went into force in 1975. From 1980 to 2000, it has been estimated that 40 deliberate uses of micro-organisms as weapons have been perpetrated throughout the world. In the United States alone, during the last decade of the last century (1988–1999), intentional use of infectious agents was considered in six cases.

2 NATIONAL PLANS

The last deliberate release of anthrax in the United States in October 2001 brought about a radical change in people's perception of the risk of bioterrorism. The impact was not limited to the United States. These bioterrorist events, unlike others before, had a worldwide impact, not only in respect of security and public health, but also in other sectors. Before that time, public-health preparedness for bioterrorism was not a political priority in most countries.

In many countries, civil protection, security and law enforcement services were put on alert, and public-health systems had to manage numerous events relating to letters suspected to be contaminated with anthrax. The disturbance and psychological effects of these incidents became of great concern to society and decision-makers alike. The need for bioterrorism preparedness and planning for response at multiple levels has been recognized in many countries. Throughout the world, these countries set up new administrative and operational structures and adapted their preparedness and response plans in order to deal with the new kind of threat. On the wider international level, a concerted global-health security action to strengthen the public-health response to the threat of international biological, chemical and radionuclear terrorism has been also initiated. Governments and international entities with responsibilities related to maintenance of peace, security, safety and health protection reviewed urgently their political, economic, diplomatic, military and legal means to face up to such attacks and embarked upon major efforts to increase their preparedness.

Most of the countries involved against bioterrorism, such as European countries, the United States or Canada, have developed plans to prepare a programme to improve national and international cooperation on the evaluation of risks, alerts and intervention, the storage of such means, and in the field of research. Countries re-examined their preparedness plans and adapted them to these new threats, and legislation needed to implement countermeasures was reviewed. The national authorities also discussed the necessity of stockpiling medicines and other medical supplies and most upgraded their stocks of vaccines and antibiotics, especially smallpox vaccine.

To improve the ability to recognize a deliberate release, countries developed local, national and international training programmes for different kinds of first responders. These programmes also cover the detection and identification of infectious and toxic agents, as well as the prevention and treatment of chemical and biological attacks.

Early diagnosis and prompt institution of effective control measures are critical determinants of the eventual impact of any infectious-disease emergency. All clinicians must remain open to the possibility that they

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat156
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

may be the first person to recognize a deliberate release and must be prepared to consult urgently with their local infectious-disease specialist, clinical microbiologist and public-health department on suspicion alone, without waiting for a definitive diagnosis. That is why numerous guidelines have been written, especially concerning the principal agents that could be used as biological weapons. Most clinicians do not know these infectious agents. Clinical aspects, diagnosis and treatments have been detailed in these guidelines.

In a few countries, the establishment of a preoutbreak national team that could investigate and manage initial suspected or confirmed cases of unusual agents has been performed. Special teams that could manage initial cases of smallpox have be vaccinated or revaccinated against smallpox. Most of the volunteers of these teams have been revaccinated using first-generation vaccine. In some countries, second generation has been used. Development of a third generation is ongoing and will be studied soon.

Specific departments of infectious diseases or emergency have been designated for receiving the first patients suspected, or actually infected with a biological agent. These departments include identifying a space (ideally one or several negative-pressure rooms) suitable for airborne infection isolation and respiratory isolation, and ensuring that staff understand when and how it should be used; review of available personal protective equipment (PPE: gloves, gowns, face and eye protection, surgical masks or other respiratory protection e.g. N95-type respirators), hand-cleaning facilities, and sharps safety and disposal arrangements; assessment of staff competency in choosing, and safely using, removing and disposing of the PPE available, ensuring that, if N95-type respirators are to be used, staff have been fit-tested and know how and when to perform fit-checks; reinforcement of the importance of hand hygiene; arrangements for cleaning and ensuring environmental hygiene; and setting triggers for notifying the infection-control team, public-health department and seeking further expert advice.

National plans for hospital preparedness have been written and tested. The overall aim of hospital preparedness for a bioterrorism attack is to be able to provide adequate medical care to those affected, whilst at the same time continuing to provide essential medical services to the community. Effective preparedness planning requires multidisciplinary involvement, involving emergency planners, clinical practitioners, laboratorians, managers and administrators, emergency responders, pharmacists, voluntary agencies, mental-health and occupational-health services, religious and spiritual advisors, and support staff, including catering, housekeeping, security, medical records, communications, information technology and transport/courier services. Clear, pre-event, designation of roles and responsibilities, clear chains of command, control and communication, and regular testing and evaluation of 'major incident' or emergency operations' plans by drills and exercises are needed.

The laboratory capacity required to diagnose most of the infectious agents that might be used in case of biological attack (biosafety level (BSL)-4) has been found in most countries. Laboratories and laboratorians have been involved in planning, and writing protocols for the safe collection, transport and external referral of clinical specimens.

Local, national and international exercises have been performed in order to test emergency teams, and effective communication. Effective communication appears crucial to management of infectious-disease emergencies, and a communication plan is an integral part of any emergency-management plan. Communication is a broad term that encompasses provision of accurate, timely, complete, easily understood information to the community about what the emergency is, what is being done to control it and what people can do to make themselves safer; provision of information to healthcare professionals about diagnosis, investigation and pre- or postexposure interventions; communication with families and others close to those affected by the emergency; communication with the media; and communication within and between all levels of those involved in managing the emergency.

Most of these countries involved against bioterrorism have compiled and planned national stockpiles of vaccines, antibiotics, antivirals and antitoxins. Most of the smallpox vaccines available have been in storage since the 1970–1980s. New vaccines were developed and studied at the end of 2002.

For smallpox vaccines, stockpiles of first generation and production capabilities for the new generations vaccines are probably sufficient in case of a massive bioterrorist attack using smallpox as an agent. For antibiotics, production capabilities are also sufficient to meet demand in the event of an emergency. A limiting factor in both cases is the lead time to increase production to meet increased demand.

Advice, algorithms and response protocols for investigation and management of possible cases or case clusters have been published, and give details of reporting mechanisms, diagnostic specimens, infection-control measures and other containment responses.

Bioterrorism has also initiated a discussion on the need to improve preparedness through reinforcing existing public-health structures that are in charge of monitoring and controlling diseases.

3 INTERNATIONAL PLANS

In parallel with these developments at national levels, many well-focussed international activities were also carried out.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat156

On the wider international level, health ministers of the G 7+ (US, Canada, Japan, France, Italy, UK, Germany and Mexico) agreed at a meeting in Ottawa in November 2001 to initiate concerted global-health security action to strengthen the public-health response to the threat of international biological, chemical and radionuclear terrorism.

In the European Commission (EC), in response to the increased threat of bioterrorism, a task force on health security was established in 2002. Task-force members address a broad range of issues related to preparedness for and response to bioterrorist events and seek to bring about a greater collaboration between the European Union (EU) member states.

On 19 October 2001, at the European Council in Ghent, Belgium, the Council of Ministers of the EU and the EC were asked by the heads of state and government to prepare a programme to improve the cooperation between member states for the evaluation of risks, alerts and intervention, the storage of the necessary means and collaboration in the field of research. The programme had to cover the detection and identification of infectious and toxic agents, as well as the prevention and management of chemical and biological attacks. Shortly afterwards, the EU Council of Ministers requested the Commission to develop an action programme of cooperation on preparedness and response to biological- and chemical-agent threats. In response, the Commission launched a series of coordinated actions across the civil protection, health, enterprise, research, nuclear, transport and energy fields. On the initiative of the European Commissioner for Health and Consumer Protection, the Health Security Committee was set up with representatives of the ministries of health from each member state. In December 2001, the Health Security Committee agreed on a programme for cooperation on preparedness and response to biological- and chemical-agent attacks. The overall goal was to improve cooperation between the member states, with the aid of the commission, and to facilitate collaboration between the different national authorities involved in public-health preparedness for bioterrorism. In May 2002, a task force was set up by the Directorate-General of Health and Consumer Protection. The task force's main objective was to implement the health-security programme. One of the initial priority activities was the setting up of a mechanism for rapid information exchange, consultation and coordination on all aspects dealing with bioterrorism. All designated authorities of the EU member states have been connected through this network by means of e-mail, fax and telephone. This tool makes it possible for the task force and the member states to disseminate information rapidly about suspected or confirmed incidents and for national authorities to evaluate measures planned with their implications for EU and for other member states. The task force is available 24 hours a day, seven days a week to facilitate the process.

