Such laboratory studies are concerned with the analytical detection, and determining the nature and relative proportions, of substances produced on thermolysis of materials under differing conditions of generation. Ideally, the analyses should be conducted under the following generation conditions; simple heating, complete combustion, oxidative pyrolysis and anaerobic pyrolysis. It is thus necessary to subject materials to a range of temperatures in atmospheres with differing oxygen contents, with the resultant effluent being analysed by appropriate instrumental procedures. In some instances highly toxic materials may be generated over a narrow temperature range, and if a differential temperature study is not carried out these materials may be missed. In addition to the influence of temperature and oxygen availability on the materials generated from combustion, it is important to study the nature of the materials generated as a function of time in the combustion phase since the pattern may change appreciably. **Table 3** gives examples of the influence of environmental variables on combustion products generated.

From a knowledge of the nature of the materials generated under different conditions of combustion, it may be possible to predict a hazard pattern for a given material, providing that there is an adequate volume of background information on the toxicology of the materials. In some cases, a major hazardous material may be identified from a large number of analytically detected substances produced by combustion of a specific material. For example, with PVC, about 75 organic products have been detected on thermal decomposition, most being aliphatic or aromatic hydrocarbons (Wooley, 1971). However, a major product that begins to be liberated at 200–300°C is hydrogen chloride, and it has been estimated that 1 kg PVC may yield about 400 g HCl on complete combustion. Hydrogen chloride causes PCSI effects of the eye and respiratory tract, and in sufficient concentrations may produce inflammatory lesions in the respiratory tract. PVC combustion is recognized as a major hazard in fires in buildings with extensive polymers in the construction and furnishings (Dyer and Esch, 1976).

Small-scale laboratory tests yield useful, though often preliminary, information on the nature of combustion products generated from specific materials under defined conditions, and allow a qualitative assessment of the hazards that may be encountered for a specific material in a fire. However, the majority of fires involve the burning of a multiplicity of materials, including structural and furnishing components. In an attempt to obtain more reliable information it may be desirable to undertake large-scale experimental fires with appropriate instrumentation. Such tests are likely to be expensive and require careful planning, specifically with respect to sampling and analysis of the atmosphere generated. Guidance on the planning of such large-scale tests will clearly be obtained from preliminary small-scale laboratory combustion-product studies.

6.3 Laboratory Exposure Studies

In a strictly physicochemical analytical approach to defining the nature and relative proportions of combustion products generated from specific materials, the likely hazards from the effluent smoke are determined by attempting to predict the probable combined toxicity of the constituents in the smoke from knowledge of their individual toxicities. Such an approach may result in misleading predictions since there is the possibility for chemical and toxicological interactions, including synergy. Attempts have therefore been made to determine the toxicity of smokes from specific materials by exposing animals to the products of thermolysis and monitoring for adverse effects by standard and special procedures. Such tests readily lend themselves to observations on irritancy and acute toxicity. The former will give an index of potentially harassing and incapacitating effects of effluent smoke from the material, and the latter can give an indication of tissue-injuring or potentially lethal adverse effects, such as lung damage, or of functional effects, such as neurobehavioural abnormalities. Such tests are frequently carried out with the smoke being generated under differing conditions of atmospheric oxygen content and thermolysis temperature. For comparative purposes, the findings from fire combustion toxicology studies are frequently referred to tests from the burning of a standard material, usually wood. Although such tests give useful information in themselves, they are particularly valuable when viewed in the light of studies on the analysis of combustion products generated under similar conditions. Thus, when interpreting laboratory data in an attempt to define possible hazards from combustion products of materials, it is highly desirable to have information on both the nature and relative proportions of combustion products, and on their effects in experimental animals exposed to combustion products generated under similar conditions. Where appropriate expertise and facilities exist, it is possible to combine analytical studies with animal-exposure tests. Also, animal exposures have been performed in large-scale fire tests.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Problems may be encountered in defining the presence of novel or highly toxic materials for several reasons: first, because of the multiplicity of materials generated, there may be limitations on the analytical capability; second, knowledge of the toxicology of some materials generated is sparse. It therefore follows that animal studies may draw attention to the presence of highly toxic, or unsuspected, materials in a test atmosphere. This is illustrated by investigations on a fire-retarded polyurethane foam. The products from nonflaming combustion of a trimethylolpropane-based rigid urethane foam fire-retarded with an organic phosphate, *O,O*-diethyl-*N,N*-bis(2-hydroxyethyl)aminomethyl phosphonate were found to produce grand mal seizures in rats; such effects were not seen when the foam was not fire-retarded (Petajan *et al*., 1974). Subsequent chemical analyses revealed the presence of 4-ethyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]octane-1-oxide in the smoke (Voorhees *et al*., 1975). This is a material of high acute toxicity (Kimmerle, 1976). Further studies demonstrated no unusual toxicity when the flame-retarded polyurethane foam was either gradually or rapidly pyrolysed at 800°C in the absence of air; however, convulsions were observed when the material was flash pyrolysed in the presence of a flow of air (Hilando and Schneider, 1977). See Purser (1992) for a discussion of caged bicyclophosphorus esters in combustion processes.

For both chemical analysis and animal-exposure studies, special equipment is usually required to permit the generation of atmospheres for the combustion of materials under differing environmental conditions. Several types of apparatus have been designed and used for combustion toxicology atmosphere generation, and have been discussed by Norris and Ballantyne (1999). The selection of such equipment will depend on the combustion conditions that are to be simulated; these may include smouldering, flaming, preflashover and postflashover.

Most recent studies on smoke-inhalation injury have called on advances in molecular toxicology. For example, Lee *et al*. (2005) developed a smoke-inhalation model and incorporated a genome-wide analysis of gene expression. Microanalysis revealed a modified brain transcriptome with changes peaking at 24 hours and subsiding seven days post smoke inhalation. Overall, smoke inhalation down-regulated genes associated with synaptic function, neurotransmission and neurotrophic support, and up-regulated genes associated with stress response, including NO synthesis, antioxidant defences, proteolysis, inflammatory response and glial activation. Thus, such investigations afford insight into the complex molecular pathophysiology of smoke inhalation in the brain. *In vitro* methods have been described for assessing toxicity of combustion products. For example, Lestari *et al*. (2006) described studies comparing three *in vitro* exposure systems coupled with cytotoxicity assays for neutral red uptake, ATP and 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2 H-tetrazolium (MTS).

6.4 Studies on Exposed Human Populations

Valuable and specific information may be obtained concerning the adverse effects of exposure to fire atmospheres and on the possible long-term hazards of recurrent exposures to fires, by appropriate investigations on fire-fighters and on the victims of fires. Major sources of information have been derived from post-mortem examination of fire victims; clinical, radiological and clinical-chemistry examination of nonlethal fire victims; and medical and epidemiological studies on fire-fighters. In the context of defining the requirements for respiratory and other protective equipment for fire-fighters based on the medical and epidemiological data, short-term repeated and chronic exposure situations, as well as acute exposure all require to be taken into consideration.

7 CHEMICAL HAZARDS TO FIRE-FIGHTERS

7.1 Background and General Considerations

Fire-fighters have one of the most dangerous and hazardous of occupations on essentially all occasions that they are summoned to situations, and have an associated high level of morbidity and mortality from various differing and sometimes combined causes. Overall, the most significant causes for adverse health effects are as follows:

- **Trauma:** notably from falling objects, during rescue situations, and during close-in fire-fighting operations; such trauma may result in significant physical injury and, on occasion, mortality. Also relevant is the fact that associated with the occupational noise exposure, several studies have shown that this may cause hearing loss (Kales *et al*., 1997; 2001; Tubbs, 1995).
- **Thermal:** as primary burns to the skin and respiratory tract, and heat stress. The latter is a function of environmental temperature, insulting properties of protective clothing and endogenous heat production from severe physical exertion, compounded by the additional weight of equipment such as self-contained breathing apparatus (SCBA).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- **Ergonomic:** the high-energy costs of fire-fighting may clearly be inter-related with, and compounded by, other health concerns.
- **Psychological:** there are multiple potential causes for the development of mental trauma in fire-fighters and these include thoughts of personal security and safety, victim rescue and loss, emotional scenes and heavy social responsibility (Guidotti and Clough, 1992). All these precipitating factors occur against a background of sustained heavy workloads, physical and mental exhaustion, heat stress and the constant need for vigilance. It is therefore to be anticipated that under these very difficult conditions that postdisaster psychological reactions may develop, including post-traumatic stress disorders (Psarros *et al*., 2008).
- **Toxic chemicals:** there is sequential exposures to smoke and contained chemicals, often at high concentrations, many of which are known or suspected to produce acute and/or long-term health problems. This aspect of health concern about fire-fighting is discussed below, and by Guidotti and Clough (1992).

Fire-fighters are recurrently exposed to a multiplicity of materials that may cause acute, cumulative and/or chronic health problems; typical examples of such chemicals are CO, HCN, sulphur dioxide, hydrogen chloride, phosgene, isocyanates, oxides of nitrogen, acrolein, acetaldehyde, asbestos, polycyclic aromatic hydrocarbons (PAHs), benzene, methanol, methane, methylene chloride and toluene (Aronson *et al*., 1994; Guidotti and Clough, 1992; McDiarmid *et al*., 1991). These illustrative examples emphasize the potential for short-term, long-term and interactive toxicity from multiple exposures. That such materials may be absorbed and cause systemic toxicity has been demonstrated by several studies. For example, that fire-fighters absorb cyanide is indicated by an increased serum thiocyanate (Levine and Radford, 1978). Several studies have demonstrated that fire-fighters have an increased COHb concentrations, Thus, Sammons and Coleman (1974) found that that there was a significant difference in COHb concentrations between nonsmoking firemen (mean 5.0%; range 2.5–13.9%) and nonsmoking controls (mean 2.3%; range 1.0–11.7. Similarly, Radford and Levine (1976) found increased COHb concentrations in firemen after fighting a fire (4.53%) compared with unexposed controls (2.17%). Increased COHb concentrations were also found after fire-fighting by Loke *et al*. (1970) and Levy *et al*. (1976) (**Figure 3**). During actual fire-fighting exposures the exposure concentration and dosages received are usually unknown, and will vary between different fires and within the same fire from time-to-time, according to combustion conditions. Thus, when measurements are made, this can be helpful to assess potential adverse effects and hazards. For example, an estimate was made during a fire-fighting exercise of exposure to PAHs (Moen and Overebo, 1997).

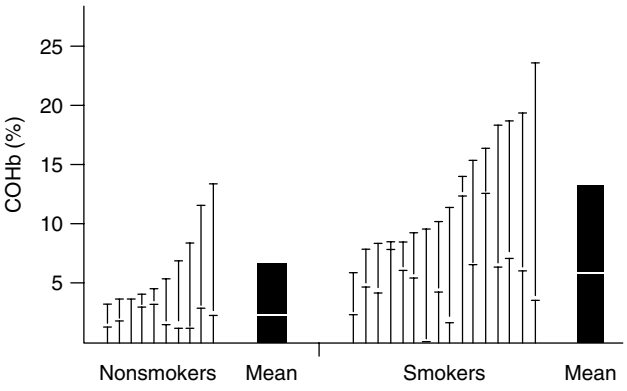

Figure 3 Increases in carboxyhaemoglobin (COHb) concentrations in fire-fighters following exposure to smoke. The lower bars represent COHb pre-exposure and the upper bars the increase in COHb postexposure. Drawn from data in Levy *et al*. (1976) and Loke *et al*. (1970).

The participants gave urine samples 6–7 hours after extinguishing burning diesel oil, and the samples were analysed for 1-hydroxypyrene by high performance liquid chromatography (HPLC). A small, but statistically significant, increase in urinary 1-hydroxypyrene was measured after the fire-fighting exercise. Because of the conditions of the exercise and the personal protective equipment used, the estimate may have represented an underestimate of actual exposure in real situations.

For a variety of reasons, fire-fighting carries a high mortality and morbidity rate. Several epidemiological studies have been undertaken with respect to general and specific causes of morbidity and mortality in fire-fighters; some of the major studies are as follows. In a study of Alberta fire-fighters, Guidotti (1993) did not find an association with cardiac or chronic pulmonary diseases, but did find a possible association with occupational exposure for renal and ureteric cancer, and limited evidence for excess urinary bladder, colon and rectal cancers. In a retrospective cohort study (1950–1989) with 5995 subjects from six fire departments in the Toronto metropolitan area (Aronson *et al*., 1994), it was found that three specific causes of death had statistically significant excesses: brain tumours (standardized mortality rate (SMR) 201; 95% confidence interval (CI) 110–337); 'other major neoplasms (SMR 238; 95% CI 145–367) and aortic aneurysm (SMR 226; 95% CI 136–354). Tornling *et al*. (1994) studied the incidences of mortality and cancer in Stockholm fire-fighters with at least one year of employment during the period 1931–1983. They found overall mortality (1951–1986, based on tracing of individuals) was lower than expected (SMR 82; 95% CI 72–91) compared with local figures. Although the overall cancer incidence was equal to that expected (SMR 100), an excess of gastric cancer was noted (18 observed vs. 9.37 expected; SMR 192). The results from various

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

studies are somewhat inconsistent, as would be anticipated from the different working conditions. However, in a review analysis of major publications up to 1995, Guidotti (1995) came to the following conclusions:

- **Lung cancer:** evidence for an association, but insufficient for a general assumption of a risk.
- **Cardiovascular disease:** no evidence for increased risk overall for heart disease.
- **Aortic aneurysm:** evidence incomplete.
- **Genitourinary cancer:** evidence strong for an association and presumption of risk.
- **Lymphohaematopoietic cancers:** some evidence and a general presumption of risk, but requires a case-by-case review.
- **Rectocolonic cancer:** sufficient evidence to conclude an association, but not sufficiently strong to determine if there is a good presumption of risk.

7.2 Respiratory Disease

Smoke exposures by unprotected fire-fighters and local community members have been associated with increased ED visits and hospitalizations for chronic obstructive pulmonary disease (COPD), bronchitis, asthma and chest pain (CDC, 2008; Sutherland *et al*., 2005). Several studies have shown that exposure to a fire atmosphere produces acute changes in pulmonary function, and may be a factor in the development of chronic lung dysfunction. For example, in a study of fire-fighters from Basel, Switzerland, it was found that frequent respiratory symptoms included rhinorrhoea, cough, dyspnoea, with an odds ratio for hyper-reactivity to methacholine of 2.24 (95% CI 1.12–4.48) compared with the a general population control group (Miedinger *et al*., 2007). Musk *et al*. (1979) studied acute changes in fire-fighters during routine duties and found an average decrease in forced expiratory volume over one second (FEV_1) of 0.005 l, which was related to subjectively assessed smoke exposure; decreases in FEV_1 of 0.1 l or more were found in 30% of subjects. Brandt-Rauf *et al*. (1989) found that for fire-fighters not wearing respiratory protective equipment, there were statistically significant postfire decrements in FEV_1 and forced vital capacity (FVC). Pre- and postfire average FEV_1 values were 5.03 and 4.81 l respectively. Gu *et al*. (1996) studied acute respiratory effects in fire-fighters tackling a sustained store fire, and in whom there were irritant effects in the eyes and upper respiratory tract. Spirometry conducted two days after the fire showed that FEV_1 and FEV_1/FVC in smokers and FEV_1 in nonsmokers were significantly less than in controls; there were no significant differences in average fire-fighting times between smokers and nonsmokers. Serra *et al*. (1996) studied pulmonary function in 92 firemen and compared the findings with a group of policemen (controls). They measured FVC, FEV_1, forced expiratory flow (FEF) at 75, 50 and 25% of the FVC, total lung capacity (TLC), residual volume (RV), functional residual capacity (FRC) and CO diffusion for alveolar capillary integrity. They demonstrated the firemen to have significantly reduced FEV_1 (3.90 ± 0.50 SD vs. controls of 4.04 ± 0.44; $p < 0.05$), FEV_1/FVC (80.07 ± 5.89 vs. 83.89 ± 6.32; $p < 0.001$), FEF_{25} (1.58 ± 0.47 vs. 1.99 ± 0.69; $p < 0.001$) and RV (1.57 ± 0.28 vs. 1.76 ± 0.45; $p < 0.01$). Alveolar capillary integrity (as evidenced by CO diffusion) was not significantly different from controls. Adverse respiratory effects may also occur during the process of overhaul, which is the later stage in which fire-fighters search for and extinguish possible sources of reignition, and during which phase respiratory protective equipment may not be worn. Burgess *et al*. (2001) monitored groups of fire-fighters who either wore cartridge respirators or did not wear respiratory protective equipment during overhaul operations. Testing at baseline (pre-exposure) and at one hour after overhaul included FVC, FEV_1, serum Clara cell protein (CC16) and serum surfactant-associated protein A (SP-A). Overhaul increased CC16 in both groups, indicating increased alveolar capillary permeability. Also, SP-A increased, and FVC and FEV_1 decreased in fire-fighters wearing cartridge respirators, indicating they may not give adequate protection during overhaul. The authors concluded that SCBA should be worn during overhaul procedures to prevent the potential for lung injury.

For cumulative effects, Peabody (1977) reported a decrease in pulmonary function for San Diego fire-fighters, which was statistically significantly greater than that of the general population, and Kales *et al*. (1997) recorded a significantly decreased percentage predicted FEV_1 in hazardous materials fire-fighters, particularly in those older than 35 years of age. Over a two year period, Peters *et al*. (1974) found that in fire-fighters, the rate of decline in pulmonary function, measured by FVC and FEV_1, was twice the expected rate; these changes were significantly related to the frequency of exposure. The rate of decline in pulmonary function in fire-fighters, as assessed by FEV_1, shows variability between individuals, but in some the accelerated decline ($\geq 60\,ml\,yr^{-1}$) that has been measured (Burgess *et al*., 2004) is in excess of the average annual rate of decline in FEV_1 of around 20–30 ml in the general population (Burrows *et al*., 1986).

Wildland fire-fighters were studied preseason, postfire and postseason with respect to upper and lower respiratory effects by Gaughan *et al*. (2008). The investigation included spirometry and measurement of albumin, eosinophilic cationic protein (ECP) and myeloperoxidase (MPO) as indicators of inflammation in sputum and nasal lavage fluid (NLF). Respiratory symptom

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat116
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

scores were higher postfire compared to preseason, and mean FEV_1 was lower postfire (4.35 l) compared to preseason (4.57 l; $p < 0.001$), and decreased postfire to postseason (4.54 l; $p < 0.001$). The mean postseason FEV_1 was not statistically significantly different from the preseason mean value ($p = 0.60$). There were no significant differences in FVC values preseason, postfire and postseason. Multifactor analysis of the inflammatory markers showed that, for individuals, increases in sputum and NLF, ECP and MPO from preseason to postfire were all significantly associated with postfire respiratory-symptom scores. Josyula *et al.* (2007) studied the association between cytokine genotypes and sputum concentrations on the longitudinal decline in pulmonary function in 67 fire-fighters, having a mean of 16.6 years of service (range 3–32 years). They analysed deoxyribonucleic acid (DNA) for functional polymorphisms of IL (interleukin)-1β, interleukin 1-receptor agonist (IL-1RA), IL-8, IL-10, tumour necrosis factor α (TNF-α) genes and sputum evaluated for cytokine concentration by enzyme-linked immunosorbent assay (ELISA). They determined the annual rate of FEV_1 decline was greater for fire-fighters with TT genotypes at IL-10 and with CT or TT genotypes at IL-1RA. These genotypes were not associated with concentrations of sputum cytokine, but increased IL-1RA was associated with a slower rate of FEV_1 decline, as was increased sputum macrophage count. The authors concluded that cytokine genotypes were associated with the rate of decline of FEV_1 but did not alter concentrations of sputum cytokine. They suggested that increased sputum IL-1RA may be protective.

Following the New York World Trade Center disaster on 11 September 2001, involving the deliberate crashing of civil airplanes into the Twin Towers by terrorists, concerns emerged and were stressed about the potential for acute and long-term health hazards related to exposures to particulate building material such as pulverized cement, glass, fibreglass, asbestos, silica, heavy metals and soot (Edelman *et al.*, 2003). The need for long-term medical follow-up, particularly in respect of the development and progression of respiratory diseases, was emphasized by the discovery that the US Environmental Protection Agency (EPA) misled New York citizens about the possible dangers from debris, dust and smoke in the air around the World Trade Center; this deceit was unveiled as a consequence of the US Democrats asking for hearings in respect of the allegations (Barrett, 2003). In August 2003, the internal watchdog of the EPA found that the agency, at the urging (instruction?) of Bush White House officials gave misleading assurances that there was no health risk from the dust (Ballantyne, 2005). According to the report of the inspector general, the EPA were urged to add reassuring statements and remove cautionary statements by having the National Security Council control EPA communications. This enforced misinformation was given against then existing credible published descriptions of harmful and persistent adverse effects, particularly on the respiratory tract; these included cough, bronchial hyperactivity, increased severity of asthma, bronchiolitis and spirometric changes (CDC, 2001a; 2001b; 2002; Lioy *et al.*, 2002; Prezant *et al.*, 2002; Rom *et al.*, 2002; Scanlon, 2002; Stephensen, 2002). Reports of long-term respiratory adverse health effects have continued to appear (Chen and Thurston, 2003; Gavett, 2006; Offenberg *et al.*, 2003; Payne *et al.*, 2004; Salzman *et al.*, 2004; Johnson *et al.*, 2005).

A raised risk for emphysema was found in a mortality study conducted by Demers *et al.* (1992). The importance of using respiratory protective equipment by fire-fighters was shown in a study by Tepper *et al.* (1991), who re-evaluated 632 Baltimore city firemen 6–10 years after baseline measurements, and found that those who never wore a mask had a 17.5 times greater decline than in mask wearers. NIOSH (1987) recommended a protective factor of 10 000 for the pressure-demand, SCBA used by fire-fighters.

Recently, attention has been drawn to the potential for adverse health effects following exposure to combustion-derived nanoparticles, which appear to have a common mechanism of injury through oxidative stress (Donaldson *et al.*, 2005). These materials, in addition to posing pulmonary hazards through oxidative stress, inflammation and malignancy, also have the potential to redistribute to other organs following pulmonary deposition. Nanoparticles are usually defined as primary particles with at least one diameter <100 nm, whilst ultrafine particles are defined as particles <100 nm in all directions (Lighty *et al.*, 2000).

7.3 Cardiovascular Disease

Fire-fighters are exposed to CO, CO_2, acrolein, sulphur dioxide, organic solvents, noise, heat, and physical and emotional stress. It is therefore to be anticipated that they would be at greater risk to develop CV disease. Acute myocardial incidents are reported, but rarely. For example, Jan *et al.* (2007) described a case of acute transient (four days) cardiomyopathy after smoke exposure; the patient developed acute cardiac failure, without evidence of CO poisoning. There is experimental evidence in Wistar Kyoto rats that repeated (subchronic) exposures to oil-combustion-derived combustion particles can cause inflammatory, degenerative and fibrotic myocardial injury (Kodavanti *et al.*, 2003). However, some epidemiological studies on fire-fighters do not demonstrate an excess of CV disease or mortality from CV disease (Beaumont *et al.*, 1991; Demers *et al.*, 1992; Deschamps *et al.*, 1995; Eliopulos *et al.*, 1984; Guidotti,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat116
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1993; Sardinas *et al*., 1986). Summarizing the available evidence, Guidotti (1992) stated that population-based mortality and disability surveillance studies suggest there is a relatively small, but significant excess for disability, but not mortality, for nonmalignant CV disease for fire-fighters. More targeted cohort and case–control studies do not support such an excess, but suggest a strong healthy-worker effect (Aronson *et al*., 1994; Howe *et al*., 1988). However, some studies do suggest an excess of coronary artery disease (Musk *et al*., 1978). Holder *et al*. (2006) conducted a retrospective review of Massachusetts fire-fighters, 362 receiving Heart Presumption pensions (1997–2004) and a comparison group of 310 professionally active fire-fighters. Of the retirements, 77% were recorded as being due to coronary artery disease and 23% for other CV conditions. CV risk-factor prevalence was high among all retiree subgroups, and the authors concluded that the results support a suggestion for improved CV prevention and risk-reduction strategies among fire-fighters. Two studies have demonstrated increased SMRs for circulatory disease with increasing years of work (Demers *et al*., 1992; Vena and Fielder, 1987), and Aronson *et al*. (1994) showed an increase in aortic aneurysms.

Table 5 Site-specific neoplasms that are probably occupationally associated in fire-fighters

Neoplasm site/type	Reference
Buccal and pharyngeal	Mastromatteo (1974)
Oesophagus	Beaumont *et al*. (1991)
Colonorectal	Guidotti and Clough (1992)
Urinary tract	Deschamps *et al*. (1995), Ma *et al*. (2006)
Testicular	Ma *et al*. (2006), LeMasters *et al*. (2006)
Prostate	LeMasters *et al*. (2006)
Uterine cervix	Ma *et al*. (2006)
Lung	Heyer *et al*. (1990)
Brain	Aronson *et al*. (1994), Demers *et al*. (1992) Howe and Burch (1990)
Thyroid	Ma *et al*. (2006)
Lymphatic and leukaemia	Demers *et al*. (1992), Heyer *et al*. (1990)
Non-Hodgkin lymphoma	LeMasters *et al*. (2006)
Multiple myeloma	LeMasters *et al*. (2006)

7.4 Reproductive and Developmental Toxicity Hazards

Several chemicals that have been detected in fire atmospheres have been experimentally associated with a potential for adverse reproductive and/or developmental toxicity effects (McDiarmid *et al*., 1991). In spite of this, there is little available epidemiological evidence available on the reproductive and developmental toxicity hazards of fire-fighting. However, one study has indicated a possible excess of birth defects in the children of fire-fighters (Olshan *et al*., 1990). Peak CO concentrations measured in fires could be immediately dangerous to an unprotected female fire-fighter and her foetus (McDiarmid *et al*., 1991).

7.5 Carcinogenic Hazards

Several known, or suspect, carcinogens are present, to variable extents, in fire atmospheres; for example, PAHs, acrylonitrile, vinyl chloride, asbestos and polychlorinated biphenyls (PCBs). There are inconsistencies between some epidemiological studies on the possible excesses of cancers at various anatomical sites in fire-fighters. However, biological monitoring for genotoxic effects, including sister chromatid exchanges and PAH–DNA adducts in peripheral blood, suggests a potential for carcinogenic effects (Liou *et al*., 1989). Specific anatomical regions for neoplasms in fire-fighters that are possibly occupationally related are listed in **Table 5**. However, there is controversy for some site-specific cancers shown in **Table 5**; for example, Golka and Weistenhöfer (2008) did not confirm an increase in urothelial cancers based on analysis of mortality studies, and studies on exposure and cancer incidence. Documentation for an association between lung cancer and occupational exposure is inconsistent. For example, a Danish study (Hansen, 1990) reported an SMR of 317 for older fire-fighters, but studies from San Francisco (Beaumont *et al*., 1991) and Buffalo (Vena and Fielder, 1987) showed no excess. Cigarette smoking is a clear confounding factor (Liou *et al*., 1989), although according to one study the incidence of smoking among fire-fighters is not excessive compared with other occupations (Gerace, 1990). The excesses of certain cancers may be the result of interactions between several factors; toxic substances, alcohol and smoking (Beaumont *et al*., 1991). Ford *et al*. (1992) suggest that the immunological detection of serum β-transforming growth-factor-related proteins may be a possible biomarker for monitoring fire-fighters for potential development of cancer.

Radiation Toxicology

Naomi H. Harley

CONTENTS

1 INTRODUCTION

Radiation and radioactivity can be both a valuable tool and a source of health effects, and thus accords with Paracelsus' dictum that everything is a poison, it is only the dose that makes it so.

There are four main sources which can be used for evaluating actual human health effects from exposure to ionizing radiation. The human risk estimates to date are derived from these studies. These are the exposures of:

1. Radium dial painters
2. Atom bomb survivors
3. Underground uranium miners exposed to radon and its decay products, together with residential radon studies
4. Those who were treated for ringworm of the scalp (tinea capitis), where X-rays were given at one time for therapy.

To date, the health effects or risk from exposure is the risk of cancer of a particular organ or tissue. The risk from ionizing radiation is that it damages DNA in specific genes.

These studies provide quantitative risk estimates for internal and external exposure. A few radionuclides are also described because they are abundant in crustal earth, although no health effects have been documented. These are uranium, thorium, lead and polonium, noteworthy as they are a significant part of the earth's background radiation and have received attention for specific reasons.

Ionizing radiation from alpha particles, beta rays or gamma ray photons are capable of causing an electron to be stripped from an atom. This results in a positive ion and an electron. DNA may no longer be capable of conducting its normal function if many such atoms are disrupted. An alpha particle has a very short range in tissue and can produce enough ionization to cause a double-strand break in DNA that is difficult to repair.

The significant DNA damage implicated from recent data is probably to checkpoint genes, such as p53, disrupting the cell cycle, allowing the cell to propagate in an uncontrolled way. The only observed health effect from high exposures and doses is cancer, except at extraordinarily high doses, when some heart disease is observed.

2 NATURAL BACKGROUND AND OTHER SOURCES OF IONIZING RADIATION

2.1 Radium

After its discovery, radium (^{226}Ra) became a popular nostrum; adverse health effects were not as yet known. It

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat117
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

was approved by the American Medical Association and from 1900 to 1930 many were exposed to radium either in therapy, for example in the treatment of rheumatism, or occupationally. Radium was used in low or negligible lighting conditions in an inexpensive zinc sulfide (ZnS) phosphor to illuminate the numbers on instrument or watch dials. Luminous paint was developed before 1917 and in World War I there were several plants in New England and New Jersey where watch dials, clocks and military instruments were painted (Woodard, 1980).

The alpha particles from radium interacted with the ZnS to yield visible light photons. It was mainly women who prepared the radium-painted instrument dials. A fine tipped brush was dipped into the radium paint and applied to the dial face. The mouth was typically used to give the application brush its fine point. The dial painters developed osteogenic sarcoma (bone cancer) in a very short time after exposure, due to the ingestion of large amounts of ^{226}Ra (Martland, 1931). Radium then became the first radionuclide to show any harmful effects of radiation.

Radium behaves somewhat similarly to calcium and is a bone-seeker. The lowest bone concentrations measured that had no observed effect were determined to be 1–3 μg ^{226}Ra in the bone. At the time 1/10 of a known health risk was considered a 'safe' concentration, thus the safe concentration in bone was selected as 0.1 μg ^{226}Ra. This concept is no longer used because it is known that the probability of cancer for a given dose is a function of many biological and genetic factors. The terminology 'safe' is no longer used.

Evans (1967) studied about 500 cases of persons with radium exposure. He estimated that a measurement of 1 μCi in the skeleton several years post-exposure represented 20 μCi at the time of exposure because of its efficient removal. Using this value for a calculation of the dose to endosteal cells on bone surfaces that are targets for osteosarcoma yields a total skeletal dose of 2.9 Gy or 58 Sv (Fisenne *et al*., 1981). The estimate of bone cancer risk can be calculated as 0.35 per Gy (0.017 per Sv), with the caveat that the threshold dose is about 2.9 Gy (58 Sv).

Several thousand people were exposed to radium salts, either as part of the modish therapies using radium in the era from 1900 to 1930, or occupationally in the radium dial-painting industry around 1920. Radium therapy was accepted by the American Medical Association, and around 1915 advertisements were common for radium treatment of rheumatism and as a general tonic in the treatment of mental disorders. Solutions were available for drinking containing 2 μg, as well as vials for intravenous injection (Woodard, 1980). Luminous paint was developed before World War I, and in 1917 there were many plants in New England and New Jersey painting watch dials, clocks and military instruments (Woodard, 1980).

Radium, is first incorporated on bone surfaces then into the mineralized portion of bone. The long half-life of ^{226}Ra (1600 years) allows distribution throughout the mineral skeleton over a lifetime. However, the removal from the body is rapid and after ingestion only about 1% remains in the skeleton after one year. The target cells for osteogenic sarcoma reside in marrow on endosteal surfaces at about 10 μm from the bone surface. At long times after exposure, target cells are beyond the range of alpha particles from radium no longer on bone surfaces.

The first large studies of osteogenic sarcoma in radium-exposed people were done by Martland (1931) and Aub *et al*. (1952), who found 30 cases of bone sarcoma; Evans and associates at the Massachusetts Institute of Technology (Evans *et al*., 1969) studied 496 cases of sarcoma out of 1064 radium-exposed persons; and Rowland *et al*. (1978), studied 61 cases out of 1474 female dial painters (Woodard, 1980). **Figure 1** shows the retention of ^{226}Ra in the body from the various follow-up studies.

The loss of radium from the body by excretion was demonstrated to follow a relatively simple power function (Norris *et al*., 1958):

$$R = 0.54\, t^{-0.52} \tag{1}$$

where

R = total body retention
t = time in days.

Radium is the only radiation exposure to date that appears to have a true threshold dose before cancer is seen.

2.2 Uranium

Uranium has never been found to cause health effects in humans, even after high exposures. Uranium is of interest because of its ubiquitous use and because it supports a chain of 13 isotopes, some of which have been shown to cause cancer, including ^{226}Ra and radon (^{222}Rn). Natural uranium exists in small concentrations in all of planet earth's materials. Uranium is a very dense metal (18.7 g cm^{-3}), more so than lead (12.3 g cm^{-3}). It has been used as ballast for aircraft, as shielding for nuclear-medicine therapy sources and, as depleted uranium, as munitions and as shielding for military vehicles.

There are two long-lived uranium decay series supporting 12–13 other radioactive isotopes. One decay series is headed by ^{238}U, another by ^{235}U. The chain members include isotopes of radium, radon, lead and polonium. The parents of both decay series are very long lived, if they were not, they would not be present on the planet at this time. The ^{238}U series is shown in **Figure 2**.

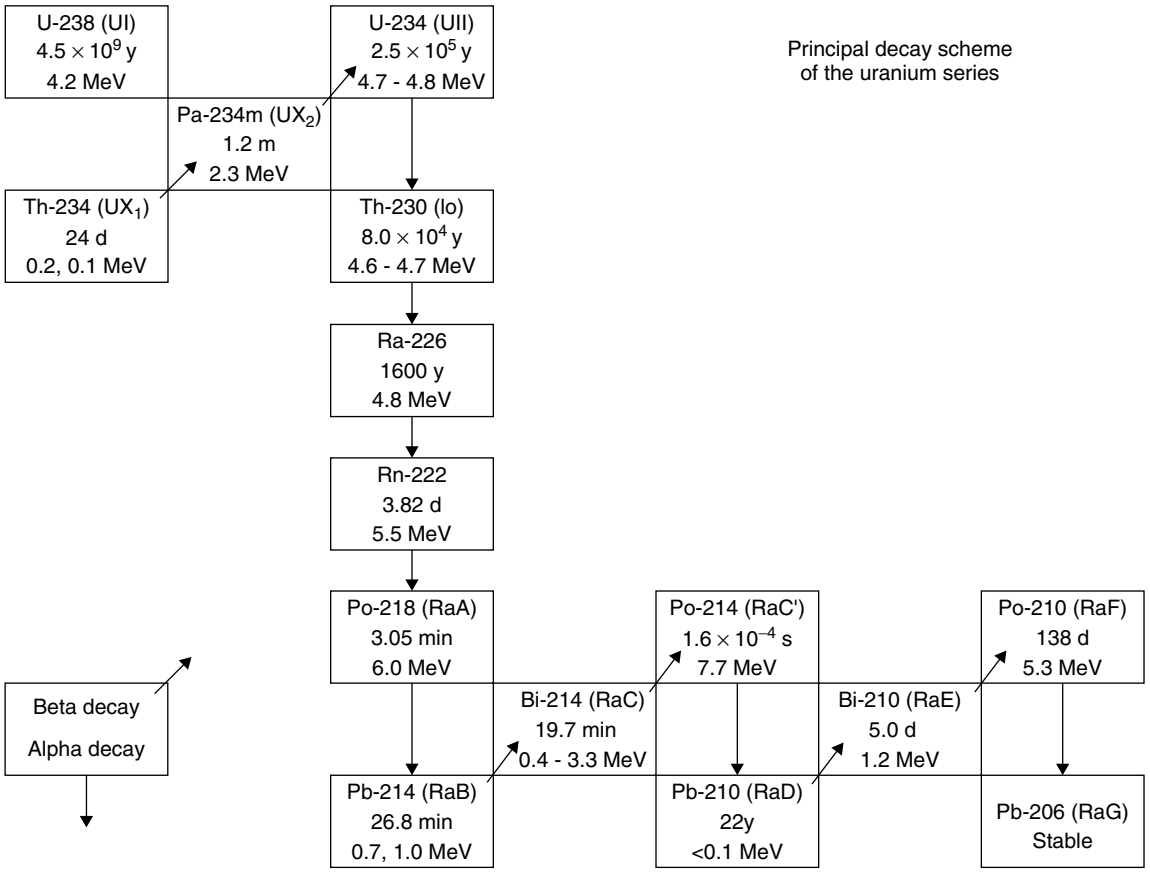

Figure 2 Uranium decay series. (Reproduced with permission from National Council on Radiation Protection and Measurements. © 1987.)

Natural ^{238}U supports its decay product ^{234}U and they are usually in radioactive equilibrium in most planetary substances. Equilibrium means that the radioactive decay rate of each is the same. In some cases, groundwater passing through soil will dissolve ^{234}U to a greater extent, and the steady-state activity in, say, drinking water is disturbed. Usually the activity ratio of $^{234}U/^{238}U$ will be from 1.0 to perhaps 1.4. The radioactivity of ^{235}U is a separate chain and it is not as radioactive as the ^{238}U series. **Table 1** shows the radioactivity of natural

Table 1 Radiological characteristics of natural and depleted uranium

Natural uranium			
Isotope	Half-life	Isotopic %	mBq μg^{-1} natural U
^{238}U	4.468×10^9	99.2745	12.40
^{234}U	2.45×10^5	0.0055	12.40
^{235}U	7.037×10^8	0.72	0.60
Total			25.4
Depleted uranium			
Isotope	Half-life	Isotopic %	mBq μg^{-1} depleted U
^{238}U	4.468×10^9	99.800	12.40
^{234}U	2.45×10^5	0.0010	2.26
^{235}U	7.037×10^8	0.2	0.16
Total			14.8

and depleted uranium. The US Environmental Protection Agency (EPA) has set a standard of 30 μg ^{238}U l^{-1} for suppliers of drinking water to more than 25 homes. Some members of the uranium decay series are gamma-ray emitters, as well as beta-ray and alpha-particle emitters. An annual external radiation dose (about 0.5 mSv) arises from these gamma rays because the uranium series isotopes are present in all rock and soil.

Natural uranium is thus composed of three isotopes of uranium ^{238}U, ^{234}U and ^{235}U. The ^{235}U is capable of sustaining a chain fission reaction and is separated from natural uranium for use in nuclear reactors and nuclear weapons. Depleted uranium, being a very dense metal with pyrophoric properties, was used in the Gulf War in munitions and as shielding in armoured vehicles. There followed concern over health effects in veterans experiencing inhalation exposures following damage to the vehicles. Uranium is not considered a radiation hazard, rather it has the toxicological properties of a heavy metal if inhaled or ingested in very large amounts. Uranium targets the kidney and has been shown to have some short-term consequences, such as increased protein excretion, but no long-term adverse effects. Depleted uranium (DU) is less radioactive than natural uranium because most of the ^{235}U and ^{234}U have been removed (**Table 1**). In a follow-up study of over 18 000 persons employed in the atomic energy industry in the 1950s, there were no health effects from uranium, even after high, long-term, occupational exposures (Polednak and Frome, 1981). No health effects have been observed in veterans in the Gulf War exposed to friendly fire who had suffered embedded DU shrapnel (McDiarmid *et al*., 2001).

Table 1 shows the parent ^{238}U is not very radioactive because of its long half-life and thus emphasis is on its heavy-metal properties. The permitted occupational inhalation exposure to uranium is greater than that to lead, which is considered to be a more toxic heavy metal.

There are no studies to show that natural uranium or DU has caused any health effects. There is a normal dietary intake of uranium in foods each day of about 1 μg. The content in individual foodstuffs can be found in reports published by the United States National Council on Radiation Protection and Measurements (NCRP) (NCRP, 1987) and the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR, 2000). The intake in drinking water is very variable and the range found in private wells, for example, can be over several orders of magnitude.

2.3 Thorium

Thorium is of interest only because it is one of the three primordial radioactive series supporting a chain of 13 radionuclides similar to the uranium series, and because of its universal presence in planetary materials. In soil it has a concentration of about five times that of natural uranium (10 vs. 2 ppm) (NCRP, 1987). No health effects have ever been demonstrated following thorium exposure, except in extraordinarily high exposures for medical diagnostic purposes.

Thorotrast, a thorium dioxide compound, was used from 1930 to 1960 as a contrast medium in X-ray diagnostic procedures. It was no longer used after long-term radiation effects were observed (Fisenne, 2000; van Kaick *et al*., 1991). Thorium has been used industrially for many years as mantels in incandescent kerosene (paraffin) and gas lamps, to increase their light output, as one of the rare earths used in video screens, in crucibles, in arc-welding electrodes and alloying. Thorium has been used as a fuel in breeder reactors. Thorium-232 captures a neutron, becoming ^{233}U, a fissionable material. Brazilian and Indian monazite sands are the major source of commercial thorium, and Madagascar mines thorianite

commercially, a mineral with high concentrations of thorium (45–88%).

Fisenne (2000) prepared an extensive review of the thorium distribution in food and water, and the global environment.

2.4 Radon and Radon Decay Products

The first toxicologic report of health effects was in underground miners dying from a then unknown respiratory disease in the Erzhertzberg mountains in Bohemia (now in the the Czech Republic) (Harting and Hesse, 1879). It was not recognized until the 1950s that the responsible agent for the disease, by then established as bronchogenic carcinoma of the lung, could be the solid decay products of radon (Harley, 1953). It was realized that their deposition on the bronchial airways provided a significant alpha-particle dose to cells in the mucosa, and that radon itself gave a much lower dose to these cells, and was therefore not likely to be the carcinogen. There were other agents in mines, such as asbestos and mineral dust fumes, that could be responsible carcinogens. However, the Lubin *et al*. (1994) and NAS/NRC (1999a) studies of 11 underground mining cohorts showed a clear dose–response for lung cancer with radon exposure, and thus determined radon decay products to be a definitive carcinogen.

The lung-cancer risk was initially documented in mines and in the late 1970s, a few measurements were made in homes. It was found that radon concentrations in some homes could be as high as in mines. This caused a flurry of activity in many countries to measure residential concentrations and to set guidelines for domestic exposure. Over 89 epidemiologic studies of radon and lung cancer have been performed, with 20 being case–control studies. The case–control studies document lung-cancer cases and paired controls along with their measured residential radon concentration. To date there are four studies that have pooled the case–control studies (using the original data), and two that have performed a meta-analysis (using published data) (Darby *et al*., 2005; Krewski *et al*., 2005; Lubin *et al*., 2004; Wichmann *et al*., 2005; Lubin and Boice, 1997; Pavia *et al*., 2003).

The measured unit of exposure in mines was the working level month (WLM). The WLM is a measure of the air concentration of the actual carcinogen, that is the short-lived radon decay products, ^{218}Po and ^{214}Po. Most measurements in mines were done in the 1950s and 1960s. The WLM is a measure of the radon decay-product alpha-particle energy in 1 l of air, adjusted to the duration of exposure in work months. One work month is equal to 170 hours.

The working level (WL), was considered a 'safe' concentration in the 1950s, and was equal to 100 pCi l^{-1} (3700 Bq m^{-3}) in equilibrium with its two alpha-emitting decay products, ^{218}Po and ^{214}Po. The WL can be estimated from the radon gas concentration using an equilibrium factor, F. In homes, the equilibrium factor is 0.4, that is the decay products are 40% in equilibrium with the gas, and in mines F is about 0.3 or 30% equilibrium. The radon corrected for equilibrium with the decay products is known as the equilibrium equivalent concentration (EEC) and is then used to estimate the WL.

For a radon concentration of 10 pCi l^{-1} (370 Bq m^{-3}) in a home, the WL = (0.4)(10)/100 and the WLM = WL (hours exposed/170). Assuming 70% occupancy in a home, the exposure time is (365)(24)(0.7) = 6132 hours; WLM = WL(6132/170) = (0.04)(36) = 1.44 WLM per year.

The US EPA suggests 4 pCi l^{-1} radon gas exposure in living areas as a guide, and the occupational limit for underground miners is 4 WLM per year. The estimated excess relative risk (ERR), determined from the studies of underground uranium and other miners, averages 0.006 per WLM while the residential studies show an ERR of 1.16 for lifetime exposure to 100 Bq m^{-3}. For comparison, the residential risk for 100 Bq m^{-3} can be converted to a lifetime exposure (40 years) of about 20 WLM or an ERR of about 0.008 per WLM, in good agreement with the mining data. Over 50 countries have conducted residential radon surveys and the average global concentration is estimated to be about 40 Bq m^{-3}. The average annual dose in residences from a radon concentration of 40 Bq m^{-3} is 1.2 mGy (2 mSv).

The ERR derived from the residential studies is estimated to be the same for smokers and nonsmokers (Darby *et al*., 2005). However, the baseline risk for smokers is a factor of 12 times greater than for nonsmokers so there is a greater lung-cancer risk from radon to smokers.

Figure 3 shows the results of the lung-cancer risk from radon exposure from the pooled studies and the meta-analyses.

2.5 Lead

There are no epidemiologic studies to show health effects of ^{210}Pb. This nuclide is found in most foodstuffs and the dietary intake per day about 37 mBq (1 pCi) (NCRP, 1987). In some industrial processes both ^{210}Pb and ^{226}Ra can accumulate. Exposure rates above background radiation are seen in the scale in down-hole pipes during oil-field pumping operations (Hamilton *et al*., 2004) and are attributed mainly to ^{226}Ra. The scale must be removed with care from equipment and pipes periodically, and the material is designated as naturally occurring radioactive material (NORM).

Both ^{210}Pb and its decay product ^{210}Po are present in tobacco products and it is suggested to be one of the

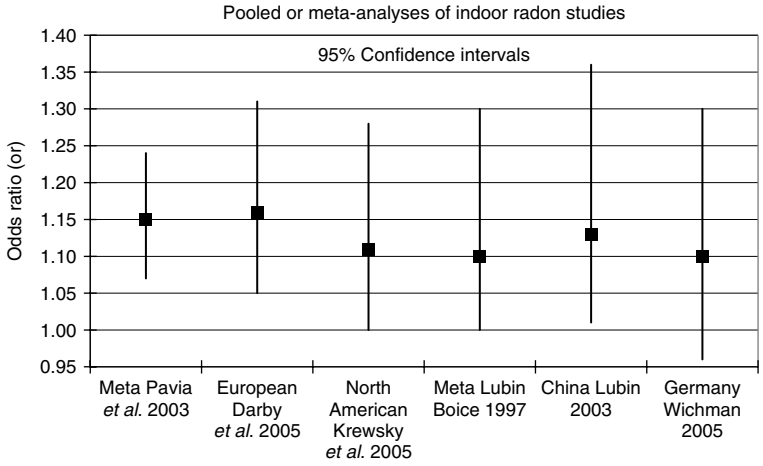

Figure 3 Pooled or meta-analysis of residential radon studies.

many carcinogens responsible for lung cancer in smokers (Cohen *et al*., 1980; NCRP, 1987).

2.6 Polonium

Polonium-210 (^{210}Po) is a decay product of ^{210}Pb in the ^{238}U series. Most polonium in the body arises from the ingestion of dietary ^{210}Pb. The fatal poisoning case of the Russian, Litvinenko, in November 2006, showed the potential for its use as an accessible poison. The use of polonium in industry is widespread, mainly for static elimination. Polonium is easily measured in urine samples as a test for dietary or other exposure. Although no human data are documented for health effects, research concerning the toxicity of polonium was conducted at the University of Rochester and is summarized by Stannard (1988).

When experimental animals (dogs, rabbits) were injected with 2.6 MBq per kg body mass, ^{210}Po lethality occurred in less than a month. Polonium distributes in the body almost uniformly and the affected organ most likely damaged enough for lethality is the bone marrow. If this is scaled to the human, 200 MBq results in a lethal internal exposure.

2.7 Potassium

Potassium is a major constituent of the human body and is a necessary requirement for human health. It is present in every functioning cell in the body. The radioactive isotope ^{40}K comprises a fraction of all natural stable potassium (^{39}K). The isotopic abundance is 0.0117% and the half-life is 1.28×10^9 years. K^{40} emits both beta and gamma rays (28 Bq beta and 3 Bq gamma per g of natural potassium). The average person contains about 120 g of potassium, thus the body content is 3.7 kBq and the annual dose from normal potassium is about 0.2 mSv. Potassium is thus the highest natural background dose from internal radioactivity, with the exception of radon.

2.8 Carbon

Naturally occurring ^{14}C is produced mainly in the stratosphere by the interaction of slow cosmic-ray neutrons with atmospheric nitrogen. It is therefore a cosmogenic radionuclide and emits a low-energy beta particle (0.16 MeV). Carbon is an important element in the human body and ^{14}C participates in body metabolism in a similar manner.

The specific activity of cosmogenic ^{14}C is 230 Bq kg^{-1} of total carbon, and the human body content is about 2700 Bq, yielding an annual effective dose of 12 μSv. The nuclear weapons tests in the 1950s and 1960s introduced about twice the cosmogenic inventory into the atmosphere. This was absorbed into the marine environment, with a half-life of six years. The current ^{14}C atmospheric residue from weapons tests is 0.05 Bq kg^{-1} carbon (UNSCEAR, 2006).

Artificially produced ^{14}C is used as an isotopic tracer to study the details of various chemical reactions involving stable carbon.

2.9 Tritium

Naturally occurring tritium (^{3}H) is produced mainly in the stratosphere by the interaction of fast cosmic-ray neutrons with atmospheric nitrogen. It is therefore a cosmogenic radionuclide and emits a low-energy beta particle (0.015 MeV). Prior to the nuclear weapons tests atmospheric ^{3}H in precipitation was about 0.6 Bq l^{-1} and the human body

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

content 26 Bq (NCRP, 1987). The nuclear weapons tests increased the ^{3}H concentrations in precipitation by more than two orders of magnitude over a period of two or three years. The annual effective dose from cosmogenic ^{3}H is about 10 μSv.

Artificially produced ^{3}H has been used as an isotopic tracer in research involving chemical and hydrologic pathways. Tritium has largely replaced ^{226}Ra in luminescent signs and watch dials.

3 MEDICAL AND OTHER SOURCES OF IONIZING RADIATION

3.1 Tinea Capitis

Ringworm of the scalp (tinea capitis) was a common fungal disease before 1960. Radiation (X-ray) therapy was a common treatment modality. From 1905 to 1960, X-ray epilation in the treatment of tinea capitis in children was performed regularly. The treatment was introduced by Sabouraud in 1904 and was standardized by Kienbock (1907) and Adamson (1909). Over the 50 years it was used, perhaps 200 000 children worldwide may have been irradiated (Albert *et al*., 1986).

The first follow-up studies of the long-term effects of irradiation were performed by Albert and Omran (1968). They reported on 2200 children irradiated at the Skin and Cancer Unit of New York University Hospital (NYU) during 1940–1959. Subsequent publications studying this group have appeared at regular intervals (Shore *et al*., 1976; 1984; 1990; 2002; 2003). Subsequently, a follow-up of 11 000 children irradiated in Israel was performed (Ron *et al*., 1995).

The mean age of children irradiated in both the NYU and Israeli studies was between seven and eight years. The age range in the NYU study was 1–15 years at the time of treatment. Dose reconstruction in the NYU series was performed using a head phantom containing the skull of a seven-year-old child covered with tissue-equivalent material (Harley *et al*., 1976).

In the NYU series there were two thyroid cancers with no expected cases and 11 thyroid adenomas with one expected (Shore *et al*., 2003). In the Israeli series there were 43 thyroid cancers with 10.7 expected cases. In the NYU series there are 128 skin lesions, mostly basal cell carcinomas, with 24 expected cases. Fairness of skin is an important factor in the appearance of skin cancer (Shore *et al*., 1984; 1990; 2002).

Skin cancer was found primarily in Caucasians even though 25% of the study population consisted of blacks. As of 2002, there were 128 cases of non-melanoma skin cancer of the head and neck in the irradiated group and 21 in the control group. In the irradiated group, 125 cases were Caucasian and three were African American. This, and the fact that there appears to be a much lower dose–response on the hair-covered scalp than on the face and neck (Harley *et al*., 1983; Shore *et al*., 2002), suggest that the promotional effects of UV radiation play an important role in skin cancer.

The dose estimates for the thyroid in the Israeli study are 0.09 and 0.06 Gy in the NYU study. The skin dose estimates range from 0.1 to 0.5 Gy on the face, but 2.5 Gy near the scalp margins. The estimate for lifetime thyroid cancer risk is difficult to determine from the tinea capitis data and can be derived from a pooling of studies of thyroid irradiation (Ron *et al*., 1995); however, the estimates per Gy are arbitrary as risk depends strongly on age at exposure and gender.

The small numbers of tumours other than skin cancers in the NYU study make it of little value in estimating the lifetime risk per Gy, although an excess is appearing (Shore *et al*., 2003). There were eight leukaemia cases with one expected and six salivary gland tumours with two expected. There were 16 intracranial tumours, seven brain cancers, four meningiomas, and five acoustic neuromas (vestibular schwannomas) in the X-irradiated group, following an average brain dose of about 1.4 Gy, compared to one acoustic neuroma in the control group. The standardized incidence ratio (SIR) for brain cancer was 3.0 (95% confidence interval (CI): 1.3, 5.9).

These are important studies because children were the exposed group and because only partial body irradiation was involved. The temporal pattern of appearance of these tumours is also important. The dose was delivered over a short time interval (minutes at NYU and five days in Israel), and lifetime patterns are indicative of the underlying carcinogenic mechanisms, such as time to tumour following short-time or fractionated exposure.

Skin and thyroid cancers are of importance in documenting health effects from ionizing radiation. However, both types of cancer are rarely fatal. NCRP (1984) reported that about 10% of thyroid cancer is lethal and more recent SEER (Surveillance, Epidemiology and End Results) data indicate 3% fatality. It is estimated that the fatality rate of skin cancer is 1% (NCRP, 1990). The lifetime risk per Gy derived by NCRP for total thyroid cancer incidence (0.003 for females and 0.0014 for males for external X-ray or gamma radiation for persons under 18 years of age) is about a factor of 10 lower than that reported by Ron *et al*. (1995) in pooled data. However, the tinea irradiations were given to children with a mean age of about seven years; also in the Israeli study there is apparently an increased sensitivity resulting from ethnicity.

The effect of gender is also suggested by for thyroid cancer NCRP (1985). There is an obvious susceptibility of women for thyroid cancer and adenomas in both the NYU and Israeli tinea capitis studies. After 50 years of follow-up in the New York study of 2224 children given X-ray therapy for tinea capitis, along with a control

Table 2 Lifetime cancer incidence per Gy from four major epidemiologic studies (in parentheses, risk per Sv for alpha emitters, $W_r = 20$, Bronchial epithelium $W_t = 0.08$)

Study, organ, type of radiation	All sites (Adults)	Leukaemia	Lung	Female breast	Bone	Thyroid	Skin
Atom bomb whole-body, gamma (ICRP, 2007)	0.041	0.0066	0.0085	0.002	0.00041	0.0008	0.0002
Uranium miner bronchial epithelium, radon decay products, alpha (UNSCEAR, 2000)	—	—	0.12 (0.08)	—	—	—	—
Tinea capitis, head X-ray (Shore *et al*., 2003; Ron *et al*., 1995)	—	—	—	—	—	0.003 female 0.0014 male	0.23
Radium ingestion, bone, alpha (^{226}Ra) (Evans *et al*., 1969)	—	—	—	—	0.35 (0.017)	—	—

group of 1380 tinea capitis patients given only topical medications, the study found a relative risk (RR) of 3.6 (95% CI, 2.3–5.9) for basal cell skin cancer (BCC) of the head and neck among irradiated Caucasians (124 irradiated cases and 21 control cases), in response to a scalp dose of about 4.8 Gy.

The base rate for the lifetime appearance of basal cell carcinoma in the US population is high, 0.3 or 30%. An estimate of the incidence per Gy is then 0.3 (3.6/4.8) or 0.23 (23%). This is shown in **Table 2**.

3.2 Atomic-Bomb Survivors

The atomic-bomb survivors are a particularly important group because the occupational radiation guidelines and some human-organ risk estimates are based on follow-up studies on these individuals. A uranium fission weapon was dropped on Hiroshima, Japan on 6 August 1945 and three days later a plutonium fission weapon was dropped on Nagasaki.

A total of 64 000 people in the two cities were killed by the blast and the thermal effects within 1 km of the explosions, and as a result of the instantaneous gamma and neutron radiation released by the weapons. Others between 1 and 2 km from the hypocentre (the point on earth directly below the detonation point in air) received radiation doses up to several Gy. Beyond 2.5 km there was no additional dose from the weapon, only natural background radiation.

A study of the mortality of A-bomb survivors was initiated by the Atomic Bomb Casualty Commission (ABCC) in 1950. This was a prospective study and is now conducted by the Radiation Effects Research Foundation (RERF). The main study, called the Life Span Study (LSS), included 120 000 people, 92 228 people within 10 km of the hypocentre and 26 850 people who were not in either city at the time of bombing (ATB). The most recent reports of the RERF (1987; 2003) are follow-ups of the cancer mortality of a subcohort over the period 1950–1997 (Preston *et al*., 2003; 2004). The cohort includes 86 611 persons with individual dose estimates. The latest updates (Preston *et al*., 2003; 2004) report that 440 (5%) of all solid cancer deaths and 250 (0.8%) of the noncancer deaths were associated with the radiation exposure.

The gamma rays account for most of the radiation doses to survivors, the neutron absorbed dose at most organ depths (and distances from the hypocentre) were about 1% of the gamma-ray absorbed dose at Hiroshima.

The occupational guidelines and risk estimates for radiation are now based on the atomic-bomb survivors. There are approximately 70 000 persons followed up since 1950. The dosimetry was re-evaluated in 2002 (*http://www.hss.energy.gov/healthsafety/IHS/ihp/japan/DS02.pdf*) to obtain a better estimate the dose received by survivors, using more modern technology than available for the first dose reconstruction in 1986 (*http://www.rerf.or.jp/shared/ds86/ds86a.html*). The risk estimates were re-evaluated by ICRP (2007) on the basis of DS02 and are shown in **Table 2**.

4 SUMMARY

The normal daily dietary intake includes naturally occurring uranium, thorium, lead-210, polonium-210, radium-226 and potassium-40. These radionuclides are present in all crustal earth. Some are gamma-ray emitters as well as alpha and beta emitters. These yield an internal body dose (about $0.2\,\mathrm{mSv\,a^{-1}}$) and an external dose from terrestrial gamma-ray radiation (about $0.5\,\mathrm{mSv\,a^{-1}}$). There are no observable health effects from this normal background radiation.

There are four major epidemiologic studies where the exposure was to high levels or concentrations of these radionuclides: the radium dial painters, the underground uranium miners exposed to radon (also in residences with high radon concentrations) or to X- or gamma-ray radiation, the atomic-bomb survivors and the tinea capitis (ringworm) patients. These epidemiologic studies provide quantitative estimates of the cancer risk from high exposures to radiation.

5 GLOSSARY

Bequerel (Bq) = A unit of radioactivity equal to 1 disintegration per second.

Gray (Gy) = A unit of absorbed radiation dose $D = E$ (energy)/M (mass). Equal to $1\,\mathrm{J\,kg^{-1}}$.

Sievert (Sv) = A unit of radiation dose E (energy)/M (mass) equal to $1\,\mathrm{J\,kg^{-1}}$, corrected by a radiation weighting factor (W_r) to account for the type of radiation, alpha, beta or gamma rays ($W_r = 1$ for beta and gamma rays, $W_r = 20$ for alpha-particle radiation) and a tissue weighting factor (Wt) that depends on the tissue ($W_t = 0.08$ for bronchial epithelium for example). $\mathrm{Sv} = (W_r)(W_t)(D)$. See (ICRP, 2007) for detailed values of W_t.

Working level (WL) = A measure of the *potential* energy in 1 l of air from 100 pCi (3700 Bq) radon in equilibrium with its decay products for complete decay of the radon and decay products. Equal to $1.28 \times 10^5\,\mathrm{MeV\,l^{-1}}$ usually rounded to $1.3 \times 10^5\,\mathrm{Mev\,l^{-1}}$. The WL was easily measured in underground mines by a single measurement and became the exposure unit of choice because it is the decay products that deliver the bronchial dose, not the radon gas.

Working level month (WLM) = The time integral of the WL. A work month is taken as 170 hours. WLM = (WL) (hours exposed)/170.

Risk Assessment of Chemicals

Leah D. Stuchal and Stephen M. Roberts

CONTENTS

1 INTRODUCTION

Risk assessment of chemicals is a process that describes the nature and magnitude of hazards posed by chemical exposure. The risk assessment results in a statement regarding potential adverse effects and the likelihood that an adverse effect will occur in specific exposure situations. The risk statement can be primarily qualitative (e.g. an effect is 'likely' or 'very likely') or can be quantitative in nature, with numerical expressions of risk, such as a 10^{-5} excess probability of developing cancer as a result of exposure. The risk assessment process constantly evolves as science refines estimates of exposure and toxicity. Therefore, each risk assessment reflects the current state of scientific knowledge, as well as uncertainties, that exist in human health and environmental responses to the chemical. New information on the toxicity of chemicals, as well as new methods of chemical detection and scientific approaches to detect adverse effects in their initial phases, continually change the perceived hazard of chemicals and estimates of risk.

The two main types of risk assessment are human health and ecological risk assessment. Although the approaches to both are the same at the most fundamental level, procedures for each have evolved separately to a large extent. Consequently, the specific steps involved in conducting a human health risk assessment are somewhat different from those used to produce an ecological risk assessment. Another aspect that sets the two types of risk assessment apart is the inherent degree of complexity. Human health risk assessments have the luxury of only dealing with a single species, while ecological risk assessments by necessity have to consider, not only an array of species, but also ways in which the species interact (e.g. transfer of chemicals through the food web, dependence of some species on others as food sources) in order to evaluate potential chemical effects. This chapter will cover basic aspects of both risk assessment types, with emphasis on human health.

2 RISK ASSESSMENT PARADIGM

Risk assessment of chemicals requires minimally two types of information: (i) the potency of the chemical, that is, how much is required to produce an adverse effect and (ii) measured or estimated exposure, that is, what dose of the chemical does an individual receive as a result of exposure. Information on potency is of little value without some knowledge of the dose. For example, just because the toxic potency of a certain chemical is high does not necessarily mean that exposure will produce toxicity. Even extremely potent toxicants can be used safely if the dose is small enough; for example, the injection of botulinum toxin (e.g. Botox®) into the face to remove wrinkles. Similarly, information on exposure is essentially meaningless in terms of risk if the toxic potency of the chemical is unknown.

People have been evaluating the risk from chemicals in their environment informally as long as humans have been in existence. Lessons learned the hard way about what plants can be eaten safely, for example, comprise an essential form of risk assessment information passed along through generations. Formalized processes that form the basis of contemporary risk assessment practice evolved during the latter half of the twentieth century. In 1983, the National Research Council (US National Academy of Sciences) described what are widely regarded as the four basic steps in risk assessment: hazard identification, dose–response assessment, exposure assessment and risk characterization.

- Step 1—Hazard identification: The first step in the risk assessment process is to determine if the chemical of concern is a hazard to human health. The type of adverse effect a chemical produces and its mode of action are considered. Information on health effects may be determined from case reports, clinical studies, epidemiological data or inferred from animal and laboratory studies.
- Step 2—Dose–response assessment: The dose–response assessment describes the relationship between the amount of chemical exposure (dose) and the severity of the adverse effect (response). This relationship is often determined in animals and then extrapolated across species for use in human assessments.
- Step 3—Exposure assessment: Exposure assessment is the process of estimating the magnitude, frequency and duration of exposure. This step also includes identifying the pathways through which the population of interest is exposed to the chemical (e.g. from contaminated drinking water). Exposure assessment considers multiple media (e.g. air, water, soil, sediments) and can include exposures to mixtures of chemicals. The objective of the exposure assessment is to derive estimates of the dose of chemical received from each relevant route of exposure (e.g. ingestion, dermal contact, inhalation).
- Step 4—Risk characterization: The final step uses information obtained from the first three steps and integrates them to obtain an estimate of risk. Typically, these estimates of risk are compared to risk thresholds to determine if the chemical imposes an unacceptable increase in risk to the population. Uncertainty associated with various aspects of the preceding steps of the risk assessment process is discussed to help users of the risk assessment to understand the strengths and limitations of the analysis.

Each of these steps is discussed in more detail in the following sections, as well as a note on how these

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

processes will support risk management. Risk assessment is important for the development of trade and transport regulations of chemicals and this is further discussed in **Regulatory Toxicology**.

3 HAZARD IDENTIFICATION

Hazard identification is an evaluation of the intrinsic toxicity of a chemical. It asks whether the chemical is capable of producing toxicity at any dose, and if so, what effects are produced. For example, hazard identification would be used to establish whether a chemical is a carcinogen or produces reproductive toxicity. There are a variety of sources of information that can be used in hazard identification, including studies in humans (clinical studies, epidemiological studies, case reports of poisonings), studies in laboratory animals, *in vitro* tests and computer simulations. Some sources of information are more highly regarded than others, and hazard identification often includes an element of professional judgement as evidence for toxicity from different types of studies is weighed. Strengths and weaknesses of various sources of information are discussed below.

3.1 Studies in Humans

In determining what constitutes a hazard for the purposes of human health risk assessment, the most reliable source of data is from well-conducted studies of humans exposed to the chemical. For example, the Joint FAO/WHO Meeting on Pesticide Residues (JMPR) has produced numerous reports and other toxicological evaluations regarding experimental studies on pesticides in humans. Case reports from accidental or intentional poisonings can be informative, particularly with regard to the types of effects associated with acute intoxication. Ethical issues generally preclude intentional exposure of humans to chemicals (other than pharmaceuticals) at doses producing adverse effects. However, studies of individuals exposed to chemicals as part of their normal activities are common and potentially useful for hazard identification. Often, these take the form of an epidemiological study. A very attractive feature of this type of study is that it can be used to identify adverse effects that occur under actual human exposure conditions, including chronic exposure. If the study is sufficiently large, differences in response due to gender, race or genetic susceptibility may be identified. Epidemiological studies also have several weaknesses. Unless the magnitude of exposure is high, effects produced by the chemical may be difficult to detect. For this reason, occupational cohorts, which often have higher levels of chemical exposure than the general population, are particularly useful in assessing hazard. Also, many adverse effects can have numerous causes. Unless confounding factors (i.e. alternative risk factors) are well controlled, it can be difficult or impossible to clearly associate increased disease in an exposed population with the chemical in question. The role of epidemiology in toxicology is further discussed in **Essentials of Epidemiology for Toxicologists**.

3.2 Animal Studies

For most chemicals, information from studies in humans is limited or nonexistent, and results from animal studies are used to characterize hazard. There are several advantages to using laboratory animals for hazard identification. Exposure conditions can be tightly controlled, eliminating uncertainty about doses received and the confounding influence of exposure to multiple chemicals that is typically the case in human studies. It is also possible to evaluate the health status of subjects in a much more detailed manner, including biochemical and histopathological examination of potential target tissues. This allows observations of not only overt, clinical effects, but also precursor events leading up to toxicity. The ability to detect precursor events, even at the molecular level, means that potential adverse effects can be detected with great sensitivity. It also raises the sometimes controversial question of what, exactly, constitutes a toxic response? Contact with a chemical invariably produces some kind of biological response, however subtle. Distinguishing between adaptive changes of no clinical consequence and preludes to frank toxicity can be challenging, but is critically important for hazard identification.

There are also disadvantages to the use of laboratory animals for hazard identification. Some toxic endpoints, such as subtle neurobehavioural effects, can be very difficult to detect in animal studies. And of course, there is always some degree of uncertainty as to whether the laboratory animal responds to the chemical in the same way as humans. Differences in metabolism and physiology among species can lead to different responses to chemicals. For example, a number of chemicals are carcinogenic in mice, but not rats, and *vice versa*. In this situation, what is the inference regarding the carcinogenicity of the chemical to humans? When extrapolating findings from animals to humans, it can help enormously to have information regarding the mode of action of the chemical in producing the effect. An often-cited example is increased kidney tumours in male rats produced by unleaded gasoline, 1,4-dichlorobenzene and D-limonene. Binding of metabolites of these chemicals to $\alpha_2\mu$-globulin, a protein synthesized primarily in the liver, results in its accumulation in renal tubular cells. This accumulation is associated with renal pathology,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

including tumour formation. Female rats and mice of both sexes produce much lower levels of the protein than male rats and do not develop renal tumours from exposure to these chemicals. Because humans do not synthesize $\alpha_2\mu$-globulin, this mode of action, and by extension the renal carcinogenicity of unleaded gasoline, 1,4-dichlorobenzene and D-limonene observed in male rats, are considered not relevant to human risk.

3.3 *In Vitro* Studies

Information on the toxic effects of chemicals can be obtained from *in vitro* studies. These studies typically involve cells in culture, but can also include studies using isolated tissues and organs, tissue extracts or homogenates, subcellular fractions or purified biochemical reagents (e.g. enzymes, other proteins, nucleic acids). The ability to control experimental variables is great, and experiments with *in vitro* systems can be extremely valuable in gaining an understanding of how the chemical produces its effects at the cellular, biochemical and molecular level. *In vitro* endpoints are also amenable to high-throughput screening to rapidly identify chemicals that may share a common effect or mode of action. For example, organophosphate insecticides and some chemical warfare nerve agents have in common a mode of action that involves inhibition of cholinesterase enzymes. By setting up automated assays to measure cholinesterase inhibition *in vitro,* a large library of chemicals could be screened to identify other chemicals that might have the same toxicological effect. The disadvantage of *in vitro* tests is that they are incapable of capturing the complexity of an intact human or animal, where adverse effects can result from interplay between different organs and systems in the body. Also, the relationship between biochemical and molecular changes observed in *in vitro* studies and toxicity at a clinical level is inferred. As such, *in vitro* tests can provide a basis to predict that toxicity will occur as a result of exposure, but a conclusion that a particular hazard exists (e.g. carcinogenicity) usually requires evidence from human or animal studies.

3.4 *In Silico* Studies

Structure–activity relationships (SARs) can be used to estimate the toxicity of a chemical. The high costs of animal toxicity testing, coupled with the need to evaluate, at least preliminarily, the potential adverse effects of an overwhelming number of chemicals for which no toxicity information exists, makes the use of computer modelling attractive. Commonly referred to as *in silico* testing, these models relate chemical structure to biological activity and potency. The assumption implicit in this process is that a chemical's structure determines its interaction with the biological system and reveals its toxicity. The most frequent use of this type of toxicity modelling is to predict a common mode of action for an entire class of chemicals. For example, the Ah-receptor binding ability of dioxin-like compounds has been predicted *in silico* based on SAR. It must be remembered that these results are only predictions and should be confirmed, when possible, by human or animal studies.

3.5 Weight of Evidence

Hazard identification is accomplished through a careful review of all of the available information from the various types of studies described above. This review needs to be critical, looking at the type and quality of information offered by each study. Many toxicity studies conducted before modern guidelines were in place may have some deficiencies, but still contain useful information. This is especially true when these older studies provide the only toxicity data available. The following are guidelines to consider when evaluating studies:

- Does the test measure an adverse effect or a nonadverse effect?
- Have the experiments been performed in a scientifically valid manner?
- Does the experiment contain the appropriate control groups?
- Is there proper accounting for confounding factors?
- Are observed effects statistically significant?
- Is the test species physiologically relevant to humans?
- Do the results conflict with other test species that are more physiologically relevant to humans?

In an effort to make the weighing of evidence more transparent and reproducible, formalized schemes have been proposed that involve clearly articulated quality criteria for evaluation of studies and methods for ranking them in terms of the value of information provided. Because this approach is analogous to evidence-based medicine, it has been called evidence-based toxicology.

It is important to keep in mind that hazard assessment must be viewed in the context of route and duration of exposure. Quantitative, and sometimes qualitative differences in response can occur when a chemical is administered by different routes. This is most obvious when the chemical produces its primary effects locally at the portal of entry. For example, a chemical that is an irritant or has corrosive properties would be expected to produce pulmonary effects when inhaled, gastrointestinal distress when ingested and dermal pathology when placed on the skin. Chemicals that act systemically

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

can also produce route-dependent toxic effects because the concentrations of chemical and its metabolites in various tissues can differ, depending upon how the chemical enters the body. Duration of exposure is important as well. It is common for the principal adverse effects of a chemical to be different for acute vs. chronic exposure. For example, the principal concern from acute exposure to many solvents is central nervous system effects, while long-term exposure (usually at lower levels) can lead to kidney and liver toxicity. The effects of these solvents on the central nervous system are immediate, accounting for acute effects, while kidney and liver toxicity requires repeated exposure unless the exposure level is quite large.

4 DOSE–RESPONSE ASSESSMENT

Only studies in humans or animals are capable of providing dose–response information of sufficient reliability to use in risk assessment. Human studies provide this information most directly, but it is often difficult to get accurate dose estimates for exposed individuals. Further, the number of chemicals for which dose–response information is available from humans is quite limited. Consequently, as a practical matter, dose–response information used in most chemical risk assessments comes from animal studies.

Well-conducted hazard identification typically reveals that several different adverse effects are possible from exposure to a given chemical. Each effect can have its own distinct dose–response relationship, and one of the goals of the dose–response assessment is to identify the most sensitive effect of the chemical; that is, the effect that occurs at the lowest dose. From a regulatory standpoint, identifying the most sensitive effect is critical—if exposure is managed to prevent that effect, all other adverse effects will be prevented as well.

Most commonly, dose–response relationships are defined based on applied dose; that is, the dose that comes in contact with the subject, not the dose that enters the body. For example, for a study involving exposure by ingestion, the applied dose would be the amount swallowed (usually per unit time, such as milligram chemical per kilogram body weight per day, $mg\,kg^{-1}\,day^{-1}$), not the amount absorbed from the gastrointestinal tract and entering the systemic circulation (see Section 5 for a more complete discussion). Because the amount of chemical absorbed and distribution within the body can vary for different routes of exposure, dose–response relationships are route dependent. This means that dose–response relationship information is needed for each potential exposure route.

Two types of dose–response models are used in risk assessment—the threshold model and the nonthreshold model. In the threshold model, there is some dose below which no adverse effect is seen. This dose is termed the threshold dose. This model is based on the assumption that, for many chemicals, protective mechanisms exist in the body that repair or prevent the damage and stop the adverse effect from occurring. When the dose of chemical is sufficiently high, the defence mechanism is overwhelmed, resulting in an adverse effect. The threshold model is utilized whenever the mode of action is thought to involve a biological threshold. This includes some carcinogens and all effects other than cancer. The nonthreshold model, in contrast, assumes that any finite dose of the chemical poses some risk of the effect occurring, and attempts to provide an estimate of the probability of effect for a specified dose. Both models are described in the following sections.

4.1 Threshold Models

The goal of the dose–response assessment for the threshold model is to identify the threshold dose for the most sensitive effect of the chemical and use it to derive a safe dose for human exposure. Operationally, the first step in this process is to identify a dose that approximates the threshold for toxicity, usually with either the no observable adverse effect level (NOAEL)/lowest observable adverse effect level (LOAEL) or the benchmark dose (BMD) approach.

The highest dose tested for which no toxicity is observed is called the NOAEL (**Figure 1**). The lowest dose tested for which any toxicity is observed is called the LOAEL. The threshold dose is assumed to lie somewhere between these two values. So as not to overestimate the threshold dose, the NOAEL is considered to represent the threshold for toxicity from the experiment, and the safe human dose is derived from this value. In some situations, an NOAEL is not identified; all doses tested produce toxicity. Ideally, the experiment would be performed again using a lower dose range so that the NOAEL can be identified. In most such cases, additional testing is not available, and the safe human dose must be estimated from the information at hand, that is, using the LOAEL.

There are several criticisms of the NOAEL/LOAEL method. One criticism is that the NOAEL and LOAEL are determined to some extent by the doses chosen for the toxicity study. If the doses were chosen far apart, then the NOAEL may be well below the true threshold. This would lead to an overprotective safe human dose as the result of poorly chosen experimental doses. For example, suppose experimental doses of 5, 100, 500 and $1000\,mg\,kg^{-1}\,day^{-1}$ were used in a chronic oral dosing study. The $5\,mg\,kg^{-1}\,day^{-1}$ dose displayed no adverse effect and was chosen as the NOAEL. However, choosing the doses 5, 20, 50 and $75\,mg\,kg^{-1}\,day^{-1}$ may have revealed $50\,mg\,kg^{-1}\,day^{-1}$ as the NOAEL. The $5\,mg\,kg^{-1}\,day^{-1}$ NOAEL chosen based on the doses in

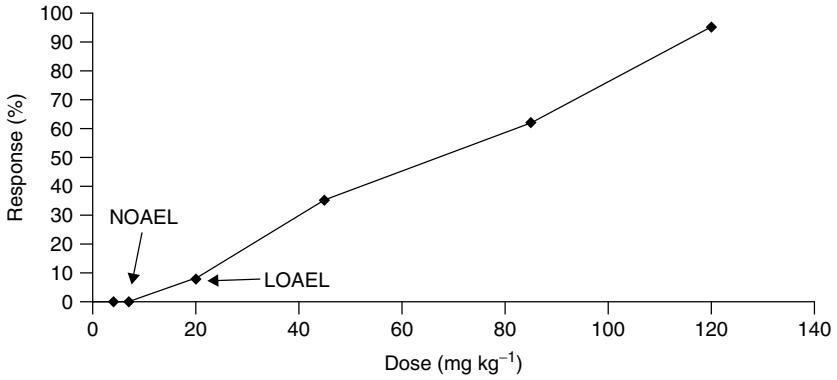

Figure 1 Dose–response relationship showing a no observable adverse effect level (NOAEL) and a lowest observable adverse effect level (LOAEL).

the first study would be at least 10 times less than the NOAEL that would arise from a different selection of doses. This would result in an overestimation of the toxicity threshold of the chemical and an unnecessarily low safe human dose. Another criticism is that the NOAEL/LOAEL method does not consider the shape of the dose–response curve or account for variability in the response. The safe human dose is derived from the NOAEL and, in essence, disregards the rest of the data points and the uncertainty surrounding them. The toxic dose of the chemical is estimated from one data point.

An alternative to the NOAEL/LOAEL approach is the BMD approach. In this approach, the shape of the dose–response curve is taken into consideration and the safe human dose is derived based on all of the response data, not just one point. The BMD approach uses mathematical models to find the curve that best fits the observed data points (**Figure 2**). This is most easily done with computer software (e.g. US EPA Benchmark Dose Software v. 2.0). Initially a benchmark response (BMR) is chosen. The BMR is the central dose estimate for a specified level of response above background. For quantal data, a BMR of 10% is usually chosen. Exceptions include a BMR of 5%, when evaluating reproductive and development studies, and a BMR of 1% for the analysis of human data. For continuous data, the BMR is defined as a 10% change in an endpoint (another term for something that is measured or assessed to show a response) that is generally considered to be biologically significant or a change in the mean value of this endpoint equal to one standard deviation from the control mean. The dose at which the BMR occurs is referred to as the effective dose (ED). For example, in a study of neurological disorders, a BMR of 10% is chosen. The dose where 10% of the study animals exhibit neurological dysfunction is referred to as the ED_{10}, or ED at an incidence of 10%. Upper and lower confidence limits are placed around the benchmark curve. For regulatory purposes, the lower confidence limit of the effective dose (LED_{10}) is chosen. The LED_{10} is known as the BMDL or the point of departure. It is used as the threshold dose below which less than 10% of the population is expected to have an adverse effect.

A BMD can be derived with three main types of data. The first is dichotomous data. These data reflect the presence or absence of an effect (e.g. an experiment in which five out of seven animals displayed kidney dysfunction). The second type of data is continuous. These data can take any value within a plausible range. Examples of endpoints yielding continuous data include body weight and sperm count. The third type of data is categorical and usually categorizes data based on the severity of the response. This is usually seen when rating histological changes (e.g. none, mild, moderate or severe tissue injury).

In order to derive an accurate estimation of the safe human dose using the BMD approach, a statistically or biologically significant dose-related trend in the data for the selected endpoint is needed. Because this method estimates the safe human dose from the dose–response curve, the software must be able to model curves that fit the data. Additionally, if there is no NOAEL in the data set, the lowest response level needs to be near the BMR. Data that have responses much greater than the BMR do not reveal the shape of the curve in the BMR region. Therefore, any shaped curve in the lower dose region would fit equally well and no additional information is gained from the software. In these cases it is more beneficial to use the NOAEL/LOAEL approach.

4.2 Application of Uncertainty Factors

Because the data available for safe human dose development usually suffer from a number of limitations, there is often considerable uncertainty whether the threshold dose approximation obtained from NOAEL/LOAEL or BMD analysis actually represents a no-effect level protective of all individuals. To address this, the approximated threshold dose may be reduced by application of one or

more 'uncertainty factors (UFs)'. Examples of UFs used by various agencies are shown in **Table 1**. Generally, the following types of UFs are used:

- A UF of up to 10 to extrapolate from animals to humans. This factor is used when animal studies are the source of the dose–response information and is meant to account for interspecies variability in toxicity and sensitivity to chemicals.
- A UF of up to 10 is used to account for sensitive subpopulations. The human population is full of variation, and different people may display widely different sensitivities to the same chemical. This factor is meant to insure that the safe human dose developed is protective for sensitive subgroups, such as the elderly, children and immunocompromised individuals.
- A UF of up to 10 is used if dose–response data are only available for a shorter exposure period than the one of interest; for example, if a safe human dose for chronic exposure is desired and suitable data are only available for subchronic exposure. For a number of chemicals, the threshold for toxicity decreases as the exposure duration increases. As a result, use of data from shorter-term studies could result in an overestimation of the threshold dose. This UF is intended to prevent that from occurring.
- A UF of up to 10 is used to when deriving a safe human dose from a LOAEL. Occasionally when the NOAEL/LOAEL method is used, a NOAEL is not available; that is, all of the doses tested produced toxicity. In this situation, the threshold dose must be approximated from the LOAEL. The additional UF

of up to 10 is used to reduce to LOAEL to a value closer to the no-effect level.

- A UF between 1 and 10 is used to reflect the quality of the toxicity database. This UF is applied if very few toxicity studies exist, the studies are poorly conducted, only a few animals were tested, or only a few toxic endpoints were examined. As the quality of the toxicity database decreases, the UF for this component increases. The number used for the assessment is based on professional judgement.

The UFs are multiplicative, meaning they are multiplied together to determine a final UF. For example, if the NOAEL for the most sensitive endpoint of a chemical is $5\,mg\,kg^{-1}\,day^{-1}$ and this was derived from multiple chronic animal studies, UFs for interspecies extrapolation and for sensitive human subpopulations could be applied. If UFs of 10 were chosen for both, the total UF would be 100 (10×10). The NOAEL of $5\,mg\,kg^{-1}\,day^{-1}$ is divided by the total UF (in this case 100) to arrive at the safe human dose of $0.05\,mg\,kg^{-1}\,day^{-1}$.

4.3 Expression of a Safe Dose Derived from a Threshold Model

The safe human dose is usually expressed as an amount of chemical per kilogram body weight per day ($mg\,kg^{-1}\,day^{-1}$), and is intended to represent an exposure level below which adverse health effects are not expected. The safe dose can vary depending upon the length of exposure, usually with the relationship: acute safe dose > subchronic safe dose > chronic safe dose. Acute exposures can be defined as those lasting less than two weeks, subchronic exposures as lasting between two weeks and one year and chronic exposures for time periods greater than one year. To avoid any confusion, the exposure period to which the safe dose is intended to apply should be specified. A variety of terms are used for the safe dose, depending upon the agency or organization developing and using them. Examples include 'acceptable daily intake' (World Health Organization), 'reference dose' (US Environmental Protection Agency (EPA)) and 'minimal risk level' (US Public Health Service).

Occasionally, a safe dose is not expressed as a dose at all, but as a concentration in an environmental medium such as water or air. In this case, the concentration is assumed to result in doses below those producing effects over a range of plausible exposure circumstances.

4.4 Nonthreshold Models

Nonthreshold models are generally reserved for carcinogens. In the absence of mode-of-action evidence to the contrary, risk of cancer is assumed to be a linear function of dose, with risk reduced to zero only when the dose is zero. Stated another way, any dose of a carcinogen, however small, is assumed to pose some risk of cancer, with the probability of cancer increasing as dose increases. The nonthreshold model for carcinogens originated with the study of radiation-induced cancer. It was observed that even very small doses of radiation could induce a DNA mutation and therefore had a finite risk of cancer associated with them. The assumption that any measurable dose has measurable risk has been extrapolated to all mutagenic carcinogens and to all carcinogens for which the mode of action is unknown. The absence of a threshold dose assumes that any mutation has the potential to be permanent and alter the phenotypic expression of the cell. These phenotypic changes could evolve and become cancerous.

Experimentally, it is difficult to detect reliably increased cancer rates below about 10% in laboratory-animal cancer bioassays, given the number of animals typically included in these studies and associated limitations in statistical power. Similarly, epidemiological studies have limited ability to detect low-frequency events, including cancer. As a consequence, when carcinogenicity is observed in a human or animal study, the cancer rates are substantial. For regulatory purposes, there is interest in identifying doses of chemicals that pose even small risks of cancer, below those that are seen experimentally or in human studies. This is an enormous challenge in risk assessment. When constructing a dose–response curve for cancer, the situation is one in which there is zero dose/zero risk on the left and doses producing relatively high, measurable cancer risks on the right, with only speculation as to what the shape of the dose–response curve looks like in between. There are several possibilities (**Figure 3**). The curve could bend in a supralinear manner, or be sublinear, even approaching a threshold. The effect of choice of shape of the curve in this region is profound, resulting in orders of magnitude differences in cancer risk estimates at low doses. With no way to determine the shape of the curve other than through theoretical arguments, this is one of the largest sources of uncertainty in cancer risk assessment. In the absence of a clear basis to choose one shape over another, the most common approach is to assume a linear relationship, which can involve simply drawing a straight line from the observed data points to zero.

4.5 Expression of Chemical Potency with a Nonthreshold Model

With the threshold model, a safe dose is one in which there is reasonably high confidence that adverse effects will not result. In contrast, with a nonthreshold model, all doses have some likelihood of producing adverse

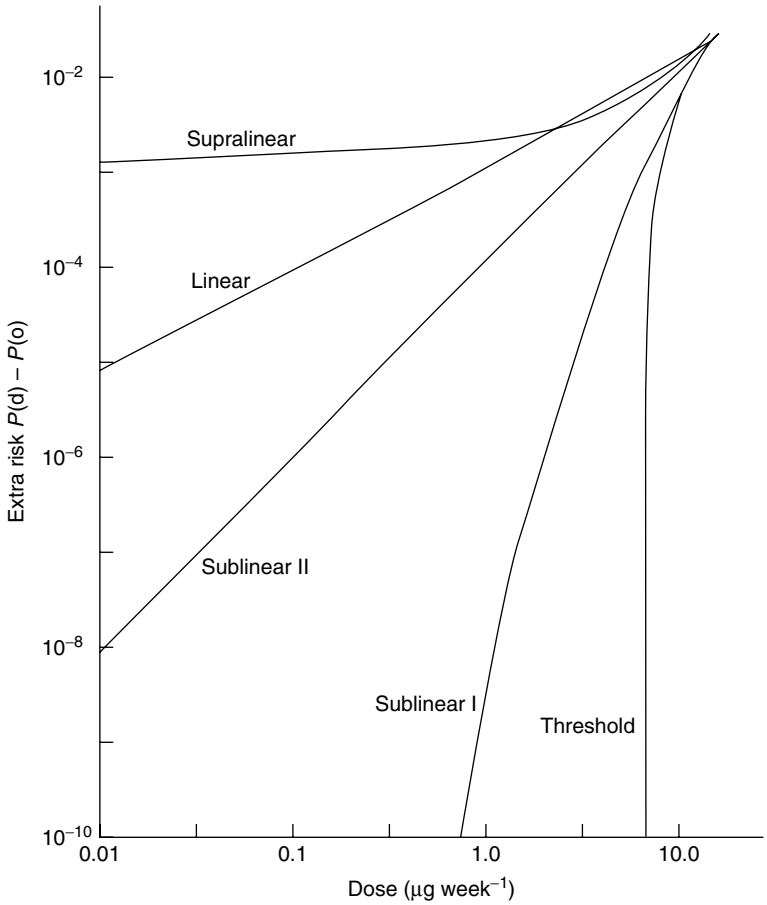

Figure 3 Results of alternative models of low-dose extrapolation of cancer risk. (From Risk Assessment in the Federal Government: Managing the Process, National Academy Press, Washington, DC, 1983.)

effects (cancer), so the concept of a safe dose must be defined differently. For the nonthreshold model, the dose–response assessment is used to determine the slope of the line that relates dose to excess probability of cancer. This value is sometimes termed the 'cancer potency factor' or 'cancer slope factor'. It is derived in such a way that the units are in reciprocal mg kg^{-1} day^{-1}. Concern for carcinogenicity is greatest when exposure is chronic. Consequently, dose–response relationships for carcinogenicity are nearly always based on long-term exposure, and in fact the cancer potency metric is generally based on lifetime exposure to the chemical. Although cancer potency could be different for shorter exposure periods, to date there has been comparatively little effort in deriving separate values for subchronic or acute exposure.

Despite the fundamental differences between toxicity values generated using threshold and nonthreshold models, there are some similarities. Toxicity values from both models (i.e. either safe doses or expressions of cancer potency) are route dependent. That means that for comprehensive evaluation of cancer risk to a chemical, separate cancer potency values are needed for each of the routes of exposure (e.g. ingestion, inhalation, dermal uptake). Also, in analysing cancer dose–response data to determine the lower end of the observation range from which extrapolation to zero should occur (termed the 'point of departure'), a process analogous to the BMD approach for threshold model data is often used. Finally, for both models, the toxicity value is sometimes expressed in concentration terms instead of an actual dose. In the case of the nonthreshold model, this takes the form of unit risk values, or concentrations in air or water corresponding to specified excess cancer risks. As with safe concentrations developed using threshold models, some assumptions regarding the extent of exposure to these concentrations, such as intake rate, must be made in order to use unit risk values.

5 EXPOSURE ASSESSMENT

Exposure assessment is an evaluation of the magnitude, frequency, duration and route of contact an individual (sometimes termed a receptor) has with the chemical. The exposure assessment is an integral part of risk assessment because, without exposure, there is no risk. For example, if soil contaminated with lead is placed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

under a maintained concrete cap, there is no contact with the soil and no chance of exposure. As long as the soil and cap remain undisturbed, there is no risk, even though high levels of lead exist in the soil. The components of an exposure assessment are discussed below.

5.1 Pathways and Media

An exposure pathway consists of four parts: (i) a source of contamination, (ii) contaminated media, (iii) contact with the contaminated media and (iv) route of exposure. Without all four of these elements, the pathway is incomplete and there is no risk to the receptor. Soil, sediment, groundwater, surface water, air and biota all function as receiving media. They become contaminated directly by a release or are indirectly contaminated through contact with other contaminated media. Relevant exposure pathways can be visualized through construction of a conceptual site model (see example in **Figure 4**). The conceptual site model conveys in concise form the source(s) of chemical release and the exposure pathways that will be considered in the risk assessment. Depending upon the level of detail, the conceptual model may also show the routes of exposure considered to be relevant. The route of exposure is the potential site of chemical entry into the body. The most common routes for environmental exposures are ingestion, inhalation and dermal absorption.

5.2 Quantifying Exposure

There are two main approaches for quantifying exposure: direct measurement and modelling. Direct measurement is usually the most accurate approach. Exposure can be quantified, for example, by analysing food intake, measuring urine output of the chemical or its metabolites or by using monitoring devices. These types of measurement are most common in controlled studies or occupational scenarios where exposure can be confined. However, in most situations, the exposure has occurred without the benefit of direct measurements. In these situations, exposure can be estimated through modelling. Fate and transport models are used to simulate the behaviour and breakdown of chemicals in the environment and estimate chemical concentrations in various media. They can estimate processes such as transport, loss, partitioning, bioaccumulation, decay and transformation. Other models or equations utilize these media concentrations to estimate intake and provide an approximate dose of chemical received during the exposure period.

Fate and transport modelling uses mathematical models to predict media concentrations, contaminant plume boundaries, effectiveness of remedial actions and time to natural attenuation. Hundreds of models exist for these purposes, including atmospheric models, surface water models, groundwater models and food-chain models. These models can be linked to integrate several media

and chemical processes together resulting in an approximation of chemical concentrations and dose received over space and time. Inputs to the model may include the concentration at the source area, chemical/physical properties of the contaminant, meteorological data, geological data and hydrological data. These models are based on assumptions and often have a large degree of uncertainty in the results. To account for this uncertainty, models tend to use parameters that may overestimate the risk. This prevents an underestimation of risk and the occurrence of adverse effects at environmental concentrations that were predicted to be without toxic effects.

5.3 Calculating Dose

Dose is the amount of chemical that is available to be absorbed into the body where it can interact with the target tissue. Dose is usually expressed per unit time, per unit body weight or both. The dose can be calculated using exposure factors. Exposure factors are variables that describe the exposed population (e.g. body weight, ingestion rate and surface area). They can be obtained from guidance such as the *Exposure Factors Handbook* (US EPA, 1997), published literature or site-specific assessments. Exposure factors will differ depending upon the population exposed (e.g. adults, children, workers) and the specific use of the contaminated area (e.g. residential or industrial). The following section provides example dose equations for some common exposure pathways.

5.3.1 Inhalation

$$\text{Dose (mg kg}^{-1}\text{d}^{-1}) = \frac{\text{CA} \times \text{IR} \times \text{EF} \times \text{ED}}{\text{BW} \times \text{AT} \times (\text{VF} \times \text{PEF})} \quad (1)$$

where

CA = chemical concentration in air (mg m^{-3})
IR = inhalation rate (m^3 day^{-1})
EF = exposure frequency (days year^{-1})
ED = exposure duration (years)
BW = body weight (kg)
AT = averaging time (days)
VF = chemical-specific volatilization factor (m^3 kg^{-1})
PEF = chemical-specific particulate emission factor (kg m^{-3})

5.3.2 Ingestion of Groundwater

$$\text{Dose (mg kg}^{-1}\text{d}^{-1}) = \frac{\text{CW} \times \text{IR} \times \text{EF} \times \text{ED}}{\text{BW} \times \text{AT}} \quad (2)$$

where

CW = chemical concentration in water (mg l^{-1})
IR = ingestion rate (l day^{-1})
EF = exposure frequency (days year^{-1})
ED = exposure duration (years)
BW = body weight (kg)
AT = averaging time (days)

5.3.3 Ingestion of Soil

$$\text{Dose (mg kg}^{-1}\text{d}^{-1}) = \frac{\text{CS} \times \text{IR} \times \text{RBA} \times \text{EF} \times \text{ED}}{\text{BW} \times \text{AT}} \quad (3)$$

where

CS = chemical concentration in soil (mg kg^{-1})
IR = ingestion rate (kg day^{-1})
RBA = chemical-specific relative bioavailability
EF = exposure frequency (days year^{-1})
ED = exposure duration (years)
BW = body weight (kg)
AT = averaging time (days)

5.3.4 Dermal Contact with Water

$$\text{Absorbed Dose (mg kg}^{-1}\text{d}^{-1}) = \frac{\text{CW} \times \text{SA} \times \text{PC} \times \text{ET} \times \text{EF} \times \text{ED} \times \text{CF}}{\text{BW} \times \text{AT}} \quad (4)$$

where

CW = chemical concentration in water (mg l^{-1})
SA = skin surface area available for contact (cm^2)
PC = chemical-specific dermal permeability coefficient (cm hour^{-1})
ET = exposure time (hours day^{-1})
EF = exposure frequency (days year^{-1})
ED = exposure duration (years)
CF = conversion factor (1 l 1000 cm^{-3})
BW = body weight (kg)
AT = averaging time (days)

5.3.5 Dermal Contact with Soil

$$\text{Absorbed Dose (mg kg}^{-1}\text{d}^{-1}) = \frac{\text{CS} \times \text{SA} \times \text{AF} \times \text{DA} \times \text{EF} \times \text{ED} \times \text{CF}}{\text{BW} \times \text{AT}} \quad (5)$$

where

CS = concentration in soil (mg kg^{-1})
SA = skin surface area available for contact (cm^2 day^{-1})
AF = adherence factor for soil (mg cm^{-2})

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DA = dermal absorption
EF = exposure frequency (days year^{-1})
ED = exposure duration (years)
CF = conversion factor (10^{-6} kg mg^{-1})
BW = body weight (kg)
AT = averaging time (days)

Dose can be summed across intake routes and media to estimate the total chemical intake per day. Time-weighted averages are commonly used when estimating dose. The time period over which the dose is averaged depends upon the length of exposure and the toxicity value that will be used to evaluate risk (i.e. acute, subchronic, etc.). For chemicals evaluated using the threshold model, the average is taken over the exposure period. For carcinogens evaluated using the nonthreshold model, cancer potency is expressed in terms of lifetime exposure (see Section 4.4). Consequently, to correspond with the toxicity value, the average dose used to estimate cancer risk should be a lifetime average. If exposure occurs for less than a lifetime, a time-weighted average that includes both exposure periods and nonexposure periods is derived. This approach basically assumes that cancer risk is a function of the cumulative cancer dose during a lifetime rather than a dosing rate during exposure (as is the case with the threshold model). With this view, for example, exposure to a chemical at a given rate for a lifetime is assumed to pose a cancer risk equal to exposure at twice that rate for half a lifetime. Experimental data to support this as a general assumption are equivocal at best, and this is another source of uncertainty in cancer risk assessment.