The system has been used in EU-wide exercises and for alerts about suspicious events communicated by the member states. The early detection of a deliberate release or bioterrorist attack is an essential part of a programme of preparedness.

When the task force was established, several lists of agents that could be involved in a biological attack and considered a major bioterrorist threat had been established and published. Against this background, an approach more suitable to the demands for focussed action in Europe was developed though a matrix model designed to provide an evaluation of the public health impact of any given agent that could be used in bioterrorism. The clinical management, including recognition, of many of the diseases caused by the bioterrorist agents is likely to be difficult, since they are, to a large extent, unknown to the average clinician in Europe today. To provide clinicians with guidance and a source of generally agreed-upon information, several clinical guidelines have been compiled and published in a European journal.

The laboratory capacity required to diagnose most of the potentially toxic and infectious agents that might be used in cases of deliberate release is believed to exist within the EU as a whole; however, no member state has the complete spectrum of diagnostic capabilities needed. To improve the collective preparedness and to make more efficient use of the available resources, the laboratory capacities already in place were studied. Additionally, concrete collaborations between laboratories were initiated to share techniques and participate in common quality assurance schemes. Assisted by the task force, the BSL-4 laboratories in the EU are currently forming a network that will enhance their research activities through common projects. They have been asked to develop procedures to make BSL-4 diagnostics available to all member states and to handle, under high safety-level requirements, a substantial workload of analysis of environmental samples that might arise following a series of bioterrorist incidents or threats.

The European Agency for the Evaluation of Medicinal Products (EMEA) has developed guidelines on the use of authorized pharmaceuticals in case of deliberate release of biological and chemical agents. This includes guidelines for treatment and prophylaxis of the agents on the so-called CDC A-list of the most important threats as bioterrorist agents.

Stockpiling of medicines and vaccines (in particular, smallpox vaccines) has been extensively discussed between the different member states and the EC. Smallpox has become the model for much of the work performed in the area of preparedness for bioterrorist incidents. Vaccination has been performed in several European countries, mainly in volunteers that have been vaccinated during the past. Severe side effects have not been reported in these European-specific groups.

Preparedness also includes improved coordination between the Commission and international

organizations working in this area such as the WHO and the parties of the Global Health Security Action Initiative (Canada, France, Germany, Italy, Japan, Mexico, the United States, the United Kingdom and the EC, with WHO participating as a resource). Multiple initiatives regarding coordination of actions in this area were pursued by the European Centre for Disease Prevention and Control in Sweden.

4 BIOLOGICAL AGENTS

Many guidelines have been published for treatments and prophylaxis of agents used as biological weapons. Prompt recognition of biological-warfare-associated diseases can lead to a more rapid mobilization of public-health and medical assets. We report examples of biological agents that could be used as biological weapons.

4.1 Anthrax and Bioterrorism

Anthrax is seen as one of the most likely biological agents for use as a weapon. *B. anthracis* spores can be transmitted by aerosolization. Inhalation anthrax has a high mortality rate and the organism's spores, compared with other potential biological warfare agents, are quite stable in the environment (Inglesby *et al*., 2002; Bossi *et al*., 2004a; Centers for Disease Control and Prevention, 2001a). It has been estimated that 50 kg of *B. anthracis* spores released over an urban population of 5 million would sicken 250 000 and kill 100 000 (Health Aspects of Chemical and Biological Weapons, 1970). The use of anthrax in warfare has been recorded throughout history. During World War I, Germany used *B. anthracis* to infect livestock during trans-shipment. In December 1941, the British Government began testing the effect of anthrax on sheep on the Scottish island of Gruinard. Due to the durability of anthrax spores, decontamination was unsuccessful, and the island was quarantined until 1986, when a determined effort was made to decontaminate the island using formaldehyde. It was finally declared safe in 1990 (Inglesby *et al*., 2002). By 1945 the Japanese programme (Unit 731) had stockpiled 400 kg of anthrax spores to be used in bombs. The United States has weaponized anthrax spores, as did other countries in the 1950s and 1960s. This was evidenced by the accidental aerosol release of *B. anthracis* spores from a Soviet military microbiology facility in Sverdlovsk in the former Soviet Union in April 1979 (Meselson *et al*., 1994). This was the largest known outbreak of inhalational anthrax in the twentieth century: 68 of the 79 patients with inhalational anthrax died (Meselson *et al*., 1994). The first victim died after four days; the last one died six weeks later. Cases have also been reported in animals located more than 50 km from the site. Initially, the Soviet Government claimed the deaths were caused by intestinal anthrax from tainted meat. It wasn't until 13 years later, in 1992, that President Boris Yeltsin admitted that the anthrax outbreak was the result of military activity at the facility.

In October 2001, 22 cases of bioterrorism-related anthrax were reported in the United States: 11 confirmed inhalational, and seven confirmed and four suspected cutaneous cases (Jernigan *et al*., 2001; Centers for Disease Control and Prevention, 2001b). It seems that the cult of Aum Shinrikyo in Japan tried on several occasions to disperse anthrax unsuccessfully in Tokyo before the sarin attack (Inglesby *et al*., 2002), but they used an attenuated vaccine strain. No other bioterrorism-related outbreak or deliberate release has been reported in the literature.

Many guidelines have been published for treatments and prophylaxis of anthrax (Inglesby *et al*., 2002; Bossi *et al*., 2004a; Dixon *et al*., 1999; Centers for Disease Control and Prevention, 2001c; EMEA, 2002b). Private room placement for patients with inhalational anthrax is not necessary.

For inhalational anthrax, the duration of treatment is eight weeks. Duration of treatment for cutaneous anthrax is shorter; 7–10 days. The same antibiotics are recommended for postexposure prophylaxis. Oral ciprofloxacin is also recommended as first choice for prophylaxis for persons at risk of inhalational anthrax and must be taken for at least 60 days, unless exposure has been excluded. It has been demonstrated that treatment with antibiotics beginning one day after exposure to a lethal aerosol can provide significant protection against death. Much stockpiling of that antibiotic has been performed in countries involved against bioterrorism: this antibiotic could also be used for prophylaxis and treatment of others agents such as *Y. pestis* or *Francisella tularensis*.

4.2 Smallpox and Bioterrorism

Smallpox is a viral infection caused by the variola virus which belongs to the family of Poxviridae, subfamily Chordopoxvirinae and genus *Orthopoxvirus*, which includes monkeypox virus, smallpox vaccine and cowpox virus (Breman and Henderson, 2002). It was declared eradicated worldwide by the World Health Organization in 1979 following a smallpox-eradication campaign begun in 1958 and intensified in 1967, and the last case of endemic smallpox occurred in Somalia in 1977 (Arita, 1979). The last fatal case was due to a laboratory-acquired infection in the United Kingdom in 1978 (Shooter, 1980).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat156
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Smallpox is seen as one of the most likely viruses to be used as a biological weapon. Using this virus in warfare is an old concept: it was used with contaminated clothing in the eighteenth century by the British to create epidemics among the native American tribes. More recently, during World War II, the Japanese military explored the weaponization of smallpox in Mongolia and China. The variola virus exists legitimately only in two laboratories in the world: one in the Centers for Disease Control and Prevention in Atlanta, Georgia, USA and the other in the State Research Centre of Virology and Biotechnology in Novosibirsk, Russia (Henderson *et al*., 1999). There is no documentation of clandestine stock of the virus. Any new case of smallpox would have to be the result of human accidental or deliberate release. The aerosol infectivity, high mortality and stability of the variola virus make it a potential and dangerous threat in biological warfare (Franz *et al*., 1997; Bossi *et al*., 2004b). In addition, animalpox viruses such as monkeypox or a recombinant variant of smallpox could be developed as biological weapons. However, for the monkeypox virus, data indicate that it has limited potential for person-to-person transmission and furthermore, is not able to sustain an epidemic indefinitely in a community by human transmission only (Huhn *et al*., 2005).

Patients with smallpox must be isolated and managed, if possible, in a negative-pressure room until death, or until all scabs have been shed (about three weeks) (The European Agency for the Evaluation of Medicinal Products, 2002; Breman and Henderson, 2002; Henderson *et al*., 1999; Franz *et al*., 1997). There is no established antiviral treatment for smallpox. Cidofovir, an antiviral drug, is active *in vitro* on isolates of variola virus (Bray *et al*., 2002). Obviously, no data are available for humans. The most effective prevention is vaccination before exposure (Frey *et al*., 2002a; 2002b). The frequency of complications is low, but is higher than the most commonly used vaccines. Vaccination can modify the course of the disease and reduce mortality if given immediately after exposure (mortality can be reduced by up to 100%) and up to four days after (mortality can be reduced by up to 50%).

The vaccine used to eradicate smallpox was highly efficacious; it was prepared using live animal skin as a substrate. During the WHO smallpox eradication programme (1967–1978) many countries produced and used such 'first-generation' products despite their known reactogenicity, as it was accepted that the benefits outweighed the risks. Nowadays, quality requirements for vaccines have become much more stringent, leading to the development and testing of second-generation vaccines. These are produced using the same vaccine strains as the first-generation vaccines on tissue-culture substrate, allowing better production consistency and quality-control testing. For Europe, the EMEA has developed guidelines for development and production of second-generation vaccines (EMEA, 2002a). In 2002, many countries implemented a preparedness programme in which smallpox vaccine was administered to volunteers.

Throughout the world, vaccination against smallpox has been discontinued since about 1982. In France, for example, routine childhood immunization using the Lister strain ceased in 1979, and reimmunization of healthcare workers in 1984. This means that a large population is susceptible and any new case of smallpox would have to be the result of human accidental or deliberate release, could be associated with a major epidemic. In March 2003, the French Ministry of Health implemented a programme on preparedness and response to a biological attack using smallpox as weapon. This programme included the establishment of a preoutbreak national team that could be revaccinated against smallpox and called upon to investigate and manage initial suspected or confirmed cases of smallpox in France. People selected to this team were eligible volunteers, had received at least one dose of smallpox vaccine in the past and had no contraindications to a reimmunization.

In the United States, 665 000 people were vaccinated against smallpox during the 2002–2004 smallpox vaccination campaign (Casey *et al*., 2005; Sejvar *et al*., 2005). Serious adverse events such as neurologic disorders, myocarditis and/or pericarditis with generalized vaccinia were infrequent (Casey *et al*., 2005; Sejvar *et al*., 2005). There is a need therefore to develop a third generation of smallpox vaccines, with an acceptable safety profile (Bozzette *et al*., 2003). This could be achieved by attenuation or genetic engineering of vaccinia vaccine strains, while retaining their immunizing properties.

After the events of September and October, 2001, many governments took actions to improve their level of preparedness against smallpox—included updating and releasing a smallpox response plan. Right now, in many countries stockpiling of smallpox vaccine to vaccinate every person in the country in the case of a smallpox emergency seems to be enough. Anyone who has had contact with a smallpox patient will be offered smallpox vaccination as soon as possible. Then, the people who have had contact with those individuals will also be vaccinated (ring vaccination). Ring vaccination of direct contacts of infected persons seems sufficient to contain an epidemic of smallpox if infectious cases are rapidly diagnosed. National and international plans (different levels) have been written to vaccinate all the population, in the case of a massive biological attack using smallpox, in a limited time.

4.3 Plague and Bioterrorism

Y. pestis appears to be a good candidate agent for a bioterrorist attack. The use of an aerosolized form of this agent could cause with an explosive outbreak of primary plague

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat156
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

pneumonia in the exposed population, or alternatively the bacteria could be used to infect the rodent population and precipitate a secondary outbreak in humans living in poor conditions (Inglesby *et al*., 2001; Levison, 2000). Intentional aerosol release should be suspected in patients presenting with plague pneumonia in nonendemic areas or in patients without risk factors. *Y. pestis* is a relatively fragile organism that remains viable for only an hour after an aerosol release. Nevertheless, as few as 1–10 bacteria are sufficient to infect rodents via the oral, intradermal, subcutaneous or intravenous routes (Brubaker, 1991). Estimates of human infectivity by the respiratory route vary from 100 to 20 000 organisms (Inglesby *et al*., 2000; McGovern and Friedlander, 1997). The Tatars were the first to use plague as a biological weapon, in 1347, during the siege of the Genoese-controlled Black Sea port of Kaffa; they hurled the bodies of their plague victims over the city walls. It has been reported that the Japanese army dropped plague-infected fleas in China during World War II; as many as 15 million fleas were used per attack to infect the population with plague (Inglesby *et al*., 2000). It has been also reported that cases of plague occurred among the Japanese soldiers shortly after a biological attack on Changteh in 1941; 1700 deaths were reported in the Japanese army. In 1970, it was reported that if 50 kg of *Y. pestis* were released over a city of 5 million, plague pneumonia could occur in as many as 150 000 people, including 36 000 deaths (Health Aspects of Chemical and Biological Weapons, 1970). In May 2000, during the virtual exercise TOPOFF (for 'top officials') in the United States, simulation of a deliberate release of an aerosol of *Y. pestis* at a performing-arts centre estimated that 3700–4000 cases of plague pneumonia and between 950 and over 2000 deaths might have resulted (Inglesby *et al*., 2001).

A live attenuated vaccine is available in the USA, but it retains some virulence and is therefore not considered suitable for human use in most countries (Tiball and Williamson, 2001). Recent vaccine research in Europe is focussed on the development of a subunit vaccine containing F1 antigens and recombinant V antigens, which proved to be efficacious against pneumonic plague in mice (Tiball and Williamson, 2001; Du *et al*., 2002).

4.4 Other Biological Agents

Many others bacteria (*Francisella tularensis, Clostridium botulinum, Brucella* spp., *Coxiella burnetii, Burkholderia mallei* and *Burkholderia pseudomallei*, etc.) have been reported to be potential agents for bioterrorism (Franz *et al*., 1997; Bossi *et al*., 2004c; 2004d; 2004e). Many of such agents are zoonotic and could have a considerable impact on agriculture, as well as on human health. Interest in such agents as a biological weapon stems from the fact that airborne transmission of these agents is possible. For example, *Brucella* spp. is highly contagious, as it can enter through mucous membranes such as the conjunctiva, oropharynx, respiratory tract and skin abrasions. It has been estimated that only 10–100 organisms are needed to constitute an infectious aerosol dose for humans (Hoover and Friedlander, 1997). For *C. burnetii*, an infectious dose of very few organisms is required to cause infection. It has been estimated that as few as 1–10 organisms could cause disease. *B. mallei* and *B. pseudomallei* infection may be acquired through direct skin contact with contaminated soil or water (abraded or lacerated skin) or through mucosal surfaces of the eyes and nose. Ingestion of such contaminated water or dust is another route of transmission. These agents have been studied for weaponization in several countries in the past. They have been used during both the First and Second World Wars (Byrne, 1997). However, all these agents might be used more as an incapacitating agent, as the disease is associated with a high morbidity combining a protracted illness.

Many other viruses are also good candidates for bioterrorist agents: encephalitis-associated viruses and haemorrhagic fever viruses could be used by aerosolization during a bioterrorist attack. Most of these viruses have been weaponized (Bossi *et al*., 2004f; 2004g).

5 CONCLUSION

At the beginning of the twenty-first century, similarly to what has been observed throughout history, among the risks of nonconventional weapons known as nuclear, radiological, biological and chemical weapons, bioterrorism remains a potentially important risk, even if terrorist acts using chemical or radiological weapons or bombs appear to be more plausible.