There are a variety of ways that dose can be expressed and it is important to understand the distinction among them. The dose metric that is likely to correlate best with response is the concentration of the chemical in the target organ or tissue, perhaps as a function of time. Measuring target organ tissue concentrations over time is difficult to do in animal studies and impossible in human studies, although it can be modelled (see Section 5.4). Provided the most relevant dose metric is known (concentration, area under concentration versus time curve, etc.) this is the optimum way of expressing dose. A more indirect way of expressing dose is the internal or delivered dose. This is the dose that is absorbed and reaches the systemic circulation. Although the precise relationship between the internal dose and target tissue concentration may be unknown, they are assumed to be proportional in some way. One of the most direct means of measuring absorbed dose is to measure the concentration of chemical in blood. This is commonly done in the clinical evaluation of potential toxicity and is used widely, for example, in evaluating risk from lead exposure in children. The internal dose can also be modelled, provided that information is available regarding the bioavailability of the chemical from environmental media for each of the routes of exposure. More indirect still is the external or applied dose. This is the dose that is ingested, inhaled or placed on the skin (as appropriate for the route of exposure). Unless toxicity is produced directly at the portal of entry into the body (e.g. irritation of the gastrointestinal tract, lung or skin), this dose is removed by at least two steps (absorption into the body and distribution to the target organ) from the target tissue concentration. The applied or external dose has one important advantage, however—it is comparatively easy to measure or estimate. Also, dose–response relationships for the vast majority of chemicals are developed using applied doses, and the dose(s) obtained from the exposure assessment need to match in order to be useful.

5.4 Physiologically-based Pharmacokinetic Models

Pharmacokinetic models (also termed toxicokinetic models when their application is in toxicology) can be used to predict chemical concentrations in target organs or tissues within the body resulting from exposure. They can serve to relate exposure measured in the form of applied doses with internal concentrations more directly related to toxicity. Further, they can be used to explore how applied dose–concentration relationships differ among species, reducing uncertainty in extrapolation of toxicity information from one species to another, including humans. They can also be used to extrapolate toxicity information obtained for one route of exposure to address exposure from other routes.

Physiologically-based pharmacokinetic (PBPK) models are mathematical models constructed to represent key anatomical compartments in the body and the flow of blood that move chemicals and their metabolites from one compartment to another. **Figure 5** shows an example of a PBPK model. The model is designed to allow input from relevant routes of exposure (in the case of **Figure 4**, from ingestion, inhalation and dermal contact) and account for elimination from the body through metabolism and excretion. Data from bioavailability studies, when available, are used to estimate the fraction of applied dose entering the systemic circulation. Flow of blood to compartments is based on physiological data. Chemical-specific data on partitioning and metabolism are used to predict movement of a chemical in and out of the compartments and conversion to metabolites. From these models, concentration of chemical and metabolite can be predicted over time as a result of specified exposures. Models are constructed for each species of interest, and model comparisons can be used to extrapolate doses across species, and as part of a determination of the appropriate interspecies extrapolation UF to use in toxicity value development.

6 RISK CHARACTERIZATION

Risk characterization combines results from the toxicity and exposure assessments to develop a risk estimate. Risk estimates may be qualitative, quantitative or both. Qualitative risk characterization gives a general estimation as to whether the risks are high or low, but it does not provide numerical estimates. For quantitative characterization of risk, the manner of characterization depends upon the dose–response relationship thought to exist for the chemical. For threshold effects, quantitative risk characterization takes the form of a ratio involving a comparison of the estimated dose with the no-effect level or safe human dose for the chemical. When a nonthreshold approach is used, risk is expressed as a probability that the effect will occur as a result of exposure, for example, the excess cancer risk associated with exposure to a carcinogen at a specified level.

6.1 Risk Characterization for Threshold Effects

When a chemical is thought to have a toxicity threshold, one approach to characterizing risk is to calculate the ratio between the estimated dose and the safe human dose. For example, the US EPA calculates a hazard quotient as follows:

$$\mathrm{HQ} = \frac{\mathrm{D}}{\mathrm{RfD}} \tag{6}$$

where

HQ = hazard quotient
D = dose from exposure ($\mathrm{mg\,kg^{-1}\,day^{-1}}$)
RfD = reference dose ($\mathrm{mg\,kg^{-1}\,day^{-1}}$) (a safe human dose in US EPA terminology)

If the HQ is less than one, the dose received is less than the safe human dose and no adverse effects are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

expected to occur. However, if the HQ is greater than one, the possibility of adverse effects is indicated. Often, that is sufficient to stimulate regulatory action. It does not necessarily mean that toxicity is likely, however. It can only be said that the chance of toxicity increases as the HQ increases. A more precise characterization of risk in terms of probability of adverse effects is difficult because safe human doses are inexact. As discussed in the section on dose–response relationships, safe human doses are based on an observed no-effect dose and one or more UFs intended to provide a margin of safety. Where the actual threshold for toxicity lies within that margin of safety for an individual is unknown, and therefore, the extent to which the safe dose can be exceeded without producing harm is unknown. Once a quantitative determination has been made that exposure results in a HQ above one, further characterization of the risk is largely qualitative. A dose marginally above the safe human dose would not likely produce toxicity, especially if the margin of safety built into the safe human dose through application of UFs is large. On the other hand, exposure producing a dose above the safe human dose and approaching or exceeding the observed no-effect level for the chemical might be viewed as 'likely' or 'very likely' to produce toxicity.

Safe doses can vary among different routes of exposure. If an individual is exposed to a chemical by more than one route of administration, a ratio of the dose from exposure to the applicable safe human dose for each route should be calculated. For the sake of simplicity, these ratios are typically added to convey the risk to an individual from exposure to the chemical from combined routes. Following through with the example using US EPA terminology, hazard quotients from relevant routes of exposure would be summed to derive an overall ratio called a hazard index (HI):

$$HI = HQ_1 + HQ_2 + \ldots + HQ_n \tag{7}$$

where

HI = hazard index
HQ = hazard quotient

Interpretation of an HI is the same as for an HQ: if the value is equal to or less than one, exposure is unlikely to produce an adverse health effect. An HQ greater than one may trigger regulatory action, but the approach does not offer a quantitative measure of the likelihood of toxicity.

A second approach is to calculate a ratio of the no-effect level with the estimated dose from exposure. For example, the BMD (or lower confidence limit estimate of the BMD) for a sensitive effect can be used as an expression of the no-effect dose and divided by an estimate of exposure to produce what is termed the margin of exposure (MOE):

$$\text{Margin of exposure} = \frac{\text{BMD}}{\text{D}} \tag{8}$$

where

$D = \text{dose } (\text{mg kg}^{-1}\,\text{day}^{-1})$

The MOE indicates the extent to which estimated exposure is above or below the observed no-effect level. Unlike the HI, where numbers less than one indicate safety, low risk is conveyed by high MOEs. An acceptably high MOE depends in part upon confidence in the toxicity data used to derive the BMD. In general, the same kinds of considerations as in the selection of UFs for a safe human dose apply. For example, a greater MOE would be likely to be required if the BMD is derived from animal data vs. studies in humans.

6.2 Risk Characterization for Nonthreshold Effects

Because the dose–response relationship for most carcinogens is assumed to follow a linear, nonthreshold model, risk is characterized in a way fundamentally different from threshold chemicals. For these carcinogens, risk is conveyed as the lifetime excess probability of developing cancer as a result of exposure. Risk is calculated from an expression of cancer potency, such as a cancer slope factor, and an estimate of dose received from exposure:

$$\text{Risk} = \text{CSF} \times \text{D} \tag{9}$$

where

$\text{CSF} = \text{cancer slope factor } (\text{mg}^{-1}\,\text{kg day})$
$D = \text{dose } (\text{mg kg}^{-1}\,\text{day}^{-1})$

As with risks from threshold effects, cancer risks are summed for each relevant route of exposure.

6.3 Addressing Risk from Exposure to Multiple Chemicals

In animal toxicity studies, exposure usually occurs to a single chemical. Real-life chemical releases are seldom this simple and often involve simultaneous exposure to many chemicals. These chemicals may interact in a synergistic or antagonistic manner to increase or decrease the toxicity of the chemicals involved. The interactions within a chemical mixture can be even more complex, with synergistic, antagonistic and additive effects all occurring at the same time. These interactions may be chemical in nature, but can also be biological and affect

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the ability of an organism to metabolize or interact with other chemicals. Current risk assessment techniques have limited ability to account for such interactions. In cases where the interaction has been studied and is well known, it can be addressed by modifying the toxicity values. However, these interactions are usually not known and are dependent not only upon the other chemicals present, but also upon their concentrations (doses).

In the absence of both qualitative and quantitative information on the existence of an interaction among chemicals present, it is usually assumed that the effects of chemicals in combination are additive. Commonly, risk for threshold chemicals is calculated by summing the HIs for the individual chemicals. The sum of these ratios gives an indication of the overall relationship between estimated and safe levels of exposure. A more refined approach sometimes used is to combine HIs only for chemicals that produce the same type of toxicity, affect the same target organ, or have the same mode of action. The rationale for this approach is that additive effects are most likely to occur when chemicals share the same target or affect biological systems the same way. The interpretation of the HI is the same as described above. An overall HI less than one for two or more chemicals indicates that together they are unlikely to produce an adverse effect. An HI greater than one indicates that adverse effects are possible, but it does not indicate the probability of an adverse effect. For carcinogens, the total excess risk of cancer is simply the sum of the cancer risk for each chemical.

Some combinations of chemicals are found together commonly, such as chemicals present in commercial mixtures or closely related chemical structures. For these mixtures, there are three basic approaches to determining the additive effects, as described in the following sections.

6.4 Testing the Mixture of Concern

The simplest way of obtaining the toxicity of a mixture with the least amount of uncertainty is to test the mixture in an *in vivo* animal toxicity study. This direct method determines how the mixture interacts within a biological system to produce toxicity. In this approach the mixture is actually treated as a single chemical because no information is obtained on the chemical or biological interactions of the components. Unfortunately, there are thousands of mixtures and every possible combination of chemicals and their relative percentage within the mixture cannot be tested. Therefore, it is not unusual to have a mixture of concern for which no toxicity data exists. In these cases, other methods must be used to estimate the toxicity of the mixture.

If two mixtures are similar in composition, then the toxicity value for one can be used as a surrogate value for the second. There is no official guidance on how to define a similar mixture, so the use of a surrogate mixture is usually left to professional judgement and can vary among risk assessors and regulatory agencies. A surrogate mixture containing the same chemicals, but in different proportions is usually preferable to mixtures including different chemicals. The introduction of additional chemicals could change the chemical and biological interactions within the body and, in turn, alter the toxicity of the mixture.

Another method for estimating the toxicity of mixtures in the absence of *in vivo* toxicity data is the application of a PBPK model to the mixture of concern. PBPK models can utilize biological information to predict chemical interactions within the body. In these models, equations that specifically account for interactions among the chemicals within a tissue compartment are integrated into the model. The PBPK modelling predicts the magnitude and type of interactions based on individual chemical concentrations and mode of toxicity.

6.5 Dose Addition

For dose addition, the chemicals within the mixture do not require similar dose–response curves or similar toxicities. The dose addition approach is identical to the HI approach. It is the most commonly used approach in assessing the toxicity of mixtures. In this approach, the hazards for individual chemicals with the same target organ are added together. The default assumption for this method is that there is no interaction among chemicals. Consequently, this method does not take into account the synergistic or antagonistic effects that may arise from chemical interaction within the body. However, in a biological system, the absorption, distribution, metabolism and excretion of one chemical can affect the internal dose or the toxic mechanism of action for other chemicals within the mixture. The more chemicals a mixture contains, the greater the likelihood that a nonadditive interaction is possible. Therefore, the estimated toxicity for a mixture increases in uncertainty as the number of chemical components increases.

When different chemicals in the mixture have a similar mode of action, their relative potencies can be used to assess the toxicity of the mixture. An example of this method is the toxicity equivalency factor (TEF) approach utilized for chemicals with dioxin-like toxicity. In this approach, the potency of dioxins, furans and polychlorinated biphenyls (PCBs) are expressed relative to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD). The concentration of each congener is then multiplied by its relative potency factor and is given as a 2,3,7,8-TCDD equivalent concentration. The toxicity of the sum of the 2,3,7,8-TCDD equivalent concentrations is an approximation of the toxicity of the mixture. TEFs for mammals,

birds and fish utilized by the World Health Organization are shown in **Table 2**.

6.6 Response Addition

Response addition is used when the mixture components do not necessarily have the same target organ and are believed to act through independent modes of action. In this situation, dose addition would not give an accurate estimation of the toxicity of the mixture since the different modes of action may not result in an additive toxicity. The most common use of response addition is to estimate total cancer risk from mixtures. In the response addition approach, the percentage of humans expected to develop toxicity at the exposure dose is estimated for each chemical in the mixture. These responses for each chemical are then summed to approximate the percentage of the population that can be expected to develop toxicity from exposure to the mixture at a specific concentration. This method is useful when the risks to each component are relatively small, but does not work well when one of the component risks is large. Similar to the dose addition approach, response addition does not account for synergistic or antagonistic interactions among the chemicals within the mixture. It assumes that the response to one component is the same no matter what other chemicals are present in the mixture. This may not necessarily be the case. However, interactions among chemicals in a mixture are not easy to characterize and assess. Currently, methods to routinely account for these interactive effects do not exist in risk assessment.

7 UNCERTAINTY ANALYSIS

An uncertainty analysis is a critical aspect of any risk assessment. Because of the extensive use of models and assumptions in calculating risks, the resulting risk values are inherently imprecise. In order to use these risk values effectively to assist sound risk management, it is important to describe as transparently as possible where the uncertainties lie and, if possible, the magnitude of error that may be associated with them. Ideally, an uncertainty analysis includes an exploration of alternative choices on models and assumptions, and a description of the impact that each selection had on the estimated risk

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(e.g. a statement that the choice of model X instead of model Y would result in a lower risk by 1–2 orders of magnitude). It is usually sufficient to focus the discussion of uncertainty on the model and input decisions that have the greatest effect on the risk output. A sensitivity analysis can be used to identify these key choices. In a probabilistic risk assessment (PRA), the contribution of various types of uncertainty can be addressed formally in the risk output, as described in the following section.

8 DETERMINISTIC VS. PROBABILISTIC RISK ASSESSMENTS

There is both variability and uncertainty associated with each input in the risk formulas described above. Variability describes the natural variation that occurs within a population. For example, measurement of the body weight of 100 adults might result in a range of weights between 45 and 120 kg. This range reflects the natural differences in body weight among this sample of the adult population and a range of results is expected for this parameter. Uncertainty arises from a lack of knowledge. Utilizing the same example, if body weight data were generated for this group of 100 adults by asking them their weight, some error is expected. This error could arise because they do not know their body weight with certainty, or because they might be less than candid about the value. Regardless of the cause, the possibility of error leads to uncertainty in the body weight estimates. This uncertainty could be reduced by actually weighing each individual, producing more accurate values. This is an important distinction between uncertainty and variability. Variability is an inherent property of the population while uncertainty can be reduced by additional examination, study or research.

There is uncertainty associated with both risk models and inputs into the formulas. With respect to inputs, uncertainty can arise due to measurement error, random error or systematic error. An example of measurement error is inaccuracy in laboratory measurements of chemical concentrations. Each chemical assay has limits in terms of accuracy and reproducibility that contribute to uncertainty in the chemical concentration values used in the risk assessment. Random error can occur due to limitations in the number of data points available for analysis in the risk assessment and their representativeness. Using the body weight example from the previous paragraph, body weight data from the 100 individuals could be used to estimate the distribution in body weight for the general population. However, there would be uncertainty whether this subpopulation is representative of the whole. Systematic error arises from a fundamental flaw in the data-gathering process. An example of systematic error would be chemical measurements using a faulty analytical standard.

The accuracy of the risk models is the source of several additional uncertainties. Models can be too simple and fail to capture all of the important facets of the processes they are intended to represent. They can also be conceptually incorrect, based on mistaken ideas about the relationships among component variables. Uncertainty can be introduced into the model by the use of surrogate variables. For example, estimation of cancer risk from chemical exposure in humans requires a potency value. Usually, these are not available from human studies, so a value derived from animal studies is used as a surrogate. The use of potency information derived from animals to represent cancer potency in humans contributes to uncertainty in the cancer risk the model predicts. Another source of uncertainty lies with excluded variables. These are variables that were not included in the model for the sake of simplicity. If their influence on model outcome is small, the omission of these variables can be justified. However, without including them in the risk assessment, it may be difficult to know with certainty that their contribution to risk is in fact minor. Yet another source of uncertainty in the use of models is their ability to deal with abnormal conditions. As a practical matter, it is desirable to keep models as simple as possible without sacrificing their predictive value. Although a model might seem to work well in its usual application, there can be uncertainty whether it is able to function effectively if unusual circumstances arise. A final source of uncertainty is incorrect model form; that is, knowing whether your model is structured correctly. In exposure analysis, different models can give different answers, for example in estimating the concentration of a chemical in air downwind from an emission source. In choosing output from one model over others to calculate risk, uncertainty is introduced as to whether the most accurate model was selected. In the dose–response assessment, the choice of model for extrapolation of responses in the low-dose range can have a dramatic influence on the risk estimates generated, and is an important source of uncertainty.

Risk assessments have to deal with both variability and uncertainty. Deterministic risk assessments take the simplest approach, selecting a single set of models and using a single value (sometimes called a point estimate) for each input parameter. The result is a solitary risk number for each exposure scenario considered. Given the variety of models that might be available and the range of inputs possible given both variability and uncertainty for each parameter, the choice of model and input values is critical in determining the risk output.

For any given exposure scenario (e.g. inhalation of a chemical in workplace air or contact with contaminated soil in a residential yard), differences in the extent of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

exposure among individuals is expected. As a consequence of differing exposure, risk posed by the chemical to different individuals will vary accordingly. For regulatory agencies, there will be an interest in characterizing the risk to individuals that are among the most highly exposed so that risk management strategies that are broadly protective can be developed. As a result, risk assessments performed for regulatory agencies generally include risk estimates developed using inputs that reflect the upper-end of the plausible range for a number of parameters. In order to avoid producing extreme (and unrealistic) estimates of exposure and risk, a combination of median and upper percentile values are selected for various parameters, such that together they result in a high-end, but reasonable, risk estimate.

There is a similar consideration in the choice of models used to generate risk values for regulatory purposes. If a clear choice of model cannot be made on scientific grounds, then the model that produces the highest estimates of exposure and risk will be selected. The reasoning for this is that regulatory decisions that protect public health cannot be made if risks are underestimated. To avoid underestimating risk, models producing higher risk estimates are selected. Choices in models and inputs that err on the side of overestimating risk are termed conservative.

The conservatism inherent in deterministic risk assessment is not easily quantified and this creates some controversy in the use of single point estimates for the calculation of risk. Uncertainty is also not well defined in a deterministic risk assessment. A point estimate must be chosen and the uncertainty surrounding this choice is usually reduced to a discussion in the uncertainty section of the risk assessment. Also, point estimates derived from largely uncertain values are given as much weight as those derived from well-known values.

PRA is a method for addressing some of the inherent problems with deterministic risk assessment. In the PRA, the exposure variables are defined as probability distributions. These distributions indicate the probability of each exposure value occurring within the population. The distributions can be based on variability or uncertainty. The distributions represent the range of variability or uncertainty in exposure and provide more complete information for the estimation of risk. For example, instead of using a single body weight of 70 kg in the risk calculation, a distribution of adult body weights is entered that reflects the variability within the population (**Figure 6**). The probability distribution functions (PDFs) from the exposure variables are entered into a computer and a simulation is run. In the most common type of simulation, a Monte Carlo simulation, the computer selects a variable at random from each of the PDFs and uses those chosen point estimates to calculate risk. That risk value is stored and the process is repeated a minimum of several thousand times to show how risk

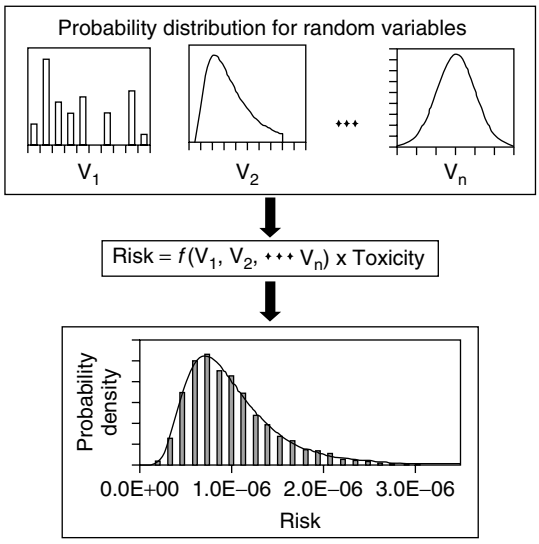

Figure 6 Probabilistic risk assessment input distributions and risk distribution output. (Reproduced from U.S. Environmental Protection Agency, 2001.)

is distributed within a population. An upper-end value (such as the 95th percentile) from this distribution is then chosen to represent the upper bound estimate of risk for the population. This number is usually compared against risk targets to determine if the exposure is of concern.

PRAs can address both variability and uncertainty simultaneously. This type of PRA is known as a two-dimensional PRA. Two-dimensional PRAs require the development of distributions for *both* variability and uncertainty for each exposure variable. While conceptually simple, separation of uncertainty from variability may not be easy in practice. The variability and uncertainty PDFs are then combined to generate a risk distribution with confidence boundaries defined by the uncertainty distributions. Another type of PRA that addresses both variability and uncertainty is called a fuzzy PRA. Fuzzy PRAs define uncertainty and variability as interval functions and then combine them in a similar manner to the two-dimensional PRA.

Variability and uncertainty exist for toxicity values as well as exposure parameters. In theory, these could be addressed in the same way, using distributions to represent variability in toxic potency among individuals within a population, and uncertainty in dose–response relationships based on model choices and source data. In practice, this has not been well accepted by regulatory agencies, usually with the explanation that methods for assigning these distributions have not been sufficiently developed.

The primary advantage of PRA is that the risk distribution includes quantitative information on variability and uncertainty. The output is not a single upper-end

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

estimate of risk; rather, the result expresses a distribution of risks for the population of concern and the percentage of the population likely to exceed the target risk level. Despite these advantages, the PRA is not as widely used as deterministic risk calculations. Compared to a deterministic risk assessment, PRAs are information and labour intensive. They require the compilation of many distributions for which good data may not exist. For site-specific assessments, the distributions must be created anew and may require expensive data collection. Finally, PRAs require a different set of assumptions on acceptable risk. Because a distribution of values is used for the exposure assumptions, the computer may pick several high-end assumptions and calculate extreme estimates of risk. To avoid using these values, an upper percentile of risk (e.g. 95th percentile) is typically used to represent individuals in the general population with the greatest risk. This suggests that a small percentage of the population may exceed the target risk level, although in reality, given the overall conservativeness of the risk assessment process, there may be no one with risks over the risk target. Although the upper percentile is an acceptable estimate of the reasonable maximum exposure, communication of these concepts to the public may be difficult.

9 EVALUATING THE RISK OF LEAD EXPOSURE AS A SPECIAL CASE

The safe human dose for the majority of chemicals is determined by utilizing the applied dose, that is the dose ingested, inhaled or dermally absorbed at the point of entry into the body. An important exception is in the case of lead. The safe human dose for lead is derived using blood levels. Enough data exists on the adverse effects of lead at different concentrations in blood to directly compare blood lead levels with concentrations known to cause an adverse effect. Lead is a neurotoxicant that decreases IQ and learning ability as blood concentrations increase. It also impairs motor function and physical abilities. The most sensitive endpoint of this chemical includes its effects on the developing nervous system, which makes children a population of special concern for the toxic effects of lead. The threshold for the adverse effects of lead is not well defined because there is no apparent blood lead level below which adverse effects do not occur. Despite the lack of a threshold for effects, the current safe limit for lead in blood set by the World Health Organization in 1995 is $10\,\mu g\,dl^{-1}$. Concentrations of lead in media (e.g. water, soil, air) that result in a blood lead level above $10\,\mu g\,dl^{-1}$ are considered of concern. Because lead concentrations in environmental media cannot be directly related to blood concentrations of lead, blood lead levels are calculated using a PBPK model such as the Integrated Exposure Uptake Biokinetic Model for lead, used by the US EPA. This model predicts the likely distribution of blood lead levels in a population given the exposure at a site and determines the probability that an exposed population will exceed the target blood lead level. This information is used to determine whether the percent of exposed individuals with blood lead concentrations above the level of concern is acceptably small.

10 PLACING RISKS IN PERSPECTIVE

One of the challenges in risk assessment is to convey risk estimates in a context that gives them meaning to the public and to risk managers who use them to make decisions. One method of placing the output of a risk assessment in perspective is through comparisons with known or familiar risks. These comparisons assist risk managers by allowing them to place priorities on certain risks and allocate resources where they will be the most effective at reducing risk. By comparing the risk from exposure to a more familiar event, a non-technical comparison can be made that increases the understanding of risk by audiences outside the field of risk assessment and aids in risk communication. Several types of risk comparisons can be made. For example, risks posed by exposure to a chemical can be compared with risks experienced voluntarily in everyday life, such as driving a car or smoking. They can also be compared with risks from natural events, such as lightening strikes. **Table 3** provides examples of comparison data on the loss of life expectancy for various activities, including more familiar, voluntary and natural occurrences.

Table 3 Estimated odds of dying from various activities in the United States

Activity	Lifetime odds of dying
Driving a motor vehicle	1 in 84
Suicide	1 in 117
Falls	1 in 194
Assault	1 in 210
Ingesting narcotics	1 in 345
Drowning	1 in 1064
Fire	1 in 1192
Flying on an airplane	1 in 6460
Drinking alcohol	1 in 11 015
Animal attacks	1 in 23 672
Lightning	1 in 79 399
Earthquake	1 in 103 004
War	1 in 141 154
Flood	1 in 317 595

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Unfortunately, comparative risk analysis is not always a straightforward process. Situations arise which complicate the process and add uncertainty into the comparison. For example, most chemicals have multiple toxic endpoints. Choosing the most sensitive endpoint to represent the chemical may be appropriate for effects screening. However, it does not reveal all the possible adverse effects that may occur from exposure to the chemical. Additionally, when chemicals produce different effects, it is difficult to compare one endpoint to another. While most people consider death a more severe effect than hypertension, it can be difficult to rank other adverse effects such as gastrointestinal effects, eye irritation and peripheral neuropathy. How, for example, should risk of kidney disease from one chemical be compared with developmental toxicity from another? It is conceivable that potential adverse effects such as these would have different relative rankings with different members of the population.

Spatial and temporal scales can also complicate the process of comparative risk analysis. It is often difficult to compare short-term adverse events such as a one-time pesticide application in a neighbourhood to a more continuous event, such as air pollution in a neighbourhood generated by a local incineration plant. The risks from the pesticide are transient, while the risks from the incineration plant may last over a person's lifetime. Differences in spatial scales can also complicate risk comparisons. Comparing the risk from a local waste site to the risk of global deposition of PCBs has little meaning.

Although some forms of comparative risk analysis can be useful in communicating risks, others can hinder that communication. The most effective forms of comparative risk analysis are those that compare risks from different chemicals released from the same source, compare risks of different chemicals to the same target organ and compare risks at different sites. Comparison of risks that are substantially different may not be effective and may even prevent comprehension. For example, comparing the risk from exposure to a chemical to the risk of being a victim of a crime may have little effectiveness since the impact of such a risk is difficult to understand. Uncertainties regarding the comparison can increase confusion and create problems in trying to communicate the risk.

Additionally, the public may interpret some types of comparative risk analysis in a negative manner. Comparison of voluntary vs. involuntary risks or natural vs. anthropogenic risks may decrease the effectiveness of the comparison. For example, comparing the risk of drinking groundwater contaminated by a local business to the risk of using a motor vehicle may not be effective. Most people understand that there is a danger in operating a motor vehicle and they willingly accept that risk every time they drive to work or a store. However, a risk from drinking water that was contaminated by someone else may be more difficult to accept, even if the actual risk is smaller. Accepted risks and imposed risks may not be different quantitatively, but they are very different qualitatively and are usually difficult for the layperson to view as equal. The same is true for comparisons of natural and anthropogenic risks. Natural occurrences (such as weather) are usually seen as beyond one's control and bear little resemblance to anthropogenic factors, which are usually seen as manageable and within the realm of control.

11 ECOLOGICAL RISK ASSESSMENT

Ecological risk assessment is a method for estimating risk to the environment as a result of physical, chemical and biological stressors. Current approaches to ecological risk assessment are utilized mainly for chemicals and focus on the risk of a chemical release into the environment. Ecological risk assessment differs from human health risk assessment in that it attempts to determine risk to a much larger entity—the environment. Human health risk assessment is focussed on one species (humans) while ecological risk assessment is concerned with the multitude of animal and plant species that inhabit an area. In addition, the ecological system as a whole and its ability to maintain current levels of diversity and types of habitat are considered. Both human health and ecological risk assessments share the same basic concepts embodied in hazard identification, dose–response assessment, exposure assessment and risk characterization. However, the way these concepts are implemented differs between the two types of risk assessment because of the greater complexity of ecological systems and somewhat different assessment goals. A summary of similarities and differences between human health and ecological risk assessment is shown in **Table 4**.

Table 4 Comparison of human and ecological risk assessment

Human	Ecological
Protects one species—humans.	Protects multiple species including plants, invertebrates and animals.
Well-established guidance and procedures.	Newer field where guidance and procedures are still evolving.
Criteria are meant to be protective of the individual, including sensitive subpopulations.	Criteria are meant to be protective of populations or habitats.
All adverse effects are considered.	Only growth, reproduction and mortality endpoints are considered.
Carcinogenic effects are considered.	Cancer is not considered an adverse effect.

11.1 Problem Formulation

The goal of ecological risk assessment is different from that of human health risk assessment. When concerned with humans, the goal is to protect each individual, including sensitive subpopulations. With the environment, protection is usually not provided on an individual level, but on a population level. When determining the critical adverse effect, ecological risk assessment is only concerned with those toxicities that affect the fecundity of an individual. Accordingly, chemicals are assessed for toxicities that effect mortality, growth or reproduction. Other adverse effects are generally not considered. As long as the animal can survive to produce offspring, the population will be maintained and the chemical exposure is not regarded as having an adverse effect on the population. The exception to this is for species with special legal protection, such as endangered and threatened species. In these situations, protection of individual animals is required and the assessment must therefore consider adverse effects at an individual level.

The number of species present in an area of concern can be very large. Attempting to assess risks to all of them would be time consuming, expensive and full of uncertainties, because most species do not have toxicity data readily available. To streamline this process, one or more ecological entities are chosen as the focus of the ecological risk assessment. An ecological entity can be defined as one species, a representative group of species (e.g. benthic invertebrates), species from different branches of the food chain (e.g. herbivorous mammal, carnivorous mammal and insectivorous mammal) or a number of species within a habitat.

Endangered or threatened species are often the focus of assessment if they are present. Because their risks are assessed on an individual rather than population level, greater risks can occur at lower chemical concentrations. In the absence of threatened or endangered species, the ecological risk assessment usually focusses on the most sensitive species. A risk assessment that supports protection of the most sensitive species will also prevent adverse effects in species that are less sensitive, thereby ensuring the integrity of species diversity within the habitat. Although seemingly straightforward, choosing the most sensitive species is not always easy because toxicity information exists for very few species other than common laboratory animals. Instead, the most sensitive species is often inferred based on habitat and biology. For example, if a bioaccumulative chemical was released into a freshwater river, the most sensitive receptors could be piscivorous birds, piscivorous fish, piscivorous mammals and other predators at the top of the aquatic-based food chain. If a metal were released into the same river, benthic invertebrates would have a larger exposure and be more likely to experience adverse effects.

What constitutes an unacceptable chemical impact is not clearly defined for ecological risk assessment. This leaves a lot of latitude in determining which ecological entity should be protected from the release of chemical stressors in a given situation. Regulatory agencies may decide not to protect a species at all. Instead, the biodiversity of a habitat or even the type of habitat itself may be considered the ecological entity to protect. In these cases, entire populations are allowed to decline or disappear. The goal may be to maintain the same number and type of species in the affected area that are present in the reference areas. In some cases, only the total number of species is used as the endpoint. Populations are allowed to diminish as long as another species takes its place. This endpoint allows succession and the presence of invading or non-native species.

11.2 Exposure Pathways

In ecological risk assessment, different exposure routes exist for different species. Terrestrial animals may be exposed to a chemical through inhalation, ingestion or dermal absorption. Aquatic animals are exposed through ingestion and dermal absorption. Terrestrial plants are exposed through root uptake and leaf uptake of both solid and gas contaminants. Aquatic plants have direct contact with water and sediments. They may also have exposure routes similar to terrestrial plants if they are emergent. In practise, dermal contact and inhalation exposure are not usually assessed for terrestrial animals. There are two reasons for this. The first is that there is almost no data on dermal and inhalation toxicity for terrestrial animals. The second is that the largest portion of risk to the animal is obtained from ingestion of the contaminant through food sources, drinking water, and from direct ingestion of soil while feeding or grooming. Dermal absorption and inhalation do not usually contribute significantly to risk. An exception is for burrowing animals. These animals are more susceptible to direct contact from soil and inhalation of vapours because they reside within the soil. If the data are available, dermal absorption and inhalation risks should be assessed for burrowing animals. It is important to keep in mind that an exposure pathway must be complete for there to be any amount of risk. For example, a herbivorous mammal will not be affected by PCB accumulation in fish. Additionally, if a contaminant is found only in soil below the root zone, plants will not be able to absorb the chemical and would not have any risk.

11.3 Exposure Media and Biomagnification

The two major types of ecosystems in an ecological risk assessment are terrestrial and aquatic. Soil, air and sometimes sediment and surface water are the media

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.
This article is © 2009 John Wiley & Sons, Ltd.
DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of concern for terrestrial animals. Soil and air are the principal media of concern for terrestrial plants. Aquatic animals are exposed to only sediment and surface water, while aquatic plants may be exposed to sediment, surface water and air (emergent plants). Groundwater is not usually considered a medium of concern for ecological risk assessment since it is not utilized directly by most plants and animals.

An ecological risk assessment must consider biomagnification when determining exposure and identifying the most exposed species. Bioconcentration is the uptake of a constituent from water that results in an aquatic animal having a higher concentration of chemical in its body than is present in its surroundings. Bioconcentration is related to the octanol–water partition coefficient of a chemical. The more likely a chemical is to partition into the lipid phase, the more likely it will move from the water into the organism. Bioaccumulation also results in a higher concentration of chemical in the organism than is present in its surroundings. However, this term is not restricted to uptake from water. It encompasses chemical uptake through respiration, prey ingestion, dermal absorption and other means. Chemicals which bioaccumulate may result in very high body burdens for top predators. Exposure through direct ingestion alone may not accurately reflect the escalating concentrations for these species.

11.4 Exposure Parameters

Some of the exposure parameters for ecological receptors differ from those used in human health risk assessments. Ecological receptors require the consideration of additional factors when determining exposure. Some of the more common parameters are listed below.

- Area-use factor: This factor relates to the fraction of the animal's home range that is within the contaminated area. If the entire home range of the animal is within the contaminated area, then the area-use factor is one. For screening purposes, the area-use factor is assumed to be one, but may be adjusted during more detailed assessments.
- Dietary composition: The percentage of the diet that consists of each food component (e.g. 20% fruit and 80% soil invertebrates). In the absence of dietary composition information, the most conservative assumption is that 100% of the diet is composed of the most contaminated component.
- Bioaccumulation: The degree to which a contaminant biomagnifies in the food chain. The highest bioaccumulation factor reported in the literature from a well-conducted study should be used to estimate this parameter.
- Body weight
- Food ingestion rate
- Bioavailability: The bioavailability is assumed to be 100% in the absence of site-specific data.

11.5 Dose Equations

The equations used to estimate dose for ecological risk assessment also differ from their counterparts in human health risk assessment. The equations have been modified to account for different types of exposure factors. As in human health risk assessments, dose is usually expressed per unit time, per unit body weight or both. Exposure factors used in these equations can be obtained from guidance, such as the US EPA *Wildlife Exposure Factors Handbook* (US EPA, 1993), published literature or site-specific assessments. The following section provides example dose equations for some common exposure pathways.

11.5.1 Ingestion of Surface Water

$$\text{Dose (mg kg}^{-1}\text{d}^{-1}) = \frac{\text{CW} \times \text{F} \times \text{IR}}{\text{BW}} \qquad (10)$$

where

CW = chemical concentration in water (mg l^{-1})
F = fraction of water obtained from the contaminated source
IR = water ingestion rate (l day^{-1})
BW = body weight (kg)

11.5.2 Ingestion of Food

$$\text{Dose (mg kg}^{-1}\text{d}^{-1}) = \sum_{n=1}^{m}\left(\frac{\text{CF} \times \text{F} \times \text{IR}}{\text{BW}}\right) \qquad (11)$$

where

m = number of contaminated food types
CF = chemical concentration in food (mg kg^{-1})
F = fraction of diet obtained from the contaminated source
IR = ingestion rate (kg day^{-1})
BW = body weight (kg)

11.5.3 Ingestion of Soil or Sediment

$$\text{Dose (mg kg}^{-1}\text{d}^{-1}) = \frac{\text{CF} \times \text{F} \times \text{FS} \times \text{IR}}{\text{BW}} \qquad (12)$$

where

CF = chemical concentration in soil or sediment (mg kg^{-1})
F = fraction of total food intake obtained from the contaminated source

FS = fraction of soil or sediment in the diet
IR = ingestion rate (kg day^{-1})
BW = body weight (kg)

11.6 Toxicity Values

Toxicity data are not often available for the species of interest. As with human health risk assessments, surrogate species are used to estimate toxicity. Chickens may be used to estimate toxicity to birds, ducks for aquatic waterfowl and rats for terrestrial mammals. Toxicity studies for each category of receptor (e.g. mammals, birds, plants and invertebrates) are compiled and compared to exposure levels to determine if an adverse effect is likely.

In contrast to human health risk assessments, there are no standard procedures to determine a safe dose for an ecological entity (termed the toxicity reference value (TRV)). As an initial screening step, the exposure dose could be compared with the lowest NOAEL. However, not all agencies choose to use such a conservative estimate. Since protection of ecological receptors occurs at the population level, use of the lowest NOAEL is not necessary and other estimates are often used. For example, in determining ecological soil screening levels for various constituents, the US EPA uses multiple studies to determine a NOAEL for a specific chemical and receptor group. In the derivation of their TRVs, at least three studies are required, with endpoints in the growth, reproduction or mortality effect groups. If there are at least three NOAELs available from these studies, the geometric mean of all of the NOAELs is calculated. Additional adjustments may be added to this value; however, the final value used as the TRV is rarely as conservative as the lowest NOAEL. NOAELs are used as preliminary screening values, but chemical concentrations up to and including the LOAELs may be chosen as acceptable levels for chemical constituents. Any concentration below the LOAEL is not expected to have an effect on the preservation of the population for most chemicals.

Ecological risk assessments protect entities on larger scales than human health risk assessments, so less conservatism is built into the derivation of a TRV than a safe human dose. The chemical concentrations remaining on site may result in the death of many individuals, but as long as the populations remain stable, the risks are often considered acceptable. Toxicity studies used to derive the TRV concern the fecundity of the receptor. Fecundity is affected by toxic endpoints including mortality, growth and reproduction. Cancer is not considered an endpoint for ecological receptors. The long latency period of carcinogenesis prevents this adverse effect from interfering in the preservation of the population through reproduction.

11.7 Ecological Uncertainty Factors

Similar to human health risk assessments, UFs are used to adjust the NOAEL in deriving the TRV. Some of the UFs used to adjust the NOAEL for ecological species are listed below.

- A UF of up to 10 is used to extrapolate an NOAEL from an LOAEL. This factor is used in an attempt to reduce the LOAEL to a value that is at or below the threshold dose.
- A UF of up to 10 is used to extrapolate subchronic data to chronic data. Higher exposure levels can be tolerated for shorter periods of time so the use of these data for chronic exposure may underestimate the toxicity of the dose received. Therefore, the subchronic data are divided by an UF to protect against the lower threshold dose that may come from longer exposure periods.
- A UF between 1 and 10 is used to reflect the quality of the toxicity database. This UF is applied if very few toxicity studies exist, the studies are poorly conducted or only a few animals were tested. As the quality of the toxicity database decreases, the UF for this component increases.

UFs are not used to extrapolate between species. Since toxicity data from the species of concern is rarely available, toxicity data from surrogate animals representative of the same class are usually used (e.g. quail toxicity data can be used to estimate an NOAEL for herons). This type of data is considered adequate to represent the species of concern. The ecological practice of protection at the population level negates the requirement for additional conservatism. UFs are also not used to account for sensitive individuals within the population. Since protection is on a population level, the individual is not considered.

11.8 Hazard Estimation

Because cancer is not an endpoint for ecological risk assessments, only hazard quotients are calculated. The hazard quotient for ecological risk assessments is determined in a similar manner as human health risk assessments. The estimated chemical intake is divided by the TRV to obtain the hazard quotient for ecological entities.

$$\mathrm{HQ} = \frac{\mathrm{D}}{\mathrm{TRV}} \tag{13}$$

where

HQ = hazard quotient
D = dose from exposure (mg kg^{-1} day^{-1})
TRV = toxicity reference value (mg kg^{-1} day^{-1})

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat118
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

If the HQ is less than one, exposure to the chemical contaminant is unlikely to cause adverse effects on mortality, reproduction or growth. Since only population level effects were considered in the derivation of the TRV, an HQ less than one is not necessarily indicative of the absence of adverse effects. Instead, it only suggests that the population level adverse effects will not manifest at current environmental concentrations. An HQ greater than one suggests that population level adverse effects are likely. As in human health risk assessment, hazard quotients exceeding one are not a guarantee of the presence of population level effects due to the UFs included in the derivation of the TRV. However, as the HQ increases, the likelihood of population level effects increases. When there is more than one chemical present at a site, the HQs for chemicals that produce their adverse effect through the same toxic mechanism can be added, to calculate a HI.

$$HI = HQ_1 + HQ_2 + \ldots + HQ_n \qquad (14)$$

where

HI = hazard index
HQ = hazard quotient

A HI less than one indicates that a population level adverse effect is unlikely. However, the likelihood of occurrence increases with the severity of the effect and the magnitude of the HI. Uncertainty in environmental concentrations and the NOAEL used to derive the TRV can result in an inaccurate estimation of the HI and population level effects occurring at a HI less than one.

To reduce the uncertainty in whether current chemical concentrations may cause population level effects, comparisons can be made to reference areas. Reference areas are ecologically similar areas that are not impacted by the chemical(s) under investigation. Potentially impacted and reference areas are compared through the use of population metrics. Examples of these metrics include number of species, abundance of various taxonomic groups, total abundance, percentage invasive species, percentage sensitive or tolerant species, and trophic composition. Comparisons with reference areas help determine if exposure to the chemicals of concern are causing a change in the population metrics of the community. A lack of difference between site and reference areas suggests that the chemicals are not causing adverse effects on the population level even if the HI exceeds one. Bioavailability, sensitivity of the organisms to the chemical, and even the spatial and temporal distribution of the contaminants can increase or decrease the likelihood of effect on the population by altering the threshold concentration for population level effects.

12 RISK MANAGEMENT

Risk assessment alone is rarely the basis for determining whether a site requires removal of chemical contaminants. Political, technical, ethical and value-based processes all contribute to the final decision, despite the science-based risk estimates for the receptors. It is the job of the risk manager to weigh these different criteria and determine the remedial actions necessary to protect human health and the environment. The processes involved in risk management decision-making include:

- Benefit vs. risk analysis: This analysis attempts to weigh the benefits of remediation with the risks inherent in the corrective actions. Examples include release of additional product into the groundwater or destruction of valuable ecological habitat during remediation.
- Cost vs. benefit analysis: Cost effectiveness attempts to obtain the most benefit for the least cost. This can alter the type of remediation chosen (capping instead of removal) or may even end remediation when cleanup requires large costs for minimal risk reduction, that is, when the cost of additional risk reduction becomes impractical.
- Comparative analysis: If the remedial action is likely to cause additional exposure or damage the ecosystem, a comparison between the risks for contaminant removal and leaving a chemical in the environment can be performed. The goal of this analysis is to determine the action that will cause the least amount of risk to human health or the environment. This type of assessment may include relative risks, cost-benefit analysis and value judgements.
- Community acceptance: The decision-making process and final remedy should also be acceptable to the stakeholders involved. Perceptions of risk may be larger than actual risk. Obtaining stakeholder acceptance of final remedial action is essential to the decision-making process.

Toxicogenomics in Risk Assessment

Susan L. Makris and Susan Y. Euling

CONTENTS

1 INTRODUCTION

1.1 Historical Perspective

The development and advancement of genomic technologies over the past decade has its roots in the Human Genome project that yielded a reference human genome sequence in 2000 (NRC (National Research Council), 2007a). Following this landmark event, biomolecular and informatic tools were rapidly developed to collect and analyse the global molecular response data. The potential applicability of these genomic tools to toxicology and risk assessment was readily recognized. It was anticipated that genomic information would have the potential for use in identifying and characterizing hazards, assessing individual exposures to toxicants, monitoring responses at the cellular level, characterizing mechanisms of action and predicting or characterizing individual variability in response. Ongoing efforts in the biological, medical, toxicological and regulatory communities are aimed at the organization and integration of all of the information from the many so-called -omics technologies (including genomics, proteomics, and metabolomics) to complete a picture of the genes, pathways and networks of pathways underlying regulation of the normal and perturbed states of a cell and whole organism.

The rush to utilize the new -omics technologies for broad toxicological screening is reminiscent of efforts in the 1970s to apply *in vitro* and *ex vivo* mutagenicity study data as an approach to carcinogenicity screening. Although mutagenicity data were not found to be unequivocal solitary alternatives for bioassay studies, these data are used in mode of action (MOA) assessments for carcinogenic materials and are well accepted. It is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

likely that -omics data will undergo a similar evolution in development and validation for use in human health risk assessment.

1.2 Definitions

Toxicogenomics refers to a set of technologies for assessing global molecular response after toxic agent exposure. In this chapter, the definitions used for toxicogenomics terms are consistent with the National Research Council (NRC) book entitled *Applications of Toxicogenomic Technologies to Predictive Toxicology and Risk Assessment* (NRC (National Research Council), 2007a). Genomics is the assessment of the genome, and includes technologies that assess the genome, genome sequencing and genotype analysis techniques that allow for identification of sequence variation or polymorphisms. Transcriptomics is the assessment of messenger RNA (mRNA) expression, most frequently measuring transcripts using microarrays. Proteomics is the assessment of proteins in an organism. Proteomes are complex due to the many forms of proteins (e.g. post-translational processing). Metabolomics is the assessment of low-molecular-weight (LMW) metabolic products of a biological system. Since metabolites are the most 'downstream' products of gene expression, a metabolomic profile most likely encompasses the most functional assessment of toxicity, among the -omics techniques.

Due to the near-global nature of these technologies, the generated datasets are necessarily large and complex. Consequently, methods for data analysis have been developed and continue to evolve. Bioinformatics is the application of advanced computational techniques to collect, manage and analyse quantitative biological data.

1.3 Toxicogenomics Technologies

Toxicogenomics technologies currently in use are described briefly in this section. For further details about the developing toxicogenomic technologies and associated bioinformatic tools, please refer to *Applications of Toxicogenomic Technologies to Predictive Toxicology and Risk Assessment* (NRC (National Research Council), 2007a).

Genomics technologies use genomic sequencing techniques. DNA sequencing methods have evolved rapidly since the Sanger high-throughput gene sequencing methods of the 1970s (Sanger *et al*., 1977). The new generation of automated sequencing methods includes the use of fluorescent tagging and capillary electrophoresis (Chan, 2005) and a cycle extension approach (Margulies *et al*., 2005). While new methods are being developed, the whole-genome shotgun sequencing method of Venter *et al*. (1996) is currently used the most frequently. The shotgun method breaks chromosomal DNA into fragments of ~500–1000 DNA bases that are then sequenced using automation in multiple rounds (three to seven rounds). The output sequence information from the fragments is then aligned to generate the chromosome's DNA sequence using bioinformatic analysis methods.

Sequencing of the genome allows for information about the genes that encode RNA and protein products as well as the regulatory DNA sequences. The DNA sequence of genes provides information that can be used to predict the amino acid sequences of the protein products. Comparing the predicted amino acid sequences of genes of interest across species can provide information about interspecies differences. Genomic sequencing of multiple individuals for a species can provide information about polymorphisms at a particular gene locus, giving information about intraspecies variability. Interspecies differences can potentially inform the relevance of a toxicological response in a test organism to a similar response in humans. Intraspecies information can potentially inform susceptibility to a particular toxic agent. Thus, both the interspecies and intraspecies information based on gene sequencing have the potential to be utilized in risk assessment.

Transcriptomics, or genome-wide expression profiling, provides information about gene expression at the mRNA level. Within the context of toxicogenomics, transcriptomics provides information about differentially expressed genes (DEGs) relative to the control. An understanding of the pathways perturbed by the toxic agent can be developed by performing pathway analysis on the DEG information. To date, microarrays are the most developed and utilized transciptomic technology, as well as being the most advanced regarding validation among all of the -omics technologies. The use of microarrays to study gene expression profiles from cells, tissues or organs began in 1995 (Lobenhofer *et al*., 2001). Microarrays provide a nearly global transcriptional profile of the cell, tissue or organ used to make the microarray. Microarrays are currently 'nearly global' because not all of the genes are currently annotated, for example, the rat microarrays currently allow for the simultaneous analysis of expression of ~30 000 genes.

The two most-developed types of microarrays are the complementary strand DNA (cDNA) microarray and the oligonucleotide array. The cDNA microarray is a glass slide or membrane with DNA spots from each open reading frame (ORF) from the organism of interest. These probes are used to detect cDNA: DNA synthesized in the laboratory from mature, fully spliced messenger RNA (mRNA) transcripts of the cell, tissue or organ. cDNA arrays use a radiolabelled detection system (^{32}P), which may be the most sensitive measure of gene expression

available. One cDNA microarray is commercially available from Clontech. Some issues with cDNA microarrays have resulted in a high variability of performance and so they are no longer used in toxicogenomic studies.

The second type of microarray is the oligonucleotide array, available commercially from Affymetrix, Agilent and others. Oligonucleotides (oligos) representing the whole genome are synthesized directly onto the glass slide via a number of different methods. For example, Affymetrix probes are directly synthesized onto the arrays uses photolithography. Briefly, the slide is coated with a light-sensitive chemical compound that prevents the formation of a bond between the slide and the first nucleotide of the DNA probe being created. Arrays are synthesized and attached to the slide multiple times in order to synthesize probes that are up to 25 base residues long and produce a high density of probes on a slide. Each gene is represented by ~20 overlapping probe sequences. Paired mismatch probes are also utilized to assess nonspecific hybridization. Probe design improvements have led to less variability and increased sensitivity in microarray study results. Consequently, oligo arrays are considered the 'second generation' of microarrays and are currently used in toxicogenomic studies.

To detect gene expression either a one-dye or two-dye system is employed. For instance, Affymetrix uses a one-dye method that employs an antibody detection system with horseradish peroxidase (HRP) and streptavidin conjugates. In the case of the one-dye detection system, the absolute intensity of the individual probes of the treated and control samples are measured. These values are then used to calculate the relative gene expression change between the treated and control samples. The Agilent microarray platform uses a two-dye system (cyanine 3 (Cy3) and Cy5-labelled fluorescein dyes). For the two-dye system, the scanner detects the relative intensities of the red and green labels and gives a relative measure of the gene expression change between the control and treated samples.

Microarray analysis can be used to produce genomic signatures for toxic agents or a class of agents. Genomic signatures represent a pattern of gene expression response that may be emblematic of the single toxic agent. Genomic signatures have also been developed for a mode of action (MOA) class of chemicals by defining the common pattern of gene expression across the class (described in more detail below).

Microarrays have also been designed to detect single nucleotide polymorphisms (SNPs). Polymorphism analysis can be used to understand intraspecies differences as well as for genes involved in the metabolism of toxic agents. For example, polymorphisms in transporters and xenobiotic metabolizing enzymes can be used qualitatively and quantitatively to inform risk differences in susceptibility between groups of individuals (Guerreiro *et al*., 2003; Shastry, 2006). After DEGs have been identified from a microarray study, it is usual practice to perform some type of confirmatory or validation study. Confirmatory studies often use protein expression methods, such as immunohistochemistry and/or transcript expression methods (e.g. northern blots, reverse transcription polymerase chain reaction (RT-PCR)). The RT-PCR method involves exponentially amplifying short DNA sequences within a longer double-stranded DNA molecule using a thermo-stable DNA polymerase called Taq polymerase. Recent developments in RT-PCR technologies have led to the real-time RT-PCR (qRT-PCR) method, a kinetic approach in which the reaction is observed in the early, linear response stage. qRT-PCR, the most sensitive technique for mRNA detection and quantitation, is currently the method of choice for confirming results obtained from microarray analyses and other -omics technologies. However, differences in microarray and RT-PCR findings require further study as such an outcome does not necessarily indicate that the microarray results are incorrect.

Proteomics is the study of the collection of an organism's expressed proteins, their structural status (e.g. phosphorylated/dephosphorylated), their functional states (i.e. activity specificity and activity level) and their interactions with other cellular components (e.g. protein–protein interactions) (Pandey and Mann, 2000). Since proteins are the functional products of genes, in most cases (e.g. snRNAs (small nuclear RNAs) being another functional product), carrying out the 'work' in cells, proteomics offers advantages over transcriptomics. Toxicology and consequently risk assessment are most interested in the use of differential proteomics, or differential expression of proteins after exposure to a toxic agent (relative to a control).

The proteomic technologies include mass spectrophotometry (MS), and protein and peptide separation techniques. Other resources for protein information are gene and protein sequence databases. Bioinformatics tools for integrating the proteomic information have also been developed (for instance, see Aebersold and Mann, 2003). Gel-based and shotgun proteomics are two methods that have been developed. Gel-based methods typically use electrophoresis to separate proteins. For example, the 2D sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) technique has been frequently employed as a first step to separating proteins. Following SDS-PAGE separation, protein spot selection identifies proteins using peptide digestions, MS analysis and protein databases. Shotgun proteomic methods include digestion of proteins to peptides and liquid chromatography-coupled MS (LC-MS) to analyse the peptides (Yates, 1998). Shotgun technologies have a much better ability to analyse complex mixtures of peptides compared with gel-based methods. As with all of the -omics technologies, bioinformatics tools to organize (i.e. databases) and analyse (i.e. software) proteomic data have been developed.

Another type of proteomics is proteomic profiling using matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry to generate a spectral profile of a tissue or biological fluid (Chaurand *et al*., 1999). This technique allows for the generation of a protein pattern, similar to a genomic signature (described above). A differential proteomic signature after toxic-agent exposure may be useful for understanding the MOA for a single chemical agent or class of chemical agents. Thus, such a protein profile may be very useful for application to toxicology and risk assessment. Other proteomic methods, not based on the use of MS, are also being developed but are currently not as reproducible and sensitive as MS-based methods.

One issue in collecting proteomic information is the rapid, dynamic changes in temporal and spatial patterns of protein expression. Therefore, teasing apart variability of response vs. toxic exposure-specific changes can be difficult. Other issues include identifying low abundance proteins, identifying the number of modified forms of each protein, and the formation of intermediates. Thus, proteomic-technology-based studies cannot currently rely on the data from a single well-designed study, as is the case for microarray studies.

Metabolomics and metabonomics refer to the study of LMW molecules in response to a treatment or stimulus. The two terms are distinguished in that metabolomics refers to the study of LMW molecules within cells, whereas metabonomics refers to more systemic and complex changes in tissues and body fluids (Ekins *et al*., 2005). Metabolic intermediates reflect the most 'downstream' products of genes, in many cases, and thus these techniques are considered to be the most useful, in theory. Metabolomics and metabonomics share some of the same issues with proteomics in that metabolic products change rapidly over time and across tissues, and in response to a variety of factors (e.g. time of day, diet, stress). Information about the diversity and sensitivity of the metabolites will ultimately prove very useful. However, capturing this diversity and sensitivity is a challenge to methods development.

Methods for metabolomics and metabonomics include nuclear magnetic resonance (NMR)-based and MS-based techniques. NMR has been used most frequently for analysis of biofluids (e.g. urine: Nicholson *et al*., 2002). Some scientists have applied the ^{1}H-NMR methodology to solid tissues (Wang *et al*., 2003). MS-based methods have the advantage of detecting lower-abundance proteins. Metabolomics and metabonomics can be useful to understand toxicity in a number of ways, including defining the MOA of an environmental toxicant, biomarkers for exposure, or perhaps provide dose–response information after exposure to a toxic agent. Throughout this chapter, no attempt will be made to distinguish between metabolomics and metabonomics; the term metabolomics will be used since it is more frequently used in the literature (NRC (National Research Council), 2007a).

In order to utilize data from any or all of the -omics technologies study design is critical to generating useful and relevant data for the question at hand. For use of these kinds of data in risk assessment, some of the important study design elements are the time of exposure, organ or tissue used, time of assessment and species selected. This topic will not be further discussed herein.

2 APPLICATION TO RISK ASSESSMENT

The basic risk assessment paradigm is defined by the landmark National Academies of Science document on the topic (NRC (National Research Council), 1983). Since that time, deliberation on the implementation of the risk assessment process has recognized the importance of conducting a preliminary problem formulation effort to develop an analysis plan based upon scoping information (US EPA (Environmental Protection Agency), 2003; 2006b). The process of risk assessment is described as having four components: hazard identification, dose–response assessment, exposure assessment and risk characterization. The hazard identification and dose–response assessment comprise the overall toxicological evaluation, which characterizes the sufficiency and strength of the dataset, discusses the confidence in the data, and may include some modelling of the outcomes to better characterize dose response. Exposure assessment derives estimates of actual or potential human exposure, based upon various (e.g. environmental, occupational or residential) scenarios. The risk characterization integrates the toxicology and exposure data. It is used along with other factors (e.g. social, economic and engineering) to determine what options are available and in making a regulatory decision; this is termed the risk management process.

While the definitions and terminology have remained constant since 1983, the process of risk assessment has evolved through constant scientific research, discourse and regulatory application or precedence. In many cases, the evolution of the risk assessment process has been significantly influenced by the availability of new tools and technologies, for both the collection and analysis of data. Currently, the risk assessment process is being confronted with the new transcriptomic, proteomic and metabolomic data.

Consideration of approaches for using toxicogenomic data in a risk assessment scenario continue to be explored by many organizations and scientists (Boverhof and Zacharewski, 2006; Chan and Theilade, 2005; Cunningham *et al*., 2003; Daston, 2007; Frueh *et al*., 2004; Hackett and Lesko, 2003; NRC (National Research Council), 2007a; Oberemm *et al*., 2005). The potential

value is widely recognized, and there have been a number of situations where these data have contributed, thus far in a qualitative manner, to some aspect of the risk assessment for an environmental agent. The following section addresses various topics that are integral to the risk assessment paradigm as it is currently applied, and discusses current and potential uses of toxicogenomic data within this context. **Figure 1** illustrates the chemical screening and risk assessment process, and the steps where toxicogenomic data may inform the process.

2.1 Exposure Assessment

Exposure is defined as the amount of a chemical or other agent presented by the immediate environment. Exposure can vary among individuals due to lifestyles, activities and life stage. In some cases it may be equivalent to the dose of the agent, although dose is often influenced by toxicokinetic (TK) factors (e.g. absorption, metabolism, excretion) and individual variability or susceptibility. The identification and quantification of sensitive predictive biomarkers to assess exposure has been and continues to be pursued for environmental agents. Traditional biomarkers of exposure have included such indicators as measurements of xenobiotic substances, metabolites, or specific molecular modifications, for example DNA adducts (Skipper *et al*., 1994). Conventional approaches used in the past have included gas chromatography and high-performance liquid chromatography.

Monitoring specific biomolecules to detect changes in expression at the individual or population level, through the use of toxicogenomic technologies, has been an important area of research. It is anticipated that the measurement of gene and protein expression, and the quantitative characterization of metabolites, will improve the sensitivity of exposure assessments.

Transcriptional profiling (i.e. mRNA), utilizing microarrays, can identify changes in most of the expressed genome that result from toxicant exposures. It has been suggested (NRC (National Research Council), 2007a) that transcriptomics could be utilized to identify

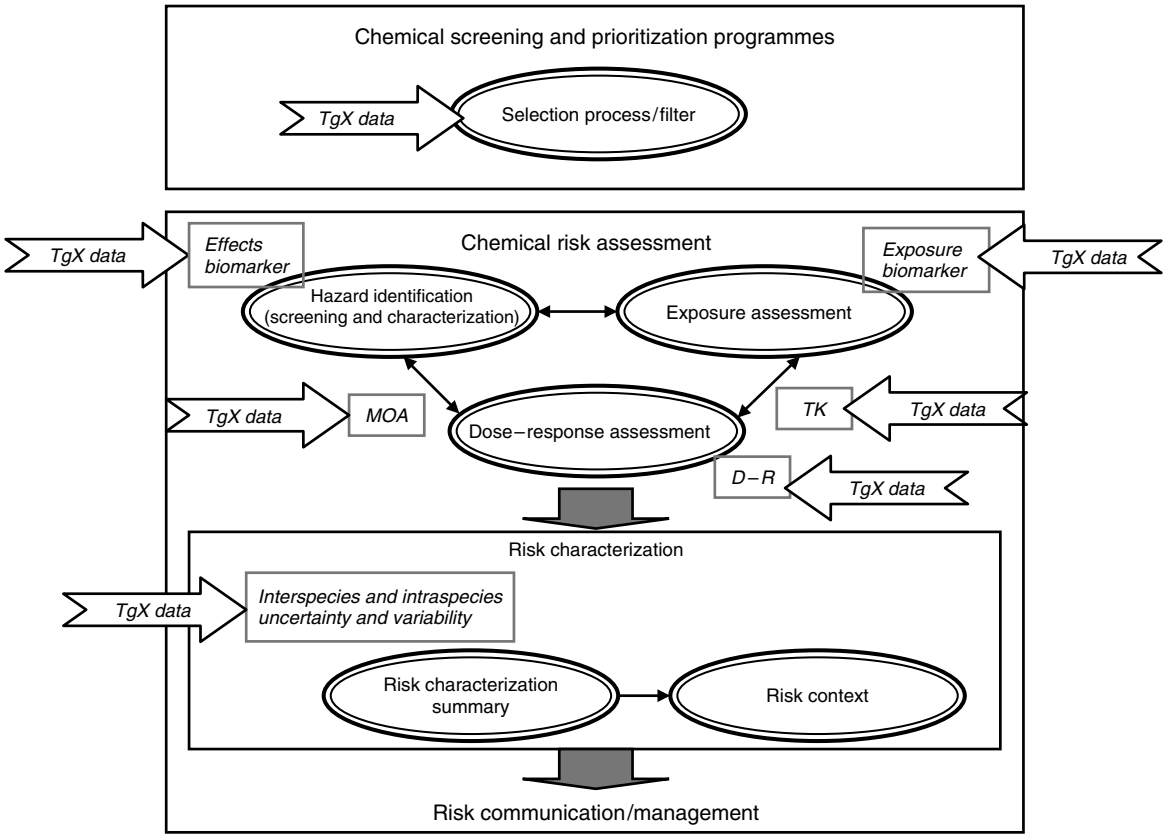

Figure 1 Chemical screening and risk assessment process: steps where toxicogenomics data may inform the process. Toxicogenomic (TgX) data, depending on the type of data and study design, have the potential to provide information to regulatory decision-making processes for chemicals. Ovals indicate the steps in screening or risk assessment. Grey boxes indicate types of information (e.g. MOA) utilized in risk assessment. Arrows with TgX data indicate places in the process where genomic data could be informative. Genomic signature data or proteomic data for oestrogen agonist chemicals, for example, could be used as a screening filter in a screening programme. Dose–response microarray data, for example, could be used in the dose–response (D–R) analysis step of risk assessment (US EPA, 2009).

the overall pattern of gene expression, rather than just focussing on changes in just a few genes, thereby generating a more specific exposure genomic signature. The specificity gained through these techniques is an important advantage of utilizing transcriptional profiling as a biomarker for exposure assessment. While these techniques are not yet sufficiently developed for the precise characterization of human exposure, their use has been demonstrated for some micro-organisms (Begley and Samson, 2004) and cultured cell lines (van Delft *et al*., 2005) for which signatures for different toxicants could be distinguished by their transcriptional profiles. Other anticipated challenges include the use of transcriptomic data to provide an actual quantitative characterization of exposure, discerning whether changes in gene expression are the result of short-term exposures or long-term/low-dose exposures, accommodating the genetic diversity of the human population as well as epigenetic variation in exposure analyses.

Proteomic techniques (such as two-dimensional polyacrylamide gel electrophoresis or 'shotgun' proteome analysis of larger numbers of proteins) enable the assessment of changes in protein expression levels and distribution profiles of modified protein forms. While this area is very promising for exposure assessment, it has not yet been determined whether proteomic data will be able to identify changes that are toxicant specific. Other identified challenges in the use of proteomics for the assessment of human exposures include (i) the selection and accessibility of tissues or biofluids (e.g. urine, bile or bronchioalveolar lavage fluid) for biomarker analysis, and (ii) the limited sensitivity for assessing protein adducts as a post-translational consequence of exposure.

Metabolomics may provide further characterization of exposures through the identification of metabolized products of environmental chemicals and endogenous metabolites. This concept relies on the fact that alterations in gene expression may affect metabolism, and thus metabolomics techniques may reveal distinct signatures of exposure. Additionally, exposure may alter endogenous metabolites in a more persistent manner than the environmental chemicals or their metabolites, thereby allowing the detection of an exposure signature through metabolomic profiling. It is anticipated that global metabolomic profiling will be a simpler technique than transcriptomic or proteomic profiling, and for that reason may lend itself more readily to high-throughput screening. Other advantages of metabolomics are that noninvasive biofluids can be used, enabling sampling of large populations as well as sampling temporally. Also, its usefulness may be enhanced by the fact that metabolism is often conserved across species, as demonstrated by Bollard *et al*. (2005) for hydrazine treatment in mice and rats. Recommendations for standardization and reporting of metabolomic analyses have been drafted through the collaborative research efforts of the Consortium for Metabonomic Toxicology (Lindon *et al*., 2005).

2.2 Hazard Screening

Currently, most applications of toxicogenomic data to risk assessment are in the area of hazard screening. Historically, many advances in toxicogenomic technology are linked to their application within the pharmaceutical industry (Boverhof and Zacharewski, 2006). In the drug discovery process, genomic methods are often used to predict the potential for *in vivo* toxicity, thus providing a basis to determine whether to continue development and testing of a candidate chemical. Further, it is recognized that toxicogenomic data can be applied in disease diagnosis and treatment; for example, in prediction of disease predisposition, early detection of disease onset, increased accuracy of prognosis following diagnosis of disease, customization of therapy to the individual and/or to the disease, and increased accuracy in monitoring disease progression or remission during therapy (Cunningham *et al*., 2003).

In the environmental chemical context, screening of agents for toxicological outcome is primarily defined by the specific organizations in order to meet the informational (and sometimes regulatory) requirements of their mandates and goals. For example, the US Environmental Protection Agency (EPA) Office of Pollution Prevention and Toxics (OPPT) and the multinational Organisation for Economic Co-operation and Development (OECD), utilize screening-level data for industrial chemicals and pollutants in the absence of more extensive toxicological data. OECD defines this programme as the Screening Information Data Set (SIDS), and the basic tenets of this programme are also accepted and applied by OPPT for High Production Volume (HPV) chemicals. The organizing premise of this screening-level dataset is to utilize high doses, reduce the number of administered doses, assign a minimal number of animals to the test, and minimize the length of the observation period and the end points evaluated. The progression of toxicological evaluation from *in silico* methods, through *in vitro* or alternative nonmammalian techniques, and on to progressively more complex mammalian studies is utilized as much as possible. This approach is also accepted in other particular contexts within the EPA, specifically for the screening of inert substances used in pesticide formulations. Conversely, for pesticide products with food-use applications or other anticipated high-exposure potential, the Office of Pesticide Programs has regulatory requirements for a rigorous battery of toxicological tests that include more apical testing in mammalian (and other) test species. However, this approach is becoming more of an exception to standard practises, as efforts are underway in the European Union to implement a new testing paradigm based upon the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) legislation (EC (European Commission), 2006). This landmark legislation is intended to ensure the adequate toxicological screening of many thousands of industrial chemicals and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

pollutants and includes a mandate to attempt to reduce the use of test animals and replace them with validated alternative testing methodologies. This screening philosophy is consistent with a National Academies of Science report on *Toxicity Testing in the 21st Century* (NRC (National Research Council), 2007b), which includes a vision and strategy to move toxicology testing to an exclusively *in vitro*-based set of assays and other predictive tools, and with a number of other ongoing research and collaborative efforts in the US such as for endocrine disruptor screening and testing (US EPA (Environmental Protection Agency), 1998; 2007a) and for developmental neurotoxicity screening (Lein *et al*., 2007).

Toxicogenomic assays can be incorporated into screening tests, to measure changes in gene, protein or metabolite expression or response at specific doses and/or time points in the study. In a screening context, such an approach may provide sufficient additional information that might refine further testing for the chemical. Thus, while toxicogenomic studies generally require the use of animal models, they may contribute to decision-making that will ultimately reduce the number of test animals used in latter steps or tiers.

At the US EPA National Center for Computational Toxicology (NCCT), a programme entitled ToxCast™ has been implemented to develop accurate predictions of *in vivo* toxic response by analysing the combined results of hundreds of *in vitro* assays for individual chemicals (Dix *et al*., 2006). This ambitious effort directly supports the National Research Council's vision and strategy in *Toxicity Testing in the 21st Century* (NRC (National Research Council), 2007b). Genomic-based assays have the potential to be more efficient and cost-effective screening assays for several types of toxicities. Phase I of the ToxCast™ assay programme includes toxicogenomic assays as part of a large suite of assays. Similar efforts in the larger scientific community are ongoing (Mattes, 2008). The first application of ToxCast™ is to support screening and prioritization of chemicals for various EPA programmes, namely the Office of Pesticide Programs (Dix *et al*., 2006). The models were designed to predict *in vivo* toxic responses for a screening application, and thus err on the side of false positives over false negatives.

Efforts to utilize genomic signatures after toxic-agent exposure have been pursued in order to develop genomic methods for screening. For example, genomic signatures were generated from microarray data from rats exposed subchronically to individual toxic chemicals that had been tested in the National Toxicology Program (NTP) two-year rodent cancer bioassay. Algorithms were developed that demonstrated the ability of the genomic signature data to predict the lung tumour incidence based on the cancer bioassay result (Thomas *et al*., 2007). This work illustrates the utility of genomic signatures as a screening tool. One outstanding issue is that the human relevance of such predictions is not known, and this information is important for use in risk assessment.

2.3 Intraspecies Variability Including Variations in Susceptibility

The variable response of humans to environmental factors is attributable in part to interindividual genetic differences, including gene polymorphisms and epigenetic modifications. The sequencing of the human genome and the rapid advancement of genetic technologies have raised expectations that genomic information will provide a greater understanding of human susceptibilities. While this information is likely to have an important impact on clinical medicine, including personalized approaches to diagnosis and treatment of disease, the information also has the potential to influence risk assessment.

Individual variations in gene expression have been investigated by a number of researchers using toxicogenomic technologies. In some cases, human genetic variability has been shown to result in differential responses to environmental exposures. One example is the differential response to cigarette smoke and its association with lung cancer, reviewed by the NRC (National Research Council), (2007a). In other situations, differential responses to environmental insult or variability in disease outcome may be related to the modification of one gene by another, such as demonstrated in a study by McKeown-Eyssen *et al*. (2004), in which individuals with rapidly metabolizing forms of NAT2 (*N*-acetyltransferase 2) and CYP2D6 (cytochrome P450 2D6) enzymes were 18 times more likely to have chemical sensitivity than individuals with normal metabolizing forms. From a public health perspective, an increased understanding of the distribution of genetic differences in the human population is needed.

Epigenetic variability in response is associated with heritable changes in gene function that are not due to a change in the nuclear DNA sequence. The well-known example of an epigenetic mechanism is DNA methylation that alters gene expression through changes in the chemical DNA structure (Jaenisch and Bird, 2003). Epigenetic consequences of environmental exposures have been reported (Anway *et al*., 2005; Sutherland and Costa, 2003; Bombail *et al*., 2004). Although there are emerging models incorporating epigenetic and nuclear genetic information (Bjornsson *et al*., 2004), more work is needed in this area. This effort is likely to include studies on the variability in gene expression, since alterations in gene expression can be attributed to epigenetic effects, in addition to mutations of the gene, its promoter or other regulatory regions.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The application of toxicogenomic data in the evaluation of genetic polymorphisms may quantitatively influence the risk assessment for a chemical, specifically in relation to interindividual variations in toxicokinetics, which in turn could potentially affect derivation of the intraspecies uncertainty factor applied in risk assessments. In typical risk assessment methodologies, a 10-fold range in sensitivity to xenobiotic exposures is assumed for the human population, and a 10-fold uncertainty factor is applied to account for this variability (US EPA (Environmental Protection Agency), 2002c). This encompasses both toxicokinetic and toxicodynamic aspects, thus allotting a factor of 3.16 for kinetic variability. For some chemical exposures, individual kinetic variability, particularly for neonates, may sometimes exceed 3.16-fold (Dorne *et al*., 2005). The use of toxicogenomic profiling to characterize susceptible life-stages has been demonstrated by Robinson *et al*. (2009). This study identified differences in toxicant-induced gene expression profiles between sensitive and resistant strains of mice that were associated with increased sensitivity to developmental toxicity (i.e. increased incidences of neural tube defects, embryo mortality and reduced foetal growth).

Uncertainties regarding the use of genetic mutations as a source of variability in human susceptibility to environmental toxicant exposure were identified by Haber *et al*. (2002). These uncertainties included (i) the relative contribution of multiple enzyme systems, (ii) the extent of enzyme induction and/or inhibition through coexposure, (iii) differences in mutation frequencies across ethnic groups, (iv) the lack of chemical-specific kinetic data for different genetic forms of the enzymes, (v) the large number of low-frequency mutations with significant effects, and (vi) the differences between *in vitro* and *in vivo* kinetic data. Additional data are needed to routinely apply integration of genetic information into physiologically based pharmacokinetic (PBPK) modelling in order to determine the impact on population variability.

SNPs and chromosome copy-number polymorphisms (CNPs) in genes important for the metabolism of environmental toxicants are sources of information on the impact of polymorphisms on enzyme function. They can potentially be useful in characterizing dose metrics for a specific subpopulation, or in determining how best to incorporate this information into probabilistic assessments that address population variability in enzyme function. For example, El-Masri *et al*. (1999) utilized such an approach for polymorphisms in glutathione transferase-1 following dichloromethane exposure.

2.4 MOA and Mechanistic Information

Genomics data can provide information about the mode and mechanism of action. In this regard, the genomics data can complement or provide discerning information to the MOA or mechanistic information based on all other *in vitro* and *in vivo* studies that have been conducted.

Some researchers have demonstrated common patterns of gene expression, or genomic signatures, for specific groups of chemicals. For example, Hamadeh *et al*. (2002) performed a microarray analysis on liver tissue from rats exposed to pharmaceuticals of different MOA classes. In this study, rats were exposed to either a pharmaceutical peroxisome proliferator (clofibrate Wyeth 14643, or gemfibrozil) or a CYP2B inducer (phenobarbital). Similar patterns of gene expression were observed after exposure to each of the three peroxisome proliferators, indicating that the genomic signature could provide a diagnostic for the common MOA. Additionally, the gene expression profile for phenobarbital exposure was not similar. In another laboratory, Naciff and Daston (2004) identified a set of genes that were expressed following exposure to oestrogenic compounds. Naciff *et al*. (2005) assessed the transcriptional profile in rat testis following administration of three oestrogen agonists (17α-ethynyl oestradiol, genistein, or bisphenol A), which bind to the oestrogen receptor (ER) with differing affinities. Fifty common genes were identified for the three oestrogen agonists, and gene expression was found to be altered in the same direction. Upon conduct of dose–response studies, an association of gene expression changes and dose was observed among these 50 common genes for each of the three oestrogen agonists. Additional important findings derived from these studies included that differences in gene expression patterns were dependent on the duration of exposure (Hamadeh *et al*., 2002), on the organ/tissue evaluated (Naciff *et al*., 2005; 2002), or on the life stage of the animal subject at exposure (Naciff *et al*., 2002; 2003).

In another example demonstrating the use of genomic data in elucidating mechanism of action for a toxicant, Tilton *et al*. (2008) identified an alternative mechanism for hepatic tumour promotion by perfluorooctanoic acid (PFOA) in rainbow trout. Using gene expression profiles, a novel mechanism was demonstrated that involved oestrogenic signalling underlying the tumour promotion activity of PFOA. Tumour promotion was not related to the function of PFOA as a peroxisome or PPARα (peroxisome proliferator-activated receptor alpha) agonist, but was phenotypically linked to oestrogenic gene signatures in trout liver.

Toxicogenomic data have also been found to be useful in assessing risks from exposures during development, and characterizing MOA. With the advances in human and rodent genome sequencing, there has been

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

an increased understanding of development at the molecular level. Comprehensive gene expression profiling can be performed in tissues at any developmental stage, enabling analysis of and insight into disruptions in normal development by toxicant exposures. Thus far, toxicogenomic studies have focussed on known teratogens, correlating gene expression changes following exposure on a specific gestation day with defined teratogenic outcomes. Examples include studies by Hard *et al*. (2005) on alteration in brain development following ethanol exposures, studies by Kultima *et al*. (2004) on valproic acid-responsive genes that might be used as biomarkers of teratogenic outcome, and studies by Naciff *et al*. (2002) on oestrogenic chemicals (described above).

2.5 Interspecies Variability and Cross-Species Extrapolation

In a majority of risk assessments conducted for environmental pollutants, studies conducted in laboratory animal species are used to predict potential risk to human health from toxicant exposures. The scientific validity of this approach is widely accepted (NRC (National Research Council), 1983). However, it is recognized that the use of animal data in human health risk assessment relies upon the assumptions that (i) toxicological response information in animals can be used to predict adverse consequences in humans, and (ii) dose–response information from an animal bioassay is relevant for predicting risk to humans at known or expected exposure levels. Often no data are available to either support or challenge these assumptions. While information may be available on mode or mechanism of action for an animal toxicant, the relevance of these data to the human MOA may be unclear.

It is recognized that with the sequencing of the human (TIHGMC (The International Human Genome Mapping Consortium), 2001), mouse (Waterson *et al*., 2002) and rat (Gibbs *et al*., 2004) genomes, and the resulting knowledge of cross-species gene and protein homologies, studies of differential gene expression in animals may contribute to a greater understanding of human disease. The rat genome project reported that nearly all human genes that are known to be associated with disease have orthologous genes in the rat genome, and that there is approximately 90% homology among the human, mouse and rat genomes (Gibbs *et al*., 2004). Nevertheless, conservation of pathways is likely to be more important in cross-species extrapolation, since the function of a specific gene and its relationship to disease outcome may not be uniformly conserved across species (Fang *et al*., 2005).

Characterizing gene changes with toxicant exposures could also be useful in selecting the most appropriate animal model for use in toxicity testing (Aardema and MacGregor, 2002). This could contribute to increased confidence in the use of animal data to predict potential human response and to reduce uncertainties in interspecies extrapolations in risk calculations. For example, Stearman *et al*. (2005) compared gene expression data from the lungs of A/J mice treated with urethane to gene expression from human adenocarcinoma cells and found exceptional concordance, suggesting common cross-species pathobiology. Similar gene expression concordance has been found between fish and human tumours (Lam *et al*., 2006). Comparative gene expression data may also be useful in exploring the relevance for human health risk assessment of toxicological responses that are quite different across animal species.

In standard risk assessment practices, interspecies variability is addressed through the application of a 10-fold uncertainty factor (US EPA (Environmental Protection Agency), 2002c), comprised of both toxicokinetic and toxicodynamic components, and the characterization of either component could be enhanced through the use of toxicogenomics data. In an example of the use of toxicogenomic data to inform the interpretation and application of toxicokinetic data in the risk assessment, El-Masri *et al*. (1996) demonstrated changes in expression of genes or proteins associated with GSH (glutathione) depletion and resynthesis following exposure to trichloroethylene and 1,1-dichloroethylene. Modelling suggested that the consideration of GSH resynthesis was important for an adequate assessment of the toxicity of these two solvents. In a similar manner, toxicogenomic data that suggest the involvement of specific proteins in the metabolic pathway could be important in refining the parameters of dosimetry modelling. Additionally, the toxicodynamic aspects of interspecies extrapolation can be enhanced through the use of transcriptomic and proteomic data. Due to a lack of information, it is often difficult to characterize and quantify toxicodynamic differences across species; however, toxicogenomic data may be useful in qualitatively and quantitatively addressing these issues, especially in cases where clear distinctions in expression profiles are observed between species.

2.6 Dose Response

Characteristic genomic profiles of associated gene expression changes can serve as biomarkers for specific toxicity end points (Aardema and MacGregor, 2002). It is anticipated that toxicogenomic data will play an increasing role in the modelling of systems biology for use in risk assessment (Andersen *et al*., 2008; Daston, 2007). Systems biology is defined as the study of all elements in a biologic system and their interrelationships in response to exogenous perturbation (Stephens and Rung, 2006). An understanding of normal biological

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

processes and compensatory mechanisms in biological systems following toxicant exposures will be needed to improve the understanding of the shape of dose–response curves at concentrations that are environmentally relevant and for adverse effects that occur at low incidences (Andersen *et al*., 2008).

Because -omics data have the potential to detect more subtle alterations at the molecular level than traditional end points collected in animal studies (Boverhof *et al*., 2004; Naciff *et al*., 2005), it is likely that these new technologies will provide greater scrutiny and insight into dose–response relationships, particularly at low doses. One difficulty in the interpretation of gene expression data over a range of doses is the ability to distinguish between homeostatic versus toxic responses. It has been proposed (Heinloth *et al*., 2004) that distinguishing toxic from nontoxic responses should take into consideration whether critical cellular systems are perturbed (e.g. stress responses, apoptosis and energy production), assessment of the magnitude of gene expression changes, and the number of genes affected as dose increases. Thus, establishing a traditional no-observed-adverse-effect level (NOAEL) may not be possible with transcriptomic data, and it may be more valid to establish a no-observed-transcriptional-effect level (NOTEL) (Lobenhofer *et al*., 2004).

Another challenge in interpreting data can result when increased dose does not just increase the magnitude of the response but also changes the response profile (i.e. affects which genes have altered expression). Such a shift in the gene expression profile at higher dose levels was observed by Sen *et al*. (2005) with dimethylarsinic acid (DMA). The nonstatic nature of gene expression data can also complicate the interpretation of dose–response relationships, as demonstrated by Boverhof *et al*. (2004), who observed time-dependent changes in hepatic gene expression in immature ovariectomized mice after ethynyl oestradiol administration.

Approaches to using microarray data in a quantitative manner in risk assessment have been developed (Yu *et al*., 2006; Thomas *et al*., 2007). Yu *et al*. (2006) utilized affected gene ontology categories as a means to quantify dose- and time-dependent effects of exposures. Thomas *et al*. (2007) developed a benchmark dose (BMD) analysis approach to identify sets of genes that were significantly altered in respiratory epithelia following acute inhalation exposure to formaldehyde. This effort demonstrated that dose–response modelling methodologies can be developed that might, with further validation, support the modelling of toxicogenomic data for chemicals with more limited *in vivo* databases. This could prove to be useful for general screening and prioritization purposes or in the future, for risk assessment. Both published approaches utilized gene ontology categorization to draw conclusions. While the use of gene ontology functional categories are useful for forming hypotheses for testing with follow up studies, some scientists consider gene ontology categories too broad to make conclusions about mechanism of action (Quackenbush, 2007).

2.7 Cumulative Risk

Cumulative risk is defined as the combined risks from aggregate exposures to multiple agents or stressors (US EPA (Environmental Protection Agency), 2003). These exposures can be accumulated over time, sources, routes or pathways. The stressors may cause the same effects or a variety of effects. When a cumulative risk assessment is conducted for multiple stressors, it may address the risks of the stressors themselves, associated health or ecological impacts one at a time, or the combined risks from some or all of the effects or impacts. This approach may need to address the potential for interactions, such as synergism or antagonism, among stressors. Considerations for cumulative risk assessment, based upon MOA or toxicological outcome, have been proposed for pesticides (US EPA (Environmental Protection Agency), 2002a) and phthalates (NRC (National Research Council), 2008). The NRC report on the cumulative assessment of phthalates cites and utilizes genomic data in the analysis of the MOA for the hazard characterization.

Typical approaches to toxicology screening and testing utilize study designs that are focussed on the effects of single chemicals. These studies, although very useful for human health risk assessment, provide no information on the potential outcomes that might result from coexposures to multiple agents. It is anticipated that gene expression data may provide a tool to help identify multisource interactions. In one example of such an application during preclinical drug development, Luyendyk *et al*. (2004) utilized toxicogenomic profiling to identify a potential pharmaceutical-induced hepatic interaction with an environmental agent (a bacterial endotoxin). Application to environmental risk assessment will certainly prove to be challenging, since coexposures are likely to be extensive, varied and poorly characterized. Utilizing toxicogenomic signatures to distinguish interactions among mixtures of toxicants, diet, pharmaceuticals, natural compounds and other environmental exposures will be a daunting task. However, the use of MOA information to define datasets and screen chemicals for similarities in gene expression may facilitate the exploration of potential pathway interactions. Such data could be utilized to test fundamental assumptions of dose or response addition that have been applied in cumulative risk assessments for environmental contaminants, for example for chemicals that activate the aryl hydrocarbon receptor (AhR) (Safe, 1990). Even for chemicals that are not structurally related, comparison of gene expression, proteomic or metabolomic profiles for individual agents could be used to identify areas in which

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

individual agents overlap, determine possible agent interactions, or suggest new mechanisms of toxicity.

The potential use of toxicogenomic data to evaluate exposures with multiple components has been recognized. There are a limited number of examples of studies that utilized microarray data to assess multicomponent exposures. Bae *et al*. (2002) evaluated and compared gene expression changes in human keratinocytes that were exposed to arsenic, *N*-methyl-*N*′-nitro-*N* nitrosoguanidine, or a mixture containing arsenic, cadmium, chromium and lead. In a study by Mahadevan *et al*. (2005), the effects of a standard reference material (SRM 1649a—particulate Urban Dust) on cultured human breast carcinoma cells (MCF-7) were assessed alone or in combination with the carcinogens benzo[a]pyrene and dibenzo[a,i]pyrene; gene expression, metabolic activation and formation of DNA adducts were evaluated. These studies demonstrated the usefulness of gene expression and DNA modification data for multicomponent exposure assessment.

3 CONSIDERATIONS REGARDING THE USE OF GENOMICS DATA IN RISK ASSESSMENT

There are a number of strengths and limitations to the current use of data from -omics technologies in risk assessment. These can be separated into issues regarding (i) the technologies/assays/measures themselves, and (ii) the tools to analyse these data (**Table 1**). Broadly speaking, -omics data technologies, including microarrays, proteomics and metabolomics, are considered powerful methods because they are nearly global in scope, as discussed above. However, the technology will eventually be truly global. A method that can assess global gene expression changes is powerful for use in risk assessment because it represents a less biased approach for identifying affected pathways, and in turn, possible modes of action, for example. All of the -omics technologies can potentially identify precursor events, mechanism of action and possibly modes of action and biomarkers of effect or exposure, depending on the experiments performed and application of interest.

3.1 Variability of Response

Limitations regarding the use of -omics technology data in risk assessment include reproducibility/variability of response, a requirement for a certain level of linkage/causation between the affected gene expression changes (e.g. at the mRNA, protein or metabolic molecule level) and the outcome of interest, as well as issues related to the cost of the 'omic' technology studies. The reproducibility of microarray study results has improved with advances in gene chip technology and the MicroArray Quality Control (MAQC) project led by the Food and Drug Administration (FDA) (described below), suggesting that interlaboratory and intra-individual variability is less of an issue when provided with the same biological sample. However, variability can be fairly high even among control samples and thus, variability and study power are issues for use of these data in risk assessment. To address the issue of variability, 'omic' studies are performed with an increased number of samples, thus increasing study power for data analysis.

3.2 Experimental Design

Linkage of gene expression changes to the outcome of interest is important for using these data in risk assessment. In the ideal, data that identify changes that are measurable at each level of biological organization (i.e. protein, gene, cellular, tissue organ, whole organism) as well as a temporal sequence of changes at each of these levels would provide strong links that likely reflect a causative chain of events. However, these data are

Table 1 Current strengths and limitation of using genomic data in risk assessment

	Strengths	Limitations
Genomic technologies	• Powerful because global • Can identify: – Precursor events – Biomarker of effect – Biomarker of exposure – Mechanism/MOA	• Reproducibility • Changes in expression (in gene, protein, pathway, etc.) may not be linked to adverse effect • Studies, particularly dose-response, are costly
Data analysis tools	• Tools available for microarray studies that can identify: – Affected processes and/or pathways – Pathway networks	• Analysis of complex and large data sets • Methods continue to evolve • Current methods use statistical significance cutoffs that may not reflect biological relevance of a gene or pathway

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

rarely available. Realistically defining the requirements for linkage of -omics changes of interest to the whole organism is an area that needs further exploration. Cost of the technologies is obviously an issue that limits widespread usage of -omics studies, but should decrease over time. Cost limits the use of a large number of samples, such as are needed in a multiple-dose microarray study.

Regarding the data analysis tools for -omics data, some strengths of microarray analysis methods are the ability to perform pathway analysis and gene network analysis allowing for the identification of affected processes, pathways and pathway networks. Some of these tools are publicly available (e.g. DAVID, *http://david.abcc.ncifcrf.gov/*, KEGG, *www.genome.jp/kegg/*, BioCarta, *www.biocarta.com/*), while others are proprietary (e.g. Ingenuity, GeneGo). However, a number of the analytical tools have been developed for screening purposes, such as in the development of pharmaceuticals. For analysing microarray data in the pharmaceutical industry, methods were developed for screening purposes. The purpose of screening is to exclude candidates with potential side effects and, thus, err on the side of false positives, with a low false-negative rate. Such analytical tools and cut-offs would not be as useful for application to risk assessment. There is a need for the development of methods that are tailored to the use of these data in risk assessment. A related issue is the difficulty and degree of training required to analyse these large and complex datasets. One solution to this issue, including methods development, is training of risk assessors in methods for analysing microarray data, and the formation of collaborations and information exchange between biologists/toxicologists, toxicogenomics experts and bioinformaticians.

3.3 Data Analysis and Training

Risk assessors need training in genomic data evaluation. For some, this will be the development of a basic understanding of the methods employed in order to understand a genomic study presented in the published literature. Other risk assessors will want to develop a higher-level understanding of the data in order to develop competency in the analysis of genomic data. In response to this need, the FDA Center for Drug Evaluation and Research (CDER) has developed successful genomic training courses for their scientists (*www.fda.gov/cder/genomics/Default.htm*). The EPA Risk Assessment Forum (RAF) implemented a series of internal EPA training sessions on toxicogenomics in 2007. The genomics training courses provided both an introduction to the potential applications of genomics for Agency managers, as well as intermediate technical training for genomic data review and analysis for scientists.

Finally, an issue not unique to -omics data is the use of statistical vs. biological gene expression cut-offs. When the biologically relevant level of change is not understood, as is often the case, the risk assessors and other scientists rely on the use of, at times arbitrary, statistical cut-offs. This may pertain to any precursor event such as a change in hormone levels. If the biological significance of an increment of change in hormone level is not fully understood at all levels of biological organization, then a statistical cut-off relative to control levels is utilized. Much discussion and debate about the increment of change considered to be adverse may occur. For the case of complex datasets such as -omics data, it may turn out that small changes in the expression of key genes (e.g. initiating events) could have an impact on the whole organism phenotype, even for cases when gene expression changes are not detectable using a statistical filter. However, in the absence of data supporting a causal connection between increments of gene expression change and the outcome, it is difficult to move towards the development and application of new analytical tools.

4 REGULATORY AGENCY GUIDANCE

4.1 FDA Guidance

Due to the voluntary submission of toxicogenomic data programme at the FDA, in support of pharmaceutical development, the FDA has taken a lead in the analysis and incorporation of these data into regulatory decision-making. The FDA has developed a guidance document for industry for the voluntary submission of pharmacogenomic data (US FDA (Food and Drug Administration), 2005). This guidance is intended to facilitate scientific progress in the field of pharmacogenomics and to facilitate the use of these data in informing regulatory decisions. It encourages voluntary submission of microarray data from exploratory studies, but does not include use of genetic or genomic techniques for the purposes of biological product characterization or quality control (e.g. cell bank characterization, bioassays). Data resulting from proteomic or metabolomic techniques are not addressed in this guidance.

FDA scientists also led an effort to bring researchers from government, industry and academia together to address issues of variability by contributing to the standardization of microarray procedures, the MAQC Consortium (Casciano and Woodcock, 2006; Frueh, 2006; Dix, *et al*., 2006; Ji and Davis, 2006; Canales *et al*., 2006; Shippy *et al*., 2006; Tong *et al*., 2006; Patterson *et al*., 2006; Shi *et al*., 2006; Guo *et al*., 2006). Since the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

MAQC is an ongoing consortium project, the preliminary effort described below is termed MAQC(I).

The goals of the MAQC(I) project were to identify sources of variability across microarray studies. The project evaluated the performance of microarray platforms, comparing cross-platform and interlaboratory performance of microarray technologies that were currently available. Seven microarray platforms were tested by three independent laboratories with five sample replicates. The working list of genes consisted of 12 091 reference genes. The MAQC(I) study demonstrated a high level of reproducibility within and between laboratories, and across the microarray platforms (Guo *et al*., 2006; Patterson *et al*., 2006; Shi *et al*., 2006). The performance of the microarray platforms was then compared to the results from three quantitative gene expression assays. The study found 'excellent correlation' between microarray results and quantitative gene expression results, although several sources were identified that may have resulted in the limited incongruence that was observed. These include a decreased sensitivity for low expression genes in the microarray platforms as compared to the gene expression technologies, and differences in probe location.

Subsequently, a toxicogenomic study in rats was conducted to examine the similarity of findings across microarray platforms (Guo *et al*., 2006). RNA samples were collected and processed following exposure of rats to three chemicals (aristolochic acid, riddelliine, or comfrey). Results from four microarray platforms demonstrated a high degree of similarity in gene expression findings.

To summarize, the MAQC(I) effort as well as that of Guo *et al*. (2006) found a high degree of reproducibility of findings between different microarray platforms that were tested at multiple locations. In addition, microarray results correlated well with RT-PCR findings. These studies provided important information leading to decreased variability in microarray data and the establishment of standardized quality control measures. Overall, the MAQC(I) project results provided a wealth of information that supports the incorporation of microarray data into risk assessments in the future.

4.2 EPA Policy on Use of Genomic Data

In response to the increasing availability and production of genomic data for chemicals regulated by the EPA, the Science Advisor and the Science Policy Council (SPC), which serves the Agency by addressing science policy issues that affect the EPA, released the Interim Policy on Genomics in 2002 (US EPA (Environmental Protection Agency), 2002b). This policy statement addressed how to use genomic data in decision-making. The policy encourages research in genomics, as it has been shown to provide information on MOA, biomarkers of effect, exposure and susceptibility. However, it currently restricts the use of these data in decision-making, stating that genomic data alone are not sufficient as a basis for regulatory decision-making. This has been interpreted to indicate that these data cannot currently be utilized as the critical effect in a chemical risk assessment. Recognizing the value of these data to risk assessment, it is stated that these data can be utilized in a weight-of-evidence (WOE) approach on a case-by-case basis in risk assessment. As of 2009, the interim policy is still in effect.

The SPC Genomics Task Force considered a number of the issues in using genomics in risk assessment and other regulatory decision-making. A white paper entitled *Potential Implications of Genomics for Regulatory and Risk Assessment Applications at EPA* (US EPA (Environmental Protection Agency), 2004a) was developed. This paper described the use of genomic information in regulatory and risk assessment at the EPA, and the implications of utilizing these data for programmes, policies and resources. Three areas to apply genomic data in risk assessment at the EPA, identified in the white paper, include (i) MOA analysis, (ii) susceptible population and life stage considerations, and (iii) mixtures assessments. Other activities to explore the use of genomic data in human health and ecological risk assessment at the EPA include a Colloquium on the Current Use and Future Needs of Genomics in Ecological and Human Health Risk Assessment (US EPA (Environmental Protection Agency), 2006a). Both of these activities recommended performing case studies as a means to develop approaches to using genomic data in risk assessment.

Efforts to develop guidance have been initiated at the EPA by the SPC. The EPA's SPC decided to first focus on the development of guidance for the acceptance and analysis of genomics data because this is a critical issue for use of these data in decision-making. A Genomics Workgroup focussed the guidance on microarray-based assays as this technology has been developed and refined to the greatest extent. The SPC developed an external review draft of *Interim Guidance for Microarray-Based Assays: Data Submission, Quality, Analysis, Management, and Training Considerations* (US EPA (Environmental Protection Agency), 2007b). This document provides recommendations regarding the data that should be considered for submission to the EPA for microarray studies, data quality, analysis, management and storage issues and considerations. However, guidance specifically for use of genomic data in EPA risk assessment has not yet been developed.

4.3 Ongoing Activities to Explore and Implement the Use of Toxicogenomic Data in Risk Assessment at the EPA

The EPA is taking a leadership role in applying -omics data to human health effects research, as evidenced by the activities described in this section. There are a number of ongoing and completed activities at the EPA to address the use of genomic data in risk assessment. These activities include guidance, risk assessments, case studies, research projects (e.g. the ToxCast™ program; collaboration in the MAQC effort), and training. There are also a number of ongoing efforts to improve toxicogenomic methods and to develop computational methods that are generating toxicological information for use in the EPA in risk assessment and/or priority setting. The EPA NCCT is developing data analysis tools and databases of *in vitro* and *in vivo* assay data to support regulatory decision-making.

There are a large number of research projects to generate transcriptomic and proteomic data on chemicals regulated by the EPA. Researchers from the EPA National Health and Environmental Effects Research Laboratory (NHEERL) have published work from a number of genomic studies on (for example) conazoles, formaldehyde, triazole fungicides and perfluoroalkyl acids (reviewed in Hamernik *et al*., 2008). A great deal of their data has been incorporated into regulatory decision-making. For example, toxicogenomic studies after exposure to DMA were utilized as part of a weight-of-evidence approach in a recent EPA risk assessment for DMA. Specifically, epidemiologic studies found an association between inorganic arsenic and urinary bladder cancer. DMA is the major metabolite excreted in humans and is known to increase the risk of bladder cancer in the rat. Sen *et al*. (2005; 2007) used genomics to assess the DMA mechanism of action between humans and rats, between *in vivo* and *in vitro* rat samples, and across toxic and nontoxic doses. DMA-induced gene expression changes were reported for the *in vivo* rat (Sen *et al*., 2005). By comparing the high and low, nontoxic, dose–response findings, their study suggested that one DMA MOA for urothelium cancer was cytotoxicity. DMA-induced gene expression in human bladder cells exhibited similarities and differences from the genes affected in rat bladder cells (Sen *et al*., 2007). Twelve pathways were found to be in common between the rat *in vivo, in vitro,* as well as the human *in vitro* studies. These pathways are involved in adhesion, cellular growth and differentiation. Genes in common between the rat *in vivo* and *in vitro* models were involved in cell cycle regulation, lipid metabolism and protein degradation. The finding of common pathways affected in rats and humans suggests that urothelial cytotoxicity and regeneration, the proposed key events in bladder tumour formation in the rat, are relevant to humans. Thus, the recent EPA assessment of DMA used the genomic data to support the human relevance of the MOA (US EPA (Environmental Protection Agency), 2006c).

Some other examples of EPA risk assessments that have evaluated and utilized genomic data are the external review draft of the IRIS (Integrated Risk Information System) Toxicological Review of dibutyl phthalate (DBP) (US EPA (Environmental Protection Agency), (2006d) and the report of the Office of Pesticide Programs (OPP) Cancer Assessment Review Committee (CARC) for acetochlor (US EPA (Environmental Protection Agency), 2004b). Both of these chemical assessments used genomic data to corroborate the MOA. In addition, a vast amount of genomic data on conazoles has been generated to investigate the modes of action for this class of pesticides (reviewed in Hamernik *et al*., 2008). In summary, genomic data have been, and continue to be, used in the weight-of-evidence evaluation to inform the MOA, human relevance, and susceptibility in risk assessment as well as in screening and prioritization programmes.

Related to the risk assessment activities, a case study to assess how to utilize genomic data in EPA risk assessment has been performed for the chemical DBP (Euling *et al*., 2007; 2008; US EPA, 2009). The DBP case study was a 'paper exercise' (i.e. no additional laboratory studies were performed). The case study focussed on the male reproductive outcomes and the qualitative application of the microarray data to risk assessment because there are no available DBP dose–response microarray studies. The DBP case study addressed the use of the genomic dataset to (i) inform multiple mechanisms and/or modes of action, and (ii) interspecies differences in MOA.

There are two previously well-established modes of action for a number of the male reproductive developmental effects occurring after *in utero* exposure to DBP: (i) a decrease in foetal testicular testosterone, mediated by effects on steroidogenesis, and (ii) a decrease in insulin-like 3 (*Insl3*) gene expression. The male rodent reproductive and developmental toxicity studies were evaluated for effects on the testes after DBP exposure. Five testes effects without an established MOA were identified. Focussing on these five testes outcomes, the genomic data were evaluated for the identification of pathways affected by DBP that could explain these end points. By evaluating the DBP genomic dataset (microarray, RT-PCR and other gene expression studies), the differentially expressed genes and the direction of effect were found to be highly consistent across studies. New analyses of a DBP microarray study were performed and affected pathways were identified that include some that are related to testosterone synthesis or *Insl*3 expression and some that are unrelated. The unrelated pathways may inform the DBP modes of action for the unexplained testes outcomes.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Interspecies differences for the steroidogenesis pathway were evaluated using three approaches. Results using all three methods found a high degree of similarity between rat and human steroidogenesis gene products. However, it is difficult to use the results to inform interspecies differences because of the difficulty in defining unequivocally a 'high' vs. 'low' degree of similarity for a given pathway.

The DBP case study draft document, provides the first systematic approach and case study example at the EPA. The approach for incorporating genomic data in risk assessment and recommendations based on the case study experience can be generalized to new risk assessments. This project also identified future research directions for integrating the genomic data evaluation within a risk assessment. One high priority research need is to perform studies to assess phenotypic linkage between the toxicogenomic results and toxicity end points of interest within a dose–response study. Specifically, one study would include a genomic assessment component (e.g. sacrifice some animals at the optimal time of assessment for use of target organs in microarray studies) and a toxicity assessment component (e.g. other animals are followed to evaluate the end points of interest). Such a study would require a large number of animals in order to identify affected *in vivo* end points at lower doses (which would occur at a low frequency). This study would be costly but beneficial to understanding the relationship between dose, genomic response and apical end-point response.

4.4 Activities of Other Organizations

A number of federal agencies (other than the FDA and EPA), nongovernmental organizations (NGOs), nonprofit organizations and industry groups have been conducting toxicogenomics studies and activities. Select examples are highlighted below. These efforts are focussed on developing standardized practices of data collection and sharing, as well as on defining and promoting research needs in the area of toxicogenomics. Additionally, the practical use of these data in multiple venues has been discussed; for example, for screening-level drug development or for human health risk assessment.

4.4.1 NIEHS Activities

The National Institute for Environmental Health Sciences (NIEHS) Division of Extramural Research and Training (DERT) issued a request for application for extramural programmes to participate in a national Toxicogenomics Research Consortium (TRC) with several goals; that is, to (i) enhance research in the broad area of environmental stress responses using microarray gene expression profiling; (ii) develop standards and practices to allow analysis of gene expression data across platforms and provide an understanding of intralaboratory and interlaboratory variation; (iii) contribute to the development of a robust relational database which combines toxicological end points with changes in gene expression profiles; and (iv) improve public health through better risk detection and earlier intervention in disease processes (NIEHS (National Institute of Environmental Health Science), 2000). The TRC was developed in 2001 and consists of six Cooperative Research Members, resource contractors and NIEHS extramural staff. This effort was followed by solicitation in Functional Proteomics in 2002 and Metabolomics Application in 2005. TRC program highlights include the conduct of ongoing standardization experiments aimed at identifying and addressing sources of technical variation in gene expression experiments across multiple technology platforms and research centres. Discourse and data sharing have been facilitated through conferences on -omics applications in the environmental health sciences (e.g. held in 2003, 2004 and 2006).

4.4.2 ILSI/HESI Activities

The International Life Sciences Institute (ILSI) Health and Environmental Sciences Institute (HESI) has been actively engaged for a number of years in the conduct of genomics studies, the analysis of genomics data and the use of these data in mechanism-based risk assessment. A standing multisector Genomics Committee was formed in 1999 to develop a collaborative scientific programme to address issues, challenges and opportunities that have emerged in the field of toxicogenomics (Pennie *et al*., 2004). The committee designed and conducted toxicogenomic studies, and analysed genomic study data. Their work was reviewed at a workshop in 2003 and resulted in a number of influential publications on the utility and conduct of DNA microarrays (Newton *et al*., 2004; Rosenzweig *et al*., 2004; Mattes, 2004); cross-laboratory analyses of gene expression changes induced by hepatotoxicants (Ulrich *et al*., 2004; Baker *et al*., 2004; Waring *et al*., 2004; Chu *et al*., 2004); the use of these data in assessing nephrotoxicity (Kramer *et al*., 2004; Amin *et al*., 2004; Thompson *et al*., 2004); and the need for qRT-PCR data (Goodsaid *et al*., 2004). Recognizing the importance of having standardized microarray data formats and public repository databases for the comparison and interpretation of these data by the scientific community, ILSI HESI has provided a publicly accessible database of the toxicogenomics work conducted from 2000 to 2004 (ILSI HESI, 2004). Additionally, ILSI HESI have continued their efforts in this area, through training courses and workshops.

4.4.3 International Activities

In 2003, the International Programme on Chemical Safety (IPCS) conducted a workshop in Berlin, which addressed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat121
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the potential use of toxicogenomic information in various stages of the risk assessment process for the protection of human health (WHO (World Health Organization), 2003). The stated objectives of this workshop were to (i) establish a scientific forum and dialogue between relevant experts including those with expertise in molecular biochemistry, genetic toxicology, epidemiology, public health, risk assessment, computational toxicology and clinical medicine; (ii) share information about scientific-level activities involving toxicogenomics including any programmes at national, regional and international levels; (iii) discuss the potential of toxicogenomics to contribute to improvements in the risk assessment process for the protection of health from environmental exposure to chemicals, for understanding the mode of action of environmental toxicants and the relevance and scope of gene–environment interactions; (iv) identify the near-term needs and necessary steps for enhancing international cooperation to contribute to improving the scientific understanding and the potential contribution of toxicogenomic research for improving chemical safety; and (v) identify and discuss any gaps in knowledge, issues and challenges that might hinder the enhancement of awareness and use of toxicogenomics for protecting human health from environmental chemical exposures (WHO (World Health Organization), 2003). Three break-out groups addressed (i) predictive models for identifying human health hazards, (ii) human exposure and susceptibility, and (iii) risk assessment. The workshop identified key information gaps, but confirmed the view that toxicogenomics had the potential to improve the specificity and range of methods used to predict chemical hazards, to identify biomarkers of exposure, and to address uncertainties in risk assessment. The need for data quality standards, mechanisms for sharing data, and development of bioinformatics and computational capabilities was emphasized.

5 RESEARCH NEEDS AND RECOMMENDATIONS

The National Academies review of *The Application of Toxicogenomic Technologies to Predictive Toxicology and Risk Assessment* summarized a number of overarching recommendations to move the science forward (NRC (National Research Council), 2007a, pp. 201–212). These are presented in their entirety below:

1. Regulatory agencies should enhance efforts to incorporate toxicogenomic data into risk assessment.
2. NIEHS should cooperate with other stakeholders in exploring the feasibility and objectives of implementing a Human Toxicogenomics Initiative dedicated to advancing toxicogenomics.
3. Develop specialized bioinformatics, statistical and computational tools and approaches to analyse toxicogenomic data.
4. Toxicogenomic technologies should be adapted and applied for the study of exposure assessment by developing signatures of exposure to individual chemicals and perhaps to chemical mixtures.
5. Upon validation and development of adequate databases, integrate toxicogenomic screening methods into relevant current and future chemical regulatory and safety programmes.
6. Use toxicogenomic information to prospectively identify, understand the mechanisms of, and characterize the extent of genetic and epigenetic influences on variations in human susceptibility to the toxic effects of chemicals, with the goal of improving the certainty about assumptions used in the regulatory processes to address population variability.
7. Steps should be taken and tools developed to continue advancing the ability of toxicogenomics to provide useful mechanistic insight.
8. Future toxicologic assessment should incorporate dose–response and time-course analyses appropriate to risk assessment.
9. Continue to use toxicogenomics to study differences in toxicant responses between animal models and humans and continue to use genotyped and genetically altered animal model strains as experimental tools to better extrapolate results from animal tests to human health.
10. Use toxicogenomics to investigate how exposure during early development conveys susceptibility to drug and chemical toxicities.
11. Use toxicogenomic approaches to test the validity of methods for estimating potential risks associated with mixtures of environmental chemicals.
12. Actions should be taken to facilitate the technical and regulatory validation of toxicogenomics.
13. Address the ethical, legal and social issues that affect the use of toxicogenomic data and the collection of data and samples needed for toxicogenomic research.
14. Develop education and training programmes relevant to toxicogenomic applications to predictive toxicology.

As described in this chapter, many efforts have already been initiated to address each of these areas. Participants include government agencies, academia, industry and various consortia. Since the relatively recent inception of this technology, progress in the use of these data for predictive toxicology and risk assessment has been extraordinary. Ongoing and future collaborations to address the overarching issues described above are needed. Since each government agency or private sector has its own specific application needs, in response to its mission and legal mandates, projects to advance the use of genomic data for specific applications are needed.

Thus, there are many community efforts that can work on validation and acceptance of toxicogenomic methods. Yet, individual groups will need to continue working on the use of toxicogenomic data in screening and risk assessment within their own context.

Dose–Response Analysis in Experimental Toxicology and Risk Assessment

Robert G. Sussman, Edward V. Sargent and Todd L. Davidson

CONTENTS

1 THE CONCEPT OF DOSE–RESPONSE

The concept of dose–response dates back to the original statement by Paracelsus: 'Poison is in everything, and nothing is without poison. The dosage makes it either a poison or a remedy'. This concept led Paracelsus to use mercury as a treatment for syphilis during the 1500s (Pachter, 1961). At low doses, mercury can be considered a 'remedy' and can effectively treat the disease. However, at high doses it is considered a 'poison', as it can be toxic to the kidney and central nervous system. This was an early use of the dose–response concept which has become one of the primary underlying principles of toxicology.

When we incorporate dose–response relationships in the risk-assessment process, we are attempting to determine the point at which the response changes from an acceptable end point to an unacceptable one (e.g. a remedy to a poison, a no-effect level to an effect level, etc.). The type of response we are looking to highlight in the risk assessment depends upon the context of the assessment and the definition of what is considered 'acceptable'. A therapeutic dose of a chemotherapeutic drug may cause severe toxicity to a cancer patient taking that drug. However, the toxic effects of the treatment are considered acceptable to the patient since it may be the only way to treat their cancer. The severe toxicity that a patient considers acceptable would not be tolerated by the pharmacist or chemical operator handling these materials in an occupational setting. They will not receive the benefit of treatment as they are disease-free, but may be subjected to the same adverse effects if exposure is significant. A less obvious example would be the direct therapeutic effect of a statin, or other lipid-modifying drug. Whereas the patient taking this drug considers

alteration of their lipid profile as acceptable, or even beneficial, alteration of a worker's lipid profile as a result of exposure to chemicals at work is considered unacceptable.

1.1 Individual Dose–Response

Individual dose–response relationships (also referred to as graded dose–response), are used to describe responses by individuals to varying amounts of chemical exposure. As the dose increases, the severity of the response increases in a continuous manner. This can be used to describe the response to a specific end point, such as an increase in liver enzymes after exposure to a solvent. As the dose increases, there is a concomitant increase in the number of damaged liver cells, resulting in progressively higher levels of liver enzymes in the blood. In addition to describing the response of a single biological end point, this terminology can be used to describe the overall response of an entire organ system. As the dose of solvent increases, the response changes from an increase in liver enzymes, to fatty infiltration of liver cells, to cirrhotic changes and eventually, to total liver failure. The concept can also be taken to the entire organism by looking at the effects on multiple organ systems. The same solvent may have central nervous system effects at low levels, liver effects at higher levels and kidney effects at even higher levels.

1.2 Population-Frequency Dose–Response

Instead of describing the effects on an individual, another way to look at dose–response relationships is to consider the number of individuals in a population that will respond with a specific end point at a given dose. This is also referred to as a quantal dose–response where an individual responds in a quantal, or 'all-or-none', manner. The population becomes divided into responders and nonresponders. As the dose increases, the number of responders generally increases as well. A quantal response is often thought of in terms of end points such as death or cancer. However, it can also be used to describe more moderate responses, such as the lowering of total cholesterol by at least 20 points. An individual whose cholesterol was reduced by 15 points would be considered a nonresponder and one whose cholesterol was reduced by 25 points would be considered a responder. The varying susceptibility to specific chemicals is a function of the biological variability within a population. It is this population-frequency or quantal dose–response that is used to define many of the parameters of toxicity we use to describe potencies of chemicals. These are the ED_{50}, LD_{50}, IC_{50} and so on that are discussed later in this chapter.

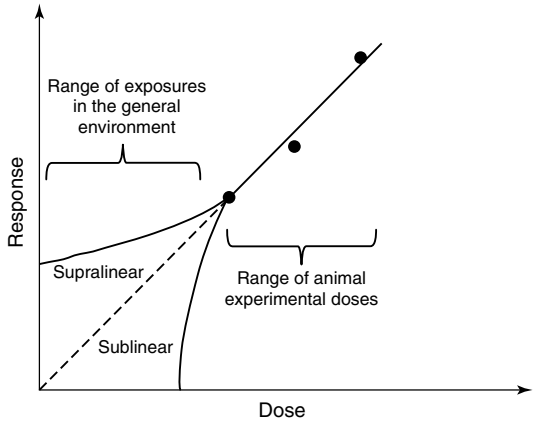

Figure 1 Hypothetical dose–response curve for an animal carcinogenicity study showing a supralinear response indicative of a background effect vs. a sublinear response indicative of a threshold effect.

1.3 Threshold Concept

If a dose–response relationship exists, we can describe that relationship graphically (**Figure 1**). Traditionally, dose is plotted on the abscissa and response on the ordinate. One of the difficulties in examining the dose–response relationship is understanding what happens when the curve approaches the origin. The data points used to plot this curve, collected from experimental animal studies, are usually orders of magnitude greater than the response rates seen in the general population. The curve may pass through the origin, but may also pass through the abscissa or ordinate. When a curve passes through the ordinate, some response is observed even at a dose equal to zero. In other words, there is a 'background' response in the population that occurs even without exposure to an exogenous chemical. However, when the curve passes through the abscissa, there is a dose below which no effect is seen. This is the concept of a threshold. The threshold is usually what we strive to identify from animal or clinical studies. As we rarely find the precise threshold dose, we use different risk-assessment methods to estimate what those thresholds may be. The assumption of the existence of a threshold implies that chemical insult at low levels will result in no damage, insufficient damage to cause a change in morphology or function, or that the body is capable of repairing itself. Noncancer or nongenotoxic end points are generally considered to be threshold responses (Renwick, 2004).

1.4 Nonthreshold Responses

The 'one-hit' theory of carcinogenesis implies that no threshold exists and that exposure to even one molecule of a chemical can result in an effect. For a nonthreshold response, an acceptable level of risk (10^{-4} or 10^{-6}) must be selected to determine the dose that may be associated with that level of risk. Extrapolation to these low response levels is usually accomplished with biologically based extrapolation models, such as those described later and supplied by the EPA (Environmental Protection Agency) (Armitage and Doll, 1961; Altshuler, 1981; Anderson, 1989; Waddell, 2006; USEPA, 2008).

2 GUIDELINES ON OPTIMUM APPROACHES TO OBTAIN DOSE–RESPONSE INFORMATION

Risk assessors do not often have the luxury of designing an appropriate study and collecting data to be used in evaluating dose–response relationships. Often the only source of data is what already exists, either in the open literature or in proprietary studies conducted by a specific sponsor. The validity of specific studies, the relevance of their end points to humans and the applicability of the routes of exposure used in the studies to risk assessment all must be evaluated. Specific criteria should be established to determine whether or not it is appropriate to use available data in a risk assessment.

2.1 Collection and Evaluation of Relevant Data

The first step in performing a risk assessment is to assemble all available data for review and evaluation. For newly developed molecules, such as pharmaceutical products in early stages of development, a limited data set may be available for review. However, an extensive data set may exist on molecules that are either structurally or mechanistically similar to the compound in question. Data collected should include those from *in vitro* as well as *in vivo* animal toxicology and toxicokinetic studies. Data from humans, whether they are from epidemiological studies, clinical trials with drug products or incidents of accidental exposures from chemical releases or poisonings, are extremely valuable. Using human studies eliminates a source of uncertainty and obviates the need to extrapolate between species. When evaluating particular studies, emphasis should be put on whether or not these were conducted according to appropriate methodology, reported by credible sources, and that the routes of exposure and mechanisms of toxicity are relevant to humans.

The criteria used to evaluate whether or not a study is valid and should be used in a risk assessment include the following:

- There should be an adequate numbers of animals and/or test subjects per dose level
- The design of the experiment should use state-of-the-art methodology
- Practices used for animal housing/husbandry should be acceptable according to the local governmental agency
- Analytical measurements should be conducted according to an accepted methodology
- Pathological and clinical observations should be according to standard accepted criteria
- Quality assurance should be evaluated according to Good Laboratory Practice (GLP)
- Interpretation of the results should use the appropriate statistical methodology
- The results, if not proprietary, should be published in a peer-reviewed journal.

2.2 Relevance to Humans

Understanding the particular toxicokinetics of a chemical, as well as its mechanism of toxicity is fundamental to deciding whether or not a particular end point is relevant to a human-risk assessment. Several adverse effects have been reported in animal studies in recent years where those adverse effects, specifically tumours, have been found to be irrelevant in humans due to species specificity of the mechanism. Some examples include $\alpha_2\mu$-globulin nephropathy in male rats and thyroid tumours in rodents.

Certain chemicals, categorized as CIGAs (chemicals inducing $\alpha_2\mu$-globulin accumulation), cause a specific renal tubule nephropathy, leading to carcinomas, in male rats only (USEPA, 1991). The mechanism of the nephropathy has been linked to a specific metabolic pathway that causes these proteins ($\alpha_2\mu$-globulin) to accumulate in the renal tubules and cause chronic irritation leading to cell proliferation and neoplasia. These compounds are not genotoxic and the phenomenon does not occur in humans. Therefore, these tumours are not relevant to humans. In the example of thyroid tumours in rodents, microsomal induction by certain chemicals leads to the rapid metabolism of the thyroid hormone, T_4 (McClain, 1995; Capen, 1997; USEPA, 1998). This results in a continued stimulation of thyroid follicular cells to produce more T_4, resulting in hyperplasia, which leads to adenomas and carcinomas. As the induction of thyroid hormone metabolism is significantly less pronounced in humans, these tumours are not relevant.

2.3 Establishing End Point of Concern

Once all the studies have been reviewed and evaluated, it is the responsibility of the risk assessor to select the end point of concern. Also known as the critical effect, the end point of concern is often one that occurs at the lowest levels of exposure and is relevant to humans. As it is the key end point that the risk assessment is attempting to prevent in exposed individuals, it is important that professional judgement be used in its selection.

3 DEFINITION OF DOSE–RESPONSE VALUES

Risk assessment entails characterizing and quantifying the potential adverse effects of hazards on humans or the environment (McClellan, 1999). This process involves hazard identification, exposure–response characterization, exposure assessment and risk characterization. While there are many aspects to performing a risk assessment, a consideration of the dose–response curve is one of the most fundamental elements. A variety of values are utilized when describing and evaluating dose–response relationships. This section will define some of these terms, as well as look at a few special situations where their definitions may change depending on the type of risk assessment being performed.

Several approaches have been and continue to be utilized in the field of risk assessment. These approaches vary, depending upon whether the effect has a threshold or is a nonthreshold response. As stated previously, most types of toxicological effects (e.g. target organ, reproductive/developmental, nongenotoxic carcinogenesis), are considered threshold responses (Sand *et al*., 2008). However, most risk assessments for genotoxic carcinogens make the assumption that no threshold exists and extrapolate to a *de minimus* risk level.

The traditional approach for risk assessment of nongenotoxic agents is to establish a point of departure (POD), typically a no observed adverse-effect level (NOAEL), and divide by uncertainty or safety factors to determine a health-based guidance value such as an acceptable daily intake (ADI) or a reference dose (RfD) (discussed in more detail later in this chapter). A NOAEL is the highest dose where no effect considered deleterious to the wellbeing of the test subject is observed. This differs from a no observed effect level (NOEL), which is the highest dose used in a study that causes no significant difference in any type of effect between the test subjects and the unexposed controls. In studies where a NOAEL is not established, a lowest observed adverse-effect level (LOAEL) can be used as a POD, but it must be extrapolated to a NOAEL. A LOAEL is generally defined as the lowest dose used in a study that results in the appearance of a significant adverse effect. This differs from a lowest observed effect level (LOEL), which is defined as the lowest dose used in a study that results in the appearance of some statistically significant mild biological effect (beneficial or deleterious). As mentioned earlier in this chapter, the POD may be different, depending on the type of risk assessment being performed. Ultimately, it depends upon what is considered 'adverse' and what is considered 'acceptable'.

Occasionally, neither a NOAEL nor a LOAEL can be identified. This is often the case when conducting an occupational-risk assessment for active pharmaceutical ingredients (APIs). In these cases, the POD may be a lowest therapeutic dose level (TDL) or a frank effect level (FEL), which can be higher than a LOAEL. Generally at the lowest TDL, the therapeutic benefits are expected to be more significant than any adverse effects. However, in certain cases (e.g. cytotoxic chemotherapeutic agents, steroid hormones), drugs may be administered at FELs. These dose levels result in overt, often clinically apparent, toxicity. For these compounds, data on dose levels lower than the FEL may not be available and the FEL must be used as the POD. Although this is not the preferred POD, extra uncertainty/safety factors can be added to account for the severity of effects and extrapolation to a NOAEL.

Since a number of disadvantages have been associated with using NOAELs in risk assessment, alternative models such as the benchmark dose (BMD) method (discussed in more detail later in this chapter) have been developed (Crump, 1984). In this method, the POD for extrapolation to a low-dose human exposure is obtained by fitting of a dose–response curve to experimental data. Several dose–response values that are used in the application of this method are defined below. The BMD is a dose calculated from the equation of the curve (see **Figure 2**), which corresponds to a predetermined change in the response (usually set at 1, 5 or 10%), generally referred to as the benchmark response (BMR). It is often represented by BMD_x, with x representing the percentage BMR. The one-sided lower 95% confidence limit of the BMD, the BMDL, can be used as the POD for determination of health-based guidance values. For a BMR of 10%, the BMDL is expressed as $BMDL_{10}$ and is considered a substitute for a NOAEL.

Another method used in risk assessment (typically for linear low-dose extrapolation) is the determination of a risk-specific dose (RSD). The RSD is a dose associated with a certain risk and is defined by the formula:

$$\text{RSD} = \text{Level of Risk (R)/Slope Factor (SF)}$$

R is predetermined and is the acceptable level of risk. For example, acceptable levels of risk for cancer vary by situation, but generally range from one extra

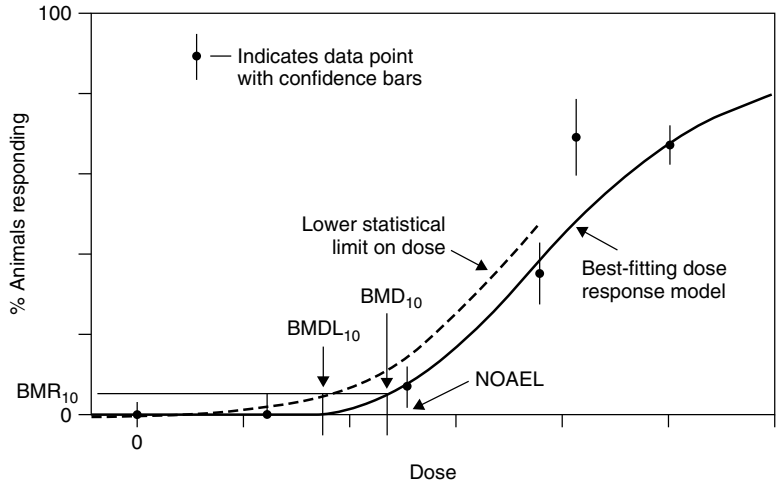

Figure 2 Graphical depiction of benchmark dose parameters.

cancer death per year per 10 000 people (10^{-4}) to one extra cancer death per million people (10^{-6}) exposed to a given contaminant over their lifetime. The SF, which is obtained from results of laboratory and/or epidemiological studies, is a numerical representation of the risk at every possible dose of a given chemical.

A number of other values are commonly used in risk assessment to describe dose–response curves. One of the most regularly used values is the median-effect dose or the ED_{50}. This dose can represent both a favourable or toxic effect of a chemical and is the dose of a chemical that causes a 50% response in a given effect. More specific ED_{50} values include the LD_{50}/LC_{50} (the dose/concentration of a substance that is lethal to 50% of the test population following a single dose), IC_{50} (the dose associated with 50% inhibition of a given biological or biochemical function), RD_{50} (exposure concentration producing a 50% respiratory rate decrease) and TD_{50} (the dose at which 50% of the population exhibit toxic effects). For drugs, the therapeutic index (TI) (also known as the therapeutic ratio) is defined as TD_{50}/ED_{50}. More specifically, it is the ratio of the median toxic dose (historically the lethal dose) to the median therapeutic dose. Drugs with a high TI have greater relative safety than drugs with a low TI. Since use of median doses in calculating the TI does not take into account the slope of the dose–response curve, another value called the margin of safety (MOS) has been used in risk assessment of drugs. The MOS is defined as TD_1/ED_{99}. It should be noted that in the risk assessment of nondrug chemicals, MOS has an alternate definition. It refers to the magnitude of the difference between an estimated exposure dose for a human population and the NOAEL or BMD from experimental animal studies. A similar term used in the risk assessment of both genotoxic carcinogens and noncarcinogenic compounds is margin of exposure (MOE). MOE refers to the ratio of a dose that causes a given effect in animals (the $BMDL_{10}$ is commonly used) to the average or predicted human exposure. The United States Environmental Protection Agency (USEPA) considers MOEs for noncarcinogens that are less than 100 to present an unacceptable risk to workers (USEPA, 2000). The European Food Safety Authority concluded that for genotoxic carcinogens, MOEs $>10\,000$ are associated with low risk and low priority for risk-management actions (EFSA, 2005).

4 FACTORS INFLUENCING DOSE–RESPONSE RELATIONSHIPS

The dose–response relationship is very complex and there are a number of modifiable (e.g. lifestyle, diet) and nonmodifiable (e.g. genetics, age) factors that can influence the shape of a dose–response curve. Several straightforward modifying factors, such as bioavailability and dosing regimen have been studied; however, this section will focus on more complex aspects that cause variability in response, such as interspecies differences, interindividual genetic variation, ecogenetics and hormesis. When all of these factors are taken into consideration, a true understanding of a dose–response curve can be attained.

Experimental dose–response data from animal studies are commonly used in risk assessments by regulatory agencies. Animal models, when properly applied, can be relevant to humans. However, differences in metabolism, pharmacokinetics and pharmacodynamics can cause vast differences in the response to any given chemical. A classic example of a species-specific metabolic difference is the hepatocarcinogenic response to the fungal toxin aflatoxin B_1. In mice, no evidence of hepatocarcinogenicity was seen at dietary doses as high as 10 000 ppb aflatoxin B_1; however, in rats, doses as low as 15 ppb caused a significant increase

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat122
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in liver tumours (Wogan *et al*., 1974). The remarkable difference between rats and mice in their susceptibility to aflatoxin B_1 has been attributed to species-specific differences in the expression of a specific form of glutathione-S-transferase that detoxifies aflatoxin B_1-8,9-epoxide, the putative ultimate carcinogen (Eaton and Gallagher, 1994). High expression of this enzyme in mice, but not rats, is responsible for resistance to the carcinogenic effects of aflatoxin B_1. In humans, a cytosolic fraction of glutathione-S-transferase isolated from liver cells was relatively ineffective at conjugating aflatoxin B_1-8,9-epoxide; glutathione-S-transferase activity towards aflatoxin B_1-8,9-epoxide was 70-, 465- and 3545-fold greater in rats, hamsters and mice, respectively, when compared to human liver cytosol preparations using microsomally generated aflatoxin B_1-8,9-epoxide (Slone *et al*., 1995). This suggests that humans may be sensitive to the carcinogenic effects of aflatoxin B_1. If dose–response data from mice or other animals resistant to the carcinogenic effects of aflatoxin B_1 were used to do a human-risk assessment, this could result in a health-based value that is too high. Therefore, it is important to understand the species-specific differences in metabolism and their effects on dose–response curves for different animals.

In addition to interspecies differences in metabolism, species-specific differences in pharmacokinetics can also affect dose–response relationships. For example, when assessing developmental toxicity, it is important to note that pharmacokinetic differences between species can affect the dose of a chemical that reaches the embryo/foetus. Factors that may differ from species to species include protein binding, half-life and maternal-conceptus pH gradient (Nau, 1986). It has also been noted that fundamental differences exist between rats, rabbits and humans in maternal-embryonic exchange during early pregnancy (Carney *et al*., 2004). It has been suggested that the varying toxic effects of thalidomide in different species may be at least partially due to pharmacokinetic (e.g. half-life, plasma-concentration–time profiles), as well as metabolic differences (Chung *et al*., 2004). Studies looking at the ability of thalidomide to cause developmental toxicity in animals treated during critical times of embryogenesis have demonstrated extreme variability in species susceptibility (Newman *et al*., 1993; TERIS, 2006). Developmental toxicity has been observed in nonhuman primates and rabbits at oral doses equal to or less than human therapeutic doses. In contrast, studies on the adverse effects of thalidomide on embryonic development in rats, mice and hamsters were generally negative or only produced positive results at higher doses. An appreciation of the species-specific pharmacokinetic factors that affect the dose–response relationship is important when conducting a human-risk assessment for thalidomide.

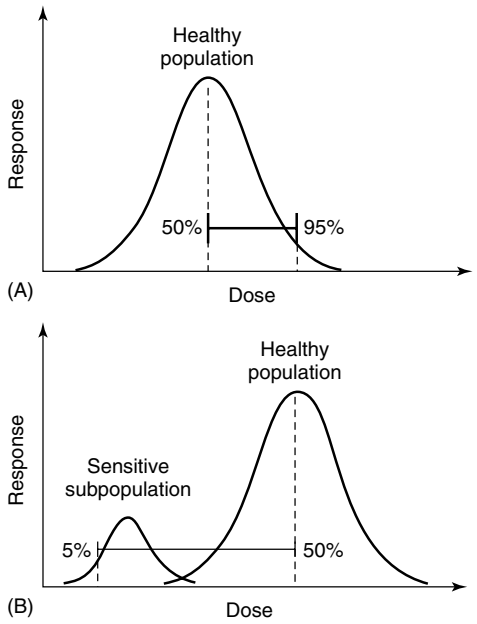

Figure 3 (a) Unimodal population showing a normal distribution for healthy individuals. (b Bimodal population showing two distinct populations, healthy individuals and a sensitive subpopulation.

Another source of variability in response is the existence of sensitive subpopulations. A healthy population can be best represented by a unimodal distribution curve demonstrating a normal distribution (**Figure 3**a). When a sensitive subpopulation is present, the population may be better represented by a bimodal distribution curve (**Figure 3**b). When a distinct sensitive subpopulation exists, the ratio of the upper tail of the most sensitive subpopulation over the mean of the healthy population provides an estimate of interindividual variability in the two populations (Naumann *et al*., 2001). It is clear from the figure that the variability in the bimodal population is greater than in the unimodal population and can be used to derive an appropriate adjustment factor in a risk assessment to account for interindividual differences.

One example of a sensitive subpopulation is the elderly. As humans age, their immune systems do not function as efficiently as younger individuals. A recent discovery in the relatively new field of immunogerontology (the study of the immune system in the elderly) was that the elderly may not develop a fever (an innate response) in response to bacterial infection and are not as efficient at producing lymphocytes as younger people. This may result in an entire subpopulation that is more susceptible to certain environmental insults than healthy individuals.

Genetic polymorphisms in critical genes can also lead to the formation of sensitive subpopulations. A genetic polymorphism exists when there are two or more clearly different phenotypes of a given gene in the population. The xeroderma pigmentosa group A

gene (XPA) is involved in nucleotide excision repair of ultraviolet-induced DNA lesions (Miller *et al*., 2006). Xeroderma pigmentosa (XP), a rare autosomal recessive disease associated with a 1000-fold increased risk of keratinocytic cancers (including basal and squamous cell carcinomas), occurs when humans have two nonfunctional copies of an XP gene. Although it is rare to lack two functional copies of the XPA gene, polymorphisms in this gene commonly exist in the human population. The GG genotype of the A23G polymorphism has been associated with a significantly increased risk of basal cell carcinoma and squamous cell carcinoma. Genetic polymorphisms in a number of other important genes, including p53, Rb and genes involved in xenobiotic metabolism/DNA repair, have been associated with an increased risk of cancer and/or other diseases.

Several regulatory agencies (e.g. EPA, Occupational Safety and Health Administration (OSHA)) are expected to promote risk-assessment procedures that protect sensitive subpopulations or sensitive individuals. As a result, the relatively new field of ecogenetics is becoming increasingly important in assessing dose–response relationships, and is likely to play a critical role in future risk-assessment procedures. Ecogenetics is the study of how genetics alterations may represent risk factors for environmentally influenced health effects associated with exposure to toxic chemicals (Costa, 2000).

Another controversial phenomenon affecting dose–response relationships is hormesis. Hormesis is most commonly described as a dose–response relationship in which there is biological activation at low doses and an inhibition at high doses, or vice versa (Calabrese, 2002). This results in a U-, J- or inverted U-shaped dose–response curve. Under this theory, many chemicals have demonstrated beneficial, rather than harmful effects at low doses. At these low doses, the initial response may be described as an adaptive response to help protect the organism and preserve homoeostasis. A number of agents have been shown to display hormetic dose–response curves, including ionizing radiation, alcohol and essential nutrients. For example, chronic low doses of ionizing radiation are thought to stimulate cellular repair mechanisms, rather than cause DNA damage. Similar effects have also been observed with other nongenotoxic carcinogenic agents such as phenobarbital, dichlorodiphenyltrichloroethane (DDT) and ethanol (Fukushima *et al*., 2005). A better mechanistic understanding of hormesis is important since current risk-assessment models do not take into account the possibility that low doses of a chemical may be beneficial. How and if hormesis will be considered in future risk-assessment models remains to be seen.

5 DOSE–RESPONSE MODELLING IN RISK ASSESSMENT

As is stated earlier in this chapter, human-effects data or human-exposure measurements are lacking for many chemical substances. Therefore, risk assessments for many xenobiotic chemicals often use data from chronic animal bioassays. The typical chronic bioassay involves a two-year exposure of rodents to several dose levels of the test article. At least one of the dose levels is at or near a maximum tolerated dose. The primary end point of focus in the chronic bioassay is cancer, although all chronic toxic end points are examined. The ultimate goal of the study is to use it in a risk assessment to estimate human risk at very low, environmentally relevant doses. The estimation of human risk requires two extrapolations: one from animals to humans and one from high experimental doses to low environmentally relevant doses. The major issue for low-dose extrapolation is determining the shape of the dose–response curve below the experimental dose range. While linear extrapolations are most common, arguments have been made for the existence of both sublinear and supralinear dose–response (see **Figure 1**).

Low-dose extrapolation models can be classified as either dichotomous or timed-response models (Altshuler, 1981). In a dichotomous response, the outcome of the animal study is determined as the number of responders and nonresponders. Timed-response (also known as time-to-occurrence) refers to the measurement of the experimental life of the animal which is impacted by the occurrence of some chronic toxicity (i.e. cancer). The best-known dichotomous models are the log probit, the multi-hit and the multistage or linear multistage, whereas the best known timed-response models are the log-normal and multistage.

5.1 Linear Multistage Model

The multistage model was first proposed as a time-to-occurrence model by Armitage and Doll (1961) to explain epidemiological data showing tumour incidence rates increasing with time. It has been adapted for use with dichotomous or quantal data. The original model is based on six assumptions: (i) a tumour develops out of a single transformed cell, (ii) time (w) is required for the transformed cell to grow into an observable tumour, and no response is observed until time (t) is greater than time delay (w), (iii) a target cell goes through a number of discrete stages (k) in its progression to becoming cancerous, (iv) the timing of the discrete changes called transitions is governed by transition rates which do not change with time, (v) background response is governed by spontaneous transition rates and (vi) the number of dose dependent transitions (m) may be less

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat122
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

than the number of transitions (k). The resulting model is expressed as a Weibull distribution:

$$-\log[1 - P(t; d)] = ad^n(t - w)^k \quad (1)$$

where $-\log[1 - P(t;d)]$ is the cumulative hazard or incidence, a is the constant of proportionality and cumulative incidence varies as the nth power of dose (d).

Crump and Howe (1984) extended the Armitage–Doll model by incorporating an assumption that the transition rate at which a cell goes through each stage is linearly related to the dose rate:

$$\gamma_{i=}\alpha_i + \beta_i d \quad (2)$$

where d is the dose rate of a continuously applied carcinogen, α_i is the background transition rate in the absence of dose and β_i is the transition rate per unit dose. The mathematical form of the linearized multistage model is:

$$P(d) = 1 - exp(-q_0 - q_1 d\_ \ldots .q_k d^k) \quad (3)$$

where q_1 is the linear term that is equal to or greater than zero, d is the lifetime average daily dose of carcinogen in mg kg $^{-1}$ day^{-1}, $P(d)$ is the lifetime probability of a cancer occurring from dose (d) and q_0 to q_k are non-negative parameters estimated from fitting the model to experimental data. Variables needed to run the linearized multistage model include dose, number of animals with a specific tumour and the number animals at risk for that specific tumour.

Due to the uncertainty in low-dose extrapolation, the upper 95% confidence limit of q_1 is used by regulatory agencies when estimating cancer risks. This new term $q_1{}^*$ is referred to as the unit cancer potency estimate and is used in the following equation to estimate risk:

$$\text{Risk} = q_1{}^*(\text{mg kg}^{-1}\text{day}^{-1})^{-1} \times d(\text{mg kg}^{-1}\text{day}^{-1}) \quad (4)$$

5.2 NOEL/LOEL Approach

Current risk assessment assumes that a threshold exists for most toxic effects other than genotoxic carcinogenicity. The traditional approach to define this threshold is to identify a NOEL or LOEL. These effect levels may be established based on statistically significant responses at the LOEL or by evidence of a continuum of response with increasing dose. LOELs are often used in conjunction with an uncertainty factor as a surrogate value for a NOEL in risk assessments (Sargent and Kirk, 1988; Naumann and Weideman, 1995). When pharmacologic effects are evaluated in conjunction with toxicologic effects, it becomes important to distinguish NOAELs and LOAELs from NOELs and LOELs. The NOEL/LOEL approach has been widely used in establishing RfDs, reference concentrations (RfCs), ADIs and occupational exposure limits (OELs) such as threshold limit values (TLVs) (ACGIH, 2008). The majority of these regulatory values have been typically derived by determining a POD based on the dose–response from the most sensitive end point(s) relative to humans.

5.3 Benchmark Dose

Since NOELs/LOELs are based on identifying statistically significant responses at specific doses or by identifying a dose-dependent response continuum, their determination is highly dependent on dose selection in the toxicity study. In addition, estimation of a NOEL or LOEL often does not explicitly utilize the entire dose–response curve and provides no extrapolation to lower risks at lower doses.

Therefore, the BMD approach was developed as an alternative to the NOEL/LOEL approach (Crump, 1984; Crump, 1995). It has gained popularity over the past 20 years, mostly in the United States, where it has been used in noncancer risk assessment to establish RfDs and OELs. The BMD approach has certain advantages over the NOEL/LOEL approach in that it is more quantitative, involves modelling the dose–response curve within the range of observable data and is not restricted to the experimental doses used in a particular study. It is not as simple as the NOEL/LOEL approach as it requires fitting a curve to a dose–response dataset using a computer model (see **Figure 2**). Also, like the NOEL/LOEL approach, a combination of end points may need to be considered in order to complete a risk assessment. The BMD is defined as an exposure due to a dose of a substance associated with a specified level of BMR, generally in the range of 1–10%, of a health effect; or the dose associated with a specified measure or change of a biological effect (CalEPA, 2004; USEPA, 2008) (see **Figure 1**). The BMD is most often based on the 95th percentile lower bound of the effective dose (LED), rather than the model's best estimate of the ED.

Guidance and software (BMDS) for deriving BMD values for use in risk assessment have been made available free of charge through the USEPA National Center for Environmental Assessment (NCEA) (USEPA, 2008). In conducting a risk assessment using a BMD approach, the usual hazard characterization is completed and end points for dose–response are selected. Generally graded monotonic responses as a function of dose and a significant dose-related trend are most useful in a BMD analysis. In addition to continuous responses, end-point data may also be quantal or dichotomous where the response

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat122
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is reported as present or absent. In either case, the latest version of the BMDS software contains different mathematical models for fitting dichotomous (gamma, Hill, logistic, multistage, probit, log-probit and Weibull) as well as continuous (linear, polynomial, power, Hill and exponential) dose–response data.

5.4 Categorical Regression

Another alternative method to the NOEL/LOEL approach for dose–response analysis of noncancer end points is categorical regression (Hertzberg and Miller, 1985; Hertzberg, 1991; Hertzberg and Dourson, 1993). Categorical regression is a metanalytical technique whereby data on how both the incidence of response and the severity of response changes as a function of dose. In this approach, severity categories are assigned to observed effects seen in a toxicity study. These categories are based on the overall toxic impact to an exposed individual. The main advantage of categorical regression is that the risk assessor is able to categorize all available data from multiple studies and is able to order those categories based on the severity of the toxic effect. A categorical regression can be run on a single end point from a single study using a generalized linear model, or it can be run on the results of different studies, each identifying a different dose–response categorical level. The different dose–response categories, including NOELs, LOELs, NOAELs, LOAELs and FELs can all be analysed and displayed as a single regression.

Evaluations using categorical regression have been conducted with a number of different chemicals (Guth *et al*., 1991; Rao *et al*., 1993). Categorical regression was used by Dourson *et al*. (1997) to evaluate risks above an RfD established by the USEPA for aldicarb. The analysis demonstrated that the combined risks of adverse effects or frank effects at 10 times the RfD are either 0.1 or 0.008% when whole-blood and red-blood-cell cholinesterase inhibition are considered as adverse effects, respectively, indicating a potential 12-fold difference in the risk estimate.

6 ISSUES WITH COLLECTION AND USE OF DOSE–RESPONSE DATA

Knowledge of dose–response relationships is not just an exercise in determining the extent of toxicity. Perhaps more important is the identification of safe and effective dosing for clinical treatments such as drug and radiation therapies. For drugs, dose–response information is needed to identify a starting dose, an appropriate means of dose adjustment, and the definition of a dose that provides the maximum benefit, while producing the least amount of unacceptable side effects (ICH, 1994). In order to select a starting dose for drug therapy, the shape of the dose–response curves for both desirable and undesirable effects must be understood. Choice of a starting dose must take into consideration interindividual differences in pharmacokinetics and pharmacodynamics, such as those arising from nonlinear kinetics, genetic polymorphism or pharmacokinetic drug–drug interactions. Utilizing dose–response data, dose adjustments can factor pharmacokinetics differences due to age, gender, race, other diseases (i.e. renal failure), diet, concurrent therapies or individual characteristics, such as body weight (Silverman *et al*., 1999).

For some drugs, safe and effective use cannot be monitored by dose–response data, but rather are followed by concentration–response information. Concentration –response data is particularly useful when pharmacokinetic differences due to diseases, like renal failure, exist or when the effects of altered pharmacokinetics of differing formulations (i.e. slow-release formulations) are assessed. In this case the concentration–response data can be better translated into dose–response information.

Dose–response data for many drugs are obtained using a dose-titration clinical study design. As a result, the tendency in interpretation of this dose–response data is to select as a recommended dose, the highest dose tested that was tolerated reasonable well. Historically, this has led to the selection of doses in excess of what was actually needed, resulting in an increased incidence of adverse effects. As an example, the initial doses of zidovudine used for the treatment of AIDS were based on the results of high-dose studies without adequate knowledge of the dose–response. When the dose–response was better characterized, it was determined that lower doses were as effective and far better tolerated in patients (ICH, 1994).

The frequency and timing of dosing also has an impact on the amount of drug administered. In a single, long dose interval, the dose–response relationships at peak and trough blood concentrations must be considered. If the dose interval is excessively long relative to the pharmacokinetic half-life of the drug, there may be a pharmacodynamic need to administer the dose at more frequent intervals.

7 APPLIED DOSE–RESPONSE IN HAZARD EVALUATION AND RISK ASSESSMENT

7.1 Establishing Acceptable Risk Values

As mentioned earlier in this chapter, the acceptability of risk is partially dependent upon the benefit being received by an individual. A patient taking a chemotherapeutic

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat122
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

agent will have a higher tolerance for the risk of adverse effects from the drug than the worker (pharmacist or chemical operator) potentially exposed to that drug occupationally. The benefit to the patient is greater than to the worker. However, although the worker does not get the benefit of treatment for a disease, they are being compensated for performing their work and should be aware of the potential hazards of handling APIs. Extending this analogy one step further, an individual in the community where the manufacturing facility is located may be exposed to the pharmaceutical product in their drinking water or air. Individuals in the community have an expectation of contaminant-free air and water, and have less benefit from the potential exposure to the chemical. As a result, the generally accepted risk for community exposure scenarios is one in 1 million (10^{-6}), whereas acceptable risk for a workplace exposure is usually one in ten thousand (10^{-4}).

7.2 Establishing Acceptable Daily Intakes

One of the ultimate purposes of understanding the dose–response relationships discussed in this chapter to determine exposures that will be considered 'acceptable' to a given population of individuals. These acceptable levels or ADIs are considered the amount of a material that individuals may be safely ingest, inhale or otherwise be exposed to every day for an average lifetime. Applications of this type of risk assessment vary depending upon the type and use of the material being handled, as well as the risk–benefit profile of the group of individuals potentially exposed. Some of the ultimate uses of these assessments are enumerated below.

7.3 Product Contamination Limits

Unfortunately, it is virtually impossible to provide products for commercial use that are 100% pure and unadulterated. As analytical techniques improve, the ability to detect impurities in products also increases. Consequently, it becomes necessary to set limits on the levels of these contaminants that are safe when found in these products.

Food products, even organic ones, can be contaminated by various types of materials. These can be naturally occurring substances, direct food additives (such as food colourings or preservatives), indirect food additives (such as leachates from packaging materials) or contaminants from food processing. They can also include residuals of pesticides used to protect agricultural products from pests or antibiotics, or other drug products used to protect the health of animals used for food. The exposure of these contaminants to the general population is calculated as an estimated daily intake (EDI). When the EDI is less than the ADI, the product is considered safe.

The manufacture of pharmaceutical molecules is often comprised of multiple synthetic chemical reactions. Residual amounts of solvents or other impurities from earlier synthetic steps may be present even after the final purification step of the drug substance. The manufacturer, in filing applications for drug approval with the FDA, must set specifications on the amounts of each impurity that will exist in the final product. The rationale for these impurity and solvent-residue specifications are supported by risk assessments derived from analysis of the dose–response relationships.

Another application of product contamination assessment is used to answer the question, 'How clean is clean?' After using a specific piece of equipment to manufacture one chemical, how much residue is permitted to remain, and potentially be incorporated into the next batch of product run on the same equipment. The FDA may require dedicated equipment for chemicals with severe adverse effects profiles (cytotoxic drugs or penicillins) as they believe that no amount of residue of these compounds may be incorporated into a subsequent batch of drug product.

7.4 Occupational and Environmental Risk Values

Similar approaches can be used to establish safe limits of exposure to environmental contaminants that may occur as a result of indirect, unintentional exposure to air, water or contact surfaces. Some of these limits are described below along with the differences in exposure scenario and acceptability of risk.

For example, workers are potentially exposed to chemical compounds they may be manufacturing directly (solvents, reagents, pharmaceuticals, etc.) or using as a tool to perform some function of their job (cleaning products, paints, finishing materials, etc.). By evaluating the dose–response relationships of these substances and applying risk-assessment principles, limits can be developed to protect workers from adverse effects that may be associated with exposure to these materials. If the concern is exposure by inhalation, safe airborne limits or OELs, can be derived. OELs are defined as levels of exposure to an airborne contaminant that are considered safe to nearly all workers. Some subpopulation of workers may exist, due to individual susceptibility, which may be adversely affected at concentrations at or below the OEL. OELs are developed by selecting a NOAEL (or LOAEL if no NOAEL is available) and applying safety and uncertainty factors to develop an acceptable concentration of the contaminant in the air (Sargent and Kirk, 1988; Galer *et al.*, 1992).

Just as limits for worker exposures can be evaluated from existing dose–response data, limits of contaminants in the ambient air can be derived to protect the general public. The EPA has established National Ambient Air Quality Standards (NAAQS) for various atmospheric pollutants such as SO_X and NO_X.

In addition to limits for acceptable levels of contaminants encountered under routine conditions, NIOSH has established short-term limits that can be tolerated during emergency situations (NIOSH, 1994). These conditions are considered immediately dangerous to life and health (IDLH) and are defined as situations 'that pose a threat of exposure to airborne contaminants when that exposure is likely to cause death or immediate or delayed permanent adverse health effects or prevent escape from such an environment'. The IDLH is established by NIOSH to 'ensure that the worker can escape from a given contaminated environment in the event of failure of the respiratory protection equipment'.

The AIHA has developed a series of similar limits known as Emergency Response Planning Guideline (ERPG) values (ERPG-Committee, 2008). They are intended to provide estimates of concentration ranges where one reasonably might anticipate observing adverse effects as described in the definitions for ERPG-1, ERPG-2 and ERPG-3 as a consequence of exposure to the specific substance.

- The ERPG-1 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to one hour without experiencing other than mild, transient adverse health effects or perceiving a clearly defined, objectionable odour.
- The ERPG-2 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to one hour without experiencing or developing irreversible or other serious health effects or symptoms which could impair an individual's ability to take protective action.
- The ERPG-3 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to one hour without experiencing or developing life-threatening health effects.

Airborne limits are not the only concern for occupational or environmental risk values. Contamination of surfaces with chemical substances that may be absorbed through the skin in toxicologically significant amounts may be a concern to workers. Workers may be exposed to more than just airborne contaminants, however. Liquids remaining on unclean surfaces or airborne dusts settling on workplace surfaces can potentially be absorbed when a worker subsequently comes into contact with a contaminated surface. Developing acceptable surface limits (ASLs) depends upon additional data that may not have been used to calculate airborne limits. The ability of a chemical to penetrate the skin and exert its toxic effect will be determined by another set of chemical and toxicological properties, such as lipophilicity, molecular weight, percutaneous absorption data and projected surface-contact scenario.

Highly specialized exposure situations call for specific risk assessments and limits set according to those situations. Spacecraft Maximum Allowable Concentrations (SMACs) are intended to provide guidance on chemical exposures during normal operations of spacecraft as well as emergency situations (NASA, 1999). Short-term SMACs refer to concentrations of airborne substances (such as a gas, vapour or aerosol) that will not compromise the performance of specific tasks by astronauts during emergency conditions or cause serious or permanent toxic effects. Such exposures might cause reversible effects, such as mild skin or eye irritation, but they are not expected to impair judgement or interfere with proper responses to emergencies. Long-term SMACs are intended to avoid adverse health effects (either immediate or delayed) and to prevent decremental change in crew performance under continuous exposure to chemicals in the closed environment of the space station for as long as 180 days.

Similar limits have been developed for submarines (National-Research-Council, 2008). When submerged, a submarine is an enclosed and isolated environment. Its crew is potentially exposed to air contaminants in this environment 24 hours a day. Unlike workers in a typical occupational environment, submariners do not leave their work environment at the end of their shift. To protect their health, the US Navy has developed one hour and 24 hour emergency exposure guidance levels (EEGLs) and 90 day continuous exposure guidance levels (CEGLs) for a number of chemical contaminants.

Finally, environmental risk values can also be set for the contaminants in our water supply. The process for setting a safe drinking-water limit is similar to setting a safe airborne limit. The major difference between the two risk assessments is the exposure scenario. Once an ADI or RfD has been determined, the limit in the drinking water can be calculated using the default assumption of 2 l of water being ingested each day. The risk assessment can be refined by considering other sources of exposure, such as dermal absorption while swimming, bathing or showering, and inhalation of high vapour pressure compounds in the shower.

Hormesis and Risk Assessment

Edward J. Calabrese and Paolo F. Ricci

CONTENTS

1 INTRODUCTION

The hormetic dose–response model has generated considerable interest within the fields of toxicology and risk assessment (Kaiser, 2003; Renner, 2004; Calabrese and Baldwin, 2003a). Considerable efforts over the past 15 years have revealed that hormesis commonly occurs, is reproducible, has distinct quantitative features (**Figure 1**) and has a sound mechanistic foundation (Calabrese, 2005). In addition, in fair, large-scale head-to-head comparisons with the threshold dose–response model with environmental and pharmacological agents, the hormetic dose–response model was very effective in estimating below-threshold responses, whereas the threshold model performed in a consistently poor fashion (Calabrese and Baldwin, 2003c; 2001; Calabrese *et al.*, 2006). These findings raised serious questions about the scientific foundations of the threshold model and especially its capacity to offer regulatory agencies and the general public reliable toxicological predictions in the low-dose zone, the principal area of public health concern given the nature of human exposures. Despite these serious limitations of the threshold model to predict low-dose responses and the inability to validate predictions of linear-at-low-dose models that are used in genotoxic carcinogen risk assessment, these models have continued to be consistently used by federal and state regulatory agencies in the USA and all other countries. Given the serious failings of these risk assessment methodologies, and the strong performance of the hormetic dose–response model accurately to predict low-dose responses and to be validated, it is important to assess how the hormetic dose–response model may affect the risk assessment process.

2 HAZARD ASSESSMENT

2.1 Animal Model

Animal models have historically been selected for use in the chronic bioassay due to their low susceptibility to infectious disease, size, ease of handling, relatively

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

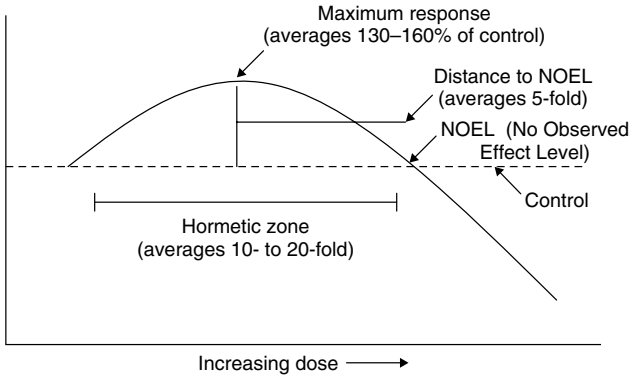

Figure 1 Dose–response curve depicting the quantitative features of hormesis.

short lifespan, fecundity, capacity to develop diseases of interest and to have a low background disease incidence in the control group. Having a high background disease incidence that is highly variable has typically been viewed as an important issue in the hazard assessment process. This issue could make it difficult to distinguish a treatment-related effect with a relatively small sample size from the control group, thus the advantage of a consistently low background disease incidence in the control.

It is not possible to assess hormetic hypotheses with animal models with very low or negligible disease incidences. In other words, it is not usually possible to practically assess whether a normally very low disease incidence may have been diminished further by the treatment, that is, demonstrating hormesis. A consideration of hormesis in animal model selection creates a conflict with traditional hazard assessment criteria that use animal models with a low background disease incidence.

A question is: is there an animal model disease-incidence optimum that could achieve an ideal compromise between being able to detect a treatment-related effect in the 'above' threshold zone (i.e. adverse treatment effect), and a treatment-related effect in the 'below' threshold zone (i.e. the hormetic effect which could be beneficial, harmful or of indeterminate medical or public-health consequence)? The answer may represent a practical balancing of research interests across a wide range of end points. To assess hormetic end points it would be of value to have a background disease incidence in the approximate range of 6–12%. A background disease incidence of less than about 6% would substantially increase treatment sample size needed to detect hormesis. Similarly, if the background disease incidence exceeded 12%, it would notably impact the sample size needed to detect a treatment effect occurring above the threshold dosage. Thus, there is a control response optimum that affects the capacity to detect below and above threshold responses. Once the hormetic concern becomes a study design priority it is necessary to base sample size calculations on balancing the goals of assessing hormetic (i.e. below threshold) and above-threshold effects. In general, there will be background disease incidence variation across end points of interest that may range from approximately 0% to greater than 20%. A key challenge for investigators is finding the optimal design for their intended purposes.

There is essentially little-to-negligible opportunity to assess disease-related hormesis hypotheses in the case of subacute toxicity studies of 13 weeks duration in which young adults are employed. An evaluation of many National Toxicology Program (NTP) subacute investigations by Calabrese and Baldwin (2003b) revealed that background disease incidences in these relatively young adults is too low to study disease-based questions related to hormesis. However, this study assessed the rate of body weight gain within a hormetic context. Other end points could be introduced if the goal was to assess hormesis within a shorter-term study. For example, numerous tumour promotion studies have been published using a single exposure protocol in which the tumour was induced within weeks to several months (Calabrese and Blain, 1999). Thus, in the case of NTP studies, hormetic hypotheses could be taken into account in the subacute and chronic bioassays but this requires proper planning.

2.2 Study Design

To study hormetic hypotheses it is necessary to reliably estimate the threshold response for the end points of interest. Since each end point would have its own threshold, the investigator needs to prioritize the end point(s) of interest or to have a sufficiently comprehensive study design for assessing multiple end points, each with a possibly different threshold. The threshold could be estimated via the traditional use of range finding tests, which identify responses of the biological model to a broad range of doses. Such an investigation provides data to guide and refine the dosing scheme for the subsequent experiment(s) to estimate the lowest dose (lowest observed adverse effect level—LOAEL) causing toxicity and an estimated threshold dose. Once the threshold and LOAEL have been estimated/determined it is possible to assess the broader dose–response continuum by explicitly including hormesis considerations into the study design.

An evaluation of more than 8000 dose responses demonstrating hormesis (Calabrese and Blain, 2005) indicates that about 80% of the examples have a hormetic stimulatory width within 1/100 of the threshold response. That is, if the threshold dose were $100\,mg\,kg^{-1}$, the hormetic zone for the strong majority of cases would be within $1\,mg\,kg^{-1}$ to less than $100\,mg\,kg^{-1}$. In general, the maximum stimulatory response has been within about

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat123
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1/5 to 1/10 of the threshold dose. In about 2% of the cases, the width of the stimulatory zone exceeded 1000-fold. Nonetheless, even in these cases the onset of the stimulatory response is very close to the threshold. Since one does not initially know what the width of the stimulatory zone may be, it reasonable to assume it could approach 1/100 of the threshold dose. Using half-log dose spacing would employ four doses (1/3, 1/10, 1/33 and 1/100 of the threshold dose) below the threshold dose. While more doses could be used, this range of four doses represents an appropriate coverage of the most likely stimulatory zone. The same study should also include a dose that is expected to approximate the threshold and at least two higher doses that assure the description of the traditional toxicological dose–response relationship. Thus, at a minimum, assessment of hormetic hypotheses would require a control group and seven treatment groups. Depending on the data obtained from this experiment, it may be necessary to alter the dose selection in a subsequent experiment.

2.3 Sample Size

Since hormetic stimulatory responses are expected to be modest, even at their maximum response, they can be difficult to distinguish from background. Thus, statistical power calculations should provide the sample sizes needed to detect statistically significant differences. This suggests that that the study designs may be unequal with respect to the number of subjects used in the treatments. For example, increasing the sample size (n) for treatments in the presumed hormetic zone at the expense of those treatments above the threshold may be an appropriate strategy.

2.4 Temporal Measures (Repeat Sampling)

Because hormesis represents an overcompensation to a disruption in homeostasis, it is best reflected in a dose–time–response relationship. This has been demonstrated in hundreds of experiments for a wide range of end points (Calabrese, 2001). Failure to recognize the compensatory response activity can result in missing the hormetic dose response. The implications of repeat measures can be different depending on the experiment. In the case of plant growth, it may represent repeated measurements of the same plants over the course of the experiment, with no loss of sample size. However, in the case of cancer bioassays the subjects are removed for sacrifice during the experiment, reducing the final sample size.

2.5 Replication

The occurrence of hormetic responses usually requires replication. The extent of the replication would depend on the strength of the original experiments, taking into consideration the study design, the statistical power and the degree that the concurrent control group shows consistency with historical control-group data, amongst other considerations.

3 EXPOSURE ASSESSMENT

The hormetic dose–response model selection would not be expected to impact the process of exposure assessment.

4 DOSE–RESPONSE

The hormetic dose–response hypothesis should be testable within standard bioassays. The data derived from the experiment should provide the basis for whether the hormesis hypothesis is supported or rejected and will provide the necessary information upon which the dose–response modelling may be constructed.

4.1 Carcinogens and Noncarcinogens

The current dominant cancer risk-assessment paradigm has assumed that genotoxic carcinogens act via processes that can best be described by linear-at-low-dose models. Essentially all other toxicological conditions have been assumed by the Environmental Protection Agency (EPA) and Federal Drug Administration (FDA) to be acting in a manner consistent with a threshold dose–response model. This dose–response dichotomy has lead to different risk assessment methodologies for the evaluation of noncarcinogens/nongenotoxic carcinogens and genotoxic carcinogens. The hormetic dose–response model, including its quantitative features, offers the distinct advantage of applying to all types of biological models, end points, chemical classes and physical agents.

5 RISK CHARACTERIZATION: DEFAULT MODEL

If hormesis were to be accepted as the default model in risk assessment, then it would be used to derive acceptable exposures for carcinogens and noncarcinogens. The hormetic dose–response model is similar to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat123
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the threshold dose–response model at the threshold and higher doses. That is, the hormetic dose includes the existence of the threshold response, as predicted by the threshold dose–response model. Immediately below the traditional threshold, the dose enters into the hormetic zone in which the response progresses below the control value, reaching a nadir and then proceeding back towards the control values, approaching another threshold on the dose–response continuum. The quantitative features of the hormetic dose–response model could become standardized using the hormesis database. In general, with respect to carcinogens and noncarcinogens it would be expected that a threshold response would occur, below which the response decreases below the control, reaching a value of about 30–60% of the control at the nadir of the dose–response relationship. The nadir would be expected to be reached at approximately 1/10 of the threshold dose. Based on the hormesis database, the width of the hormetic zone would be approximately over a 40-fold range.

5.1 Goal of Risk Assessment: Noncarcinogens

The goal of risk assessment for noncarcinogens has been to estimate the highest dose of an agent that will not cause toxicity in the experimental model and then apply appropriate uncertainty factors (UFs), relative source contributions and adjust for gender and possibly age differences. This would ensure that the risk of experiencing toxicity from a prolonged exposure would be very low to negligible. This is based on the assumptions that the average human is 10 times more sensitive than the average animal model, that human interindividuality is 10-fold and that the experiment was relevant to human exposures including route and duration of exposure.

5.2 Carcinogens

The goal of risk assessment for carcinogens has been to estimate a dosage that will result in an acceptable level of risk. Linear-at-low-dose modelling assumes that there will be no safe level, with the risk being proportionate to dose in the low-dose domain.

5.3 How Hormesis Impacts Risk Assessment

Hormesis has the capacity to significantly affect both noncarcinogen and carcinogen risk assessment. Since hormesis provides an assessment of responses above and below the threshold it offers risk assessors more information about the agent(s) being studied. In the case of **carcinogens**, the hormetic model not only assumes that there is a threshold below which there is no adverse treatment effect, but also a response zone in which the risk decreases below that of the control and does so for normal and high-risk segments of the population. If the goal is to prevent an agent-induced cancer response, then the agent could be handled via the use of UFs, or biomathematically modelled. If traditional interspecies and interindividual UFs were selected, then it is likely that there would be little likelihood of such exposures causing cancer in the population, assuming that humans are 10 times or less more sensitive than the animal model. On the other hand, this approach ignores low-dose hormetic effects in which exposure to the agent would be expected to reduce background cancer risks. If the beneficial effects were to be assessed then decision makers could consider optimizing health within the entire population. In this case the standard may ensure that the exposure was within the hormetic zone of the normal segment of the population. This may mean that some predicted adverse effects would be expected in the high-risk segment. Alternatively, the hormetic effects could be optimized for only the high-risk segment of the population. Consequently, the hormetic dose–response model has a significant effect on how risk assessment is applied to carcinogens. It would also notably impact risk–cost–benefit assessments of carcinogen exposure standards.

In the case of **noncarcinogens and nongenotoxic carcinogens**, the hormetic model provides risk assessors with the opportunity to consider selection of dosages that would be expected to optimize the population response, rather than simply focus on the avoidance of harm for all groups within the population. As in the case of genotoxic carcinogens this would also significantly affect risk–cost–benefit evaluations.

6 RISK ASSESSMENT MODELS AND ISSUES IN PERSPECTIVE

The current models that are used as defaults in risk assessment are the threshold model with noncarcinogens and nongenotoxic carcinogens and linear-at-low-dose modelling for genotoxic carcinogens. The use of these models continues to play a dominating role in the derivation of exposure standards for environmental contaminants, food additives and chemical residues in essentially all countries. While these risk assessment models have differing historical and scientific foundations, both are now questionable.

6.1 Threshold Model

In the case of the threshold model, it was readily adopted in the early decades of the twentieth century, institutionalized within the scientific and regulatory communities in the middle decades of the past century, never seriously questioned as judged by the published literature and, surprisingly, never explicitly tested and been attempted to be validated, until recently (Calabrese and Baldwin, 2001; 2003c; Calabrese *et al*., 2006). In two large-scale studies, designed to evaluate the capacity of the threshold model to reliably predict responses of doses below the estimated threshold, using no-adverse-effect levels (NOAELs) and various benchmark dose (BMD) values, the threshold model consistently failed to accurately predict how chemicals (from a broad range of chemical classes and causing a wide spectrum of toxic end points) acted in the low-dose zone or below the threshold. This was as surprising as it was alarming, because most regulatory actions throughout the world have been based on the assumption that the threshold model is valid and that most human exposures occur in the low-dose zone. These recent investigations have detected a serious flaw in the threshold model, a flaw that has important implications that affect its application for assessing low-dose effects. Ironically, when the hormetic dose–response model was tested it provided excellent predictive abilities, without restriction to biological model, end point or chemical class.

6.2 Linear-at-Low-Dose Modelling

In the case of the linear-at-low-dose model, it was adopted by the US EPA following the recommendation of the US National Academy of Sciences Safe Drinking Water Committee (1977), which based their acceptance on a two-decade-old decision of national and international advisory committees assessing risks from ionizing radiation. It had adopted the linear-at-low-dose model, rather than the threshold model. The linear-at-low-dose modelling was theoretically based and strongly influenced by societal fears concerning cancer.

The US government attempted experimentally to determine the shape of the dose response in the low-dose zone for genotoxic carcinogens in the late 1970s in a massive FDA-lead study, called the mega-mouse study, due to its use of over 24 000 animals. Given the significance of the study, the data underwent considerable analyses, including a detailed review by an expert committee created by the US Society of Toxicology (SOT), the findings of which were published in nearly an entire issue of the Society's journal (Bruce *et al*., 1981). The analysis indicated that the genotoxic carcinogen, 2-acetylaminofluorene (2-AAF) displayed a hormetic-like biphasic dose response with respect to bladder cancer. The findings were striking in that the hormetic response was observed in each of the six rooms that were used to house the large number of animals, in effect serving as a type of multiple internal replication of findings. While the hormetic dose–response findings were unanticipated, the major conclusions were that the study design was inadequate to assess risks below the risk of 1 cancer per 100 animals, hence it was called the ED01 study (ED—effective dose). This conclusion is particularly important because it demonstrated that linearity-at-low-zone modelling can not practically be evaluated for cancer incidence, and certainly never routinely considered. Yet the study demonstrated that the hormetic model could be evaluated and validated.

6.3 Hormetic Model

The general conclusion concerning the current risk assessment default models is that the threshold dose–response model has been demonstrated to have an inherent serious flaw, preventing it from making accurate predictions in the low-dose zone. The other modelling approach, that is, linear-at-low-dose modelling, cannot be validated at risk levels ($<1/100$) that are important to the public health. If a model's predictions can not be validated, then they are based on theoretical constructs that require 'belief' in an unverifiable model, rather than the data. Taken either separately or together, this is an untenable position for a highly industrialized and chemically dependent society.

Given these serious issues and weaknesses with respect to the current default dose–response models, it suggests the need for either model modification and/or the use of alternative models that offer the potential for improvement. The hormetic model is one such alternative since it has been observed to commonly occur, being highly generalizable according to animal model, end point and chemical class/physical stressor agent. It also has a strong mechanistic foundation. Furthermore, it has been shown to offer accurate predictions of low-dose responses in tests in which the threshold model performed poorly. It can also be tested in the 'observable' zone of experimental studies, thereby meeting a significant societal requirement that decisions should be data driven, not based on beliefs of theoretical constructs.

Practically, it may not attractive to revise the standard hazard assessment methodology to conform to the needs of the hormetic dose–response model because it affects animal model selection and study design considerations. For example, the analysis discussed indicates enhanced testing requirements for assessing hormesis, including more rigorous study designs (i.e. more doses, more subjects per dose in the below-threshold zone, and the greater need for replication of findings). However, if it were necessary to test the hormesis hypothesis,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat123
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

this task could be effectively accomplished. That is, the hormetic dose–response could be employed as a default model with validation on a case-by-case basis, as needed.

A public health advantage of the hormesis model is that it is capable of predicting and detecting possible beneficial and harmful effects below the traditional threshold dose–response model. In this respect the hormesis model provides a quantitative estimate of the dose response in the below-threshold zone that could be used by risk assessors. The magnitude of either type of response will be constrained to be usually no greater than 30–60% different from control group values. Such dose–response constraints on the quantitative features of the hormetic dose–response model offer particular value to risk assessors, as they would be able to assess the biological and population-based significance of these low-dose effects.

The hormetic dose–response model can also address the issue of mixtures more effectively than either the threshold or linear-at-low-dose models. The occurrence of chemical interactions in both of these models always assumes adverse effects, and in the case of the threshold model, effects that occur at doses greater than a threshold. In the case of hormesis, it could be similarly effective in predicting toxic interactions at the above-threshold response. However, it can also predict interactions in the below-threshold portion of the dose response. As with the case of singly tested agents, interactions could be beneficial, harmful or neutral. The magnitude of the hormetic response from chemical interactions will also be constrained by plasticity limits of the biological systems similar to that noted above for singly tested agents. Consequently, the hormetic models offer more potential value in assessing chemical interactions than the current two default models.

The issue of high-risk groups can also be effectively addressed by the hormetic dose–response methodology. Hormetic effects occur across the spectrum of susceptibilities. The quantitative features of the hormetic dose–response model are independent of the differential susceptibilities. The hormetic dose–response model creates opportunities and challenges for the risk assessor and public policy by providing the capacity for better information on the proportion of individuals who will benefit and be harmed at each level of contaminant exposure. Within this context the hormetic model takes into account harm that is expected to occur from the toxic substance as well as background disease incidence from indeterminate causes, but nonetheless real effects. This is a feature that neither of the current default models is capable of addressing and taking into account.

The hormetic model has the potential to bring various subpopulation stake holders into conflict as policy makers attempt to determine what the exposure standard may be. This is because the optimal dose for the general population may be at a dose that increases the risk of harm for a high-risk group. Since the high-risk group segment may usually be only a small fraction of the size of the general population, the conflict lies in the fact that to protect the high-risk group, a decision maker will increase the risks of the general population. These biological-based conflicts have been submerged in the present governmental risk assessment methodology because of one or more agencies' goals have been to reduce exposures to pollutant-induced risk for all groups, while completely ignoring any possible benefit that is differentially distributed across the normal and high-risk segments of society.

Chemical Incidents—Emergency Planning, Preparedness, Response and Recovery. Community Considerations

David Russell and John Simpson

CONTENTS

1 BACKGROUND

Chemical incidents may occur at any time and at any place, reflecting a complex and well-developed chemical industry and society's needs for chemicals, whether for health, agriculture, manufacturing, food preservation, household goods and products, sanitation or leisure activities. The chemical industry, therefore, is necessarily diverse, producing 'basic' chemicals, such as plastics and additives, sealants, catalysts and coatings, soaps, detergents, bleaches, fragrances, pesticides and biotechnological products (Organisation for Economic Co-operation and Development; OECD) (2007).

The scale of this dependence on chemicals is reflected by the fact that annual sales of chemicals in the European Union amounted to €556 billion in 2003, with an estimated global market of €1736 billion in 2004 (European Chemical Industry Council (CEFIC), 2009; European Social Investment Forum (EUROSIF), 2009). Based on cross-border trade flow analyses, it is estimated that between 2002 and 2006, global export of inorganic chemicals, organic and primary plastics grew at an annual rate of approximately 17.1%, whilst future projections suggest that by 2020, the global output will be 85% higher than in 1995 (*www.global-production.com/chemicals/trendstudy/index.htm*; OECD). This increase in production not only reflects an increase in quantity of chemicals, but also the number of chemicals produced. Accordingly, within the European Union, approximately 200–300 new chemicals are produced per annum within a global market of tens of thousands of substances, some of which are produced in quantities of greater than 1 million metric tonnes (OECD).

This global market for chemicals requires both a manufacturing base and transportation of chemicals, with vast amounts of chemicals transported by road, rail, pipeline, sea and air. Therefore communities, whether rural or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

urban, are potentially at risk of exposure to industrial chemicals and subsequent health effects as a consequence of a chemical incident. The Chemical Industries Association reports that in the UK in 2004 there were 36 reported transportation accidents, equating to approximately one incident per million tonnes transported (Chemical Industries Association (CIA), 2006).

A chemical incident is defined by the World Health Organization (WHO) as being *'an uncontrolled release of a chemical from its containment that either threatens to, or does, expose people to a chemical hazard'* (International Programme on Chemical Society (IPCS), 1999). Other definitions include *'an acute event in which there is, or could be, exposure of the public to chemical substances which cause, or have the potential to cause ill health'* (The Health Protection Agency, 2007).

The potential catastrophic impact of chemical incidents upon communities and public health is graphically illustrated by the Union Carbide incident at Bhopal in 1984. Following the accidental release of approximately 2500 kg of toxic methyl isocyanate (MIC) gas, a reported 200 000 people were exposed in the nearby community and there were over 3500 deaths, with ongoing concerns regarding chronic neurological, reproductive, psychological, ocular and respiratory effects (Dhara, 1992; Dhara and Dhara, 2002). Therefore, acute exposure following a chemical incident may result in both acute and chronic health effects.

Similarly, following an explosion at a fireworks storage facility in a residential area of Enschede in the Netherlands, self reporting of somatic symptoms, sleeping disorders and anxiety and depression were at higher rates than for the general Dutch population (Van Kamp *et al*., 2006), whilst a longitudinal epidemiological study reported similar effects in both the short term and longer term (18 months) (Van Kamp *et al*., 2006; Grievink *et al*., 2007); similar results have been reported after flooding incidents.

Rural communities have also experienced chemical incidents. In 1993, following the leakage of oil from a ship (the *Braer*) off the coast of Shetland, Scotland, UK, potentially exposed individuals had significantly higher rates of headache, sore throat and itchy eyes compared to controls (Campbell *et al*., 1993; 1994). Similarly, in 1996, the *Sea Empress* grounded in Milford Sound, Pembrokeshire, Wales, UK, and resulted in the spillage of 72 000 tonnes of crude oil. A retrospective cohort study undertaken by Lyons *et al*. revealed significantly greater self reporting of physical and psychological symptoms in communities residing in the vicinity of the incident (Lyons *et al*., 1999).

Such accidental releases are not uncommon, as underlined by the fact that the Health Protection Agency reports that public-health surveillance in England and Wales demonstrates approximately 1200 chemical incidents per year, whether the result of spillage, leakage, fire or explosion in industrial complexes, recreational facilities or transportation accidents (The Health Protection Agency, 2007).

In the present climate, however, in addition to *accidental* release of chemical agents, *deliberate* release of chemicals is a possibility. The potential impact of such releases is illustrated by the release of chemicals during the First World War, with over 113 000 tonnes of chemicals utilized. Over 5000 allied troops died and 15 000 were injured. Chlorine was the first chemical to be used as a warfare agent during the campaign, having been released by German Forces in April 1915 at the Ypres Salient, resulting in many casualties and fatalities. Similarly, phosgene was used by German forces on 19 December, 1915, when 88 tonnes were released, resulting in 1069 casualties and 120 deaths (Marrs *et al*., 2007). It was subsequently utilized by the allies, and accounted for 85% of all deaths attributed to chemical warfare during this campaign (*see* **Toxicology of Chemical Warfare Agents**, **Chemical Terrorism**). Both chemicals have since developed legitimate industrial usage, with chlorine being used extensively in the production of chlorinated organic polymers, solvents and other organic chemicals, whilst phosgene is used industrially in organic synthesis, dye manufacture, in pharmaceuticals, agrochemicals, synthetic foams, resins and polymers. Therefore, chemicals with legitimate industrial usages could be utilized as agents of chemical terrorism with the potential for large numbers of casualties and fatalities ('toxic industrial chemicals').

Community chemical terrorism has already been observed, as illustrated by the release of the organophosphate chemical warfare agent sarin on the Tokyo underground in 1995, resulting in 12 deaths and approximately 5000 casualties (Okumura *et al*., 1996) (*see* **Chemical Terrorism**).

There are a vast number of globally available chemicals and an almost infinite number of scenarios for airborne, waterborne and land-borne releases. Accordingly, it is not possible to plan for all eventualities, but rather, planning should be generic, based upon a risk-prioritized strategy, following risk assessment and subsequent risk mitigation and providing an interface between occupational and community considerations.

The remainder of this chapter will therefore focus upon risk assessment and mitigation and subsequent planning and thus preparedness for a response and ultimately, recovery.

2 RISK ASSESSMENT

Before risks can be mitigated or reduced, a risk assessment procedure must be undertaken to identify and prioritize such risks. Risk assessment is the process whereby

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

Table 1 The risk assessment paradigm, composed of the four steps of hazard identification, dose–response assessment, exposure assessment and risk characterization

Hazard identification—An assessment of all available evidence to explore the possibility that a chemical may cause a health effect. It is not a statement of probability, but rather of potential to cause harm.
Dose–response assessment—An assessment of available data from a number of different sources, including animal models, to assess health effects at given concentrations. This involves an examination of the relationship between dose and effect.
Exposure assessment—An estimation of population exposure to the chemical(s) of concern from all environmental sources, namely air, water and soil, according to chemical characteristics.
Risk characterization—This part of the process integrates all the information from the three steps, which, after analysis, provides a qualitative or quantitative risk, allowing subsequent decision-making by policy makers (*see* **Risk Assessment of Chemicals**).

the probability or likelihood of an event occurring is assessed (*see* **Risk Assessment of Chemicals**). In this context, it refers to the likelihood of a chemical incident occurring and its subsequent likely impact on public health, such as acute health effects, birth defects (congenital malformation) or cancer. In many instances, data are incomplete and as a consequence, the risk assessment process is an inexact science requiring utilization of limited toxicological data, extrapolation from available methodologies and expert consensus opinion. Therefore, risk assessment is more appropriately used as a policy as opposed to a scientific tool. It may be applied generically and thus be utilized to inform national policy on chemical incidents, as well as being utilized to address specific local and regional chemical industries and concerns. In this way, plans are developed that are proportional to risk and provide a basis for integration of local, regional and national chemical-incident plans (see below).

The classical risk assessment paradigm is composed of four steps (**Table 1**).

In practice, this typically entails identifying the use and storage of chemicals at industrial sites and associated transportation, the proximity and density of the local populus, together with the proximity and location of water courses, agricultural and grazing land. In addition, consideration needs to be given to all the relevant available data to enable as complete as possible a toxicological profile of the chemicals to be drawn up.

Consideration should also be given to the historical nature and frequency of chemical incidents, the accessibility of a site in the event of an incident, together with an assessment of whether the site poses a significant risk of sabotage or for chemical terrorism (Crawford *et al*., 2004a). Such an assessment may be undertaken at local, regional or national level.

Table 2 Examples of risk mitigation

Clear labelling and inventories of hazardous chemicals
Chemical substitution
Isolation and reduced storage capacity of hazardous chemicals
Bunding
Relocation of chemical industries from urban areas
Diversion of chemical transportation away from urban developments
Remediation of contaminated sites

The information from each component should be readily available and accessible and communicated in an open and transparent manner (risk communication).

Following the undertaking of the risk assessment process described above, risk deemed to be unacceptable should be reduced as far as possible by implementation of a number of practical measures (risk management or mitigation).

Examples of risk mitigation are illustrated in **Table 2**.

Such a procedure has been utilized by the US Environmental Protection Agency (EPA) for undertaking a risk assessment of hazardous waste sites. In this approach, acute hazards were identified, toxicity assessed, exposure estimated and the risk subsequently characterized. This process in turn informed risk management. (The US Environmental Protection Agency (US EPA), 2009)

In a similar fashion, major chemical installations in Europe are subject to the Seveso II Directive (1996), the principle aim of which is to prevent accidents at major installations and limit the impact of any spills on human beings and the environment. The Directive therefore covers the need for on-site—and in some instances—off-site-emergency plans, as well as the need to demonstrate adequate and appropriate safety and reliability in the design, storage and maintenance of facilities. Within this framework, industries subject to Control of Major Accident Hazard Regulations (1999) in the UK must ensure that primary, secondary and tertiary containment, pipework and pipelines, valves, control instrumentation, bunding and underground storage tanks all comply with appropriate standards, capable of being safely isolated and subject to inspection, testing and maintenance.

The risk remaining following instigation of risk mitigation is referred to as the residual risk, and forms the basis of subsequent planning and preparedness for chemical incidents and the response and recovery in their aftermath.

3 PLANNING AND PREPAREDNESS

3.1 Planning

Emergency planning is an integrative and iterative process that collectively involves risk mitigation, planning and preparedness, response and recovery. In essence, it is the process whereby plans for incident management are constructed. Planning for major incidents and disasters (such as train and aircraft disasters, flooding and bomb explosions) has been comprehensively developed throughout much of the world. In most places, there will be a general plan covering such major incidents and disasters. In addition, there will often be a general plan covering the roles of the *emergency services* in chemical incidents. There will also usually be major incident plans in hospitals, covering most types of incidents. However, *public-health* plans to deal with *chemical incidents* historically have been less well developed; such plans need to be distinct from, but integrated with, major incident plans (Crawford *et al*., 2004b).

The purpose of the chemical-incident planning is to reduce, mitigate or prevent the public-health impact of exposure to chemicals following an incident, whether 'minor' or 'major'. The Inter Organisation Programme on the Sound Management of Chemicals (IOMC) concluded that '*Having plans ready and rehearsed has been shown to make a major difference to the management and outcome of chemical events.*' (International Programme on Chemical Society (IPCS), 1999). Therefore, a planned, prepared and practised response to incidents contributes to preparedness and serves to protect the public; preparedness refers to a state of readiness and the two aspects are closely linked (see below).

As a chemical incident is likely to involve a number of agencies and organizations, it is imperative that all are involved in the planning process (*Integrated Emergency Management),* allowing respective roles and responsibilities to be clarified, defined and mutually understood. Typical agencies and organizations likely to require participation and contribution are illustrated in **Table 3**.

This allows a multidisciplinary, multiagency, integrated approach to planning for chemical incidents, allowing an all-encompassing chemical-incident plan to be constructed. This collaborative and integrative approach can be further reinforced by developing written agreed procedures, such as memoranda of understanding, or equivalent cooperative mechanisms. It is vital that community engagement is an integral part of the process, such that risk can be put in context, and concerns and fears raised, addressed and allayed. Involvement of the community is illustrated by the activities of the petrochemical industry at Fawley Refinery, Southampton, UK, where the industry has established clear channels of communication with the community, involving written safety instructions to follow in the event of an incident, together with a dedicated contact number.

Table 3 Examples of agencies, organizations and institutions likely to be involved in emergency planning as part of integrated emergency management

Emergency services
Local government
Public-health professionals
Environmental protection agencies
Water authorities
Maritime/coastguard/port agencies
Government departments and agencies
Other non-departmental public bodies
Analytical laboratories
Academics
Voluntary agency services
Community leaders

Engaging with the media will also be an important part of planning for chemical incidents. Accordingly, media protocols and liaison panels should be in place to ensure consistency of communication messages. Any incident is likely to generate huge media interest, and thus the link with the media should be an integral part of emergency planning. The media are important for a variety of reasons, but particularly because they are one of the main channel for public communication and thus should be used for dissemination of information at each stage of the incident; local media will keep the local communities updated whilst national media reach millions and thus require timely information (International Programme on Chemical Society (IPCS), 1999).

In addition to complimentarity of major incident and chemical-incident plans, it is also necessary that plans constructed at local, regional and national level are dove-tailed. The *national* plan is strategic, reflecting government policy, identifying and leading government response, addressing national and international co-ordination arrangements, the control and command, the response of healthcare organizations and overseeing national resilience. The *regional* chemical-incident plan should address regional co-ordination of incidents, ensuring good regional communication and collaboration, but also establishing channels of communication with the public, whilst the *local* plan need to be constructed in full co-operation with local partners, local industry and communities; all plans whether national, regional or local must be fully integrated and thus provide a seamless approach to chemical-incident management.

From the above discussion regarding the vast number of chemicals and potential scenarios, chemical-incident

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat124
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

plans are necessarily generic. However, they should recognize both overt and covert releases of chemicals. Overt releases of chemicals include the release of a chemical or chemicals from a fixed industrial site, whether a major industrial complex or small factory, or during transportation. Such events are typically obvious and may involve a fire or explosion or leakage/spillage of large quantities of material. The response (see below) will typically warrant a multiagency/multidisciplinary input, with first-line responders attending the scene, with clinical and public-health professionals advising, supporting and managing casualty and community concerns.

Covert releases, by contrast, are not initially detectable and will only be recognized by the presentation of unusual symptoms or symptom frequency. Such scenarios include deliberate release of chemicals, such as the poisoning of a water supply; under such circumstances detection will depend upon clinical acumen, surveillance mechanisms and alerting at points of care, such as general practitioners and emergency departments. Therefore, there is no obvious 'scene' as such, and the response therefore is in marked contrast, without the need for multiagency integrated response at a distinct location. Rather, the emphasis is on recognizing symptoms (in which Poisons Centres will have a major role to play *see* **The Role of Poison Centres in Basic and Clinical Toxicology**), identifying the source of release and the community potentially exposed, and putting in place appropriate medical, diagnostic and epidemiological measures.

3.1.1 Major Incidents

The UK Cabinet Office describes a major incident as *'... any emergency that requires the implementation of special arrangements by one or more of the emergency services..., rescue and transport of a large number of casualties; the involvement either directly or indirectly of large numbers of people, the handling of a large number of enquiries likely to be generated both from the public and the news media, usually to the police... the mobilisation and organisation of the emergency services and supporting organisations... to cater for the threat of death, serious injury or homelessness to a large number of people'* (Cabinet Office, 2003).

Major incidents therefore cannot usually be managed within the normal service arrangements and thus require the implementation of extraordinary procedures by first-line responders, healthcare professionals and local government. Such incidents have been divided into the major categories shown in **Table 4**.

In order to successfully manage such an incident, it must be underpinned by a major incident plan, the essential features of which are described by the UK's Department of Health, and highlighted by **Table 5** (Department of Health, 2007).

Table 4 Examples of types of major incidents requiring the implementation of extraordinary procedures and measures

'*Big bang*'—a major incident such as an industrial accident or transportation disaster triggers a focal, multiagency/multidisciplinary response of which the health component is likely to be a major contributor.
'*Rising tide*'—the incident is of a gradual or 'creeping' nature, such as an infectious disease outbreak or epidemic. It is only retrospectively that it becomes apparent at which point the incident became 'major'.
'*Cloud on the horizon*'—preparation is required for a threatened event which may or may not occur. Examples include a nuclear or chemical release in another country, an armed conflict or the possibility of an epidemic.
'*Headline news*'—this is a media driven headline and subsequent public concern over an actual or perceived health threat.
'*Internal incidents*'—this refers to any event, such as fire, flooding or loss of electricity supply that impairs the ability of a given service to respond to an incident.
'*Chemical, biological and nuclear materials*'—this specifically refers to the release of such materials deliberately by terrorists, disaffected individuals or dissident groups; it also includes hoaxes.

Table 5 Essential components of a major incident plan (Department of Health, 2007)

Multiagency input
Tailored to risk assessment
Addresses planning, preparedness, response and recovery
Coordinated and integrated
Establishment of appropriate command and control
Identifies and incorporates mutual aid
Regularly updated and tested
Based on best practice and information dissemination
Flexible, addressing numerous scenarios
Takes account of vulnerable populations
Incorporates business continuity management
In the public domain
Consistent with existing legislation

Reproduced from NHS, 2005.

The role of the community in emergency planning is well established, with several reports of government representatives, first-line responders and civic leaders providing input to constructing local emergency plans, raise community awareness and fully involve communities in exercises and volunteer programmes. The United Nations Environment Programme (UNEP) has developed a tool known as *the Awareness and Preparedness for Emergencies at Local Level (APELL): a Process for Responding to Technological Accidents,* which serves to mitigate the risk of exposure following the release of chemicals through the development of local plans, with particular emphasis upon community awareness of the risks and preparedness for contingencies (United Nations Environment Programme, 1998).

DOI: 10.1002/9780470744307.gat124
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.2 Preparedness

Preparedness reflects a state of readiness and thus requires more than merely planning. Planning itself does not guarantee preparedness. Preparedness is a dynamic process and thus is ongoing (Perry and Lindell, 2003). It is composed of several components, including planning, but also comprising training, alerting and detection systems, robust communication, advance preparation of information likely to be of use during an incident, purchase and testing of necessary equipment and facilities, and ensuring access to quantitative risk-assessment tools. The whole procedure needs to be underpinned by a comprehensive exercise programme.

3.2.1 Training

The most important resource in managing acute chemical incidents is the human resource. Therefore, in order to ensure a timely, efficient, effective and appropriate public-health response to acute chemical incidents, it is necessary to identify available human resources, build capacity through training, and ensure that access to this expertise is available at all times. In the modern era, online training modules and materials have been developed, such as those developed by the Centers for Disease Control and Prevention (CDC) in the USA and the Health Protection Agency (HPA) in the UK. Examples include the Centers of Public Health Preparedness (CPHP) programme (*www.bt.cdc.gov/training/cphp/*), whilst the American Medical Association has developed web-based competencies (Weiner and Trangenstein, 2007). In addition to academic training, emergency planning also needs to address character and team building, with the virtues of '*prudence, courage, justice, stewardship, vigilance, resilience and charity'* being stated as being essential for emergency team members (Larkin and Arnold, 2003).

3.2.2 Skill Mix

The fact that chemical incidents may involve a large number of chemicals (as well the products of combustion, environmental reactions and degradation), widespread environmental contamination and the possibility of acute and chronic health effects, necessitates considerable collective expertise in a number of distinct, but related fields. These include the disciplines of environmental chemistry, environmental science, public health and epidemiology, as well as environmental and clinical toxicology. It is only through the collection, assimilation and subsequent critical analysis of available data that a risk assessment—and thus potential impact upon public health—can be undertaken. Therefore, preparedness for responding to chemical incidents requires a diverse group of skills.