Technology moves with time. It thus appears prudent to consider the use of modified infectious agents by not very scrupulous spirits. Infectious agents are more virulent, have a shorter incubation, are associated with more serious clinical signs, are more easily transmitted human-to-human, are more difficult to diagnose and would be more resistant to standard treatments. Due to this significant risk, our governments must remain vigilant and, as best as possible, prepare to face such a situation. The preparation for clinicians, general practitioners and specialists consists of a better knowledge of the little taught, not-well-known clinical signs generated by infectious agents, which are rarely observed in the majority of our countries. Let us be vigilant, let us be ready, without pouring in an exacerbated alarmism.

Mycotoxins and Mycotoxicoses: Significance, Occurrence and Mitigation in the Food Chain

Wayne L. Bryden

CONTENTS

1 INTRODUCTION

Invasion of human food and animal feed supply chains by filamentous fungi or moulds can result in contamination by secondary fungal metabolites. Many of these metabolites are toxic and are called mycotoxins. Mycotoxicoses are the diseases resulting from ingestion of these compounds. There are some 100 000 species of mould, and though not all are toxigenic, thousands of secondary metabolites have been isolated in the search for antibiotics and mycotoxins and many are toxic to man and animals (Cole *et al*., 2003). Historically, contamination of foodstuffs has been of concern because of the economic cost of spoilage rather than the potential hazard to animal and human health. Nevertheless, as mycotoxins are associated with field crops and stored plant produce, it is likely that they have affected man since the beginning of agriculture. It has long been recognized that mouldy food can be toxic, with reports from China some 5000 years ago and a suggestion of a biblical role for mycotoxins (Schoental, 1980; 1994), including the 10 plagues of Egypt in the Old Testament (Marr and Malloy, 1996). Ergotism has been known since the Middle Ages (Matossian, 1989) and the association of mouldy food with disease has been recognized in Japan, Russia and the USA for over a century (Joffe, 1986; Matossian, 1989; Richard, 2008). The neglect of the disease aspect of mouldy foods and feeds was altered dramatically by outbreaks of 'Turkey X' disease in England in the 1960s (Allcroft *et al*., 1961; Blount, 1961) and the concurrent report of an epizootic in trout from the USA (Halver, 1965). In both instances the causal agent was shown to be aflatoxins, which is a group of highly toxic metabolites produced by some species of the fungal genus *Aspergillus* (Austwick and Ayerst, 1963). Subsequent research has shown that aflatoxin B_1 is an extremely potent carcinogen (Wogan and Newberne, 1967). This finding highlights the potential health hazard of these natural chemical environmental contaminants and has prompted worldwide interest in toxigenic fungi.

Since the discovery of aflatoxins, research has continued apace on these mycotoxins (Richard, 2008). It is generally accepted that aflatoxin is the causative agent of 'Turkey X' disease, but Cole (1986b) has presented a persuasive case for the involvement of cyclopiazonic acid in this syndrome. The neurological signs (including opisthotonus) and enteritis observed in 'Turkey X' disease are not associated with aflatoxicosis of turkeys and he suggested that cyclopiazonic acid, which is a tremorgenic mycotoxin (Bryden, 2008) and produced by *A. flavus*, may have been a co-contaminant and have given rise to the clinical neurological signs exhibited by the turkeys. Subsequently, Bradburn *et al.* (1994) found cyclopiazonic acid in a sample of peanut meal from the original 'Turkey X' disease outbreak during the intervening period much has been accomplished in delineating the toxicology of the other major mycotoxins; the trichothecenes, ochratoxin, ergot alkaloids, zearalenone and fumonisins (see **Mycotoxins with a Special Focus on Aflatoxins, Ochratoxins and Fumonisins**). However, the mycotoxins likely to be encountered by human and animal populations differ between countries. This reflects different crops, agronomic practices and climatic conditions, which dictate the fungi that are present in a farming system. Mycotoxins may also be produced during storage and transport of food commodities. The temperature and humidity of the storage/transport environment are major factors determining fungal growth and toxin production. These aspects of the food chain, which mediate the level of food contamination, coupled with local socioeconomic factors and food cultural practices determine exposure to mycotoxins (Wild and Hall, 1996; Miller, 1998; Bryden, 2007; Wild, 2007; Shephard, 2008).

Globally, mycotoxins have significant human health, economic and international trade implications, which are considered in the opening section of this chapter. The subsequent sections are concerned with the ecology of toxigenic fungi and the elaboration of mycotoxins and strategies that have been developed to control and manage the occurrence of these naturally occurring compounds in the food chain. Emphasis, in these sections, is given to cereal crops as the most important source of mycotoxins. The prevention of mould growth and subsequent mycotoxin formation in crops and in other components of the food chain requires an integrated understanding of crop biology, agronomy, fungal ecology, harvesting methods, storage conditions and food processing. It is beyond the scope of this chapter comprehensively to describe all of these aspects and the interested reader is referred to texts (including Abbas, 2005; Barug *et al.*, 2004; 2006; Beasley, 1989; CAST, 1989; 2003; Chelkowski, 1991; Cole, 1986a; Cole *et al.*, 2003; De Vries *et al.*, 2002; Desjardins, 2006; Eaton and Groopman, 1994; Jackson *et al.*, 1996; JEFCA, 2001; Joffe, 1986; Logrieco and Visconti, 2004; Magan and Olsen, 2004; Matossian, 1989; Miller and Trenholm, 1994; Oswald and Taranu, 2008; Richard and Thurston, 1986; Sinha and Bhatnagar, 1998; Smith and Henderson, 1991; Summerell *et al.*, 2001) that detail mycotoxin occurrence, toxicology and control in the food chain.

2 GLOBAL SIGNIFICANCE OF MYCOTOXINS

It has been estimated that some 25% of the world's grain crops are effected annually by fungal invasion and mycotoxin contamination (Mannon and Johnson, 1985). It is interesting to speculate that with global warming, the threat from fungal invasion of crops will increase (Garrett *et al.*, 2006). It is therefore imperative that all measures be taken to reduce the occurrence of these compounds in the food supply chain. The complexities of this task can be gauged from **Figure 1**. Once formed either pre- or postharvest, mycotoxins, most of which are chemically stable, remain intact during food processing.

All food commodities can be contaminated with mycotoxins (**Table 1**) and prominent foodstuffs include: barley, cheese, coffee, cottonseed, grapes, maize (corn), milk, peanuts (groundnuts), rice, sorghum, tree nuts and wheat, especially maize and peanuts. The level of contamination found in these commodities varies with location and reflects climatic conditions and the invading fungal species. Globally, the most important genera of mycotoxigenic fungi are *Aspergillus*, *Fusarium* and *Penicillium* (Miller, 1998). The major toxins produced by these genera include: aflatoxins, ochratoxins, trichothecenes, fumonisins and zearalenone (Miller, 1998). The ergot alkaloids produced by *Claviceps* (Bryden, 1994) and toxins produced by *Alternaria* (Ostry, 2008) also cause disease-related problems from time to time. Mycotoxins produced by *Fusarium* sp. are invariably found in cereals and include trichothecenes (Beasley, 1989), fumonisins (Marasas *et al.*, 2001) and zearalenone (Hagler *et al.*, 2001). Aflatoxin and ochratoxin can be found in a wider range of food commodities preharvest. Significant quantities of aflatoxin can be found in maize, peanuts and treenuts. Wheat, rye, barley, grapes and coffee can be contaminated with ochratoxin.