The essential role of toxicologists in providing advice and support on toxi-cosurveillance, recognition of clinical syndromes, treatment and management of casualties, advising upon antidotes and decontamination procedures is well established (*see* **Clinical Toxicology**) (Schwenk *et al*., 2005). The invaluable role of toxicologists is further highlighted by the development of specific community exposure limits following the airborne release of chemicals. Community exposure limits were developed to anticipate the likely health consequences of exposure of the general public to airborne chemicals. Whilst occupational exposure limits have been developed for workers who are typically healthy adults, community exposure limits take account of susceptible populations, such as children, those with pre-existing health conditions (such as asthma or allergies, cardiovascular disease, etc.), the elderly, frail and infirm. Based upon peer review of available animal, occupational and epidemiological toxicological data and evidence, Emergency Response Planning Guidelines (ERPGs) were developed, providing quantitative data on the likely impact of exposure to a given chemical over a given period of time. For example, ERPGs predict that exposure to 1 ppm of chlorine for 1 hour would result in a noticeable odour in the majority of individuals, whereas exposure to 3 ppm of chlorine for 1 hour would probably result in sensory irritation; 20 ppm for 1 hour would result in potentially irreversible and life-threatening effects (Hansen, 1999). More recently, Acute Exposure Guideline Levels (AEGLs) have been developed by a National Advisory Committee to the US EPA, and subsequently reviewed by the National Academy of Sciences. AEGL values have been set for the time periods of 30 minutes, 1 hour, 4 hours and 8 hours, and for three levels of severity (thresholds for mild/transient effects, more significant effects including impaired ability to escape, and life-threatening effects), and have been developed for industrial chemicals and chemical warfare agents alike (see *www.epa.gov/oppt/aegl/*). Such exposure limits can be factored into emergency planning and may provide a yardstick for assessing exposure and planning for protective actions, such as evacuation or sheltering (Hansen, 1999).

3.2.3 Meteorological Data

Complementary to the need to organize beforehand is the need for rapid and prompt access to meteorological data, which provides key information on likely dispersion of the chemical(s) in question and thus populations at risk of exposure. Many chemicals are either gaseous or volatile (such as chlorine, ammonia, phosgene, the nerve agent sarin, and mustard) and therefore a release, whether deliberate or accidental, is likely to result in airborne contamination and dispersion. This information is usually requested by fire services at the scene of an incident, but is also of great value to public-health professionals. Key

Table 6 Key components of meteorological data that may aid risk assessment following release of volatile and gaseous chemicals. Such information provides rapid access to data pertaining to potential community exposure

Wind speed and direction
Air temperature
Relative humidity
Weather conditions
Cloud cover
Air stability
Height of mixing layer
Maps of nearby communities

pieces of information that are required are illustrated by **Table 6**.

The advantage of such information is its rapid availability, whereas detailed computational modelling requires the use of complex mathematical models and the necessity of detailed environmental data.

3.2.4 Computational Modelling

Modelling of likely environmental contaminant concentrations and thus likely community exposure is time consuming and thus unlikely to be available at the beginning of an incident.

3.2.5 Datasheets

A key feature of chemical incidents is the short latency with which symptoms occur following exposure. For example, the release of ammonia at an ambient concentration of 50 ppm may induce ear, nose and throat irritation within 2 hours, whilst at 100 ppm symptoms occur rapidly; at 700 ppm symptoms occur immediately, with death likely to ensue at approximately 4500 ppm (for review see *www.hpa.org.uk*). It is therefore necessary to prepare in advance toxicological datasheets, based upon the risk assessment paradigm discussed above and addressing the key issues shown in **Table 7**.

Table 7 Key components of toxicological datasheets. The rapidity of symptom development following chemical exposure means such datasheets need to be prepared beforehand on a risk-prioritized basis

Chemical synonyms
Physicochemical properties
Acute and chronic toxicity
Environmental fate
First aid
Incident management
Decontamination (casualty and environment)

Datasheets have been developed by the Agency for Toxic Substances Disease Registry (ATSDR, *www.atsdr.cdc.gov/MHMI/mmg.html*) at the CDC in Atlanta, USA; these provide concise information on a number of industrial chemicals and chemical warfare agents. Other sources include the International Programme on Chemical Safety (IPCS) concise international chemical assessment documents (CICADs) (International Programme on Chemical Safety (IPCS), 2009). The HPA has also produced over 100 datasheets which address the commonest industrial chemicals and chemical warfare agents for the purposes of health care professionals, first-line responders and local authorities (The Health Protection Agency, 2007).

3.2.6 Communication

Communication is also a key component of preparedness, with tried and tested communication channels being an essential component of a timely, coordinated and effective response. Recently, informatics has been utilized to improve the quality and speed of information transfer. For example, cellular phone transmission of data from pre-hospital field workers to emergency departments has allowed information to be transferred on the number of casualties, clinical condition of patients, mode of transport, estimated numbers of those to be transferred and likely time of arrival. Other developments include utilizing wireless technology for secure transfer of incident and patient data between field and hospital, thereby enhancing information communication and allowing for more efficient care (Weiner and Trangenstein, 2007).

The importance of communication after an incident cannot be over emphasized, with several examples of major incidents resulting in difficulties. During the response to Hurricane Katrina, information-sharing regarding supply and demand for essentials such as bottled water was limited. Further, during the London bombings of 2005, massive demand by the public for information led to the saturation of mobile-phone networks and subsequent overload; communications involving pagers and text messaging were reported to be more resilient (Bland *et al*., 2006).

3.2.7 Alerting

As chemical incidents are by their very nature unpredictable, access to expert public-health advice will be required on a 24-hour, 365-day-per-year basis, with access provided to all agencies and organizations who may wish to provide an alert for, or seek advice on, chemical incidents. Such a system can then be utilized for accessing timely and authoritative public-health advice.

Such planning undoubtedly contributes to national preparedness. However, many incidents have the potential to be, or are, of actual concern internationally. Examples include those shown in **Table 8**.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat124
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 8 Examples of incidents chemical which may be of international concern

Incidents close to national borders
Water pollution of major arterial rivers
Contamination of major food production sources
Clusters of unusual illnesses
Deliberate release of toxic chemicals
Plumes from industrial fires and explosions

Table 9 Key components of international communication

Identify key individuals
Establish rapid, robust, timely, efficient and effective channels of communication
Standardize incident classification
Promote mutual aid

Therefore, it is also necessary to open and maintain international channels of communication, which should meet the essential criteria given in **Table 9**.

In this context, the International Health Regulations (IHRs) are legally binding regulations involving 194 countries. Their principle aim is to help the global community to prevent or respond to international crises. The regulations stipulate that countries must report to the WHO outbreaks and incidents that may have international implications. Such threats include pandemic flu and Severe Acute Respiratory Syndrome (SARS), as well as chemical incidents with an international dimension (World Health Organization, 2005).

3.2.8 Surveillance

Surveillance provides invaluable information regarding the number of chemical incidents, their nature, frequency, location, type and chemicals involved, together with a range for the number of people estimated to be exposed and/or exhibiting symptoms. Therefore, the timely collection, collation and analysis of such data provides an insight into the commonest chemicals involved and the nature of incidents. For example, data collated by the HPA demonstrates that chlorine, mineral acids, carbon monoxide and mercury, are commonly released during chemical incidents; this information can be utilized to further assist risk assessment, mitigation and planning, and contribute to the development of risk-prioritized toxicological datasheets. The importance of surveillance has also been recognized in planning and preparedness for, and responding to, international chemical incidents. The World Health Assembly in 2002 agreed a resolution to strengthen surveillance systems for chemical and biological agents and nuclear/radiation events. This reflects the continuing growth of the chemicals industry as well as the fact that chemical incidents may have an impact distant from their origin (e.g. the release of cyanide into the river Tisza in Romania following a dam burst killed fish in three countries). Accordingly, the WHO has developed an international system for the verification, investigation and subsequent response to communicable disease events, chemical incidents and events of possible chemical aetiology (Global Outbreak Alert and Response Network (GOARN) (Olowokure *et al*., 2005).

3.2.9 Personal Protective Equipment

Preparedness for acute chemical incidents also requires the purchase and provision of suitable personal protective equipment (PPE) that allows first-line responders and Emergency Department staff to treat chemically contaminated casualties without becoming secondarily contaminated themselves. In essence, PPE for use in the warm zone should ensure liquid protection (including respiratory protection) against common toxic industrial chemicals and chemical warfare agents, provide good visibility and allow rapid communication. PPE, however, by its very nature is cumbersome and limits dexterity and communication. Accordingly, only limited clinical treatment can be undertaken whilst donning such clothing; it is necessary that those who use such equipment are familiar and comfortable with its use.

Complimentary to the need to utilize PPE is the need to prepare for decontaminating casualties and to be able to do so rapidly, as symptoms may occur rapidly following exposure, as discussed above. Therefore, there is a need to be able to rapidly transport and subsequently erect mobile decontamination facilities at the scene of an incident. This in itself poses a considerable challenge that is compounded by the need to be able to decontaminate a range of casualties from very few to very many (mass casualties), together with a requirement to provide copious amounts of warm water (to reduce the risk of hypothermia), basic equipment such as buckets, sponges, detergents and paper towels and replacement clothing. Further consideration needs to be given to the deployment of essential medical equipment, first aid equipment and pharmaceuticals, as highlighted by **Table 10**.

Table 10 Essential medical equipment required at the scene of a major chemical incident involving casualties

Drugs and antidotes
Intravenous lines and fluids
Resuscitation equipment (defibrillators, face masks, endotracheal tubes, etc.)
Ventilators
Oxygen
Modesty clothing
Wound dressings
Needles and syringes

Quality assurance procedures, including standard operating procedures for sampling, collection, transportation and analysis
Regional/local distribution of sample kits
Staff training
Data interpretation
Timely reporting

Table 12 Essential components of a successful exercise strategy

Undertaken regularly
Be well planned
Provide realistic scenarios
Involve all appropriate agencies or focus on specific practice
Test operating procedures, communications and practical issues
Tease out strengths and weaknesses
Provide timely feedback, consulting representatives of all participants
Be used for improving practice and thus preparedness

3.2.10 Sample Analysis

Provision should also be in place for environmental sampling. This requires provision for sampling at the scene of an incident and thus access to sampling equipment. Many *environmental* samples can be analysed at the scene of an incident in either a qualitative or quantitative manner. Examples include carbon monoxide, chlorine and ammonia. More complex analyses can also be undertaken at the scene, but typically are undertaken in a laboratory; examples include volatile organic compounds and heavy metals.

Biological samples are invariably sent to a laboratory for analysis (*see* **Clinical Chemistry in Toxicity Testing: Scope and Methods**). It is essential that arrangements are in place for distribution of sample collection tubes to the scene and to local emergency departments. Laboratories will advise as to appropriate sample tubes and specimens to be collected.

As part of preparedness, therefore, it is essential that the certain components of analytical sampling are in place; see **Table 11**.

As this is a complex and time-consuming process, it is vital that such procedures are in place prior to chemical incidents; establishing such channels of communication in the aftermath of an incident is too late.

Many contaminated casualties may, however flee the scene of an incident and present at hospitals. Therefore, as part of the planning and preparedness stage, it is imperative that hospitals have decontamination facilities and tried-and-tested decontamination protocols and appropriately trained staff (Dethick and Hicks, 1999).

3.2.11 Emergency Operations Centre

Major incidents will require a coordinated public-health response, collecting, collating and critically analysing information pertaining to the incident that will allow a dynamic risk assessment and the provision of advice and support to all major agencies and organizations as outlined above. This is typically achieved by planning for an Emergency Operations Centre (EOC), an essential part of preparedness. Such a centre will require robust and secure communications and access to tools such as geographical information systems, computational modelling and toxicological data. Manning of the incident over a prolonged period of time will necessitate planning for access to suitable expertise on a rota basis over days to weeks.

3.2.12 Exercises

Exercises are recognized as being a valuable tool in reducing the impact of an emergency upon communities, minimizing the interruption to businesses, increasing the chances of postincident survival and minimizing the financial, social, legal and political impact. Exercises also provide a means of measuring an organization's relative strengths and weaknesses and provide an invaluable learning tool, if well constructed (Cabinet Office, 2003). They also allow the development of interpersonal relationships and thus enhance communication. Furthermore, exercises may serve to publicize the fact that planning is under way, and signal to public and community representatives that preparedness is being attained (Perry and Lindell, 2003).

In order to test the resilience, reliability and effectiveness of the planning and preparedness discussed above, it is necessary to undertake exercises. Exercises should fulfil the criteria given in **Table 12**.

Exercises can vary in magnitude from small 'desk-top' exercises involving one aspect of the emergency planning to large multi-agency, multi-disciplinary exercises with the involvement of large numbers of 'casualties' and deployment of PPE, decontamination, ambulance, fire and hospital facilities. Some exercises also have an international dimension in order to gauge international alerting and response (see **Table 13**).

Planning and preparedness are key components and require considerable preparation and ongoing testing, with one author stating that '*you cannot be overly prepared for an emergency*' (Tumosa, 2007). They form the platform for subsequent response and recovery. The importance of this point is illustrated by a review of the Madrid bombings of 2004 which noted that there

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 13 Exercise 'Common Ground', an international communications exercise

Exercise COMMON GROUND was conducted as a Command Post Exercise, where organizations played into the exercise from their own emergency operations centre, over a two-day period on 23–24 November 2005. The aim of this European Commission-funded exercise was to evaluate the ability and capabilities of member states to respond to a health-related crisis, in this case an influenza pandemic. In addition to the then 25 member states, players in the exercise included the European Commission (EC), European Centre for Disease Prevention and Control, European Economic Area states, Switzerland, the World Health Organization (WHO) and other relevant European agencies and organizations. The exercise was intended, amongst other objectives, to provide the players with an opportunity to explore international coordination with the EC and was based on a model of an influenza pandemic developed by modellers at the HPA. Not surprisingly with this level of participation between national organizations, communication and coordination became a major theme of the postexercise lessons. Many areas for improvement were identified and embraced both by the European Commission and other participating organizations.
The value of exercises has clearly been recognized by the EC and it is intended that exercises become a regular feature of enhancing preparedness across Europe.

was a lack of effective emergency planning, limited interagency communication, absence of overall command and control, and no triage system (López Carresi, 2008).

4 RESPONSE

A rapid, coordinated and effective response is the best means of ensuring the reduction, minimization or prevention of the community consequences of chemical incidents and therefore of a successful public-health outcome. Its successful implementation will require multi-agency, multi-disciplinary involvement, with different skills and disciplines being required at different time points following the incident.

The response to an incident can conveniently be divided into discrete sections according to the timing of the response.

4.1 Immediate; 0–2 Hours

Following notification of a chemical incident, the first response is to assess the situation from the viewpoint of potential or actual public-health implications. It is predominantly associated with assessing emergency clinical care and will be undertaken by the emergency services in particular, targeting the areas shown in **Table 14** (Cullinan, 2002).

In the immediate aftermath of an acute incident, whether deliberate or accidental, the emergency services are responsible for managing the incident, whether a fire, explosion, leak, spillage or a toxic plume. The immediate priorities are to recognize that a chemical incident has occurred, triage and remove casualties from the immediate vicinity of the incident, decontaminate chemically contaminated casualties, provide first aid for physical injuries, such as blast injuries, wounds and trauma, and cordon the area to prevent unexposed individuals from entering the area (and to prevent contaminated and potentially contaminated individuals from leaving the scene).

Table 14 Initial assessment of a chemical incident. Immediate assessment requires a dynamic risk assessment of the actual or potential public-health implications

What, if any, are the public-health implications?
What geographical areas have been involved?
How many people are threatened, affected, injured or dead?
What are the exposure pathways?
Are critical infrastructures affected (power, water supplies, sanitation, etc.)?
What environmental media are affected?
What chemicals are involved/thought to be involved (including products of combustion/degradation)?
What other agencies and organizations are involved?
Have key personnel been notified and the emergency plan implemented?
What response actions have been taken?

4.1.1 Command and Control

A command-and-control structure will need to be rapidly established. The first act of the incident commander is to establish control of the site for the protection of attending emergency services, casualties and the wider public. This involves the establishment of an *exclusion zone* (the '*hot zone*'), where there is a risk of direct contamination from chemical exposure. It is therefore accessed only by specifically trained rescue personnel wearing *gas* tight (Type A) PPE and self-contained breathing apparatus (SCBA). In most instances, such personnel are from the fire services or 'Hazmat' teams, although considerable thought has been given to the forward deployment of medical and paramedical staff into this zone. The 'hot zone' is always established upwind of the incident, to prevent further contamination, although changes in wind direction may prove problematical and require changing the location of the zone. Casualties are brought to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat124
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the contamination reduction zone (*'warm zone'*), where decontamination takes place. The risk in this zone is from indirect exposure to chemicals from contaminated casualties and equipment. Therefore, workers in this zone (ambulance, paramedical and medical staff) require *liquid* tight PPE (see Section 3.2). Following decontamination, casualties enter the support zone (*'cold zone'*) before transportation to hospital as appropriate.

This command-and-control structure forms part of a combined and co-ordinated response regardless of the individual role of the respective agencies and irrespective of the nature of the incident, whether chemical, biological or radiation. The overarching aims of such a joint response are to contain the emergency, save and protect lives of responders and the community alike, relieve suffering and protect property and the environment, whilst providing a channel for a unified and united channel of communication with the media and public. It also provides a mechanism for the restoration of normality and thus recovery and for identifying and implementing lessons learnt (Cabinet Office, 2003).

Within the overall command and control of the incident, the emergency services will need to instigate a mechanism for co-ordination. Typically, each service will provide strategic *command* ('gold'), *tactical* ('silver') and *operational* ('bronze') command. One or more agencies may establish a strategic command, with the express remit of establishing an overall framework, establishing clear channels of communication with tactical commanders, providing an integrated response to media enquiries, prioritizing the demands of the incident and assimilating appropriate expertise, and plan beyond the immediate aftermath of the incident, including recovery. Tactical command's primary purpose is to provide overall incident management, allocating resources according to priorities, and to ascertain when tasks will be undertaken. Operational command is established in both minor and major incidents and is active at the scene, managing front line operations (Cabinet Office, 2003). 'Big bang' incidents are likely to require invoking such a concentric command structure, whilst in others the model may vary. For example, a train crash may require several operational command sectors answering to one tactical command, whilst an underground train incident may require the establishment of one operational command centre with two tactical commands (Chemical Industries Association (CIA), 2006).

As the numbers of casualties may be large and immediate rescue and healthcare capabilities may be exceeded, it may be necessary to triage individuals.

4.1.2 Decontamination

Decontamination should always be undertaken prior to casualty treatment and medical management, thereby preventing secondary contamination of medical equipment, such as ventilators, as well as ambulances and Emergency Departments. This is of paramount importance. It means that attending staff do not have to attempt complex medical manoeuvres such as intravenous line insertion and intubation whilst donning cumbersome PPE. Decontamination is undertaken in the warm zone following removal of clothing; its purpose is to remove contamination from the body surfaces such that the toxicological consequences are minimized. It therefore needs to be undertaken rapidly. Several means of decontamination have been utilized and proposed, involving both 'dry' decontamination (using adsorbents such as fuller's earth) or 'wet' decontamination with water or weak (0.5% v/v) solutions of detergent or bleach. There is no categorical evidence regarding the best means of decontamination. However, it is widely assumed that application of water or bleach/detergent solutions through a rinse–wipe–rinse regime is the best means of removal.

Contaminated effluent, as far as possible, needs to be contained to minimize contamination of the wider environment. There is therefore a need for collection media, such as bowsers, tanks and vessels for subsequent disposal at a hazardous-waste facility. However, it is recognized that this is not always possible, and effluent may well need to be allowed to drain to waste, despite potential environmental pollution; human life should always take precedence.

4.1.3 Communications

Communications will also need to be established with key personnel, such as hospitals and general practitioners, the emergency services, laboratories, local government and other agencies and organizations. In addition, a channel of communication with the *public* will need to be established. This may involve relaying messages through the media, electing a trained spokesperson or establishing a public-health information 'hotline'.

Whatever the mechanism for dealing with the public, it is essential that communication uses appropriate, clear and concise vocabulary and is transmitted in all appropriate languages (**Table 15**).

Table 15 Risk communication with the public; key components of successful interaction. The message conveyed to the public should be:

Simple
Concise
Timely
Accurate
Relevant
Credible
Consistent

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat124
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.2 Intermediate; 2–6 Hours

Further and ongoing assessment of the incident will be required. A risk assessment of the potential implications for the *wider community* requires knowledge of the nature of the release, the chemical(s) and quantities involved, the environmental media contaminated and the proximity of communities. Therefore, chemical incidents may result in contamination of land and crops, pollution of rivers, lakes, ground and surface water and, through the production of a plume, air pollution. It may be necessary to advise on washing or avoiding crops, the necessity for potable water supplies or for the need to shelter or evacuate.

In the great majority of incidents, *sheltering* following the production of a potentially toxic plume is the preferred option, being the most feasible—that is, staying indoors, closing all the windows and doors, and shutting down any ventilation or air-conditioning systems, until the chemical (usually in a cloud) has passed. This procedure will usually protect the community for up to 12 hours, thus providing adequate protection in the great majority of incidents. Incidents of longer duration, however, may require a different strategy, and evacuation may well be necessary. Likewise threat of exposure, such as an impending plume from the leakage of material from a transportation incident or fire at a chemical factory or storage facility (Baxter, 2005).

4.2.1 Evacuation

Evacuation may be a life-saving measure, as is illustrated by the fact that it has been reported that 34 residents were presumed to have drowned following refusal to leave a nursing home in Louisiana in the aftermath of *Hurricane Katrina* (Dosa *et al*., 2007) It entails the removal of people away from the area of (likely) contamination to a place of safety. It will often involve complex arrangements ranging from the provision of transport, to shelter, food, water and appropriate medical care (for pre-existing conditions as well as the health effects of the exposure) in the area of safety. It may also require ensuring the security of the properties left uninhabited.

In the context of a chemical incident, the major argument for evacuation is risk of explosion; sheltering in nearby accommodation during an explosion almost certainly leads to death due to the propagation of pressure waves. It may also be considered for areas that may be exposed at a later time and the likely duration of exposure is such that the protection offered by in-place sheltering will become insufficient. Risks to the evacuation process include the attendant risks of moving large numbers of people, such as falls and road traffic accidents, and disturbing the health of frail, elderly and disabled people. Generally speaking, as a rule of thumb, if the evacuation involves more than 1000 people, it is not practical or feasible to do so.

The decision to authorize return is dependent upon monitoring/modelling and multiagency experience data adequate to be able to assert that the area is safe and there is an ability to provide adequate services.

It is therefore vital that the public are informed rapidly following a chemical incident, such that they are informed and remain informed of the incident and any developments that may arise. It is therefore essential that agencies involved in an incident provide a consistent and harmonized message that can subsequently be relayed and updated through the local media; residents are often advised to '*Go in, stay in and tune in'*.

4.2.2 Environmental Sampling

Environmental sampling following a chemical incident is commonly warranted. It may involve collection of air, water and soil samples in order to assess extent and level of environmental contamination. This in turn serves as a proxy for population exposure and thus allows direction of resources towards communities or sections of communities who are potentially exposed. This allows such communities to be targeted, and clinical and epidemiological follow-up commenced, as appropriate. Initiation of sampling, following an incident, may therefore need to be commenced rapidly. Environmental Sampling should therefore be undertaken as shown in **Table 16**.

It is important to ensure that all samples taken are complimented by completion of all necessary forms (document control) and that chain of custody is maintained. These procedures allow an audit trail to be established and ensure that it may be followed at a later date. Samples will need to be kept for an agreed period of time. Further information is available from the UK Department for Food, Environment and Rural Affairs (DEFRA) (*www.defra.gov.uk/environment/chemicals/accident/sampling*) and the US Agency for Toxic

Table 16 Environmental sampling following a chemical incident. Successful and representative sampling strategies require comprehensive emergency planning:

By fully trained staff
As rapidly as possible following an incident, when safe and appropriate to do so
Utilizing standardized operating procedures
In a coordinated, systematic and representative manner
Inclusive of potentially sensitive sites, such as allotments, schools, homes and playing fields
In full consultation with all involved agencies and laboratories
Utilizing approved and, if possible, accredited methodologies
To allow rapid turnaround

Table 17 Key characteristics of the ideal bio-marker

Be easily measurable
Be detectable rapidly and only following exposure
Decline rapidly upon cessation of exposure
Be closely correlated with environmental levels
Be closely related to acute and chronic health effects in a dose-dependent manner
Guide patient management, and community clinical and epidemiological follow-up

Disease Registry (*www.atsdr.cdc.gov/ednpha.html*). A well constructed and coordinated procedure for sampling can provide invaluable data regarding the degree and extent of contamination, and guide subsequent community biological monitoring.

4.2.3 Biological Monitoring

Biological monitoring is the process whereby a chemical or closely associated metabolite is measured in body excreta, fluid or organ, such as expired air, blood, urine or hair. The process can be subdivided into biomarkers of effect and biomarkers of exposure. The former refers to measuring the effect of a chemical on a body organ, such as the liver or kidney, whereas the latter directly measures the chemical. Ideally, a biomarker should fulfil the criteria given in **Table 17**.

Unfortunately, very few biomarkers fulfil all these criteria. In addition, the number of chemicals for which biomarkers are established is very few; the great majority do not have established biomarkers. However, collection of samples should be encouraged at every opportunity as even if the relationship between dose and health effects is poorly understood, biological monitoring may be of great value in further understanding this relationship. Examples of chemicals where biomonitoring may be helpful include carbon monoxide, lead, mercury, nerve agents and mustard.

Again it is important to liaise with laboratories prior to commencing sampling, in order to ensure appropriate specimen collection including correct timing, sample collection and transportation to the laboratory. In order to ensure appropriate sampling, the criteria given in **Table 18** need to be fulfilled.

Table 18 Pre-analytical considerations for environmental and biological sampling

Prior communication with laboratory
Sampling at appropriate times by trained staff
Correct sampling procedure (collection, appropriate media and vessels, labelling, packaging and transportation)
Laboratory accreditation
Appropriate sample turnaround and interpretation

Addressing the needs of vulnerable populations, such as children, the chronically ill (such as dialysis patients), disabled, housebound, institutionalized and transient communities should also commence, whilst continuing to communicate with, and update, the public. Comments regarding document quality assurance, document control, chain of custody and establishing an audit trail equally apply to biological specimens.

4.3 Intermediate; 6–12 Hours

In this period, the situation should continue to be frequently assessed, health response objectives updated and reviewed, requests for advice and assistance evaluated, risk communication continued, legal issues apprised, and samples collected, analysed and interpreted, whilst documenting all activities. Any available health surveillance data needs to be considered and factored into the incident management.

4.4 Extended Response; 12–24 Hours

The situation should continue to be assessed, health response objectives updated and reviewed, appropriate communications with adjacent public-health and medical structures should be initiated, requests for advice and assistance addressed, risk communication continued, legal issues apprised, and samples collected, analysed and interpreted, whilst documenting all activities. Any available health surveillance data needs to be considered and factored into the incident management.

Any voluntary aid should also be coordinated.

4.5 Longer Term; Post-24 Hours

The criteria outlined above should continue to be assessed as appropriate. In addition, however, clinical and epidemiological follow-up may be appropriate. Data obtained in this way may be invaluable in the identification of exposed individuals and subsequently may guide clinical follow up, such as clinical investigation, cancer registries and epidemiological investigation. Epidemiological investigation comes into its own in this phase, although collection of data on who may have been exposed should be implemented as soon as possible. This may well be a daunting task as those exposed may extend well into the wider community and well beyond those seeking medical care. It will be determined by the nature of the release and the environmental media contaminated. For example, an airborne release

Table 19 Holistic overview of major components of chemical-incident management from the immediate phase through to the longer term

Detection of chemicals, both environmentally and biologically
Evaluation of the nature and magnitude of the release
Contacting specialists and reference centres
Assessment of current and delayed mass casualty needs
Risk communication
First-line responder protection
Command and control
Decontamination (rapid)
Triage implementation
First aid and medical care
Public-health protection
Collectively these procedures can be fed in to hone and improve planning and preparedness and thus mobilization of regional, national and international sources through mutual aid
Monitoring of residual hazard levels
Long-term follow up of casualties

may result in a dense plume, the footprint of which determines those potentially exposed. Enumeration therefore requires access to appropriate demographic data and identification of vulnerable/susceptible groups, whilst risk is the product of such data and expected acute and chronic health effects. All these factors should be considered before embarking upon an epidemiological investigation (Cullinan, 2002).

In summary, the response to an incident, whether accidental or deliberate should cover the systematic response steps given in **Table 19**.

5 RECOVERY

Recovery following a chemical incident encompasses the economy and the environment as well as health, which all contribute to sustainable communities.

Chemical incidents undoubtedly influence the economy, particularly in local communities. Chemical industries are major employers in developed countries, and in the aftermath of chemical incidents employment opportunities may be limited, and this together with the health consequences of incidents may result in a significant decrease in economic prosperity, wealth and standard of living. Coupled to this may be the need for clean up, remediation and restitution, which together with any ensuing litigation may be extremely costly and thus further influence economic prosperity. Alternative accommodation for residents and key facilities will need to be available if clean-up is not practical or possible, further contributing to the overall cost.

Rehabilitation following an environmental incident is a mixture of remediation and restitution of the environment, action to prevent a further occurrence, and work to improve the community's health.

5.1 Remediation

Remediation is the process of making the environment safe and clean. It may occur naturally, as with a volatile gas, or where the chemicals involved degrade rapidly. It may however, involve the physical collection of the contaminated medium and its subsequent safe removal, or it may require other measures to reduce the toxicity of the chemical. Many chemicals, such as chlorinated hydrocarbons, are environmentally persistent with long half-lives, and thus may result in ongoing contamination.

A range of expertise is needed to assess the extent of residual contamination of environmental media, such crops, soil, air and water, to devise appropriate decontamination measures where needed and to ensure that it is safe for evacuated populations to return. The extent to which contamination has contaminated environmental media, and subsequent human exposure (such as contamination of crops and livestock, with subsequent risks to the food chain) must also be appraised, and preventive or protective measures put into place. Significant contamination of the food chain is likely to require destruction of crop products, and animals grown for food. Collectively, it is a reflection of the nature and scale of the incident together with the physicochemical properties of the chemicals released and their reaction products.

Cleaning up contaminated sites or land may entail standard soil stabilization disposal technologies or biological methods of decontamination, which are developing rapidly. Material such as topsoil, equipment or crops may need to be removed for cleaning or disposal, (without endangering the new site). Rehabilitation of large bodies of waste therefore may be expensive and extremely resource intensive and time-consuming, especially when the chemical(s) have become bound to the sediment.

Individual decontamination of affected wildlife may also be thought necessary, as following a major oil spill, for example. Decontamination of the drinking water or source water may not be possible and the system may have to be flushed out, potentially causing further contamination of soil, surface and groundwater, and seawater. Alternative sources of drinking water may therefore be required.

Complete removal of the chemical or chemicals may not be possible, as it may be too difficult, hazardous or economically non-viable. If full remediation cannot be accomplished, it may be necessary to declare the area as 'limited entry' or 'limited use'. These declarations may have to be in force for many years and may seriously

Table 20 Principle objectives of rehabilitation

Effect remediation of and restoration of the environment
Restore the health of the population at least to its state before the incident, or minimize the ill effects
Answer unanswered questions
Restore health care and community services prevailing before the incident and, whenever possible, improve these services
Provide evaluation and feedback on incident response and effect indicated changes
Monitor for unexpected effects or for potential effects when risk is uncertain
Continue risk reduction and prevention activities

disrupt the life of the community, and environmental recovery.

5.2 Restitution

Restitution is the process of returning the environment to its original state and may involve extensive remediation. Restoring the environment may involve landscaping, as well as rebuilding, replacing equipment and buildings, replanting of crops and replenishing animals and wildlife, and thus may entail considerable cost.

Addressing health concerns of communities following an incident is also of paramount importance, with a timely and effective response to community concerns vital for such community recovery. Psychological implications may well be significant even for incidents which pose no physical hazard and require few or no protective actions. Such psychological effects typically manifest as anxiety, insomnia and depression, as well as nonspecific symptoms such as nausea, vomiting and headaches. Often such stress can be resolved by good (and timely) communication of measures taken to prevent exposure whilst additional investigations to confirm a lack of health effects and environmental contamination are helpful. Involving the community in plans to reduce the risk of further incidents and to quickly alert the public-health team and the public if further incidents occur are reassuring and protective of the public's health.

The aims of rehabilitation are summarized in **Table 20**.

6 EVALUATION

At the earliest possible opportunity, the public-health response to a chemical incident should be critically evaluated. It is possible to conduct three types of review of the performance of the public-health response to the incident, but these should all be undertaken in a 'no-blame' environment. The time, effort and resources allocated to any or all of these will depend upon the nature of the incident, the complexity of the response, the time since, and the lessons learned from the last review, and the resources available. Evaluations should be set out in a methodological way, to analyse the events and to assess what impact the response made on the outcome. In particular, questions are asked and judgements made as to the difference in outcomes if there had been no public-health response, or if different responses had been given. Ideally, outside experts are brought in to add their expertise and a level of objectivity. The outcome, conclusions and recommendations should subsequently be factored into the chemical-incident planning and preparedness.

6.1 Wash-ups

Wash-ups are perhaps the simplest of the reviews, and involve a re-run of the events of the incident and the response of the public-health environmental health professionals. Errors, deviations from the plan and problems in communications are highlighted in a non-threatening way so that participants can learn as much as possible from the actual incident and the rerun, in a 'no-blame' environment. The wash-up is conducted as soon as possible after the incident, while the events are still fresh, and as soon as possible. It is usually an 'in-house' affair.

In summary, chemical-incident planning, preparedness and subsequent response is a complex process, but if undertaken in a comprehensive manner can reduce, mitigate or prevent subsequent public-health consequences.

ACKNOWLEDGEMENTS

We are very grateful to Ms. Deborah Purnell for her help in preparing this manuscript and to Mr. Paul Riley from the HPA's Centre for Emergency Preparedness for his technical assistance and support.

Biomonitoring of the Workplace and Environment

Peter J. Boogaard

CONTENTS

1 INTRODUCTION

Biomonitoring is, in its simplest definition, the measurement of a parameter in a biological specimen. This parameter is often referred to as a 'biomarker', and can be a chemical, its metabolite or an adduct to a macromolecule, or an effect, such as a change in enzymatic activity or a chromosomal aberration. In a more complex definition, a biomarker is an analytical measurement of any substance, structure or process that indicates an exposure, susceptibility or prediction of the incidence or outcome of disease (Toniolo *et al*., 1997). This chapter is restricted to human biomonitoring and aims to describe the biomonitoring of chemical exposure to humans, both in the occupational setting and through the environment. The main goal of human biomonitoring is usually to assess exposure. Biomonitoring has a number of specific characteristics that make it particularly useful for this purpose. In general, individuals may be exposed via inhalation, ingestion and uptake through the skin or mucous membranes. In contrast to most other exposure monitoring techniques, such as personal air monitoring in occupational settings or food-basket analysis in consumer settings, biomonitoring integrates all routes of exposure. In addition, biomonitoring may allow the assessment of both spatial and temporal differences in exposures between individuals. Moreover, it may also take into account differences between individuals such as variations in genetics and physiology. These advantages have been recognized for a long time, and the first human biomonitoring dates back to the beginning of last century. Amongst the first chemicals that were biomonitored were lead and benzene, substances that are still of considerable interest (Kehoe *et al*., 1933; Yant *et al*., 1936). In the 1960s and 1970s, the development of more sensitive analytical techniques not only allowed measurement of lower concentrations of chemicals in complex matrices like urine and blood, but also enabled the analysis of larger series of samples. In addition, limit values were proposed to avoid health effects of exposure (Hartogensis and Zielhuis, 1962; Zielhuis, 1959; 1971; Walkley *et al*., 1961). These developments led to an increasing importance of biomonitoring to assess occupational exposures. Historically, human biomonitoring was mainly applied in occupational settings. As

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat126
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

a consequence, methodologies, techniques and interpretation of results focussed on biomonitoring of chemical exposure in the working place and during industrial applications. These principles were summarized in 'Industrial Chemical Exposure—Guidelines for Biological Monitoring' in 1983 (Lauwerys, 1983). The second edition, in 1993, had more than doubled in size (Lauwerys and Hoet, 1993), and the latest edition, again, doubled in size (Lauwerys and Hoet, 2001), reflecting the increased application of human biomonitoring in industrial settings. Similarly, in 1985 the German Research Foundation's Commission for the Investigation of Health Hazards of Chemical Compounds in the Work Area started publishing well-validated biomonitoring methods for important industrial substances under the title 'Analysis of Hazardous Substances in Biological Materials', and has over the years published 10 volumes with procedures for the biomonitoring of more than 200 substances (DFG, 2006). The World Health Organization (WHO) has also published guidance on occupational biomonitoring (IPCS, 1993; WHO, 1996a; 1996b). The importance of biomonitoring of occupational exposure is also reflected in the European Regulations, as the European Union (EU) has adopted several directives that form the base for setting biological limit values (BLVs) (Bolt and Thier, 2006).

The continuous advancements in analytical technologies and capabilities, both with respect to sensitivity and specificity, enabled the determination of increasingly lower concentrations of substances and their effects in biological media. This opened up the possibility of applying human biomonitoring to the assessment of environmental exposures. Since the capacity for testing has grown, increasingly larger numbers of individuals have themselves checked for the presence of substances in their bodies. This human biomonitoring may occur as part of national programmes, such as the German Environmental Survey (GerES) (GerES, 2009), or the USA's National Health and Nutrition Examination Survey (NHANES) (CDC, 2009) programmes, as part of scientific studies, or as a mere service. In the vast majority of cases, results from biomonitoring to assess environmental exposures show that these exposures are low. For substances for which a health-based limit value has been established, the biomonitoring values associated with environmental exposures are usually several orders of magnitude lower than the health-based limit values for occupational exposures. However, the differences in exposure patterns, potentially more susceptible subpopulations and a potential lifetime exposure make the interpretation of biomonitoring data for environmental exposures challenging. Nevertheless, in recent years a number of reports providing guidance in the interpretation of such values have been published (Boogaard *et al*., 2005; Boogaard and Money, 2008; Burke *et al*., 2006).

2 TYPES OF BIOMONITORING

Biomonitoring is a general term comprising the following subcategories:

- **Biological monitoring,** which identifies the assessment of *biomarkers of exposure*. This type of biomarker is also referred to as 'internal dose' or 'body burden'. Typical examples of biological monitoring are the determination of metals (e.g. mercury, arsenic or lead) in blood or urine, the determination of unchanged substances (e.g. dioxins, polychlorinated biphenyls (PCBs) or benzene) in adipose tissue, milk, urine, or blood, the determination of specific metabolites of a chemical (e.g. *S*-phenyl-mercapturic acid (S-PMA) or *trans,trans*-muconic acid (tt-MA) as metabolites of benzene) in urine, or volatile compounds (unchanged substances or metabolites) in exhaled breath.
- **Biochemical effect monitoring,** which identifies the assessment of *biomarkers of effective dose*, which is also referred to as 'tissue dose'. Typical examples of biochemical effect monitoring include the determination of adducts of a specific chemical (e.g. ethylene oxide or polycyclic aromatic hydrocarbons) to DNA or a protein such as albumin (Alb) or haemoglobin (Hb). It should be realized that both biological and biochemical effect monitoring solely provide evidence for exposure and cannot be interpreted in terms of health risk assessment without additional data on dose–response relationships (see also gat005). Some forms of biochemical effect monitoring, such as the determination of Hb adducts, have additional benefits since they allow time-integrated exposure monitoring over long periods of time (up to several months) at a point in time that intervention may still be possible.
- **Biological effect monitoring,** which identifies the assessment of *biomarkers of effect* and gradually flows over into the assessment of clinical parameters or *biomarkers of disease*. Typical examples of biological effect monitoring include measurements such as cholinesterase activity in blood to monitor exposure to organophosphate or carbamate pesticides; zinc protoporphyrin or δ-aminolaevulinic acid to monitor exposure to lead; sister chromatid exchanges and other chromosomal aberrations to monitor exposure to genotoxic or clastogenic substances; and several specific forms of (micro)proteinuria to detect exposure to a variety of substances.

Biological effect monitoring measures early and, in most cases, reversible biological effects, which do not necessarily lead to health effects, whereas abnormal clinical parameters are an expression of (beginning)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat126
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

disease. In general, in biological effect monitoring, natural phenomena are measured for which a 'normal' background value may be established, which may be influenced by various physiological and environmental factors that are not related to chemical exposure. This renders most methods of biological effect monitoring intrinsically nonspecific. Various parameters assessed in biological effect monitoring may also be used in clinical practice, and form a seamless continuum with clinical monitoring, as a more-or-less arbitrarily set value may demarcate the shift from a minor biological effect to an effect that is considered clinically relevant. For example, albuminuria may be used in biological effect monitoring (microalbuminuria) as a biomarker of early renal function effects, but it is also used as a clinical parameter for instance to assess renal function impairment in diabetics.

In addition to biomarkers of exposure, of effective dose, of effect, and of disease, sometimes genotyping and phenotyping are referred to as *biomarkers of susceptibility*. Biomarkers of susceptibility are indicators of an inherent or acquired ability of an organism to respond to the challenge of exposure to a specific substance. Some examples are the expression of certain isoforms of cytochrome P450, glutathione transferases or *N*-acetyltransferases. In addition, factors such as nutritional status, iron status, and so on, may also be regarded as biomarkers of susceptibility. These biomarkers differ from the other biomarkers in that they reflect potential interindividual differences in uptake and metabolism of chemicals and, consequently, potential differences in health risks. Biomarkers of susceptibility may, like lifestyle factors such as smoking and drinking behaviour, explain differences in biomarker results between individuals with identical exposure profiles (DFG, 2004).

Both biological monitoring and biochemical effect monitoring are essential methods to help better understand the complex relationships between external and internal exposure and, consequently, the potential adverse health effects that may result from exposure. Both monitoring methods should be regarded as exposure assessment with high specificity for the substance that is being measured, just like most ambient monitoring methods. In fact, in biological monitoring as well as in biochemical effect monitoring each individual serves as its own dose monitor. Although both methods measure the total, actual exposure regardless of the route of exposure, there is a fundamental difference. Biological monitoring simply reflects total internal exposure and is applicable to most substances, whereas biochemical effect monitoring reflects the effective internal exposure of a chemical, usually a potentially genotoxic substance, by measuring its reaction product with an endogenous macromolecule. Biochemical effect monitoring hence proves that the chemical was not only bioavailable but also bioactive. It not only indicates that the chemical was absorbed into the body but also that it reached the tissues (hence: tissue dose). In some cases, it is possible to measure reaction products in the ultimate target tissue and in these instances the concentration may be referred to as target tissue dose.

For genotoxic compounds, the ultimate target would theoretically be the organ in which the substance might induce cancer, and the biomarker the responsible DNA adduct. However, induction and development of cancer is a highly complex process. DNA adduct formation is considered crucial in this process, and the distribution of DNA adducts in the body usually, but not always, reflects the risk, although the concentration of adducts may be higher in nontarget tissues than target tissues (Ríos-Blanco *et al*., 2000; 2003; Potter *et al*., 1989; Otteneder *et al*., 2002; Otteneder and Lutz, 1999). This apparent lack of correlation may be due to the contribution of additional biological processes needed for the progress of an initiated cell to a malignant tumour, but it may also be due to the specific contribution of a minor DNA adduct in the development of a tumour, or a combination of both processes. For most substances, these processes are largely unknown. Moreover, since it is in the vast majority of cases not feasible to determine DNA adducts in the target tissue itself, generally DNA adducts in white blood cells are measured as a surrogate merely reflecting the effective internal exposure. In most instances protein adducts, such as Alb, and in particular Hb adducts, are better surrogate biomarkers for effective internal exposure due to their greater stability and ease of determination (Richter and Branner, 2002; Törnqvist *et al*., 2002; Boogaard, 2002; Koc and Swenberg, 2002; de Kok *et al*., 2002). Although mostly applied to the biomonitoring of genotoxic substances, it should be borne in mind that the concept of target tissue dose may also be used for other compounds with a specific target tissue, for instance cadmium in the kidney (Lauwerys *et al*., 1993; 1994; Roels *et al*., 1983).

As depicted in **Figure 1**, the accuracy of the exposure determination as well as the relevance for health increases from nonpersonal ambient monitoring (i.e. static air monitoring, monitoring of drinking water, 'food-basket' monitoring), via personal ambient monitoring (e.g. personal air monitoring, dermal exposure monitoring), to biological monitoring and biochemical effect monitoring. The relevance for health increases further with biological effect monitoring and clinical effect monitoring, but with a loss of specificity with regard to the chemical (or physical) factor associated with the health effect. In general, for health risk assessments biological monitoring and biochemical effect monitoring provide the best and most reliable information both in term of exposure and potential health effects related to certain exposures.

Biomarkers are potentially influenced by various factors, such as lifestyle and physiology, including genotype and phenotype. The influence of physiological factors may be illustrated by a number of studies where albuminuria was determined, amongst a series of other

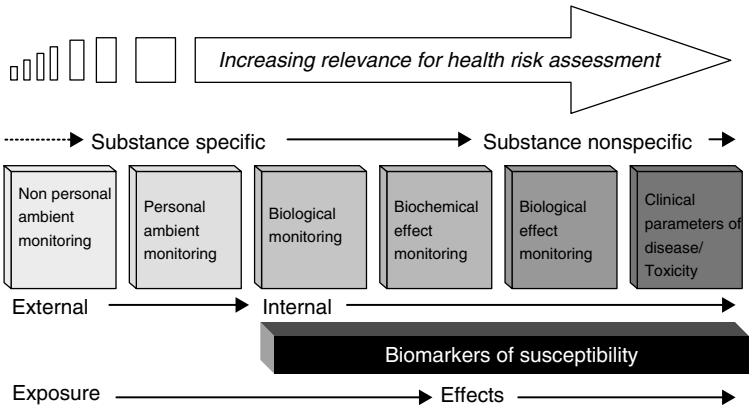

Figure 1 Monitoring techniques as part of the exposure–effect continuum in relation to risk assessment.

renal function parameters, in potentially exposed workers. In a study in 53 male oil refinery workers with potential exposure to hydrocarbons, sensitive biochemical markers of kidney function and damage were compared to those of a control group of 61 age-matched nonexposed males. No difference was found in the urinary tubular parameters β-*N*-acetyl-D-glucosaminidase (NAG), β-2-microglobulin (β2 M) and retinol-binding protein (RBP). Surprisingly, the mean albuminuria, which is considered a less sensitive parameter for renal function effects, was slightly higher ($p < 0.005$) in the refinery workers compared to the controls, although all values were in the normal range. The authors concluded that chronic low-level hydrocarbon exposure in these refinery workers did not lead to clinically significant renal abnormalities but that some findings were consistent with the possible role of hydrocarbon exposure in the induction of renal disturbances (Viau *et al*., 1987). In a study in 73 male workers of an organochlorine plant, biochemical effects on renal function were assessed by determination of urinary NAG, RBP, alanine aminopeptidase (AAP) and Alb, and compared to 35 nonexposed males. Again, albuminuria was within normal limits in both groups but slightly higher in the potentially exposed workers than the controls (Boogaard *et al*., 1993). Further investigations with additional control groups indicated that the observed effect was a physiological effect induced by shift working. In both studies with increased albuminuria, the potentially exposed operators worked in shifts or had physically strenuous workloads, whereas the controls worked only during daytime and did physically nondemanding work. As nonexposed male shift workers displayed the same small increase in albuminuria, it could be concluded that the effect was unrelated to potential chemical exposures but rather to shift work or physical work load (Boogaard and Caubo, 1994). These studies also illustrate that interpretation of biological effect monitoring data in terms of health effects in relation to chemical exposures should be undertaken with utmost caution.

In contrast, biochemical effect monitoring—due to its substance specificity—can directly be related to chemical exposures and may be highly useful in risk assessment. This is illustrated by the studies on the mycotoxin, aflatoxin B_1. From epidemiological studies the association between hepatocellular carcinoma and aflatoxin B_1 intake has been established. In large biomonitoring studies, the incidence of hepatocellular carcinoma was strongly correlated with urinary biomarkers for aflatoxin B_1 and with serum hepatitis B surface antigen, whilst there was no significant association with dietary intake of aflatoxins (Qian *et al*., 1994; Ross *et al*., 1992). The association between aflatoxin B_1 exposure and DNA-adduct levels in the liver, and with the urinary excretion of aflatoxin-*N*7-guanine was also demonstrated in animal studies (Groopman *et al*., 1992a) and confirmed in humans (Groopman *et al*., 1992). Despite the importance of hepatitis B status as an influencing factor on the development of hepatocellular carcinoma, the robust correlation of urinary aflatoxin-*N*7-guanine with biological effects strongly supports its use as biomarker in the risk assessment process (Groopman *et al*., 1993).

The characteristics of biomonitoring to evaluate internal exposure and early biochemical and biological effects make biomonitoring a potentially more accurate risk assessment tool than external monitoring such as air monitoring and surface contamination monitoring. Unfortunately, the number of substances for which a validated biomonitoring method is available is limited compared to those for which validated ambient air monitoring methods are on hand (**Tables 1** and **2**).

3 CHOICE OF SPECIMEN

Human biomonitoring is typically performed in urine or blood, but occasionally in exhaled breath, or tissues such as hair, nails or buccal cells are used. Breast milk may also be used for biomonitoring, usually to assess exposure to highly lipophilic compounds, such as chlorinated

The volume-based concentrations from the Finnish Institute of Occupational Health refer to values corrected to a relative density of 1.024. A—end-tidal breath; B—blood; BAL—biomonitoring action level; BAT—Biologische Arbeitsstofftoleranzwerte (biological tolerance value); BEI—biological exposure index; BMGV—biological monitoring guidance value; E—erythrocytes; EKA—Expositionsäquivalent für krebserzeugende Arbeitsstoffe (exposure-equivalent for carcinogenic substances); Hb—haemoglobin; P—plasma; RL—reference limit for nonexposed; S—serum; U—urine; ×—the marker has been listed without a reference value. Timing of sampling: T1—end-of-shift; T2—not critical; T3—in continuous exposure, after several shifts; T4—increase during the shift; T5—end-of-shift, end of working week; T6—during exposure but at least 2 h after beginning of exposure; T7—post-task; T8—prior to (next) shift; T9—prior to last shift of working week; T10—during or end of shift; T11—16 h after end of shift; T12—prior to the shift on the first day after the weekend; T13—paired samples: baseline specimen prior to shift and end-of-shift sample at end of working week or exposure period.

[a] EKA value corresponding to 7 mg m^{-3}.
[b] EKA value corresponding to 0.01 mg m^{-3}.
[c] EKA value corresponding to 3.3 mg m^{-3}.
[d] EKA value corresponding to 4.5 mg m^{-3}.
[e] EKA value corresponding to 0.05 mg m^{-3} CrO_3 in air, not valid for welding fumes.
[f] EKA value corresponding to 0.025 mg m^{-3}.
[g] EKA value corresponding to 200 mg m^{-3} cyclohexane in air.
[h] EKA value corresponding to 61 mg m^{-3} p-dichlorobenzene.
[i] EKA value corresponding to 175 mg m^{-3} dichloromethane.
[j] EKA value corresponding to 0.20 mg m^{-3} dimethylsulfate.
[k] EKA value corresponding to 440 mg m^{-3} ethylbenzene.
[l] EKA value corresponding to 117 mg m^{-3} ethylene.
[m] EKA value corresponding to 1.83 mg m^{-3} ethylene oxide.
[n] EKA value corresponding to 0.013 mg m^{-3} hydrazine.
[o] EKA value corresponding to 0.1 mg m^{-3} Ni (as metal, as nickel oxide, nickel sulfide or sulfidic ores).
[p] EKA value corresponding to 0.1 mg m^{-3} Ni (as easily soluble nickel salts like nickel acetate and comparable soluble salt, nickel chloride, nickel hydroxide, nickel sulfate).
[q] EKA value corresponding to 0.10 mg m^{-3} PCP.
[r] EKA value corresponding to 206 mg m^{-3} tetrachloroethylene.
[s] EKA value corresponding to 0.035 mg m^{-3} toluylenediamine.
[t] EKA value corresponding to 55 mg m^{-3} trichloroethylene.
[u] EKA value corresponding to 0.05 mg m^{-3} V.
[v] EKA value corresponding to 2.6 mg m^{-3} VCM.
[w] Women of child-bearing potential: 100 µg l^{-1}.
[x] Women <45 years: 100 µg l^{-1}.
[y] For foetus and pregnant women: 0.015 µM.
[z] T1 for inhalation and T8 for dermal exposure.
[aa] T1 for inhalation and T9 for dermal exposure.
[bb] For chromium platers.
[cc] For manual metal arc welders.
[dd] For shield gas welders.
[ee] Nonsmokers.
[ff] Smokers.
[gg] Fasting serum.

pesticides, dioxins and PCBs (Zietz *et al*., 2008; WHO, 2007). In principle, any bodily fluid or tissue can be used for biomonitoring. However, most tissues are not suitable for routine monitoring or for risk assessments. For routine monitoring it is essential that the body fluids or tissues are easily accessible, which rules out most tissues and fluids apart from those mentioned above. For risk assessment it is of paramount importance that the data can be compared to a reference value (see below) or at least to a dose–response curve. This is usually the most crucial factor, limiting biomonitoring to primarily urine, blood and, for some substances, hair. For some volatile substances exhaled air may be used as specimen for exposure monitoring, however the methodology, especially the sampling, is rather complex (Corradi and Mutti, 2005; Wilson and Monster, 1999). Specific advantages and disadvantages of various specimens used for biomonitoring are listed below.

3.1 Urine

Urine is in most cases the specimen of choice due to its easy collection, the large quantities and the fact that it is a noninvasive method. Many substances are excreted into the urine either as the substance itself or as water-soluble metabolites. When exposures are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat126
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

intermittent, urinary concentrations usually reflect the average exposure better than blood or exhaled air concentrations because the excretion into the urine acts as an integrator. For substances with short systemic half-lives of a few hours or less, urinary concentrations also may reflect exposures better as apparent urinary half-lives are usually considerably longer than those in blood or breath. Ideally, 24-hour urine samples are collected and analysed, but in practice spot samples are more generally used. Timing of the sample collection then becomes an important factor (see **Table 1**). Differences in hydration amongst individuals due to variations in fluid intake and perspiration may lead to significant variations in the density of the urine produced and consequently the concentration of the analyte under investigation in a spot sample. Correction of the results for the density of the urine may be essential for some substances and this can be done either by determination of the urinary density or by measuring the urinary creatinine concentration. However, whether or not correction for differences in urinary density is warranted needs to be assessed for each substance (Barr *et al*., 2005b; Alessio *et al*., 1985; Dell'Orto *et al*., 1987; Boeniger *et al*., 1993).

3.2 Blood

Blood constitutes the most important means of transport in the human body for most substances, and virtually all systemically active substances can be measured in blood. In addition, blood usually closely reflects the concentration of a substance at its place of action since blood is either itself in contact with the receptor or in equilibrium with other bodily fluids (e.g. cerebrospinal fluid), which are in contact with the receptors. As a consequence, interpretation of a biomarker measured in blood is generally more straightforward than the interpretation of a biomarker in other specimens, provided the half-life of the substance is sufficiently long. The major drawbacks of blood as a specimen are the invasive nature of sampling, and, consequently, the need for specialized personnel to collect samples, and the potential biohazards associated with blood (hepatitis, HIV), which may hamper transportation due to legal limitations. Additional practical considerations include the choice of an appropriate anticoagulant if needed, and whether the analysis is best performed on whole blood, serum, plasma or specific blood cell types (e.g. red blood cells for Hb adducts and white blood cells for DNA adducts).

3.3 Breath

For volatile substances breath may be an excellent specimen. Probably the best-known use of breath as specimen for biomonitoring is traffic alcohol controls. Alveolar air collection represents a noninvasive method, but the actual collection may be cumbersome for most substances (Wilson and Monster, 1999). Even more so than with blood or urine analysis, the timing of a breath sample collection is crucial, as most volatile substances have a relatively short half-life in alveolar air (see **Table 1**). In addition, a differentiation between 'mixed exhaled air' and 'end exhaled air' should be made in the interpretation of the results since the concentration in the latter tends to be lower during, but higher following, the exposure period.

3.4 Milk and Adipose Tissue

In environmental biomonitoring milk and adipose tissue may be suitable specimens for highly lipid-soluble substances, such as chlorinated pesticides, brominated flame retardants, and polyfluorinated compounds. Adipose samples can only be collected by (highly) invasive methodology and are therefore of limited practical use. Lipophilic compounds tend to have very long half-lives in adipose tissue and reach a steady-state level upon prolonged exposure in fat. Milk samples can be collected from lactating women and represent not only the body burden of the mother but also the exposure of the baby (Berlin *et al*., 2005; LaKind *et al*., 2005). Biomonitoring surveys using human breast milk are primarily used to assess the efficacy of policy measures to reduce exposures by measuring the trends over time in the biomarker concentration following the introduction of exposure reduction strategies (Zietz *et al*., 2008; Wang *et al*., 2005; Cerna *et al*., 2007; 2000).

3.5 Nails and Hair

Nails and hair are traditionally less commonly used for biomonitoring but provide specific opportunities for biomonitoring where other specimens are difficult to obtain, for instance in the biomonitoring of infants and small children where collection of blood or urine samples is cumbersome. More recently, methods are being developed and validated to use specimens like nails and in particular hair for biomonitoring (Bader *et al*., 1999; Legrand *et al*., 2005; Rodrigues *et al*., 2008; Schramm, 1997; 2008; Wilhelm *et al*., 2007; Bergdahl and Skerfving, 2008). Most substances have long half-lives in hair and nails. In principle, the history of exposure could be read over the length of hair.

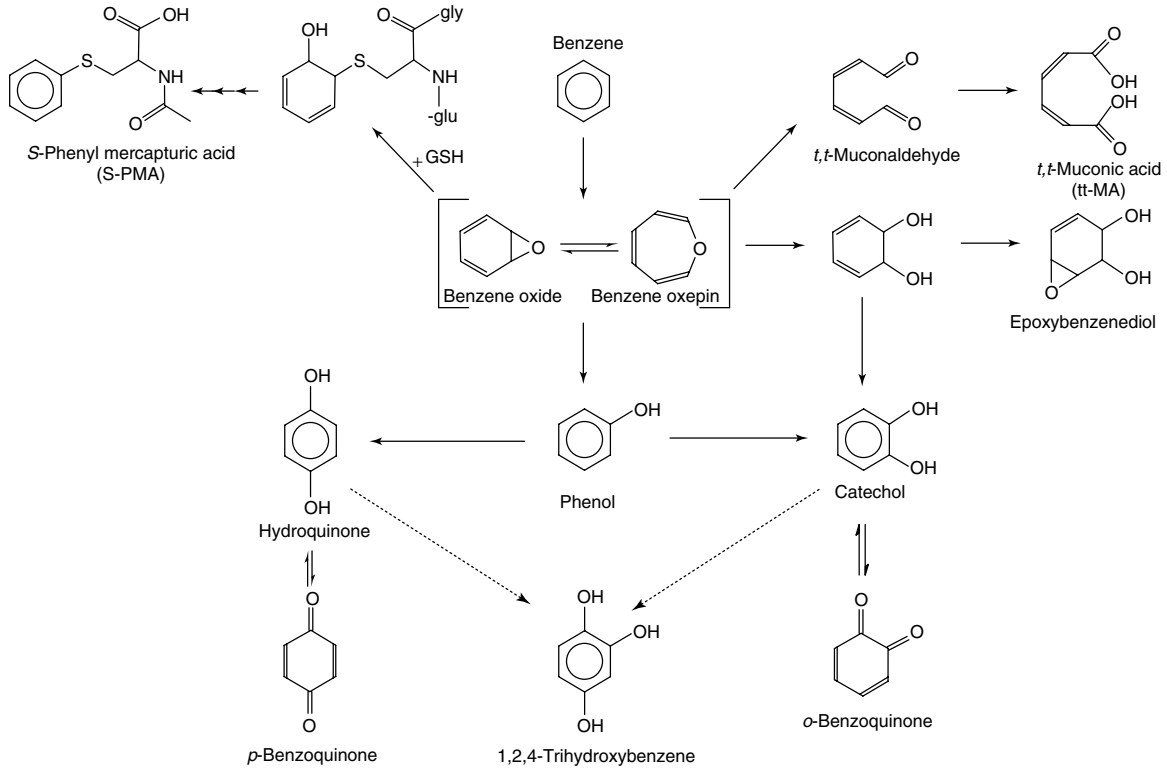

Figure 2 Simplified benzene metabolism scheme with potential urinary biomarkers for benzene exposure (GSH—glutathione).

4 CHOICE OF BIOMARKER

The choice of a biomarker for a certain substance is crucial and depends largely on the aims of the investigations and the required sensitivity and specificity. The considerations for selecting a biomarker can best be illustrated by some examples. A good example is benzene, which has been of concern for a long time and of which both metabolism and kinetics are reasonably well known. In **Figure 2** an overview of the main pathways in the metabolism of benzene is given. Its major metabolite is phenol, which is mainly excreted into the urine as sulfate or glucuronide. As mentioned in the introduction, benzene was amongst the first substances that were being biomonitored in the first half of the twentieth century, and urinary phenol was the biomarker used for this purpose. In individuals without exposure to benzene, however, background levels of urinary phenol from dietary sources may be found which correspond to airborne levels of 5–10 ppm of benzene. This background was no problem for using urinary phenol as compliance check in industrial settings when the occupational exposure limits (OELs) were in the order of 100 ppm. However, when, over time, the OELs were lowered to values below 10 ppm, phenol became useless as biomarker and other urinary metabolites, such as tt-MA and S-PMA, were investigated as biomarkers (van Sittert *et al*., 1993; Ducos *et al*., 1992). Both tt-MA and S-PMA have specific advantages and drawbacks (Boogaard and van Sittert, 1995a). As can be seen in **Figure 2**, tt-MA is part of the metabolic pathway through muconaldehyde, and more likely linked to some of the toxic effects of benzene. Theoretically tt-MA might therefore be expected to be more closely related to potential health effects of benzene. However, like phenol, tt-MA also has a background in nonexposed humans, possibly as a metabolite of sorbitol, a common food additive (Marrubini *et al*., 2002; Renner *et al*., 1999). This limits the use of tt-MA to detect exposures of up to approximately 0.5–1 ppm of benzene at the individual level. So far, no background for S-PMA has been found in nonexposed humans, which makes S-PMA suitable to assess benzene exposures also at the individual level (Boogaard and van Sittert, 1996; Aston *et al*., 2002; Pople *et al*., 2002). In addition, S-PMA has a two-times longer half-life in urine than tt-MA, which makes it a more reliable biomarker for intermittent exposures (Boogaard and van Sittert, 1995a). Several other urinary metabolites of benzene, such as 1,2,4-trihydroxybenzene, hydroquinone and catechol have been investigated as biomarkers for benzene exposure, but proved less sensitive and specific than tt-MA or S-PMA (Qu *et al*., 2000). Biochemical effect monitoring has also been developed for assessing exposures to benzene. Alb as well as Hb adducts of benzene oxide and benzoquinones have been investigated for this purpose (Waidyanatha *et al*., 1998; Yeowell-O'Connell

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat126
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

et al., 1998; Lindstrom *et al*., 1998). Unlike the biological monitoring methodology using S-PMA or tt-MA, which can be applied routinely, the biochemical effect monitoring of benzene using Alb or Hb is too sophisticated at the present time for routine applications.

For many electrophilic substances, however, biochemical effect monitoring is the method of choice. This applies in particular to genotoxic substances. Although for many genotoxic substances biological monitoring methods which apply urinary metabolites are available, the use of biochemical effect monitoring has several advantages (van Welie *et al*., 1992). In particular, the use of Hb adducts to assess exposure to epoxides (e.g. ethylene oxide) or epoxide-forming substances (e.g. 1,3-butadiene) and aromatic amines (e.g. aniline) has proven very sensitive and useful (Boogaard, 2002; Sepai and Sabbioni, 1996; Sabbioni and Beyerbach, 2000; Sabbioni and Jones, 2002; van Sittert *et al*., 2000a; Törnqvist *et al*., 2002; Richter and Branner, 2002). Biochemical effect monitoring is especially useful for the biomonitoring of genotoxic substances where adducts to the Hb molecule can be used as a surrogate for the DNA adducts in the target tissue. The benefits of Hb adduct assessment as an internal dose monitor for industrial exposures were first suggested in 1976 by Ehrenberg and co-workers (Ehrenberg *et al*., 1977; Osterman-Golkar *et al*., 1976; Segerback *et al*., 1978). In industrial settings genotoxic substances are generally well contained. As a consequence the exposures are usually at low and variable levels and occur intermittently, which makes personal air monitoring very difficult. Biochemical effect monitoring may overcome these problems because it allows integrating the exposure over longer time periods. This is especially the case with Hb adducts of smaller molecules such as ethylene or propylene oxide, which have apparent half-lives of approximately four months. Over the last few decades, the methodology has improved and is now routinely applied to a large number of substances (Törnqvist *et al*., 2002; Ball *et al*., 2004; 2005). Due to the specificity and high sensitivity of Hb adducts, they can also be applied for biomonitoring of low environmental exposures. Mathematical models have been developed which allow quantitative assessments of variable external exposures based on biomarker data (Granath *et al*., 1992; Fennell *et al*., 1992).

Due to its nonspecific nature, biological effect monitoring is in general more useful for research purposes than for health risk assessments, since it is usually difficult or even impossible to relate the observed effects with certainty to a specific exposure. Biological effect monitoring can, however, be extremely useful in situations with potential exposures to a variety of substances with the same effect, as for instance may occur in the area of crop protection. Both during manufacturing and application of organophosphates and carbamates workers may potentially be exposed to a variety of products over a period of days or weeks. The mechanism of action of both organophosphates and carbamates is the inhibition of insect cholinesterases. However, human cholinesterases are also inhibited to a significant but variable extent by these products, and determination of serum cholinesterase is routinely applied to effectively monitor exposure to pesticides for decades (Aitio, 1999; Anwar, 1997; Bellino *et al*., 1978; Cocker *et al*., 2002).

Toxicogenomics, proteomics and metabolomics have opened a whole new area of biomonitoring technologies which has yet to be fully explored. Metabolomics (also called metabonomics) is basically metabolic profiling and a form of biological effect monitoring where a large range of (endogeneous) compounds is determined in a biological specimen to define the response to some external challenge. Although metabolomics has proven useful as a tool in drug development and in basic research, its application in biomonitoring is as yet very limited due to its highly unspecific nature (Griffin, 2003; Griffin and Bollard, 2004; Robertson, 2005). Toxicogenomics and toxicoproteomics, the determination of gene and protein expression in response to exposure to a toxic substance, are biological effect monitoring. Although both promising tools, they cannot be used at the present time for exposure assessment, let alone risk assessment. This is mainly due to the fact that both gene and protein expression are highly dynamic, and to the fact that one often cannot differentiate between adaptive and adverse effects with the current knowledge. Extensive studies with known toxicants using multiple doses and many time points will be required to map out the response of the genome and proteome to a toxic challenge. However, the area is highly promising since it may detect effects at concentrations lower than the lowest-observed-effect levels for more traditional end points (Andersen *et al*., 2008; Daston, 2008; Navas-Acien and Guallar, 2008; Ghosh *et al*., 2008). This may make it feasible to investigate dose–response relationships, including the shape of the curve, at the low levels of exposure which may occur in environmental settings. In addition, toxicogenomics may provide a better understanding of the effects of genetic variability on toxicity.

5 INTERPRETATION OF BIOMONITORING DATA

In general, biomonitoring data are used to assess actual exposures with the ultimate goal of making an assessment of the health risks associated with that exposure. Biomonitoring integrates all routes of exposure and can therefore be used to follow up the fate of occupational or environmental substances in the human body and may provide insight into the relative contributions of different environmental compartments (e.g. air, food, water) and emission sources to body burden, provided the external

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

sources can be linked to internal exposure. In addition, biomonitoring allows the assessment of spatial and temporal differences in exposure and may therefore be used to assess the effectiveness of exposure-reduction strategies and policy decisions. Biomonitoring, especially biological effect monitoring, may provide early warning signals and be used in surveillance programmes. However, it should be born in mind that for proper interpretation of biomonitoring data, a number of factors are of paramount importance. These factors include (i) the quality of the analysis, (ii) basic understanding of the toxicokinetics of the compound under study, and (iii) basic knowledge of the dose–response curve. In addition, a weight-of-evidence approach is recommended, taking into account circumstantial evidence and additional knowledge about the compound. Only if sufficient information on these parameters is available, may quantitative reference or guidance values be derived.

5.1 Analytical Integrity

Analytical integrity of laboratory results, regardless of whether they are air measurements, food-basket analyses or biomonitoring, is crucial since they form the basis of any conclusion or action following from the results. It is beyond the scope of this chapter to address analytical integrity in detail, but like all laboratory assessments, biomonitoring analyses are potentially subject to various sources of errors. The first source relates to the preanalytical phase; that is, the phase of sample collection, sample treatment if required, sample storage and transport to the laboratory. Contamination of samples is a common problem and may be introduced at various points in the sampling procedure: from airborne dust, soiled surfaces and clothing, contaminated skin, sample vials, and so on. This is for instance illustrated by the biomonitoring of bisphenol A where contamination, resulting from leaching from plastic containers, may represent a serious problem, hampering interpretation of the biomonitoring results (Dekant and Volkel, 2008; Volkel *et al*., 2008). The contamination with metals and volatile organic solvents from collection vials is well known (Moyer *et al*., 1991; Streete and Flanagan, 1993). Usually, contamination is only a serious potential problem if the mother compound is measured, and less of a problem when a specific metabolite or adduct is measured. However, this is not always the case. A good example is the blood sampling for the determination of Hb adducts of ethylene oxide, where blood samples have to be collected in γ-radiation-sterilized tubes. Blood collected in tubes sterilized with ethylene oxide displays huge background values of Hb adducts, as traces of ethylene oxide absorbed to the glass may react after collection with the Hb in the erythrocytes (Boogaard, 2002).

For many industrial chemicals and occupational settings, optimal conditions for the preanalytical phase, such as selection of suitable specimen containers and the storage conditions under which the analyte is stable in the specimen, have been established. This information should be available as standard operating procedures at the sample collection site as well as in the analysing laboratory. For several biomarkers, standard operating procedures have been published that address the preanalytical phase (e.g. the methods series by DFG mentioned above and by the WHO (DFG, 2006; WHO, 1996b)). Other sources of error relate to the analytical phase itself. These are related to equipment, materials and training of personnel, and can be minimized by using standard operating procedures. General procedures are available for a wide variety of substances (see **Tables 1** and **2**), which can serve as the basis for standard operating procedures. As for all analytical chemistry, quality control is of utmost importance also for the analytical phase in biomonitoring, especially external quality control, which is available for a variety of substances (Schaller *et al*., 2001; 2002).

Whereas biomonitoring in occupational settings is well established, environmental biomonitoring is still developing. However, most of the lessons learned from occupational biomonitoring are also valid in the environmental field. The most important challenge is the validation of the methodologies with ever increasingly lower detection limits and concomitant greater risk of contamination.

5.2 Toxicokinetics

The main goal of biomonitoring is usually to assess exposure. In biomonitoring, individuals serve as their own dose monitors integrating all routes of exposure (oral, dermal, inhalatory), and reflecting physiological variation (including variations in workload). However, the data represent a snapshot of the presence of the substance under study in the body and, unless something is known about the toxicokinetics of this substance, the data cannot be explained in terms of exposure, let alone risk characterization. The toxicokinetics of a substance comprise its absorption, distribution, metabolism and excretion. As stated above, biomonitoring has a unique feature over other exposure monitoring techniques in that it integrates all routes of exposure, and biomonitoring accounts also for interindividual variations in toxicokinetics. In occupational settings the typical exposure routes, usually inhalation and skin contact, are often known. In environmental settings, however, the exposure routes are mostly more variable and may include, in addition to breathing and dermal contamination, also the intake via foodstuffs and drinks. In addition, dermal contact may be more extensive

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

than in occupational settings (e.g. bathing and swimming). For most substances, details on absorption and distribution for the various exposure routes are not readily available. For substances with a systemic effect, this is not necessarily problematic if the aim is to characterize the overall exposure or risk. However, the impossibility of disentangling routes of exposure may hamper the evaluation of exposure sources and exposure controls.

Many substances are not biomonitored as such, but as a metabolite or reaction product with some endogenous macromolecule (e.g. protein or DNA). Using the metabolite or reaction products may increase the sensitivity and specificity. For example, 1,3-butadiene, an industrial chemical used for the production of rubbers but also a constituent of cigarette smoke, may be metabolized to several different epoxides. These epoxide metabolites form different mercapturic acids which are excreted into the urine, and also different adducts with Hb and DNA (Boogaard *et al*., 2004; Richardson *et al*., 1998; 1999; 1996; Powley *et al*., 2005). Both the urinary metabolites and the adducts can be used as biomarkers of exposure in risk assessment and were proven more reliable than personal air monitoring (Albertini *et al*., 2003; 2001; 2007; van Sittert *et al*., 2000b; Begemann *et al*., 2001; Hayes *et al*., 2001; Swenberg *et al*., 2001). On the contrary, metabolism may also pose problems if the biomarker can also be formed endogenously or from dietary components, and also when different substances can be metabolized to the same adduct or metabolite. As discussed previously, background levels due to dietary intake prevent the use of phenol and tt-MA as reliable biomarkers for benzene exposure at low exposure levels. For low-level exposures, such as might occur in environmental settings, the parent compound in urine, air or blood might therefore be a more reliable biomarker (Manini *et al*., 2008; Crebelli *et al*., 2001; Fustinoni *et al*., 1995). An other example is *N*-2-hydroxyethylvaline, one of the most commonly measured Hb adducts, and a biomarker for both ethylene oxide and ethylene (Csanády *et al*., 2000; Pauwels and Veulemans, 1998; Walker *et al*., 2000). In industrial settings, this is usually not a problem, since normally it would be known whether exposure to ethylene or to ethylene oxide could occur. In addition, the amount of *N*-2-hydroxyethylvaline formed from ethylene oxide is several orders of magnitude higher than from the same concentration of ethylene. However, in environmental settings the interpretation of *N*-2-hydroxyethylvaline levels may be less straightforward as to its source, because the adduct may be formed from ethylene oxide, for instance from cigarette smoke, or from ethylene, which is a plant hormone and present in fruits, and may also be formed by bacteria in the gut (Törnqvist *et al*., 1989; 1986). An example of interpretation problems that may arise where different compounds are metabolized to the same metabolite is that both n-hexane and 2-hexanone are excreted as 2,5-hexanedione in the urine (Prieto *et al*., 2003; Cardona *et al*., 1993). If confusion could exist about the source of the biomarker, again determination of the parent compound in exhaled air might be the preferable approach (Hamelin *et al*., 2004; Periago *et al*., 1993).

Another important toxicokinetic issue related to metabolism and excretion is the apparent half-life of a biomarker. In general terms, parent compounds in blood, urine or exhaled air have very short half-lives (minutes to hours), urinary metabolites have longer but still relatively short half-lives (hours to days), whereas DNA adducts and Alb adducts have long half-lives (days to weeks) and Hb adducts have very long half-lives (weeks to months) (Henderson *et al*., 1989). There are notable exceptions to these general rules especially after prolonged (environmental) exposures. In particular, heavy-metal biomarkers, such as lead in blood or urinary cadmium, may have very long apparent half-lives as they are stored in bone and renal tissue, respectively, from which they are only very slowly released (Philip and Gerson, 1994; Jin *et al*., 1998; Lauwerys *et al*., 1993; 1994; Sartor *et al*., 1992; Staessen *et al*., 1996). Also many highly lipophilic compounds, such as organochlorine insecticides, may have long biological half-lives since they are stored in adipose tissue and only slowly released in an equilibrium between the blood and the fatty tissues (Hunter and Robinson, 1967; Hunter *et al*., 1969). Substances may also be deposited in hair and nails and be present for measurement for long periods of time. For DNA adducts, the stability is highly dependent on the nature and the chemical structure of the adduct (Farmer and Singh, 2008). For instance *N*7-guanine adducts tend to be labile and have half-lives of only a few days due to depurination, whereas O^6-adenine adducts are more stable. Hb adducts theoretically have half-lives of about 126 days, the average lifetime of the erythrocyte before it is taken up in the spleen, and following accidental exposure of a number of individuals to high levels of ethylene oxide, indeed half-lives ranging from 120 to 130 days were found (Tates *et al*., 1995). The half-lives of Hb adducts, however, may be considerably shorter if bulky adducts or adducts with highly polar groups are formed, which is likely due to altered configuration of the Hb chains and subsequent malformation of the erythrocytes which are then more rapidly removed from the circulation (Boogaard *et al*., 1994a; 1994b).

5.3 Dose Response

Biomonitoring data indicate the mere presence of a chemical or its effect in the body. To make any attempt to characterize the health risk associated with this presence, some form of dose–response relationship is required. Usually, the first evaluations of an adverse

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

health effect are based on animal data obtained from toxicological studies or from human experience resulting from accidental exposures or epidemiological evidence. An inherent problem of toxicological studies is that to observe adverse effects in experimental animals, usually very high doses are needed compared to the exposures that may occur in humans. Unfortunately, dose–response relationships at low-dose ranges relevant for the human population are generally lacking. Since at high exposure rates deviations from normal metabolism, for instance due to saturation of certain pathways, may occur, it is of paramount importance for an appropriate risk assessment that the underlying toxicological mechanisms or mode-of-action are known. Epidemiological data play a crucial role here but are often underestimated, especially when the results are negative (ECETOC, 2004).

The present analytical capabilities make it feasible to collect vast amounts of biomonitoring data in human populations (Koppen *et al*., 2007; Staessen *et al*., 2001; Denham *et al*., 2005; Schell *et al*., 2008). Although such studies may be very powerful in delineating health risks associated with (environmental) exposures, they suffer from an inherent risk of statistical chance findings. As a consequence, it is imperative that biomarker studies are hypothesis driven. The hypothesis of a causal relationship between the biomarkers and observed health effects should be based on epidemiology, animal data, or an understanding of the mode of action of a substance, and be well defined in advance, prior to the initiation of the study. Moreover, appropriate, predefined statistical methods need to be applied to the data gathered to evaluate the significance of the findings (IPCS, 2001; Boogaard and Money, 2008).

An additional problem in the interpretation of exposure data in terms of health risks, regardless of whether they are externally measured through personal air monitoring or food-basket analyses or through biomonitoring, is the interpersonal and intrapersonal variability (Symanski *et al*., 2006). This variability may hamper health risk assessment on an individual level (Cocker *et al*., 2006), but on a group level, for instance for epidemiological studies, biomarker data may provide more reliable information on exposure than air monitoring data (Lin *et al*., 2005).

5.4 Weight of Evidence

As stated above, the evaluation of causal relationships between exposures and a specific effect is highly complex. In most cases it requires the integration of data from several studies differing in terms of experimental design and parameters studied. Moreover, since often large numbers of parameters are assessed, there is a substantial risk of finding false positive associations. It is recommended to apply the criteria originally developed by Hill, and further refined for biomarker studies by Vineis and Porta, to establish whether or not an association between exposure and effect is likely to be causal (Hill, 1965; Vineis and Porta, 1996). This approach links in with the weight-of-evidence approach, which basically checks the biological plausibility and consistency for a specific hypothesis or dataset. The plausibility check may include an evaluation of the mode of action to see whether the presumed relationship can be biologically explained (Boobis *et al*., 2006; Williams, 2008). The consistency check aims to resolve contrasting findings in the literature which may be due to differences in study design, but may also be an indication that other factors than those addressed in the study have an influence on the results. If the plausibility or consistency is weak for a certain hypothesis, regardless of whether it is in favour or against, further study is required and alternative hypotheses should be evaluated.

5.5 Quantitative Interpretation

Probably the most fundamental principle of risk assessment is that adverse health effects are related to dose and, consequently, to levels and duration of exposure. In the domain of occupational biomonitoring, BLVs have been established for a number of substances. The criteria used to set BLVs may differ from one country or agency to another as well as from one substance to another (Morgan and Schaller, 1999). In many cases, these limit values correspond to an occupational limit value for airborne substances because they are based on a correlation between biomonitoring values and personal air monitoring data. These personal air monitoring data are, in turn, related to an understanding or estimation of the level of exposure associated with adverse health effects. These adverse health effects may be based either on actual data obtained from human exposure or, more and more frequently, on extrapolation from data obtained in animal experiments.

Among the most widely used BLVs are the biological tolerance values (Biologische Arbeitsstoff Toleranz-Werte, BAT values) as introduced by the Deutsche Forschungsgemeinschaft (German Research Foundation, DFG) (DFG, 2007) in 1979, and the biological exposure indices (BEI®) as published annually by the American Conference of Governmental Industrial Hygienists (ACGIH, 2008) since 1981. BAT values are by definition human-health based, and originally defined as 'the maximum permissible quantity of chemical substance, its metabolite, or any deviation from the norm of biological parameters induced by these substances in human beings' (Lehnert, 1980). The values published by the DFG since 1981 are therefore in fact ceiling values. In general, according to the scientific knowledge at present,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat126
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

exposures leading to the BAT value do not impair the health of workers, even in the case of prolonged or repeated exposures. BAT values are intended for workers, which implicitly assumes an exposure of maximally 8 hours per day or 40 hours per week for a maximum of 40 years (working life). BAT values may, however, be applied without a correction factor to other working patterns or working hours (DFG, 2007). The fact that some biological changes may be observed at exposures leading to the BAT value implies that not every variation in a biological parameter is viewed as an illness or adverse health effect. Recently, the DFG has therefore revised the concept of BAT values to describe 'the concentration of a chemical substance, of its metabolites or an effect indicator of an appropriate biological material derived by occupational medical and toxicological criteria, at which the health of an employee is usually not affected, even after repeated or long-term exposure' (Drexler *et al*., 2008). This brings the BAT values in line with the BEI® values and current scientific knowledge, assuming that changes in biological parameters are adaptive and tolerable, and that even after long-term exposure, if they are reversible, do not lead to disruption of function or the ability to compensate for effects of the exposure, do not increase the sensitivity of an individual to other external agents, and do not affect reproduction (Morgan and Schaller, 1999). Since these criteria do not apply to genotoxic substances or proven carcinogens, the DFG cannot derive BAT values for such substances. For these substances a range of values, the so-called EKA values (Exposure Equivalent for Carcinogenic Substances) are developed that reflect the biomonitoring concentration that would be observed at a corresponding range of external (airborne) exposures. In **Table 1**, EKA values are listed for concentrations that correspond closely to the threshold limit value (TLV®) of the substance where possible (the concentration chosen is listed in the footnotes).

In contrast to BAT or EKA values, BEI® values reflect the internal dose or dose surrogate arising from exposure, by inhalation only, to the TLV®. As the BEI® would of course also reflect exposure via other routes than inhalation, the underlying assumption in these cases is that any health effect is related to the internal dose irrespective of the route of exposure. In most cases this is a valid assumption. However, it should be borne in mind that, in principle, the same criteria as are used for establishing a TLV® are also applied in the setting of a BEI®. This implies that, just like for TLV® values, there is no sharp distinction between hazardous and nonhazardous exposures due to biological variabilities and, consequently, that there is not necessarily an increased health risk for an individual for whom the BEI® is exceeded. In addition, the American Conference of Governmental Industrial Hygienists (ACGIH) has recognized that for certain chemicals for which the TLV® is not based on a systemic effect but rather on local effects, such as irritation, a BEI® corresponding to such a TLV® would be less meaningful. Nevertheless, BEI® values may be derived for such chemicals to prevent systemic effects, especially when the skin is a significant route of exposure. In those cases, the BEI® does not reflect the TLV® but indicates the internal dose at which no health hazard is expected. For a limited number of substances a BEI® has been established based directly on the relationship between the internal dose and a systemic adverse health effect.

In principle, the biological limit values such as the BAT, EKA and BEI® are limited to the occupational situation. Thus far, only a limited number of health-based BLVs have been established for the general population. Some of these include the reference and guidance values for heavy metals and persistent organic pollutants established by the German Human Biomonitoring Commission (Ewers *et al*., 1999; Wilhelm *et al*., 2003; 2004). The interpretation of biomonitoring data for health risk assessment for the general population is more challenging than for occupational populations since the exposure levels are usually much lower than the exposure levels that may be present in occupational settings and usually several orders of magnitude lower than the no-adverse-effect levels (NOAELs) in animal experiments. An additional complicating factor resides in the fact that the general population is much less homogeneous than occupational populations, because it comprises individuals with greater variability in age (infants, children, elderly) and health status (Boogaard *et al*., 2005; Burke *et al*., 2006). To aid in the interpretation of human biomonitoring data, the concept of Biomonitoring Equivalent (BE) was recently developed (Hays *et al*., 2007). BE values represent quantitative benchmarks of safe or acceptable concentrations of biomarkers which are consistent with selected reference values based on the understanding of the toxicokinetics of the substance. For many substances useful reference levels have been established by a variety of regulatory bodies such as the European Food Safety Authority (EFSA), the Joint Food and Agriculture Organization (FAO)/WHO Expert Committee on Food Additives (JECFA) and the US Environmental Protection Agency (EPA). These organizations establish reference values which represent safe, acceptable or tolerable intake levels, such as reference dose (RfD) and reference concentration (RfC), acceptable daily intake (ADI) or tolerable daily intake (TDI), or minimal risk level (MRL). These values are based on epidemiology and/or animal studies and are considered to represent a safe exposure level for the general population. In essence, the BE translates such a reference value into a biomarker concentration (Hays *et al*., 2008a). This conversion can be done with greater or lesser reliability based on the available scientific information, and a communication system has been proposed to communicate the results to the general public (LaKind *et al*., 2008). BE values have been developed for a number of substances such

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

as the heavy metal, cadmium (Hays *et al*., 2008b), the volatile organic solvent, toluene (Aylward *et al*., 2008a), acrylamide (Hays and Aylward, 2008), the pesticide, 2,4-dichlorophenoxyacetic acid (2,4-D) (Aylward and Hayes, 2008) and trihalomethanes (Aylward *et al*., 2008b). Applying the BE concept to large biomonitoring datasets such as obtained in the NHANES (CDC, 2009) demonstrated its usefulness in the priority setting for risk assessment follow-up.

Derivation of BE values may also be useful under REACH (Registration, Evaluation and Authorization of Chemicals), the European chemicals legislation, that was adopted at the end of 2006 (European Parliament and Council, 2006) and will gradually be applied to all chemical substances manufactured in or imported into the European Union. Under REACH, the concept of derived no-effect level (DNEL) was introduced. In principle, a DNEL needs to be derived for each relevant toxicological end point and each relevant route of exposure. The risk to human health is considered negligible if the actual exposure is less than the DNEL. Biomonitoring may be applied to assess the exposure under REACH and may have great benefits over other exposure assessment methodology to demonstrate that the actual exposure is below the DNEL. This is particularly the case since DNELs may be derived not only for workers but also for the general population, both as 'consumers' and as 'individuals indirectly exposed via the environment'. For industrial settings, OEL values—such as TLV®, permissible exposure limits (PELs) and maximum accepted concentrations (MACs)—serve as reference values. OELs may also serve as DNELs, provided they are health based and derived by recognized experts, such as the EU Scientific Committee on Occupational Standards. Applying the same principles, BEs may be derived for OELs as well, and subsequently serve as DNELs. This is very advantageous for all occupational scenarios where inhalation is not the route of exposure or not the only route of exposure. If biomonitoring results indicate that the levels of exposure are below the BE, and hence below the corresponding DNEL, it would indicate that the combined exposure via all potential exposure routes poses no human health risk. Acceptance of the use of BEs in combination with biomonitoring by regulatory authorities will not only make repetitious assessments for different exposure scenarios superfluous, but will also provide a more accurate estimate of actual exposure and hence lead to improved risk management.

6 ETHICAL ASPECTS AND CONSIDERATIONS

Biomonitoring generates data describing the exposure of an individual to certain substances. These data may be used to limit or prevent exposure in occupational settings and for health risk assessment and policy measures in environmental settings, and are consequently linked to ethical questions. It is beyond the scope of this chapter to focus on ethical considerations in detail, but a number of essential issues will be addressed here, including the nature and organization of the study, informed consent and confidentiality, and communication and interpretation of the results.

The primary ethical requirement for any biomonitoring study is a valid scientific approach. Although several issues are identical with regard to ethical aspects, it is useful to differentiate here between survey projects and research projects. Survey projects focus on periodic measurements to produce information on the prevalence of exposure to substances, whereas research projects aim at the generation or the improvement of knowledge on causal links between exposure and health effects by generation and testing of hypotheses (Knudsen, 2004). In occupational settings the vast majority of biomonitoring relates to survey projects, which includes medical health surveillance when biological effect monitoring is conducted. Occupational biomonitoring surveys are a long-standing practice, and ethical aspects are well developed. In general, a biomonitoring method must be chosen for its validity and relevance for protection of the health of the worker concerned, with due regard to its sensitivity, specificity and predictive value. As discussed, for many relevant substances biological limit values have been established that allow the proper selection of biomarkers for survey purposes. In environmental settings, where generally exposure levels are low, only a very limited number of biomonitoring methods are available that allow interpretation in terms of health risks. The classic example is lead in blood, for which guidance and limit values have been well-established and incorporated in European law (CEC, 1982).

For any study, regardless of whether it is a survey or a research project, the selection of the population under study, with well-defined inclusion and exclusion criteria, is essential, and a risk–benefit analysis (including choice of specimen) on individual and/or group level should be part of the study design. These aspects may be fairly straightforward in the case of occupational biomonitoring using well-validated biomarkers with established BLVs or reference values, as there would be no fundamental difference from personal air monitoring. However, for research studies where the validity and/or toxicological significance of the biomarkers used is less certain, ethical requirements and procedures are more stringent, and a thorough assessment by, and approval of, a competent ethical review board may be required, regardless of whether it involves an occupational setting or the general population.

Informed consent is an essential ethical requirement for research projects involving invasive procedures or not-yet-validated biomarkers. Special attention should be given to minors involved, as in mother–child studies,

where the subjects may be not (fully) aware of the risk–benefit ratio. In all cases, clear and adequate information on the uncertainties, risks and potential benefits (either on the personal or group level) of the testing should be provided. This information should at a minimum comprise the aim of the testing and the interpretation of the possible results, including potential actions in terms of risk management, communication and publication, the sample collection procedures, the confidentiality of the data collected, and the right to withdraw at any time from the study without explanation. It is essential that informed consent is obtained by a trained professional and that it is checked whether or not the provided information is correctly understood. In general, biomonitoring data should be treated confidentially. In occupational situations the results should in principle not be treated differently from other personal occupational health data obtained (including personal air monitoring data), for which procedures are usually established. Individuals, or their legal representatives, should have the right to know their individual biomonitoring results but should also have, if they so wish, the right to not know their data. Communication of the results and their interpretation in terms of health risks is of paramount importance. The potentials and limitations of the interpretation of biomarker data, both on an individual and on a group level, are often not well understood. Moreover, the perception of the advantages and limitations of biomarker studies often differs between the investigators and the subjects as well as between health professionals (Viau, 2005). Guidance on clear communication of biomonitoring data can be found elsewhere (LaKind *et al*., 2008; Keune *et al*., 2008).

The Role of Poison Centres in Basic and Clinical Toxicology

Alan H. Hall and Chantal Bismuth

CONTENTS

1 INTRODUCTION

1.1 Poison Centre Functions

Poisoning is a significant global health problem. For example, in 2002, an estimated 3 50 000 persons died throughout the world from unintentional poisoning. In the USA, '911' emergency telephone calls can safely and cost-effectively be diverted to Poison Centres (Anderson *et al*., 1998).

Poison Centre involvement and assistance are correlated with measurable reductions in length of hospital stays for poisoned patients, and result in substantial savings in healthcare costs and resource utilization (Vassilev and Marcus, 2007). Utilization of Poison Centres is cost effective in decreasing the number of poisoning admissions to rural hospitals (Zaloshnja *et al*., 2006).

Poison Centres are an information resource for prehospital emergency responders for chemical exposures, and participate in international alerting and surveillance for toxic terrorism (Martin-Gill *et al*., 2007; Waring *et al*., 2007). Poison Centre data can be used to develop treatment protocols and policies (Bateman, 2005a). Poison Centres have a role in protecting public health and in global risk assessment (Mathieu-Nolf, 2005), and data collected by Poison Centres can proceed from clinical practice to promoting public health (Bateman, 2005b). Poison Centres can respond to 'surges' of calls when neighbouring Centres are affected by communications failures or during widespread power outages (Vassilev *et al*., 2007; Klein *et al*., 2007) (see **Table 1**).

In the USA, non-English speakers are less likely to utilize Poison Centre services (Shepherd *et al*., 2004), although 24 hours a day, 7 days a week consultations in Spanish are available from the West Texas Poison Center in El Paso, Texas.

Table 1 Poison Centre activities, besides providing substance and ingredient identification information and making recommendations for patient decontamination and treatment, can include:

Coordination of:
Regional antidote availability
Data Collection on/for:
Adverse events involving dietary supplements
Drug abuse trends
Hazardous materials (HAZMAT) incidents
Human experience data for risk-assessment priority setting
Infant therapeutic misadventures
International differences in toxic exposure patterns and poisoning trends over time
National epidemiological information on poisonings
Poisoning information for particularly sensitive populations, such as children and the elderly
Reflecting storm-related health hazards during hurricane seasons
Developing:
Exposure profiles for drug poisoning in children
Profiles of childhood poisoning
Structured triage protocols for paediatric poisonings
Surveillance for emerging toxic threats
Toxicological features of deliberate self-poisoning
Treatment protocols and policies
Identification of bystander pesticides exposures:
Crop dusting
Other exposure routes
Planning for:
Mass gatherings, such as the Olympic Games
Developing integrated surveillance systems for mass gatherings, such as the Olympic Games
Providing:
Drug identification services to law enforcement personnel
Environmental information
Information and consultation services during hazardous materials (HAZMAT) incidents
Information services during infectious disease outbreaks, such as the severe acute respiratory syndrome (SARS)
Poison education and Poison Centre awareness training
Public announcements on treatment errors and omissions in drug manufacturers' overdose management recommendations
Responding to:
Animal poisonings
Toxicovigilance:
Developing profiles of poisoning by country
Drug abuse/prescription-drug diversion surveillance
Early detection of poisonings with public health significance
Elucidating the varying spectrum of pesticide poisonings
Food-borne illness surveillance
Generating alerts on adverse drug events and other products of public health interest, such as contaminated foodstuffs and product recalls
Hazard identification
Longitudinal surveys of childhood poisonings
Participating in international alerting and surveillance for toxic terrorism
Pesticide-related illness and injury surveillance
Toxicant assessment in humans

(Alonzo and Laborde, 2005; Bateman, 2005a; Bentur *et al*., 2004; Bochner, 2007; Bronstein *et al*., 2007; Bryden *et al*., 2005; Burgess *et al*., 1997; Cicero *et al*., 2007; Coco *et al*., 2005; Crouch *et al*., (2004a; 2004b); Dennehy *et al*., 2005; Derby *et al*., 2005; Descotes and Testud, 2005; Dyer *et al*., 2007; Forrester, 2006; Forrester and Stanley, 2004b; Geller and Lopez, 1999; Izuora and Adeoye, 2001; Kearney *et al*., 2007; Kotwica and Czerczak, 2007; Mallows *et al*., 2005; Martin-Gill *et al*., 2007; Mazzoleni *et al*., 2006; Mehler *et al*., 2006; Mena *et al*., 2004; Mirza *et al*., 2006; MMWR, 2006; Mucci *et al*., 2006; Rutkowski, 2006; Settimi *et al*., 2007; Srivastava *et al*., 2005; Szkolnicka *et al*., 2005; von Mach *et al*., 2006; Wananukul *et al*., 2007; Waring *et al*., 2007; Wolkin *et al*., 2006; Wu and Sun, 2004).

2 HISTORY OF THE POISON CENTRE MOVEMENT

2.1 USA

The history of poisons goes back to biblical times. Moses, in Deuteronomy 14: 9–10, describes what marine life can safely be eaten (Shannon and Haddad, 1998). Going from there to Mithridates, King of Pontus who attempted to develop antidotes, to Paracelcus in the sixteenth century who, while studying such potential therapeutic compounds as antimonials and arsenicals, noted that: 'All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy.' (Shannon and Haddad, 1998).

The first meeting of the American Association of Poison Control Centers (AAPCC) was held in Chicago on 21 October, 1958, following an early 1950s study by the Accident Prevention Committee of the American Academy of Pediatrics (AAP), who found that 50% of reported childhood accidents involved some type of poisoning (Arena, 1970; Crotty and Verhulst, 1970; Shannon and Haddad, 1998). As of July, 1967, there were 550 Poison Control Centres in the USA, one or more in each of the States (Arena, 1970). In 1956, a grant was obtained from Plough, Inc. (Memphis, Tennessee) to study 14 different types of safety closures for drug containers, specifically for children's aspirin preparations, which were then responsible for almost 25% of all reported poison exposures (Arena, 1970). The results of this study were published in 1959 (Arena, 1970).

The Poison Centre movement was mainly spearheaded by paediatricians in the USA (Arena, 1970; Dart, 2004). Poison Centres were also founded in the UK, Canada, France, Germany and Italy as early as the 1960s (Dart, 2004). By 1970, there were nearly 600 Poison Centres in the USA and over 800 Centres in the USA and Canada combined (Lovejoy and Alpert, 1970). There were great variations from Centre to Centre in the size of the population served, the number of telephone calls handled, and the quality and quantity of services offered (Lovejoy and Alpert, 1970).

Prior to the 1950s, there was no formal system for poison information or treatment advice in existence in the USA (Burda and Burda, 1997). The first Poison Centre in the USA was founded in November, 1953 at Presbyterian-St. Luke's Hospital in Chicago, Illinois (Burda and Burda, 1997; Kostic *et al*., 2005). This was followed by the founding of the US Food and Drug Administration's (FDA's) National Clearinghouse for Poison Control Centers in 1957, and the AAPCC in 1958 (Burda and Burda, 1997; Cann, 1958). The National Clearinghouse contacted manufacturers and distributors for ingredient and concentration information for their products (Cann, 1958). During the 1960s to 1970s, hundreds of Poison Control Centres were created by hospitals in the USA (Kostic *et al*., 2005).

A 1998 survey of all 73 Poison Centres in the USA, which included 52 Certified Regional Poison Centres, showed that call volume had been steadily increasing, with 2 475 010 calls regarding poison exposure answered in 1997 (Youniss *et al*., 2000). The average Poison Centre utilization rate was 9.2 human poison exposures per 1000 population, and the cost was less compared with the alternative, emergency-department patient management (Youniss *et al*., 2000).

2.1.1 Poison Centres and Emergency Departments

In the USA in the 1980s, there was some debate over whether the availability of telephone poison information by Poison Centres was diverting patients away from emergency departments, or whether, in fact, this service was saving money by managing patients in the home setting who did not require evaluation in a health-care facility. In an editorial in the *Annals of Emergency Medicine*, Rumack and Rosen (1982) noted that one polarized opinion in this debate was that *all* patients exposed to a toxic substance should be evaluated by a physician. The opposing view was that 85% of children exposed to a toxic substance could be adequately managed over the telephone without being evaluated by a physician or in hospital, with subsequent cost savings.

Rumack and Rosen (1982) also noted that about 60% of telephone calls to major Poison Centres involved children of aged two years or less, and that the exposures consisted of a taste or a touch and never developed into any significant clinical condition. From one major US Poison Centre, data showed that over a 10-year period, Poison Centre referrals to emergency departments had shown a large increase. It was therefore *not* that Poison Centres' telephone advice was producing inappropriate patient management or removing patients from the emergency department. Rather, Poison Centre telephone advice was decreasing the numbers of young children unnecessarily brought for emergency department evaluation while simultaneously increasing the number of patients with potentially significant poisoning referred to emergency departments (Rumack and Rosen, 1982).

2.1.2 Institute of Medicine Report

An Institute of Medicine report commissioned by the US Health Resources and Services Administration (HRSA), published in 2004 (IOM, 2004) recommended that all Poison Centres should perform a defined set of core activities: telephone consultation; chemical and biological terrorism preparedness; capturing and reporting exposure data; training staff, physicians and pharmacists; and conducting quality-improvement activities. They should also collaborate with state and local health departments to

develop, disseminate and evaluate public and professional educational activities.

2.2 UK and Europe

It is difficult to determine exactly when the first Poison Centre was established in Europe (Govaerts, 1970). There was a special hospital ward devoted to clinical toxicology as early as 1949 in Budapest, and a limited poisons information service was established at the General Infirmary Hospital in Leeds, UK about the same time. The UK National Poisons Information Service was founded in 1963. Gaultier's emergency service was established in Paris in 1959, and special hospital wards for the treatment of poisoning were established quite early in Budapest, Copenhagen, Edinburgh and Paris.

In the UK, a comprehensive National Poisons Information Service was inaugurated in 1963 with a principal Centre in London at Guy's Hospital and other Centres in Edinburgh, Cardiff and Belfast (Goulding, 1991; Turner, 1991). In 1967, an analytical laboratory was established at New Cross Hospital in London, and the aggregate named the Poisons Unit (Turner, 1991). Since that time, additional services have included information and treatment recommendations for the adverse effects of toxic substances in humans and animals with dedicated expertise from several disciplines, as well as planned programmes of research (Turner, 1991). Goulding (1991) also noted that in addition to acute poisonings, Poisons Units or perhaps Academic Clinical Toxicology Units, must deal with the diversity of poisoning, including chronic poisoning, occupational poisoning, forensic toxicology, chemical disasters and exotoxicology.

The European Association of Poison Control Centres was founded in Tours, France in 1964 and a European conference on poison control under the auspices of the World Health Organization's (WHO's) Regional Bureau in Europe was held in Istanbul in 1965, where several experts helped develop the concepts for organizing Poisons Centres (Govaerts, 1970). In June, 1969, the foundations for a world association for poisoning services were established in New York City (the World Federation of Associations of Poison Control Centres and Clinical Toxicology Centres) (Govaerts, 1970).

As of 1970, Govaerts (1970) noted that there were poison control programmes or clinical toxicology treatment programmes of one sort or another in 20 European countries (**Table 2**) (Govaerts, 1970).

Table 2 European countries with poison control programmes or clinical toxicology treatment programmes of one sort or another as of 1970

Belgium
Bulgaria
Denmark
France
Finland
German Democratic Republic (as it was in 1970)
German Federal Republic (as it was in 1970)
Great Britain (United Kingdom)
Holland (the Netherlands)
Hungary
Ireland
Italy
Norway
Poland
Portugal
Spain
Sweden
Switzerland
Yugoslavia (as it was in 1970)
Soviet Union (as it was in 1970)

2.2.1 EAPCCT

It has already been noted that the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) was founded in 1964 in Tours in France (Perrson, 1992). According to its constitution, the object of the EAPCCT is 'the study, in Europe and within the context of Europe as defined by the European Office of the WHO, of problems relating to all forms of poisoning'. The association holds regular scientific congresses, some of which have been in cooperation with the International Programme on Chemical Safety (IPCS) and the Commission of the European Communities (CEC). The EAPCCT has also fostered collaboration between individual Poisons Centres by such means as regular newsletters, toxic alerts, and computer and telefax connections, recognizing that there is mutual benefit to member Centres in routine daily work (Perrson, 1992).

The EAPCCT provides advice and information to governments and government departments, as well as to industry and professional organizations, on issues involving toxicology (Perrson, 1992). The Association has promoted development of clinical toxicology as a medical discipline in its own right, and has promoted the development of technology for data storage and retrieval. It has increasingly collaborated with other international organizations such as the WHO, the IPCS, the World Federation of Clinical Toxicology Centres and Poison Control Centres, and the International Union of Toxicology (IUTOX) (Perrson, 1992).

2.3 Role of the IPCS

The International Programme on Chemical Safety (IPCS) is a cooperative programme of the International Labour

Organization (ILO), the United Nations Environment Programme, and the WHO, established in 1980 for the purpose of responding to the needs of member states for ensuring that essential chemicals are used in such a way that they do not harm human health or the environment (Haines, 1992). IPCS activities have been undertaken jointly with the CEC and in conjunction with relevant professional associations such as the World Federation of Associations of Clinical Toxicology Centres and Poison Control Centres, the EAPCCT, the Latin American Society of Toxicology, and the International Society on Toxicology.

A meeting was held at WHO headquarters in Geneva in October 1985 and identified priority areas requiring international cooperation in the poison-control field, which included a need for provision of internationally evaluated poison information (Haines, 1992). To this end, the IPCS began preparation of a poison information package called INTOX. Poison Information Monographs (PIMs) on about 500 substances were being prepared in English, French and Spanish, beginning about 1988, and were to be supplied on CD-ROM in collaboration with the Canadian Centre for Occupational Health and Safety (CCOHS) and the Centre de Toxicologie du Québec (QTC). Some financial assistance was provided by the International Development Research Centre of Canada (IDRC). By 1992, about 80 PIMs were being put on a CD, with plans to produce another 60–80 PIMs per year over the following five years (Haines, 1992). Part of this programme will allow international data collection for validation of treatment recommendations for more rare poisonings where no one Centre or country can collect enough cases for meaningful interpretation, and for validation of chemical risk assessments based on nonhuman data (Haines, 1996).

2.4 Developing Countries

Poison Centres have multiple roles in developing countries, which include toxicology information services, training, access to laboratory services, and antidote availability (Laborde, 2004; Clarke, 2004). They may concentrate efforts on childhood and pesticide poisonings (Gupta *et al*., 2003).

2.5 Poison Centres and Standards Setting

Poison Centres organizations, such as the EAPCCT, have established activities that member Centres must carry out, and have developed minimum and maximum required standards (Della Puppa *et al*., 2006).

3 POISON CENTRE DATA COLLECTION

3.1 USA TESS/NPDS

In the USA, the name of the AAPCC national database has been changed; formerly the Toxic Exposure Surveillance System (TESS), it is now called the National Poison Data System (NPDS). The most recently published version available is for 2006 (Bronstein *et al*., 2007).

Of the 61 reporting Poison Centres, 60 now submit data electronically every 1–60 minutes, making it a real-time national surveillance system (Bronstein *et al*., 2007). In 2006, there were over 4 million calls to reporting Poison Centres recorded, including 2 403 539 human poison exposure calls. There were 1229 human poison-related fatalities reported to the NPDS in 2006. The large majority of human poison exposures were acute cases in 2006 (91.2%), and of total human poison exposures, 83.4% were accidental while 8.3% were of suicidal intent.

Since its inception in 1983, over 43 million poison exposure calls have been captured in the TESS/NPDS database. In 2006, the average daily call volume at US Poison Centres was 6937.

In 2006, the majority of cases (72.9%) were managed over the telephone and the patients were not referred to a healthcare facility/provider (Bronstein *et al*., 2007). Follow-up calls are an important part of Poison-Centre patient management. When a patient is referred to a healthcare facility/provider, telephone follow-up is done until the case has been resolved. In 2006, one follow-up call was made in 22.4% of human exposure cases, and more than one follow-up call was made in 22.0% of cases (range: 2–158).

It is noted that patients may be taken directly to a healthcare facility/provider who may not call the Poison Centre for advice or to report the case. Thus, the NPDS does not capture all the poison exposures in the USA.

It is also noted that data collection and telephone management of poison exposures and poisonings do not reflect the full extent of Poison Centre activities, which include, amongst others, poison prevention and education, and Poison Centre awareness (Bronstein *et al*., 2007). Information-only calls also comprise a major Poison-Centre activity. In 2006, such information calls involved drug identification (for the public and law enforcement agencies), drug information, environmental information, medical information, occupational information, poison information, poison prevention/safety/education, teratogenicity information, substance abuse information, administrative issues and caller referrals (Bronstein *et al*., 2007). Of drug identification calls, only 9.7% of those involved could not be identified over the telephone. Environmental calls represented 1.9% of all information calls in 2006,

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

with questions relating to clean-up of mercury spills from broken thermometers and pesticides being most common.

A unique feature of NPDS is the ability to generate system alerts on adverse drug events and other products of public heath interest such as contaminated foods or product recalls (Bronstein *et al*., 2007). If a report of potential public health importance is received, more information is obtained from the reporting Poison Centre by telephone or email and then is brought to the attention of the National Center for Environmental Health at the Centers for Disease Control and Prevention (CDC). Appropriate state and local health departments may also be alerted.

In 2006, all 61 participating Poison Centres reported to the NPDS. Of these, 58 (95%) are AAPCC Certified Regional Poison Centres (Bronstein *et al*., 2007). US Poison Centres are staffed by healthcare professionals, including board-certified medical toxicologists, pharmacists, pharmacologists, registered nurses, and poison information providers (PIPs) who are allied healthcare professionals. Registered nurses and pharmacists may be either specialists in poison information (SPIs) or, after having logged a minimum of 2000 calls over a 12-month period, may take an approved examination and become certified poison information specialists (CSPIs). US Poison Centres employ (full-time equivalents) 123 PIPs, 250 SPIs and 615 CPSIs.

The NPDS verifies the difference between deaths (an observable clinical end point) and poison-related fatalities through its fatality review team (Bronstein *et al*., 2007). Of 1515 deaths reported in 2007, there were 1229 verified fatalities (Bronstein *et al*., 2007). Children 6 years of age and younger represented only 2.4% of fatalities, while 80% of fatalities occurred in patients aged 20–59 years. A single substance was implicated in 91.1% of fatalities, and 5.9% of fatality patients were exposed to two or more substances.

Poison Centre data collections, such as the AAPCC TESS data, can be 'data-mined' to understand poisoning in selected groups, such as adverse drug reactions in the elderly (Cobaugh and Krenzelok, 2006). They can also be used to show an increased relative risk of fatal outcomes in the elderly with medication poisoning. In one study using AAPCC TESS data, Rogers and Heard (2007) found that 2% of poison exposures in 1990 were in adults 60 years of age and older; this had increased to 4.7% in 2004. In addition, while persons aged 60 years and older comprise approximately 5% of poison-exposed individuals reported to Poison Centres, they make up approximately 15% of poison-related deaths (Rogers and Heard, 2007).

National data collected by Poison Centres, such as the AAPCC TESS data, have multiple uses, such as national surveillance of dietary supplement exposures (Gryzlak *et al*., 2007). Poison Centre data can be used by regulatory agencies, such as the US Environmental Protection Agency, to track pesticide poisoning incidence (Blondell, 2007) and can be used to track such exposures longitudinally (Sudakin and Power, 2007). Pesticide poisonings have been of interest to Poison Centres, particularly internationally (Kalkan *et al*., 2003), amongst both humans and animals (Motas-Guzmán *et al*., 2003). Poison Centres also identify international differences in toxic exposure patterns (Wananukul *et al*., 2007), and poisoning trends over time (Kotwica and Czerczak, 2007). They develop profiles of childhood poisonings (Szkolnicka *et al*., 2005). Food-borne illness surveillance is a potential function of Poison Centres (Derby *et al*., 2005).

One problem with Poison Centre data collections is that fatal poisoning cases that come to the attention of Medical Examiners may *not* be reported to Poison Centres (Blanc *et al*., 1995; Linakis and Frederick, 1993).

4 POISON CENTRES AND OCCUPATIONAL HEALTH

4.1 Occupational Illness Reporting

Occupational illness reporting in an important part of Poison Centre activities (Blanc *et al*., 1990; Litovitz and White, 1990). Reporting systems other than those used by Poison Centres in the USA may capture only 68–92% of occupational exposure cases, and tend to focus on clinically serious cases (Litovitz and White, 1990). Also, for each case of occupational exposure reported to a Poison Centre, there may be an average of 12 other persons exposed (Litovitz and White, 1990).

4.2 Adolescents at Work

Poison Centres provide surveillance of adolescent workplace toxic exposures (Woolf and Flynn, 2000). Each year an estimated 2 00 000 US workers between 14 and 17 years of age experience job-related injuries, and about 64 000 require emergency department treatment (Rubenstein and Bresnitz, 2001). About 70 adolescents yearly are killed in work-related incidents (Rubenstein and Bresnitz, 2001). In a study using the AAPCC TESS database (for 1997), Rubenstein and Bresnitz (2001) found 3442 cases of reported workplace poison exposures in workers aged 6–19 years, representing 7.5% of the total occupational exposure cases. The principal exposure routes in these cases were inhalation/nasal (27.2%), ocular (26%) and dermal (24.6%). The main substances involved were household cleaning substances, chemicals, and fumes/gases/vapours. In 56.6% of the cases, some symptoms ranging from minor to significant developed; there were no deaths.

5 ADDITIONAL POISON CENTRE ACTIVITIES

5.1 Quality Improvement

Poison Centres participate in quality improvement adherence to treatment guidelines, such as those established by the American Academy of Clinical Toxicology (AACT)/European Association of Poison Control Centres and Clinical Toxicologists (EAPCCT) for gastric decontamination (Chyka and Winbery, 2006).

5.2 HAZMAT Incidents

Poison Centres provide information and consultation services during hazardous materials (HAZMAT) incidents, and collect data on such incidents (Burgess *et al*., 1997).

5.3 Sensitive Populations

Poison Centres collect information on particularly sensitive populations, such as elderly adults (Crouch *et al*., 2004a). They also follow epidemiological trends in other sensitive populations internationally, such as children under five years of age (Mena *et al*., 2004). They can define the toxicological features of deliberate self-poisoning (Bentur *et al*., 2004). Poison Centres can emphasize the dangers of maternal exposures to potential teratogens such as alcohol and anticonvulsant medications during unrecognized pregnancies (Forrester and Stanley, 2004a). Poison Centre elucidation of trends in nonprescription drug abuse in children and teenagers can assist public health officials, physicians, pharmacists and educators in attempts to curb such abuse (Crouch *et al*., 2004b). Poison Centre data can define trends in childhood poisoning (Vassilev *et al*., 2004). Poison Centres can provide information on poisoning trends and educate patients about poison prevention (McGoodwin and McKeown, 2004), as well as developing antidote stocking guidelines (Dart *et al*., 2000). Poison Centres help differentiate mass psychogenic illness from mass poisoning incidents (Doyle *et al*., 2004). They can profile iatrogenic poisonings (Ballesteros *et al*., 2003).

5.4 Treatment Recommendation Variations

Using the EAPCCT/AACT guidelines on gut decontamination for four common drug ingestions, Good *et al*. (2007) found considerable variation in recommendations amongst 11 Poison Centres in 11 different countries, although each Centre had established internal protocols. There was also a certain amount of variation regarding the 'top 20' poison exposures recorded in the various Centres, with those in developed countries tending more towards medications and household products and those in developing countries tending towards pesticides. A single Centre in Australia had a large number of envenomations by fauna (Good *et al*., 2007).

6 CONCLUSION

Poison Centres have a role in a wide variety of activities in education, research, chronic toxicity (occupational and environmental), poison prevention and public health, in addition to their primary function of providing information and treatment recommendations for patients with acute poison exposure or poisoning.

Ethical, Legal, Social and Professional Issues in Toxicology

Steven G. Gilbert and David L. Eaton**

CONTENTS

A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise.

Aldo Leopold (1949)

Being mindful of suffering caused by taking poisons into our bodies and minds, we are determined to take into our bodies and minds only those things that nourish awareness, life, and love.

The Five Wonderful Precepts—Blue Iris Sangha

1 INTRODUCTION

The fewer clear facts you have in support of an opinion, the stronger your emotional attachment to that opinion.

Anonymous

Philip Handler about balancing risks and benefits: 'A sensible guide would surely be to reduce exposure to hazard whenever possible, to accept substantial hazard only for great benefit, minor hazard for modest benefit, and no hazard at all when the benefit seems relatively trivial.' (Philip Handler, former President of the National Academy of Science) (Handler, 1979).

Toxicology is the study of the health effects of chemical or physical agents. Paraphrasing Spiderman's Uncle Ben, 'With great knowledge comes great responsibility.' Toxicologists have some of the most in-depth knowledge about the adverse health effects of chemical and physical agents of any scientific discipline. Given this knowledge and the impact it has on human and environmental health, what are the toxicologists' ethical responsibilities?

Ethical issues related to the profession of toxicology have become more pronounced with the expanded knowledge about the health effects of chemicals and evolution of society. Ethical consideration in any discipline is an evolving process that reflects basic knowledge and as well the social and culture perspectives of the time. In some ways ethics is deceptively simple, for example, 'I will honour honesty and truth, I will not deceive', but there are many dimensions to ethical conduct for a toxicologist.

Ethics begins with the knowledge and perspective that we have a responsibility to consider the health and well being of other people, animals and the environment. The ethical, legal, social and professional issues that confront toxicologists have grown increasingly complex and interwoven with the demands of society. The information generated by or used by toxicologists and policy makers has enormous implications for human health and the environment, to say nothing of the financial implications. As

our industrial, manufacturing and chemical-based society has developed, toxicological information has become an integral part of the decision-making process. We will not address issues of outright fraud or data falsification, as these actions are clearly antithetical to honesty and the scientific process (Purchase, 2004). The goal of this chapter is to present an overview of various ethical considerations that a toxicologist may need to address in the design, conduct, interpretation and assessment of toxicological studies for the greater good of the environment and human health. Our focus will be on the development of ethical concerns and decision-making process as the toxicological sciences have assumed a greater role in societal decision making. In part, this chapter provides a perspective on the interaction and evolution of toxicology and society.

The chapter is divided into five broad topic areas. *Ethical Considerations* discusses basic duties and responsibilities of toxicologists and provides a historical perspective. *Legal Considerations* explores the implications of toxicology for the regulatory system. *Social Implications* examines the broader context of toxicology in society. *Professional Considerations* addresses integrity issues that confront toxicologists and questions related to research on animals or humans. *Ethics in Education* considers how toxicologists need to be thoughtful public-health advocates while maintaining scientific integrity. While not directly discussed, several of the leading professional toxicology societies ask their members to adhere to a code of ethics. The code of ethics from the Society of Toxicology (SOT) and Society of Environmental Toxicology and Chemistry (SETAC) are included in the appendix. These serve as good examples of the issues that toxicologists need to address to demonstrate a professional and ethical approach to the issues (Saady, 2001).

2 ETHICAL CONSIDERATIONS

All human beings are born free and equal in dignity and rights. They are endowed with reason and conscience and should act towards one another in a spirit of brotherhood.

Article 1 of the United Nations Universal Declaration of Human Rights *(1948)*

We've poured our poisons into the world as though it were a bottomless pit and we go on gobbling them up. It's hard to imagine how the world could survive another century of this abuse, but nobody's really doing anything about it. It's a problem our children will have to solve, or their children.

Daniel Quinn

Human and Environmental Health: Conditions that ensure that all living things have the best opportunity to reach and maintain their full genetic potential.

Steven G. Gilbert (1999)

The emphasis on the ethical foundation of toxicology has increased in importance with the increased use of toxicological data in public health policy decisions that have broad impacts on society. Judgements and decisions based on toxicological data influence a wide range of endeavours such as drug development, manufacturing, hazardous waste site clean up, household cleaning products, and many rules and regulations governing air and water pollution, pesticide use, food safety, and consumer products, to name a few. Toxicologists must consider their duties and responsibilities to the general field of toxicology as well as the broader needs of society.

Toxicology, like all scientific disciplines, has a foundation built on ethical considerations. The Greek physician Hippocrates (460–377 BC) noted the effect of food, of occupation, and especially of climate in causation of disease. He integrated this understanding in his books, *De aëre, aquis et locis (Air, Waters and Places),* one of the earliest works on humans and the environment. He is also credited with the basic medical tenet of 'do no harm'. Bernardino Ramazzini (1633–1714), an Italian physician, identified the link between worker occupation and health, which he documented in his book *De Morbis Artificum Diatriba* (*Diseases of Workers*). He outlined the health hazards of chemicals, dust, metals and other agents encountered by workers in 52 occupations. These are but two examples, but they illustrate that knowledge was available and with that knowledge comes the ethical challenge of what to do.

Aldo Leopold, the father of 'conservation biology', and considered by many to be America's first bioethicist, summarized ethical responsibilities in a simple statement in 1949: 'A thing is right when it tends to preserve the integrity, stability and beauty of the biotic community. It is wrong when it tends otherwise.' Leopold (1949). Toxic agents can rob humans or the environment of their integrity, stability and beauty. The toxicological sciences have clearly demonstrated that some individuals, humans or animals, are more susceptible than others to the effects of a toxic agent. Susceptibility may be related to genetics, age, diet or numerous other factors. This is particularly true for children, whose rapidly developing organ systems make them more vulnerable and susceptible to the effects of many hazardous agents, and the elderly, who may have failing adaptive response systems that leave them more vulnerable, as well. Assuming that there is an obligation to protect the more vulnerable in our society, this means that children and the elderly have a right to an environment in which they can reach and maintain their full potential (Gilbert, 2005a).

More modern approaches to ethics in toxicology are grounded in biomedical ethics, which developed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

following the lessons learned from the widespread abuses of humans during the Second World War. The four principles of biomedical ethics—respect for autonomy, beneficence (do good), nonmaleficence (do no harm) and justice (be fair)—are the well defined philosophical approach to human healthcare and research (Beauchamp and Childress, 1994). These principles are also particularly applicable for toxicologists. Respect for autonomy implies that individuals have certain rights to control their bodies that must be respected by others. For example, individuals have a right to control their exposure to hazardous agents, which implies a right to know and understand what they are being exposed to. Respect for autonomy increases the importance of acknowledging and understanding individual sensitivity to agents, for example susceptibility related to age or genetics. An individual's right to know and understand what they are being exposed to also implies informed consent, which is a major part of evaluating the safety of drugs, through the process of 'clinical trials'. Beneficence and nonmaleficence implies the need to minimize the risk of a hazard, in other words, do no harm. An obligation or duty to do no harm asserts that proponents of an activity must have the information to ensure that no harm is being done to human health or the environment. Justice requires that the burdens and benefits be shared equally. In recent years this principle has been articulated as environmental justice and the unequal distribution of sources of exposure to hazardous substances or activities. More detailed discussion of these issues is available (Gilbert, 2005a; Weiss, 2001). Expanding or modifying these four principles to include sustainability and veracity has also been proposed (Gilbert, 2006).

Another important consideration involves the tension between scientific uncertainty and causation. Toxicology exemplifies science in that uncertainty is a fundamental driver of research. Uncertainty in toxicological studies or results can complicate interpretation and application to public policy related to protecting human health and/or the environment. While some level of uncertainty is inherent in almost all scientific investigations, ultimately some conclusion must be reached with regards to causation. Bradford Hill and others developed the following list of criteria to establish causation (Hill, 1965). This work was stimulated in part by the effort to assert that tobacco products caused lung cancer as well as other health effects.

1. Strength of association (relationship between independent and dependent variables).
2. Consistency of findings (replication of results by different studies).
3. Biological gradient (strength of the dose–response relationship).
4. Temporal sequence ('cause' before effect).
5. Biologic or theoretical plausibility (mechanism of action).
6. Coherence with established knowledge (consideration of alternative causes).
7. Specificity of association (cause is tightly linked to an outcome).

Hill (1965) went on to note that 'All scientific work is incomplete—whether it be observational or experimental. All scientific work is liable to be upset or modified by advancing knowledge. That does not confer upon us a freedom to ignore the knowledge we already have or postpone the action that it appears to demand at a given time.' There is thus an important responsibility to take action based on available knowledge and not use uncertainty as a rationale for inaction. This statement is also a prelude to the formulation and discussion of the precautionary principle.

In 1968, Garrett Hardin defined the 'tragedy of the Commons' and pointed out that many problems have 'no technical solution' (Hardin, 1968). The Commons was defined as a shared common area which requires management for the good of society that receives benefit from the Commons. This view of the Commons can also have implications for toxicology. For example, toxicologists have explored and characterized the foetal consequences of *in utero* alcohol exposure. The consequences of alcohol consumption during pregnancy are well established. While the way to prevent foetal alcohol exposure is obvious- provide clear advise to women to not drink alcohol during pregnancy- it also requires that society manage this issue. Society must manage this problem by investing in the education of parents and care givers, and provide support for abstinence from alcohol during pregnancy. There is a duty to use available knowledge to protect the most vulnerable.

The gradual recognition of ethical consideration in managing human and environmental health was most recently articulated as the precautionary principle, which is an interesting blending of science and philosophical considerations. The precautionary principle was first articulated in the 1992 Rio Declaration as an aid to decision making in environmental and human-health-related issues (Raffensperger and Tickner, 1999). The most widely accepted definition of the precautionary principle is from the Wingspread Conference of 1998:

> *When an activity raises threats of harm to human health or the environment, precautionary measures should be take even if some cause and effect relationships are not fully established scientifically.*
>
> Wingspread Conference *(1998) (Raffensperger and Tickner, 1999).*

The precautionary principle is not only a tool, but also provides an ethical foundation for decision making. The precautionary principle addresses the application of scientific information to protect human and environmental

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat128
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

health. The implementation of the precautionary principle requires action even while acknowledging a level of uncertainty. The central elements of the precautionary principle can be summarized as follows (Gilbert, 2005b):

Central components of the precautionary principle

- establish public health goals
- taking preventive action in the face of uncertainty
- shifting the burden of responsibility (proof) to the proponents of an activity
- exploring a wide range of alternatives to possibly harmful actions
- increasing public participation in decision making.

Although controversial, the precautionary principle has been utilized as an important approach to risk management and decision making (Gilbert, 2005b; Goldstein, 2001; Grandjean *et al*., 2004; Kriebel *et al*., 2001; Myers and Raffensperger, 2006; Ter Meulen, 2005; Tickner, 2002). Opposing views have pointed to potentially unintended consequences of this approach to risk management in the face of uncertainty (Marchant, 2003).

The Earth Summit in Rio de Janeiro in 1992 also produced the foundations for an Earth Charter which was ultimately adopted by many countries, states and organizations (UNCED, 1992; Bourdeau, 2004; Strong, 1992). The Earth Charter is a broad ethical statement with the goal of establishing a global civil society. Relevant to toxicologists is one of the principles which states 'Prevent harm as the best method of environmental protection and, when knowledge is limited, apply a precautionary approach.' This clearly refers back to the precautionary principle as an important tool in decision making. The Louisville Charter for Safer Chemicals offers another statement on creating a safer and healthier environment (Geiser *et al*., 2007; Rossi, 2007).

3 LEGAL CONSIDERATIONS

Laws related to toxicology have a long history, often fraught by tragic effects of hazardous agents. One of the first laws dealing with toxicology was passed in 82 BC, by the Roman Emperor Sulla. Called *Lex Cornelia*, this law was intended to deter intentional poisoning, and came about because of the increased frequency of women poisoning men to acquire their wealth. Food adulteration in 1880 spurred Peter Collier, chief chemist, US Department of Agriculture, to recommend passage of a national food and drug law. In 1883, Germany adopted workers' insurance laws to protect workers exposed to organic chemicals, and in 1897 England adopted workers' insurance laws. These as well as other rules and regulations were adopted based on knowledge acquired from unfortunate experience with a hazardous agent.

The regulation of drugs and required testing to demonstrate efficacy and safety developed only through tragic experience. In 1937, the Elixir Sulfanilamide, containing the poisonous solvent diethylene glycol, was marketed and tragically killed 107 persons, many of whom were children. This incidence resulted in the US Congress passing, the Federal Food, Drug and Cosmetic Act of 1938, which required, among other things, drug safety testing. The next event to increase regulation on drugs occurred in 1962 with the discovery that exposure to thalidomide during a small window of susceptibility during pregnancy caused specific limb birth defects. This resulted in the passage of the Kefauver-Harris Drug Amendments which further tightened drug safety testing requirements (for a history of the US Food and Drug Administration (FDA) see *www.fda.gov/oc/history/*).

To address industrial and product-based chemicals, the US Congress passed the Toxic Substances Control Act (TSCA), which became law on 11 October 1976. TSCA was to 'prevent unreasonable risks of injury to health or the environment associated with the manufacture, processing, distribution in commerce, use, or disposal of chemical substances'. One provision of this act was that chemicals currently in use did not require additional safety assessment. TSCA Section 6 gives the US environmental protection agency (EPA) authority to control any chemical that poses an 'unreasonable risk of injury to health or the environment'. The legal, and in part, ethical question is determining, or in a court proving, what is 'unreasonable risk'. In large part TSCA failed to encourage alternatives to hazardous substances or the development and substitution of safer chemicals for industrial or commercial products. For detailed information on TSCA see the EPA web site *www.epa.gov/compliance/civil/tsca/index.html*. This situation raises the question of who is responsible for ensuring that chemicals are safe for the environment and do not harm human health.

The broad societal relevance of toxicological data to human and environmental health has resulted in a variety of laws and regulations administered by a variety of agencies. Some of these rules and regulations were derived to codify ethical conduct or as a result of unethical activities. Laws and regulations that use toxicology data have implications for occupational health and safety, hazardous waste clean up, the food supply and healthcare. In some instances the regulations are not consistent. One simple comparison is that the FDA requires that canned tuna cannot contain more than 1 ppm (1 mg/kg) of mercury, while the EPA sets a reference dose (RfD), the amount of mercury that can be safely consumed each day for a lifetime, at $0.1\,\mu g\,kg^{-1}\,day^{-1}$. Yet a 55 kg (120 lb) pregnant woman that consumed 4 ounces of tuna fish each day would receive a dose of approximately 2 µg/kg/day or 20 times the EPA's estimated 'safe' level. The EPA standard is based on an extensive risk assessment based on a solid foundation of scientific data (as well as standard assumptions and uncertainties) while the basis for the FDA standard is unclear.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat128
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Guidelines are also established by government agencies to advise public health officials. In 1990 the Centers for Disease Control and Prevention (CDC) established a blood lead action level of $10\,\mu g\,dl^{-1}$ for children. Currently there are several studies and reports indicting that the blood lead action level should be significantly lowered (Gilbert and Weiss, 2006) to adequately protect children's health. What is the appropriate role of the toxicologist in addressing issues that combine both science and policy?

The development of the rules and regulations governing toxicological data relevant to drug development was in part implemented because of unethical conduct. Since the early 1970 s toxicological data were required to register pesticides and set exposure guidelines. During reviews of various datasets it was determined that some of the data were not accurately reported, and in some instances clearly falsified. This ultimately resulted in US and international agencies issuing Good Laboratory Practice (GLP) guidelines to ensure quality control and the ability to review and monitor all aspects of study data collection and interpretation. The US FDA specified rules for GLP in Federal Regulation 21 CFR 58. These rules are used for preclinical studies (animal-based studies) prior to clinical research in humans. Research not conducted under GLP guidance may be rejected if submitted in support of new drug applications. The Organisation for Economic Co-operation and Development (OECD) has similar rules. Similarly guidelines also govern the manufacture of drugs and collection of data from human studies. In essence these rules and regulations were developed to help ensure the trustworthy conduct of toxicological research and accurate interpretation of study data (Purchase, 2004).

4 SOCIAL IMPLICATIONS

Toxicologists must also consider the social implications of their science. For example, children's health has additional ethical and social considerations (Gilbert, 2005a). The SOT code of ethics indicates that toxicologists should be thoughtful public-health advocates (see appendix). Although not explicitly stated, codes of ethics such as that of the SOT are commonly based on the following fundamental concepts: (i) a responsibility to share and use knowledge, (ii) a duty to promote the health and wellbeing of children, and (iii) that all species have a right to reach and maintain their full potential.

The social implications of toxicology are evident in the daily media. Examples of popular reports in the media range from recalled drugs, contaminated pet food, lead-contaminated toys, cosmetics with harmful chemicals, and other chemical-laden products. These situations require the consumer to be knowledgeable about a confusing set of choices in an effort to purchase the least hazardous product. Manufacturers also struggle to produce safe and cost-effective products using the least hazardous materials. Currently many issues related to chemical exposure are addressed through the legal system. Toxicologists play an important role in addressing both sides of these issues (Eaton, 2003). The toxicologist must confront difficult issues of judgment and ethics that involve the intersection of science, legal and social concerns.

Toxicologists should be encouraged to engage with their local communities. One proposal is to actively promote the socially responsible toxicologist or citizen toxicologist (CT) (Gilbert, 2005a). The CT would be seen as a thoughtful public-heath advocate and engage in some of the following (modified from (Gilbert, 2005a)):

- Speaks to public interests.
- Recognizes the ethical, legal and social implications of toxicological research.
- Shares scientific knowledge with public.
- Volunteers time to local groups.
- Testifies before local, state and national government committees.
- Meets with local, state or national government representatives.
- Writes review papers or other papers for lay public.
- Teaches in elementary, middle and high-school classrooms.
- Encourages others to be thoughtful advocates for human and environmental health.
- Serves as a member of the board of directors or volunteering for nonprofit organizations associated that promote human and environmental health.
- Serves as a mentor for students in elementary, middle and high school or beyond.
- Lectures on or discusses science and toxicology issues with public and community groups.
- Volunteers to lecture at local community colleges or technical schools.
- Participates as a member of local groups that volunteer for public speaking.

5 PROFESSIONAL CONSIDERATIONS

5.1 Conflict of Interest/Integrity

Concern about real or perceived conflict of interest has risen in parallel with increased use of toxicological data in the decision-making process and subsequent public policies that may have a significant impact on society and financial interests (Maurissen *et al*., 2005). Essential to this discussion is a clear definition of what constitutes a conflict of interest, as opposed to a bias or opinion on the issue. Conflict of interest is often considered as some form of financial involvement related to the issue.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat128
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Defining, and disclosure of, conflicts of interest remains an important issue despite the development of guidelines (Goozner, 2004; Krimsky and Rothenberg, 2001; NAS (National Academy of Sciences), 2003). Many professional societies, such as the SOT (see appendix below), have developed codes of ethics for members that address conflicts of interest. The SOT code of ethics specifically addresses conflict of interest, stating that members should 'abstain from professional judgments influenced by undisclosed conflict of interest, disclose any material conflicts of interest and avoid situations that imply a conflict of interest'.

In recent years charges of conflict of interest that might influence professional judgment have been directed at individuals serving on government committees. Government agencies have responded by issuing additional guidelines and requiring greater disclosure of any potential conflicts. Possible conflicts of interest have also been a concern of journal editors. Journal editors increasingly require authors to disclose any potential conflicts of interest such as financial involvement or professional relationships related to the study.

The evaluation of the toxicity surrounding the manufacture and use of vinyl chlorine (VC) is an interesting example of how issues associated with conflict of interest can effect data review (Sass *et al*., 2005). VC is used almost exclusively in the production of polyvinyl chloride (PVC). In 2002 global production of PVC was over 26 billion kg, valued at approximately US $19 billion. The article's authors charged that a 2000 review of VC toxicity was influenced by industry-funded scientists and did not fully consider all the available data (Sass *et al*., 2005).

There have also been questions related to the interpretation of the health effects of benzene (Infante, 2006). These are limited examples of the importance and implications of toxicology evaluation and the need to address conflict of interest issues. An important challenge is recognizing that conflict of interest is different from a bias, which is based on an reasoned interpretation of the available data that itself is influenced by the lifelong experiences and perceptions of the individual. Everyone has 'biases'. Thus, while it is important to acknowledge bias, it does not represent a conflict of interest, and most organizations that empanel scientists for purposes of scientific review that might impact policy clearly distinguish between conflict of interest and bias in the creation of such panels. For example, the National Academy of Sciences/National Research Council require all potential committee members to disclose all sources of both conflict of interest and bias, but only the former may be used to preclude the participation of someone on a committee. The bias information is used to ensure balance on the committee across a spectrum of perspectives, but typically will not preclude someone from serving on an NAS/NRC expert committee.

5.2 Research Considerations

The design, conduct and interpretation of results of research require that toxicologists adhere to the highest ethical standards as well as beware of appropriate rules and regulations. The experimental design must be developed to yield the best possible results with the least amount of uncertainty. It is critical to acknowledge the potential weaknesses and limitations of a study's design, or constraints due to time or material. A common problem in toxicological studies is that uncertainty can be reduced by increasing the number of subjects, but this inevitably requires more resources and time. Finding the right balance is both a scientific and ethical challenge.

5.3 Human Research Considerations

Ultimately some aspect of toxicology research will involve assessing the health effects of chemicals on humans. The principles of biomedical ethics that inform the rules and regulations that govern human subject research were largely developed out of the lessons of the Second World War and the subsequent Nuremburg trials. Another pertinent example is the Tuskegee Syphilis Study conducted from 1932 to 1972. This medical study followed black men with syphilis in Tuskegee, Alabama, that was continued even after the development of effective antibiotics for treatment (Jones, 1981; Thomas and Quinn, 1991). These experiences initiated a fundamental re-examination of the ethical implications of research on humans and ultimately lead to the development of regulations governing human-subject participation in research or data collection.

This re-examination coalesced into the four principles of biomedical ethics discussed above—respect for autonomy, beneficence (do good), nonmaleficence (do no harm) and justice (be fair) (Beauchamp and Childress, 1994). These four principles became the basis for decision making in healthcare and formed the basis for establishing Institutional Review Boards (IRBs) that oversee human subjects research. The US Federal Policy for the Protection of Human Subjects (Public Welfare: Protection of Human Participants, 2005) defines research on human subjects and addresses measures to protect human subjects. Additional information is available from the Office for Human Research Protections (OHRP) on the conduct and oversight of IRBs (OHRP (Office for Human Research Protections), 2005). The majority of US government agencies comply with the Common Rule on human subjects research (OHRP (Office for Human Research Protection), 2006).

Perspectives on human subjects research have expanded with the concept of community-based participatory research which focusses on proactive engagement of the broader community, not just the individual subjects (Arcury *et al*., 2002; O'Fallon and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat128
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Dearry, 2002). Community-based participatory research can be summarized by the following six principles (adapted from O'Fallon and Dearry, 2002 and Gilbert, 2006):

1. Promotes active collaboration and participation at every stage of research. All parties should share ownership of the project.
2. Fosters co-learning. Researchers and participants share their knowledge and learn together.
3. Ensures projects are community driven. Projects address questions and concerns of the community, not just the researchers.
4. Disseminates results in useful terms. Project results are communicated to the participants in an appropriate and sensitive format.
5. Ensures research and intervention strategies are culturally appropriate. Investigators must be culturally sensitive to achieve the best results.
6. Defines community as a unit of identity. In collaboration with participants, consideration must be given to defining the community involved in the project.

To ensure appropriate community engagement in the research project, it has been proposed that the traditional IRBs be supplemented or even replaced by an Environmental Health and Community Review Boards (EHCRBs) (Gilbert, 2006). This approach also involves an expanded ethical construct which includes a focus on dignity, veracity and sustainability.

5.4 Animal Research Considerations

Concerns about animal welfare and discussion about the ethical use of animals in toxicology research have steadily increased over the past decades (Rollin, 2003). If animals are utilized in the research, additional ethical, animal-welfare and legal issues must be considered. In part out of ethical considerations, there has been an ongoing effort to reduce, refine the use, or seek to replace animals used in toxicity testing (Balls, 2004). The use of animals requires that study designs be reviewed by the Institutional Animal Care and Use Committee (IACUC). An important source of information about animal welfare and the use of animals in research is the American Association of Laboratory Animal Sciences (AALAS) (*www.aalas.org/index.aspx*). Organizations such as the SOT and the American College of Toxicology have policy statements on the care and use of animals in research.

6 ETHICS IN EDUCATION

Discussion of ethical issues should be incorporated into elementary, middle and high-school classrooms and continue throughout undergraduate and graduate education. Ethics primers have been developed to assist teachers in integrating ethical discussions into science classroom instruction (e.g. see Northwest Association for Biomedical Research *www.nwabr.org*). The intersection of society and science requires ongoing discussion. It is important for students and scientists to develop a basic understanding of ethics as a discipline and how to integrate ethical principles into critical and reasoned decision making. These discussions can range from the use of humans and animals in research to the use of stem cells to issues of conflicts of interest. It is very important to foster discussions and encourage critical thinking at the earliest ages in the classroom as well as within society.

7 SUMMARY

The purist idea of ethical behaviour and decision making requires the thoughtful development and articulation of fundamental principles upon which to base any action. The ethical toxicologist must consider and integrate basic ethical principles into the decision-making process. This approach moves beyond what is legally required to consider what should be done to contribute to the greater and long-term good of society. The fundamental principles that an ethical toxicologist should consider are depicted in **Figure 1**. These principles are summarized as: (i) dignity, which includes the respect for the autonomy of human and animal subjects; (ii) veracity, an adherence to transparency and presentation of all the facts so all parties can discover the truth; (iii) justice, which includes an equitable distribution of the costs, hazards and gains; (iv) integrity, an honest and forthright

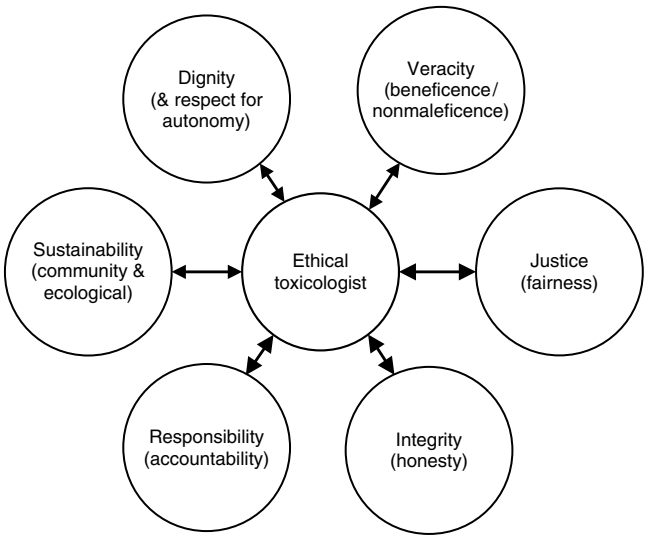

Figure 1 Key principles for consideration by the ethical toxicologist.

approach; (v) responsibility, an acknowledgement of responsibility and accountability to all parties involved; and (vi) sustainability, consideration that actions are sustainable over a long period of time. An ethical approach requires ongoing discussion and considerations as the toxicological sciences and society evolve. Toxicologists must not only be familiar with the rules and regulations regarding the ethical conduct of research but also the underlying ethical principles. The challenge is to move beyond a purely legal adherence to the rules but towards an ethical approach grounded in carefully considered and articulated ethical principles that drive the responsible conduct of research in modern societies.

APPENDIX A

A.1 SETAC Code of Ethics

(Society of Environmental Toxicology and Chemistry—code of ethics *www.setac.org/node/18*.)

Environmental professionals are expected to exhibit the highest standards of honesty and integrity. Accordingly, our activities require honesty, impartiality, fairness and equity and we must be dedicated to the protection and welfare of environmental resources. Environmental professionals must perform under a standard of professional behaviour that requires adherence to the highest principles of ethical conduct.

Commitment to ethical professional conduct is expected of every member of the Society of Environmental Toxicology and Chemistry, and each member shall:

- Conduct themselves honourably, responsibly, ethically and lawfully, with objectivity and integrity, so as to enhance the honour and reputation of the profession.
- Avoid conflicts of interest and situations that may imply a conflict of interest.
- Give proper credit for intellectual property and honour property rights.
- Recognize and respect confidentiality, but be honest and forthcoming in all issues of public record.
- Abstain from deceptive acts such as fabricating, falsifying or suppressing results, deliberately misrepresenting research findings, or otherwise committing scientific fraud.
- Strive to accurately communicate scientific understanding and knowledge, and to avoid and discourage dissemination of erroneous, biased or exaggerated statements.
- Conduct research and related activities (i) so as to avoid or minimize adverse environmental effects of that research, and (ii) in compliance with legal requirements for protection of researchers, human subjects, or research organisms and systems.
- Abstain from discriminating against others.

A.2 SOT Code of Ethics

The Society of Toxicology is dedicated to developing and communicating knowledge to improve the health and safety of living beings and to protect the environment upon which we depend.

To attain this objective, each member must maintain high ethical standards, recognize a duty to share this knowledge with the public, and be a thoughtful advocate for human, animal and environmental health. To this purpose, this code requires a personal commitment.

Society of Toxicology members shall:

- Conduct their work with objectivity and themselves with integrity. Being honest and truthful in reporting and communicating their research.
- Hold as inviolate that credible science is fundamental to all toxicological research and is the basis for communicating results.
- Recognize a duty to communicate information concerning health, safety and toxicity in a timely and responsible manner, with due regard for the significance and credibility of the available data.
- Give due consideration to the ethical, legal, social and policy implications of their research and communications.
- Be a thoughtful advocate for human, animal and environmental health.
- Abstain from professional judgments influenced by undisclosed conflict of interest, disclose any material conflicts of interest and avoid situations that imply a conflict of interest.
- Observe the spirit, as well as the letter of laws, regulations and ethical standards with regard to the conduct of human and animal research.
- Practise high standards of environmental and occupational health and safety for the benefit of themselves, their coworkers, their families, their communities and society as a whole.

Animals in research statements:

- Position statement regarding the use of animals in toxicology (*www.toxicology.org/ai/air/air5.asp*).
- Guiding principles in the use of animals in toxicology (*www.toxicology.org/ai/air/air6.asp*).

Ethical Issues Related to Animal Welfare Considerations in the Toxicology Laboratory

Robert F. Phalen

CONTENTS

1 INTRODUCTION

Ethics is a discipline that includes studying the standards of right and wrong, and analysing the values that govern or modify human behaviour. Ethics also refers to the rules that people are expected to follow. Ethical rules may vary both in time and in location. Local ethical standards, which incorporate applicable regulations and customs, are those that govern any given toxicology study. Such standards are currently evolving in the direction of increased accountability for the use of vertebrate animals.

In the context of animal toxicology, ethics involves the balancing of two contrasting 'goods': (i) the need for information for the protection of humans, animals and the environment, and (ii) the minimizing of pain, distress and death of sentient research subjects. In all cases, achieving a proper balance between these goods is a matter of judgement, good experimental design, good experimental technique and proper review by an ethics body that is not directly connected to the study. In the USA, the Institutional Animal Care and Use Committee (IACUC) reviews a proposed study, considering its importance, the necessity for use of animals, and its design. The IACUC requires modifications, or approves the study if it is appropriate, and periodically monitors all approved studies that are actually conducted. The IACUC is also required to report significant deviations from an approved protocol to the proper authorities (usually a federal agency) (NRC (National Research Council), 1996; ARENA/OLAW (Applied Research Ethics National Association/Office of Laboratory Animal Welfare), 2002; Pitts, 2002; Silverman *et al*., 2006). Similar requirements and recommendations obtain in Europe and elsewhere (Smith *et al*., 2007; Takahashi-Omoe and Omoe, 2007). Ethical review of protocols is necessary for the public acceptance of animal research.

The necessity for toxicologists to use the highest practicable ethical standards cannot be overstated. Pressure from interested public and private groups and individuals has led to the intense scrutiny of animal toxicology studies. Deviation from stringent ethical standards not only jeopardizes individual projects, but it also may

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat129
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

lead to increasingly burdensome requirements, if not outright bans, on future animal studies. The primary responsibility for protecting valuable medical research falls directly on individual investigators, their personnel and their institutions. There is no adequate justification for performing poorly designed, or ill-conducted toxicology studies that involve live vertebrate animal subjects.

On the other hand, there is an ethical requirement, if not a mandate, for performing well-designed, well-conducted toxicology studies. Without such studies, new cures/treatments for diseases cannot be found, endangered species cannot be protected and other information for improving the quality and quantity of life for humans and other species will not be forthcoming. In short, a *toxicology research imperative* must be recognized, and it can be argued that it is unethical to block, impair, or otherwise impede valid institutionally approved animal studies. Nevertheless, extremists are committed to curtailing all use of animals in research, testing and teaching (Morrison, 2001; Kennedy, 2006; Young *et al*., 2006; Brumfiel, 2008).

2 PERSPECTIVE

2.1 History

Although animal studies most likely predate recorded history, Aristotle (384–322 BC) and Galen (AD 129–199) reported both dissections and demonstrations with live animals. Later, numerous reports of animal experiments, such as those by William Harvey (1578–1657), Claude Bernard (1813–1878) and Louis Pasteur (1822–1895) became commonplace (NRC (National Research Council), 1988; Bishop and Nolen, 2001). Such studies firmly established the basic principles of modern anatomy, physiology and medicine, as well as the importance of animals to medical knowledge and advancement. Toxicology has its origins in the use of animal and plant extracts as poisons and remedies over 2000 years ago (Gallo, 1996). Today, animal studies are essential to the study and understanding of carcinogens, teratogens, biological toxins, chemical toxicants, environmental pollutants, nutrients, vitamins, medications, consumer products and numerous other natural and anthropogenic substances. Although animal studies have produced unmeasurable benefits for humans and other animals, they have also generated both concern and widespread opposition (Morrison, 2002).

2.2 Regulatory Activity and Pressure

Early legislation, as in Massachusetts (1641), and England (Martin's Act of 1822), was directed against farm-animal cruelty, but antivivisectionists in England (who attempted to abolish all animal research) prompted the enactment of the 'Cruelty to Animals Act' in 1876, which required licensing of investigators who might subject vertebrate animals to pain (NRC (National Research Council), 1988; Zurlo *et al*., 1994). Since these early attempts to regulate, and even abolish, the use of animals in research, an enormous amount of public pressure, regulation and legislation has emerged (NRC (National Research Council), 1988; Sideris *et al*., 1999; VandeBerg *et al*., 1999). Today, it is clear that there is continuing pressure worldwide to restrict and regulate animal research, as well as attempts to intimidate organizations, institutions and individuals that pursue the advancement of scientific knowledge, medicine and product safety (Morrison, 2001; Kennedy, 2006; Brumfiel, 2008).

2.3 Current Regulations

The *Association for Assessment and Accreditation of Laboratory Animal Care International* (AAALAC International) (*www.aaalac.org*) publishes information on current international regulations and resources in addition to promoting 'the humane treatment of animals in science through voluntary accreditation and assessment', **Table 1** lists only a very small sample of resources on laws, guidelines and regulations for toxicologists; it demonstrates the rigorous commitment to animal welfare on the part of governments and the scientific community.

The philosophy behind current regulations relating to laboratory animals can be traced to the international guidelines for the use of human research subjects. After the Second World War, the Nuremburg Tribunal developed a list of criteria for judging whether Nazi investigators were guilty of 'crimes against humanity'; **Table 2** summarizes these criteria. By way of comparison, the US Government's 'Principles' for experimental animals (**Table 3**) mirrors the Nuremburg Code. These principles have subsequently been greatly extended and clarified as is evidenced by the most recent *Guide for the Care and Use of Laboratory Animals* (NRC (National Research Council), 1996) (the 'Guide'); **Table 4** shows the contents of the most recent 'Guide', which is widely used by Institutional Care and Use committees. Investigators should be aware that additional local regulations and guidelines are likely to apply to their specific studies. Such requirements will usually be distributed by a local institutional animal research ethics committee.

Table 1 A small sample of sources of key international animal research regulations and guidelines

Country/region	Source of regulations/guidelines
Multinational	Council for International Organizations of Medical Sciences (CIOMS) (*www.cioms.ch/*)
	Guide for the Care and Use of Laboratory Animals (NRC (National Research Council), 1996)
	International Council for Laboratory Animal Science (ICLAS) (*www.iclas.org/*)
Asia	Japanese Association for Laboratory Animal Science (*wwwsoc.nii.ac.jp/jalas/index_e.html*)
	Korean Animal Protection Law (*www.koreananimals.org/animals/apl.htm*)
	Philippines Animal Welfare Act of 1998
	Taiwan Animal Protection Law (1998)
Australia and New Zealand	Australian Code of Practice for the Care and Use of Animals for Scientific Purposes, 7th edition, 2004.
	Australian and New Zealand Council for the Care and Use of Animals in Research and Testing (ANZCCART)
Canada	Canadian Association for Laboratory Animal Science (CALAS/ACSAL) (*www.calas-acsal.org/*)
	National Research Council, NRC-CNRC, Canada
Europe (not included are individual country resources)	Directive 86/609/EEC, (1986)
	European Biomedical Research Association (*www.ebra.org/*)
	European College of Laboratory Animal Medicine (*www.eclam.org/*)
	Federation of Laboratory Animal Science Associations (FELASA) (*www.felasa.eu/*)
India	Government of India Ministry of Environment and Forests: Animal Welfare Division
Mexico	NORMA Official Mexicana NOM-062-ZOO-1999, Especificaciones técnicas cuidado y uso de los animales de laboratorio
Russia	Russian Academy of Sciences
United States	The Animal Welfare Act, US Department of Agriculture
	Institutional Animal Care and Use Committee (*www.IACUC.org*)
	US Department of Agriculture: Animal and Plant Health Inspection Service (APHIS)
	Institute for Laboratory Animal Resources (ILAR)
	Office of Laboratory Animal Welfare, US Department of Health and Human Services (OLAW)

Adapted from *www.aaalac.org*.

Investigators are advised to begin their protocol review and approval process, which can be lengthy, well in advance of their study. Although cumbersome, the requirements for approving and performing studies must be met, as they are actually in place to protect the privilege of using animal subjects. The ultimate responsibility for compliance rests with the Principal Investigators.

2.4 Accreditation

'Accreditation', which is an institutional responsibility, is a formal acknowledgement that the institution ensures that studies are conducted under stringent requirements. Although accreditation is voluntary, many funding agencies will not support research, testing or training

Table 2 Abbreviated elements of the Nuremberg Code for human experimentation

1. 'The voluntary consent of the human subject is absolutely essential.'
2. 'The experiment should be such as to yield fruitful results for the good of society . . . '
3. 'The experiment should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problem . . . '
4. 'The experiment should be conducted as to avoid all unnecessary physical and mental suffering and injury.'
5. 'No experiment should be conducted where there is an a priori reason to believe that death or disabling injury will occur . . . '
6. 'The degree of risk to be taken should never exceed that determined by the humanitarian importance . . . '
7. 'Proper preparations should be made . . . to protect the experimental subjects against even remote possibilities of injury, disability, or death.'
8. 'The experiment should be conducted only by scientifically qualified persons.'
9. ' . . . the human subject should be at liberty to bring the experiment to an end . . . '
10. ' . . . the scientist in charge must be prepared to terminate the experiment . . . (if) . . . continuation of the experiment is likely to result in injury, disability, or death . . . '

Table 3 Abbreviated US government principles for vertebrate animals used in testing, research and training

1. 'The transportation, care, and use of animals should be accordance with the Animal Welfare Act . . . and other applicable Federal laws, guidelines, and policies.'
2. 'Procedures involving animals should be designed and performed with due consideration of their relevance to human or animal health, the advancement of knowledge, or the good of society.'
3. 'The animals selected for a procedure should be of an appropriate species and quality and the minimum number required to obtain valid results. Methods such as mathematical models, computer simulation, and *in vitro* biological systems should be considered.'
4. 'Proper use of animals, including the avoidance or minimization of discomfort, distress, and pain when consistent with sound scientific practices, is imperative.'
5. 'Procedures with animals that may cause more than momentary or slight pain or distress should be performed with appropriate sedation, analgesia, or anaesthesia.'
6. 'Animals that would otherwise suffer severe or chronic pain or distress that cannot be relieved should be painlessly killed at the end of the procedure or, if appropriate, during the procedure.'
7. 'The living conditions of animals should be appropriate for their species and contribute to their health and comfort.' 'In any case, veterinary care shall be provided as indicated.'
8. 'Investigators and other personnel shall be appropriately qualified and experienced for conducting procedures on living animals. Adequate arrangements shall be made for their in-service training, including the proper and humane care and use of laboratory animals.'
9. 'Where exceptions are required in relation to the provisions of these principles, the decisions should not rest with the investigators directly concerned but should be made, with due regard to Principle 2, by an appropriate review group such as an institutional animal care and use committee.'

Adapted from Appendix D, NRC (National Research Council) (1996).

activities with vertebrate animals in an institution that is not accredited by a body such as the AAALAC. Originally, the AAALAC was formed in 1965 by several scientific and educational organizations under the name *American Association for Accreditation of Laboratory Animal Care*. In 1996 the name was changed to reflect the organization's growth in other countries. AAALAC accreditation has been achieved by over 750 companies, hospitals, universities, government agencies and other institutions in 29 countries (*www.aaalac.org*). Accreditation is a clear demonstration that the institution is committed to stringent, responsible animal care and use, and that it maintains the administrative structure to accomplish that commitment.

2.5 Animal Welfare and Animal Rights

2.5.1 An Important Distinction

It can be safely assumed that the great majority of adults accept the concept of 'Animal Welfare'. For example, a recent survey of 750 New Zealanders' attitudes towards animals used for research, testing and teaching (RTT) found that just 33% were interested in the issue generally, and only 8% knew at least a 'fair amount' about legislation related to such uses of animals. The authors concluded 'the majority of New Zealanders were neither interested nor concerned about the use of animals in RTT (research, testing, and teaching)'. Also over two-thirds agreed that such animal use 'was acceptable as long as there was no unnecessary suffering by the animals' (Williams *et al*., 2007). A concern for animal welfare (and a personal attachment to animals) is also true for those who work directly with animals in the laboratory, which must be recognized and responded to by investigators (Herzog, 2002).

The elements of animal welfare according to the *American Veterinary Medical Association* (*AVMA*) (*www.avma.org*) include: a consideration for proper housing, management, nutrition, disease prevention and treatment, responsible care, humane handling and humane euthanasia. These elements are species-specific and are dealt with in laboratories under the supervision of veterinarians or other trained experts (Siglin and Rutledge, 1995). 'Animal Rights' in contrast, is a philosophy that blurs the distinction between humans and other animals, and denies the primacy of human interests over those of other species (Smith, 2007). Differential concern for, and treatment of, various animal species is often labelled as 'speciesism' by animal rightists, and even humane euthanasia in the laboratory is described as 'murder'. Yet, animal rights groups have been known to engage in euthanasia of animals left in their care (Anonymous, 2007). The animal rights philosophy is incompatible with any use of animals by humans, including for food, products, labour, exhibition and animal research and testing; it demands abolishment of such activities.

2.5.2 Activism

Although animal welfare in research, testing and teaching activities has been incrementally regulated, some individuals and groups have engaged in activism. Activism

(exerting influence to further a specific goal) can be conducted legally, for example through public education, free speech and peaceful protest, but there are numerous instances of illegal activities (Kennedy, 2006; Wohlsen, 2008). Such illegal activities have included theft, vandalism, arson and even attempted murder (Borum and Tilby, 2005; Wohlsen, 2008). When individual scientists are targeted by extremist activists, a likely sequence of events has been outlined (Kennedy, 2006). These events include: photographs of apparently distressed animals being distributed to news media outlets; circulation of leaflets accusing the investigator of 'atrocities'; residential picketing; and property damage including, in the extreme, planting firebombs or other potentially lethal devices. Such activities have been officially labelled as 'terrorist acts' and they have stimulated legislation for protection of animal users, as well as widespread law enforcement responses (Borum and Tilby, 2005).

2.6 Protecting Animal Research, Testing and Teaching

It is important to realize that those who wish to abolish the use of animals for research, testing and teaching will succeed unless there are significant efforts to protect it. Several organizations (**Table 5**) are engaged in supporting animal studies by providing information resources, advice to scientists and, in some cases, education of public officials. However, they can only do so much, as the battleground is in hundreds, if not thousands, of communities and institutions. Furthermore, the high-level administrators of institutions whose scientists are attacked are often initially inclined to lay low rather than support their scientists. Therefore, it is necessary for individual scientists and teachers to become directly involved in public education.

Providing public education on how and why animals are used in research, testing and teaching can be a rewarding experience. Most people have never personally met a biomedical scientist, but they probably have an admiration of such scientists, based on their experience with medicine, dentistry, science courses, and so on. Not only are members of the general public anxious to hear the scientist's side, but they are usually completely unaware of the many protections, the approval and monitoring processes, and the efforts of investigators to protect their animals from unnecessary suffering in scientific research, testing and teaching. Science teachers in public schools, science and nonscience department chairs in colleges and universities, librarians, officers of civic groups and many others can be contacted by individual scientists to arrange visits and presentations. The audience will be especially interested in the 'big picture', that is, why the activity is important, and what the scientist's attitudes towards the use of animals are. When speaking, scientists should remember that they are, at least for that audience, representing biomedical scientists in general. It is helpful if they speak clearly, bring items of interest to display, and openly respond to all questions. Public education on the part of scientists worldwide is one of the most important aspects of protecting biomedical research and its great promise to humans and animals alike. The organizations listed in **Table 5** can offer help and teaching aids.

2.7 If You are Targeted by Activists

Acts of vandalism, including theft or release of animals, and public demonstrations attacking individuals, are among the acts of animal rights extremists (Morrison, 2001; Borum and Tilby, 2005; Kennedy, 2006). Although initially alarming, such acts also present the opportunity for public education (and education of family, friends, neighbours, administrators, members of the print and electronic media, the community and public officials). A scientist who is attacked will need to set aside considerable time to defend themselves and their activities. Meeting with neighbours to discuss their work is advised so that they can recognize false claims, especially if leaflets or pickets arrive. Neighbours and their children will benefit from laboratory visits. If possible, one's laboratory or other facility should be open to other legitimate visitors; members of the press and other media will insist on this, and they will usually take photographs and will film activities and interviews for broadcast. As scientists are usually not experienced in such activities, 'media training' by experts should be sought. Such training is not training to deceive; rather it is intended to prepare one for clear, effective, forthright communication. Reporters are very busy, so clear and efficient communication is required in order to help them do their jobs. They will want to see what you do, hear why you do it, and will want succinct and honest answers to their questions. It must be understood that contact with reporters presents an opportunity to educate them and the public. That opportunity can be very rewarding as well as a great service to the community. If done well, the targeted scientist will gain in stature, and even establish lasting positive relations with the public and members of the media.

3 LABORATORY ANIMAL WELFARE

3.1 General Considerations—the Three Rs

The principles listed in **Table 3** summarize the elements of humane animal use, and they must be strictly adhered to. In the toxicology laboratory, many practical issues must be considered. These include: recognition and control of pain and distress, selection and use of appropriate sedatives, anaesthetics, analgesics, tranquilizers and euthanasia agents, selection of humane end points, care in handling, use of humane food and water restriction, and attention to health and safety considerations. These and other related topics are covered in several references (Siglin and Rutledge, 1995; NRC (National Research Council), 1996; ARENA/OLAW (Applied Research Ethics National Association/Office of Laboratory Animal Welfare), 2002). In addition, the 'Three Rs', which were codified by Russell and Burch (1959), are important considerations that should be part of the planning of all research and testing procedures (Flecknell, 2002). The three Rs, 'Reduction', 'Refinement' and 'Replacement' have become mandated by legislation in the USA and Europe (Goldberg *et al.*, 1996), and they are the impetus for the increased interest for developing 'alternatives' to animals in research, testing and teaching (ARENA/OLAW (Applied Research Ethics National Association/Office of Laboratory Animal Welfare), 2002; Goldberg *et al.*, 1996), 'Reduction' usually relates to minimizing the number of animals used. Good statistical designs that insure that excess numbers of animals will not be used to test hypotheses are essential, and typically require the inclusion of an 'applied statistician' in the planning process. Good statistical planning also improves the efficiency of the study and its contribution to knowledge. Another aspect of 'Reduction' relates to only performing those animal studies that are required for answering important research questions or acquiring needed toxicity data. 'Refinement' usually relates to modifying procedures, wherever possible, to reduce and/or eliminate pain and distress. Many examples could be given, but skilful administration of sedatives and analgesics, proper handling, humane postexperimental care, use of nonlethal end points and expert humane euthanasia are some methods. 'Refinement' requires a thorough understanding of what the animals require, and what they might experience, in the study; consultation with, and participation by, an expert veterinarian is recommended. 'Replacement' commonly refers to the use of nonsentient models (e.g. cell cultures, computer models, etc.) instead of animals, or substituting lower

Table 6 Some signs of acute and chronic pain in laboratory animals

Sign	Description
Abnormal posture	Hunching, head down, curled position, unusual gait, lameness.
Vocalization	Crying out, abnormal breathing sounds, whining, and so on.
Lethargy	Stillness, abnormal time spent lying down and poor response to stimuli.
Guarding, restlessness	Moving away, attempting to bite or scratch when approached, pacing, shifting weight, shaking or trembling.
Self mutilation	Licking, biting, scratching, rubbing, shaking.
Other behaviour	Failure to eat or drink, poor grooming, facial distortion, reluctance to move.
Clinical signs	Abnormal or absent elimination, breathing, or heart rate, lacrimation, salivation, pallor, bleeding, sweating, hypothermia, and so on.

Adapted from ARENA/OLAW (Applied Research Ethics National Association/Office of Laboratory Animal Welfare) (2002).

animals (e.g. nonvertebrates) in the procedures. Nonsentient models are usually called 'alternatives' (Zurlo *et al*., 1994). 'Replacement' is often a problem in that certain species may be required either scientifically (e.g. in exercise studies), or by regulations for testing medicines, food additives, consumer products and so on. However, many scientists are not trained in the use of alternatives, and some models, such as cell or tissue culture, require specialized facilities and training that are not always available.

3.2 Pain and Distress

Investigators must be able to identify and eliminate significant pain in laboratory animals, unless an exception is specifically obtained from the IACUC (or an equivalent review committee). Exceptions are not common, but allowed when essential to a research question that is sufficiently important in relation to the pain. 'Significant pain' may be defined as pain that is more severe than that associated with a single injection into a vein, the skin, or a muscle with a needle and syringe. The pain associated with surgery, or other significant tissue damage, must be always be anticipated and eliminated by prior administration of analgesics or other means. But pain which is more difficult to anticipate may be associated with administered pharmacological agents, toxicants, irritants, restraints, dietary manipulations, injuries, extreme environmental conditions and other intended (or unintended) factors. **Table 6** lists some of the signs of acute and chronic pain, or distress, in animals. **Table 7** describes some general methods for controlling pain or distress in animals.

It is imperative that investigators and their assistants learn to recognize the signs of pain and distress, and apply methods for eliminating these states in the specific species that they use. Siglin and Rutledge (1995) provide species-specific doses for several common species. However, it is important to consult with a qualified veterinarian who is familiar with the procedures and species involved. Prior to performing a study, it is also essential that all persons that administer pain relief be properly trained, and that the needed skills are verified.

3.3 Use of Humane End Points

The term 'end point' has two meanings that should not be confused. From the investigator's point of view it usually means the type of data that are acquired; for example blood pressure, respiration rate, tumour mass, size or number, or a variety of other responses to treatment. For the institutional review committee, inspectors, or attending animal care staff, 'end point' usually relates to how the experiment/procedure is terminated; for example, the termination of postprocedural care or intensive monitoring, return to normal housing, transfer to another study, or euthanasia. The selection of scientifically valid and humane end points is a key consideration.

Table 7 Means of eliminating and reducing pain or distress

Means	Description
Sedation	A state of decreased awareness and relaxation or sleepiness. Analgesia is not present.
Analgesia	Complete lack of pain.
Tranquilization	A state of mental calming, decreased responsiveness and relaxation. Analgesia is not present.
Anaesthesia	A complete loss of sensation in part or all of the body.

Adapted from ARENA/OLAW (Applied Research Ethics National Association/Office of Laboratory Animal Welfare) (2002).

Survival surgeries are an example of procedures that may cause significant pain and distress in animals. Survival surgeries must be demonstrated to be essential to the study, and performed by well-trained personnel, preferably medical or veterinary surgeons, or highly skilled, experienced technicians. It is recommended that new surgical procedures be witnessed and, if necessary, supervised by a veterinarian not otherwise involved in the study. In many cases, the IACUC or other approving committee will request a report on the first new surgical procedure before permitting others. Also, the committee can require modification, or termination, of the protocol in response to the initial report. Proper presurgical preparations, including selecting a sterile suite, appropriate sedation and anaesthesia, and training of the surgical team are necessary. The means for monitoring and supporting the subject's condition (blood pressure, level of anaesthesia, and body temperature) must be available and used throughout the procedure. If complications that cannot be dealt with during the surgery are encountered, euthanasia of the fully anaesthetized subject must be performed, or at least seriously considered. Postsurgical care with initial intensive monitoring is an essential component of the procedure. Continuous monitoring is required before the animal regains consciousness. If the recovery period is lengthy, monitoring at frequent intervals for 24 hours or more may be necessary. Failure to notice and deal with postsurgical complications is considered to be serious negligence, and is likely to result in temporary or permanent cancellation of the protocol's approval.

Death by any means other than euthanasia is strongly discouraged in animal studies unless there is assurance of complete pain control. Traditional lethality studies, such as the classical LD_{50} (lethal dose for 50% of the animals during a defined postadministration period) study, have been largely replaced by studies that provide euthanasia when a premorbid state is achieved. Classical LD_{50} studies required 40 or more animals for statistical validity. Animal tests of lethality are sometimes required for toxicity testing related to chemical labelling (as for transportation), treatment of poisoning, establishing maximum dosage of therapeutics, setting dose levels for subsequent studies, and validating alternative (those not involving animals) test methods (Zurlo *et al*., 1994). Whenever possible, LD_{50} tests should be replaced with other tests. Such tests that require fewer animals have been described in a review by Rispin *et al*. (2002). As regulatory requirements for lethality testing are in a state of rapid evolution, the current regulations and literature should be searched prior to designing such studies, so that more humane procedures can be used.

Similarly, study designs involving significant food or water deprivation, noxious/irritant stimuli, cancer/tumour induction, extreme environmental conditions and other pain-producing procedures must be carefully considered. A review of toxicology testing methods edited by Derelanko and Hollinger (1995) describes traditional and available alternative testing methods. For such studies, elimination of unnecessary pain and distress, as well as minimizing the number of subjects, is necessary.

3.4 Euthanasia

Euthanasia (from the Greek, meaning 'good death') is routinely performed in toxicology studies for a variety of reasons including: to prevent suffering; to obtain tissue and other samples for analysis; to harvest organs, tissues and cells for *in vitro* preparations; and to end the lives of animals at the termination of a study. Because euthanasia itself has the potential to cause pain and distress it must be performed by trained personnel using techniques that are appropriate to the study and species used; ethical considerations should outweigh practical ones, such as cost or convenience. In recognition of the foregoing considerations, the *American Veterinary Medical Association (*AVMA*) Panel on Euthanasia* provides guidelines, which are periodically updated. The 2007 update comprises a 40-page report which is available on the AVMA web site (*www.avma.org*). The report is thorough, covering: 'general considerations'; human (scientific staff, not research subjects) and animal 'behavioural considerations'; 'inhalant agents'; 'noninhalant pharmaceutical agents'; 'physical methods'; and 'special considerations' that take into account species, age, and the reason for euthanasia (e.g. food production, or disease control). Appendices cover: 'agents and methods by species'; 'acceptable agents and methods'; 'conditionally acceptable agents and methods'; and 'unacceptable agents and methods'. The report emphasizes the responsibilities to prevent predeath anxiety, to verify death, and to insure that those who administer the euthanasia are properly trained and properly employ humane techniques; gentle handling and calming techniques are recommended. The guidelines of the AVMA Panel should be thoroughly examined and strictly followed to the extent possible in the laboratory. Scientists seeking approval for their studies can expect to be held to the AVMA Panel's guidelines by approval committees (NRC (National Research Council), 1996; ARENA/OLAW (Applied Research Ethics National Association/Office of Laboratory Animal Welfare), 2002).

4 HEALTH AND SAFETY

Investigators and their institutions are responsible for the health and safety of the animals that they acquire, transport, house and use. Discharging this responsibility requires: establishing and maintaining facilities appropriate to the species acquired; having professional (scientific and administrative) and technical staff (scientific

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 8 Some responsibilities that investigators have towards the health and safety of animals

Item	Comment
Diet and nutrition	Dietary modification, including food and water restriction, should not produce unrelieved pain or excess distress.
Disease	Unintended diseases should be prevented, and all diseased animals should have adequate care and treatment to the extent the study permits.
Pain and distress	Species-appropriate handling and humane treatment and procedures, to the extent permitted by the study, must be assured. This includes relief of pain and distress.
Environmental quality	Animals should not be subjected to unhealthful or stressful confinement, temperature, humidity, lighting, vibration, noise, or air quality to the extent possible in the laboratory.
Safety	To the extent possible, animals must be protected from injury in the laboratory. Attention to temporary caging, handling and laboratory equipment is required.

assistants, and vivarium personnel) that are qualified and trained; establishing protocol review and monitoring processes; providing healthful housing and caging conditions; meeting the animals' nutritional needs and environmental requirements; providing access to exercise and environmental enrichment for some species; having effective plans for protecting animals in the event of mechanical and power failures; having preparations for disasters (fires, floods, etc.); and protecting the animals from theft. These responsibilities, which fall mainly on the institution and its administration, are largely covered by regulations and by guidelines such as those used for accreditation (NRC (National Research Council), 1996).

The responsibilities of Principal Investigators and other animal users supplement those of their institutions. Some of these responsibilities are described in **Table 8**.

Education of the Toxicologist

Robert Snyder and Jason R. Richardson

CONTENTS

1 INTRODUCTION

The idea that there can be training programmes for toxicologists bears within it the inherent concept that toxicology is a distinct scientific discipline. Among the biological sciences it has long been accepted that anatomy, biochemistry, physiology, microbiology, pathology, and even pharmacology are distinct disciplines. Although the body of scientific effort in these areas justified disciplinary designation, the requirement for learning these sciences as part of professional medical education bolstered their claim to individuality. Toxicology came late to acceptance as a unique discipline, and in some quarters that concept is not yet accepted today. Nevertheless, the knowledge that chemicals can adversely affect biological organisms has been known for many centuries. We have been familiar with the concept of poisons from the death of Socrates, through Paracelsus and Lucretia Borgia. In the nineteenth century, Orfila is credited with carrying out the first scientifically based studies of toxicity, and subsequently a number of great biologists, including Magendie, Bernard, Schmiedeberg and others performed seminal research defining the effects of chemicals on biological systems, in the study of physiology, and later, pharmacology. Today, their work could legitimately be considered mechanistic studies in toxicology.

The need to recognize a formalized profession and separate discipline of toxicology arose primarily from several distinct sources in the USA. The Food, Drug and Cosmetics Act of 1938 demanded that, prior to marketing a new drug, the US Food and Drug Administration must be supplied with data from the manufacturer showing that when taken as directed the drug is safe. While some side effects may be observed, it must be demonstrated that no serious toxicity will occur through normal use of the drug. As a result, drug companies were forced to perform toxicological studies to evaluate their new products and to present the resultant data to the agency for approval before the drug could be marketed. The second milestone in the solidification of the discipline of toxicology came when the National Academy of Sciences/National Research Council established the Committee on Toxicology in 1947. The mandate of the Committee on Toxicology extends beyond foods and now

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

covers the entire range of potentially toxic industrial and environmental chemicals. A third milestone derives from the formation of the Society of Toxicology, the first professional society in toxicology, which dates from 1961–1962. Finally, the establishment of a Toxicology Training Program by the National Institute of Environmental Health Sciences (NIEHS) recognized that the discipline existed and that programmes for toxicology training would be supported by the federal government because people well prepared to study the toxicology of a large range of chemicals were essential for the health of the nation.

Although the Society of Toxicology was founded in 1961–1962, rapid expansion of training programmes in toxicology, except for a few pioneer programmes, began in the 1970s, and accelerated growth continued into the 1980s. The impetus for the rapid expansion of toxicology training came from several sources. The NIEHS, the National Institute of Occupational Safety and Health (NIOSH), the Environmental Protection Agency (EPA) and other federal agencies were established because of concern over the impact of chemicals on health and the environment. These agencies required trained personnel to carry out their functions, and created a demand for people which could only be accommodated by the development of new training programmes.

A stimulus of greater significance to the scholar resulted from a pattern of development of thought in the biological sciences which made inevitable the eventual coalescence of the discipline of toxicology. Toxicology is the study of the adverse effects of chemicals (and radiation) on biological systems. The study of adverse effects suggests that there must be a pre-existing understanding of normal biological functions before abnormal effects can be recognized and studied. The evolution of medical training in this country during the twentieth century led to the establishment of anatomy, physiology, biochemistry, pharmacology, microbiology, nutrition, immunology and pathology as the basic biomedical sciences. The accumulation of information on anatomy, which occurred over many centuries, led gradually, in the nineteenth century, to the development of physiology and then biochemistry. Pharmacology could not function as a separate discipline until the database in physiology and biochemistry, which utilized chemicals as tools to study biological functions, expanded to a critical level. Pathology was an extension of anatomy, which concentrated on a number of abnormal biological events, including effects of chemicals. Certainly, the development of new drugs required a full examination of their toxicological potential. Thus, after sufficient knowledge in the basic biomedical sciences was attained, and the practical examination of the potential toxic effects of chemicals became routine, the discipline of toxicology emerged.

Those involved in training graduate students in toxicology realize that their job is to launch the student into a lifetime of learning. The late Arnold J. Lehman, of the US Food and Drug Administration is credited with stating that 'You too can be a toxicologist in two easy lessons, each of 10 years.' (Gallo, 1996). In this discussion we will emphasize the training of graduate students and postdoctoral fellows. The average time required for formalized training is about six to eight years as a graduate student and then as a postdoctoral fellow. The bulk of the remaining 20 years of training takes place as part of career development.

2 SITES FOR TOXICOLOGY TRAINING

Historically, toxicology training programmes were housed in established pharmacology departments in medical and pharmacy schools. However, toxicology programmes are becoming increasingly more interdisciplinary and are often found as joint programmes incorporating faculty staff from a wide variety of departments in medical schools, schools of pharmacy and schools of public health. Listings of toxicology graduate programmes can be found by going to the web sites of the major toxicology societies including the Society of Toxicology (*www.toxicology.org*), the Federation of European Toxicologists & European Societies of Toxicology (*www.eurotox.com*) and the British Toxicology Society (*www.thebts.org*).

3 AIMS OF TOXICOLOGY TRAINING PROGRAMMES

The principal aim of any toxicology training programme is to offer a curriculum which will prepare the student to function at the highest possible level as a toxicologist. Although some toxicology training is available at the undergraduate level, the majority of toxicology training venues are in graduate schools. Each of the biomedical sciences can be approached at either the fundamental or the practical level, and both approaches are needed by society. If we recognize that the toxicologist is a scientist and that scientific training requires both the assimilation of known information and research to increase our knowledge, then the training of toxicologists requires a series of courses plus an opportunity for the student to learn the principles of research by performing a research project. Some aspects of the curriculum may be devoted to applied research in toxicology, but the major effort should be in basic research, preferably at the mechanistic level, which will expand our fundamental understanding of the biological responses that underlie toxicology.

Graduate training in toxicology is, of necessity, broad based. Students must be exposed to the basic biomedical sciences and chemistry because these disciplines will be the tools of their trade regardless of where

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat130
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

their career paths lead them. In the course of graduate training, students will become expert in their field of study and may develop other areas of expertise as their careers develop. Although they need not be expert in the approaches of all of the biomedical disciplines, they must be sufficiently knowledgeable to know when to apply otherwise unfamiliar methodology necessary to solve specific problems. Consultation with specialists in other fields may be essential to complete the work, but the toxicologist must have sufficient knowledge to ask the proper questions, to understand the results of such studies and to involve the results in the next stage of the work.

To ensure that programmes succeed in meeting their aims there must be a faculty dedicated to graduate education. Often there is a Director for graduate education which may, or may not, be the department chair. The Director, with the help of the faculty, administers the programme by overseeing recruitment of students, admissions, record keeping, progress towards the degree, examinations, grievances and the degree-granting process. The Director is usually responsible for much of the fund-raising activities which go to support the students. Thus, obtaining teaching assistantships, externally supported fellowships, travel funds and other needs of the students falls, in large measure, on the shoulders of the Director.

Perhaps of greatest importance is the necessity for the Director to ensure that students select laboratories of mentors where they can best proceed through the process of earning the degree. Usually this requires a meeting of minds between mentor and student regarding the nature of the research project, but the issue of compatibility between the two protagonists should not be discounted. The mechanisms by which student–mentor relationships are established vary among programmes. They almost always involve a trial period in which the student spends a limited amount of time in the prospective mentor's laboratory, to permit each to determine whether a successful research partnership can be established. Once a collective decision involving student, mentor and Director is made, the student relies on the mentor for advice on courses, research, and career planning.

Most mentors follow the careers of their students and stand ready to offer assistance long after they have left to develop their own careers. Senior professors are often called upon by those seeking to fill a variety of positions in toxicology. The professor then has the opportunity to recommend former students to positions of advancement. The interplay is a two-way street; in some cases, former students having advanced in their careers may find ways to help enhance the programmes from which they graduated through teaching, providing entrees to obtaining financial assistance, offering positions to more recent graduates, and so on. The concept of the 'doctor father' in German universities, which grew out of the citing of scientific lineages, exemplifies the lasting relationships that are possible between student and mentor.

4 PREREQUISITES TO GRADUATE TRAINING IN TOXICOLOGY

Those students best prepared to study toxicology at the graduate level will have earned a bachelors degree in chemistry or biology. In addition to introductory study in chemistry, the student will benefit from courses in analytical, organic and physical chemistry. A course in biochemistry is helpful but can be taken at the graduate level. In biology, a general introductory course followed by electives in areas such as comparative anatomy, histology, cell physiology, and so on, would be helpful. Students are urged to study physics and mathematics in preparation for graduate school because of the rapid advances in application of these disciplines in modern toxicology.

5 REQUIRED GRADUATE COURSES

Although most curricula in toxicology require a basic course in general toxicology, it need not be the first course taken in graduate school. Most students require graduate-level courses in physiology, biochemistry and molecular biology. The area of biostatistics and experimental design and interpretation of results should be part of every graduate programme. Finally, the NIEHS has mandated that each programme offer a course in ethics as they apply to scientific research. Many programmes require pathology, which would be most helpful if it could precede or run in parallel with the toxicology course. Programmes associated with institutions devoted to medical training often ask students to study pharmacology because of the significant overlap between the two disciplines.[a] Other more relevant courses might be substituted for students in nonmedically related areas; for example, students directed towards a career in environmental toxicology might include courses more directly related to their interests, such as ecotoxicology. All students should be required to hone their communications skills by participation in seminar courses.[b]

The most important course offering is the first course in general toxicology, which goes by a variety of names in various institutions and is required of all students. Among the subjects that it must cover to adequately introduce students to toxicology are:

1. A brief discussion of the history and scope of toxicology.
2. A discussion of general basic principles of toxicology.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat130
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3. Toxicodynamics; that is, what does the chemical do to the body?
4. Toxicokinetics; that is, how does the body deal with the chemical?
5. A survey of the effects of various chemicals.
6. A description of the specific toxic responses of various body organs?
7. Venues; that is, toxicity observed in the home, workplace, environment, and so on.
8. Applied toxicology: safety evaluation and risk assessment.
9. Mechanistic toxicology.

The extent to which any of these areas is covered will depend upon the time allotted to the course, the availability of advanced courses to cover any of the areas in detail, the interests of the faculty, and so on. In every course in toxicology, however, there should be sufficient emphasis given to the paracelsian admonition:

> *In all things there is a poison, and there is nothing without a poison. It depends only upon the dose whether a poison is a poison or not…*
>
> *(Jacobi, 1988)*

6 ELECTIVE COURSES

The selection of elective courses will depend upon which courses are available in any given institution, but can generally be separated into those in toxicology versus those in allied disciplines. Many students opt to take advanced courses in chemistry or the biological sciences. Advanced courses in chemistry are many and varied. Course selection is often driven by the research project in which the student is engaged. In the biological sciences, graduate students in toxicology should become familiar with microbiology, immunology and genetics.

Electives in toxicology depend upon the expertise of the faculty and may encompass such areas as neurotoxicology, pharmacogenetics/toxicogenetics, pesticide toxicology, and so on. Electives are also a mechanism for introducing students to the more applied areas of toxicology, such as safety evaluation, risk assessment, public health and the environment, and so on.

An important message for any student is that the best thing you can learn in graduate school is how to learn. Courses teach what is currently known, but cannot predict the future. Once the student has initiated an independent career, most learning will be self stimulated and will not involve attending classes. To be sure there are many opportunities for formal continuing education. Both the Society of Toxicology and the American College of Toxicology offer continuing education courses at their annual meetings. Ultimately, however, most toxicologists should keep up with recent advances through their own efforts. Therefore, the value of time spent in classes, beyond learning the basics and enough advanced information to permit the beginning of a research project, must be balanced against the value of time spent in the library and the laboratory.

7 QUALIFYING EXAMINATIONS

Advancement through graduate school is characterized by study and research on the part of the student, and evaluation of the student via a variety of metrics. Courses require that students perform well on objective exams, essay-type exams, or in the writing of research papers. Despite hurdling these barriers, in most programmes students must pass qualifying exams. The requirements for the Master of Science and the Doctor of Philosophy degrees may be dissimilar. Thus, a single examination for the MS often suffices. For the PhD, the process is usually more complex. Often there are two sets of exams: written and oral. Some programmes use a comprehensive written exam at the end of the first year of graduate school to determine whether the student should continue. Some offer the comprehensive examinations as a prelude to the oral examination to determine whether the student is prepared for the oral. Other programmes do not have written comprehensive examinations. There are a number of variations on this theme.

For many years students were required to pass one or more examinations in a foreign language, but that custom has become less popular as English has assumed a predominant position as the international language of science.

The oral examination is usually the point of decision with respect to whether or not the student becomes a candidate for the degree. There is more riding on the oral examination than on any other examination in the student's career. As a result, students study long and hard to prepare for the examination. Examination committees should inform students embarking on the candidacy process regarding faculty expectations. Toxicology is among the broadest of the biological sciences, and in each of the subdisciplines within toxicology, deals with an extensive database. Furthermore, because of the breadth, much of the information that students should know comes from other areas such as biochemistry, physiology, pathology, and so on. Thus, the oral exam may become a free-for-all, with faculty members asking questions on subjects that range from a discussion of dose–response curves to estimating the weight of Saturn (the latter as an example of how a professor once thought that a student's reasoning powers might best be measured.) A wise faculty will establish with the student the limits of required subject areas and will find a way to learn what they must from the student within the defined area.

There are many methods for defining the range of the oral examination, but one general form which can have many benefits for the students can be addressed here. In some universities, students, with the advice of their mentors, submit to the Director, early in their graduate-school careers, a list of, perhaps, 10 hypotheses, or propositions, which together define a broad area of toxicology, but result in some delimiting of the total range of information for which the student is responsible at the time of examination. An example might be: 'The lethal effects of parathion can be explained solely on the basis of cholinesterase inhibition.' The student would then collect all of the information in the literature on this question and would defend or attack the proposition in a written paper which is presented to the members of the examination committee in advance of the examination for use as the basis of questioning. It has been demonstrated that 10 such papers prepared over a two-to-three-year period offers the committee a chance to determine how well the information has been collected, evaluated and used in creative decision making by the candidate. The proposition method permits a narrowing of the range of areas on which the student will be questioned but permits the faculty to delve as deeply into the subject as seems warranted to make candidacy decisions.

Success in the oral examination is often difficult to attain for some students because of the significance of the exam to their future careers and perceived trauma they experience during the process. Often, excellently prepared students fail to measure up to the expectations of the faculty because of nervousness, or forgetfulness induced by the pressure-packed nature of the examination. To help prevent, or to overcome, the impact of emotions on examination performance several approaches have been used. Often, graduate students within programmes offer a chance for candidates to participate in 'mock orals', in which their fellow students, or faculty members, act as the examining faculty and ask the questions they anticipate will be asked at the exam. If students appear to be in great difficulties during an exam the committee may decide to delay a decision and offer the candidate the option of completing the examination at a later date. The student is expected to complete the examination successfully at the continuation. Despite the recognized shortcomings of the oral exam system it continues to play a significant role in graduate education, both as a valuable mechanism for evaluating the qualifications of a student, and for the sense of accomplishment engendered in the successful candidate.

8 THE RESEARCH EXPERIENCE

The essence of a PhD programme in toxicology is to train people to perform scholarly research. Although the requirements of many MS programmes can be met by having the student write a library-based paper without doing a research thesis, many others require a small-scale research project leading to a written thesis. For the PhD an extensive research project is required. The subject of the research is decided upon through discussions between the student and the mentor. Some students enter graduate school with the intention of working in a specific area of toxicology, or with a specific mentor. High-quality research training can result from work in any area of toxicology. Since most students select their mentor on the basis of compatibility, they naturally work in the area of interest to the mentor, and many remain in this area long after they have completed their degrees and move on.

The components of research training include an appreciation of the concept of a hypothesis and how hypotheses are developed, selecting an experiment model, use of appropriate controls, designing experiments to test the hypothesis, data evaluation, including biostatistics, and interpretation of the data. During the training of graduate students, the mentor should provide opportunities for the student to sharpen those communication skills necessary to report the results of a research project. These would include writing of abstracts and research papers, oral presentation of results, and preparation of posters showing the work for presentation at scientific meetings. The opportunity to meet with others working in the same field should be made available by sending the student to meetings of scholarly societies.

It is during the development of the dissertation that the student should be imbued with a concept of scholarship. The importance of gaining a complete understanding of the literature in the field under study before planning a full-scale project is of the utmost importance. It is all too easy to unknowingly perform studies which have been done previously and already appear in the literature. Students tend to rely on computerized databases for literature searches. Although some online databases contain research performed prior to 1960–1970, in most cases the conscientious student has no choice but to leave the safe confines of the laboratory, venture into the challenging culture of the library, and rummage around in the stacks for what may be valuable nuggets of otherwise lost information which could be of great value in the student's research.

Hypotheses derive from creative evaluation of existing literature and seminar presentations, discussions involving the mentor, and often with other members of the research team in the laboratory, and the performance of pilot experiments to indicate whether or not there is a reasonable chance that the project will succeed. Once the hypothesis is established it is incumbent upon the student to develop an experimental design to challenge the hypothesis. Consultation with the mentor will enable the student to determine the feasibility of the planned studies. If the hypothesis is reasonable, it is necessary to ensure that it is technically possible to perform

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat130
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the experiments in the specific laboratory chosen for the research. Research costs, availability of necessary instrumentation, and, where necessary, help from other people, are issues that must be settled before a research project can begin. Assuming that these problems can be solved, the mentor must ask whether the student has selected a suitable problem. Is it sufficiently challenging to be worthy of the PhD upon completion? Can it be completed within approximately three to five years? The mentor must also consider the issues of costs, facilities and other people in the laboratory. These issues must be satisfactorily addressed to engender success in a graduate student thesis project.

In many universities the mentor–student relationship is complemented by a thesis committee, which follows the student through the process, meets with the student for regular updates, acts as a quality control mechanism, eventually decides when the project is completed, and sits as thesis defence committee. Outside reviewers are often asked to participate at some stage in the development of the thesis to act as impartial referees. An important job of the committee is to ensure that the student completes the thesis in as short a time as possible. Graduate disciplines often have cases of students who have been either improperly advised or insufficiently stimulated, who subsequently remain in graduate school for inordinately long times. The thesis committee is an important mechanism for maintaining an acceptable rate of progress towards the degree.

In toxicology the aims of the specific piece of research may vary considerably. Until the early 1980s most research in toxicology was aimed at describing the effects produced by chemicals administered via any of several routes to one or more species of animals. End points such as lethality or pathology resulting from acute or subchronic treatments were common. With the emphasis placed on cancer prevention in the USA, the National Toxicology Program was developed specifically to expose animals to chemicals for a lifetime. After the death of the animals they were examined for signs of cancer. Chronic exposure studies of this type were less commonly performed in university laboratories because of the cost and the need for specialized personnel and facilities. Nevertheless, shorter-term carcinogenicity studies were performed in a number of laboratories.

The impetus towards maturation of toxicology as a discipline came from many sources, but the emphasis by toxicologists on mechanisms of toxicity served to demonstrate that toxicology could contribute to the basic understanding of biological functions. The role of metabolism of xenobiotic chemicals, especially the formation of biologically reactive intermediates, was a significant factor in the development of mechanistic toxicology. Studies of the interactions of chemicals with enzymes or nucleic acids and the ensuing adverse effects led to a better understanding of structure–activity relationships and our ability to predict some types of toxic effects. Currently, many mechanistic studies revolve around the problems of mutagenicity, carcinogenicity, oxidative stress and mechanisms of cell death. The enrichment of mechanistic studies by the application of the principles of exposure assessment represents an ideal extension of traditional mechanistic toxicology and has been used to develop animal models of chemically induced diseases. These approaches are being used in university laboratories with the goal of understanding the underlying principles which lead to the production of adverse effects by chemicals on biological systems.

In any scholarly discipline the ultimate measure of quality research is the contribution it makes to understanding of the most fundamental issues with which the discipline is concerned. In the course of their training, graduate students play a significant role in the scientific process. They share in the development of hypotheses, perform the experiments, and focus on the results. Thoughtful interpretation of the results will lead to the emergence of new avenues of research which will benefit science, but which also enrich the training of the student and will help the student mature as a scientist.

Some students plan on careers that do not focus on laboratory research. There is a great need for toxicologists in regulatory agencies in federal and state government, in regulatory departments in industry, as consultants, in law firms, and in a number of other occupations. Nevertheless, in any work as a toxicologist it will be important to review the results of both applied and basic research. Research training is the best way to prepare a student to read and understand the results of other researchers' work. The more rigorous their research training, the better the job they can do in evaluating and criticizing research results which apply to the problems they are attempting to solve.

9 STUDENT PRESENTATIONS

At each stage in the training of a student in toxicology it is important that they learn how to communicate with their peers. Early in graduate education students should be asked to participate in exercises which will give them the opportunity to communicate is several ways. For example, the short-paper form of delivery provides an excellent training ground. Many societies offer their members the opportunity to publish an abstract of their work in advance of a meeting and then present the work in a 10–15 minute paper accompanied by a visual presentation to illustrate the data. This format makes for a good first year course for graduate students. They may work on a topic, the data for which they may find in the literature, learn how to write an abstract, prepare appropriate slides and make their presentation to other students and faculty. In the course of this activity they will gain ease in making presentations before their peers,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat130
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

learn to write concise reports and become familiar with ways of presenting their data. Learning how to make presentations in the classroom situation will help prepare them for presentations at scientific meetings.

When students go beyond the first year or two in graduate school their seminar responsibility should take on a different form. The research that they are performing for inclusion in their theses will progress from year to year, and annual oral presentations of their data in 20–30 minute reports provide a useful training tool. One approach is to have all advanced students present their progress reports in symposium format. It is an opportunity for a programme to have a day devoted to student presentations attended by the entire faculty and invited guests. The students may be asked to prepare an extended abstract to be given to the audience in advance of the presentation. The students will have benefited by having prepared short presentations earlier in their careers and can make use of that experience in the symposium format.