2.1 Developed and Developing Countries

Mycotoxin contamination can occur throughout all phases of the food supply chain. However, there are differences between developed and developing countries (Wild, 2007; Shephard, 2008). In developed countries, most mycotoxin contamination occurs preharvest, in contrast to developing countries, where contamination occurs both pre- and postharvest. The differences reflect agronomic practices in the different regions and also the storage facilities available in developed compared to developing countries. As will be discussed later in

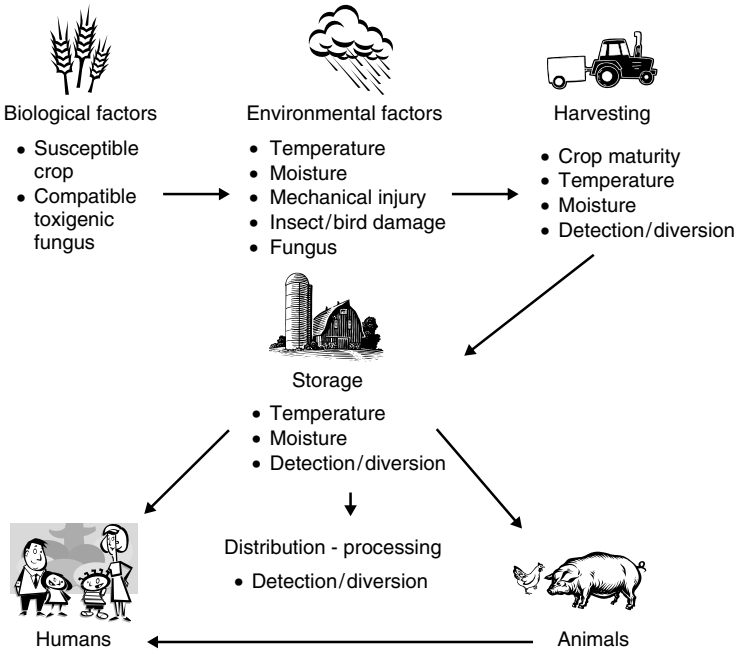

Figure 1 Factors affecting mycotoxin occurrence in the human food and animal feed chains. (Adapted from Pestka and Casale, 1990.)

Table 1 Food commodities and major associated fungi and mycotoxins

Commodity	Fungal species	Mycotoxins
Peanuts; maize; dried fruits	*Aspergillus flavus; A. parasiticus*	Aflatoxins
Peanuts	*A. flavus*	Cyclopiazonic acid
Cereal grains; coffee	*Penicillium verrucosum; A. ochraceus*	Ochratoxin A
Grapes	*A. carbonarius*	Ochratoxin A
Cereal grains	*P. citrinum; P. expansum*	Citrinin
Apple products	*P. expansum*	Patulin
Cereal grains	*Fusarium sporotrichioides; F. poae*	T-2 toxin
Cereal grains	*F. sporotrichioides; F. poae*	Diacetoxyscirpenol
Cereal grains	*F. culmorum; F. graminearum*	Deoxynivalenol
Cereal grains	*F. culmorum; F. graminearum*	Zearalenone
Maize	*F. verticillioides; F. proliferatum*	Fumonisins
Fruit; vegetables; cereal grains	*Alternaria alternata*	Tenuazonic acid
Rice	*P. citreoviride*	Citreoviridin
Cereal grains	*Claviceps purpurea*	Ergot alkaloids

the chapter, conditions of moisture and temperature, especially during storage, have a major impact on fungal growth and mycotoxin production. The well constructed and maintained storage facilities in developed countries largely mitigate against fungal growth. In developing countries, where storage facilities are often rudimentary, it is not unusual for grain to become moulded during storage. The human populations in developing countries will therefore have greater exposure to mycotoxins than their counterparts in developed countries. The major concern of mycotoxin contamination in developing countries is its impact on human health (Miller, 1998; Shier *et al*., 2005; Wild, 2007). In developed countries, mycotoxin contamination in the food and feed chains is tightly regulated to reduce human and animal exposure. The additional costs to the producer and/or the consumer to meet the economic burden of regulating the food and feed supply is the major mycotoxin concern in developed economies (Shier *et al*., 2005). The second major concern in both developed and developing countries is the impact of mycotoxins on animal health and production (Shier *et al*., 2005).

2.2 Mycotoxin Exposure and Disease

Mycotoxins pose a significant risk to the health and wellbeing of humans and animals and are a significant

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

food safety issue. Regulations and limits to the levels of mycotoxins that can be permitted in foods require that Governments and international agencies have a transparent process for arriving at acceptable levels (Moy, 1998). The process of risk assessment, which is overseen by a number of different international agencies, including the World Health Organization (WHO) and the Food and Agricultural Organization of the United Nations (FAO), is the paradigm used to determine the probability of risk posed by mycotoxins (FAO/WHO, 1995). It involves a number of different steps including hazard identification, hazard characterization, exposure assessments and, finally, risk characterization and evaluation, culminating with the communication of risk (Kuiper-Goodman, 1998; 2004). Each step in this process involves the collection and analysis of data based on scientific principles. It is obvious from the discussion in this chapter that the hazards from different mycotoxins have been identified in both man and animals. However, in many instances it is difficult to determine actual mycotoxin exposure and toxicity in human populations (Kuiper-Goodman, 1990). These important aspects of risk assessment are explored below. Risk assessments have been prepared for aflatoxin B_1, aflatoxin M_1, deoxynivalenol (DON or vomitoxin), fumonisins, ochratoxin A (OTA) and zearalenone (see Kuiper-Goodman, 2004; JEFCA, 2001). It is necessary to revise risk assessments as more data becomes available.

2.2.1 Exposure

Human populations are predominantly exposed to mycotoxins through plant-derived foods (Miller, 2008) and on occasion can be subjected to mycotoxins in the air, where dust or airborne spores are the vehicle, and occasionally dermally (Jarvis, 2002). Only trace levels of mycotoxins or their metabolites are likely in animal products (Pestka, 1995), with the possible exception of milk (van Egmond, 1989). When acute intoxications occur, it is possible to determine the source of the toxin, but in situations where mycotoxin exposure occurs at low levels for a prolonged period, the source and degree of exposure is more difficult to delineate. Diagnosis of a mycotoxicosis has largely depended upon the absence of other readily diagnosed diseases and the finding of a mycotoxin in the suspect food (Richard and Thurston, 1986). In making a diagnosis, not only must mycotoxins be considered for their unique effects, but they must be evaluated for possible interactions with other toxins, infectious agents and environmental stressors commonly encountered (see **Figure 2**) which can determine the severity of an intoxication.

Analysis of food commodities for mycotoxins, which is discussed below, is not always the appropriate approach when attempting to delineate human mycotoxin exposure. In situations where the subject may have been subjected to low-level, long-term exposure to heterogeneous distributions of mycotoxins in food, the time lag between mycotoxin intake and the development of chronic disease and the inaccuracy associated with food-intake questionnaires suggest that biomarkers are the most robust approach when attempting to delineate the epidemiology of human exposure and the aetiology of diseases associated with mycotoxins (Wild, 2007; Groopman *et al*., 2008).

A detailed understanding of the toxicology of aflatoxin has allowed the development of a biomarker (aflatoxin albumen adduct in serum) which is reliable in assessing aflatoxin intake (Wild and Turner, 2002). Its application has allowed the definition of the relationships between aflatoxin intake and immunosuppression, impaired child growth and development (Gong *et al*., 2002; Williams *et al*., 2004), and the role of aflatoxin in the aetiology of hepatocellular carcinoma. The demonstration of aflatoxin-induced mutations in the p53 tumour suppressor gene, *TP53*, has contributed significantly to the confirmation of aflatoxins as human carcinogens (Groopman and Kensler, 2005). Biomarkers have not been as well defined for other mycotoxins. Nevertheless, the use of clinical measures and mycotoxin levels in foodstuffs and body fluids has allowed an estimation of population exposure to mycotoxins. Using these approaches it has been shown, both in developed and developing countries, that exposure to mycotoxins, including fumonisins (Shephard, 2008) and DON (Turner *et al*., 2008a; 2008b), may exceed the recommended maximum tolerable daily intake.

2.2.2 Mycotoxicoses

A mycotoxicosis is the final stage in a series of events and the interaction of many factors that commenced with the growth of a mycotoxigenic fungus. The diseases arising from ingestion of one or a combination of mycotoxins may affect every system of the body resulting in various toxicity lesions which have been reviewed by Haschek *et al*. (2002). The adverse effects of mycotoxins may result in acute, overt disease or chronic, insidious conditions. Fortunately, contamination levels in food are usually not high enough to cause an overt toxicosis. Low levels of toxins in foods are likely to result in an array of metabolic disturbances (Riley, 1998), which may or may not be accompanied by pathological changes (Haschek *et al*., 2002). The effects will be unpredictable, as toxicity will depend on the toxin(s) present, dosage, duration of exposure and a variety of other factors, including age, nutrition and concurrent disease (Bryden, 2007; Wild, 2007). The gut microflora may also modify mycotoxin toxicity (Swanson *et al*., 1988; Annison and Bryden, 1998; Eriksen *et al*., 2002).