The first presentation by a student at a society meeting these days is most likely to be a poster presentation. Here the student presents the results of thesis research in a series of panels mounted on a board that is often 1.2×1.8 m. The poster usually contains an abstract of the work, a brief note on methodology, several panels on data and a summary statement. The poster is intended to generate discussion between the presenter and colleagues who stop to ask about the work as they stroll through the poster presentation area. Under these circumstances the student meets the questioner one-on-one, rather than as a member of a large audience. These can be much more difficult interactions since they often require detailed information at the fingertips of the student. In some cases the poster sessions are followed by a discussion period where the essential information of the posters is briefly reported by the presenters. Thus, poster sessions and poster-discussion sessions present a challenge to the student which is different from that posed by the short platform presentation or the longer symposium presentation.

The most important type of communication is the written report intended for peer review. A published report will enter the literature and become available for reference in perpetuity. As a result it is the most critically reviewed and criticized. During training the student should be prepared not only to perform the research project with excellence, but should also be trained to prepare a paper for publication at the highest possible level. The writing of the thesis, albeit a somewhat longer item of prose, should set the standard for the writing of papers which will emerge from the thesis work. Students who perform in exemplary fashion in the writing of papers may be asked to participate in the preparation of review articles. Reviews in excellent journals also undergo intensive peer review and serve as an important mechanism for deriving new ideas and research pathways based on compilation of reports from many sources. The authorship of a review article by a graduate student is unusual but can be an important step in developing a successful scientific career.

10 APPLIED TOXICOLOGY

Toxicology training as discussed above involves a series of classroom exercises and the completion of a basic research project. Toxicologists trained in this way are well adapted to careers in basic research. Many others enter careers in applied toxicology for which their university training did not prepare them directly. To be sure, learning how to understand and do science is critical for any career in toxicology. However, learning methods in areas of applied toxicology requires additional course work or on-the-job training. Historically, chemical and drug companies developed new chemicals and evaluated both their potential beneficial biological effects and their adverse effects. More recently the cost of toxicological studies has motivated companies to perform safety evaluation in laboratories whose main business is safety evaluation. Thus, the companies which develop the chemicals employ toxicologists termed ‘study directors’ to design, monitor and evaluate the toxicology studies while performed at remote laboratories. They require knowledge in the techniques of safety evaluation and should be prepared to manage and to perform these studies.

Among their responsibilities will be issues relating to the utilization of experimental animals. Animal welfare issues are of great significance. Often large numbers of animals of different species are involved; times of exposure may vary from single doses to lifetime; pathology studies, performed after the death of the animals, must be analysed; detailed reports must be prepared, often accompanied by recommendations for further action. While some of these problems may have been the subject of classroom discussion, and some similar types of studies may have been included in the thesis project, more frequently studies of these types are completely new to the recent graduate. Thus, both employee and employer must realize that advanced training, especially when the specific needs of the company must be met, is the responsibility of the company.

The processes that are termed risk assessment involve utilization of data gathered from many sources regarding the toxicology of chemicals. Risk assessment is the attempt to predict the risk to health resulting from exposure to chemicals at specific dose levels based on prior observations in animals, and when available, humans. Thus, toxicologists frequently become involved in the risk assessment process because of their training in the interpretation of the data produced in toxicology studies. The use of graphical techniques to analyse data

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat130
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

leads biometricians to play an increasingly greater role in the interpretation of toxicological data. They use their understanding of mathematical functions to influence the interpretation of data. Their input is particularly critical when it is necessary to extrapolate from data observed under laboratory conditions to the real world situation in which people are exposed to chemicals. For example, given a specific response to a chemical in an animal study involving specific doses via a defined route, for various lengths of time, what might the response be in humans in a specific exposure scenario? The accuracy of these predictions depends upon the biology of the system, but the extrapolations are frequently driven by mathematics rather than by biology because we lack sufficient understanding of the underlying mechanisms. Thus, a common approach is to fall back on mathematics, making use of a variety of assumptions, rather than to do more experiments to verify the accuracy of the extrapolation. Regardless of the virtues or shortcomings of the process, toxicologists are frequently involved in risk assessment. Some may have had classes in risk assessment, but these are insufficient to prepare them for performing such an exercise and to appreciate the responsibility entailed. This is another example of where on-the-job experience is essential.

There are training locations for forensic and clinical toxicology, which are often separate from academic toxicology training programmes. Forensic laboratories are concerned with toxicological issues relating to legal matters. Their specialty is analytical chemistry. Among the most frequent calls upon these laboratories are requests to measure blood alcohol concentrations in samples from people involved in traffic accidents. Measurements of body fluids or tissues are often made in questions of poisoning. The forensic toxicologist is usually associated with a government laboratory such as a city, county or state medical examiner. The FBI has one of the largest and most complete forensic laboratories. Forensic toxicologists are frequently called upon to provide testimony in court regarding their findings. There are relatively few sites for training in this field and there has for some time been a critical shortage of personnel with sufficient expertise to work in these laboratories.

Clinical toxicology is a medical specialty concerned with the detection and treatment of poisoning in people. Victims usually arrive in the emergency ward of a hospital in a state which suggests that they have either administered a poisonous level of a chemical or drug to themselves or have been poisoned by someone else. The clinical toxicologist must decide on the basis of whatever evidence is available (i.e. interview and observe the patient, have evidence of a container in which the material was found, physical examination, laboratory analyses, etc.) and make decisions regarding treatment of the patient. The forensic laboratory plays an important role as a resource to which the clinician can turn to learn about the specific chemical, the dose, the blood level, and so on. Since this is a medical specialty, training is not usually performed in academic toxicology training centres, but as part of advanced medical training at the intern or resident level, and board certification is available to those who wish to make a career as clinical toxicologists.

11 THE POSTDOCTORAL EXPERIENCE

Toxicology training does not end with the award of the PhD. Many graduates, upon completion of the degree, take positions in companies, in government agencies, with environmental groups, and so on. In each of these venues they must undergo training to meet the specific needs of the job to meet the expectations of the employer. For those toxicologists who wish to enter a career in which research is a major component, most employers require postdoctoral training.

The postdoctoral fellowship offers the trainee an opportunity to become a full time researcher under the aegis of an experienced investigator. Postdoctoral mentors are selected by the trainee on the basis of the area of research in which they work and on the excellence of their productivity as scientists. Their laboratories may be in various departments or schools in universities, in research institutes, or in government agencies. Popular locations for postdoctoral training in the USA include those institutions awarded NIEHS training grants, or laboratories within the various National Institutes of Health. A variety of research centres, such as NIEHS Centers of Excellence offer postdoctoral training opportunities. Additional opportunities can often be found in more specialized environments such as cancer research institutes or environmental health centres. In any of these locations the postdoctoral fellowship is intended to provide the fellows with the opportunity to demonstrate their scientific creativity and productivity in an environment in which they are totally devoted to research.

The postdoctoral experience begins with the selection of a specific problem, which in most laboratories is one of a group of problems in the same general area. In an active laboratory one often finds technicians, graduate students and postdoctoral fellows. Although each works on a separate problem, proximity leads to communication which helps all in the group. Learning techniques and approaches from each other enhances the total output of the laboratory. It is clear that the success of a laboratory is related to interaction among the various participants, and the postdoctoral fellows usually take a leading role in such interactions. A frequent result of these deliberations is often to work collaboratively with one or more other members of the team. The increasing complexity of research in toxicology, and the need for the application of advanced techniques, which only some members of the team can contribute, may require the

assembly of a group of workers each of which brings essential talents to the joint solution of the problem. Learning to operate within a collaborative framework can be an important aspect of career development for a toxicologist.

Ideally, a postdoctoral fellow should spend two to three years in training, at which point it is time to seek an independent position. Nevertheless, it has recently become more common for postdoctoral fellows to complete more than one postdoctoral training position in order to be competitive for tenure-track positions at many universities. This trend has arisen partly because of the increased complexity and breadth of science involved in the profession of toxicology, as well as the increased competition for research funds. In order to be competitive for tenure-track positions, it is advisable that postdoctoral fellows demonstrate the beginnings of independence as a scientist by successfully competing for postdoctoral research fellowship awards. There are a variety of sources for these awards from government agencies and private foundations. The experience of writing applications for postdoctoral fellowship grants is not only valuable to those with the goal of achieving a faculty position but to those that have other career plans. The ability to convey a hypothesis and an experimental plan in a written format and to then have the document undergo peer review is a valuable experience in creative thought that forces the applicant to critically evaluate the literature, identify gaps in current knowledge, and portray the importance of the research proposed as it relates to the advancement of the area proposed for study. At this point the postdoctoral fellows leave the safety, the support, the financial backing and the stipend paid by the mentor and must fend for themselves. Mentors usually help in securing positions for postdoctoral fellows, but a variety of placement services are available to assist in the job-hunting process. Clearly, those fellows who have trained in highly respected laboratories and have been productive during the training period will have the upper hand in the job search. Upon securing a position beyond the postdoctoral level the toxicologist must now direct considerable effort towards securing research funding and developing an independent laboratory. It is the most challenging time in the career of toxicologists, and success will in large measure depend upon the quality of training that they have enjoyed.

12 CONTINUING EDUCATION OF THE TOXICOLOGIST

Lehman's statement that 'You too can be a toxicologist in two easy lessons, each of 10 years' (Gallo, 1996) brings to light the necessity of continuing education, particularly for the second part of this 20 year training. Continuing education comes in a variety of forms, but is most often associated with specialized classes offered at the annual meeting of the various toxicology societies or other scientific societies to which the toxicologist belongs. However, this is not the only form of continuing education. Keeping abreast with the scientific literature, attending meetings and presenting data, networking with colleagues, and performing service to the scientific community in the form of grant and manuscript reviews all encompass aspects of continuing education. Another important form of continuing education is mentorship. For professional toxicologists in their first years of the profession, mentorship by a senior toxicologist, be it formal or informal, is an important aspect of career development that is often overlooked. These types of mentorships provide an invaluable source of advice and perspective as the toxicologist continues along their career progression. Furthermore, it lays a foundation and provides an example for the more junior toxicologist to one day become a mentor to others.

13 TRAINING IN OTHER COUNTRIES

13.1 Great Britain

An example of toxicology training in Great Britain is taken from the curriculum at the University of Surrey; here students have the opportunity to initiate their training in toxicology at the undergraduate level. Those students concentrating in biochemistry may elect to take courses in drug metabolism and pharmacokinetics, in mechanisms of toxicity, regulatory toxicology, pathology for toxicology, practical toxicopathology and forensic toxicology. Following the Bachelors degree, students may enrol in the Master of Science in Toxicology programme. Progress towards the degree requires 338 hours of lectures, 125 hours of laboratory training and 400 hours devoted to laboratory research on a dissertation project over a total of 44 weeks. The course includes tutorials, visits to industrial laboratories and utilizes a variety of assessment modes. The course work is varied, ranging from whole animal studies to molecular biology, as well as regulatory affairs and safety evaluation. The student wishing to go on to the PhD registers for the Master of Philosophy, completes the course work and writes a report on the progress in a laboratory research project, which is used to determine whether or not the student will be permitted to transfer to the doctoral programme. Upon approval of the report the student becomes a candidate for the PhD, which is awarded upon completion of the project. The total time required is usually about four years.

13.2 Germany

Historically, toxicology in Germany has been closely associated with medical pharmacology. Toxicologists tend to be members of the German Society of Experimental and Clinical Pharmacology and Toxicology (DGPT). Indeed, a subdivision of the German Pharmacology Society is termed the German Toxicology Society, for which a separate web site has been established. In recent years the society has developed a mechanism by which individuals who hold doctorates in medicine, veterinary medicine, chemistry, biochemistry, biology, pharmacy or related disciplines can earn a certificate by which they are named Expert in Toxicology, DGPT. The certificate is awarded on the basis of an examination. However, to be eligible to take the exam the applicant must have had at least five years of experience in a toxicology laboratory, plus comprehensive knowledge in 1 area of toxicology, broad knowledge in 2 other areas of toxicology and basic knowledge in 15 areas of toxicology. They must submit three independent peer-reviewed papers or assessments of their professional skill. To meet the educational objectives of the programme, courses in specific areas of toxicology are offered in universities in Germany periodically. The courses run from three to five days. The areas covered by the courses include: animal welfare and techniques in animal experimentation; statistics and experimental design; principles of chemical and physical analysis in toxicology; pathological anatomy and histology of experimental animals; general principles of toxicology and target organ toxicology; drug metabolism and principles of toxicokinetics; principles of cellular and molecular biology and toxicology; chemical mutagenesis; chemical carcinogenesis; reproductive toxicology; immunotoxicology; epidemiology; ecotoxicology; regulatory toxicology. The German approach, unlike the American approach, embodies both training and professional certification.

More recently, the European Union has adopted a plan to ensure minimal health risks from chemicals manufactured or imported into Europe in amounts greater than a ton. The plan, which went into effect on June 1, 2007, is termed REACH (registration, evaluation, authorisation and restriction of chemical substances), and is managed by the European Chemicals Agency, under the auspices of the European Union. For each chemical a registration dossier containing the identification and the management of potential risks is prepared. This is a substantial undertaking, and as a result an increased effort at training toxicologists to help meet the requirements of REACH has begun. Training grants have been awarded at several German universities for the establishment of Masters degree programmes specifically designed to train people to meet the need of the REACH legislation. It is similar in many ways to the earlier programme cited above but is conducted within a single university and students with more diverse backgrounds may be eligible for participation.

14 BOARD CERTIFICATION

Although the formalities of earning the degree are somewhat different when comparing the American, the German and the British approach, the subject matter is largely the same. The German system carries with it the opportunity to achieve board certification. In the USA most toxicologists can apply for and earn board certification from the American Board on Toxicology by passing an examination. For more senior toxicologists who have an established career and evidence of productivity and accomplishment, the Academy of Toxicological Sciences offers the opportunity of certification on the basis of peer review.

15 SOME QUESTIONS ON RECENT DEVELOPMENTS IN TOXICOLOGY POSED TO COLLEAGUES

During the preparation of the revision of this chapter some questions arose regarding the status of toxicology as it has evolved over the past decade. Colleagues were queried with respect to their evaluation of how toxicology has fared in their countries. They were asked (i) whether there has been an increase or decrease in toxicology training programmes, (ii) what is the outlook for employment and career-building opportunities for toxicologists, and (iii) which areas appear to have the greatest need for toxicologists? Although the number of colleagues approached and the number of responses was small, the answers were informative.

It would appear that in countries where there were previously established training programmes there has been little growth, and in some cases, declines in the number of programmes. To some extent the cause is a decrease in funding and in other cases shifts in emphasis within the biological sciences. In some situations, where a single department had chairs in both pharmacology and toxicology, restructuring of resources often resulted in greater emphasis placed on pharmacology.

Despite the expected need for many toxicologists to work in the area of safety assessment, advances in biology related to genomics, proteomics, information science, and so on, have begun to play a significant role in the training of toxicologists. It was natural in the course of these communications to raise the issue, with some of the respondents, of the degree to which training programmes need to balance education in the new 'omics' with training in 'classical toxicology'. It is clear that there is a need to train students in the most modern technology

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat130
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

needed for toxicological problem solving. We are still in the midst of understanding how the data obtained with these technologies can be interpreted with respect to whole-animal physiology and pathology. History has shown that the emergence of new technologies when applied to toxicology and pharmacology has ultimately led to significant advances, and there is no reason to doubt that eventually the same will be said for data derived from 'omics'.

16 THE LITERATURE OF TOXICOLOGY

Toxicology training in all countries seems to involve the classical approaches which include classroom studies highlighted by lectures and discussions, practical laboratory experience, and exercises in which students read literature and either write reports or present them orally. These are frequently termed seminars, and are an essential part of toxicology training. Although it is important that the student can write well or make oral presentations which are clear and understandable, the basis of these reports is the literature which the student has read, assimilated and is prepared to offer as evidence of having learned the material.

The literature of toxicology over time reflects a parallel growing maturity of both the biomedical sciences and toxicology. Although much has been known about the descriptive toxicology of pure chemicals and mixtures since ancient times, it is only with the past few decades that important advances in our in-depth knowledge of mechanisms of toxicity have been uncovered. Much of that information can be accessed via online databases such those of the National Library of Medicine; that is, Medline, Toxline, and so on. The explosion in online databases acted as a tool for the rapid expansion of the scope of toxicology. Formerly a literature search was conducted in the several journals with which the investigator was familiar. Asking a question to an online database often brings in references in journals heretofore thought to be outside the mainstream of toxicological publications. Although most studies published before the advent of databases must be accessed in library stacks or storage areas, there are many instances of journals and databases now scanning older documents; for example, the Journal of Pharmacology and Experimental Therapeutics has made available papers published as far back as 1909. Regardless of whether the literature can be reached online or in paper form in the library, students should trace the development of thought in the field in which they work back to its origins. Students should realize that, although technology may change with time, the thought processes behind the development of hypotheses, experimental design, and the process of gaining insight into the problem based on data from well-designed studies can be observed in the work of any era. A significant admonition worth offering to every new student is 'Science did not begin the day you walked into the laboratory'.

17 TRAINING TOXICOLOGISTS FOR THE FUTURE

Unfortunately for people who plan structured curricula, changes in the sciences occur at rates faster than they can plan. Thus, within the past few decades the basic medical sciences have largely lost their distinctive boundaries in research. The result has been mergers of departments and changing modes of teaching the basic subjects. Since toxicologists have always had to deal with approaches to problems which crossed these classical boundaries, they are prepared to take advantage of changing curricula to the advantage of their students. Furthermore, with advances in the understanding of the molecular basis of physiological function it is possible to apply the techniques generated by these exciting successes to the solution of toxicological problems. Toxicology has been called 'a borrowing science'. Scientists in any given discipline have always 'borrowed' techniques and approaches to research from each other. Borrowing of techniques from other disciplines was less common. In toxicology, however, it was the rule because there were few, if any, methods which were strictly tied to our discipline. Thus, in the current climate where the disciplines have, to a large extent, merged, the toxicologist is quite at home in 'borrowing', for example, the tools of the molecular biologist for the solution of fundamental problems in toxicology. Thus the first, and most important, message related to the training of toxicologists in the future is that we must continue to teach students broadly and to be prepared to accept new ideas in science and apply them to understand mechanisms of toxicity, as well as to apply them to the process of safety evaluation.

Toxicology, as well as its sister science, pharmacology, have been termed the study of poisons. Both toxicologists and pharmacologists are proud of that designation because the results of their studies have been a better understanding of how chemicals can cause damage to biological systems as studied by toxicologists, and the development of new and better therapeutic agents by the pharmacologists. In many cases ground breaking efforts in the nineteenth and early twentieth centuries were based on studying the effects of known poisons such as strychnine, eserine (physostigmine), nitrogen mustard, and so on. While the breakthroughs resulted in practical advances in the disciplines, they were accompanied by an increasing understanding, in these cases, of the physiology of the spinal chord, the mechanism of action of cholinesterase, and certain aspects of the biology of cancer cells. Many other examples have shown

DOI: 10.1002/9780470744307.gat130
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

that as we have extended knowledge in our own discipline we have made significant contributions to the study of biology. Thus, the training of students in toxicology should include ensuring that they understand the potentially greater significance of their results that may go beyond administering a given chemical to an animal in a given protocol followed by the observance of specific responses. The student should be aware that the responses observed are reflective of the underlying physiology of the animal and may shed light on those mechanisms. In the study of cancer, early workers had no trouble identifying tumours that resulted when they painted a solution containing any of several polycyclic aromatic hydrocarbons on the backs of mice. The mouse skin assay remains one approach to determining the carcinogenicity of chemicals. However, investigations of how and why the tumours occurred, in studies where the chemical was a tool in the experiment, rather than the object of study, have led to a clearer understanding of the process of carcinogenesis.

As the biological sciences in general and toxicology in particular advance, new forms of technology are developed on a frequent basis. It is possible to gauge advances in the biological sciences associated with the development of tools such electrophysiology, the use of isotopes and their measurement, spectroscopy and chromatography in their various forms, application of immunological techniques, and now flow cytometry and imaging systems, and the computer. Toxicologists have always grasped at these innovations. In the training of toxicologists they should be made aware of advances in technology which will help them now, and to also be receptive to new technologies as they develop, since it is clear that they will develop and can represent significant improvements in our ability to find solutions to problems in toxicology. However, excellent scientific studies have been performed by toxicologists long before the advent of new high-tech laboratory equipment became available. The training of toxicologists, while making use of new technologies, should concentrate on the knowledge base of toxicology, how to solve problems using the empirical approach, and how to apply creative thought to the interpretation of data, the development of new hypotheses, and the planning of new experiments to challenge our hypotheses.

Toxicology of Chemical Warfare Agents

Robert L. Maynard and Robert P. Chilcott

CONTENTS

1 HISTORICAL INTRODUCTION

Throughout history, humans have sought more effective means of killing and disabling their fellow men. Stones, clubs, spears, bows and arrows, gunpowder, muskets, rifles, high explosives, machineguns, tanks, warplanes, rockets and nuclear weapons comprise an apparently unending catalogue of increasing military sophistication designed for the destruction of one's enemies, while exposing one's forces to decreasing risk. Accompanying this development of military hardware, the effects of which are based on the physical disruption of men or materials, has been a very much less marked development of chemical means of attack. Some chemicals have been used as a means of killing and others as a means of incapacitating. Recently, attempts have been made to stem the development of chemical weapons, but ensuring complete destruction of such weapons is difficult (Pearson, 2007).

Chemical weapons probably began with smoke and flame, and the hurling of various concoctions of pitch and sulphur (Greek fire) dates from classical times, as recorded in the Ebers' papyrus circa 1500 BC (Bryan, 1930). Irritant smokes were described by Plutarch, hypnotic substances by the Scottish historian Buchanan, compounds allegedly capable of producing incessant diarrhoea by classical Greek authors (SIPRI, 1971) and preparations containing the saliva of rabid dogs by Leonardo da Vinci (1452–1519) (Reprint Society, 1938).

At the time these authors were writing, chemistry and chemical technology were in their infancy, and the chemical weapons developed had probably only a marginal effect on the outcome of battles. However, during the medieval period the widespread use of poisons acquired, rightly, an evil reputation and the use of such compounds came to be despised by military men. The use of poisons was seen as running counter to the tenets of chivalrous conduct; this view has persisted and lies close to the root of the objections raised during the twentieth century to the use of chemical weapons (Haldane, 1925).

At the end of the nineteenth century the first international convention to address, among other topics, chemical warfare was held. This, the First Hague Convention (1899), led to a wide-ranging prohibition of the use of chemicals in war: 'The contracting powers agree to abstain from the use of all projectiles the sole object of which is the diffusion of asphyxiating or deleterious gases' (Prentiss, 1937).

Despite this prohibition, chemical warfare was deployed on a large scale during World War I, some 113 000 tonnes of chemical weapons being used in all (Prentiss, 1937). Lefebure (1921) reported that, on 9 March 1918, German forces fired some 200 000 mustard gas shells. This resulted in many casualties, but compared with the total casualties produced during World War I, the number of casualties from chemical warfare was low. This is shown in **Table 1** (Prentiss, 1937).

From the figures given in this table a number of deductions can be made: (i) the proportion of deaths attributable to chemical warfare during World War I was

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

Table 1 Chemical warfare and other casualties during World War I

Country	Battle casualties due to gas				
	Nonfatal	Deaths	Total	Total battle deaths	Total wounds including battle deaths
Russia	419 340	56 000	475 340	1 416 700	6 366 700
France	182 000	8000	190 000	1 131 500	5 397 500
British Empire	180 597	8109	188 706	585 533	2 590 509
Italy	55 373	4627	60 000	541 500	1 488 500
USA	71 345	1462	72 807	52 842	272 138
Germany	191 000	9000	200 000	1 478 000	5 694 058
Austria/Hungary	97 000	3000	100 000	1 000 000	4 620 000
Other	9000	1000	10 000	684 436	1 580 318
Total	1 205 655	91 198	1 296 853	6 890 511	28 009 723

Wounded due to chemical warfare as percentage of all wounded (including fatalities): 4.63%.
Deaths due to chemical warfare as percentage of total chemical warfare injured: 7.03%.
Deaths due to chemical warfare as percentage of all deaths: 1.32%.
UK forces deaths due to chemical warfare as percentage of total UK forces deaths: 4.3%.
After Prentiss (1937).

low; (ii) the ratio of dead to injured among those affected by chemical warfare was very low; (iii) ill-prepared forces, for example, Russian troops on the Eastern Front, suffered badly. These observations have been examined in detail elsewhere (Maynard, 1988) and have been adduced by some as evidence of the efficacy of chemical warfare, and by others as evidence of its inefficacy. Space here does not permit an examination of these interpretations.

After World War I, a widespread campaign to ban chemical warfare was mounted and the Geneva Protocol, promulgated in 1925, encapsulated widely held opinion. However, during the Italian campaign in Ethiopia (1935–1936) Italian troops used mustard gas on a large scale against unprotected native forces (SIPRI, 1971). Many casualties were produced. During the late 1930s, fear that fascist countries might use chemical warfare on a substantial scale during a future war led to the incorporation of antigas drills into Air Raid Precautions (ARPs) in the UK and the issue of gas masks to all troops and civilians (Haldane, 1938). These fears were not demonstrated to have been justified during World War II, despite the production of large quantities of chemical warfare munitions by both sides. Germany's reluctance to use chemical weapons has never been satisfactorily explained, particularly as she had what many might have considered a great advantage in having synthesized very toxic nerve agents which were unknown to the Allied Powers. The discovery of large stocks of these compounds, the acquisition of the means of production by the USSR and the worsening state of international relations, led to the expansion of research into chemical warfare in both the UK and the USA during the years following World War II.

The UK's programme of research, designed to produce chemical weapons, sometimes described as 'offensive research' (in contrast to work on antidotes and means of protection: 'defensive research'), was halted permanently in 1956, with the decommissioning of the nerve-agent production plant at the Chemical Defence Establishment out-station at Nancekuke in Cornwall, UK. Production of nerve agents continued in the USA until 1969 and began again in 1981 in order to produce the components of the so-called 'binary weapon system' (Meselson and Perry Robinson, 1980). Production in the USSR probably continued in parallel with that in the USA.

Accusations of use of chemical weapons have been common since World War II. Those of their use by Egyptian forces in the Yemen (1963–1967) seem better supported than many others. US forces used defoliants and irritants on a large scale during the war in Vietnam. That this represented a use of chemical warfare has been strenuously denied by US sources and the view that the use of CS (2-chlorobenzylidene malononitrile) tear-gas, which had been sanctioned for use in the USA against rioting civilians, could not be regarded as an exercise in chemical warfare has been voiced.

Iraq, during the Iran–Iraq war in the early and mid 1980s used chemical weapons on a large scale, mustard gas and probably the nerve agent tabun were used (United Nations, 1987). Many casualties resulted, and in one particularly distressing incident, at Halabja (Iraqi Kurdistan), some 5000 civilians were killed. Death from chemical warfare on this scale had not been known since the gas cloud attacks of 1915 and attracted international condemnation.

Among less well-known accusations are the use of 'yellow rain' in South East Asia (Seagrave, 1981) and the use of 'knock down agents' and 'black body agents' by USSR forces in Afghanistan. More recently, Russian forces are alleged to have employed an incapacitating agent (possibly a fentanyl

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

analogue) against Chechen terrorists in a Moscow theatre (Wax *et al*., 2003). During 1988 reports that Libya had constructed a chemical warfare production plant appeared in the press. This report fuelled fears that terrorists might gain access to chemical weapons.

In 1988, major steps were taken by both the USA and the USSR towards a verifiable ban on chemical weapons. The chemical weapons convention came into force on 29 April 1997: this completely prohibited the use of chemical weapons (Pearson, 2007). Expansion of the capacity to wage chemical warfare has, however, continued in a number of other countries.

There is no evidence that chemical weapons were used during either Gulf War, though the production of such weapons by Iraq is not doubted. US and UK troops were provided with pyridostigmine as a pretreatment against nerve agent attack: see below.

A detailed account of the subjects considered in this chapter may be found in the recent publication: *Chemical Warfare Agents: Toxicology and Treatment* (Marrs *et al*., 2007).

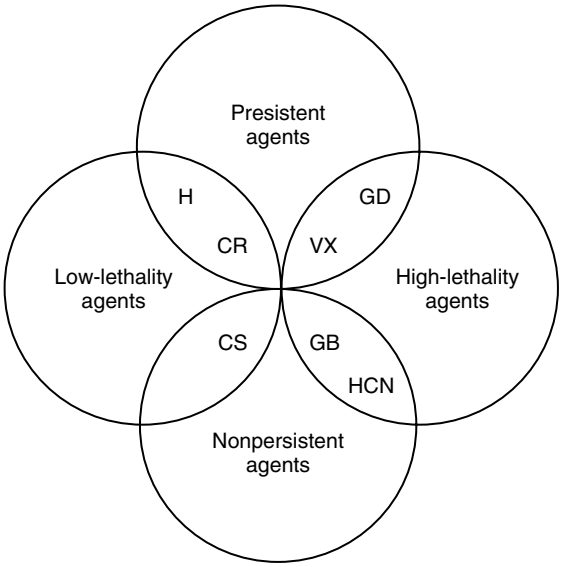

Figure 1 Categories of chemical warfare agents.

2 CONCEPTS OF USE OF CHEMICAL WEAPONS

It is often assumed that chemical weapons would be used during a war to kill as many of the opposing forces as possible. This is fallacious and misrepresents the professed purpose of modern warfare. Modern warfare is, it is generally agreed, waged to compel governments to amend their actions and not to annihilate populations (Fotion and Elfstrom, 1986). It is a fact of military experience that weapon systems which produce many casualties are likely to be more effective than systems which produce fatalities. Casualties require evacuation, nursing care and may sap morale. Because of this, chemical weapons would more likely be used to incapacitate than to kill. Some established chemical weapons, such as mustard gas, are rather ineffective as regards killing (death rate in mustard casualties during World War I was about 2%), although particularly effective as incapacitants (Haldane, 1925).

Chemical weapons can be effectively defended against by the use of protective clothing, including a respirator, gloves, boots and special overgarments. Prophylactic drugs play a much less important part in providing protection. Physical protection inevitably carries the penalty of impaired performance and commanders might be loath to institute such measures. Indeed, aggressors might consider the use of, or the expression of willingness to use, chemical warfare as successful if they force their opponents into protective clothing. Because of this, a policy of intelligent avoidance of contaminated areas would be likely to be observed. This has led to the development of the concept of use of chemical warfare agents as agents of 'ground denial' rather than as deliberate producers of casualties. Such an effect could well be exploited by an aggressor by attacks on centres of strategic and tactical importance, some 'behind the lines'. Such a use would inevitably lead to the exposure of civilians, probably less well-trained and protected than members of the armed forces, and the production of many civilian casualties. Lethal chemical warfare compounds could be used in high concentrations to permit the rapid breakthrough by well-protected troops through strongly defended points.

These concepts of use permit a number of categories of chemical warfare agent to be defined (see **Figure 1**). Only a few well-known chemical warfare agents have been included in **Figure 1**. Other compounds, such as Lewisite, could well appear in more than one category. CS has been included as a nonpersistent agent on the grounds of its rapid hydrolysis in contact with water.

It should be remembered that military concepts of use could well vary from area to area, and reports of the use of specific chemical warfare agents may prove very difficult to understand unless details of the operational scenario are available.

Much of the thinking or doctrine as regards the use of chemical warfare agents was developed during periods of East–West tension when a war between NATO (North Atlantic Treaty Organization) and Warsaw Pact forces was a possibility. Such a threat has now receded and the thinking looks dated. It is now more likely that chemicals would be used by terrorist organizations than by national forces.

Table 2 Standard classifications of chemical warfare agents

Medical classification	Service classification
1. Agents liable to be met in warfare	
Nerve agents (G and V)	Lethal agents (nerve)
Lung-damaging agents (phosgene and chlorine)	Lethal agents (choking)
Vesicant agents (sulphur mustard, Lewisite, etc.)	Damaging agents (blister)
Psychotomimetic agents (LSD, BZ: 3-quinuclidinyl benzilate)	Incapacitating agents (mental)
Miscellaneous agents	
Cyanide	Lethal agents (blood)
Arsine	—
Herbicides	
2. Agents liable to be met in riot control and/or war	
Sensory irritants CS and CR	Riot control agents
Vomiting agents, for example, DM	Incapacitating agents (physical)

3 STANDARD CLASSIFICATION OF CHEMICAL WARFARE AGENTS

A number of different classifications of chemical warfare agents have been devised. Two broad systems, 'medical' and 'service', are in general use and are compared in **Table 2** (HMSO, 1972, 1987). Both of these systems would be regarded by many experts as outmoded. Several of the compounds listed in the table, for example, LSD (lysergic acid diethylamide), and DM (10-chloro-5,10-dihydrophenarsazine), are no longer seen as likely to be used in war, and chlorine and arsine are very unlikely to be used, though they might figure in terrorist incidents.

The possible means of production of chemical weapons have also changed in recent years, as genetic engineering and the production of complex molecules on a large scale by cultures of bacteria and yeasts have been developed. Today, chemical weapons form a spectrum ranging from the classical chemical weapons, such as nerve agents and mustard gas, to the classical biological agents, such as the anthrax bacillus or the smallpox virus. Between the two extremes are compounds originally discovered as natural products, for example, bacterial toxins, and which were classified as biological weapons, but which are, in fact, chemicals. The chemical–biological warfare spectrum is shown in **Figure 2** (Pearson, 1988). Useful though this classification is, it is likely that the simple military classification will remain in widespread use, as it lends itself to use in training and defining standard means of dealing with casualties.

4 GENERAL MANAGEMENT OF CHEMICAL WARFARE CASUALTIES

Few civilian doctors have any experience of the management of chemical warfare casualties; indeed, few military doctors in Western countries have ever

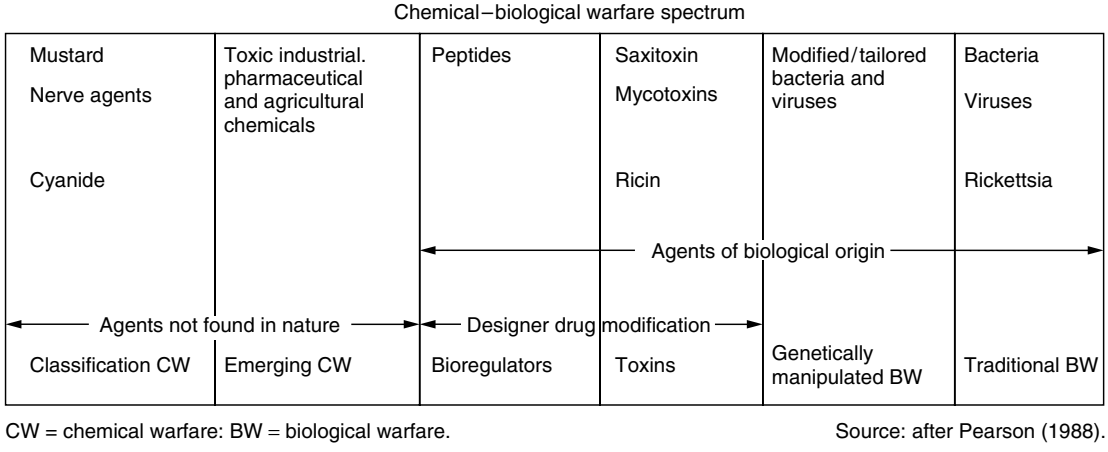

Figure 2 Chemical–biological warfare spectrum.

seen a chemical warfare casualty. If casualties are to be well cared for and the carers are not to be placed at risk, a number of key points must be borne in mind.

1. Early treatment of casualties is essential
2. Attendants must be adequately protected from contamination
3. Disrobing and decontamination of casualties is the priority once life-saving measures, including the establishment of adequate ventilation and the administration of antidotes, have been undertaken. Fullers' earth is an excellent decontaminant for liquid agents, though it has been largely replaced by water or very dilute solutions of sodium hypochlorite (bleach). Any source of water will suffice as a means of removing liquid agents from the eyes. Care must be taken that solutions of bleach are not allowed into the casualty's eyes
4. Casualties should be moved as soon as possible after decontamination into a clean environment where clinicians may work under conditions with which they are familiar. Defence of this environment must be absolute
5. Casualties will range from the mildly affected to the moribund and the rules of triage must be rigorously applied if optimal use is to be made of clinical resources
6. Early identification of the agent responsible for the poisoning will be of great value to the clinician and every effort should be made to use such detectors and monitors as are available. Identification may, in practice, depend on the recognition of toxicological effects
7. Some casualties will require intensive nursing and should be moved along evacuation routes as quickly as possible.

5 VESICANT COMPOUNDS

Vesicant compounds were introduced as chemical warfare agents on 12 July 1917 when German forces used sulphur mustard at Ypres (Ieper), Belgium (Prentiss, 1937). Mustard gas became the most effective chemical warfare agent used during World War I, 14 000 British casualties being produced during the first three months of its use and 120 000 by the end of the war (HMSO, 1923). This efficacy earned for mustard gas the sobriquet 'King of the Battle Gases' but, despite this, it carried only a low lethality. This low lethality, of the order of 2%, was one of the points which convinced J. B. S. Haldane (Haldane, 1925) of the desirability of chemical warfare as compared with conventional warfare.

5.1 Physicochemical Properties of Mustard Gas

'Mustard gas' is an unfortunate misnomer as the compound which at room temperature gives off vapour and smells of mustard, garlic or leeks, is a liquid with a boiling point of 217 °C. Sulphur mustard is often referred to as HS (Hun Stoff) or more commonly as HD. The nitrogen mustards are referred to as HN1, HN2 and HN3. The formulae and some of the characteristics of the mustards are shown in **Table 3**.

Sulphur mustard is poorly miscible with water, but, on mixing, hydrolysis takes place leading to the production of thiodiglycol and hydrochloric acid (**Figure 3**). The low miscibility and solubility of sulphur mustard in water leads to lengthy persistence of the compound in the field, particularly if protected from wind and rain. Sulphur mustard vapour passes quickly through clothing, although properly designed, modern military protective clothing

Table 3 Physicochemical characteristics of mustard vesicants

Characteristic	H	HN_1	HN_2	HN_3
Formula				Appearance	Yellowish, oily liquid	←Colourless or yellowish oily liquids→

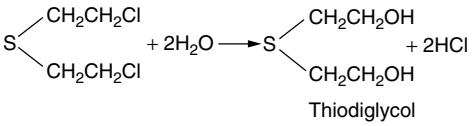

Figure 3 Hydrolysis of sulphur mustard.

provides good protection. Sulphur mustard in the liquid state passes quickly through ordinary surgical rubber gloves and heavy gloves made of butyl rubber should be worn when decontaminating casualties. The standard issue UK military respirator provides excellent protection against mustard gas vapour.

5.2 Absorption of Sulphur Mustard

Sulphur mustard, as a liquid or vapour, is lipid soluble and is absorbed across the skin. Under unoccluded conditions, ~80% of an applied dose of liquid sulphur mustard evaporates from the skin surface (Chilcott *et al*., 2000; Renshaw, 1946). Studies conducted during World War II indicated that the remaining 20% is rapidly 'fixed' in the skin. This led to the conclusion that catch-up therapies based on neutralizing the absorbed dose within the skin must 'necessarily be valueless' (Renshaw, 1946). However, other studies have demonstrated that the absorbed dose forms an appreciable reservoir of 'free' mustard which can be extracted by the topical application of appropriate solvents (Chilcott *et al*., 2000; Smith *et al*., 1919). Removal of this reservoir may represent a strategy for the future development of effective decontaminants (Chilcott, 2007; Graham *et al*., 2005).

Cameron *et al*. (1946) demonstrated, in rabbits, that some 80% of inhaled vapour was absorbed in the nose. Clinical experience suggests that the majority of inhaled sulphur mustard is absorbed in the upper airways.

5.3 Toxicity of Sulphur Mustard

The toxicity of sulphur mustard as an incapacitating agent is militarily of much greater importance than its capacity to kill, in terms of LD_{50}, and compared with the nerve agents, sulphur mustard is a comparatively nontoxic compound. Intravenous LD_{50} figures include the following: rat, 3.3 mg kg^{-1}; mice, 8.6 mg kg^{-1} (Anslow *et al*., 1948). Much more important are the effects of exposures to differing concentration/time products (*Ct* products). These are listed in **Table 4**. It should be noted that, weight for weight, sulphur mustard can be considered equipotent to nerve agents in terms of its ability to incapacitate unprotected individuals. **Figure 4** shows the interdependence of concentration and time in defining the effects of mustard gas vapour.

Table 4 Effects of sulphur mustard vapour on humans

Exposure dose (mg min m^{-3})	Effects[a]
20–50	Onset of eye effects
70	Mild reddening of the eyes—tearing
100	Partial incapacitation from eye effects
100–400	Erythema of skin
200	Total incapacitation from eye effects
200–1000	Skin burns produced
750–10 000	Severe incapacitation from skin effects

[a]The effects of sulphur mustard vapour on the skin are very dependent on ambient temperature and the range shown for skin burns encompasses the effects of decreasing ambient temperature from 80 to 50 °F.

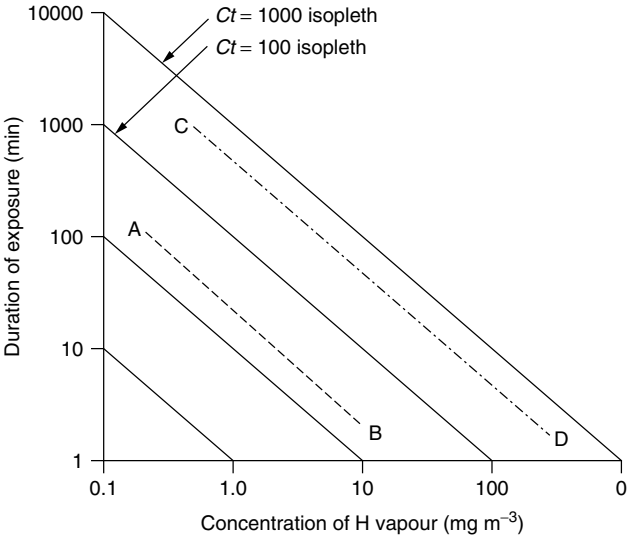

Figure 4 Effects of sulphur mustard vapour on humans. Lines AB and CD are offered as guides to early eye effects (AB: Ct = 20 mg min m^{-3}) and skin burns of significance (CD: Ct = 500 mg min m^{-3}). Because of uncertainty regarding the Ct = constant, relationship, extrapolation to extremes of time and concentration will be inaccurate.

5.4 Mechanism of Action of Sulphur Mustard

Despite nearly a century of research, the mechanism(s) through which sulphur mustard induces lesions of the epithelial cells of the skin, lung and intestinal tract remain

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131

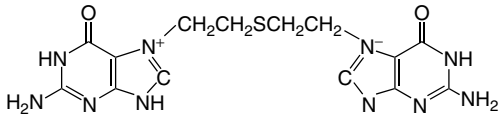

Figure 5 Crosslinking of guanine residues by sulphur mustard.

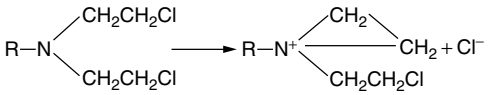

Figure 6 Formation of a quaternary ammonium compound.

to be elucidated. Research to date has identified a number of biochemical effects of sulphur mustard, although none provides an adequate link between exposure and onset of specific pathological consequences, such as skin blistering.

Sulphur mustard is an alkylating agent and a detailed account of the mode of action of such compounds can be found elsewhere (Goodman and Gilman, 1980; Fox and Scott, 1980). Both sulphur mustard and the various nitrogen mustards are bifunctional alkylating agents possessing two side chains capable of undergoing cyclization. Crosslinking of guanine in nucleic acids results from this property. Crosslinked guanine molecules are shown in **Figure 5**.

Binding of the ethylenesulfonium ion (sulphur mustard) or the ethylimmonium ion (nitrogen mustard) to DNA produces a range of effects including:

- Alkylated guanine residues tend to form base pairs with thymine rather than with cytosine, leading to coding errors and hence inaccurate protein synthesis
- Damaged guanine residues may be excised from the DNA molecule
- A pair of guanine residues may become crosslinked as shown below. This is considered by some as the most serious effect of alkylating agents on DNA (Rink and Hopkins, 1995).

Repair to DNA may take place, as long as damage is not too widespread. Juarez-Salinas *et al*. (1979) reported the polymerization of nicotinamide adenine dinucleotide (NAD^+) under the influence of the poly(ADP ribose) polymerase (PADPRP) enzyme as part of the DNA repair process. Papirmeister *et al*. (1984a; 1984b) suggested that the reduction in the cellular levels of NAD^+ following DNA repair could lead to cell death. However, there is come contradictory evidence to the PADPRP hypothesis. For example, in rat keratinocytes, NAD^+ depletion does not occur until the concentration of sulphur mustard is sufficient to cause inhibition of DNA repair (Lin *et al*., 1994); DNA repair in human keratinocytes may be accomplished within 90 minutes of exposure, whereas NAD^+ depletion is not observed until 1–3 hours postexposure (Meier *et al*., 1987) and elevation or maintenance of NAD^+ in human keratinocytes does not confer protection against the cytotoxic effects of sulphur mustard (Mol *et al*., 1989).

Early work by Dixon (1946) suggested a correlation between skin injury and inhibition of glycolysis. Although the effects of alkyating agents, such as mustard, on nucleic acids are usually stressed, it should be recalled that they also alkylate a wide range of other cellular components and enzymes. Membrane proteins at both the plasmalemma and the surfaces of intracellular organelles are liable to alkylation.

Despite this apparent understanding of how the alkylating agents act, no clear explanation of how mustard produces blisters is yet available. Miskin and Reich (1980) proposed increased protease synthesis and release after mustard-induced damage to cells. Release of such enzymes would be expected to set up an inflammatory response and would explain some of the effects of sulphur mustard. Acute inflammation does not, however, usually lead to blistering. Recent studies by Lindsay and Rice (1995; 1996) have suggested that laminin is a target for protease activation at the dermal–epidermal junction. Experiments in Yucatan minipigs showed that sulphur mustard induced microblister formation at this site. Damage to laminin was not accompanied by damage to Type IV collagen. Monteiro-Riviere and Inman (1995) have undertaken similar studies and have shown that the precise site of separation of the dermal–epidermal junction is beneath the hemidesmosomes in the upper part of the lamina lucida of the basal lamina.

The cholinomimetic effects of nitrogen mustard may be explained by cyclization leading to the formation of a quaternary ammonium compound (**Figure 6**).

5.5 Histopathology of the Skin Effects of Sulphur Mustard

Extensive experimental work was undertaken during World War I to discover the effects of sulphur mustard on human skin. This work has been reported in detail by Ireland (1926).

Volunteer studies were undertaken involving exposure of personnel to various concentrations of sulphur mustard; in some instances, biopsies of damaged skin were taken. In one study, small quantities (0.0004 ml drops) of sulphur mustard were placed on the skin. Small blisters were produced. The evolution of the lesions was followed by a timed series of biopsies.

Early vacuolation of the deeper layers of the epidermis was reported, as were nuclear changes in the stratum granulosum. Capillary dilation and leukocyte diapedesis

Table 5 Mann's classification of mustards by effects on the eye

	'Mustard gas group'	'Nitrogen mustard group'
Compounds	Sulphur mustard and HN_3	HN_1 and HN_2
Latent period	Present, may be some hours	Absent
Limits of early damage	Cornea and conjunctiva main site of damage	Rapid penetration to anterior chamber, pupil contracts and ciliary body releases a cellular exudate within 1 h of exposure
Later effects	Petechial haemorrhages Iridocyclitis rare	Haemorrhage Iridocyclitis common Intraocular haemorrhages often seen
Resolution	Usually complete	Permanent damage likely

Modified from Mann (1948).

were also noted. These changes were established some 30 minutes after exposure. Later separation at the dermal–epidermal junction occurred with liquefaction of the epidermis near the centre of the lesion. Epithelial cells of hair follicles and sweat glands were also affected. These changes were maximally developed by 18 hours after exposure. Necrosis was followed by formation of an eschar by 72 hours, sloughing by four to six days, a pigmented scar being present by 19 days.

Histochemical studies by Vogt *et al*. (1984) have confirmed the above and, furthermore, have demonstrated two phases of increased capillary permeability. Papirmeister *et al*. (1984a; 1984b) have undertaken detailed studies using athymic human-skin-xenografted mice and have extended the above descriptions to the ultrastructural level. Their papers should be consulted for details. Damage to the extracellular matrix has been studied at the electron microscopic level by Chauhan *et al*. (1995).

5.6 Histopathology of the Effects of Sulphur and Nitrogen Mustard on the Eyes

These effects were investigated in detail by Mann (1948) who divided the compounds into two groups. These are described in **Table 5**. Note that the division does not correspond with the usual classification: sulphur mustard/nitrogen mustard.

5.7 Histopathology of the Effects of Mustard Gas on the Respiratory Tract

Several reports are available (Warthin and Weller, 1919; HMSO, 1923; Vedder, 1925; Ireland, 1926). These effects are largely confined to the conducting airways, with damage being particularly marked in the larger airways. The pseudostratified ciliated columnar epithelium becomes necrotic and sloughs; haemorrhages and inflammatory changes occur in the lamina propria and a false, diphtheritic membrane of sloughed cells, blood and exudate is formed. In severe cases, damage to the submucosa and other layers of the airway wall may occur. Surface repair is by squamous metaplasia and complete restoration, of a normal ciliated epithelium is suspected to be slow.

In the deeper lung, damage is usually less marked, although severe exposure can produce haemorrhagic pulmonary oedema. During World War I, this was clearly recorded at post mortem and found to be most marked in the alveoli adjacent to conducting airways. Repair of damage at the alveolar level involves initial organization of the exudate and its subsequent removal by macrophages. Extensive fibrotic changes following exposure to mustard gas have not been demonstrated.

The findings described above have been confirmed in rats by Anderson *et al*. (1996). In addition to the already described effects, damage to bronchus associated lymphatic tissue (BALT) and chondrocytes was reported. Examination of interalveolar septae with the electron microscope revealed perivascular oedema, though extensive pulmonary oedema was not reported.

5.8 Histopathology of the Effects of Mustard Gas on Bone Marrow

Alkylating agents in general have profound effects on rapidly dividing tissues and damage to the cells of the bone marrow produces an aplastic anaemia (Smith, 1986). The granulocyte series is first affected followed by the megakaryocytes and finally the erythropoietic series. In mustard gas casualties, the peripheral white cell count has been observed to begin to fall on about the fourth day postexposure after an initial postexposure rise.

5.9 Symptoms and Signs of Exposure to Mustard Gas

The following is based on the accounts of Vedder (1925) and Warthin and Weller (1919) and one of the author's

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 6 Symptoms and signs of exposure to mustard gas

Time postexposure	Symptoms and signs
20–60 min	Nausea, retching and eye smarting have all been reported. More commonly a latent period of up to an hour occurs and was clearly recorded at first hand by Adolph Hitler from experience in 1918 (Hitler, 1925)
2–6 h	Inflammation of the eyes occurs with intense and burning eye pain. Lachrymation, blepharospasm, photophobia and rhinorrhoea appear; the face becomes reddened and the voice hoarse
6–24 h	Blisters develop on skin exposed to vapour or liquid. The blisters are delicate and are often rubbed off by the patient turning in bed. Blisters are not *per se* painful, although if they occur over flexure lines at joints, pain may be produced on moving. The warm areas of the body are particularly liable to blistering with the axillae, inguinal folds, perineum and genitalia being badly affected. In contrast, the palms and soles appear to invariably escape blistering
24–48 h	Blistering becomes more marked and fresh crops of blisters appear. Coughing develops and sloughed tissue is expectorated. Intense itching of the skin may occur and frequently prevents sleep. Darkening of the skin, due to an increase of melanin in the basal layer of the epidermis, occurs and areas of dark brown or black hyperpigmentation are produced. Eye effects are maximal at this time and patients may be temporarily blinded
48 h to 6 wk	Blisters heal slowly and healing areas of skin are sensitive, and secondary blistering may be produced by friction. Peeling of areas of hyperpigmentation to leave areas of hypopigmentation occurs and a striking piebald appearance may be produced. The eye problems resolve slowly and persistent roughening of the cornea may be observed
6 wk to 6 mon	Many patients will have recovered by 6 wk although in some the process takes much longer. A state of functional neurosis was described during World War I, with depression and continuous eye problems. Persistent lachrymation and photophobia represent a particularly difficult problem

(Robert L. Maynard) observations of Iranian casualties during 1985 and 1986. The comprehensive review of Willems (1989) should be consulted for further details. The symptoms and signs are listed in **Table 6**.

5.10 Clinical Investigations

Blood should be taken for estimation of thiodiglycol. Regular chest X-rays and standard haematological investigations are clearly indicated. Pulmonary function testing should be undertaken in all whose respiratory problems appear to be resolving particularly slowly.

5.11 Management of Mustard Gas Casualties

It is the personal experience of one of the authors (Robert P. Chilcott) that human skin contaminated with liquid sulphur mustard will 'off-gas' for up to 24 hours postexposure. A similar (though less pronounced effect) has been observed with laboratory animals (Logan *et al*., 2000). Therefore, it is imperative that medical personnel treating contaminated casualties use appropriate personal protective equipment.

As already stated, casualty management divides into two parts.

5.11.1 First Aid

Casualties should be moved quickly from the source of contamination by adequately protected attendants and decontaminated thoroughly with fullers' earth. Washing of the skin with kerosene to remove liquid contamination was strongly advocated by Vedder (1925), but if undertaken should be continued for 30 minutes.

5.11.2 Medical Management

There is no specific therapy for mustard gas lesions and no antidote has been demonstrated to be clinically effective in removing mustard from the body. Despite this, considerable amelioration of the effects may be achieved and secondary infection prevented.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

5.11.2.1 Management of Skin Lesions

Large blisters should be aspirated aseptically as they are likely to be broken accidentally. Blister fluid is not harmful, despite the oft-repeated assertion that it contains free mustard and may cause damage to attendants. That blister fluid is harmless was conclusively demonstrated in volunteer studies by Sulzberger (1943). After aspiration, blisters should be covered with sterile dry dressings. Treatment by exposure seems to be as effective as by wet dressings and demands less nursing care. A variety of ointments have been used in cases of mustard gas burns, although none has been shown to enhance their rate of healing. Silver sulfadiazine cream (Flamazine) has been widely used and is useful in preventing secondary infection.

Severe itching and pain from damaged skin has been reported and in some cases narcotic analgesics have been used. This is probably unnecessary in the majority of cases and a milder analgesic combined with a sedative would be more appropriate therapy.

Most mustard gas burns are superficial or partial thickness burns. Deeper burns are occasionally seen and for these skin grafting should be considered as this may increase the rate of healing. Recent work by Rice and coworkers has demonstrated that physical removal of mustard-damaged skin by mechanical or laser debridement can significantly enhance healing rates (Rice *et al*., 2000; Evison *et al*., 2006).

5.11.2.2 Management of Eye Lesions

Early decontamination of liquid splashes in the eye is essential as a delay of more than a few minutes may make later decontamination ineffective and allow serious damage to occur (HMSO, 1972, 1987). For damaged eyes the following are recommended:

- Daily saline irrigations
- The use of petroleum jelly on the follicular margins to prevent sticking
- Chloramphenicol eye drops to prevent infection
- Mydriatics, for example, hyoscine drops, to prevent iridolenticular adhesions and to reduce pain caused by spasm of the ciliary muscle
- It has been suggested that if eye pain is particularly severe local anaesthetic drops should be used, amethocaine hydrochloride being recommended. Ophthalmological opinion should be sought before local anaesthetic or corticosteroid drops are used
- Potassium ascorbate (10%) and sodium citrate (10%) drops 'alternately, each once an hour, that is, half hourly drops, for 14 hours or the waking day', are also recommended
- Dark glasses to alleviate photophobia
- Perhaps most important of all: constant reassurance that blindness will not be produced and that recovery *will* occur, albeit slowly.

5.11.2.3 Management of Lesions of the Respiratory Tract

Antibiotic cover is recommended if the respiratory effects are more than very mild. Codeine linctus is of value in preventing coughing at night. Mucolytics, including acetylcysteine, have been used in some cases, although evidence of their efficacy is lacking. Calvet *et al*. (1996) have reported that betamethasone, given from 7 to 14 days postexposure to sulphur mustard enhanced regeneration of the airway epithelium. No clinical trials of glucocorticoids in mustard gas injuries of the respiratory tract have been reported, but this is a potentially important finding. In cases of very severe respiratory damage, a chemical pneumonitis may be produced and may demand intensive care. Respiratory physicians and anaesthetists should be consulted if evidence of deteriorating respiratory function appears.

5.11.2.4 Management of Depression of the Bone Marrow

Until recently no treatment has been available to restore the damaged bone marrow. However, recent studies have indicated that administration of granulocyte colony stimulating factor (GCSF) may be effective in reducing the duration of sulphur-mustard-induced leukopenia (Anderson *et al*., 2006).

5.12 Prognosis of Mustard Gas Casualties

Most mustard gas casualties recover fully. In a small proportion of cases, late-onset corneal problems producing blindness occur (Mann, 1948). Sulphur mustard is a recognized carcinogen and a study in Japanese mustard-gas-factory workers demonstrated an increase in the incidence of cancer (Yamada, 1963). The risk of cancer occurring as a result of a single exposure to sulphur mustard is exceedingly low.

6 LEWISITE

Lewisite, developed as a chemical warfare agent in 1918 by Lee Lewis, has never been proven to have been used in war. Despite this it has acquired a reputation as an agent of likely great effectiveness and lethality. In fact, this is unlikely to be true. In the early 1920s Lewisite was considered as a compound likely to produce more severe effects than mustard gas and was nick-named 'The Dew of Death'. It has retained its place in the standard lists of chemical warfare agents, although often as a mixture with sulphur mustard, the Lewisite lowering the freezing point of the mustard and making it more effective under cold conditions. Fears that Lewisite might

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be used during World War II prompted the work of Peters *et al*. (1945), Peters (1948) and Peters (1953) and led to the development of the chelating agent dimercaprol or British anti-Lewisite (BAL). The view that Lewisite is rather unlikely to be used in war has limited interest in the compound and only a short account of its effects and the recommended management of those effects will be provided.

6.1 Physicochemical Properties of Lewisite

These are shown in **Table 7**. Unlike sulphur mustard, Lewisite decomposes rapidly on contact with water or even in a 'damp atmosphere' (Sartori, 1939). The reaction taking place is shown in **Figure 7**.

6.2 Absorption of Lewisite

Lewisite is absorbed rapidly through the skin and mucous membranes. Its distribution in the body follows that of other arsenical compounds.

Table 7 Physicochemical characteristics of Lewisite

Formula	$ClCH{=}CHAsCl_2$

30 °C	1.8682
Appearance	A colourless oily liquid. Impure samples may be blue–black in colour and smell, faintly, of geraniums

Figure 7 Hydrolysis of Lewisite.

6.3 Toxicity of Lewisite

Lewisite has a much higher systemic toxicity than sulphur mustard and 0.5 ml allowed to remain on the skin would be expected to produce severe poisoning; 2.0 ml allowed to remain in contact with the skin has been said to represent a lethal dose in humans (Vedder, 1925). Because of its systemic toxicity, few volunteers have been exposed to Lewisite and data available regarding the effects of vapour on the skin are scanty. It is the authors' impression that Lewisite vapour is more toxic to the skin and eyes than mustard gas vapour and the effects could be expected at lower concentrations.

6.4 Mechanism of Action of Lewisite

Peters *et al*. (1945) demonstrated that Lewisite attacked the pyruvate dehydrogenase system by combining with the coenzyme lipoic acid to form a cyclic compound (**Figure 8**). The essential and ubiquitous nature of lipoic acid accounts for the widespread effects of Lewisite on the body. Interestingly, as in the case of sulphur mustard, the exact link between the primary biochemical effect of Lewisite and the production of blisters remains unknown. It should be recalled that other arsenical compounds such as sodium arsenite are not vesicants.

6.5 Effects of Lewisite on Humans

Both in terms of histopathology and general patterns of symptoms and signs it is believed that Lewisite would produce effects similar to those described above for mustard gas. However, certain important differences exist and instead of repeating much of the above only these will be considered:

- Exposure of the eyes to Lewisite vapour is immediately painful and the damage produced is likely to be more severe than that produced by mustard gas vapour. Liquid contamination of the eyes is particularly painful, dangerous and demands immediate treatment
- Skin blister fluid contains Lewisite; rupture of blisters can lead to secondary blister formation if

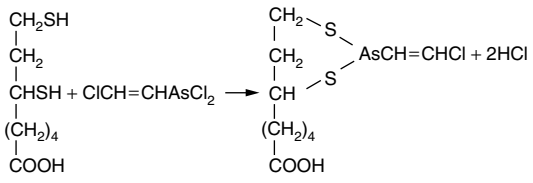

Figure 8 Reaction between Lewisite and lipoic acid.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the fluid comes into contact with unexposed skin. Sulphur mustard-induced blisters do not contain active vesicant
- Skin blisters produced by Lewisite appear more quickly postexposure than those produced by mustard gas (Friedenwald and Hughes, 1948)
- The inflammatory response associated with Lewisite lesions is likely to be more severe than that associated with mustard lesions
- Healing of Lewisite-induced skin lesions is likely to be more rapid than of those occurring as a result of exposure to sulphur mustard. Hunter (1978) described a case of blistering following exposure of another vesicant arsenical compound, phenyl dichlorarsine, and reported that the skin lesions healed by the 10th day
- The collapse of the bone marrow seen in severe cases of mustard-gas poisoning would not be expected after exposure to Lewisite. Goyer (1986), however, has pointed out that large doses of arsenical compounds can lead to leukopenia.

6.6 Clinical Investigations

Blood and urine should be analysed for arsenic. Under military conditions, analysis should certainly be undertaken, as information regarding the identity of chemical weapons used on the battlefield might be of tactical importance.

6.7 Management of Lewisite Casualties

6.7.1 First Aid

This is as described for mustard gas.

6.7.2 Medical Treatment

Perhaps the most cheering difference between Lewisite and sulphur mustard is that specific therapy is available for the former, but not for the latter.

Dimercaprol (BAL) binds the arsenic of Lewisite and produces a harmless complex. BAL competes avidly with binding sites in the body for arsenic and removes arsenic from them. BAL is available in a form suitable for injection and is used as such in the treatment of poisoning by a range of heavy-metal compounds. Dose regimens for the management of arsenical poisoning vary from author to author, the following being given by Martindale (1989): 400–800 mg on first day of treatment, 200–400 mg on second and third days of treatment, 100–200 mg on fourth and subsequent days of treatment, all administered as divided doses.

For an alternative regimen, the HMSO publication *Medical Manual of Defence Against Chemical Agents* (HMSO, 1972, 1987) should be consulted. It is unlikely that one would need to continue treatment for more than about 14 days.

Marked reactions may be produced by the injection of BAL including tachycardia, nausea, vomiting, headache and sweating. Individual doses should not exceed $3\,mg\,kg^{-1}$ and an interval of at least four hours should separate these doses.

BAL may also be prepared as an ointment or as eye drops. Both preparations contain 5–10% dimercaprol. BAL ointment should not be used in conjunction with silver sulfadiazine (Flamazine) as chelation of silver will occur.

Recently, newer chelating agents have been proposed as replacements for BAL in the management of poisoning. The work of Graziano *et al*. (1978), Lenz *et al*. (1981), Aposhian *et al*. (1982; 1984) and Inns and Rice (1993) should be consulted for details. Despite the apparent advantages of some of the newer compounds in the treatment of systematic arsenic poisoning in experimental animals, it should be remembered that the high lipid-solubility of BAL will probably lead to the ointment retaining its place in the management of Lewisite burns.

6.8 Prognosis of Lewisite Casualties

Given that adequate, early decontamination followed by the administration of BAL is undertaken the prognosis should be good.

In war, eye splashes with liquid Lewisite would, fortunately, be expected to be rare, but if such did occur the difficulties of immediate decontamination under battlefield conditions could lead to serious eye damage.

7 NERVE AGENTS

Nerve agents, produced first in Germany during the late 1930s, are often described as second-generation chemical weapons to distinguish them from those developed during World War I. Schrader synthesized the first nerve agent, tabun, in late 1936 or 1937. Sarin followed later in 1937 and soman in 1944. Tabun was stockpiled in Germany on a large scale, 12 000 tonnes being stored by 1945. Sarin was produced on a smaller scale with some 600 tonnes being available by 1945. Tabun, sarin and soman are usually referred to by the abbreviations GA, GB and GD, respectively. Other G agents exist including GE and

GF (cyclosarin). During the 1950s another group of nerve agents was developed and stockpiled in large quantities. These were the rather more toxic V agents including VE, VM and VX (Tammelin, 1957). Of these only VX has become well known. The history of the development of the nerve agents has been presented in some detail by Holmstedt (1963).

7.1 Physicochemical Properties of Nerve Agents

These are shown in **Table 8**. Exposure to chemical warfare agents, including nerve agents, may occur during or as a result of destruction of military stockpiles. This problem has been considered by Watson *et al*. (1992). Care should be taken in re-entering areas potentially contaminated by the nonvolatile agent VX. Nerve agents are hydrolysed by water. Khordagui (1996) has calculated that the half-life of G agents in seawater should be of the order of a few hours or less.

7.2 Military Use of Nerve Agents

Nerve agents may be disseminated on the battlefield by a variety of means and may be encountered as a vapour, liquid or artificially thickened liquid in the case of soman. Sarin is a comparatively volatile compound and presents a severe vapour hazard when encountered in the liquid state. VX on the other hand is a compound of very low volatility and presents little vapour hazard. The standard UK military respirator provides excellent protection against the effects of nerve-agent vapour.

7.3 Use of Nerve Agents by Terrorists

In 1995 sarin was used in an attack on the public in a Tokyo subway: several deaths and 5000 cases of poisoning resulted (Masuda *et al*., 1995). Some 10 weeks before the sarin attack, three individuals were attacked with VX by the same terrorist group (Nozaki *et al*., 1995). The publications associated with these attacks provide details of the symptomatology of such cases of poisoning and insights into the efficacy of standard treatment. A detailed account of the medical aspects of this incident has been provided by Okumura *et al*. (2007). Interestingly, see below, the clinicians caring for the casualties found pupil diameter a reliable guide in assessing the effects of treatment with atropine.

7.4 Toxicity of Nerve Agents

Nerve agents are probably the most toxic compounds yet produced on a large scale. Many studies of their toxicity have been undertaken using animal models

and a very wide range of LD_{50} values are known. A small selection of these values are shown in the **Table 9**. Fortunately, the number of accidental exposures of people to nerve agents has been small and, in consequence, information on the lethal doses of the compounds in humans is scarce. Many volunteers have, however, been exposed to low concentrations of nerve agents and the effects of such exposures are well understood. Recent accounts (Maynard and Beswick, 1992; Sidell, 2007) should be consulted for details. **Table 10** gives some indication of the approximate lethal toxicity figures for nerve agents in humans.

7.5 Absorption of Nerve Agents

Nerve agents in the liquid form are absorbed across the unbroken skin and mucous membranes. There is some evidence to suggest that dermal exposure to liquid nerve agents such as VX may result in the formation of a skin depot (Chilcott *et al*., 2005). Formation of a dermal reservoir has considerable implications for the clinical management of casualties, as prolonged leaching of agent from the skin into the systemic circulation may cause the agent to outlive antidotes administered via intramuscular bolus (Chilcott, 2007). Vapour is not absorbed across the skin in significant amounts, although it is absorbed across the cornea in sufficient quantities to produce miosis as a local effect. Absorption of vapour by the lung is rapid and more than 80% of inhaled agent is absorbed. This important point should be borne in mind whenever the $L(Ct)_{50}$ figure for a volatile nerve agent is quoted. During exercise, respiratory minute volume is increased, but absorption of the high percentage of the inhaled vapour is maintained. The $L(Ct)_{50}$ for sarin in resting humans is approximately $100\,mg\,min\,m^{-3}$. On exercise, producing a fivefold increase in minute volume, this value could fall to $20\,mg\,min\,m^{-3}$. Off-gassing of vapour from contaminated clothing posed a significant hazard to medical staff dealing with the incident in Tokyo in 1995.

[a]BEA, bovine erythrocyte acetylcholinesterase.
Modified from Ligtenstein (1984).

7.6 Mechanism of Action of Nerve Agents

Nerve agents are organophosphorus anticholinesterases (anti AChEs) and exert their toxic effects by long-lasting inhibition of acetylcholinesterase (AChE) at sites of activity of acetylcholine (ACh) in the body. The action of anticholinesterase compounds, both nerve agents and pesticides, has been discussed at length by Koelle (1963; 1992), Taylor (1980), Murphy (1986) and Pope (2005) and also in **Toxicology of Pesticides**: it will not be considered here. One point should, however, be borne in mind: many organophosphorus compounds undergo a reaction generally known as 'ageing' after they have combined with AChE (Fleisher and Harris, 1965). The rate at which this reaction occurs varies with the anti-AChE and is particularly rapid in the case of GD. Ligtenstein (1984) has compiled data illustrating this point (*see* **Table 11**).

The values given in **Table 11** should not, of course, be taken as representative of the half-lives of ageing of the nerve agents at human synaptic or neuromuscular junctions, and are shown only for the purposes of comparing the rates of ageing of different agent–enzyme complexes. Differences in rates of ageing are important as regards the treatment of nerve-agent poisoning with oximes (see below).

7.7 Clinical Effects of Nerve Agents

The clinical effects of nerve agents may be deduced by recalling the sites of action of ACh in the body (Koelle, 1975). As well as acting at autonomic ganglia, peripheral parasympathetic terminals and the neuromuscular junction, it should be recalled that ACh also plays an important role in transmission within the central nervous system (CNS).

The symptoms and signs of anti-AChE poisoning are described in **Toxicology of Pesticides** and will not be described in detail here. **Table 12** shows the symptoms and signs of nerve agent poisoning in terms of short-term exposure and AChE depression.

Information from volunteer studies on the effects of nerve agents relates only to comparatively short duration exposures and, in the main, to exposures to concentration-time profiles of less than 30 mg min m^{-3}. It will be noted that considerable variations in the expected degrees of depression of AChE have been indicated in **Table 12**. This is important and all workers have stressed the considerable variation in the effects observed in different individuals at identical levels of AChE depression. This point will be returned to in the next section.

7.8 Clinical Investigations

Measurement of whole blood, erythrocyte and plasma cholinesterase activities are often undertaken in cases of organophosphorus compound poisoning. Plasma contains butyrylcholinesterase and red cells contain acetylcholinesterase. It is often assumed that a measurement of the level of active, that is, uninhibited, red-cell cholinesterase will provide an accurate reflection of levels of AChE at synaptic and neuromuscular junctions and thus reflect the severity of the poisoning which the patient has sustained. This is not so. Willems (1989) studied the patterns of cholinesterase depression in 53 cases of poisoning by organophosphorus insecticides and showed there was a poor correlation between clinical severity of poisoning and the extent of enzyme depression. It is difficult to imagine that a better relationship would exist in cases of nerve-agent poisoning.

7.9 Management of Nerve-Agent Poisoning

7.9.1 First Aid

Casualties should be removed from risk of further contamination and be decontaminated by adequately protected and trained attendants. Contaminated clothing should be removed as quickly as possible, taking care not to transfer liquid from the casualty's clothing to his skin. If protective clothing has been worn then this should be decontaminated with fullers' earth or a dilute solution of bleach before being removed. Under battlefield conditions, clean areas occupied by staff not wearing

Table 12 Signs and symptoms of nerve agent poisoning

Short-term *Ct* (mg min m^{-3})	AChE inhibition (%) (± SD)	Symptoms and signs	
		Vapour exposure	Systemic exposure (eyes protected)
2	?	Incipient miosis, ?slight headache	Nil
5	20 ± 10	Miosis, headache, rhinorrhoea, eye pain, injection of conjunctivae, tightness of chest	?Tightness of chest
5–15	20–50 ± 10	Eye signs maximal, bronchospasm in some	Symptoms in some, ?bronchospasm
15	50 ± 10	Effects as above but more severe	Wheezing, salivation, nausea, vomiting, miosis, local sweating, muscle fasciculation in cases of skin contamination
40	80 ± 10	As above but more severe with weakness, involuntary micturition and defaecation, paralysis and convulsions	
100	100	Respiratory failure. Death	

respirators and protective clothing must be protected at all costs. Monitoring equipment should be used to confirm adequate decontamination before casualties are transferred into these clean areas. One of the most serious consequences of nerve-agent poisoning is respiratory failure produced by inhibition of the medullary respiratory centre. If respiration can be maintained while the drugs discussed below are administered, then the casualty's chances of recovery will be much enhanced. Under battlefield conditions the artificial ventilation of casualties presents formidable problems. 'Ambu'-style bags (protected by suitable rubber coverings and equipped with adequate filtres) and oropharyngeal airways can reduce these problems.

Preparations for dealing with casualties produced by the use of chemicals by terrorists and also by chemical accidents have led to the definition of three zones: (i) the hot zone, where primary contamination due to contact with disposed chemicals may occur; (ii) the warm zone where the only source of contamination is from casualties and, (iii) the cold zone. Rescue staff working in the hot zone may need closed-circuit breathing apparatus and will need impermeable protective suits. This limits the range of clinical procedures that can be undertaken in the hot zone, but the administration of antidotes to nerve-agent poisoning is possible and very important. Portable ventilators and light-weight oxygen cylinders can be deployed in both the hot and warm zones. Appropriate filters should be fitted to ventilators using ambient air.

7.9.2 Medical Treatment

Drug therapy for nerve-agent poisoning, as for poisoning by other anti-AChE compounds, divides into three: (i) cholinolytics, such as atropine, (ii) reactivators of the inhibited AChE, such as oximes and (iii) anticonvulsants, for example, diazepam or other benzodiazepines. To these should be added oxygen, which may be needed in cases of respiratory failure. The use of oxygen will not be considered further here.

In addition to the above, research has been undertaken to try to provide drugs, which if taken in advance of exposure to nerve agents, would reduce the effects of the exposure and make the treatment of poisoning resulting from that exposure the more effective. It was noted in the late 1940s that cats given the carbamate physostigmine became comparatively resistant to the effects of other anti-AChE compounds (Gilman and Cattell, 1948). It was suggested that the combination of a proportion of the available AChE with the carbamate would prevent subsequent combination of the enzyme with the organophosphorus compound and, furthermore, that the carbamate-combined enzyme would, later, spontaneously reactivate and provide the body with a supply of normal uninhibited enzyme. This hypothesis is now generally accepted. A great deal of work has been done in developing the carbamate pyridostigmine bromide for use in this way and Inns and Leadbeater (1983) summarized work on the efficacy of pretreatment, combined with the treatment detailed above, in cases of GD poisoning in guinea pigs. **Table 13** shows some of the results

Table 13 Effectiveness of oximes and bispyridinium compounds against soman poisoning in guinea pigs receiving various supporting drug treatments. Pyridostigmine (0.32 μmol kg^{-1} im) was injected 30 minutes before challenge with soman (sc). One minute after poisoning P2S (130 μmol kg^{-1}) was injected im with atropine (50 μmol kg^{-1}). Diazepam (25 μmol kg^{-1}) was given as a separate im injection

Compound	Protective ratio (95% confidence limits)[a]			
	Atropine	Atropine, diazepam	Pyridostigmine, atropine	Pyridostigmine, atropine, diazepam
—	1.5 (1.2–1.9)	2.2 (1.8–2.7)	5.2 (4.1–6.6)	8.7 (5.7–14)
P2S	1.7 (1.5–1.9)	2.5 (1.9–3.1)	6.8 (5.4–8.5)	14 (10–19)

Modified from Inns and Leadbeater (1983).
[a]The protective ratio is defined as the ratio of the LD_{50} treated compared to the LD_{50} untreated.

obtained. This research has been most successfully prosecuted in the UK and all UK forces are issued with pyridostigmine bromide tablets (30 mg three times daily) for use, should the risk of exposure to nerve agents be deemed significant. Pyridostigmine bromide was taken by UK, US and some other forces during the Gulf War (1991). Sharabi *et al*. (1991) reported that nonspecific side effects, including dry mouth, general malaise, fatigue and weakness, were reported. Nausea, abdominal pain, increased frequency of micturition and rhinorrhoea were infrequent. Side effects tended to appear during the first few hours following each dose and then resolved. Interestingly, no correlation between AChE inhibition and symptoms was detected. Keeler *et al*. (1991) reported a study of 41 650 soldiers who took pyridostigmine bromide, in the dose described above, for between one and seven days. About half the study group reported side effects, including increased flatus, abdominal cramps, soft stools and urinary urgency. About 1% of soldiers 'believed their symptoms required medical attention', but in less than 0.1% were the side effects so severe as to require withdrawal of pyridostigmine. It was concluded that military efficiency was not impaired by taking the drug. Suggestions that the Gulf War Syndrome might have been caused by the use of pyridostigmine bromide do not appear to be well founded (Wessely and Hotopf, 2007).

7.9.2.1 Cholinolytics

Atropine is the drug of choice and should be given intramuscularly or preferably intravenously, in aliquots of 2 mg, as soon as possible after poisoning. Use of nerve agents by terrorists may lead to children being affected. For children less than eight, but more than one year of age, 600 μg of atropine should be adopted as the standard dose. For those under one year of age, 200 μg should be used. To enable servicemen to self-administer atropine and in some cases oxime, a wide variety of autoinjection devices have been developed commercially. Most contain 2 mg of atropine per injection and permit injection through clothing. Speed of administration as soon as the first signs of poisoning are detected is critical, as the progress of symptoms and signs may be very rapid. It is essential, therefore, that servicemen should be well trained in the recognition of the early signs of poisoning and in the use of the autoinjection devices. As in cases of poisoning by other organophosphorus compounds, large total doses of atropine are often said to be likely to be needed. However, in casualties surviving to reach hospital, it is unlikely that the heroic doses of atropine reported by some who were managing cases of organophosphorus pesticide poisoning would be required. In preparing supplies of atropine for treating casualties, the assumption that a casualty might need up to 30 mg of atropine would be reasonable.

The dangers of atropine overdose should always be borne in mind:

- Drying of bronchial secretions making them tenacious and difficult to remove; the careful use of suction may be required
- Large doses of atropine may induce arrhythmias particularly if the myocardium is hypoxic as a result of respiratory failure
- Bladder dysfunction may necessitate transurethral catheterization.

Atropine drops are sometimes recommended for the relief of visual impairment and eye pain caused by contraction of the iris and spasm of the ciliary muscle. Atropine drops may be expected to relieve the eye pain to some extent, but seem to do little to improve vision. The combination of mydriasis and impairment of accommodation seems to produce at least as severe an impairment of vision as the miosis produced by exposure to the nerve agent. The use of oxime, instead of atropine, eye drops has been suggested, but not widely adopted. It has already been noted that in the Tokyo subway incident, atropine eye drops were found to be helpful in those with mild poisoning (Nozaki *et al*., 1995). This may reflect a difference between military and civilian objectives as regards therapy. In the military environment further impairment of vision as a result of paralysis of accommodation might be critically disabling, whereas in a civilian context this might be acceptable, given that effective pain relief was obtained.

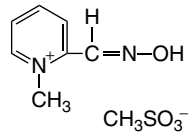

Figure 9 Pralidoxime methanesulfonate (P2S).

7.9.2.2 Oximes

The oximes, developed in the early 1950s (Wilson and Ginsburg, 1955; Wagner-Jauregg, 1956) represented a major step forward in the treatment of nerve-agent poisoning. Atropine opposes the effect of excess acetylcholine at muscarinic receptors, but has no effect at nicotinic receptors at the neuromuscular junction. Atropine cannot, therefore, relieve paralysis of respiratory muscles. Hydroxylamine was the first compound demonstrated to be capable of reactivating the AChE/nerve agent complex. More effective oximes followed and the work of Davies and Green (1956; 1959) and others led to the development of pralidoxime (PAM) methanesulfonate (pralidoxime mesilate or P2S). This compound and other PAM salts have maintained their place as the oximes of choice in the treatment of organophosphorus poisoning in many countries. P2S is included in the autoinjection device issued to the UK armed forces. A number of studies have shown that oximes block ion channels and thus work not only by reactivating inhibited acetylcholinesterase. Papers by Tattersall (1993), Alkondon *et al*. (1988) and van Helden *et al*. (1991) have stressed this mode of action. That oximes show some effectiveness in animals poisoned by soman, in which the nerve-agent–enzyme complex ages rapidly, may be explained by these direct effects.

P2S is a monopyridinium oxime; its chemical structure is shown in **Figure 9**.

A number of bispyridinium oximes have been developed, including obidoxime (Toxogonin) and those of the series of oximes referred to as the Hagedorn, or H, oximes (Oldiges and Schoene, 1970). The structures of some of the better-known compounds are shown in **Figure 10**.

If P2S is used, it should be given intramuscularly, as soon as possible after poisoning, or better by slow intravenous injection, at a dose of 30 mg kg^{-1}. The dose should be repeated at 15 minute intervals to a total dose of 2 or possibly 4 g. This dose is also regarded as appropriate in children. It should be remembered that very little experience of management of nerve-agent casualties has been accumulated. Oximes should be administered carefully and a close watch kept on the patient's condition. Side effects include headache, disturbances of vision and muscular weakness, and care should be taken to monitor the patient's condition before and after the administration of oxime to permit differentiation between the signs of deepening organophosphorus toxicity and the side effects of therapy. If given too quickly, bronchospasm and laryngospasm may occur. The use of an intravenous infusion of 2 g of P2S in 250 ml of normal (0.9%) saline delivered over 30 minutes has also been recommended. Ligtenstein (1984) has made a strong case for the continuation of the use of oximes beyond the often-suggested limit of a day or two.

The choice of oxime, if more than one is available, may be difficult. The following points should be recalled:

- PAM salts are probably still the most widely available oximes
- PAM is likely to be markedly more effective in cases of sarin and VX poisoning than in cases of tabun and soman poisoning
- Although obidoxime (Toxogonin) (3–6 mg kg^{-1} iv, four hourly) is likely to be effects in cases of tabun, sarin and VX (but not soman) poisoning, cases of liver damage following its use have been reported. A recent review has cast doubt on the likely efficacy of obidoxime in tabun poisoning (Marrs *et al*., 2006)
- The Hagedorn oximes such as HI6 and HGG12 have been shown to be effective in soman poisoning in some animal models, but are rather less effective than had been hoped in tabun poisoning (Wolthuis and Kepner, 1978; Harris *et al*., 1981; Clement, 1981; 1982a; 1982b; Clement and Lockwood, 1982). Recent studies by Kassa and Bajgar (1995) have shown that HI6 is a better antidote than obidoxime in rats poisoned with cyclosarin
- The recently developed Hagedorn oximes HLö-7 and pyrimidoxime are effective both in tabun and soman poisoning in some animal models (Eyer *et al*., 1989; 1992; Clement *et al*., 1992; Lundy *et al*., 1992)
- In general, the Hagedorn oximes are unstable in solution and demand more complex (wet–dry) autoinjection devices than the conventional oximes (Eyer *et al*., 1989). Göransson-Nyberg *et al*. (1995) reported a study of the efficacy of a new binary autoinjector containing 500 mg of HI6 and 2 mg of atropine sulfate in pigs poisoned with soman. The combination proved effective in opposing a lethal dose of soman (9 μg kg^{-1}, iv, per 20 minutes). The autoinject device contained two chambers: mixing is initiated prior to injection.

In addition to the above it should be recalled that atropine and oximes are synergistic in their effects and the administration of atropine and oxime has been shown to raise the LD_{50} of some nerve agents in animal models by a factor of more than 20 (Inns and Leadbeater, 1983). Soman remains a major problem, and the publications of Wolthuis and Kepner (1978), Wolthuis *et al*. (1981) and Clement (1981; 1982a; 1982b) should be consulted for details of the intractability of poisoning with soman, and for arguments regarding the use of H oximes. The

recent account by Eyer and Worek (2007) should also be consulted.

7.9.2.3 *Anticonvulsants*

Diazepam, a benzodiazepine γ-aminobutyric acid (GABA) agonist, has come to be regarded as a valuable addition to the combination of atropine and oxime in the management of nerve-agent poisoning. Benzodiazepines, such as diazepam, do not activate the $GABA_A$ directly; rather they alter GABA binding at the $GABA_A$ receptor in an allosteric manner (Charney *et al*., 2001). Nerve-agent poisoning, and particularly poisoning with soman in monkeys, is often complicated by convulsions and the control of these convulsions with diazepam has been shown to enhance the likelihood of survival (Lipp, 1972; 1973). There is evidence from experimental nerve-agent poisoning in animals that benzodiazepines may ameliorate or prevent the development of histopathological changes in the central nervous system that are produced by organophosphates (Anderson *et al*., 1997; Hayward *et al*., 1990). A number of theories have been put forward to explain these effects, including the suggestion that diazepam may prevent the rise in cyclic GMP levels observed in the CNS of animals suffering soman-induced convulsions (Lundy and Magor, 1978): the significance of this finding is uncertain (Liu *et al*., 1988) and the phenomenon is likely to be secondary to the effect on the $GABA_A$ receptor. A number of other anticonvulsants have been studied in organophosphate poisoning and midazolam has been used clinically (see Marrs and Vale, 2005).

Diazepam should be given in a dose of 5 mg orally, intramuscularly or better intravenously. Diazepam is not suitable for combination in solution with atropine and P2S, but a recently developed lysylglycine derivative of diazepam (avisafone) is. This has been incorporated in the autoinjection devices issued to the UK armed forces.

7.10 Prognosis of Nerve-Agent Casualties

Animal studies have suggested that the combination of the pretreatment and treatment described above would probably be effective in cases of nerve-agent poisoning. It is, however, difficult to extrapolate from such work to the case of the soldier poisoned on the battlefield at a considerable distance from medical attention. For those casualties who have self-administered one or perhaps more of their autoinjection devices, but who are slipping deeper into the effects of the nerve agent, the prognosis can hardly be other than poor. Those who sustain a dose of nerve agent sufficient to produce respiratory failure are unlikely to survive. It is believed that self-administration of therapy will delay the onset of symptoms and signs of nerve-agent poisoning, and make it more likely that the poisoned person will survive and reach medical attention. The prognosis for civilian casualties exposed to significant amounts of nerve agent cannot be good: delays in administration of therapy and, of course, the absence of pretreatment will both militate against likely recovery. In those exposed to lower concentrations, survival is possible, but the need for rapid therapy remains paramount.

7.11 Long-Term Effects of Nerve-Agent Poisoning

It is well known that organophosphorus compounds can produce permanent damage to the nervous system (delayed polyneuropathy). These effects, thought to be dependent on the combination of the organophosphate with the enzyme known as neuropathy target esterase (NTE), have been studied in detail by Johnson (1992)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and Moretto and Lotti (2005) and, in relation to insecticides, are discussed in **Toxicology of Pesticides**. Studies in animal models have demonstrated that the nerve agents are capable of producing these effects, but only when administered to animals protected by the prior administration of atropine and oxime, in doses many times in excess of their LD_{50}s. It is likely that a soldier who survives nerve-agent poisoning on the battlefield will not have been exposed to a dose of nerve agent capable of inducing delayed polyneuropathy. This also applies to civilian casualties.

Since the Gulf War, a great deal of publicity has been given to the so-called 'Gulf War syndrome'. A very wide range of psychological and physical effects have been reported in soldiers who fought in the campaign. It seems clear that veterans of the campaign have a higher self-reported prevalence of medical and psychiatric conditions than other personnel who did not see active service in the Gulf. Whether such effects are causally linked to exposure to pretreatment against nerve-agent poisoning, perhaps in combination with immunization schedules, remains unknown. The reader should consult the excellent series of papers published in 1997 (Iowa Persian Gulf Study Group, 1997; Haley and Kurt, 1997; Haley *et al*., 1997a; 1997b). Hyams *et al*. (1996) have pointed out that outbreaks of difficult-to-explain symptoms have been seen after every major war since the US Civil War and that many questions remain unanswered regarding these 'war syndromes'. The recent review by Wessely and Hotopf (2007) should also be consulted.

8 PULMONARY OEDEMA-INDUCING COMPOUNDS

During World War I, the chemical warfare compounds with the highest lethality were those which induced pulmonary oedema, and included chlorine and phosgene. Phosgene was first used by German forces on 19 December 1915 and soon acquired a reputation as a dangerous compound: 85% of deaths resulting from exposure to chemical warfare compounds during World War I were caused by phosgene (HMSO, 1972, 1987). Despite this, well-protected troops using modern respirators should not be placed at serious risk as a result of exposure to these compounds, and little development of pulmonary-oedema-producing compounds for use as chemical warfare agents has taken place since World War I. During World War I, great efforts to develop other pulmonary-damaging compounds were made and a large number of compounds were used, albeit sometimes on a comparatively small scale. Accounts dating from the 1920s should be consulted for details of these compounds. Among accounts generally available, that of Prentiss (1937) is particularly detailed and reliable. In a civilian context, chlorine and phosgene are especially worrying as they are widely used in industry, and transported by road and rail. The possibility of a terrorist organization releasing a large quantity of chlorine needs careful consideration. It will be recalled how effective chlorine released from cylinders was against unprotected troops in 1915.

During World War I, phosgene acquired a particularly evil reputation, as it was soon realized that men who had inhaled a potentially lethal dose of the compound might show few symptoms and signs during the first few hours following exposure (Vedder, 1925). Early diagnosis was therefore difficult. It was further noted that men in the symptomless latent period could collapse with florid pulmonary oedema if exposed to physical stress (HMSO, 1923). It will be appreciated that the sensible clinical advice to rest all those thought to have been exposed, for 24–48 hours, preferably in bed, was ill-received by commanders in the field. Similar problems would be faced by accident and emergency department staff (ER department staff) dealing with a large number of people all potentially exposed to phosgene as a result of a terrorist incident.

While phosgene might not present a severe toxicological risk to modern troops, it is not detected by all detectors and monitors in general military use, and troops thought to be at risk would be forced to don respirators and accept the concomitant drop in their performance.

The general effects of lung-damaging compounds have been described in **Inhalation Toxicity** and **Air Pollution**, and only those aspects of the toxicology of phosgene of importance to chemical warfare and antiterrorism are mentioned here.

8.1 Physicochemical Properties of Phosgene

These are given in **Table 14**.

8.2 Likely Mode of Exposure

Phosgene is rapidly dispersed by wind and is regarded as an agent of short persistence likely to be used only in surprise attacks. It may, however, linger in cellars, tunnels and hollows, as it is heavier than air. This point was discussed by Haldane (1938) who pointed out that rapid mixing with air would produce a mixture only very slightly heavier than air and that this would disperse rapidly in open air conditions. Lefebure (1921) described experiments undertaken during World War I in an attempt to convert phosgene into a more persistent compound by impregnating porous powders with the gas. These experiments do not seem to have been successful.

8.3 Absorption of Phosgene

Phosgene is not absorbed to a significant extent through the skin; it is of course absorbed by the lung. Nash and Pattle (1971) studied the reaction of phosgene with water at moist surfaces and concluded that the rate of hydrolysis would render penetration by phosgene of more than 'a few tens of microns' unlikely.

8.4 Toxicity of Phosgene

The toxicity of phosgene has been widely studied, and **Table 15** shows the range of toxicities encountered in different species.

As in the case of nerve agents, $L(Ct)_{50}$ is dependent on the respiratory state and will fall with exertion.

8.5 Mechanism of Action of Phosgene

Despite its long history, the exact mechanism of action of phosgene remains obscure. The hypothesis that phosgene acts by combining with water and forming hydrochloric acid (Winternitz, 1920; Vedder, 1925), which then produces tissue damage, was challenged by the work of Nash and Pattle (1971). These authors showed that the 'maximum concentration of acid in a blood–air barrier of thickness 1 μm, in contact with 25 ppm of phosgene is 7×10^{-10} M, which is negligible. Buffering by tissue constituents would prevent any significant change in pH'. At high concentrations it was accepted that the formation of hydrochloric acid might play a role.

Potts *et al*. (1949) proposed that phosgene combined with the amino groups of proteins to form diamides (**Figure 11**). Diller (1978) proposed a series of reactions to explain the combination of phosgene with a wider range of chemical groups (**Figure 12**). Frosolono and Pawlowski (1977) studied the biochemical changes produced by phosgene in various lung fractions prepared from rats exposed to close to an $L(Ct)_{50}$ of phosgene. A number of enzymes showed decreased activity, but the data did not allow a distinction to be drawn between reduction in enzyme activity as a result of direct inhibition and that resulting from loss from damaged cells. Recent studies shed new light on the mechanism of action of phosgene. Work by Kennedy *et al*. (1989), Guo *et al*. (1990), Sciuto *et al*., (1995; 1996; 1997; 1998; 2001; 2003) and Scuito and Hurt (2004) has led to the following conclusions:

1. Free-radical formation with associated lipoperoxidation and leukotriene formation lie at the heart of the toxicity of phosgene
2. Exposure to phosgene induces a decline in intracellular cyclic adenosine triphosphate (cAMP)

Table 15 Toxicity of phosgene

Species	Route	Term	Units	Value	Source
Rat	Inhalation	LC_{50}	mg m^{-3} per 30 min	1400	NTIS[a]
Mouse	Inhalation	LC_{50}	mg m^{-3} per 30 min	1800	NTIS

Dog	Inhalation	LC_{LO}	ppm per 30 min	80	NIOSH
Rat	Inhalation	100% mortality	ppm per 20 min	37	

[a]NTIS, National Technical Information Service.
[b]NIOSH, National Institute for Occupational Safety and Health.
The values quoted are often described in toxicological databases as LC_{50} values, for example, the LC_{50} of phosgene for a 30 min exposure in mice is 1800 mg m^{-3}. Attempts to convert such values to $L(Ct)_{50}$ values by simple multiplication should be avoided as it is known that the $L(Ct)_{50}$ of phosgene is time dependent. It will be noted that as the duration of the exposure is increased the $L(Ct)_{50}$ value rises. This has also been noted by Ballantyne (1987) for hydrogen cyanide. A widely quoted statement of the toxicity of phosgene to humans is '50 ppm may be rapidly fatal' (for phosgene 1 ppm = 4.419 mg m^{-3} at STP). See **Table 16**.

with an increase in capillary permeability, possibly resulting from effects on the endothelial cytoskeleton

3. Phosgene-induced decrements in tissue glutathione (GSH) levels affect regulation of intracellular calcium concentrations and this may lead to activation of transcription factors for genes controlling production of inflammatory mediators.

Jugg *et al*. (1999) reported interactions between phosgene and surfactant, and thus linked phosgene with changes in the regulation of water flux at the alveolar epithelium.

Table 16 Variations in lethal index of phosgene with duration of exposure (dogs)

Time of exposure (min)	Minimum lethal) dose mg l^{-1})	Lethal index (mg min m^{-3})
2	2.00	4000
5	1.10	5500
10	0.55	6500
15	0.46	6900
20	0.37	7400
25	0.30	7500
30	0.27	8100
45	0.20	9000
60	0.17	10 200
75	0.16	12 000

After Prentiss (1937).

In addition to the above, efforts have been made to produce a pathophysiological hypothesis to explain the production of pulmonary oedema. Phosgene clearly damages the blood–air barrier in the lung and allows the leakage of fluid from the pulmonary capillaries. At first this leak may be contained by increased flow in the pulmonary lymphatic system, but later an increase in fluid in the connective tissue spaces occurs and finally fluid spills over into the alveoli. This sequence, the standard pattern of 'permeability' as compared with 'hydrostatic' pulmonary oedema, has been most competently reviewed by Staub (1974), Teplitz (1979) and Robin (1979) and is further discussed in **Inhalation Toxicity** and **Air Pollution**. Some authors, including Everett and Overholt (1968) and Ivanhoe and Meyers (1964), have suggested that phosgene could lead to massive reflex vasoconstriction and the production of oedema as in neurogenic pulmonary oedema (NPE). In this condition a sudden redistribution of blood from the systemic to the pulmonary circulation is believed to occur, producing damage to the pulmonary capillary endothelium. The damage is believed to be such that, even when intravascular pressures have returned to normal, a leak of fluid continues. That phosgene acts by this mechanism seems unlikely, as the extraordinary systemic hypertension recorded in cases of NPE has not been observed in animal models of phosgene poisoning.

It should be understood that the exact mechanism by which phosgene causes an increase in pulmonary capillary permeability is not known. Pulmonary capillaries possess a complete endothelium, the cells being joined by tight junctions. It is often assumed that compounds such as phosgene produce some loosening of these junctions, although the changes involved at the ultrastructural level are ill understood. It would be particularly interesting to know whether phosgene produces any change in the pattern of strands of particles, revealed upon the p-face of the cell membrane by freeze-fracture techniques, which appear to be important in the structure of the tight junction.

8.6 Histopathology of Phosgene-Induced Lung Damage

The light microscopic appearances of phosgene-damaged lungs were accurately described by Winternitz in 1920. Since then many studies have been carried out, Pawlowski and Frosolono's work, 1977 at the ultrastructural level being particularly valuable. The sequence of changes described by Pawlowski is as follows:

- The epithelium of the terminal bronchiole appeared to be first affected. Intracellular vesiculation of ciliated epithelial cells and Clara cells was observed.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

These effects appeared very soon after exposure

- An increase in the amount of extracellular fluid visible in the interalveolar septae was noted
- Frank oedema of cells of the interalveolar septae was observed
- Swelling of Type II alveolar cells was noted
- Type I alveolar cells showed areas of focal disruption
- Interalveolar septae became widely distended with fluid
- Oedema fluid appeared in alveolar spaces.