Mycotoxins have been associated with a number of human diseases, some acute and others chronic (**Table 2**), but only rarely has a direct involvement of a mycotoxin been established in the aetiology of the disease (Beardall

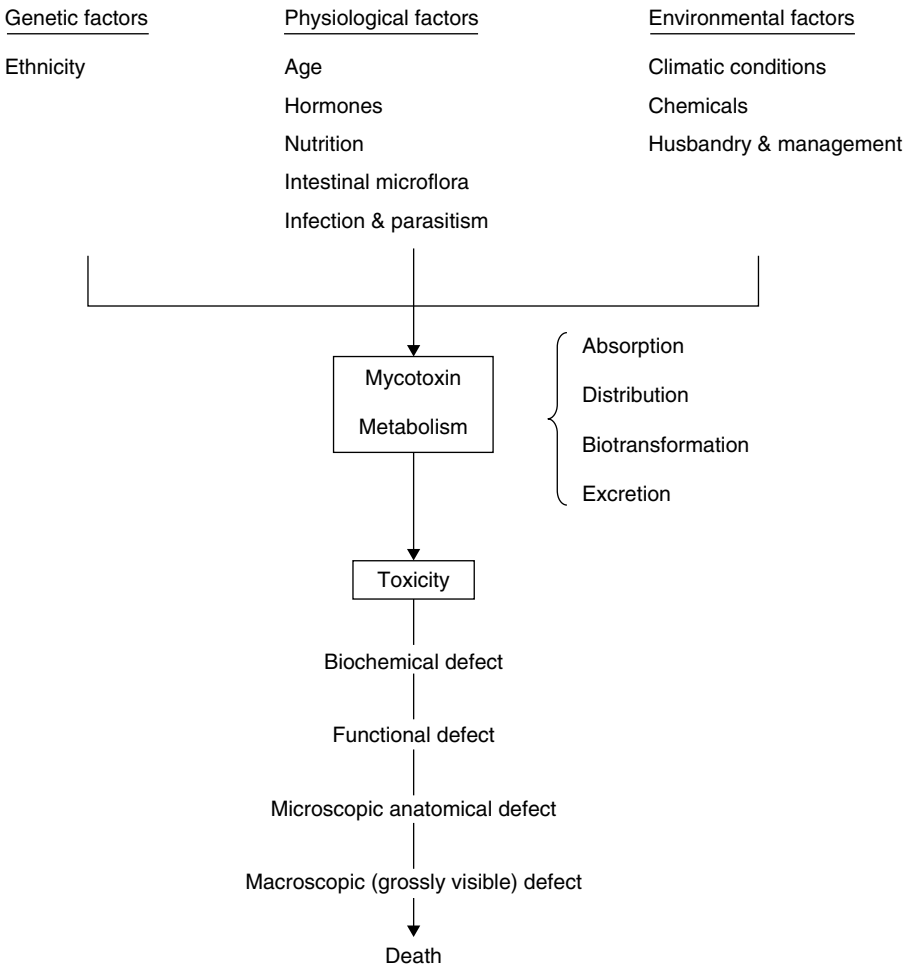

Figure 2 A simplified representation of some general relationships in a mycotoxicosis. (Adapted from Bryden, 1982.)

and Miller, 1994). Although rare, acute human intoxication with mycotoxins does occur, with the most recent case of aflatoxicosis occurring in Kenya in 2004 (Lewis *et al*., 2005). There are other recent recorded cases of intoxications with DON (Bhat *et al*., 1989) and fumonisins (Bhat *et al*., 1997) in India. The last major outbreak of ergotism occurred in Ethiopia (King, 1979). In developing countries, the vast majority of the population have limited food choices and rely on major dietary staples. If these staples are contaminated with mycotoxins, the human population will be exposed, in most instances, to low-level mycotoxin intake. If exposure is prolonged, the population is likely to suffer from a number of associated chronic diseases. It has now been demonstrated unequivocally that low-level aflatoxin intake in conjunction with hepatitis infection are major aetiological factors in the development of hepatocellular carcinoma worldwide (Henry *et al*., 1999; Groopman and Kensler, 2005). There is increasing evidence from both Africa and China that children may be exposed to aflatoxin *in utero* and this increases substantially after weaning. The result is childhood stunting and reduced growth rate, and suppressed immune function (Williams *et al*., 2004; Groopman *et al*., 2008). When this occurs, other infections and vaccination failures are likely to be the sequel (Bondy and Pestka, 2000; Oswald *et al*., 2005). During infection, the body will repartition nutrients away from growth and development to the immune system (Elsasser *et al*., 2000) and this phenomenon may contribute to the growth depression noted in children exposed to aflatoxin. Aflatoxin exposure has also been implicated in the aetiology of kwashiorkor (Hendrickse, 1991).

There is increasing evidence that other populations may also be exposed to low levels of mycotoxins. The data are indicative of a much wider global public-health problem. OTA has been associated with Balkan endemic nephropathy (BEN) and chronic interstitial nephropathy in northern Africa, and kidney tumours in humans (Bayman and Baker, 2006). There is epidemiological evidence to suggest that the fumonisins which cause equine leukoencephalomalacia and porcine pulmonary oedema (Haschek *et al*., 2002), and are carcinogenic in rats (Howard *et al*., 2001), may be a major aetiological factor in the incidence of human oesophageal cancer in southern Africa and China (Marasas *et al*., 2001). Recent epidemiological evidence demonstrate a higher

Table 2 Some human diseases in which mycotoxins have been implicated

Disease	Mycotoxin source	Fungus
Akakabio-byo	Wheat, barley, oats, rice	*Fusarium* spp.
Alimentary toxic aleukia	Cereal grains (toxic bread)	*Fusarium* spp.
Balkan nephropathy	Cereal grains	*Penicillium* spp.
Cardiac beriberi	Rice	*Aspergillus* spp., *Penicillium* spp.
Celery harvester's disease	Celery (Pink rot)	*Sclerontinia*
Ergotism	Rye, cereal grains	*Claviceps purpurea*
Hepatocarcinoma	Cereal grains, peanuts	*Aspergillus flavus, A. parasiticus*
Kwashiorkor	Cereal grains	*Aspergillus flavus, A. parasiticus*
Neural-tube defects	Maize	*Fusarium verticillioides, F. proliferatum*
Oesophageal tumours	Maize	*Fusarium verticilloides, F. proliferatum*
Onyalai	Millet	*Phoma sorghina*
Reye's syndrome	Cereal grains	*Aspergillus*
Stachybotryotoxicosis	Cereal grains (grain dust)	*Stachybotrys atra*

incidence of neural tube defects (NTDs) in babies from Texas, China, Guatemala and southern Africa, where the populations rely on foods prepared from maize (Marasas *et al*., 2004). International surveys of maize for fumonisin contamination has found that there are very few instances where maize can be shown to be totally free of this mycotoxin (Shephard *et al*., 1996) and this reflects the endophytic relationship of the fungus with maize (Bacon and Hinton, 1996). An association between NTD and fumonisins is likely (Voss *et al*., 2006), as these mycotoxins induce folate deficiency, which is a known cause of NTDs in humans (Stevens and Tang, 1997). Recent studies in mice, both *in vivo* and *in vitro* have demonstrated that fumonisins may cause NTDs (Gelineau-van Waes *et al*., 2005). The teratogenicity of other mycotoxins has been demonstrated for some 40 compounds which have been shown to be teratogenic and/or embryotoxic (Cawdell-Smith *et al*., 2007b) and is another potential consequence of low-level mycotoxin ingestion (see **Developmental Toxicology**).

The accepted paradigm is that the chronic effects of mycotoxins occur in populations in developing countries that rely heavily on a limited number of food staples. However, recent research in the United Kingdom demonstrates that low-level mycotoxin intake can occur in highly industrialized populations. In this study, Wild and his colleagues (Turner *et al*., 2008a; 2008b) developed an analytical procedure for the quantification of DON in human urine. They subsequently carried out a survey where they calculated cereal intake from the UK Adult National Diet and Nutrition Survey and compared it to 24 hours urinary DON excretion. The results demonstrated that the majority of adults in the United Kingdom were exposed to DON on the basis of urinary excretion of the toxin (Turner *et al*., 2008b). It was estimated that some individuals may exceed the European Union (EU) recommended maximum tolerable daily intake of 1000 ng DON (kg bodyweight)$^{-1}$ (Turner *et al*., 2008b). In a follow-up study it was demonstrated that removal of wheat-based foods from the diet reduced DON urinary excretion rates 11-fold (Turner *et al*., 2008a). These are very interesting and very disturbing results, as they are the first indication that populations in developed countries could be subjected to ongoing low-level mycotoxin ingestion. Implications of continued low-level DON ingestion by human populations has been reviewed (Pestka and Smolinski, 2005). In animal studies it has been demonstrated that chronic dietary exposure to DON causes impaired weight gain, anorexia, decreased nutritional efficiency and immune dysregulation (Trenholm *et al*., 1984; Rotter *et al*., 1996; Haschek *et al*., 2002). Trichothecenes, including DON, are immunostimulatory or immunosuppressing depending on dose, and frequency and duration of exposure (Pestka, 2008). The implications of these findings are further complicated by a recent Canadian survey of breakfast cereals which found frequent low-level multiple contamination with DON, fumonisins, OTA and zearalenone (Roscoe *et al*., 2008).

The scenarios following low-level mycotoxin ingestion are similar to what has been observed in different intensive animal production systems (cattle, pigs and poultry), which rely on grain-based diets. In these systems it has been shown that low-level mycotoxin intake can result in reduced feed intake, poor growth rate, lower egg production, changes in carcass composition, reduced fertility and hatchability of eggs, and immunosuppression (Bryden, 1982; Hamilton, 1982; Smith and Henderson, 1991; Dersjant-Li *et al*., 2003; Oswald and Taranu, 2008). However, the most insidious effects of low-level mycotoxin ingestion result from impairment of native and acquired resistance to disease. These effects are often difficult to recognize because signs of the disease are associated with infection rather than with the toxin that predisposed the animal to infection (Oswald *et al*., 2005). This is because the immunological effect of mycotoxins usually occurs at much lower levels of intake than do toxin effects on production parameters, such as growth rate or egg production (Bryden, 1982). Changes in the composition of grain following fungal

growth and alterations in nutrient intake and utilization that accompany mycotoxin ingestion further complicate diagnosis (Bryden, 1982; Hamilton *et al*., 1988; Dersjant-Li *et al*., 2003). Grazing animals may also consume mycotoxins if pastures are infected with fungi, especially endophytes (Bryden, 1998). The endophytic fungal genera *Neotyphodium* colonizes pasture grasses (tall fescue and perennial ryegrass) and produces a series of ergot alkaloids and related compounds (Bryden, 1994; Haschek *et al*., 2002; Cawdell-Smith *et al*., 2007a). The severity of any of these effects in different animal-product systems will depend on the level of mycotoxin present in the feed supply chain, the duration of exposure, the physiological status of the animal, and other environmental and disease factors that impact on the uptake, biotransformation, deposition and excretion of these toxins.

2.3 Economic Impact of Mycotoxins

A number of authors (Charmley *et al*., 1994; Lubulwa and Davis, 1995; Lamb and Sternitzke, 2001; Vardon *et al*., 2003; Robens and Cardwell, 2003) have attempted to quantify the potential costs of mycotoxins to society, but have found it difficult because of the uncertainty of the level and variability of contamination; variable price of affected commodities, and the costs associated with attempts to mitigate contamination. Nevertheless, the annual cost of mycotoxin contamination of food and feed in the United States is of the order US$1–2 billion (Robens and Cardwell, 2003). Moreover, the insidious nature of many mycotoxicoses, in both humans and animals, make it difficult to estimate their incidence and economic impact. If the various aspects of possible loss during a mycotoxicosis are considered, a multitude of possibilities exist. Obviously, they are complex and deal with many aspects of crop and animal production, storage, transport and processing of food commodities and implementation of food-safety regulations. Many factors would have to be considered in attempting to determine economic loss: reduced crop yield and quality; mycotoxin analysis; epidemiological surveys, including clinical and laboratory procedures; impaired human health and associated losses in productivity; reduced animal productivity, increased mortality, and morbidity and predilection of animals and birds, ingesting mycotoxins, to infection (Charmley *et al*., 1994). There is also a considerable cost to the industry as a whole, in terms of research, monitoring and extension; extra handling and distribution costs; increased processing costs and loss of consumer confidence in the safety of food products (Robens and Cardwell, 2003). Development and use of simulation models will greatly assist in the quantification of losses from mycotoxin contamination (Vardon *et al*., 2003).

Table 3 National maximum tolerated levels for aflatoxins in human food (Food and Agriculture Organization, 2004)

Nation	Total aflatoxin standard in human food ($\mu g\,kg^{-1}$)
Australia	5
China	20
European Union (EU), harmonized	4
Guatemala	20
India	30
Ireland	30
Kenya	20
Taiwan	50

With the establishment of the high toxicity and carcinogenicity of some mycotoxins, international regulations that limit levels in food and feedstuffs for both man and animals have been imposed (Food and Agriculture Organization, 2004; van Egmond and Jonker, 2004). Maximum tolerated levels of aflatoxins in human food for selected countries appear in **Table 3**. These limits have implications for international trade in grain crops and in some instances can result in a barrier for the export or import of commodities from different parts of the world. Interestingly, the outbreak of 'Turkey X' disease that occurred in the United Kingdom in 1960s was the result of the importation of peanut meal from Brazil, which was subsequently incorporated into turkey diets and resulted in the death of many thousands of poults (Richard, 2008). This is an example of how the international grain trade can result in the movement of mycotoxins between continents. Moreover, it should be remembered that fungi do not recognize international boundaries, as fungal invasion and toxic production is associated with seasonal conditions and particular crops.

Wu (2004) has completed a comprehensive risk and economic analysis of lowering acceptable levels of fumonisins and aflatoxin in world trade. In that study she demonstrated that the United States would experience significant economic losses from tighter controls. The developing countries China and Argentina were more likely to experience greater economic losses than sub-Saharan Africa. The disturbing outcome of this detailed analysis was that tighter controls were, overall, unlikely to decrease health risks and may have the opposite effect (Wu, 2004). Otsuki *et al*. (2001) estimated health risks would be reduced by 2.3 deaths per million people per year in the EU if a lower aflatoxin standard was implemented. In other words, very stringent international trade regulations could lead to the situation where exporting countries, especially developing countries, would retain higher risk commodities, which would subsequently be available for their own populations, communities which are already exposed to higher level of mycotoxins than consumers in developed countries (Wu, 2008).

3 OCCURRENCE OF TOXIGENIC FUNGI AND MYCOTOXINS

Fungi are a normal part of the microflora of standing crops and stored foods, but the production of mycotoxins depends upon the fungi present, agronomic practices, the composition of the commodity and the conditions of harvesting, handling and storage.

3.1 Biology and Ecology of Mycotoxigenic Fungi

Many studies have examined the fungal flora of food commodities from all climatic zones of the world. The species most often encountered belong primarily to five genera: *Alternaria*, *Aspergillus*, *Cladosporium*, *Fusarium* and *Penicillium*. Other genera, including *Chaetomium*, *Claviceps*, *Diplodia*, *Myrothecium*, *Phoma*, *Phomopsis*, *Pithomyces* and *Stachybotrys*, also contain mycotoxic fungi (Moss, 1991). These moulds produce many different toxic compounds, but not all isolates of the same species produce toxins. The genera of most concern globally are *Aspergillus, Fusarium* and *Penicillium* (Miller, 1998), which are predominantly soil borne. An understanding of fungal biology and ecology, especially the manner in which fungi interact with their plant hosts, gives a good indication of the likely occurrence of mycotoxins, that is, where mycotoxins will be found, and the conditions that promote their synthesis and production by toxigenic fungi. Moreover, toxin production is often unrelated to total fungal biomass and the ecological requirements for growth and mycotoxin production may differ considerably between fungal species (Magan, 2006).