Oedema fluid in phosgene-induced lung damage is protein-rich and, by light microscopy, classically eosinophilic. Damage to Type II alveolar cells is interesting, although a clear demonstration of a decline in surfactant production in phosgene-induced oedema is lacking. It is, however, known that by lowering the surface tension of the lining film of the alveoli, surfactant may reduce the forces acting to move fluid out of pulmonary capillaries (Pattle, 1965). Damage to cells which produce surfactant would then be expected to enhance the likelihood of alveolar oedema.

8.7 Symptoms and Signs of Phosgene Exposure

Because of the extensive use of phosgene during World War I, many detailed accounts of its effects on humans are available, Ireland (1926) and Vedder (1925) providing particularly valuable accounts. Accidental exposures occur and Diller (1978), Seidelim (1961), Fruhman (1974) and Bradley and Unger (1982) have also provided accounts.

Some authors describe eye irritation, coughing, lacrimation, choking and a feeling of tightness of the chest as early symptoms and signs of phosgene exposure. Doubtless these do occur in some patients, but it was clearly demonstrated during World War I that an absence of such effects did not preclude serious and sometimes lethal exposure.

The hallmark of phosgene poisoning has been recognized to be the occurrence of a latent period intervening between exposure and the onset of the symptoms and signs of pulmonary oedema. This period may range from 30 minutes to 24 hours depending, in part, on the severity of the exposure. During this period it is notoriously difficult to distinguish the mildly exposed from the severely exposed.

Once the latent period is over, dyspnoea, a painful cough and cyanosis appear rapidly. Increasing quantities of, initially whitish, but later pink, fluid are expectorated, a marked efflux of fluid, the 'champignon d'écume', sometimes appearing just before death. The cause of death is usually cardiac failure and circulatory collapse caused by hypoxia.

A World War I description of a chemist dying some hours after a brief exposure to a high concentration of phosgene during a laboratory accident gives the clinical picture:

> *His condition now (4.5 hours post exposure) rapidly deteriorated. Every fit of coughing brought up large quantities of clear, yellowish, frothy fluid of which about 80 ounces (2272 ml) were expectorated in one and a half hours. His face became of a grey, ashen colour, never purple, though the pulse remained fairly strong. He died at 6.50 pm without any great struggle for breath. The symptoms of irritation were very slight at the onset; there was then a delay of at least four hours and the final development of serious oedema up to death took little more than an hour though the patient was continually rested in bed.*
>
> (Vedder, 1925)

8.8 Management of Phosgene Poisoning

8.8.1 First Aid

Casualties should be removed from risk of further exposure by suitably protected attendants. Because phosgene would not be encountered in the liquid state, decontamination with fullers' earth or a dilute solution of bleach is unnecessary.

8.8.2 Medical Treatment

The management of phosgene poisoning is the management of permeability pulmonary oedema. No antiphosgene drug of any proven value has been discovered although hexamethylenetetramine (HMT) is discussed briefly below. Steroids, antibiotics, bronchodilators, respiratory stimulants and cardiac stimulants have all been suggested, although none has received universal support. Two measures are, however, generally agreed.

8.8.2.1 Rest

All persons thought to have been exposed to phosgene should be confined to bed. It was demonstrated repeatedly during World War I that exertion during the latent period following exposure to phosgene could precipitate acute and fatal pulmonary oedema.

8.8.2.2 Oxygen

Patients unable to maintain an adequate arterial oxygen tension when breathing air should be given supplementary oxygen. This was stressed during World War I by

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Barcroft (1920) and Haldane (1917), when experience in the management of phosgene poisoning was unrivalled.

Of measures not commanding universal support, the following should be considered:

8.8.2.3 Corticosteroids

Arguments both for and against the use of steroids in pulmonary oedema have been plentiful for some years and have been considered by Everett and Overholt (1968), Diller (1978) and Bradley and Unger (1982). Everett reported the successful use of glucocorticoids; Diller also supported their use, although Bradley found the evidence of their efficacy unconvincing. It is known that inflammatory changes are likely to occur in lung tissue damaged by phosgene and that these changes involve the release of mediators which are likely to increase capillary permeability and therefore worsen the oedema. That such release can be prevented by the prophylactic administration of corticosteroids seems likely; that such release can be reduced significantly once initiated remains doubtful. Some clinicians, perhaps the majority, have felt that the lack of serious side effects usually associated with the short-term administration of large doses of corticosteroids and the seriousness of permeability pulmonary oedema, justifies the use of these drugs. Others have felt that the lack of clear evidence of efficacy should preclude their use. In some military manuals (HMSO, 1972, 1987), the use of a large single dose of corticosteroid as soon as possible after exposure has been advocated.

8.8.2.4 Antibiotics

The provision of antibiotic cover in phosgene poisoning has been supported by both Diller (1978) and Everett and Overholt (1968). During World War I, the absence of antibiotics made pneumonia a feared complication of lung damage arising as a result of exposure to a variety of chemical warfare compounds. Selgrade *et al.* (1995) showed that exposure to phosgene impaired the capacity of mice to deal with an inhalation challenge with bacteria. This was ascribed to impairment of macrophage and natural-killer-cell activity. The choice of antibiotics is wide, penicillin G, amoxycillin and chloramphenicol all having been recommended.

Of measures not receiving wide support, only one will be considered.

8.8.2.5 Hexamethylenetetramine ('Hexamine', 'Methanamine', HMT)

Hexamine is used prophylactically as an antimicrobial drug in cases of recurrent urinary-tract infections. It has been demonstrated to be of value in animal models, if given before exposure to phosgene. Stavrakis (1971) argued that hexamine was also of value if given post-exposure in cases of phosgene poisoning and recommended the administration of 20 ml of a 20% solution, intravenously, as soon as possible after exposure. Diller (1978) reviewed the use of hexamine and concluded that there was no firm evidence to support the view that hexamine is of value if given after poisoning.

Studies by Sciuto *et al.* (1995; 1996) have investigated the use of *N*-acetylcysteine (NAC) and dibutyryl cyclic AMP (DBcAMP) in phosgene poisoning. Postexposure intratracheal administration of NAC in isolated perfused rabbit lung was shown to reduce the formation of oxidized glutathione and a number of markers of lipid peroxidation, which was shown to be induced by exposure to phosgene. Similarly, DBcAMP acted as an antioxidant. No clinical studies of the efficacy of these methods of treatment are yet available.

As in all cases of permeability pulmonary oedema, the administration of intravenous fluids should be approached with great caution.

8.9 Long-Term Effects of Phosgene Poisoning

Chronic bronchitis and emphysema have been reported as a consequence of exposure to phosgene (Cucinell, 1974). Chronic pneumonitis has been reported in rats exposed to phosgene (Gross *et al.*, 1965).

9 HYDROGEN CYANIDE

Of the poisons known to the general public, cyanide, arsenic and strychnine are perhaps the best known and it is often assumed that cyanide would be a dangerous chemical warfare agent. Despite this, hydrogen cyanide has been but little used as a chemical warfare agent and the physicochemical and toxicological characteristics of hydrogen cyanide make it unsuitable for such use on any other than a fairly small scale. It has, however, been used as a means of judicial execution and was used for the large-scale murder of prisoners in German concentration camps during World War II.

Only France used hydrogen cyanide as a chemical warfare agent during World War I, the first use of hydrogen cyanide shells being on the Somme on 1 July 1916 (Prentiss, 1937). German respirators offered poor protection against hydrogen cyanide, although this was quickly remedied and hydrogen cyanide lost most of its advantages over the alternative lethal compound, phosgene. It will be recalled that phosgene has a density equal to 3.5 times that of air, but that hydrogen cyanide is less dense than air. Rapid dispersion of hydrogen cyanide

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

greatly reduced its value as a chemical warfare agent. Prentiss (1937) commented: 'Because of its extreme volatility and the fact that the vapours are lighter than air, it is almost impossible to establish a lethal concentration of hydrocyanic acid in the field and this is particularly true when the gas is put over in artillery shells.' Few authorities today believe that hydrogen cyanide would be used on a large scale as a chemical warfare agent, although it has retained its place in military chemical warfare handbooks on the grounds that successful use, at high concentration, on selected targets could probably be achieved.

In view of the above, the discussion of hydrogen cyanide as a chemical warfare agent will be limited.

9.1 Physicochemical Characteristics of Hydrogen Cyanide

These are shown in **Table 17**. Below 26 °C hydrogen cyanide occurs as a colourless to yellowish–brown liquid. In its usual slightly impure state it is unstable, although it is said to be stable when highly purified. On standing, polymerization takes place and the compound may present an explosive hazard. The risk of explosion may be much reduced by the addition of a small quantity of an acid, for example, phosphoric acid. Prentiss (1937) commented: 'Anhydrous hydrocyanic acid is extremely unstable and is quickly decomposed with the formation of a black resinous mass.' This tendency to decomposition led to difficulties with munitions and Sartori (1939) commented: 'Even in the anhydrous condition it cannot be kept long as it gradually decomposes, occasionally with explosive force. Filled in projectiles it soon becomes harmless.' Hydrogen cyanide smells of almonds, although not all individuals are able to detect the odour. The capacity to detect hydrogen cyanide rapidly wanes on exposure, owing to failure of cells of the olfactory mucosa.

9.2 Absorption of Hydrogen Cyanide

Hydrogen cyanide vapour is readily absorbed across the lung, but only to an insignificant extent across the skin.

9.3 Toxicity of Hydrogen Cyanide

The L(Ct)$_{50}$ value for hydrogen cyanide in humans is not known with any accuracy. It is, however, known that the L(Ct)$_{50}$ value is likely to be very time dependent. This is shown by the estimates of human toxicity given in **Table 18**. The variation in L(Ct)$_{50}$ with time is believed to relate to the detoxification of cyanide by enzymatic conversion to thiocyanate. Ballantyne and

Table 19 Estimated toxicity of hydrogen cyanide in humans

Toxic effects	Concentration (mg m^{-3})
Mild symptoms on inhalation for many hours	24–48
Maximum tolerance limit for 1 h	50–60
Hazardous to life on inhalation for 30–60 min	112–150
Death in 5–10 min	240–360
Death in 5 min	420
Death after several breaths	1000

Schwabe (1981) have shown the variation in graphical form (**Figure 13**).

Further guidance on the estimated toxicity of hydrogen cyanide may be gained from **Table 19**.

9.4 Symptoms and Signs of Hydrogen Cyanide Poisoning

It is often assumed that exposure to a given concentration of hydrogen cyanide either produces sudden death or very few ill effects. In military circles this is often summed up by the observation that the use of hydrogen cyanide leaves 'the quick and the dead', but no incapacitated or partly incapacitated individuals. This is incorrect. Work in animal models (D'Mello, 1987) has shown that exposure to sublethal doses of hydrogen cyanide can produce incapacitation. Dizziness and nausea have been recorded in people exposed to sublethal quantities of hydrogen cyanide, the effects lasting for some hours.

At lethal concentrations, collapse and death are rapid. Vedder (1925) has provided the following description:

> *In an atmosphere containing a lethal concentration the odour of bitter almonds is noticed. This is followed rapidly by a sensation of constriction of the throat, giddiness, confusion and indistinct sight. The head feels as though the temples were gripped in a vice and there may be pain at the back of the neck, pain in the chest with palpitation and laboured respiration. Unconsciousness occurs and the man drops. From this moment if the subject remains in an atmosphere of hydrocyanic acid for more than two or three minutes death almost always ensues, after a brief period of convulsions followed by failure of respiration.*

9.5 Management of Hydrogen Cyanide Poisoning

Here only a few points of relevance to battlefield casualties will be made:

- The usual points regarding the rapid removal of casualties from the risk of further contamination should be noted
- Decontamination of casualties is unnecessary unless the clothing is contaminated with liquid hydrogen cyanide. This is very unlikely
- All forms of treatment currently available demand intravenous administration. This will probably be impossible on the battlefield
- Bearing the last point in mind, it is likely that casualties who reach aid posts will be incapacitated by sublethal doses of hydrogen cyanide. Given that adequately trained medical orderlies, nursing staff or medical staff are available, antidotal therapy would be used. When deciding which therapy to recommend it should be borne in mind that the exact diagnosis of the cause of collapse may, under battlefield conditions, be difficult, and treatment known to produce severe side effects if given to casualties who have, in fact, not been exposed to hydrogen cyanide should perhaps be avoided.

9.6 Prophylaxis in Hydrogen Cyanide Poisoning

It is generally accepted that treatment of casualties suffering from hydrogen cyanide poisoning, under battlefield conditions, will be difficult and often unsuccessful. Because of this, attempts to provide a measure of pharmacological protection against the effects of hydrogen cyanide have been made. The conversion of a fraction of haemoglobin to methaemoglobin, thus providing a ready-made binding site for the cyanide, has been a favoured line of research and in 1948 Gilman and Cattell reported studies undertaken during World War II in America. *p*-Aminopropiophenone was found to be the best compound tested for the production of methaemoglobinaemia and oral doses of 2.0 mg kg^{-1} were given to volunteers. This produced a methaemoglobinaemia of some 20–30%. This was maintained by repeated dosing over seven days without ill-effects although 'at the end of this period there were

observed the beginnings of a haemolytic anaemia'. Methaemoglobin levels of up to 15% were not found to interfere with exercise at light workloads. Animal work was reported to have shown that such levels of methaemoglobin (15%) would have provided protection against 10 lethal doses of hydrogen cyanide. On the battlefield, recalling the difficulty likely to be experienced in establishing a lethal concentration of cyanide, such a level of protection would be very valuable. Work by Bright (1987) in dogs has confirmed the above results although the issue of *p*-aminopropiophenone to troops for use in anticipation of an attack with hydrogen cyanide has, as far as is known, not been undertaken by any country.

10 LESSER CHEMICAL WARFARE AGENTS

In addition to the compounds described above, many other substances have been considered, although in the main rejected, as possible chemical warfare agents. During World War I, dozens, probably hundreds, of compounds were examined and during World War II several hundred mustard derivatives and variants were synthesized. The large number of compounds in this group which *could* be used in war makes any detailed consideration of individual compounds impossible. Instead a few comments will be made on some older compounds of interest and on the riot-control agents which could be encountered during modern warfare.

10.1 Early Irritant Compounds

Smoke from fires, used since classical times to discommode forces defending strong positions, exerted its effects by producing choking and eye irritation. In the early twentieth century, the Paris police force used grenades containing ethyl bromoacetate against rioters and it has been alleged that some of the police involved, later conscripted into the French Army, used the same grenades against German forces. The use of ethyl bromoacetate seems to have been taken up by the French and was also studied in London at Imperial College. (The military abbreviation for ethyl bromoacetate, SK, is said to stand for South Kensington, the location of Imperial College.) German workers also studied irritants and on 27 October 1914, at Neuve-Chapelle (France), high-explosive (HE) shells containing lead balls embedded in the irritant *o*-dianisidine chlorosulfonate were deployed (SIPRI, 1971). This incident was followed by the use of other compounds, including xylyl bromide, chloroacetone, benzyl bromide and iodide, ethyl and methyl chlorosulfonate, 2-chloracetophenone and bromobenzyl cyanide. Prentiss (1937) held the latter to be the most powerful irritant introduced during the war. In addition to the lacrimators, more toxic irritant smokes were developed. These included diphenylchlorarsine (DA), chlorodihydrophenarsazine (DM or Adamsite) and diphenyl cyanarsine (DC).

These compounds were described as vomiting agents and as well as producing nausea and vomiting, produced acute pain in the nose, uncontrollable sneezing, coughing, eye pain and lacrimation (HMSO, 1972, 1987). The marked sneezing led to these compounds being termed sternutators (Latin *sternuto* ... sneezing). Of these compounds only Adamsite has survived to modern use and has been used as a riot-control agent, although not in the UK.

Other arsenical compounds developed during World War I included methyl-, ethyl- and phenyldichlorarsine, collectively known as 'The Dicks' (HMSO, 1972, 1987). These were vesicant compounds of considerable toxicity and were developed in an attempt to find a 'faster-acting mustard gas' which would incapacitate casualties on contact. Attempts were also made to develop compounds combining irritancy with the lethality of hydrogen cyanide. Cyanogen bromide and chloride were produced, both effective irritants capable of killing. Despite this, neither proved a very successful chemical warfare agent (Prentiss, 1937).

10.2 Modern Riot-Control Compounds

The development of modern riot-control compounds has been dominated by the perceived desirability of developing a compound with the following characteristics:

- Rapid incapacitating effect even when used against highly motivated individuals
- Insignificant toxicity even to the very young or the very elderly bystander
- Capacity for easy dissemination
- Capacity for easy decontamination
- Long shelf-life
- Low cost.

It will be appreciated that these are difficult criteria to meet in full. At first glance, the first two criteria listed might appear likely to be mutually exclusive and yet each is met remarkably well by compounds such as CS and CR (dibenz(b.f)-1,4-oxazepine) discussed below.

A detailed review of those compounds which might be considered for use today in riot control has been provided by Ballantyne (1977) and much of the present account has been based on his work. Information on the individual compounds is given in **Table 20**.

10.3 Dangers Associated with Exposure to Riot-Control Compounds

Despite the low toxicity of these compounds, exposure is not entirely without risk. The following points should be borne in mind.

- Exposure to levels much in excess of those anticipated, for example in a closed room, might produce significant toxic effects. CN (2-chloroacetophenone) in large doses may produce corneal damage, particularly if the compound enters the eye in the form of powder. Five deaths due to the pulmonary damage following exposure to high concentrations of CN in enclosed spaces have been reported (Gonzales *et al*, 1954; Stein and Kirwan, 1964). Exposure to high concentrations of riot-control agents can occur as a result of use of personal protection devices. These are illegal in the UK, but incidents involving their use are not uncommon. In 1995, Wheeler and Murray reported that 354 calls to the National Poisons Information Service (London) regarding CS had been received. Advice on management has been provided by Gray (1995).
- Exposure to irritants may produce transient, although significant, elevations of blood pressure. These have generally been regarded as not likely to do harm in healthy individuals, although those suffering from hypertension, aneurysms or myocardial disease might be placed at some risk (Ballantyne *et al*., 1976).
- Hysteria and panic may be produced by exposure to irritants, particularly if the means of escape from exposure are blocked. Secondary injuries may be produced by stampeding crowds.
- Each of the compounds listed in the above table, with the exception of CR, can produce contact sensitization (Holland and White, 1972; Rothberg, 1970).

10.4 Management of Casualties Exposed to Riot-Control Agents

As for all other compounds discussed in this chapter, removal of casualties from the risk of further contamination by adequately protected attendants is of first priority. Contaminated clothing should be removed and placed in polythene bags: CS and CR are notorious for spreading during decontamination of casualties. Lacrimation, blepharospasm, blepharoconjunctivitis and eye pain disappear quickly after removal from an irritant cloud. The effects on the eyes may be initially so distressing that casualties may require a great deal of reassurance that permanent eye damage has not been produced. The eyes should be kept open and those who have been regularly exposed to CS advise standing with the eyes open 'facing the wind'. Irrigation of the conjunctival sacs with 0.9% saline brings rapid, although in the authors' personal experience, sometimes temporary, relief.

Skin should be decontaminated with soap and water. In the case of CS, hydrolysis occurs quickly and decontamination is rapidly accomplished. Showering is often advised, but it should be remembered that CR, and to a lesser extent CS, may be washed out of the hair and produce secondary contamination of the eyes. Erythema generally subsides without treatment, although primary contact dermatitis may require treatment with corticosteroid ointment.

11 ALLEGED CHEMICAL WARFARE AGENTS

One of the commonest misconceptions regarding chemical warfare is represented by the view that compounds of great toxicity must, *ipso facto*, be likely effective chemical warfare agents. This view is so commonly put that it may be worth noting that in assessing the potential of a compound as a putative chemical warfare agent, a number of factors have to be considered of which acute toxicity is only one and probably not the most important. These criteria include:

- Ease of manufacture in large quantities. Chemical warfare waged on a small scale during a major war is unlikely to produce significant results. It is sometimes argued that assassinations have been carried out using small quantities of highly toxic compounds. This is true, but assassination should not be confused with chemical warfare
- The conditions of storage of the compound should not be demanding and the compound should not deteriorate on storage
- The compound should be easy to disperse using inexpensive munitions and should not be destroyed by the dispersal system. The compound should be active in the form in which it is likely to be encountered by the opposing forces: a compound only active by the intravenous route would be an unsatisfactory chemical warfare agent
- On the whole, compounds producing severe and care-demanding incapacitation are more effective chemical warfare agents than those which are inevitably lethal
- It should be possible to protect one's own forces against the effects of the chosen compound without excessive expense or loss of efficiency

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat131
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- The compound should offer advantages when compared with already available compounds which meet the above criteria.

A rigorous application of these criteria will serve to remove many substances from accounts which purport to list possible or probable chemical warfare agents. In assessing the *probability* that a compound would be used as a chemical warfare agent the question, 'Why should this compound be chosen?' should always be asked rather than the question, 'Could this compound be used as a chemical warfare agent?'

A considerable range of exotic compounds have been examined as potential chemical warfare agents: batrachotoxin, tetrodotoxin, saxitoxin, palytoxin, botulinus toxin, staphylococcal enterotoxin B, ricin and abrin have all been examined in detail. Ricin was used to assassinate G. Markow in 1978. Figures are not available for the toxicity of staphylococcal enterotoxin B when absorbed by inhalation, although it is felt the compound would be significantly more toxic when administered in this way than by ingestion (Mattix *et al*., 1995).

During the early 1980s, considerable attention was paid to toxins of fungal origin: mycotoxins. It was alleged that a group of mycotoxins known as trichothecenes had been used in Southeast Asia. The compounds on which attention centred were: T2 toxin (*Merck Index*, 11th edn, ref no. 9711) and nivalenol (*Merck Index*, 11th edn, ref no. 6581).

T2 is a caustic skin irritant which may cause dizziness, nausea, vomiting, diarrhoea and haemorrhage. The LD_{50} of T2 toxin (oral, rat) is $4.0\,mg\,kg^{-1}$. Nivalenol, also known to be capable of producing similar effects, has an LD_{50} (ip, mice) of $40\,\mu g\,kg^{-1}$. Further discussion of the toxicity of these compounds may be found in the work of Tatsuno (1968), Wade (1981), Rosen and Rosen (1982), Marasas *et al*. (1969) and Wang *et al*. (1998). Irrefutable evidence that these compounds were deliberately used as chemical warfare agents, is, however, lacking. During the Soviet occupation of Afghanistan, it was alleged that Soviet forces had used chemical warfare agents against rebel tribesmen. No clear identification of the compounds alleged to have been used has appeared and the effects reported—the induction of unconsciousness with recovery with few ill-effects an hour or so later and the production of blackened and very rapidly decaying bodies—have been hard to explain.

In examining reports of alleged uses of chemical warfare agents factors, such as the likely naivity of observers, deliberate attempts to mislead and the more common causes of death in war should be borne in mind. Before dismissing such reports, however, it should also be remembered that small-scale use of chemicals on an *ad hoc* basis might occur during a war waged by poorly disciplined forces.

All the compounds considered thus far have been characterized as likely to have effects on humans. If the definition of chemical warfare is widened a little and the attack on food production resources or woodland, which provides hiding places for troops, is included, then a number of herbicidal compounds could also be considered. Such compounds may be *per se* toxic to humans or, in the forms deployed, contain toxic contaminants. During the Vietnam War, American forces used large quantities of herbicides, including the phenoxyacetates, 2,4-D and 2,4,5-T, some preparations being contaminated with TCDD (tetrachlorodibenzodioxin). The mixture was often referred to as Agent Orange (Young *et al*., 1978). Exposure to the mixture has been alleged, though not proven, to have produced long-term effects in both Vietnamese and American veterans. Details of the toxic effects of herbicides may be found in **Toxicology of Pesticides**.

12 CONCLUSIONS

Chemical warfare has a long history, although only in the twentieth century has it been developed as a means of waging war on a large scale. In the late 1980s moves to ban the production and stockpiling of chemical weapons have been made and may yet prove completely successful between countries involved in these negotiations. It should, however, be recalled that treaties have been violated in the past and that a number of countries currently believed to have acquired or to be acquiring chemical weapons are not involved in treaty negotiations. It seems, therefore, that although the risk of chemical warfare has diminished during the past decade, such a risk still exists.

Chemical Terrorism

Bryan Ballantyne

CONTENTS

1 BACKGROUND

Man has lost his capacity to foresee and to forestall. He will end by destroying the world.

(Albert Schweitzer)

Terrorism has a very long history. Those living in English-speaking countries will be familiar with the gunpowder plot, where a group of catholics tried to blow up parliament and King James I (James VI of Scotland) in 1605 (Fraser, 1996). In the nineteenth century, numerous assassinations were carried out by anarchists, notably that of Empress Elisabeth of Austria (Avril, 1993). It should also be remembered that states may use terror against populations, including those of neighbouring states; an example of that is the behaviour of France in the Palatinate in 1688 (Lynn, 1999). A more recent incident that could be considered terrorism against a state's own inhabitants is the use of chemical weapons in Halabja (Iraqi Kurdistan) against the Kurdish population of Iraq, by the government of Iraq in 1988 (Gosden, 1998). Nor should be forgotten the terror and the judicial murder of the King that took place during the French Revolution (Carlyle, 1906) and the terror of the Russian revolution (Pipes, 1990). Many of the actions of the Hitler government in Germany against both Germans and inhabitants of other European states could be considered as terrorism (Kohn, 1960; Lee, 1987). For a discussion of the origins and causes of terrorism see Burleigh (2008).

Richardson (2006) has defined terrorism as 'deliberately and violently targeting civilians for political purposes', with seven characteristics, as follows: (i) politically inspired, (ii) involves violence or the threat of violence, (iii) the objective is not to defeat, but to send a message, (iv) the act and the victim have symbolic significance, (v) terrorism is usually the deliberate action of substate groups, (vi) victims of the violence are usually a means for altering behaviour of a larger audience, usually a government and (vii) there is deliberate targeting of civilians.

1.1 Response to Terrorism

One of the objectives of terrorism may be to generate a disproportionate response and thereby alienate the population against the state. This creates, within organized communities, a situation of distrust, suspicion and a tendency to political dictatorship. This is a consequence

of, and a reflection of, for example, government spying on citizens' private communications, gaining access to personal information and creating files for stated use by homeland security and government/military intelligence agencies, but clearly such information may be used for other purposes, other than those for which they were purportedly intended. Also there is a clear danger that overreaction to terrorism may damage the democracy that authorities are trying to protect.

Despite the discussion above, there are many measures that governments and other organizations may take in order to prepare for and mitigate effects of chemical terrorism and these measures are discussed below.

2 THE SPECTRUM OF TERRORIST ACTIVITIES

2.1 General Considerations

From a practical overview perspective, the term terrorist incident covers a wide spectrum of situations, the common feature of which is a desire by an individual or a group of individuals to produce an assault on organized law-abiding societies in order to attempt to draw attention to inequalities or perceived political malpractices, or to alter popular attitudes, opinions, legislation or political dictate, by the use of methods designed to make the terrorist motivation clearly and fearfully known to the appropriate members or sectors of that society. The more sophisticated terrorist will employ tactics designed to destroy the fabric of organized societies by means of occult infiltration into the social structure in order to interfere with political and governmental processes and/or financial and economic dominance. In the more usual terrorist approach, the techniques employed are designed to cause fear or panic in the targeted population, and in some cases there may be a deliberate objective to cause random or targeted deaths and mutilations. The range of weaponry potentially available to terrorists is wide and variable: weapons used may include guns or explosive devices, radioactive/nuclear sources, biological organisms and toxins (bioterrorism) or xenobiotic chemicals (chemical terrorism). It should be noted that there may be classification and use overlap between biological toxins and xenobiotics (Pearson, 2007). The use of chemicals of differing classes is generally recognized by the public as being very likely in certain situations by some terrorist groups.

At one end of the spectrum of those who might be described as terrorists are individuals, or small groups of individuals, who have, for very variable reasons, aberrant behaviour patterns against either a whole civilized society or individuals of that society. Terrorists of this type may seek vengeance or desire to frighten (terrorize) individual citizens or the population at large in order to demonstrate, and make known, the reason(s) for their antisocial and often destructive physical and amoral activities. At the other extreme of the spectrum of terrorists are larger groups or organizations, national or international, whose destructive motivation is based on cult beliefs, extreme political/ethnic persuasions, religious dogma or a combination of some or all of these factors, frequently aggravated by abnormal behavioural attributes. Furthermore, a terrorist–terrorized confrontation is frequently not a one nation vs. a different nation, but may involve one national or religious group against another within a nation or against the remainder of the same national population. This is usually the case with individuals or small-group activities.

2.2 Individual and Small-Group Terrorist Activities

An individual, or small group of individuals can draw attention to grievances or the reason(s) for such grievances, by physical or chemicals means. This type of activity is usually, though not invariably, based on circumscribed objectives and directed against a specifically targeted population. An example is the attacks by the Aum Shinrikyo cult in Japan (see below).

2.3 Major and International Terrorist Activities

Here a group of individuals will try to draw attention to grievances or the reason(s) for such grievances, by physical or chemicals means and will take on a state or a large proportion of the population therein. This type of activity is usually, although not invariably, based on circumscribed objectives and directed against a specifically targeted population. Often the number of individuals is quite small, but they may enjoy the passive support of a proportion of the population. Examples include Al Qaeda (BBC, 2008a), the Provisional Irish Republican Army (IRA) (Shanahan, 2009) and Euskadi Ta Askatasuna (ETA) (BBC, 2008b).

3 AGENTS FOR CHEMICAL TERRORIST ACTIVITIES

Until 1994, the use of chemical weaponry by terrorist groups was considered unlikely, but this all changed with

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat132
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the deployment of chemicals by a terrorist group in Japan (see below). After this, many countries started to consider the possibility that chemicals might be used elsewhere against civilian populations; indeed the United States Government organized a seminar on the consequences of chemical and biological terrorism as soon as 1995, which included British, Canadian and Japanese participants (DHHS, 1995).

3.1 Criteria for Choice of Agent

Widespread discussions and resultant recommendations have concluded that chemicals of various and different classes are likely be used by terrorist groups, depending on the depth of knowledge and degree of sophistication of the group or individual. Chemicals that might be used, and in some cases chemicals that have been used, vary widely, as do their modes of delivery. It must be appreciated that the world chemical industry is very large and that large quantities of toxic industrial chemicals (TICs) are continually being produced and transported by rail, road and ship, both within states and internationally. Whether a particular TIC could practicably be used depends on numerous factors.

On a generic basis, classes of chemicals that could be used include the following:

- Irritant and/or disorienting materials (for inducing panic)
- Nauseating materials (for inducing revulsion)
- Psychogenic materials (for inducing panic and fear)
- Severely toxic and lethal agents (for inducing panic and/or deliberate injury or murder).

It is assumed that most terrorists, or individuals using terrorist-like approaches, will choose appropriate chemicals that have the following attributes:

1. Cheap to purchase
2. Can be readily purchased or otherwise obtained, if necessary in bulk, or readily manufactured (synthesized) in 'home' laboratories; the relative ease of access to purchase and recipes using the internet requires attention and control (Yoshida, 2008)
3. Capable of causing mass incapacitation, fear, social disruption and/or mortality
4. Comparatively easy to handle and use
5. Have high biological activity and, for most circumstances, having effects that are rapid in onset
6. Can be acquired, with associated dispersal systems, without high levels of suspicion.

3.2 Possible Modes of Delivery

3.2.1 General Comments

The mode of delivery of chemicals to intended targets will depend on several factors, which include the following:

- The target population and its size, and whether individuals or random groups
- Whether the aim is deliberate killing and/or to cause fear and panic
- Whether the target is intentionally selective or random
- Whether the incident is planned and is to be conducted by individual(s) or group terrorist activity
- The planned location
- The facilities available
- The physicochemical properties of the chosen agent
- The ease of access to chosen location
- The possibility of concealment of any signs of suspicious activity
- Whether the perpetrator is prepared to die during the incident.

3.2.2 Specific Routes

Some potential scenarios are presented as follows:

1. **Inhalation exposure**: Volatile materials and substances that can be used as aerosols are likely to be used in enclosed spaces, such as rooms, indoor entertainment areas and tunnels, such as subway systems. With airborne dispersion in closed, crowded areas, the resultant panic caused by exposure to xenobiotics may lead to physical injuries and lethalities due to attempted escape to outdoor fresh air. This was seen in a Chicago nightclub as a result of a security guard discharging an irritant chemical (oleoresin capsicum) from an aerosol generator in an attempt to break up a fight; the resultant panic and stampede towards the door in a limited escape situation resulted in the deaths of 21 persons (USA Today, 2003). Lesser, but definite degrees of panic, sometimes with physical injury, have been recorded following release of irritant materials such as CS (2-chlorobenzalmalononitrile) into the atmosphere in subways (BBC, 2005) and nightclubs (BBC, 2002a).
2. **Peroral exposure**: Food and drink poisonings as terrorist-like attacks have been experienced in several countries, including Japan. Toxic substances used have included paraquat, organophosphate (OP) pesticides, cyanide and arsenate (Yoshida, 2008). Clearly there is a requirement to be aware of the potential

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat132
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

for possible massive chemical poisoning exposure through locally contaminated and imported food and drink. To deliver by mouth in food there can be deliberate incorporation of the toxin randomly within shops or at distributor locations, or more specifically in foods at the locations of planned functions. For uncontrolled and widespread effects, toxin can be incorporated in basic crops at storage locations; for example, excess treatment with pesticide. For inclusion in fluids for drinking a variety of delivery modes are available depending on the planned size and geographical location of the target population. For individuals or small groups, direct precontamination of the drink may be possible, or incorporation into bottles or fluid containers. For larger-scale contamination of drinking water then it might be possible to introduce poison into fluid in storage vessels/cisterns. Cult killings, as a means of conveying a sinister message, has been effectively demonstrated by incorporating poison into drink (Thompson *et al*., 1987). With chemicals it is highly unlikely that effective intoxication would be possible by contamination of large-scale storage units, including reservoirs; the problems associated with marked dilution and nonhomogenous distribution would make this approach not feasible. It is more likely that bacterial or biotoxin contamination would be more effective in these circumstances. Other possible methods for peroral administration of potent toxins include the repacking of medicinal capsules for a specific target or, if done in pharmacies, for random 'hate' killings (see Section 3.4.2.1), although this activity has now been essentially stopped with the introduction of tamper-proof wrappings.

3. **Percutaneous absorption**: Highly potent chemicals or drugs, which are absorbed percutaneously, have been noted to be potentially a means of lethal intoxication of selected or random individuals.

3.3 Diagnosis

Preparedness for chemical incidents is described below in Section 4 and diagnostic measures for specific chemicals is discussed in Section 3.4, but it must be emphasized that determinative diagnosis should not take precedence over immediate aid to victims. Diagnosis will depend on characteristic symptomatology, possibly aided by field-deployable tests and chemical agent monitors (CAMs) (see Section 4), may be useful. There may be other clues that something untoward has happened, for example the characteristic smell or colour of a gas in the vicinity or even a labelled cylinder. Biochemical tests on blood will almost always take too long to influence management. The index of suspicion that a chemical terrorist incident has occurred will be higher with incidents where the chemical used has immediate effects and many people are involved.

3.4 Specific Chemicals

3.4.1 Organophosphate Anticholinesterases

3.4.1.1 Basis for Selection

The OP anticholinesterase (antiChE) chemical-warfare agents are known to be of high acute toxicity from studies in animals, and, to a limited extent, their use in chemical warfare and terrorism; these compounds are divided into the volatile G agents and the nonvolatile V agents (see Marrs, 2007; **Toxicology of Chemical Warfare Agents**). The related OP ester insecticides are of lower acute toxicity and in some cases of very low acute toxicity. Thus malathion has an oral rodent LD_{50} (median lethal dose) in the range of $1-5\,g\,kg^{-1}$, depending on the purity of the preparation (FAO/WHO, 1998); nevertheless some OP insecticides are of sufficiently high acute toxicity to merit consideration as possible compounds of interest to terrorists, for example mevinphos (FAO/WHO, 1997) and phorate (FAO/WHO, 1995); however these would be difficult to obtain in many countries. Details of chemistry, nomenclature and toxicology of OP pesticides are available in Ballantyne and Marrs (1992), Gupta (2006) and Marrs (2001) (see also **Toxicology of Chemical Warfare Agents**; **Toxicology of Pesticides**). OPs may be available commercially, notably as pesticides, but in developed countries, OPs of high acute toxicity are not much used. With appropriate facilities, OPs can be synthesized, although the handling of fluorine, needed to synthesize G agents other than tabun, would present challenges.

3.4.1.2 Routes of Exposure

Of the classical nerve agents, the G agents are generally considered as inhalation and skin hazards, whereas the nonvolatile V agents, for example VX, would be skin hazards, unless aerosolized (Marrs, 2007). As with V agents, OP insecticides are generally not very volatile and would not generally present an inhalation hazard unless aerosolized. OPs are generally of high vapour density and thus do not readily diffuse. In view of this and coupled, in the case of the G agents, with their volatility and the rapid onset of clinical signs and symptoms, the OPs are capable of causing large-scale mass casualties that would have significant impacts on emergency medical services (Okumura *et al*., 1998a; 1998b; Tokuda *et al*., 2006). It is generally considered that the volatile OPs would be more effective in a confined space; however, using a programme designed to model releases of environmental pollutants, Salzman *et al*. (2005) determined that the release of sarin in an open-air environment has the potential to affect more people than a similar release

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat132
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in a relatively closed space. However, it is important not to neglect routes of exposure other than inhalation and the percutaneous route. Depending on the specific OP and its physicochemical properties, OPs could be incorporated into food, drink or medicinal products for exposure by the peroral route. The toxic effectiveness with respect to contamination of foodstuffs and drink has been demonstrated by two large outbreaks of delayed-onset peripheral neuropathy from tri-*ortho*-cresyl phosphate (TOCP), namely ginger-jake paralysis in the US during 1930–1931 and in Morocco in 1959, both of which produced delayed polyneuropathy (see below).

Were a toxic OP ester to be deployed in a public space, for example a railway station, it is important to consider contamination of food and drink outlets, and, of course, a terrorist might deliberately and specifically adulterate food and water supplies with OPs.

3.4.1.3 Clinical Effects

The acute manifestations of OP intoxication are usually rapid in onset. The most widely published accounts of terrorism with OPs have been the use of sarin (*O*-isopropyl methylphosphonofluoridate; GB) in Japan by a religious cult against randomly selected human targets (Aum Shinrykio, Supreme Truth). The first incident occurred in 1994 at Matsumoto City (Nagano Prefecture, Honshu) when impure sarin was released from a truck for about 10 minutes using a heater and a fan (Morita *et al*., 1995; Okudera *et al*., 1997). About 600 people were exposed, of whom seven died and 50 were hospitalized. Secondary contamination occurred in about a third of rescuers who started relief activities within five hours of sarin release (Nakajima *et al*., 1997). A two-year follow-up revealed that of the patients who has been severely ill, some still had symptoms and clinical signs, including palpitations, dyspnoea, low-grade fever and even seizures; one victim developed sensory neuropathy seven months postexposure (Nakajima *et al*., 1999; Sekijima *et al*., 1997). The second incident involved the release of the vapour into commuter trains in the Tokyo subway (underground railway) during a Monday morning rush hour in March 1995 (Okumura *et al*., 1996; Ohbu *et al*., 1997; Okudera *et al*., 1997; Simon, 1999; Tokuda *et al*., 2006; Woodall, 1997). Five cult members released sarin vapour from plastic bags containing about 600 ml 35% diluted sarin by puncturing with the tips of umbrellas; 10 bags were distributed among five different commuter trains (Tokuda *et al*., 2006). Twelve individuals were killed, and over 5000 became symptomatic; had the sarin used been of greater purity and the delivery system more effective, casualties could have been in the thousands. Secondary contamination occurred in some physicians and nurses. See also Section 3.4.1.5 below.

3.4.1.4 Mechanisms of Toxicity

Most of the early signs and symptoms of OP antiChE intoxication are the result of inhibition of acetylcholinesterase (AChE; acetylcholine acetylhydrolase; EC 3.1.1.7) at cholinergic synapses and cholinergic effector organs, and the neuromuscular junction, as well as in the central nervous system (CNS), resulting in an accumulation of the neurotransmitter acetylcholine (ACh) and a cholinergic crisis. Cholinergic neurones release ACh which stimulates ACh receptors on the cell surface mediating the response. Cholinergic nerve fibres include preganglionic sympathetic and parasympathetic fibres, postganglionic parasympathetic fibres, somatic motor fibres and CNS ones. ACh (cholinergic) receptors are classified as nicotinic (N-cholinoceptors) and muscarinic (M-cholinoceptors) based on their response to the corresponding alkaloids. N-cholinoceptors mediate effects of ACh at the cholinergic skeletal muscle neuromuscular junction, autonomic ganglia and within the CNS. M-cholinoceptors are found at smooth muscle myoneural junctions and in the exocrine and endocrine systems. Typical acute cholinoceptor effects are as follows:

- **Muscarinic effects**: Predominant features are hyperhydrosis, hypersalivation, excess lacrimation, miosis, intestinal cramps, vomiting, diarrhoea, urinary and faecal incontinence, bronchorrhoea and bronchoconstriction
- **Nicotinic effects**: These include muscle cramps, fasciculation, weakness, paralysis and pallor.

Under normal physiological conditions, ACh at the postjunctional cholinoceptor is rapidly hydrolysed by AChE, which terminates its activity at the postjunctional membrane. The ACh molecule binds to an anionic site on the AChE molecule, and then combines with an esteratic site of the enzyme; this is followed by hydrolysis and rapid reactivation of AChE. AChE has the capacity to hydrolyse 3×10^5 ACh molecules per molecule of AChE, equivalent to a turnover of 150 µs. Inhibition of ChEs by OPs is a multistage process, with formation of a Michaelis enzyme–substrate complex and phosphorylation of a serine hydroxyl group at the esteratic site of the enzyme (see reviews by Marrs, 2001; Thompson and Richardson, 2004; Sultatos, 2006). Spontaneous reactivation of the inhibited ChE may occur, whose rate depends on factors such as species, tissue, groups (most often alkoxy ones), other than the leaving group attached to the phosphorus atom and the presence of nucleophiles that catalyse the reactivation process (see WHO, 1986; Wilson *et al*., 1992; Mason *et al*., 1993). The rate of reactivation is a major determinant of the rate of recovery from the intoxication. In some cases, a process of 'ageing' occurs, in which there is cleavage of an alkoxy–phosphorus bond with the loss

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat132
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of the alkyl group and formation of a charged monosubstituted phosphoric acid residue still attached to the enzyme protein; this structure is very stable and the aged enzyme is no longer responsive to nucleophilic reactivating agents (Wilson *et al*., 1992). Ageing is time dependant and most notably a problem with soman-inhibited AChE, where the aging $t_{1/2}$ in human erythrocytes is known to be rapid (1.3 minutes) (Harris *et al*., 1978). If the alkyl groups in the phosphorylated enzyme are methyl groups, spontaneous reactivation takes hours, if they are ethyl groups somewhat longer. Secondary or tertiary alkyl groups further enhance the stability of the phosphorylated enzyme, and the return of ChE activity may depend on new enzyme synthesis (Taylor, 1985). Tabun, an *O*-ethyl-*N*,*N*-dimethylamidophosphoro derivative, produces an inhibited enzyme that is slow to reactivate (Heilbronn, 1963), but this is not due to ageing: tabun binding of mouse AChE causes conformational changes in the enzyme that appears to stabilize the enzyme inhibitor complex (Ekstrom *et al*., 2006).

Many OP insecticides require metabolic activation mainly by mixed-function oxidases, hydrolases and transferases, For example, phosphorothioates are generally toxicologically inert until activated by conversion of the P=S to an oxon (P=O), resulting in a latent period between exposure and the appearance of cholinergic effects (see **Biotransformation of Xenobiotics**). Some lipophilic OPs are not rapidly excreted, resulting in prolonged activity or the recurrence of clinical features after treatment and apparent initial recovery.

3.4.1.5 Clinical Manifestations

3.4.1.5.1 Acute Effects

The acute central and peripheral clinical manifestations of OP antiChE intoxication are listed in **Table 1**; individual signs and symptoms appear within a few minutes to a few hours. The time to onset of symptoms and signs, and the order of their appearance varies between different OPs. Patients with severe OP poisoning typically present with pinpoint pupils, excessive sweating, reduced consciousness and difficulty with respiration. Effects on the cardiovascular (CV) system are determined by the relative predominance of M-cholinoceptor effects (bradycardia, hypotension) vs. N-cholinoceptor effects (tachycardia, hypertension). Typically there is transient sinus tachycardia followed by sinus bradycardia, A-V block, S-T and T-wave abnormalities and ventricular arrhythmias (Jorens *et al*., 2008; Karki *et al*., 2004; Kumar and Lloyd-Jones, 2007; Ludomirsky *et al*., 1982). Respiratory failure, hypoxaemia and cyanosis result from bronchospasm, bronchorrhoea, respiratory muscle paralysis and central depression of breathing; paralysis of the diaphragm has been described (Rivett and Potgieter, 1987). Respiratory effects, together with ventricular arrhythmias are the major cause of death.

In theory, the acute effects of cholinesterase inhibition are reversible, but long-term and/or irreversible neurological effects from OP antiChEs can occur. Such effects include the intermediate syndrome, delayed polyneuropathy and, probably, long-lasting central nervous system effects.

Table 1 Acute central and peripheral symptoms and signs of organophosphate anticholinesterase intoxication

Muscarinic effects[a]	
Ocular	Miosis Blurred/dim vision/ decreased visual acuity Lacrimation
Respiratory tract	Rhinorrhoea Bronchial hypersecretion Bronchoconstriction Dyspnoea
Gastrointestinal tract	Sialorrhoea Nausea Vomiting Diarrhoea and bowel incontinence Abdominal cramps
Urinary	Urinary incontinence
Cutaneous	Hyperhydrosis
Nicotinic effects[b]	
Skeletal	Twitching, fasiculations and cramping Skeletal muscle weakness and flaccid paralysis
Cardiovascular	Tachycardia Hypertension Pallor
Central nervous system effects	
Headache Irritability Ataxia Convulsions Coma Respiratory failure	

[a]Effects due to ACh accumulation at peripheral neuroeffector junctions.
[b]Effects due to ACh accumulation at skeletal myoneural junctions and autonomic ganglia.

3.4.1.5.2 Intermediate Syndrome

The intermediate syndrome which is seen after OP poisoning gains its name from the fact that signs and symptoms appear after the acute cholinergic phase, but before the anticipated time for appearance of delayed onset peripheral neuropathy. Onset is usually 24–96 hours postexposure. Clinically, the intermediate syndrome consists principally of weakness or paralysis of proximal limb muscles, neck flexors, respiratory muscles and motor cranial nerve involvement, particularly those

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat132
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

innervating the extraocular muscles (Senanayake and Karalliedde, 1992). Unlike delayed polyneuropathy the intermediate syndrome is potentially lethal because of respiratory depression. If respiratory insufficiency is correctly managed, recovery occurs within 4–18 days. Using repetitive nerve stimulation techniques it was demonstrated that there was an apparent correlation between the decrement–increment pattern and the development of intermediate syndrome, and that such neurophysiological approaches may be of value in predicting the development of intermediate syndrome (Jayawardane *et al*., 2006). Karalliedde *et al*. (2006) concluded that the cause of intermediate syndrome was down-regulation of nicotinic receptors. Although intermediate syndrome has not been described with nerve agents, it has been reported with many OP insecticides, and it would be as well to be prepared for its occurrence with OP chemical-warfare agents.

3.4.1.5.3 Organophosphate-Induced Delayed Polyneuropathy

Organophosphate-induced delayed polyneuropathy (OPIDP) appears to result from covalent binding to and inhibition of a membrane-bound esterase (neuropathy target esterase (NTE)). From studies with NTE-null mice and *Drosophila*, Glynn (2006) concluded that OPs producing OPIDP caused a transient loss of NTE activity, possibly disrupting membrane phospholipid homeostasis and endoplasmic reticulum functions, such as glial–axonal interaction and axonal transport. Histopathologically, the lesion consists of axonal degeneration and demyelination of the larger diameter and longer fibres. Delay to onset of clinical signs ranges from one to several weeks. It is characterized by a distal symmetrical and sensorimotor polyneuropathy, with tingling and burning sensations, progressing to atrophy and flaccid paralysis of the lower limbs (DeJager *et al*., 1981; Lotti *et al*., 1984). The upper limbs may be affected subsequently (Cherniack, 1986). Measurement of lymphocyte NTE may predict the development of OP-induced polyneuropathy (Lotti *et al*., 1986). Most OP pesticides on the market do not give rise to OPIDP, nor is it likely to occur with chemical warfare OPs (see Marrs, 2007).

3.4.1.5.4 Long-Term Central Effects

There is evidence from laboratory studies that exposure to OP antiChEs may result in altered patterns of neurobehaviour (Chambers and Chambers, 1989; Gardner *et al*., 1984; Geller *et al*., 1987; Haggerty *et al*., 1986; Russell *et al*., 1986; Scott, 2007a; Joosen *et al*., 2009). Longer-term psychological problems that have been described following acute and chronic OP poisoning in humans include depression, schizoid reactions, impaired vigilance, memory deficit and exacerbation of pre-existing psychiatric problems (Dassanayake *et al*., 2008; Lotti, 1992; Namba *et al*., 1971; Savage *et al*., 1988). There is some evidence for sequelae, including neuropsychiatric effects, in survivors of the Japanese terrorist incidents using sarin (Yanagisawa *et al*., 2006; Okumura *et al*., 2007). The long-term and delayed effects of acute OP exposure and the effects of low-dose OP exposure have been reviewed (Institute of Environment and Health (IEH), 1998; Committee on Toxicity of Products in Food, Consumer Products and the Environment, 1999; Lader, 2001; Romano *et al*., 2001). In relation to pesticides, attention has been paid to the fact that the foetus and young children may be more sensitive to OPs than adults (Slotkin, 2005). Four pregnant women were exposed to sarin in the Tokyo exposure at 9–36 weeks' gestation (Ohbu *et al*., 1997) and all had normal offspring. Nevertheless, because of the profound effects of OPs, including chemical-warfare nerve agents, on neurotransmission, there is a strong theoretical basis for concern that effects which in adults would be reversible, would in the embryo, foetus and neonate be irreversible.

3.4.1.6 Essentials of the Management of Acute Poisoning

Detailed reviews of the management of OP antiChE intoxication are available in Marrs and Vale (2006) and Vale *et al*. (2007). The following account gives an overview of essentials, which include decontamination and protection, respiratory support and antidotes. Although severity scoring systems are described for acute OP antiChE poisoning (Johnson and Vale, 1992), in the context of chemical-terrorism incidents, because of the complexity of the situation with possible physical injuries, it is probably most appropriate to apply a general triage system.

3.4.1.6.1 Decontamination

Those responsible for management should wear appropriate protective clothing and equipment to prevent secondary contamination. If there is sufficient warning, then it may be appropriate for first responders and healthcare staff to have intramuscular prophylactic oxime (see Section 3.4.1.6.4). Decontamination of the patient should occur at the earliest stage possible and include removal of clothing and showering (Roberts and Maynard, 2007).

3.4.1.6.2 Monitoring

Activity of two enzymes are commonly measured for the diagnosis and monitoring of OP poisoning, erythrocytic AChE and butyrylcholinesterase (BChE), an enzyme that is present in the plasma and, in humans, not in the red blood cell. Erythrocyte AChE activity measurement provides a better functional index of toxicity from OPs then BChE, because of the former's identity with the enzyme at cholinergic structures, where enzyme inhibition forms the mechanistic basis for antiChE poisoning. Many OPs are more potent inhibitors of plasma BChE activity than they are of AChE activity, and thus BChE may be a sensitive index of recent exposure (Eddleston

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat132
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

et al., 2005). However, BChE inhibition is not related to the clinical severity of exposure. Alkyl phosphates may be useful as markers of OP exposure, but are of little use in monitoring clinical status (Black and Noort, 2007). In addition to routine periodic clinical examination, there should be continual monitoring of heart rate, blood pressure, ECG (electrocardiography) and periodic measurement of arterial blood gases, and acid-base status.

3.4.1.6.3 Respiratory Support

Because of the potential for respiratory failure, bronchospasm and hypoxaemia, there should be provision for maintenance of the airway and the use of oxygen to combat tissue hypoxia. With severe and progressive cases of respiratory failure, intubation and mechanical ventilation may be needed, using positive end-expiratory pressure (PEEP).

3.4.1.6.4 Antidotes

Descriptions of the antidotal treatment of antiChE OP poisoning have been presented in detail elsewhere (Eddleston *et al*., 2008), and only the essentials are discussed below, with particular reference to the use of atropine, oximes and anticonvulsants.

Atropine is the mainstay of treatment as a nondepolarizing competitive blocker of the action of ACh at peripheral M-cholinoceptors (Heath and Meredith, 1992). Rapid full atropinization is required, as indicated by mydriasis, tachycardia, flushing and dry mouth. Atropine is beneficial in reducing bronchorrhoea and reversing changes in ventilation-perfusion resulting from the uneven distribution of ventilation caused by airway constriction, and atropine counteracts the convulsive effects of OPs (see McDonough and Shih, 2007).

Oximes are useful for the reactivation of inhibited AChE. The salts of pralidoxime (chloride, mesilate or methylsulfate) or obidoxime are the most commonly used. A limitation with oximes is ageing of the enzyme (see Section 3.4.1.4), and they generally become less effective with increasing time after exposure. The role of oximes is not completely clear and there are disputes about oximes in OP poisoning; for example, although oximes show value in the treatment of OP antiChE intoxication, some physicians have suggested that they are of little value in treating human OP poisoning cases. Also, there are disagreements concerning the dose and frequency of oxime administration. Oximes have been investigated extensively as agents for prophylaxis in CW situations or occupations where there is a high risk of occupational exposure to OP antiChEs, which can now include responders to antiterrorist threats where OP use is a high possibility. Clearly drugs used in prophylaxis must have a high safety ratio, and be devoid of complications that may be acceptable in antidotal usage (see reviews by Szinicz *et al*., 1996; Marrs *et al*., 2006; Eyer and Worek, 2007).

Combining atropine and oxime seems to produce antidotal synergy, and in most cases of OP antiChE intoxication, the combination is more effective than either alone. This is, in part, because separate components of the cholinergic intoxication are treated; atropine antagonizing the peripheral M-cholinoceptor effects and some central effects, and oximes producing reactivation of N-cholinoceptor AChE. Combined atropine–oxime formulations are available commercially in autoinjectors for intramuscular use.

Anticonvulsants, such as benzodiazepines, both relieve anxiety and counteract some CNS effects not alleviated by atropine (Vale and Scott, 1974). Diazepam may be of value in antiChE poisoning by reducing anxiety, reducing muscle fasciculations, arresting seizures and reducing morbidity and mortality when use in conjunction with atropine and 2-PAM (pralidoxime chloride) or P2S (pralidoxime mesilate) (Johnson and Vale, 1992 see reviews by Marrs, 2003; 2004a; Marrs and Sellström, 2007).

Pyridostigmine bromide has for many years been available to the armed forces as a pretreatment primarily to prevent soman-inhibited AChE from ageing (see reviews by Inns and Marrs, 1992; Scott, 2007b). Pyridostigmine bromide could considerably be used for high-risk civilians, for example first responders.

3.4.1.6.5 Follow-Up Care

It was the experience of the Japanese terrorist that drew attention to the high incidence of late or sustained complications that may occur with OP antiChE intoxication. For example, with the Tokyo subway incident a one year follow-up revealed that of 303 surveyed respondents, 46% still experienced physical or psychological symptoms, which included ocular effects, fatigue, headache, depression, lack of concentration, flashbacks and phobias of subways (Ohyoku *et al*., 2003; Yokoyama *et al*., 1998). There is therefore a need for provision of physical and psychological follow-up facilities for those involved in such terror incidents.

3.4.2 Cyanides

3.4.2.1 Basis for Selection and Generation

Cyanides are well known for their acute lethality, and as such make an obvious universal choice as an agent for a terrorist action intended to have acute lethal effects. The following is a brief consideration of the properties of cyanides relevant to potential use in terrorist activities. Details of the general and clinical toxicology of cyanides have been presented elsewhere (Ballantyne, 1987; Ballantyne and Salem, 2006; 2007a; Ballantyne *et al*., 2007).

Cyanides are readily available as the low boiling point and volatile hydrogen cyanide (HCN) and as soluble solid salts, generally of sodium and potassium (NaCN and KCN). They are readily available from laboratories, fumigation services and industrial organizations. Also, cyanides and cyanogens can be extracted from pips

Table 2 Examples of information obtained about the use or potential use of cyanides (CN) in major and small group terrorist actions

Date: location: information	Reference
Major terrorist situations	
1995: Tokyo subway attack: precursors of CN found in subway bathrooms	Sauter and Kein (2001)
2002: Arrests of four Moroccans, with ties to Al Qaeda, who were plotting the use of CN to poison water supplies in areas around the American Embassy in Rome	BBC (2002b)
2002: September 18: Police raid on North London (UK) apartment: discovery of instructions for manufacturing various poisons, including cyanide from fruit pips	O'Neill (2005)
2002: December: Recovery of a store of CN in Paris: linked to three Al Qaeda operatives	Cloud (2004)
2003: Police raid on a North London (UK) apartment: crude laboratory discovered for producing CN	O'Neill (2005)
2003, May: CN 'bomb' found in the possession of white supremacists in Texas	CNN (2004)
2003: The US Central Intelligence Agency (CIA) uncovered a plot, apparently by an Al Qaeda cell, in which HCN vapour would be released into the New York Subway system, using a small device which would generate HCN vapour from NaCN and hydrochloric acid	Suskind (2006)
Small group situations	
Early 1990s and mid 1980s: Repacking of medical capsules with CN salt, either for personal individual target or for random killings by leaving bottle on pharmacy shelves	Brahams (1991) CDC (1991) Dunea (1983)

and cherry stones. Cyanides have the advantage, for the aspiring terrorist, that their toxic effects are rapid in onset. This is because the cyanides are rapidly distributed in the body and because their toxic action on cytochrome oxidase activity swiftly interrupts intracellular respiration. HCN has the advantage of having a low boiling point (26.5°C) and high volatility (vapour pressure of 600 Torr at 20°C) and thus rapidly generates a colourless vapour of high concentration (saturated vapour concentration 884 211 mg m^{-3} at 20°C). However, because of the low vapour density (0.947 at 31°5) and molecular weight of HCN (27.04), the vapour is readily diffusible, and thus its use by a terrorist would be limited to enclosed spaces, such as buildings, in-door entertainment centres, subways and small shopping centres, to be effective.

In many counties cyanides are chemicals listed as among the more likely agents to be used for chemical terror in national and international situations (Khan *et al*., 2000; NTARC, 2004; 2009). Some reported uses or potential uses of cyanides for small-scale and major terrorist uses are listed in **Table 2**. The methods used by terrorist groups and organizations for the delivery of cyanides to intended targets are likely to be variable, depending on resources available, knowledge and scientific/technical sophistication, proposed location and intent for the incident. Vapour generation could be from cylinders, or crude devices for the mixing of cyanide salts with acidic fluids. Larger-scale use could be by the adulteration of food and/or drink, as was effectively done in the Jonestown religious cult killings (Thompson *et al*., 1987). Cyanide salts could be used to contaminate food or drink. For smaller-scale incidents this could be done by incorporating cyanide into food and drinks in shops or restaurants, or into drinking-water supplies close to their entry into buildings. Larger-scale operation would involve contamination of major food and drink production, storage and transportation sites (Ballantyne *et al*., 2007). Attempted distribution by contamination of public reservoirs would not be feasible because of the massive amounts of solid cyanides that would be required to be dumped to achieve toxic concentrations in the effluent water. For use against smaller-scale or targeted groups, or against individuals, the following have been suggested/encountered; repacking of medicinal capsules (see **Table 2**), intramuscular injection from concealed syringes (Ballantyne *et al*., 1972); incorporation into cigarettes; spraying HCN in the face from a pressurized canister (Gee, 1987; Harris and Paxman, 1982; Seagrave,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat132
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1982). Some of these incidents were really political assassinations or murder rather than terrorist incidents as previously defined.

3.4.2.2 Clinical Manifestations

Cyanides cause mental and physical incapacitation and lethality. Notable symptoms and clinical signs include dyspnoea, hyperpnoea, a cherry-red appearance (not cyanosis), anxiety, apprehension, agitation, convulsions, cardiac arrhythmias and eventually coma. A smell of bitter almonds may be detected (Hall *et al*., 1987). The occurrence of disturbances of consciousness and perception, together with muscle weakness and ataxia, will markedly impair the ability of victims to escape from an area and to undertake coordinated tasks. For humans, the concentration range required to cause lethality within 1–5 minutes is of the order of 500–4000 mg m^{-3}, and concentrations of the order of 112–224 mg m^{-3} are necessary to induce incapacitating effects (Ballantyne *et al*., 2007). A test paper (Cyantesmo®) is available for the detection of cyanide in aqueous solutions and extracts (Macherey-Nagel, 2008).

3.4.2.3 Essentials of Management

Detailed reviews of the management of cyanide poisoning are available (see Meredith *et al*., 1993; Marrs, 1998; Ballantyne *et al*., 2007). There are a number of antidotes available, including dicobalt edetate, hydroxocobalamin and the classical treatment of sodium nitrite and thiosulfate.

3.4.3 Irritant Chemicals

3.4.3.1 Basis for Selection

Under this heading fall numerous chemicals, many industrial, that can cause peripheral chemosensory irritant (PCSI) effects (Ballantyne, 2006a; see **Peripheral Chemosensory Irritation: Fundamentals, Investigation and Applied Considerations**) and, at higher concentrations, inflammatory lesions and possibly lethal respiratory tract damage or lethal systemic toxicity; some of these compounds are potentially very dangerous, for example phosgene. The PCSI effects will cause harassment and distress and could be used as warning of displeasure, or as a distraction to permit other activities. Examples of irritant chemicals include phosphine, chlorine, chloropicrin, acrolein and phosgene, which can be obtained or stolen from industrial sources. Also, terrorists may be able to obtain grenade-generated screening smokes for purposes of distraction or harassment; these include the irritant and potentially ocular- and pulmonary-injuring white and red phosphorus, titanium tetrachloride and zinc-hexachloroethane smoke compositions. Details of the toxicology, clinical effects and medical management of overexposure to such smokes have been discussed by Ballantyne and Salem (2007b). If the intent is mainly to harass without injury, then riot-control agents might be chosen for use; devices containing these agents can be purchased commercially and openly in many countries, such as the USA and Germany, their ready availability being indicated by the fact that such devices have been in the possession of some schoolchildren (Wattigney *et al*., 2008). Details of the nature, effects, toxicology and medical management of exposure to chemicals used as riot-control agents have been published by Ballantyne (2006a; 2007) and Ballantyne and Salem (2004). For maximum effects, irritant chemicals will be used by atmospheric dispersion, either as vapour or aerosol. As noted in Section 3.2.2 above, release of irritant materials into the atmospheres of enclosed spaces can result in panic, with secondary physical injuries. In addition to causing PCSI and inflammatory effects, some irritants may be absorbed and cause systemic toxicity; for example chloropicrin and phosphine may produce CV and hepatorenal effects.

3.4.3.2 Clinical Manifestations

The PCSIs effects can cause distress and distraction because of the local discomfort and associated reflexes that develops from contact with skin and exposed mucosal surfaces (Ballantyne, 2006a). For example, in the eye they produce transient discomfort or pain, excess lacrimation and blepharospasm, the last two effects producing a temporary disturbance of vision; respiratory-tract PCSI effects include discomfort in the respiratory tract, chest tightness, rhinorrhoea, cough, increased tracheobronchial secretions, bronchospasm and changes in breathing rate (see Section 3.1). At higher atmospheric concentrations than those causing PCSI effects, there is often injury to the respiratory tract; for example, both acrolein and phosgene can produce inflammatory lesions in the nasal mucosa with bronchoconstriction, tracheobronchial epithelial desquamation and inflammation, pulmonary oedema and alveolar haemorrhages (Ballantyne *et al*., 1989; Steffens, 2003). Several irritants have been used for chemical-warfare purposes with horrific consequences; for example chlorine and phosgene. For example, phosgene (carbonyl chloride) was responsible for more than 1100 casualties when 88 tonnes of the gas was used against British troops at Bieltje, Belgium on 19 December 1915 (Spiers, 1986). The use of phosgene as a chemical-warfare agent continued during World War I, being dispersed in shells, mortar bombs and projector drums, and it has been estimated that phosgene was responsible for 85% of all respiratory-related deaths attributable to chemical weapons (Karalliedde *et al*., 2000).

The severity of pulmonary damage, such as bronchiolar obstruction and/or alveolar injury, may be of a magnitude that causes hypoxic hypoxia, with resultant tissue hypoxic injury, for example renal tubular necrosis (Ballantyne and Callaway, 1972). Also, as noted above, in addition to producing PCSI and local inflammatory

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat132
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

effects, some inhaled irritants may also cause systemic toxicity following absorption, and the treating physicians should be aware of this for both diagnostic and management considerations. For example, phosphine (hydrogen phosphide; PH_3), a colourless, heavier-than-air gas, is flammable and explosive, and may cause asphyxiation in enclosed, poorly ventilated spaces. It can be generated by adding water to aluminium phosphide, a rodenticide, insecticide and fumigant. NIOSH (1996) recommended that 50 ppm be considered immediately dangerous to life or health (IDLH) and the ACGIH recommendation is 0.3 ppm, as a threshold-limit-value–time-weighted average (ACGIH, 2008). It can be fatal after a 30 minute exposure to >300 ppm, and serious adverse health effects may develop after exposure to 7 ppm for several hours (Musshoff *et al*., 2008). It is a respiratory-tract irritant causing pulmonary congestion, oedema and alveolar thickening. Additionally it can cause CV, neurological and hepatorenal toxicity. CV effects include tachycardia, arrhythmia, reduced cardiac output and decreased systemic vascular resistance, with hypotension. CNS neurotoxic effects include headache, dizziness, disturbed gait, intention tremor and convulsions. Hepatotoxic effects generally develop within 48–72 hours, with the development of hepatomegaly, jaundice and elevated serum aminotransferases; additionally haematuria and proteinuria may appear. The toxicity of phosphine has been reviewed (Brautbar and Howard, 2002).

3.4.3.3 Management of Casualties

After any necessary decontamination, those having only PCSI effects usually recover following transfer to a clean-air environment and possibly flushing of the eyes with water. However, to avoid any later possible sequelae, they should be observed; those exposed to respiratory tract irritants should have an initial chest radiograph and, if considered necessary, arterial P_aO_2 testing. If inflammatory lesions have developed, they may require the use of antibiotics to prevent secondary infection and also corticosteroids, both systemic (intravenous; iv) and inhalation spray (Steffens, 2003). Symptomatic patients may require supplemental oxygen, and aerosolized bronchodilators may be considered if bronchospasm is present. Also, the development of metabolic acidosis may require the iv infusion of bicarbonate. For severe cases, mechanical ventilation may be necessary. The possibility for secondary tissue and organ injury from hypoxic hypoxia due to pulmonary damage or systemic toxicity from absorbed materials needs to be borne in mind.

3.4.4 Systemically Toxic Materials

A very large number of chemicals exist that can be absorbed into the systemic circulation, tissues and organs, and may, in sufficient dosages, be severely injurious or lethally toxic. Some of the chemicals noted above (Section 3.4.3) as having irritant properties may also exert systemic toxicity in addition to local irritation. Additionally there are a multiplicity of systemically toxic materials that can be absorbed by various routes, but causing no or little local irritant warning effects, many of which are readily obtainable through commercial or industrial sources. OP antiChEs and cyanides have been considered above, and a few additional illustrative examples are noted below that have toxicity, making them likely as candidate agents for use in urban terrorist incidents.

3.4.4.1 Arsine

Arsine is a gas of vapour density 2.7 which is readily absorbed by inhalation exposure, and causes malaise, fever, nausea, vomiting, paresthesia, haemolysis, haematuria, rhabdomyolysis, acute renal failure and anuria. Treatment of severe poisoning may require DMSA (dimercaptosuccinic acid) chelation, erythrocyte exchange, plasmapheresis and haemodialysis (O'Connor *et al*., 2005; see review by Pakulska and Czerczak, 2006).

3.4.4.2 Paraquat

Paraquat is a bipyridylium herbicide (1,1-dimethyl-4,4-bipyridinium), whose toxicology has been discussed in detail elsewhere (Bismuth and Hall, 1995; FAO/WHO, 2004; Marrs, 2004b, see also **Toxicology of Pesticides**).There have been deaths due to paraquat poisoning, some accidental and others in suicidal attempts, most cases having resulted from drinking agricultural concentrates, rather than home-garden preparations (Carson and Carson, 1976; Fletcher, 1974). Agricultural paraquat formulations are mostly sold as solutions, and because of its toxicity and low volatility it is likely that any attempt to use paraquat in terrorist situations would likely involve contamination of food or drink. The estimated human acute peroral LD_{50} for paraquat is of the order of 30 mg kg^{-1} (Fletcher, 1974), and it causes local and systemic toxicity, the former being concentration dependent and the latter dose dependant (Proudfoot, 1999). After swallowing paraquat, local effects occur (see below), but except with very large doses, there is commonly a latent period of many hours or days before the clinical symptoms and signs of systemic pulmonary toxicity occur; the effect on the lung is usually the most serious of the toxic injuries. This latency may present a diagnostic and medical management problem. Toxicity also affects the liver, kidneys and heart. Thus, swallowing paraquat causes widespread organ injury, but with the most severe and lethal action on the lung. Pulmonary toxicity is a consequence of the active uptake of the material by the lung by a saturable process in Type II alveolar cells (Chen *et al*., 1992; Smith, 1982; Smith *et al*., 1990). After swallowing paraquat, there is irritation of the mouth, throat, oesophagus and gastrointestinal tract, resulting in dysphagia, epigastric pain, nausea,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat132
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

vomiting and diarrhoea. The initial signs of systemic toxicity are usually of renal tubular injury starting at one to three days, with increased blood urea, reduced creatinine clearance and diminished urine output (Gardiner, 1972). Renal dysfunction may be a combined result of nephrotoxicity coupled with hypovolaemia. Hepatotoxicity is common, with centrilobular necrosis (Bullivant, 1966). Respiratory effects include pulmonary oedema and haemorrhage followed by marked fibrosis, leading to severe respiratory distress. Although it may not be clinically apparent until later, pulmonary injury may start early in paraquat poisoning, particularly if large amounts of paraquat are swallowed (>6 g). For example, Yoneyama *et al*. (1969) described death with pulmonary haemorrhage one day after swallowing a large dose of paraquat, and von der Hardt and Cardesa (1971) found pulmonary haemorrhage and loss of alveolar and bronchiolar epithelium two days after swallowing paraquat. Death from pulmonary injury secondary to swallowing of smaller doses (>5 g) is frequently delayed for several weeks (Fletcher, 1974). Autopsy findings in the lung following lethal paraquat poisoning include pleural effusion, pulmonary and subpleural haemorrhages and pulmonary oedema. Histopathologically there is a destructive alveolitis, with oedema and initial involvement of Type I cells and subsequently of Type II alveolar and Clara cells. This is followed by fibroplastic proliferation in the alveolar walls with infiltration by mononuclear cells, polymorphonuclear cells, macrophages and eosinophils (FAO/WHO, 2004; Marrs, 2004b; Marrs and Proudfoot, 2003). The longer the survival time, the greater is the degree of proliferation of alveolar epithelium and fibroblasts (Carson and Carson, 1976). Plasma paraquat concentrations measured within 24 hours of exposure are predictive of outcome in around 90% of cases (Proudfoot, 1995). In spite of the large number of substances that have been tried experimentally and clinically for the treatment of paraquat poisoning (Fletcher, 1974), currently there is no specific antidotes, and management is directed mainly at restriction of absorption and increased elimination, and symptomatic treatment (Bismuth and Hall, 1995; Marrs, 2004b). It has been noted that when pulmonary effects occur, the use of oxygen should be postponed for as long as possible, since it may exacerbate pulmonary fibrosis (Bismuth *et al*., 1982).

3.4.4.3 Thallium

Thallium is a soft, grey malleable metal, used and available industrially, which produces systemic multiple organ toxicity. Thallium has no smell, It has been used for intentional criminal poisonings (Rusyniak *et al*., 2002; Saddique and Peterson, 1983) and maliciously contaminating food (Meggs *et al*., 1994). There is a report of food being intentionally contaminated with thallium in Iraq and causing acute poisoning with delayed mortalities in two families in Baghdad during January 2008 (CDC, 2008a). By acute peroral poisoning, thallium causes abdominal pain, nausea and vomiting within a few hours of ingestion, that could be misdiagnosed as being due to other causes. However, within a few days, and even with acute poisoning, there is hair loss and a painful ascending peripheral neuropathy of the lower limbs, with paresthesia and muscle weakness. Hypertension and tachycardia may develop. Diagnosis can be confirmed by measurement of thallium in blood and urine. Treatment includes the use of ferric hexacyanoferrate (FHF: Prussian blue) as a sequestering agent (Rusyniak *et al*., 2003; Yang *et al*., 2008). The physical properties of the material and its acute and delayed onset effects make this a candidate agent for listing as a potential agent for incorporation in foods for a localized or generalized terrorist threat. In such circumstances, the sudden appearance of gastrointestinal symptoms followed in a few days by signs of alopecia and peripheral neuropathy should prompt clinical consideration of thallium poisoning. Thought should be given to stockpiling of FHF in a few selected centres for distribution when and where necessary.

3.4.4.4 Fentanyls

Fentanyls are synthetic opiates having short-acting and highly potent narcotic, analgesic, anaesthetic and immobilizing properties (Salem *et al*., 2005). Fentanyl (*N*-phenyl-*N*-[1-(2-phenylethyl)-4-piperidinyl]propanamide) is a potent narcotic analgesic also used for the induction and maintenance of general anaesthesia. Several analogues of fentanyl have been synthesized for use in anaesthesia. All are synthetic opiates that produce short-acting and potent analgesic, anaesthetic and immobilizing effects (Hess and Knakel, 1985; Janssen, 1984; Salem *et al*., 2006). Because of their high lipid solubility, the fentanyls penetrate the blood–brain barrier rapidly, which accounts for their quick onset of action. They all have the pharmacological characteristics of opium, including analgesia, euphoria, miosis and respiratory depression. The respiratory depression has been shown to be the result of direct rhythm-generating respiratory neurones in the pre-Boetzinger complex of the brain stem (Manzke *et al*., 2003). 5-Hydroxytryptamine (5-HT) 4(a) receptors are strongly expressed in these neurones, and their selective activation protects spontaneous respiratory activity. Rats dosed with a 5-HT 4 receptor-specific agonist overcame fentanyl-induced respiratory depression and re-established stable breathing rhythm without loss of analgesic activity. Several studies have been conducted on dissociating respiratory depressant effects from opiate-induced sedative activity of fentanyls (Brown and Pleuvry, 1992; Mioduszewski, 1994; Mioduszewski and Reutter, 1991). Adverse effects of opiates include bradypnoea, respiratory depression and hypoxic hypoxia. Narcotic antagonists are effective to various extents when given simultaneously with fentanyl/analogues (receptor

competitive exclusion) or when given postfentanyl for reversal of effects (receptor displacement) (Langguth *et al*., 1990). Some of these investigations were carried out to improve safety in patients receiving fentanyl, and other studies were probably conducted in government laboratories to produce a formulation that could be used in antiriot/antihostage situations.

One incident where fentanyl/fentanyl analogues were used on a large scale, producing mortalities was by Russian authorities in 2002. Many innocent citizens were killed in an antihostage situation in Moscow on 23 October, the incident involving a Chechnian terrorist group holding about 800 hostages in the Moscow Dubrovka Theatre Centre. Government authorities incapacitated the hostage-takers possibly by pumping fentanyl into the building (Couzin, 2003), although some believe that a mixture of fentanyl and halothane was used (Salem *et al*., 2006; Zilker *et al*., 2003). The result was at least 129 of the hostages died. It is possible that remifentanil might have been used because of its extreme potency coupled with relatively fast onset of action, short duration of action and its rapid metabolism (Salem *et al*., 2006). It has further been suggested that massive doses of the potent opiate carfentanil were used to saturate the theatre and obtain a maximum effect by inhalation (Salem *et al*., 2006), or a mixture of carfentanil and halothane (Wax *et al*., 2003) There is reason to believe that the authorities did not inform local hospitals and physicians of the agent used (Glasser and Baker, 2002). It has been argued that since fentanyl is not listed in any of the Schedules of the Chemical Warfare Convention and because of its rapid-onset–short-duration analgesic effects, it can be legally considered a riot-control agent and not covered by international conventions banning chemical-warfare agents (see Pearson, 2007). It is to be hoped that the tragic consequences of the Russian incident will be used as a lesson against such a conclusion or perhaps that the conventions need to be modified.

Several fentanyl analogues have been illegally synthesized for sale on the illicit drug market as Persian white, China white, Mexican brown and synthetic heroin (CDC, 2008b; Kram *et al*., 1981; Poklis, 1995; Salem *et al*., 2006). Nonpharmaceutical fentanyl is apparently easy to synthesize, recipes being available on the Internet (CDC, 2008b). The Drug Enforcement Agency (DEA) on 23 April 2007 began regulating access to *N*-phenylethyl-4-piperidone, a chemical used in the manufacture of illicit fentanyl. Abusers use these substances by iv injection, snorting or smoking, and these practices can lead to addiction or habituation. Additionally, fentanyl is available in transdermal patches, which have been increasingly abused by extracting fentanyl gel from them with a syringe (Arvanitis and Satonik, 2002; Reeves and Ginifer, 2002; Shoemaker *et al*., 2006). Many epidemics related to the illicit abuse of fentanyl have been reported, particularly in the USA (Hibbs *et al*., 1991; Martin *et al*., 1991; Schumann *et al*., 2008; Smialek *et al*., 1994). Fentanyl abuse has been common amongst healthcare workers (Silsby *et al*., 1984). The serious health consequences in outbreaks of fentanyl or analogue distribution by drug dealers is demonstrated by mortality statistics; for example, in a Chicago April 2005 to December 2006 epidemic, there were 342 fentanyl-related deaths (Schumann *et al*., 2008); in Detroit during 2006 illicit fentanyl was the cause of death in 178 cases (Boddiger, 2006; Goodman, 2007); terrorists could obtain fentanyls from illicit drug producers or by stealing from healthcare institutions, for use in operations where it is desired to induce a narcotic and immobilizing state. Because of the lack of a morphine-derivative metabolite, most conventional urine drug screens cannot detect fentanyl, and there is thus a need in such circumstances for a sensitive and specific method to be developed for diagnosis.

The management of opioid intoxication includes airway support and the use of narcotic antagonists such as naloxone; large doses of naloxone may be required for reversal (Marquardt and Tharratt, 1994; Poklis, 1995; Schumann *et al*., 2008).

3.4.4.5 *Osmium Tetroxide*

This is included to demonstrate that some chemicals selected as being potentially toxic by terrorists, may not be suitable because of technical problems with generation and dispersion. British antiterrorist police conducted raids at 24 locations throughout London on 30 March 2004 following the tracking of groups of terrorist suspects and after the British electronic eavesdropping agency, the Government Communications Headquarters, Cheltenham (usually known as GCHQ), intercepted some interesting telephone calls. Suspected British terrorists of Pakistani origin were arrested for allegedly discussing the use of osmium tetroxide in a chemical bomb in crowded civilian locations in London (Norton-Taylor and Cowan, 2004). Exposure to the vapour causes severe irritant effects on the eye, skin and respiratory tract, with delayed onset pulmonary oedema. Another latent effect from vapour is 'blacking' of the cornea. Although the plot did not go beyond the planning stage it is highly unlikely that the use of osmium tetroxide by dispersal from an explosive device would be successful because of its ready thermal decomposition (Baker and Kosai, 2004), although the possibility for dispersion as a vapour by other means requires that this material should be kept on the list of suspect potential terrorist threat chemicals that could be used in small-scale attacks (Makarovsky *et al*., 2007).

3.4.4.6 *Miscellaneous*

The above examples of systemically active chemicals indicate the wide range of chemical classes that are likely to be encountered in chemical terror incidents, the choice of which depends on a multiplicity of factors. The list could be extended significantly, depending on whether

the intention of the terrorist/organization is to be deliberately focal or randomly to kill or to engender fear and in this way influence society. The antiterrorist authorities, who presumably are maintaining preparedness by keeping records of chemicals and drugs likely to be used by terrorists, need to consider the wide choice of alternatives available and how these can be obtained. Additional substances likely to be employed include hallucinogenic drugs (e.g. indoleamines, phenylalkylamines, anticholinergics and cannabis).

3.4.5 Biotoxins

The bacterial toxin *Clostridium botulinum* neurotoxin (Tendler and O'Neill, 2005; **Toxicology of Chemical Warfare Agents**) and the plant toxin, ricin (see **Ricin: Chemistry, Sources, Exposures, Toxicology and Medical Aspects**) are of extreme toxicity and have been acknowledged as possible agents for use in terrorist operations.

3.4.5.1 Ricin

Ricin, a highly potent glycoprotein toxin derived from the castor bean plant, *Ricinus communis (Euphorbiaceae)*, and is proscribed in the Biological and Toxin Weapons Convention and listed in Schedule 1 of the Chemical Weapons Convention (Pearson, 2007). Ricin has been used for political assassination purposes in public places (Simon, 1999), including assassination on Waterloo Bridge, in London, by agents of the Bulgarian secret police assisted by the Komitjet Gosudarstvjennoj Bjezopasnosti (KGB) (the secret service of the Union of Soviet Socialist Republics), in 1978 of the Bulgarian defector Georgi Markov. Mr Markov, who had sought refuge in the United Kingdom, was injected in the thigh with a small ricin-containing metal pellet using a specially devised umbrella (Crompton and Gall, 1980; Knight, 1979).

Ricin has been discovered with production instructions during security force raids on apartments housing terrorists in London (Craven, 2005; O'Neill, 2005). It had, apparently, been planned to smear ricin on door handles in London, and to contaminate toiletries, including face creams, mouthwashes and toothbrushes. Other apparently unconnected discoveries have been made suggesting terrorist intent in various countries (Mirarchi and Allswede, 2008). Ricin has been considered by terrorists because it is highly toxic, noninfective, easy to extract, relatively stable and a solid. It is likely that the major threat from ricin is powdered material that could be dispersed in the atmosphere, although food and drink contamination is a possibility. An electrochemoluminescence immunoassay has been developed to screen samples of food and drink for ricin (Garber and O'Brien, 2008). The estimated human lethal dose is $1\,\mu g\,kg^{-1}$ (Wannemacher and Anderson, 2006).

The toxin consists of two dissimilar polypeptide chains joined by a disulfide bond, which links cysteinyl residues near the carboxy terminus of the A-chain and the amino terminus of the B-chain. The A-chain polypeptide chain is a potent inhibitor of protein synthesis, and the B-chain is a galactose- or an *N*-acetylgalactosamine-binding lectin (Lin *et al*., 1971). The toxicity of ricin is attributed to A-chain biological activity, and the B-chain function is to bind toxin to cell-surface receptors (Wannemacher and Anderson, 2006). By inhalation, ricin aerosols cause acute-onset alveolar oedema, alveolitis, peribronchovasculitis and acute bronchitis (Hewetson *et al*., 1996; Fritz *et al*., 1993; Griffiths *et al*., 1995). With mice, and depending on the strain, the whole body aerosol LD_{50} in the range of $2.8–11.2\,\mu g\,kg^{-1}$ (Hewetson *et al*., 1996; Wilhelmson, 1997). Parenteral dosing of experimental animals with ricin causes lymphoid tissue necrosis, liver injury, adrenal gland haemorrhagic necrosis, myocardial degenerative lesions, renal tubular hyaline changes and gastrointestinal haemorrhages (Bingen *et al*., 1987; Griffiths *et al*., 1987). There is currently no effective antidote for ricin intoxication, and the major treatment is supportive for respiratory distress. The Department of Health and Human Services (DHSS) has published a response guideline for ricin (DHHS, 2006). See also **Ricin: Chemistry, Sources, Exposures, Toxicology and Medical Aspects**.

3.4.5.2 Botulinum Neurotoxin

During and following World War II, botulinum neurotoxins were developed as biological weapons because of their ability to cause a high incidence of morbidly and mortality (Middlebrook and Franz, 1997). Several countries have developed programmes to produce and stockpile botulinum toxin as an effective bioweapon. If employed by terrorists, botulinum neurotoxin would be capable of causing massive loss of life (Arnon *et al*., 2001). There have been attempts to use botulinum toxin as a terrorist weapon, notably by the Japanese extremist group Aum Shinrikyo, who spread botulinum toxin over Tokyo three times between 1990 and 1995 (Arnon *et al*., 2001). These attempts failed because of poor microbiological techniques, deficient aerosol-generating equipment and internal sabotage, The *Clostridium botulinum* neurotoxins act by impairing the release of acetylcholine (ACh) at cholinergic neuromuscular and neuroeffector junctions (Simpson, 1981). Eight immunologically distinct botulinum neurotoxins exist (A, B, C1, C2, D, E, F and G). Neurotoxins A, B, E and F are responsible for human poisoning. Botulinum neurotoxins are anaerobically secreted as inactive 150 kDa single-chain protoxins, surrounded by a complex of several associated proteins. The protoxin is subsequently cleaved to form the active disulfide-linked dichain neurotoxin consisting of a 100 kDa heavy chain (HC) and a 50 kDa light chain (LC) (DasGupta and Sugiyama, 1972). The amino-terminal region of the HC promotes translocation of the LC into the cytosol (Koriazova and Montal, 2003). The LC is a

Zn-containing endoprotease that blocks ACh-containing synaptic vesicles for from fusing with the subsynaptic membrane at cholinergic neuroeffector and neuromuscular junctions. With peroral poisoning, the earliest symptoms are generally observed 12–36 hours postexposure and include visual disturbances including diplopia, dysphasia, dysphonia and dysarthria, reflecting the high susceptibility of cranial-nerve efferent terminals (Brin, 1997). Gastrointestinal effects sometimes occur, including nausea and diarrhoea, which may be of parasympathetic origin (Ambache, 1951). A progressive descending symmetrical skeletal muscle paralysis occurs from upper to lower limbs, and involving the diaphragm and intercostal muscles, which can progress to respiratory failure (Robinson and Nahata, 2003), but without sensory or CNS involvement (Brin, 1997; Simpson, 2004). Management includes the use of respiratory support, but further work is still required in the development of therapeutic inhibitors of LC protoxins (Adler *et al*., 2001). It is likely that use in terrorist incidents would involve contamination of food with toxin spores, and possibly by aerosol generation, both requiring specialist knowledge (Adler, 2006). Botulism is discussed in detail in **Toxicology of Chemical Warfare Agents**.

4 PREPAREDNESS FOR CHEMICAL TERROR INCIDENTS

4.1 General Considerations

In general with major terrorist incidents or suspected incidents, preparations for should be made as for any large industrial or transportation chemical incident, but it should be remembered that there may be secondary devices or other further action by the terrorist. The security forces and first responders should be prepared for this. In general, incidents may be of two general types: (i) those involving an obvious abrupt local incident, such as the abrupt release of a chemical into the environment and (ii) those involving the covert use of a toxic substance so that there is likely to be widespread, and possibly scattered, outbreaks of intoxication, which may at first not be obvious. For example, contamination of food might be mistaken for food poisoning of microbiological origin, and symptoms and signs might not occur for some hours. Were food outlets at transport hubs involved, the victims might be far away before adverse effects became apparent.

In the case of an abrupt use of a toxic chemical, the fact that something untoward has happened will be apparent immediately, but the incident may not be ascribed to terrorism. The necessary preplanned readiness actions can be put into operation immediately the cause is known. However, in many cases there may be a relatively slow appreciation of the possibility of terrorist activity, particularly with occult use of a chemical.

Detailed reports on how to plan for, and cope with, terrorist incidents have been published by national and local organizations (see Khan *et al*., 2000; Roberts and Maynard, 2007; Ballantyne, 2006b; Baker, 2007), and the following is a résumé of the more important overview considerations.

1. There should be frequent liaison between military, civil and intelligence agencies (and the governments) in order that all may be kept informed on the likelihood, nature, possible geographical location(s) and timing of possible incidents. This was stressed by one of the unfortunate lessons of the 11 September 1991 New York City World Trade Center incident, in which informed discussion and exchange of information between government agencies was far from optimum. Subsequent incidents suggest that there is still work to be done in respect of information and communication needs at both major and individual incidents, as exemplified by the police killing of an innocent Brazilian in the UK.
2. Continual updating of lists of the materials likely to be used in major and restricted terrorist situations is necessary, together with details on methods of obtaining, dispersal and likely locations of use. There needs to be continual updating and maintenance of manuals and checklists for of what is needed for management of incidents; for example, medical and rescue equipments, protective and precautionary measures, antidotes.
3. Frequent collaborative training sessions for dealing with terrorist actions in all likely scenarios, and for dealing with situations on discovery, before actual planned incidents, are necessary.
4. An essential element of preparedness is to ensure that adequate supplies of protective equipment and clothing are available; planning should provide for the needs not only of the on-site situation, but also of healthcare institutions where there may be secondary contamination as casualties are brought for medical and/or surgical management. This need should cover, at least:
   (a) Respiratory protective equipment. At the active on-site area, and, because initially the agent may be unknown, positive-pressure, self-contained breathing apparatus (SCBA) will be needed.
   (b) Whole-body protective clothing and gloves should be available.
5. Essential for on-site identification of agents used is the need for constant updating of analytical methods for specific threat chemicals; the specificity and sensitivity should be noted. Ideally, methods should be available for the on-site sampling analysis, preferably by portable instant readout devices for quantitative evaluation; such devices include the Improved

Chemical Agent Monitor (DOD, 1999; Smiths Detection, 2009; Ram and Bhethanabotler, 2009).

4.2 On-Site Provisions

With abrupt-onset terrorist situations, at the actual site of an incident there may a multiplicity of initial complex considerations and uncertainties, such as the nature of the agent(s) used and the extent and severity of the possible degree of contaminations. Therefore, from the outset it is essential that the most rapid and efficient responses must be obtained by the interactive cooperation between official and trained first responders and appropriately qualified experts in chemical terrorism. In this manner the most appropriate resources can be deployed in a correct manner. The division of the site into a hot zone, with an inner cordon separating it from the warm zone, with triage facilities between the two, is advised. There should be decontamination facilities before casualties are moved into the cold zone, and an outer cordon should be established (see ASA, 2004; Home Office, 2004). In nearly all incidents, the most important immediate measure will be to remove casualties from further exposure.

4.3 Role of Healthcare Establishments and Professional Healthcare Providers

Hospitals dealing with the general public have major incident plans. However, a lesson from the Tokyo use of sarin was that people tended to leave the scene of the incident by all means available and many made their way to hospital or to general practitioners by means other than ambulance. Moreover, many individuals went home when they felt better as, even after getting to healthcare facilities, they did not feel inclined to wait. There was some evidence of secondary contamination of hospital staff in Tokyo (see Vale *et al*., 2007).

5 CONCLUSION

Terrorism has a very long history and it is unwise to assume it will go away soon. There are obvious attractions for the terrorist in the use of chemical substances, and it is wise for governments to prepare for the use of chemicals, as previous uses in incidents (e.g. in Japan) have shown that facilities in unprepared countries can be quickly overwhelmed.

Evaluating the Long-term Health Consequences of United States Combat Deployments: Toxicology and the Law

Mark Brown and Kenneth Hyams

CONTENTS

1 INTRODUCTION

For as long as there have been wars, combat veterans and their families have expressed concerns about potential long-term health consequences from exposure to deployment-related hazards. One of the oldest stories ever written describes how Gilgamesh, the King of Uruk—who coincidentally lived about 2700 BC in what is today Iraq—goes off to war in the 'Great Cedar Forest'. This ancient story of a foreign military campaign includes a vivid account of the fears and worries of deployed warriors and their families, both before and after the battle. The equally vivid description of the serious readjustment issues for Gilgamesh and other survivors following their successful war is perhaps the first description of combat-related post-traumatic stress disorder (PTSD) (Mitchell, 2004).

More recent conflicts involving US forces and troops from other Western countries are no exception to this history of war-related health concerns. Particularly since the Vietnam War, US veterans and their supporters have spent a great deal of effort trying to identify and understand possible long-term health consequences associated with deployment-related exposures to occupational and environmental hazards. For the Vietnam War, military herbicides contaminated with dioxin (like Agent Orange) became the focus for a wide range of health concerns among combat veterans.

US veterans of the 1991 Gulf War have raised similar concerns but over a much broader array of potential deployment-related health hazards, including vaccines and prophylactic drugs, pesticides, chemical warfare agents, depleted uranium (DU) munitions, oil-well fire smoke, and many other potential exposure risks (Joseph *et al.*, 1998). For the 1991 Gulf War, all of these potential health hazards have become contentious issues as well in the United Kingdom (UK), Canada and Australia, because these countries deployed substantial numbers of troops to this conflict.

In contrast to the first Gulf War, health concerns for the current conflicts in Iraq and Afghanistan have so far focussed primarily on the long-term mental health impacts of deployment-related stress and various degrees of traumatic brain injury (TBI) from encounters with

explosive weapons. Deployment-related environmental health concerns are still unfolding for the present conflict. Recently, some veterans relate apprehension over additional environmental and occupational exposures, which will probably increase in the coming years if the Vietnam and Gulf War experience is any guide.

Once the fighting stops in Iraq and Afghanistan, the focus may shift from acute physical and psychological trauma to long-term health problems, like cancer, which will inevitably be attributed to environmental exposures. A survey of new combat veterans coming to the Department of Veterans Affairs (VA) War-Related Illness and Injury Study Center (WRIISC) programme between June 2004 and January 2006, found that most veterans (55%) had mental-health concerns, but exposure concerns were commonly reported for DU, multiple vaccinations and poor air quality related to smoke from burning trash (Helmer *et al*., 2007).

The VA in the USA is responsible for providing a wide range of federal benefits to the nearly 24 million military veterans alive today and to their dependents, including nationwide programmes offering healthcare, financial assistance, education and training, home loans, pensions, rehabilitation, vocational training, burial and survivor benefits, and other assistance for veterans and their families. The broad scope of this mission is reflected in its budget and staff, making VA the second largest Cabinet level department in the Executive Branch of the US government.

The USA does not have a national healthcare system that serves all citizens. However, VA is the largest US healthcare provider, offering a full spectrum of medical, surgical and rehabilitative care to 5.5 million unique veteran patients at VA medical facilities in 2007, up from 3.8 million in 2000. Counting repeat appointments, in 2007, VA outpatient clinics accommodated 55.7 million visits. To handle this patient load, VA operates more than 1000 sites of care, including 153 hospitals, 731 community-based outpatient clinics, 135 nursing homes, 47 domiciliaries for veterans needing living quarters adjacent to VA healthcare facilities and 207 Veterans Centers for readjustment counselling.

The VA generally does not provide healthcare to US troops currently serving on active military duty. And, not all US military veterans are eligible for VA healthcare, although the VA serves a large number of military veterans. Veterans who do not have a health problem related to military service and veterans in higher income brackets may not be able to enrol for VA healthcare or may have to pay for a portion of their healthcare.

VA's disability and pension benefits are important for the support of veterans, just as healthcare is. VA disability assistance affects millions of Americans by providing a form of worker's compensation for former military personnel, in the form of monetary support paid to veterans who are disabled by injuries or illnesses they suffered or which were aggravated during their active military service. These include health problems thought to be due to deployment-related environmental and occupation hazards. Other veteran benefits include education assistance, home-loan guarantees, life insurance and survivor benefits.

The VA in the USA has learned one fundamental lesson from responding to the diverse needs of new combat veterans since the Vietnam War: for each combat deployment, critical stakeholders—veterans and their families, the general public, government leaders and the media—all demand to know how the health of new combat veterans has been affected and how best to care for these veterans. Along with the US Department of Defense (DoD), the VA will inevitably be asked to respond to the following key health questions following each wartime deployment:

1. Are combat veterans experiencing greater health problems than their nondeployed military counterparts?
2. Do returning veterans suffer from greater rates of specific diseases, like cancer, lung disease and endocrine disorders, and are they experiencing higher rates of mortality?
3. What is the impact of combat deployment upon veterans' families and upon their reproductive health?
4. Which specific environmental and occupational hazards encountered during deployment may be causing health problems among returning veterans?

Veterans' supporters often focus on the immediate healthcare and disability needs of recent combat veterans. They generally have limited patience for governmental statements that answering essential questions about the health status of combat veterans takes time in order to conduct epidemiological studies or overcome technical hurdles, like the absence of reliable exposure data in war zones during active hostilities. In the absence of immediate information, and pressed with the real concerns of ill veterans, supporters of veterans' interest may push the VA, DoD and other responsible government agencies into short-term solutions that do not adequately address veterans' needs. Although the best guidance on veteran health issues comes from well-designed, longitudinal mortality and morbidity studies that focus on veterans from a specific deployment, the government has to respond to veterans' health concerns long before this process can be implemented.