3.1.1 Conditions Favouring Mycotoxin Production

All food commodities serve as a suitable substrate for mould growth and mycotoxin formation. Toxigenic fungi can demonstrate variable toxin production depending on physical factors (moisture, relative humidity (RH), temperature and mechanical damage), chemical factors (carbon dioxide, oxygen, composition of substrate, pesticide and fungicides, etc.) and biological factors (plant variety, stress, insects, spore load, etc.) (Frisvad, 1995; Wicklow, 1995). Moisture and temperature are two factors that have a crucial effect on mould growth and mycotoxin production and are so intimately linked that it is difficult to discuss one independently from the other. Moisture is expressed in terms of RH and water activity (a_w). a_w has taken the place of moisture percentage or content as the most useful expression of the availability of water for micro-organism growth (Pitt and Hocking, 1997). The a_w is the ratio of the vapour pressure of the water in the substrate or feedstuff to that of pure water at the same temperature and pressure. The lower the a_w, the less available water is for micro-organisms. All micro-organisms, including toxigenic fungi have a minimum, optimum and maximum a_w for growth. Minimum water requirements for growth are different as temperature and substrate changes. The minimum a_w for growth can be lowest at the optimum temperature for growth and highest near the minimum and maximum growth temperatures. Also, the better the substrate for growth, the lower will be the limiting a_w. In general, the higher the a_w, the lower the temperature at which moulds will grow and produce mycotoxins (Pitt and Hocking, 1997).

Although a_w is the best measure of the availability of water in a commodity to fungi it is often more convenient to measure and think in terms of the moisture content (Wicklow, 1995) and the relationships for different cereals are shown in **Table 4**. Pathogenic fungi that invade crops prior to harvest usually require high moisture levels (20–25%) for infection compared to fungi that can proliferate during storage and grow at moisture levels in the range of 13–18%. Hence, most foods with moisture contents above 13% are susceptible to growth of toxic moulds and mycotoxin formation; although some commodities that have a high oil content (i.e. oilseeds) may be susceptible to mould growth at moisture contents below 13% (CAST, 1989; Wicklow, 1995).

3.1.2 Crops and Field Conditions

The accumulation of *Fusarium* toxins in cereal grains occurs during high moisture conditions around harvest (Sutton, 1982) (**Figure 3**), whereas preharvest aflatoxin contamination of crops, including peanuts (Diener *et al*., 1987) and maize, is associated with high temperatures, insect damage and prolonged drought conditions (Payne, 1998). Moreover, because *Aspergillus* can tolerate lower a_w than *Fusarium,* it is more likely to contaminate commodities both preharvest and postharvest, whereas *Fusarium* is more likely to be found as a contaminant preharvest (Abramson, 1998). Likewise, *Penicillium* usually invades plant produce postharvest (Leistner, 1984). These examples demonstrate that although it may be convenient to describe fungi as pre- and postharvest contaminants, the actual colonization and proliferation of fungi is not clear cut, but depends on the environmental and ecological circumstances, and the contaminating toxins will differ accordingly (**Table 5**).

Fusarium plant pathogens can cause major economic losses to crop production as they may cause seedling blights, root rots, crown rots, leaf blights, head blights and head and cob rots. These different plant pathological conditions result from infection by different *Fusarium* species and occur on different crops (Summerell *et al*.,

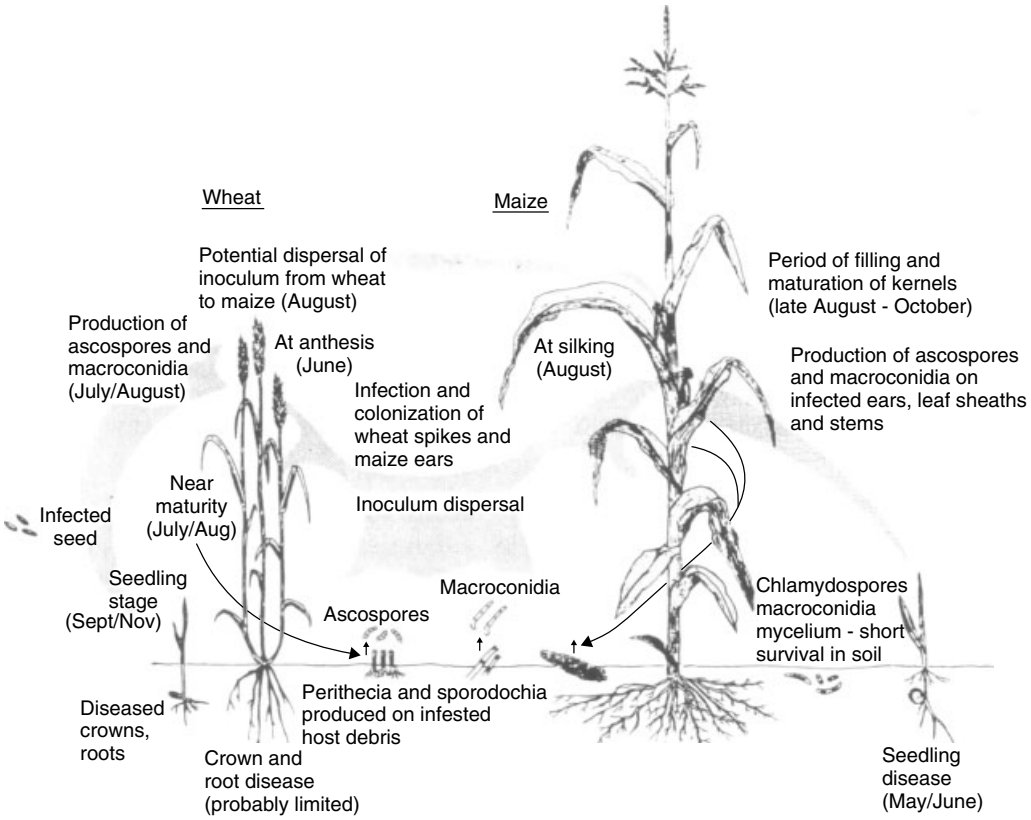

Figure 3 Disease cycle of *Fusarium graminearum* in wheat and maize. (Reproduced with permission from Sutton, 1982. © Canadian Phytopathological Society.)

2001). Glenn (2007) and Miller (2008) have recently reviewed the role of *Fusarium* species in mycotoxin contamination of small grains and maize. The most prominent DON-producing *Fusarium* species are *F. graminearum* and *F. culmorun*. These fungi are closely related and cause *Fusarium* head blight in small grains and *Gibberella* ear rot in maize. These infections occur more frequently when rainfall is high during flowering. Which of the two species will dominate depends on the temperature, with *F. graminearum* being associated with cereal grain in warmer areas and *F. culmorun* in cooler areas. *F. verticillioides* and *F. proliferatum* are associated with maize and produce fumonisins. These fungi cause *Fusarium* kernel rot, which occurs in warm, dry years and often in insect-damaged plants. Descriptions of the role of *Fusarium* species in plant disease can be found in a number of books, including Miller and Trenholm (1994), Leonard and Bushnell (2003) and Summerell *et al*. (2001).

Mycotoxin production by *Fusarium* species can be confusing for those who are new to mycotoxicology. In the past, *Fusarium* species were sometimes misidentified and recent changes to fungal taxonomy has resulted in the changing of the names of a number of species. In the last 20 years, the number of mycotoxigenic *Fusarium* species has increased from 13 to 42 (Desjardins, 2006). Marasas *et al*. (1984) were the first to attempt to reconcile *Fusarium* taxonomy and mycotoxin production. This was an excellent beginning and it has since been followed by Burgess *et al*. (1994), Leslie and Summerell (2005)