Well-conducted research studies take time to design, to assemble a population-based cohort, to locate a comparable control group, and finally to generate long-term data. Because years and even decades of research may be needed, exclusive use of a scientific and research approach by the government is often viewed as nonresponsive or even as governmental stonewalling.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat133
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The VA's more immediate mission, to provide healthcare to veterans and to compensate them for disabilities caused by injuries received during military service, can be accomplished without time-consuming research, although occasionally these responsibilities distract from opportunities for careful scientific inquiry. Furthermore, because of the paucity of useful exposure data, particularly in combat zones, epidemiological studies have often been inconclusive in tying specific illnesses to a specific deployment-related environmental hazard.

Demonstrating a plausible link between specific exposures and unique illnesses among veterans has frequently been achieved only via the use of all available science related to a potential health hazard. Studies of veterans themselves have often not been sufficient for this purpose because of the noted limitations of these studies. However, for conclusions based on broad reviews of mainstream science to gain acceptance from veterans and their supporters, an independent assessment from a scientifically credible group is often needed.

In addition to research studies, much more immediate but less informative clinical data can be obtained from special health examination programmes; but specialized clinical 'registries' often suffer from being unrepresentative of a deployment cohort. Recent combat veterans can also be surveyed rapidly for self-reported health problems and exposures via telephone contacts and mass mailings. However, the data from these surveys generally cannot be confirmed. Reporting bias is a major problem in populations sensitized to potential health hazards by inaccurate and sensational media reports.

Although clinical registries and self-reported surveys fall far short of well-designed epidemiological studies, they can answer some basic questions about the types of illnesses and concerns exhibited by recent combat veterans. Consequently, they are viewed as a highly responsive approach by the government to immediate health questions from stakeholders.

As will be more thoroughly discussed, the VA in the US has utilized a number of approaches to evaluate the health consequences of military deployments and to address veterans' health concerns. As one of two US federal agencies directly responsible for military and veterans' health, the VA has tried the following:

1. establishment of deployment-unique clinical registries
2. epidemiological studies of veterans' health status
3. independent reviews of scientific literature relevant to specific deployment-related occupational and environmental hazards
4. recent use of 'combat veteran rosters', which are employed to provide comprehensive data on healthcare utilization based on VA and DoD electronic records.

2 HEALTHCARE REGISTRIES

For every US combat deployment, Congress and the general public rally in support of the troops. One way to show support is to demand solid answers to questions about the impact of combat deployment on veterans' health, and then to make sure troops receive optimal healthcare. The DoD is responsible for the health of US troops before they leave the military and become veterans eligible for VA benefits. After these veterans leave active military duty, the VA has the lead for veterans' health needs, including the tracking and monitoring of health status.

Historically, the quickest answers VA can supply about the health of recent combat veterans have come from review of the clinical-care needs of these veterans, often via establishment of special, voluntary 'clinical registries'. To obtain comparable clinical information, these registries entail a systematic examination with uniform requirements and reporting for the medical history, clinical examination and laboratory testing. Of course, registry participants are also clinically evaluated for outstanding health problems that are not specifically addressed by a registry protocol.

Once begun, these registries generally are not stopped even long after initial health questions are answered. The VA has ongoing special health-examination registries for veterans of the Vietnam War and the 1991 Gulf War—the 'Agent Orange' and 'Gulf War' registries. As of December 2007, the VA had provided 443 767 'Agent Orange' registry examinations for Vietnam War veterans and 102 535 Gulf War registry examinations for veterans from that conflict. Recently, the 'Agent Orange' registry has been opened to non-Vietnam War veterans who may have been exposed to herbicides contaminated with dioxin during military service outside Vietnam, and the Gulf War registry has been opened to veterans who served in the current conflict in Iraq.

Despite the focus on specific groups of veterans, special clinical registries have in general not been very useful in answering basic questions about the overall health impacts of a specific combat deployment or exposure (Institute of Medicine, 1998; Murphy *et al*., 1999). This fact should come as no surprise because participation in a special clinical registry is of necessity voluntary; with most veterans electing not to undergo additional examination, registries are not population based, and focus on healthcare-seeking patients; registries generally are a one-time clinical examination and lack any plausible control group, and clinical registries produce only limited data on combat-related hazardous exposures, usually based solely upon self-reports (Gray *et al*., 1998; Kroenke *et al*., 1998).

These limitations together render clinical registries ineffective for establishing scientifically defendable conclusions about the health of combat veterans as a whole or the causes of their health problems. The

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

primary advantage of clinical registries is how quickly they can generate information on veterans' health problems, regardless of their limitations. Inevitably, clinical registries are no substitute for the data supplied by well-designed, population-based epidemiological studies.

2.1 Findings of the VA's Gulf War I Registry Examination

Officially authorized by Congress and the President in November 1992, all veterans of the 1991 Gulf War became eligible for participation in the VA's Gulf War registry. Despite the limitations of registries in general, the large number of veterans who have been examined and the systematic examination process used in the VA's Gulf War registry programme has produced important clinical insight into the variety of illnesses suffered by Gulf War veterans. This registry also has served as a source of hypotheses for further research. Moreover, any widespread serious physiologic disease should have been detected in this very large case series. Of note, the US DoD, the Ministry of Defence in the UK and Canada, and the Australian government all established similar clinical registries after the first Gulf War (Lee *et al*., 2002; Goss Gilroy, Inc., 1998; Kelsall *et al*., 2004).

Review of the diagnoses among over 100 000 1991 Gulf War veterans who participated in the VA's clinical registry indicates that these veterans presented with a wide range of common illnesses, which would be expected among any group of adult veterans (Department of Veterans Affairs, Veterans Health Administration, 2002). Interestingly, approximately 12% of participants in this registry had no outstanding health problem, presumably participating out of concern or interest to be registered. Although no unique illness stands out in this predominantly outpatient population, the self-selected nature of the group, lack of controls and absence of good exposure data make detailed interpretation problematic.

Unfortunately, the media have misinterpreted routine outpatient health problems as indicating substantial and serious illness among all Gulf War veterans. One misinterpretation of the data is that the >100 000 Gulf War veterans volunteering for an outpatient examination out of a total of 700 000 Gulf War veterans serving in that conflict means that one out of seven Gulf War veterans had a serious mystery illness or 'Gulf War Syndrome' (Department of Veterans Affairs, Veterans Health Administration, 2002).

In actuality, these veterans were diagnosed as having a wide range of health problems expected in an adult population of veterans. Importantly, a new or unique syndrome was not identified by systematic clinical examinations of over 100 000 Gulf War veterans. Similar common health problems without evidence of a new syndrome were also found in the British, Canadian and Australian Gulf War registries (Lee *et al*., 2002; Goss Gilroy, Inc., 1998; Kelsall *et al*., 2004).

Review of 1999 VA revised registry data indicates that many participants were 'well' when they were evaluated. While 74% of evaluated veterans report their health status as 'all right', 'good' or 'very good', the remaining 26% report 'poor' or 'very poor' health. **Table 1** shows the most common symptoms reported by Gulf War veterans in decreasing frequency: (i) loss of memory, (ii) headache, (iii) fatigue, (iv) skin rash, (v) muscle/joint pain, (vi) sleep disturbances, (vii) diarrhoea and other gastrointestinal symptoms, and (viii) shortness of breath.

These are common symptoms frequently reported in outpatient populations. During the Gulf War Syndrome controversy, statistics on symptoms were

Table 1 Most frequent complaints among 19 721 veterans in the VA's revised Persian Gulf registry[a]

Complaints	Frequency	Percentage[b]
Loss of memory and other general symptoms	5794	29.4
Headache	5204	26.4
Fatigue	4639	23.5
Skin rash	4574	23.2
Muscle/joint pain	4096	20.8
Sleep disturbances	2553	12.9
Diarrhoea and other gastrointestinal symptoms	2352	11.9
Shortness of breath	2050	10.4
Chest pain	1041	5.3
Choking sensitivity	939	4.8
Abdominal pain	916	4.6
Other symptoms involving skin and integumentary tissue	692	3.5
Cough	676	3.4
No complaint	1527	7.7

[a]Data as of February 1999, prepared by the VA Environmental Epidemiology Service.
[b]Percentage of 19 721 veterans.

often misreported without noting whether the symptoms were inconsequential and transient or whether they were associated with well-known health problems. This type of symptom reporting led to substantial confusion about a potential mystery illness. As will be noted, subsequent improvements in VA's electronic medical record allowed for a much more rapid and comprehensive compilation of actual, physician-derived diagnoses rather than just symptoms, which obviated much of the speculation about a new symptom-defined syndrome among veterans following the invasion of Afghanistan and Iraq.

Table 2 shows that the most common primary diagnoses among veterans of the 1991 Gulf War are diverse and related to: (i) musculoskeletal and connective tissue conditions, (ii) mental disorders, (iii) respiratory conditions, (iv) skin and subcutaneous conditions, (v) digestive conditions, and (vi) nervous system conditions. As found here among Gulf War registry volunteers, musculoskeletal problems are consistently identified to be the most common medical problems in young populations of military veterans. Although it is difficult to identify control patients for comparison purposes in clinical case series, the VA's clinical registry data were very similar to the diagnoses found among British, Canadian and Australian veterans in their clinical registry programmes.

The VA registry provided limited information about the relative severity of diagnosed illnesses among Gulf War veterans. However, some information about severity is found in disability statistics for veterans awarded financial compensation (Department of Veterans Affairs, Veterans Benefits Administration, 2007). Of 621 230 Gulf War veterans separated from military service and eligible for VA programmes, 160 461 have had illnesses or injuries connected to military service with a disability rated to a level of 10% or more, which is compensable. A 1999 review found that the most common claim was for impairment of the knee, followed by skeletal system disability, back strain, arthritis due to trauma, scars and hearing loss (Department of Veterans Affairs, 1999).

There were 3280 veterans granted claims for disabling symptoms due to undiagnosed illnesses—a new compensation claim category, established by Congress in 1994, to assist veterans debilitated from unexplained symptoms. By 1999, there were 3077 claims granted for disability caused by undiagnosed illnesses. Granted claims represented a wide range of conditions, with the most common relating to: (i) musculoskeletal disease, followed by (ii) miscellaneous neurological conditions, (iii) systemic disease, (iv) lower digestive system, (v) skin, and (vi) skull and ribs (Department of Veterans Affairs, 1999). For determination of the number of veterans who may suffer from the putative 'Gulf War Syndrome', this group of veterans, who received compensation for undiagnosed illnesses, is probably the most representative because their unexplained symptoms were the cause of demonstrable disability.

2.2 Value of Registries

Ultimately, clinical registry programmes for Vietnam and Gulf War veterans fulfilled an initial short-term role as a rough and quick assessment of the health of combat veterans. For example, at the end of the 1991 Gulf War, VA healthcare experts, who saw televised images of enormous dark clouds of smoke from burning oil wells in Kuwait, became concerned about potential long-term respiratory problems among returning veterans, and in response established the initial Gulf War clinical registry programme. Early analysis of data from the programme served to dispel concerns about widespread respiratory illnesses in this combat cohort. The value today of all registry programmes may ultimately lie in the area of outreach and education. The registry examinations offer a unique opportunity for veterans to discuss their

Table 2 Distribution of diagnoses for the 19 721 veterans in the VA's revised Persian Gulf registry[a]

Diagnosis	Number	Percentage
Musculoskeletal and connective tissue	7286	36.9
Mental disorders	6887	34.9
Skin and subcutaneous tissue	3813	19.3
Respiratory system	3626	18.4
Digestive system	3451	17.5
Nervous system	3441	17.4
Circulatory system	2083	10.6
Injury and poisoning	2020	10.2
Infectious diseases	1785	9.1
Genitourinary system	1126	5.7
Neoplasm (malignant)	149	0.8
No medical diagnosis	4664	23.6

[a]Data as of February 1999, prepared by the VA Environmental Epidemiology Service.

deployment-related health concerns with an informed VA healthcare provider.

The noted limitations of clinical registries linked to participation in particular combat deployments do not necessarily apply to registries based on specific diseases. These types of registries have a long history of usefulness. Clinical registries of specific diseases, like cancer or neurological disease, can be very helpful for research purposes and for outreach efforts to patients with unique health problems and health risks.

3 EPIDEMIOLOGICAL STUDIES OF VETERANS

Military veterans and their supporters, and many medical researchers have advocated epidemiological studies as the gold standard to assess the health consequences of military service. Properly designed epidemiological studies of combat veterans' health offer advantages over specialized clinical registries for evaluating the overall health of new combat veterans and for studying potential risk factors of illness. In particular, epidemiological studies can provide information on a population as a whole, rather than just sick and healthcare-seeking groups.

Note that epidemiological studies are not as useful in identifying a new disease because the most critical initial requirement in this process is to find unique clinical characteristics among affected patients; that is, identification of pathognomonic symptoms or signs. Clinical case–control studies are often a better approach for identifying new diseases than epidemiological studies. Epidemiological research is therefore not the first step when predominantly clinical questions, like the possible existence of a new or unique syndrome, need to be answered.

In recognition that properly designed epidemiological studies are critical in answering general questions about long-term deployment health effects, the US federal government has to date committed more than $274 million on Gulf War veteran health research, which includes a significant number of epidemiological studies (Department of Veterans Affairs, 2004; Department of Veterans Affairs, Deployment Health Working Group Research Subcommittee, 2006). A number of excellent reviews and summaries of the remarkably large number of studies of Gulf War veterans have been published (Institute of Medicine, 2006; Wessely, 2006).

The 2006 report *Gulf War & Health Vol. 4: Health Effects of Serving in the Gulf War*, which was produced by an independent committee of the National Academies of Sciences Institute of Medicine (IOM), represents a particularly deliberate and thorough review of all published scientific literature on veterans of the 1991 Gulf War (Institute of Medicine, 2006). For this IOM study, which was requested by the VA, the expert committee identified over 4000 potentially relevant scientific reports and focussed on 850 epidemiological studies. They concluded that the 'VA and DoD have expended enormous effort and resources in attempts to address the numerous health issues related to the Gulf War veterans. The information obtained from those efforts, however, has not been sufficient to determine conclusively the origins, extent, and potential long-term implications of health problems potentially associated with veterans' participation in the Gulf War'.

Tellingly, the IOM committee also identified serious limitations in existing epidemiological studies of Gulf War veterans, resulting largely from the lack of reliable exposure data. However, they did 'not recommend that more such studies be undertaken for the Gulf War veterans'. Rather, they recommended that there is 'value in continuing to monitor' Gulf War veterans for a few illnesses that they may be at greater risk for; specifically, brain and testicular cancer, amyotrophic lateral sclerosis (ALS), birth defects and postdeployment psychiatric conditions.

The IOM committee further noted that 'every study reviewed by this committee found that veterans of the Gulf War report higher rates of nearly all symptoms examined than their nondeployed counterparts.' Given this finding, not surprisingly the IOM committee concluded that symptom-defined illnesses, consistent with chronic fatigue syndrome, fibromyalgia, irritable bowel syndrome and multiple chemical sensitivity, were the most common health problem reported in these studies. They also found that 'Gulf War veterans consistently have been found to suffer from a variety of psychiatric conditions', including PTSD, anxiety, depression and substance abuse.

The IOM also reported that studies have 'not demonstrated differences in cognitive and motor measures' in deployed versus nondeployed veterans, and show no apparent increase in risk of peripheral neuropathy, cardiovascular disease or diabetes. They reported finding no consistent pattern of birth defects among offspring of male or female Gulf War veterans, but that congenital urinary tract abnormalities were found to be increased in 'more than one well-designed study'. They also found little data supporting objective respiratory illnesses among Gulf War veterans.

Finally, the IOM concluded that 'the results of that research indicate that although deployed veterans report more symptoms and more severe symptoms than their nondeployed counterparts, there is not a unique symptom complex (or syndrome) in deployed Gulf war veterans'. This report underlined the important fact that after more than one-quarter of a billion dollars of research, a unique 'Gulf War Syndrome' has not been confirmed.

For future deployments, the IOM committee recommended better use of predeployment and postdeployment health screening, better exposure assessments and continued surveillance among Gulf War veterans for

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cancer, ALS, birth defects, adverse pregnancy outcomes, postdeployment psychiatric problems and mortality. As recognized by the IOM, longitudinal mortality and morbidity studies have provided the most reliable data on the general health status of Gulf War I veterans. For example, according to a VA study of mortality among all Gulf War veterans, mortality risk for Gulf War veterans was essentially identical compared to their nondeployed military peers (except for a small increased risk for accidental death in the first five years postdeployment). Interestingly, the mortality of US veterans of the 1991 Gulf War was less than one-half the mortality of a demographically similar US civilian population, which is probably a reflection of the healthy worker or warrior effect (Kang and Bullman, 2001).

Mortality studies are useful because relatively objective and accurate mortality data is available for the entire cohort of US war veterans. Consequently, mortality studies have already been started by the VA for the current cohort of combat veterans who served in Iraq and Afghanistan.

Because many health questions remain unanswered, substantial government funding continues for studies of Gulf War veterans more than 17 years after the war (Department of Veterans Affairs, 2004). Most research has focussed on the possibility of a neurological abnormality as the cause of chronic unexplained symptoms among Gulf War veterans. Evidence has been found in studies conducted at Southwestern Medical School in Texas that some Gulf War veterans may be suffering from a previously uncharacterized neurological disease, possibly due to exposure to pesticides or organophosphate chemical agents during the Gulf War (Haley *et al*., 1997).

4 INDEPENDENT REVIEWS OF ALL RELEVANT SCIENTIFIC LITERATURE—CURRENTLY THE MOST ACCEPTABLE APPROACH

A key weakness of epidemiologic studies of combat veterans has been their frequent inability to find evidence of a link between specific health outcomes and exposures during combat deployment. This problem results from the nearly complete absence of useable environmental and occupational exposure data among combat troops deployed to a war zone. The difficulty of accurately recording the location of individual troops during hectic wartime deployments adds to this problem.

4.1 Impact of Poor Exposure Data

Lack of exposure and troop location data have seriously handicapped governmental efforts to craft fair and equitable policies for linking specific deployment hazards to specific injuries and disabilities among returning veterans, and to provide appropriate compensation. A critical problem for policy makers and veterans alike has been how to document exposure to wartime health hazards, including even basic information about where deployed troops were located. From a preventive medicine and research study standpoint, the well-understood model of work-place occupational exposures monitoring cannot be translated to the battlefield.

In general, occupational monitoring has not proven practical during active engagement in war situations. Combat deployments are not large epidemiological studies. In fact, attempts to collect extensive exposure information could hinder war-fighting capabilities and endanger combat troops. Accurate documentation of troop locations is similarly difficult and hazardous during chaotic wartime events.

These serious limitations in obtaining exposure data have generally frustrated attempts to evaluate long-term health consequences of combat-related exposures and to develop sound policies to respond to affected veterans. Similarly, disentangling military deployment-related from civilian, non-military-related risks has been problematic. In general, military environmental and occupational health risks are comparable or even identical to risks experienced by civilians with similar occupations. Consequently, it is hard to make distinctions between risks accrued during military service and risks encountered during civilian life.

A good illustration of these problems is the federal government's response to health concerns related to Vietnam War veterans and their potential exposure to herbicides contaminated with dioxin. Many returning veterans developed health problems that have been attributed to exposure to Agent Orange and related herbicides used in Vietnam, and these concerns extended to birth defects among their children. Congress held their first of many hearings on herbicide use in Vietnam in 1970, and Congressional interest in this topic remains high to this day.

Initially, the US government had difficulty in responding to Agent Orange health concerns. In part this was because at the beginning of the controversy scientists were only just beginning to understand the various health effects that could be caused by exposure to dioxins. Similarly, the VA had few well-developed policies and procedures in place for evaluating and compensating illnesses potentially related to military environmental and occupation hazards in cases that were not clearly linked to military service.

Those early concerns initiated a long struggle by the government to fairly and equitably evaluate possible long-term health effects among Vietnam veterans exposed to herbicides. Many observers at the time—back in the late 1970s—considered that the obvious approach would be to study Vietnam veterans themselves. That

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is, the ideal way to evaluate potential health effects from Agent Orange exposure would be a well-designed epidemiological study of Vietnam War veterans. Congress supported this approach in 1979, by passing Public Law 96–151, which directed the VA to 'conduct an epidemiological study of the long-term health effects on individuals from exposure to dioxins (including 'Agent Orange') used during the Vietnam conflict'.

Conduct of an epidemiological study was the research approach that the VA was directed by law to embark upon in 1979. Four years later, in 1983, VA representatives were forced to announce that they had been unable to develop a feasible study, primarily because of inadequate herbicide exposure data (Institute of Medicine, 1994). In frustration, Congress then urged the VA to transfer the study to the CDC (Centers for Disease Control) (United States Government Accountability Office, 1990). In response, the VA and CDC signed an interagency agreement transferring funds ($70.4 million dollars in 1980s-appropriated VA dollars), personnel positions, prior work, and the authority for the CDC to conduct the study (United States Government Accountability Office, 1990). Several years and tens of millions of dollars later, the CDC also concluded that available military records were not adequate for establishing meaningful herbicide exposure data among Vietnam veterans, and that an adequate Agent Orange epidemiological study was not feasible.

In retrospect, this approach was fated to be disappointing because we now appreciate that trying to conduct an occupational-health-type study on combat-deployed troops is extremely challenging, due primarily to the lack of usable exposure and troop location data. The basic problem is that this information is generally not available. Similarly, more than a decade later following the 1991 Gulf War, essentially the same high initial expectation arose over the value of epidemiological studies in understanding battlefield health hazards. A similar history could unfold in the aftermath of the current conflicts in Iraq and Afghanistan (Helmer *et al*., 2007).

The inability of epidemiologic studies of Vietnam War veterans to prove a link between their health problems and herbicide exposure because of a lack of basic information—reliable exposure and troop location data—was difficult for nonscientists to understand. Efforts are still underway to develop reliable exposure models more than 30 years after the last American soldier left Vietnam (Institute of Medicine, 2008b).

Given the lack of reliable exposure data, Congress and the President bypassed this problem for policy development purposes in 1991 by enacting Public Law 102-4, the 'Agent Orange Act of 1991', which stipulates that all Vietnam veterans—any veteran who spent even one day 'in-country'—be considered as exposed to Agent Orange. Further, this law directed the VA to develop a new approach for incorporating scientific data into Vietnam veteran disability compensation policies relative to Agent Orange exposure.

Instead of relying solely on studies of Vietnam veterans themselves, the mandated approach was based upon regular, biennial reviews by the independent and prestigious National Academies of Science Institute of Medicine of the entire scientific literature on health effects from herbicides and related dioxin in any exposed population. Veterans would thus potentially benefit from scientific findings in any exposed human population and not just research on veterans who had participated in hectic and confusing combat operations.

This new approach, still used today, requires the VA to use the IOM reports to help determine whether an automatic link should be recognized between a specific illness and Vietnam service. In bureaucratic terms, that is whether a 'presumption' of service connection for disability compensation is warranted by virtue of a 'positive association' between herbicide exposure and disease as identified by the IOM. The law defines a 'positive association' as existing when the credible scientific evidence for the association is equal to or outweighs the credible evidence against the association. In making the determination, the VA is given latitude to consider all other credible medical and scientific information, in addition to the IOM reports.

In evaluating IOM reports for this purpose, Public Law 102-4 directs the VA to consider whether the findings of an association are statistically significant, are capable of replication, and withstand peer review. VA is required then to announce any new policies for compensating Vietnam veterans for injuries related to herbicide exposure, or to publish an explanation of the scientific basis for why not. Thus, a standard was set for disability determination that does not rely on establishing the dose of dioxin exposure or the probable health effects of that exposure on any individual veteran.

The first IOM report, 'Veterans and Agent Orange', published in 1994, set the pattern for all future reports as a *tour de force*, exhaustive review of the entire published scientific and medical literature on health effects from exposure to herbicides used in Vietnam. Since then, the 'Agent Orange Act' has required that the IOM report be updated every two years, taking into account new scientific and medical publications that may affect the results of previous IOM reviews.

Based upon findings contained in that initial 1994 and subsequent biennial IOM updates through 'Update 2006', (Institute of Medicine, 2008b), the VA has established new presumptions of service connection for Vietnam-era veterans who served in Vietnam and are diagnosed with:

1. soft tissue sarcoma
2. non-Hodgkin's lymphoma
3. chronic lymphocytic leukaemia
4. Hodgkin's disease

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat133

5. chloracne
6. respiratory cancers
7. prostate cancer
8. multiple myeloma
9. early-onset transient peripheral neuropathy
10. porphyria cutanea tarda
11. Type 2 diabetes
12. spina bifida among the children of Vietnam War veterans.

Even before this formal review process was set in motion, the VA had previously on its own authority recognized chloracne, non-Hodgkin's lymphoma and soft tissue sarcoma as related to herbicide exposure for Vietnam veterans. The IOM review process confirmed the validity of these earlier decisions and has subsequently added many additional diseases to this list.

In effect, IOM is used as a scientific arbiter so that Vietnam veterans benefit from service connection for any health effect positively associated in studies of populations exposed at any level to Agent Orange or other herbicides used in Vietnam. Most of the hundreds or thousands of studies reviewed by the IOM are in fact of non-Vietnam veterans, and include civilian workers exposed on the job and civilians exposed during industrial accidents. Studies based upon nonmilitary veteran subjects have been quite helpful because they almost always involve much better-characterized exposure data with correspondingly substantially larger and longer exposures, compared to that experienced by the average Vietnam veteran. Veterans gain the advantage of disability compensation policies based upon studies that provide more reliable information than studies of potentially affected veterans themselves.

This part-legislative, part-scientific and part-administrative approach to determining eligibility for disability is still used today. It is generally accepted as having worked to the benefit of potentially affected veterans by all stakeholders, because it is viewed as giving the benefit of the doubt to veterans. Congress has found this approach acceptable and has renewed the VA's authority to use it through 2015.

4.2 Limitations in Evaluating Commonplace or Well-Characterized Health Effects

More recent attempts to extend this approach of using the IOM to help link disability to military service among other groups of veterans have been more difficult and have produced few new benefits. For example, in response to concerns of veterans of the 1991 Gulf War and their families that their health may have been affected by exposure to a wide variety of environmental and occupational hazards during that conflict, two federal laws, Public Laws 105–277 and 105–368, were enacted. Drawn directly from the Agent Orange Act of 1991, these two statutes invoked the now-familiar formal IOM committee review process, including regular and thorough reviews of all the scientific and medical literature relevant to health and Gulf War exposures.

Several problems have emerged from using this approach with more recent war veterans. The environmental and occupational exposures experienced by Gulf War veterans were quite different compared to the Vietnam War. In contrast to the relatively narrow range of herbicides used in Vietnam and their dioxin contaminant, hazardous exposures potentially related to the 1991 Gulf War involved many dozens of different and unrelated agents (Joseph *et al*., 1998). The two laws actually specified at least 33 different Gulf War-related environmental and occupational hazards, all to be evaluated through this formal process (**Table 3**).

In addition to these differences, when the Agent Orange Act was enacted in 1991 there was a relatively small number of relevant scientific publications on herbicides and dioxin health effects for IOM committees to evaluate. In contrast, many of the Gulf War environmental and occupational hazards are well studied, with an abundant health-effects literature, much of which suggests a small health risk from low-level exposure. Consequently, the six major and a couple of minor IOM committee reviews produced as of 2007 have generated few new or original insights into the health effects of exposure relative to these agents. In fact, the IOM reports tend more to mirror summaries of human health effects found in standard occupational health and toxicology textbooks.

In 2000, the first IOM committee report in this series on 1991 Gulf War health effects reviewed relevant scientific literature on sarin, cyclosarin, pyridostigmine bromide (a chemical warfare pretreatment used by the US and UK military), DU and anthrax botulinum toxoid vaccines (Institute of Medicine, 2000). The second (2003) IOM study reviewed the potential long-term health effects from insecticides and solvents used in the Gulf War (Institute of Medicine, 2003). The third IOM study (Institute of Medicine, 2005) examined health effects from Gulf War fuels, combustion products and rocket propellants. The fourth study (2006) reviewed all scientific studies on health effects of serving in the Gulf War (Institute of Medicine, 2006). Potential infectious disease risks were reviewed in 2007 (Institute of Medicine, 2007a). The sixth study (2008) reviewed health effects associated with deployment-related stress (Institute of Medicine, 2008a). Finally, the potential health effects of sarin exposure was re-reviewed in 2004 because of new research findings (Institute of Medicine, 2004).

In addition to this legally mandated series of studies, since the 1991 Gulf War the IOM has produced

Table 3 Statutory list of potentially hazardous exposures during the 1991 Gulf War to be evaluated by the IOM

The OP pesticides chlorpyrifos, diazinon, dichlorvos and malathion	The methyl carbamate pesticides proxpur, carbaryl and methomyl
Pyridostigmine bromide	Mustard agents 'at levels below those which cause immediate blistering'
Nerve agents 'at exposure levels below those which produce immediately apparent incapacitating symptoms' including sarin and tabun	Other pesticides and repellents including lindane, pyrethrins, permethrins, rodenticides and DEET[a]
Volatile organic compounds	Hydrazine
Red fuming nitric acid	Solvents
Uranium and depleted uranium	Microwave radiation
Radio frequency radiation	Hydrogen sulfide
Oil fire by-products	Diesel heater fumes
Sand 'microparticles'	
Time compressed administration of multiple live, 'attenuated' and toxoid vaccines	Diseases endemic to the region including leishmaniasis, sandfly fever, pathogenic *Escherichia coli* and shigellosis

[a]N,N-diethyl-m-Toluamide

nearly 20 other, separate studies for the VA and DoD on a wide range of Gulf War veteran health issues. (Joellenbeck and Hernandez, 2002). The breadth and thoroughness of the IOM scientific review process and their reputation for independence and scientific excellence make them a highly credible source for what often are contentious questions surrounding health and possible deployment-related hazardous exposures. Taken together, these IOM committee studies on potential health effects from participation in the 1991 Gulf War have produced somewhat predictable findings on well-understood environmental exposures.

As with the Agent Orange Act of 1991, the new statutes covering Gulf War veterans give the IOM responsibility for evaluating the underlying science, but the VA retains responsibility for translating their conclusions into relevant healthcare and disability policy, as appropriate to its mission. The end result of this process has not led to many new presumptions for disability compensation. Nevertheless, the IOM's largely negative findings about serious health consequences from participation in the 1991 Gulf War have been generally acceptable to all stakeholders because of the IOM's reputation for competence and fairness.

4.3 Toxicology versus the Law

The VA has had difficulty applying IOM committee findings to 1991 Gulf War veterans precisely because many of the proposed Gulf War-related hazards represent well-characterized occupational exposures that are commonly experienced by US citizens (Brown, 2005). For example, the pesticides, solvents and air pollutants reviewed by IOM committees represent virtually the identical agents that US civilians are frequently exposed to domestically. Similar low-level exposures in both the civilian and military setting are no accident because the DoD generally adheres to civilian guidelines established by the US Environmental Protection Agency and others when selecting pesticides or other agents for use in combat deployment situations.

Even the seemingly more unusual exposures such as to sarin (a chemical warfare nerve agent) or DU (used in special armour-piercing munitions) still have a substantial health effects literature derived from exposed workers and other populations (Brown and Brix, 1998). Many people have been involved in the manufacturing of chemical warfare agents and DU and other uranium components, and general populations have been exposed to terrorist incidents, like the 1994 Tokyo, Japan, incident involving thousands of civilian exposures and some deaths (Morita *et al*., 1995). There is also extensive clinical experience in the use of pyridostigmine bromide for the treatment of myasthenia gravis.

Because of the relatively short-term (a few months) and low-level exposures experienced by most 1991 Gulf War veterans to hazardous agents associated with that deployment, the VA has had particular difficulty applying the IOM's conclusions based upon studies of involving long-term (years or decades) occupational exposures among civilian workers or short-term but relatively high-dose exposures in industrial accidents. To complicate policy development, the laws governing this process, like those for Agent Orange, do not take into account exposure magnitude or duration, leading to the somewhat scientifically implausible result of treating any exposure level as equally likely to lead to a specific long-term health effect, no matter how universal or trivial

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat133
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the exposure magnitude may have been for most Gulf War veterans.

As an example of the difficulty in developing fair disability policies, the 2003 IOM committee report on long-term health effects from insecticides and solvents documents a slight increase in leukaemia risk among chemical industry workers with large and prolonged occupational exposure to benzene (Institute of Medicine, 2003). But such findings do little to inform us about the potential leukaemia risk for the typical Gulf War soldier experiencing an unremarkable benzene exposure during a few months of wartime deployment.

On the other hand, there are certainly examples of 1991 Gulf War veterans who experienced more than just everyday or commonplace benzene exposure, for example, veterans who regularly worked on vehicle maintenance. Such cases may involve benzene exposure at levels more comparable to the typical civilian occupational exposures that formed the bases of the studies reviewed by the IOM. Importantly, the applicable laws do little to distinguish between these two exposure extremes. However, individual veterans in the USA can still provide evidence of significant hazardous exposure to any known health threat and receive compensation based on their distinctive circumstances.

In a similar vein, many IOM committee findings about long-term health effects arise only in cases involving an unusually large exposure sufficient to cause immediate (acute) and serious health effects at the time of exposure. For example, certain well-documented long-term health effects from organophosphorus (OP) pesticides are found only as the result of severe and immediate initial poisoning, typically via an occupational exposure, and usually leading rapidly to hospitalization (Brown and Brix, 1998). Lesser exposures not leading immediately to serious clinical signs and symptoms have generally not been associated with long-term effects. For the 1991 Gulf War, all potential exposures to sarin and related OPs are thought to have been subclinical because there were no documented instances of acute OP-type toxicity reported among deployed coalition troops from any country (Institute of Medicine, 2000).

From a policy standpoint, how should the VA apply such findings by the IOM to the vast majority of veterans who experienced only unexceptional, asymptomatic exposures to these agents? All Americans experience small, perhaps continuous exposures to common OP pesticides (available at gardening stores everywhere) or benzene (a component of gasoline) during their lifetimes. However, such exposures are generally considered to have negligible health risks, given their small magnitude.

For these reasons, the VA has been hindered in developing new presumptive service-connected disability policies in response to IOM committee findings on the health effects posed by the wide range of common but potentially hazardous occupational and environmental exposures associated with the 1991 Gulf War. However, the IOM findings have generally been considered credible and the VA's response to these findings appropriate.

As noted, a presumption of service-connection allows the VA to award disability compensation without the individual veteran having to provide evidence that they were harmed due to their military service. As previously noted, it is important to understand, however, that even without a presumptive service connection, veterans can, on an individual basis, provide evidence that they were exposed to a toxic agent and suffered harm and then receive compensation. Disability compensation is usually awarded through this direct method in the VA. As a result, IOM findings have not precluded veterans from obtaining medical and financial assistance for health problems caused by hazardous exposures during military service.

5 LESSON LEARNED—BETTER WAYS TO ASSESS VETERANS' HEALTH THROUGH ELECTRONIC 'COMBAT VETERAN ROSTERS'

The type of voluntary clinical registry used by the VA for Vietnam and Gulf War veterans has become obsolete. The VA's recent advances in developing a comprehensive electronic patient record and the development by the DoD of an accurate roster of Iraq and Afghanistan veterans has led to enormous improvements in the VA's ability to track and evaluate the healthcare needs of new combat veterans. The VA's recent experiences tracking VA healthcare utilization for specific groups of veterans using electronic 'combat veteran rosters' demonstrates that this approach has many advantages over special clinical registries. The approach also provides very rapid results, which have been well received by all stakeholders concerned about the health of new combat veterans.

Key to this improved approach has been the VA's electronic outpatient and inpatient clinic records, which include diagnostic and demographic data for all veterans who receive VA healthcare, including International Classification of Disease (ICD-9) codes, for every clinic visit and hospitalization at a VA medical facility. The recorded data is mainly administrative data that reflects clinical impressions at the time of the clinical encounter, which means that not all diagnoses are confirmed when recorded. Nevertheless, each recorded diagnosis requires clinical follow-up and evaluation, and so accurately reflects healthcare needs. All inpatient and outpatient encounters are now captured by the VA's electronic health record, whereas only inpatient data was computerized just after the 1991 Gulf War. By matching this electronic database with the DoD's roster of recently deployed combat troops, the VA can identify all combat veterans accessing VA healthcare, and track their healthcare needs.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat133
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The capturing of both inpatient and outpatient visits in an electronic health record is a major advance in VA healthcare that has occurred since the first Gulf War. The use of VA electronic healthcare records to monitor veterans' health needs first took place in early 2000, in an evaluation of recent VA healthcare utilization among Project Shipboard Hazard and Defense (SHAD) veterans who may have been exposed to biological and chemical agents in military tests conducted during the Cold War. Potential SHAD exposures include infectious agents, possible carcinogens, and chemical warfare nerve agents.

Although not a new combat deployment, nevertheless Project SHAD veterans and their supporters in Congress and the media had similar questions about potential long-term health effects from involvement in these tests as has been asked previously for recent combat troops. Using its electronic health record, the VA was able to quickly supply some answers about possible health problems among this veteran cohort of about 5000 identified individuals.

Although this clinical information is not research data and did not represent a formal epidemiological study where rates of various diseases could be compared, it nevertheless provided a rapid assessment of the healthcare needs of this cohort. No unusual health problems were identified in this aging group of veterans.

Perhaps the most useful conclusion from this summary of clinical care was that since no particular health problem stood out among Project SHAD veterans, no recommendations for specific testing or evaluation of this cohort were feasible. SHAD veterans therefore should be assessed individually on the basis of their clinical presentation to receive optimal healthcare.

Although this electronic health record approach generates rapid results, it is limited in that it only contains health information for those SHAD veterans electing to seek healthcare from the VA, and there is no comparison group to assess rates. Thus, clinical findings cannot be generalized to the overall health status of SHAD veterans. More detailed analysis clearly requires a properly designed population-based epidemiological study. Consequently, in 2002 the VA contracted with the IOM for a study of potential long-term health effects among SHAD veterans in comparison to suitable controls.

Because the IOM study of SHAD veterans required more than four years to complete, the initial analysis of their clinical care using the VA's electronic health record was very helpful in understanding their healthcare needs and answering veterans' questions. Much later, the formal IOM epidemiological study was unable to definitely identify any long-term health effects among SHAD veterans that occurred at greater rates compared with controls (Institute of Medicine, 2007b).

5.1 'Operations Iraqi Freedom/Enduring Freedom' Combat Veteran Roster

The electronic Combat Veteran Roster approach has also proven remarkably successful in meeting the short-term requirements for information on new veterans returning from the current conflicts in Iraq and Afghanistan. The VA produces healthcare utilization reports with summary statistics for these combat veterans on a quarterly basis. The January 2008 report includes information on healthcare needs among 799 791 Operation Iraqi Freedom/Operation Enduring Freedom (OIF/OEF) veterans (both former active duty and Reserves/National Guard) who left active duty and became eligible for VA healthcare since fiscal year (FY) 2002 ('Analysis of VA Health Care Utilization Among US Global War on Terrorism (GWOT) Veterans, Operation Enduring Freedom Operation Iraqi Freedom', Veteran Health Administration Office of Public Health and Environmental Hazards, January 2008).

Among all 799 791 separated OEF/OIF veterans, a cumulative total of 299 585 (37%) received VA healthcare since FY 2002, with most (96%) seen as outpatients only. Their diagnosed health problems covered more than 8000 discrete ICD-9 diagnostic codes, with the three most common problems being musculoskeletal ailments (principally joint and back disorders), mental disorders, and 'Symptoms, Signs and Ill-Defined Conditions' (a frequent initial diagnosis in outpatient populations that includes 160 subcategories of symptoms and clinical findings not coded elsewhere in the ICD-9).

This clinical information demonstrates that new Iraq and Afghan veterans are presenting to the VA with a wide range of medical and psychological health problems. As with SHAD veterans, no unexpected conditions stand out, and therefore these new combat veterans are being assessed as individuals to identify all outstanding health problems.

5.2 Combat Veteran Roster Approach—Advantages over Conventional Registries

Although not a research study with confirmed diagnoses, the electronic Combat Veteran Roster approach continues to be useful in meeting immediate information needs on the health of new combat veterans. This nonresearch approach to evaluating healthcare needs—matching the DoD-provided roster of new combat veterans with VA electronic patient care data—clearly offers significant advantages compared to earlier special clinical registries such as the Vietnam War and Gulf War health examination registries. It is faster to implement, popular with stakeholders, generates a snapshot of major diagnoses and

clinical care requirements, and encompasses every single veteran who uses VA healthcare—not just veterans who elect to volunteer for a special health registry programme.

As an example of its advantages, in contrast to the approximately 14% (103 000) of Gulf War I veterans who underwent a special Gulf War registry examination during the last 17 years, already the healthcare needs of more than 37% of OIF/OEF veterans are being followed in the new electronic database maintained by the VA. Moreover, the Combat Veteran Roster approach documents every time OIF/OEF veterans obtain VA care, not just on the one occasion that they elect to have a registry examination.

The evaluation of all healthcare encounters provides a much more in-depth and longer-term assessment of the healthcare utilization of these veterans because many of them return frequently for VA healthcare, and because veterans are often seen in different clinics or even different parts of the country for specialized healthcare. Lastly, this approach gives a more accurate assessment of veterans' health problems because it relies on physician-diagnosed health problems and not self-reported symptoms, which may not be significant because they are transient or nondebilitating.

Although medical research, particularly epidemiological studies, is still necessary to answer questions about the long-term health of combat veterans and to investigate potential hazardous exposures and other risk factors (Kang *et al*., 2000; Cowan *et al*., 1997) the VA's OIF/OEF Combat Veteran Rosters have proven to be enormously popular with veterans and their supporters, who deserve rapid answers to questions about their healthcare needs. Consequently, the VA has committed to continue to monitor the healthcare utilization of recent OIF and OEF veterans using updated deployment rosters provided by the DoD to ensure that the VA tailors its healthcare and disability programmes to meet the needs of this newest generation of war veterans.

6 CONCLUSIONS

The VA is repeatedly called upon by critical stakeholders—veterans and their families, the US public, government leaders and the media—for data on the health consequences of military deployments. The VA therefore must be ready to rapidly address many difficult-to-answer questions each time troops are sent into combat. Are combat veterans experiencing more health problems than they should be? Have specific environmental hazards encountered during deployment caused health problems among returning veterans? Do returning veterans suffer from greater rates of specific diseases including cancers or mortality? And, what is the impact of combat deployment upon veterans' family and upon their reproductive health? Everyone of course wants immediate answers to these questions.

Although the best data on deployment-related health problems eventually comes from well-designed, long-term mortality and morbidity studies, the VA has developed a range of more rapid responses, including voluntary health examination registries, which have had many limitations, and more recently, electronic 'Combat Veteran Rosters' based on VA universal electronic healthcare records, which have been quite successful.

A unique clinical programme has also been developed within the VA to provide in-depth clinical assessments and healthcare to US veterans with health problems that are difficult to diagnose and treat. These health problems, which are often characterized as unique war syndromes, have been encountered after every major modern war (Hyams *et al*., 1996). There are now three WRIISCs in Washington, DC, New Jersey and Palo Alto, CA that provide for this specialized healthcare (Department of Veterans Affairs, 2008). Besides these clinic-based efforts, a concerted outreach and risk-communication programme is maintained by both the VA and DoD to inform veterans and their families about deployment-related health hazards and availability of healthcare and compensation (Brown *et al*., 2002).

Well-designed epidemiology studies are still needed after wartime deployments because they provide the most reliable information about the risks to veterans' health and because they are fixed in the public mind as the gold standard of research. However, they are generally not satisfactory for linking specific deployment-related exposure to specific occupational or environmental hazards with any specific health outcome, primarily because of the lack of useful exposure and troop location data during chaotic wartime conflicts.

Without good data linking hazardous military exposures to specific illnesses, policy development in the USA to assist military veterans often has had to rely on systematic reviews of all relevant medical literature for various exposed groups, whether military or civilian, by an independent scientific group such as the National Academies of Sciences Institute of Medicine. The development of fair and helpful policy for the healthcare and assistance of combat veterans potentially exposed to environmental hazards is not totally reliant on good science and frequently cannot be based on research studies of the exposed veterans themselves.

Biological Toxins in Warfare and Terrorism

R. Gregory Evans

CONTENTS

1 INTRODUCTION

Toxins are harmful biological agents produced by bacteria, plants and animals. They differ from chemical agents in that they are naturally occurring, are nonvolatile and, except for mycotoxins, are not dermally active. Toxins can be much more toxic than chemical agents (US Army Medical Research Institute of Infectious Diseases, 2005). They are also not persistent in the environment and are not transmittable from person to person. Toxins that are stable in the environment, highly toxic and easy to produce are candidates for use as biological weapons. Some toxins, such as mycotoxins and ricin, require much larger quantities than toxins such as botulinum to be effective in an open-air aerosol exposure; however, they can be effectively used in an indoor release. In this chapter, we will discuss the four toxins that are considered most likely to be used as biological weapons either by state entities or terrorist organizations (Franz *et al*., 1997). The list includes one highly lethal toxin, botulinum, two fairly lethal toxins, ricin and mycotoxins, and one that is considered primarily an incapacitating agent, staphylococcal enterotoxin B (SEB). Botulinum is a Center for Disease Control and Prevention (CDC) Category A agent, while the other toxins are CDC Category B agents. The likely route of intoxication for outdoor and indoor release of these toxins is aerosol; however, gastrointestinal intoxication can occur through poisoning of food. Aerosol release might be in a building, subway or tunnel. Water supplies might also be contaminated; however this is less likely because of chlorination and dilution. It is most likely that these toxins will be delivered by aerosol release because their lethality is much greater when inhaled than when ingested (Franz *et al*., 1997).

2 BOTULINUM TOXINS

2.1 Introduction

The botulinum toxins are a group of seven neurotoxins (types A through G) produced by bacillus *Clostridium botulinum* (*C. botulinum*) and two other *Clostridium* species. All seven types of neurotoxins act by inhibition of presynaptic acetylcholine release. Humans are naturally exposed to the toxins through food poisoning and through rare incidents of wound botulism and infant botulism (Tacket *et al*., 1989). *C. botulinum* toxin is a likely agent for use in biological warfare or as a terrorist agent because of its toxicity, stability, ease of production, and because humans are generally not immunized against it (Villar *et al*., 2006). Also, large quantities can be produced through fermentation. The toxin can be delivered by aerosol or can be used to contaminate food. One gram of crystalline toxin, evenly dispersed and inhaled, could kill more than 1 million people (Arnon *et al*., 2001). If the toxin is released outdoors, it would be widely dispersed and contaminate far fewer people than if the same amount were released indoors. Botulinum neurotoxin (BoNT) is easily denatured by environmental conditions that detoxify it within 12 hours in air and 1–3 hours in sunlight (US Army Medical Research Institute of Infectious Diseases, 2005). It is also inactivated by 20 minutes exposure to 3 mg l^{-1} free available chlorine.

Botulinum spores are found worldwide in soil and can germinate into vegetative bacteria that produce toxins during anaerobic incubation (Popoff, 1995). Naturally occurring animal and human disease arises from exposure to spores that germinate and produce BoNT *in vivo,* or from ingestion of preformed BoNT in edible or potable materials. Botulinum is the first biological toxin to be licensed for treatment of human disease such as cervical torticollis, strabismus, blepharospasm associated with dystonia, and cosmetically to treat wrinkles. Medical uses do not pose a bioterrorist threat because the amounts dispensed are far below a lethal dose.

Botulinum toxin was one of the first agents to be weaponized by the USA in the now-defunct offensive bioweapons programme begun during the Second World War and ending in 1970 (Arnon *et al*., 2001). Since then several countries and terrorist groups have used the toxin as a weapon. Evidence from the United Nations indicates that in 1995, Iraq had filled and deployed over 100 bombs with approximately 10 000 l of botulinum toxin (United Nations Security Council, 1995), although these weapons were destroyed prior to the US invasion of Iraq. The Japanese cult Aum Shinrikyo manufactured and attempted to disseminate botulinum toxin obtained from soil in Tokyo prior to their 1995 sarin nerve gas attack on the Tokyo subway (Tucker, 2000). The attacks failed because of faulty microbiological technique and inadequate aerosol-generating equipment (Arnon *et al*., 2001).

2.2 Description

C. botulinum produces neurotoxins that are the most toxic substances, per weight of agent, known to man, requiring only one nanogram per kilogram of body weight to kill 50% of the animals exposed. Botulinum toxin type A is 15 000 times more toxic by weight than the well-known organophosphate nerve agent VX, and 100 000 times more toxic than sarin (US Army Medical Research Institute of Infectious Diseases, 2005). BoNT is a protein with a molecular mass of approximately 150 kDa. The incubation period and severity of botulism depend on the rate and amount of toxin absorbed. Symptoms of food-borne disease may begin between 2 hours to 8 days after exposure (typically 12–72 hours) (Koenig *et al*., 1967). Timing of the onset of symptoms in inhalational exposure is difficult to estimate because of inadequate data; however, monkeys showed signs of botulism 12–80 hours after exposure (Franz *et al*., 1993). The incubation period might be considerably shorter after an aerosolized release of large amounts of BoNT.

C. botulinum is a classification that is applied to four diverse groups of organisms that produce similar neurotoxins (Aureli *et al*., 1986). They are anaerobic, motile by peritrichous flagella and are initially Gram positive but are often Gram negative or Gram variable after longer growth. When cultured anaerobically on blood agar, they are greyish-white translucent, round colonies with irregular borders that are encircled by a thin zone of partial haemolysis (Popoff, 1995). The four groups of *C. botulinum* are based on phenotypic physiologic characteristics (Hatheway and Bartlett, 2004; Popoff, 1995), and all are proteolytic. Group I organisms are proteolytic, producing BoNT/A and some produce BoNT/B or BoNT/F. Group II organisms are nonproteolytic and have a lower optimal growth temperature and lower maximum temperature of spore resistance than other groups. All BoNT/E producing strains are in Group II along with some that produce BoNT/B and BoNT/F. Group III organisms produce BoNT/C and BoNT/D but are distinguished from Groups I and II by their production of propionic acid as a product of fermentation. Group IV organisms lack any sugar fermentation or lipase production, but are proteolytic. BoNT/G is produced only by group IV (Greenfield *et al*., 2005).

Botulism, the disease caused by the BoNT has historically been a by-product of unsuccessful food preservation. *C. botulinum* grows and produces the neurotoxin in the anaerobic conditions encountered in home canning and other forms of food preservation such as smoking. The term *botulism* derives from the Latin for sausage, *botulus,* because frequent outbreaks in Germany resulted from making sausage by stuffing pig's stomach and then smoking it (Erbguth and Naumann, 2000). The spores can only be inactivated by heating to at least 85°C for 5 minutes.

Botulinum toxin is a simple dichain polypeptide made up of a 100 kDa 'heavy' chain joined by a single disulfide bond to a 50 kDa 'light' chain (Lacy *et al*., 1998). The toxin's light chain is a Zn^{2+}-containing endopeptidase that blocks acetylcholine-containing vesicles from fusing with the terminal membrane of the motor neuron, resulting in flaccid muscle paralysis (Montecucco, 1995). The mechanism of action is described by Arnon *et al*. (2001) in a consensus paper.

Release of acetylcholine at the neuromuscular junction is mediated by the assembly of a synaptic fusion complex that allows the membrane of the synaptic vesicle containing acetylcholine to fuse with the neuronal cell membrane. The synaptic fusion complex is a set of SNARE proteins, which include synaptobrevin, SNAP-25 and syntaxin. After membrane fusion, acetylcholine is released into the synaptic cleft and then bound by receptors on the muscle cell. Botulinum toxin binds to the neuronal cell membrane at the nerve terminus and enters the neuron by endocytosis. The light chain of botulinum toxin cleaves specific sites on the SNARE proteins, preventing complete assembly of the synaptic fusion complex and thereby blocking acetylcholine release. Botulinum toxins types B, D, F and G cleave synaptobrevin; types A, C and E cleave SNAP-25; and type C cleaves syntaxin. Without acetylcholine release, the muscle is unable to contract. SNARE stands for 'soluble NSF-attachment protein receptor'; NSF for '*N*-ethylmaleimide-sensitive fusion protein'; and SNAP-25, 'synaptosomal-associated protein of 25 kDa'.

2.3 Clinical Disease

Symptoms of botulism include difficulty seeing, speaking and/or swallowing. Neurological findings include ptosis, diplopia, blurred vision, often enlarged or sluggishly reactive pupils, dysarthria, dysphonia and dysphagia (Arnon *et al*., 2001; Franz *et al*., 1997; Shapiro *et al*., 1998; US Army Medical Research Institute of Infectious Diseases, 2005). Because of peripheral parasympathetic cholinergic blockage, the mouth may be dry and the pharynx injected. There are few sensory changes except infrequent circumoral and peripheral paraesthesias from hyperventilation resulting from fright. Extension of paralysis beyond the bulbar musculature results in loss of head control, hypotonia and generalized weakness (Arnon *et al*., 2001). Gastrointestinal symptoms of nausea, vomiting, diarrhoea or constipation and abdominal cramps may be present with food-borne exposure, but occur in only a little over half of the patients observed (Arnon *et al*., 2001). In the absence of secondary infection, fever is not present (Arnon *et al*., 2001; Bleck, 2000). Patients do not exhibit confusion or obtundation because BoNT does not pass the blood–brain barrier. The lethal dose of botulinum toxin in humans has been estimated at 0.09–0.15 μg intravenously, 70 μg orally and 0.70–0.90 μg inhalationally (Schantz and Johnson, 1992). In untreated patients death results from airway obstruction and inadequate tidal volume.

Some patients may be mildly affected and others so paralysed that they appear comatose and require months of ventilatory support. Severity and time of onset depend on dose. Recovery results from new motor axon twigs that sprout to reinnervate paralysed muscle fibres (Duchen, 1972; Mann *et al*., 1981).

A mouse bioassay that demonstrates BoNT in blood or stool neutralized by antisera is used for confirmatory diagnosis; however the test takes several days to complete (Middlebrook and Franz, 1997).

Mortality from food-borne botulism is approximately 6% (CDC, 1998). In surviving patients, paralysis requiring fluid and nutritional support, assisted ventilation and treatment of complications can last for weeks to months (Arnon *et al*., 2001). Therapy consists of supportive care and passive immunization with equine antitoxin. If passive neutralizing antibodies are administered early, nerve damage and severity of disease will be minimized but existent paralysis will not be reversed (Tacket *et al*., 1984). A pentavalent toxoid of *C. botulinum* toxin types A, B, C, D and E is available as an IND (investigational new drug) for pre-exposure prophylaxis, but is not widely available.

3 RICIN TOXIN

3.1 Introduction

Ricin toxin is derived from the bean of the castor oil plant *Ricinus communis*. It is one of the most toxic plant toxins, classified as a Category B bioterrorism agent and a Schedule Number 1 chemical warfare agent. Ricin is a likely agent for use in biological warfare or as a terrorist agent because of its toxicity, heat stability, relative ease in acquiring the castor bean, and the fact that the toxin can be extracted with little difficulty through a salting-out process (Wannemacher *et al*., 1992), and large quantities can be produced with low-technology equipment (US Army Medical Research Institute of Infectious Diseases, 2005). The toxin can be delivered by aerosol, ingestion and injection. Although the median lethal dose for ingestion in mice is $30\,mg\,kg^{-1}$, it is only $3–5\,\mu g\,kg^{-1}$ for inhalation, a 1000-fold difference (Audi *et al*., 2005). As little as $20\,\mu g\,kg^{-1}$ was a lethal inhalation dose in mice (Wong *et al*., 2007). If ricin was released outdoors, it would require a quantity that would be difficult for a terrorist to amass; however, an indoor release would require a much smaller quantity. It is stable under ambient conditions, can be detoxified

after 10 minutes at 80°C, inactivated by 100 mg l^{-1} free available chlorine, and decontaminated with soap and water (US Army Medical Research Institute of Infectious Diseases, 2005).

Over 1 000 000 tonnes of castor beans are processed annually. The waste mash is 3–5% ricin by weight. Humans can be naturally exposed to the toxin through the consumption of the castor bean. The US Chemical Warfare Service began studying the weaponization of ricin near the end of the First World War and this continued during the Second World War (Cookson and Nottingham, 1969). It was only in the 1990s after ricin was believed to be a potential terrorist weapon that work began on therapies and prophylactic measures (Franz and Jaax, 1997). Recently, ricin has been used by several extremist groups (Sharn, 1995; Goodman, 1996), and was mailed to a South Carolina postal facility (Schier *et al*., 2007).

3.2 Description

Ricin is a globular protein of 66 kDa that when purified is a water-soluble white powder (Parker *et al*., 1996). The toxic heterodimer consists of a 32 kDa A-chain that is bonded to a 32 kDa B-chain (Robertus, 1988). Both chains must be associated for toxicity. Both the A- and B-chains are globular proteins, with the A-chain tucked into a gap between two domains of the B-chain (Franz and Jaax, 1997). It is in a family of compounds that includes diphtheria, cholera, shiga and pseudomonas toxins (Kotb and Bronze, 2005). The toxicity of ricin varies between different animal models and route of exposure (Balint, 1974). Oral toxicity is 1000 times less than inhalational toxicity because of poor absorption of the toxin from the gastrointestinal tract (Franz and Jaax, 1997). Ricin's toxicity requires an association between both its catalytic A subunit and its B subunit. The ricin A-chain is a *N*-glycosidase that depurinates adenine, making the depurinated RNA susceptible to hydrolysis. The modified ribosomes are then unable to support protein synthesis, resulting in the toxicity.

The B-chain of ricin can bind to galactosides of cell-surface carbohydrates, while the A part is enzymatically active. The B-chain facilitates the transport of the A-chain into the cytosol (Youle and Neville, 1982). After entering the cytoplasm, the A-chain enzymatically attacks the 28S ribosomal subunit, causing cell death in 8–24 hours *in vivo* (Franz and Jaax, 1997). The endocytotic uptake of the protein is initiated by the binding of the B-chain to glycoside residue on the carbohydrate-containing protein and glycolipids (Franz and Jaax, 1997). The Golgi apparatus is involved in the pathogenesis of ricin intoxication (Gonatas *et al*., 1998).

3.3 Clinical Disease

The clinical signs and symptoms of ricin toxicity vary with the dose and route of exposure (Olsnes and Pihl, 1982); however ricin is deadly by all routes of exposure (Kotb and Bronze, 2005). Most of the information that we have on signs and symptoms comes from animal studies; there are limited data from human poisonings except from assassination attempts (Crompton and Gall, 1980) using injected ricin, and from children and adults ingesting castor beans (Rauber and Heard, 1985). Inhaled ricin will probably result in respiratory distress and airway and pulmonary lesions within 8 hours of exposure (Franz and Jaax, 1997). Symptoms might include cough, dyspnoea, arthralgias and fever (Audi *et al*., 2005). From 12 to 30 hours after exposure, inflammatory cells and total protein counts increase. Ricin binds to ciliated bronchiolar epithelial cells, alveolar lining cells and alveolar macrophages (Franz and Jaax, 1997). Toxicity increases with dose, and death occurs from severe hypoxaemia resulting from pulmonary oedema and alveolar flooding (Kotb and Bronze, 2005).

As indicated above, ricin is much less toxic by oral ingestion; however, eating 3–20 beans can be fatal (Bradberry *et al*., 2003; Franz and Jaax, 1997). Ingestion of sufficient quantities of ricin usually results in abdominal pain, nausea, vomiting, diarrhoea, dehydration, decreased urine production, gastrointestinal haemorrhage, hypotension, haemolysis, and necrosis of the liver, spleen and kidneys, vascular collapse and shock (Bradberry *et al*., 2003; Franz and Jaax, 1997; Kotb and Bronze, 2005). Other symptoms may include fever, sore throat, thirst, headache, confusion, convulsions and papillary dilation (Bradberry *et al*., 2003). Death in fatal cases is the result of multiorgan failure.

Information on injected ricin is quite limited, but in these limited studies, injections of high doses result in local lymphoid necrosis, liver necrosis, gastrointestinal haemorrhage, diffuse nephritis, diffuse splenitis (Franz and Jaax, 1997), nausea, vomiting, fever, chest and abdominal pain, myalgias and headache (Crompton and Gall, 1980; Fine *et al*., 1992; Targosz *et al*., 2002). Death is due to multiorgan failure.

Treatment for ricin poisoning by all routes is primarily supportive. It includes intravenous fluid and vasopressors for hypotension (Audi *et al*., 2005).

4 TRICHOTHECENE MYCOTOXINS

4.1 Introduction

Mycotoxins are a group of compounds that are products of fungal metabolism. They have been associated with disease in humans and animals that have

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat134
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

eaten fungus-infected agricultural products (Ciegler and Bennett, 1980; Sudakin, 2003). Mycotoxins are usually associated with terrestrial filamentous fungi commonly called moulds (Moss, 1989; Bennett and Klich, 2003). Mycotoxins that are of primary concern for causing disease are aflatoxins, rubratoxins, ochratoxins, fumonisins and trichothecenes (Wannemacher and Wiener, 1997; Ciegler and Bennett, 1980). They have acute, chronic, carcinogenic and teratogenic toxicity. This toxic effect is called mycotoxicosis (Peraica *et al*., 1999; Pitt, 2000).

The trichothecene mycotoxins are a group of 40 compounds that are the most likely mycotoxins to be used as a bioweapon against humans (Etzel, 2002; Zapor and Fishbain, 2004; Madsen, 2001; Holstege *et al*., 2007); therefore, we will limit further discussion to this group of toxins. They are of small molecular weight and are stable in the environment (US Army Medical Research Institute of Infectious Diseases, 2005), are active in small amounts, and can be delivered as dusts, droplets and aerosol from a variety of dispersal devices (Kotb and Bronze, 2005; Wannemacher and Wiener, 1997). They are the only biologically active toxins that are effective through dermal exposure. They are, however, maximally effective through the respiratory and gastrointestinal portals. There is evidence that mycotoxins were used as a bioweapon by the former Soviet Union in aerial attacks in Laos, Kampuchea and Afghanistan in the 1970s, and much of our information on human exposure derives from these attacks that were described as 'yellow rain'. There is still some controversy about this contention; however, there is substantial epidemiological and intelligence information to support the claim of use of trichothecenes in Southeast Asia and Afghanistan (Ember, 1984; Wannemacher and Wiener, 1997). This evidence indicates that trichothecenes are an effective bioweapon because they can be delivered by aerosol, can be produced in large quantities, and in powder and liquid forms that are stable when exposed to air, light and UV radiation (Committee on Protection Against Mycotoxins, Board on Toxicology and Environmental Health Hazards, Commission on Life Sciences, National Research Council, 1983). They also require high heats, over 580°C for 10 minutes or 260°C for 30 minutes for complete inactivation (Wannemacher and Wiener, 1997). Although past use has been outdoors, they can also serve as an effective terrorist agent that can be used in smaller quantities indoors.

4.2 Description

Trichothecenes are nonvolatile proteins of low molecular weight, between 250 and 550 Da (Cole and Cox, 1981), that can be absorbed slowly through skin but rapidly from the gastrointestinal tract and pulmonary mucosal surface. The major organ for metabolism is the liver (Matsumoto *et al*., 1978); however other tissues are capable of metabolizing the toxin (Wannemacher and Wiener, 1997). Carboxylesterase is important for detoxifying trichothecenes (Johnsen *et al*., 1986). The metabolized toxin is excreted in the urine and faeces but very little of the parent trichothecenes is excreted intact; they are eliminated via detoxification by biotransformation (Wannemacher and Wiener, 1997).

Trichothecenes have low solubility in water but are highly soluble in organic solvents (Cole and Cox, 1981). When extracted, they form a yellow-brown liquid that forms a greasy, yellow crystalline product upon evaporation. They rapidly inhibit protein synthesis (Zapor and Fishbain, 2004), and are toxic to eukaryotic cells (Wannemacher and Wiener, 1997). Trichothecenes act by inhibiting the initiation or the elongation process of translation and possibly by interfering with peptidyltransferase reactions (Wannemacher and Wiener, 1997). The primary toxic effects of the trichothecenes are caused by their ability to inhibit protein synthesis and the activation of the stress response that synergistically induces apoptosis and cell death (Pestka and Bondy, 1994). They are particularly cytotoxic to rapidly dividing cells such as in the bone marrow, gastrointestinal tract, skin and germ cells. These cytotoxic effects are referred to as radiomimetic because they imitate the haematopoietic and lymphoid effects of radiation sickness. They also have an immunosuppressive effect that increases susceptibility to infections (Kotb and Bronze, 2005), and do not appear to require metabolic activation prior to exerting their biologic effect (Busby and Wogan, 1981).

4.3 Clinical Disease

Unlike many toxic materials, a number of toxic responses are similar for all routes of exposure to trichothecenes, but can vary depending on whether the exposure is acute or chronic (Wannemacher and Wiener, 1997). The most likely mycotoxins to cause human disease are the T-2 mycotoxins (Kotb and Bronze, 2005). Acute exposure is most likely with warfare or a terrorist attack, and symptoms can begin within minutes to hours (Henghold, 2004). In these situations, T-2 can penetrate the skin, be inhaled, or be ingested, causing a multitude of symptoms (Nelson *et al*., 1994; Peraica *et al*., 1999; Hussein and Brasel, 2001; Etzel, 2002; Sudakin, 2003).

All routes of exposure produce gastric and intestinal lesions. Haematopoietic and immunosuppressive effects are radiomimetic (Wannemacher and Wiener, 1997). Central nervous system toxicity results in anorexia, lassitude, nausea and vascular effects resulting in hypotension and shock. In addition to these common symptoms,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

there are specific symptoms for dermal, oral, gastrointestinal and ocular exposure. Dermal symptoms such as burning pain, redness, tenderness, blistering and skin necrosis frequently begin within minutes of exposure (Henghold, 2004). Exposure to the mouth and throat causes pain and bleeding and, if swallowed, gastrointestinal toxicity resulting in abdominal pain, nausea, vomiting and bloody diarrhoea. Symptoms of ocular exposure include pain, burning, conjunctivitis, tearing and impaired vision. Inhalation results in nasal pain, itching and rhinorrhoea; the throat will be painful with possible voice change; bloody cough, low-grade fever, dyspnoea, wheezing and chest pain are frequent (Wannemacher and Wiener, 1997; Etzel, 2002). Systemic toxicity occurs via all routes of exposure. Symptoms include dizziness, loss of coordination, weakness and prostration. Death can occur in minutes, hours or days and is frequently accompanied by hypothermia, hypotension and tachycardia.

All therapy for mycotoxin toxicity is supportive, including respiratory support. There is no specific antidote or therapeutic regimen available. If ingested, standard poison therapy includes use of superactivated charcoal to absorb the toxin.

5 STAPHYLOCOCCAL ENTEROTOXIN B

5.1 Introduction

Staphylococcal Enterotoxin B (SEB) is produced by the *Staphylococcus aureus* bacterium (Jay, 1992). SEB is an exotoxin because it is excreted by the organism. It normally affects the intestines and therefore is referred to as an enterotoxin (Le Loir *et al*., 2003). SEB is one of the pyrogenic toxins that are produced by unrefrigerated meats, dairy and bakery products. It is the second most common source of food-borne outbreaks. Inhalation of SEB does not occur naturally and should be considered an act of terrorism. Most likely, an aerosol attack would occur in a closed environment such as a theatre, sports arena, conference centre or subway. Although an attack would not likely produce significant mortality, it could render 80% or more of exposed people incapacitated for one to two weeks (US Army Medical Research Institute of Infectious Diseases, 2005; Henghold, 2004). Symptoms from inhalation appear at doses 100 times less than the lethal dose (US Army Medical Research Institute of Infectious Diseases, 2005).

SEB was one of the biological agents stockpiled by the USA until 1969 (Ulrich *et al*., 1997). Because it could produce significant incapacitation after inhalation, SEB was considered valuable for military uses (Franz *et al*., 1997). It is also a potential terrorist agent if used in large-enough quantities to cause death.

5.2 Description

SEB is one of seven enterotoxins produced by strains of the *S. aureus* bacteria. It is a clump-forming, Gram-positive cocci that consists of 239 amino acid residues and has a molecular mass of 28 kDa (Ulrich *et al*., 1997; Johns and Khan, 1998). SEB is a relatively stable protein that is soluble in water. SEB production can be inhibited by sodium chloride and acetic acid; and alkaline conditions can also decrease production of SEB (Le Loir *et al*., 2003). It can withstand temperatures of up to 100°C. The effective dose (ED_{50}) for an aerosol release is $0.0004\,\mu g\,kg^{-1}$, and the lethal dose (LD_{50}) is $0.02\,\mu g\,kg^{-1}$ (Henghold, 2004).

The primary effects of SEB are mediated stimulation of T lymphocytes. SEB binds to the major histocompatibility complex (MHC) class II proteins, resulting in the stimulation of the proliferation of large numbers of T lymphocytes. It belongs to a class of immune stimulants referred to as 'superantigen's. They can bridge the MHC II on the antigen-presenting cells, and the T cell receptors on the CD4- and CD8-T cells (Kotb, 1998). This bridging results in a cascade of pro-inflammatory cytokines (interleukin-6, tumour necrosis factor-alpha and interferons) responsible for the systemic effects of the toxin (Proft and Fraser, 2003; Stiles *et al*., 1993). The gastrointestinal disease is, however, associated with histamine and leukotriene release from mast cells (Scheuber *et al*., 1987). Lethality of the pyrogenic toxins may be enhanced by endotoxin from Gram-negative bacteria (Stiles *et al*., 1993).

The cytokines cause a recruitment of additional immune effector cells, and the counter-regulatory feedback loops become poorly activated. Therefore, it is the body's own inflammatory response that mediates many of the toxic effects of SEB. The pulmonary oedema sometimes reported with aerosol exposure is more than likely secondary to T cell proliferation within the respiratory mucosa (Ulrich *et al*., 1997; Stiles *et al*., 1993).

5.3 Clinical Disease

There are markedly different clinical signs and symptoms when SEB is inhaled compared to when ingested. Gastrointestinal SEB toxicity is generally debilitating but can be fatal (Schlievert *et al*., 2000). The incubation period for ingestion is 4–6 hours (Bergdoll, 1985). Symptom onset is usually abrupt and includes intense nausea, vomiting, acute salivation, malaise, abdominal pain and diarrhoea. Physical examination may show hypotension, hyperperistalsis, tachycardia and diffuse nonlocalizing abdominal pain. Fever is generally present in gastrointestinal SEB toxicity. Most cases resolve in 8–24 hours.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat134
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There is little data available on the morbidity and mortality of inhalational SEB. Most of our information comes from studies on rhesus monkeys, other animals, and a small number of accidentally exposed laboratory workers (Ulrich *et al*., 1997; Rusnak, 2004). Symptoms associated with inhalation would most likely appear within 3–12 hours and include anorexia, emesis, diarrhoea and mastication. After 48 hours, symptoms can progress to lethargy, dyspnoea and facial pallor (Ulrich *et al*., 1997). Gastrointestinal symptoms may accompany inhalation due to swallowing of the toxin after mucocilliary clearance. On physical examination, patients are acutely short of breath and have substernal severe chest pain. Unlike gastrointestinal toxicity, patients may have a fever up to 41°C. Disease may progress to respiratory failure from pulmonary oedema caused by systemic inflammation that might lead to death. In general, evidence indicates that SEB is a potent immune stimulant and that the intense stimulation of T cells plays an important role in mediating the pathology of the disease (Ulrich *et al*., 1997).

Treatment is limited to supportive care that might include artificial ventilation and pain control.

6 SUMMARY

Protecting people from biological toxins that might be used by states or terrorist groups requires more research on rapid diagnostic methodologies to improve our ability to rapidly treat victims of toxin release. It is equally important that we develop improved vaccines, antitoxins and therapies to provide prophylactic and treatment alternatives if intelligence indicates an increased likelihood of the use of a specific toxin (Middlebrook, 2005). Although the toxins discussed in this chapter are the ones that current knowledge indicates are the most likely to be used, we must also keep our minds open to the possibility that there are other toxins that might also be used as bioweapons. Finally, we must be aware that innocuous microorganisms can be genetically altered to produce a toxin that is even more lethal than those naturally available.

Radiation Terrorism

Robin Beverly McFee

CONTENTS

1 INTRODUCTION

Hospitals and healthcare professionals (HCPs) are symbolic of public preparedness, healthcare leadership and safety within a community. The public hold healthcare facilities (HCFs) in esteem and hold high expectations that when a crisis occurs, hospitals and clinicians will be ready to respond and deliver appropriate care. Yet, the medical response to radiation—whether the result of radiological warfare, terrorist deployment of improvised radiation dispersal weapons, political assassination, occupational or industrial accidents, or the medically radiated patient—remains one of the least taught among all disciplines within medical education and least emphasized in non-nuclear designated facilities. This is in spite of a generation raised on the Cuban Missile Crisis, Three Mile Island and Chernobyl!

Research continues to demonstrate that many HCFs lack even the most basic and necessary antidotes suggested by the toxicology community (McFee *et al*., 2005; Geller *et al*., 2003; Waselenko *et al*., 2004; Leikin *et al*., 2003). If the most commonly used antidotes are inadequately stocked, what can be said about the supply of medications critical to treat WMD, especially radiation toxicity?

Going one step further, even within professional preparedness circles and in the aftermath of 9/11, when government initiatives focussed on medical vulnerabilities to toxicant threats, of all the categories of weapons of mass destruction (WMD)—whether using the CBRNE (chemical, biological, radiological, nuclear, explosive) or NBC (nuclear, biological, chemical) acronym—radiation is the least taught in professional schools, responder cultures or civil preparedness organizations. Yet a radiological event remains considered to be one of the most significant preparedness vulnerabilities, especially in terms of knowledge about and responding to such an emergency. To date, few HCPs—prehospital (emergency medical services (EMSs)) or hospital-based—possess the fundamental knowledge or skills to identify, let alone treat, a radiation victim; this vulnerability is made even more obvious in the aftermath of the high-profile assassination of former Russian agent Alexander Litvinenko. He was poisoned with polonium-210 (Harrison *et al*., 2007; McFee and Leikin, 2009; 2008; Stather 2007; International Atomic Energy Association (IAEA), 2009a).

Moreover, most HCPs and first responders consider themselves inadequately prepared for radiation events. Consider a recent online poll conducted by the *Journal of Emergency Services* (*JEMS*). The question was posed 'do you feel prepared to handle victims of a dirty (radioactive material) bomb?' (McFee and Leikin, 2008). Of the 246 respondents, 82% replied 'NO!' Compound this with the fact that most HCFs remain underprepared—from training to detection equipment to appropriate management materials. Since clinicians at HCFs are often insulated from the environmental circumstances or actual event, EMS can offer important insights; better training can enhance their ability to assist HCPs, especially emergency department (ED) personnel if a radiological event occurs.

Clearly, not all radiological events will be obvious. Nuclear materials or radiation-based weapons, without an explosion, may not be readily considered. Radiation is odourless, tasteless. An index of suspicion in the appropriate context will enhance the likelihood of considering and ultimately properly responding to such an exigency.

Mass or individual exposures to radiation present unique challenges to the entire response continuum from law enforcement, first responders and emergency medical care (Leikin *et al*., 2003).

For the prehospital responder, who often is the only medical provider with access to or first-hand experience of the event, recognition of signs and symptoms of exposure, focussing on the appropriate decontamination of patients and observing the entry/no-entry rules concerning hot, warm and cold zones is essential. Enhanced training should be initiated in the diagnosis, management and follow up of radiation among prehospital and emergency department professionals (Leikin *et al*., 2003; Flynn and Goans, 2006; Walter *et al*., 2000; 2003; NCRP, 2001; Thomas and Walter, 2008; National Institute of Occupational Safety and Health, 2009). As such, it is critically important for the first responder to convey as much information as possible to the receiving HCF. Self-protection of rescue personnel and reducing the risk to bystanders, as well as patients, is of paramount concern.

Most major metropolitan areas have designated nuclear-response hospitals, which are staffed and equipped to handle such an event. However, a radiation incident may occur closer to a rural or community hospital rather than a tertiary care or designated specialty facility. Consider the transit routes that radioactive wastes and medical radioactive materials traverse nationwide, and it is readily apparent that an incident en route could occur in any type of area—isolated or urban.

Given that radioactive substances are ubiquitous—from university, government and industrial research facilities to energy plants and military installations—it is likely that additional resources may be regionalized. However, in the immediate aftermath of an event—intentional or accidental—first response may be inadequately equipped or trained before transport is possible to advanced care. With radiation sources being in or transported through virtually every region nationwide, it is essential to increase preparedness, even among community and rural HCFs.

Managing radiation injuries effectively requires access to specialized equipment and expertise (Leikin *et al*., 2007; McFee and Leikin, 2005; 2008; 2009; Stather 2007; International Atomic Energy Association (IAEA),

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2009a; Jarrett, 1999; Christensen *et al*., 2008a; 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Schleipman *et al*., 2004; NCRP, 1979; REAC/TS, 2009; Fliedner *et al*., 2001; Gusev *et al*., 2002). Once at the HCF, clinicians must realize patients with radiation injuries can suffer from complex patterns of injury, reflective of the tissue and organs damaged, as well as trauma. Radiation sickness is progressive and may require acute, critical and long-term care throughout the course of illness.

Regardless of the source, preparedness rests upon acknowledging a threat exists and dedicating the resources to address the risks, including the enhancement of training and equipment. Accepting a threat exists suggests we go beyond thinking in terms of a nuclear holocaust or Chernobyl-like meltdown, to include dirty bombs or industrial incidents.

In this chapter you'll be introduced to the critical information you need to prepare for, diagnose and manage victims of radiation/nuclear events, assist your facility in identifying vulnerabilities, including training gaps, as well as opportunities to enhance awareness about the security of radioactive materials that might be easily stolen. Various threat scenarios, as well as well-documented events that have involved radiation will be discussed. Additionally, the type of equipment, agencies, experts and resources available to assist you in radiation response and other key considerations necessary to enhance your ability to respond and manage these patients will be covered in this chapter.

2 THE GLOBAL NUCLEAR THREAT

The chilling reality is that nuclear materials and technologies are more accessible now than at any other time in history.

Source: Former Director—US Central Intelligence Agency, John Deutch

Few threats evoke images of horror and raise as much concern as nuclear weapons or radiation events. The proliferation of nuclear and radiological materials globally, and the technology to create radiation-based weapons is evolving and spreading. Consider the growing group of nations in possession of nuclear weapons and others pursuing dual-use programmes—for energy and weapons. Numerous suitcase-sized one kilotonne thermonuclear weapons reportedly are missing and unaccounted for from the former Soviet Union. Concerns persist that they will appear on the black market and in the hands of terrorists or rogue nations (Graham and Talent, 2008). Terrorist groups, including Aum Shinrikyo—the cult that already demonstrated the willingness *and* ability to harm people in a mass casualty incident in Tokyo using the nerve agent sarin, resulting in more than 5500 people requiring medical treatment, and several deaths—Al-Qaeda and other terrorist groups, as well as Chechnyan extremists, have expressed interest in obtaining, have tested and attempted to deploy various types of radiological weapons.

The devastation from a nuclear device was clearly demonstrated when, in 1945, a 15 kilotonne weapon (by today's standards an improvised nuclear device (IND)) detonated over Hiroshima, Japan. In the blink of an eye there were an estimated 150 000+ casualties and 75 000 fatalities, thus illustrating the power resulting from unleashing nuclear energy weapons (Graham and Talent, 2008; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999).

Although the possession of nuclear weapons, even improvised ones, can dramatically alter the balance of power in a region (think North Korea, or India and Pakistan, or the potential for Iran to become a nuclear weapons nation) one of the primary reasons terrorists may elect to use radiological weapons is not necessarily to cause immense physical damage or loss of life, but to create widespread panic, psychological fear and undermine civilian authorities (Graham and Talent, 2008). The mere mention of a potential radiological release could cause significant and immediate public concern. Consider the number of inquiries the British Authorities received in the aftermath of the Litvinenko event (Harrison *et al*., 2007; McFee and Leikin, 2008; 2009; Stather 2007; International Atomic Energy Association (IAEA), 2009a).

In the December 2008 report to the United States President and Congress *World At Risk* by the Commission on the Prevention of Weapons of Mass Destruction Proliferation and Terrorism, 'unless the world community acts decisively and with great urgency, it is more likely than not that a weapon of mass destruction will be used in a terrorist attack somewhere in the world by the end of 2013'. The Commission further believes that terrorists are more likely to be able to obtain and use a biological weapon than a nuclear weapon. But they hasten to caution, nuclear materials are increasingly unaccounted for worldwide; worrisome since certain terror groups have expressed interest in deploying a radiological or nuclear weapon (Graham and Talent, 2008).

According to the US Secretary of Defense Robert Gates, 'every senior leader, when you're asked what keeps you awake at night, it's the thought of a terrorist ending up with a weapon of mass destruction, especially nuclear'.

The WAR report suggests unsecured materials, weapons trafficking and the ability for 'dual use' of nuclear materials—items that can be used in civilian energy or weapons - is an increasing threat worldwide.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

On 28 October 2008, Dr Mohamed El Baradei, the Director General of the International Atomic Energy Agency (IAEA), stood at the rostrum of the United Nations General Assembly and warned the world about nuclear terror (International Atomic Energy Association (IAEA), 2009b). 'The possibility of terrorists obtaining nuclear or other radioactive material remains a grave threat,' said Dr El Baradei. 'The number of incidents reported to the Agency involving the theft or loss of nuclear or radioactive material is disturbingly high,' he said. 'Equally troubling is the fact that much of this material is not subsequently recovered. Sometimes material is found which had not been reported missing'.

In every terrorist strike anywhere in the world, to every innocent life lost must be added thousands more who were just hours away from having been at that ground zero—in those moments of danger, we are all, first and foremost, citizens of a WAR, with the common cause of protecting the innocent and preserving our way of life.

According to National Intelligence Estimates by the US, as well as security evaluations from Interpol and other global watch-dog agencies, there is high likelihood of increasing numbers of nuclear nations, including North Korea and probably Iran in the not distant future, as well as increased trafficking of radiological materials—for legal and peacetime uses and black-market enterprises.

The future stability of Pakistan is a significant source of concern as a nuclear nation, that is, increasing its arsenal; their ability to secure those weapons in an unstable and dangerous region remains unknown. In a 2007 poll sponsored by the well-respected magazine *Foreign Policy*, among 117 terrorism experts queried about nuclear threats, 74% considered Pakistan the country most likely to transfer nuclear technology to terrorists in the next three to five years.

According to the National Nuclear Security Administration, Russia is a great concern as a source for radioactive materials. Then President, Vladimir Putin, admitted there were several suitcase thermonuclear weapons unaccounted for after the fall of the Soviet Union and international inspectors raise concern that some fissile and radioactive materials remain poorly secured in certain regions of Russia.

The availability of radioactive and nuclear materials to terrorist organizations is widely considered both a grave international threat and realistic exigency. It is well recognized that instructions on how to make a crude radiological or nuclear weapon are available on the Internet. The expertise is also available. The 'x' factor—and final, lethal step to successfully developing a viable weapon, is acquiring the appropriate radioactive materials.

Though beyond the scope of this text, while numerous agencies operating out of the United Nations and individual nations are tasked with controlling the spread of nuclear materials, it is important to realize that radioactive sources are in HCFs and universities, largely poorly secured, and provide an opportunity for theft and crude weapons development.

From a security, military perspective, **Table 1** lists the high-value radioactive materials (Jarrett, 1999).

Over the years there have been numerous industrial and criminal events, as well as terrorist actions and foiled attempts to disperse radioactive materials (**Table 2**).

2.1 Nuclear Terrorism: Radiation Threat Vulnerabilities

Nuclear terrorism is defined as the use of radioactive material in various forms to produce maximum disruption, panic, injury and fear in the general population (McFee *et al.*, 2004; Timins and Lipoti, 2003; Jarrett, 1999; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004).

Table 1 Threat-potential radioactive materials (Jarrett, 1999; Christensen *et al.*, 2008b)

Radioactive material	Radionuclides	Type of ionizing radiation
Americium	Am^{241}	Alpha, detectable by FIDLER from gamma. Heavy metal toxicant
Caesium	Cs^{137}	Beta and gamma
Cobalt	Co^{60}	Beta and gamma
Depleted uranium	DU	Alpha, beta and gamma (an inhalation and wound threat more than an emission threat. Absorption based upon chemical state of uranium)
Iodine	$I^{131,132,134,135}$	Beta and gamma
Phosphorus	P^{32}	Beta
Plutonium	$Pu^{238,239}$	In pure form alpha; when contaminated with americium it will have a detectable X-ray with the use of thin walled gamma probe.
Tritium	H^3	Beta emitter
Uranium	$U^{238,235,239}$	Alpha, beta and gamma

Table 2 Worldwide events associated with radiological/nuclear materials (McFee and Leikin, 2005; ED Management, 2002; Timins and Lipoti, 2003; Jarrett, 1999; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004)

Date	Location	Event
1987	Iraq	Allegedly tests radiological weapon. Does not generate high radiation levels; considered a failure.
	Brazil	The worst radiation incident in the Western Hemisphere. A source containing 1375 curies of ^{137}Cs is removed from a medical unit and its shield by scavengers. Numerous people are exposed. More than 100 000 individuals are screened, 249 are contaminated and four deaths and numerous hospitalizations result.
1991	Russia	Authorities are warned of a planned Chechnyan attack on a nuclear power plant.
1993	Russia	The Russian Mafia allegedly places gamma-emitting pellets in the office of a Moscow businessman, who subsequently dies.
1995	Russia	Chechnyan rebels bury a container with ^{137}Cs in a Moscow park.
1996	United States	Three individuals are arrested after discovery of their plot to place radium in the food, cars and toothpaste of Long Island politicians.
	Russia	Authorities are warned of a planned Chechnyan attack on a nuclear power plant (Balakovo).
1998	United States	Nineteen tubes of caesium used for treating cancer are reported missing from a North Carolina hospital. They are not recovered.
	Chechnya	Chechnyan Security Service discovers/defuses an RDD booby trap near a railway.
1999	Chechnya	In September, unidentified thieves attempt to steal a container housing 200 g of radioactive material from a chemical factory in Grozny. One of the thieves dies half an hour after exposure to the container; the other is hospitalized in critical condition. (Each carried the container for only a few minutes.)
	United States	The government issues a high alert during a search for six men who allegedly have photos and details of a US nuclear power plant.
	Russia	In December, two people scavenging for lead in a lighthouse on the northern coast are hospitalized after exposure to the powerful radioactive strontium source used to power the lighthouse. (In January 2003, the US government announces a plan to aid Russia in safely replacing the energy sources of all of its nuclear lighthouses.)
	Republic of Georgia	In December, heat-emanating containers, each housing 40 000 curies of strontium, are found by woodcutters in Lilo. Within hours, the men become ill with nausea, vomiting, and dizziness, and later develop severe radiation burns on their backs. The International Atomic Energy Agency (IAEA), on recovering the containers, finds that the amount of radiation of each is equivalent to the amount of radioactive strontium released immediately after the Chernobyl accident of 1986.
2002	United States	In June, the FBI arrests Jose Padilla, a US citizen also known as Abdullah al-Mujahir, at Chicago's O'Hare airport. Padilla is known to have ties to al-Qaeda and is suspected of researching dirty bombs with the intention of detonating one inside the country's borders.
2003	Afghanistan	Evidence uncovered in Herat leads British intelligence agents and weapons experts to conclude that al-Qaeda has succeeded in constructing a small dirty bomb, although the device has not been found. They believe the terrorist organization received radioactive sources used in medical devices from the Taliban regime.
	Iraq	In April–May, after the fall of Saddam Hussein's regime, a US military team finds that extensive looting has taken place at nuclear facilities. An IAEA team is allowed to inspect the looted facilities in June. It finds radioactive materials lying on the floor.
	Republic of Georgia	In May, Georgian police conducting a routine search of a taxi find two boxes of ^{137}Cs and ^{90}Sr, and another box containing nerve gas concentrate. The materials appear to have been headed to Turkey for resale. This event is one in a series of recoveries of radioactive materials in Georgia.
	Thailand	Thai police arrest a public school teacher in Bangkok after he attempts to sell a container filled with ^{137}Cs (believed to be of Russian origin) for $240 000.
	Great Britain	In July, a van containing 30 lbs of depleted uranium is stolen outside a British radioactive waste-processing firm.
	China	A Chinese nuclear medicine expert buys ^{192}Ir. He then places the pellets in his colleague's ceiling as a form of revenge. Soon after, the poisoned colleague begins complaining of memory loss, fatigue, loss of appetite, headaches, vomiting and bleeding gums. Before the radioactive pellets are uncovered, another 74 hospital staff members are found to have similar symptoms.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There are several forms of threat that could result in a radiological event (McFee and Leikin, 2005; Jarrett, 1999; Leikin *et al*., 2003; Walter *et al*., 2000; Christensen *et al*., 2008b; Schleipman *et al*., 2004; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004).

Five categories of terrorist threat can be considered:

- Simple radiological device (SRD) sometimes referred to as a simple dispersal device (SDD)
- Radiological dispersal device (RDD)
- Nuclear reactor sabotage
- Improvised nuclear device
- Nuclear weapon.

The most plausible threat would be an SRD or RDD, because hundreds of thousands of radioactive sources are available in industry and medicine around the world.

2.1.1 Simple Radiological Devices (SDRs); Simple Dispersal Device (SDDs); Radiation Exposure Device (REDs)

Use of an SRD, SDD or radiation exposure device (RED) is the deliberate act of placing a high-energy source or spreading radioactive material in a highly populated area, such as an airport, train station, port or sports venue, to expose people to various levels of radiation (McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008b).

SDRs/SDDs or REDs have been deployed and remain a threat that can be utilized by terrorists (**Table 2**). A psychological weapon, this form of radiation threat is more suited to cause panic than widespread injury. The mere mention of radiation causes concern and can create a panic, overwhelming HCFs with worried well, in addition to actual victims. Consider the 2006 murder of Alexander Litvinenko in London by polonium-210. Although widespread panic did not occur, nevertheless, the British National Health Service was deluged with calls and visits by people who feared they were exposed; albeit most were the worried well, and this was a selective target of one person, nevertheless, when over 1000 are concerned, imagine the impact, had the entire community or a section of London been targeted. However, the toxicity of such a device should not be taken lightly, especially given the radioactive materials suitable for such a weapon are ubiquitous and widely available sources are found in radiation oncology, industrial radiography and any number of other applications in medicine.

Caesium (Cs) is one of the most likely radioactive materials to be used in an SRD/SDD or RDD. It is widely available and utilized industrially. Other radionuclides include americium, which can be found in smoke detectors, and iridium.

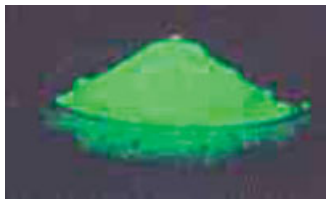

Figure 1 Caesium (McFee and Leikin, 2005). (Reproduced with permission from Radiation Emergency Assistance Center/Training Site (REAC TS).)

Especially problematic is the stealth with which an SDD could be deployed. If not announced as a weapon, no one would know about the device until patients presented with a variety of symptoms. Unless the clinician considered radiation—and this is unlikely in the early stages of illness based upon the level of radiation knowledge and preparedness among healthcare workers, and the results of the Litvinenko case where he was initially misdiagnosed—appropriate management would be delayed (Harrison *et al*., 2007; McFee and Leikin, 2008; 2009; Stather 2007; International Atomic Energy Association (IAEA), 2009a).

Though not an intentional act of terrorism, the events of 1987 in Goiânia, Brazil demonstrate the impact upon a community that 'innocently' spread radioactive materials can have and underscore our vulnerabilities (McFee and Leikin, 2005; Oliveira *et al*., 1991a; 1991b). Two thieves stole a hospital therapy device, and sold it for scrap metal. Unbeknownst to them it contained caesium-137 (^{137}Cs) in its shielding. The source consisted of 1375 Ci of ^{137}Cs. The source was broken up and shared among various individuals. At the time, these persons were not aware they had a radioactive source, and the incident was not detected for 15 days. When the container was opened, the contents, characteristically gave off a slight iridescence (**Figure 1**). Children and others started handling the caesium and subsequently started to develop a variety of symptoms. The medical response and cleanup phase took several months to complete. In this situation there was both exposure and contamination. When the government became involved, it developed into a significant public-health concern. The regional authorities required outside logistical support. The overall findings were as follows: 112 800 persons were surveyed for contamination, which involved providing a urine sample. The Brazilian government utilized a local sports venue to aggregate the population.

Victims included were as follows:

- 249 persons were contaminated
- 120 persons were externally contaminated on clothes and shoes
- 129 persons were both externally and internally contaminated

Figure 2 The early phase of acute local radiation injury is marked by atypical erythema extending roughly beyond the irradiated areas. Changes of sensitivity, burning pain, intense itching and tingling may occur (McFee and Leikin, 2005). (Reproduced with permission from Radiation Emergency Assistance Center/Training Site (REAC TS).)

- 20 persons required specific hospital treatment
- 14 persons had subsequent bone-marrow depression
- Eight persons received treatment with granulocyte-macrophage colony-stimulating factor (GM-CSF)
- Four persons died as a result of haemorrhage and infection.

A child ended up having an amputation. One deceased child at autopsy emitted several Gy.

^{137}Cs is ubiquitous as a medical and industrial radiation source. A common industrial usage is in the construction of highways, in which it is used in devices that measure density of asphalt. During the last 36 months, several such devices in the southeastern United States have been stolen or are missing; their whereabouts remain unknown. Sixteen brachiotherapy sources of ^{137}Cs were stolen from a hospital in North Carolina and, in Florida, an industrial radiography source of iridium-192 (^{192}Ir) was stolen. These sources have not been found. In addition to radiation risk from ^{137}Cs, this substance is highly toxic. There are numerous forms of Caesium. Some are explosive when exposed to air and water, some must be stored in special containment and, as a β-emitter, can cause significant dermal injury on direct contact. The initial burn can look like a thermal or sunburn (**Figure 2**).

Hospitals, industry and scientific research facilities, as opposed to military installations, are especially vulnerable to theft of radioactive materials. Industries that use such materials must implement safeguards and surveillance systems to ensure that these radiation sources remain fully accounted for.

2.1.2 Radiological Dispersal Devices (RDDs)

In an RDD, explosives are attached to a radioactive isotope and detonated. This can result in large areas of local environmental contamination, as well as patients being contaminated. RDD, though not posing the risk of devastation associated with thermonuclear devices, can nevertheless spread radioactive materials. The materials integrated in an RDD could be in several forms: gas, aerosol, solid, particulate, liquid or other. RDDs use conventional explosives, for example, trinitrotoluene (TNT), dynamite, plastic explosives or others, to pulverize or vaporize, then spread radioactive materials. This is commonly called a 'dirty bomb'. Radioactive materials that could be used in such devices are the same as those that could be used in SDDs above. However, RDDs as terror weapons would be highly effective; the explosion causing serious physical injuries from blasts, shrapnel/flying debris and thermal injuriess in addition to the threat of radiation toxicity. Moreover the psychological impact of 'radiation' in addition to the terror associated with a bombing would be highly effective (McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008b).

^{137}Cs has been identified as a potential radiation source for such a 'dirty' bomb or RDD. In this era of terrorism, responders must be aware of the secondary risk in responding to an explosion threat (McFee and Leikin, 2005; Jarrett, 1999; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; US Environmental Protection Agency, 2009). The targeting of first responders using secondary devices, usually explosives such as the IED (improvised explosive device) is well known. The additional threat of toxic substances—radioactive or not—enhance the risk. Therefore, the risk of a potential secondary device as well as a 'dirty' primary device must always be considered. The wide distribution of lower-level radioactive hazards that are frequently found in academia, medicine and industry are a persistent vulnerability, given they are relatively unsecured or located in moderately controlled settings.

2.1.3 Nuclear Reactor

In the Western world, the probability of a terrorist attack on a nuclear reactor is low, but recent events highlight the possibility. The low probability is due to the high security surrounding a nuclear reactor and the safety systems incorporated into it. There is extensive shielding around a reactor; therefore, very significant amounts of explosive would be required to breach the reactor core. Terrorist events could include use of very large amounts of explosives, but it would be extremely difficult for terrorists to breach the security cordon. It is possible that a jumbo jet could crash into a reactor or a nuclear pond of used reactor cores; given the events of 9/11, not as far fetched an exigency as previously considered (McFee *et al*., 2004; McFee and Leikin, 2005; Christensen *et al*., 2008b; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004).

Recently published results of computer and engineering studies suggest that the construction of most reactors would sustain a direct hit from a commercial aircraft flying into a reactor at less than 300 mph. However, some scientists question these findings. Most people are aware of the reactor accidents at Three Mile Island in Pennsylvania and the deadly explosion in 1986 at Reactor 4 of the nuclear power plant of Chernobyl, in the Ukraine, which at the time was a satellite member of the now former Soviet Union. The amount of radiation released from Three Mile Island was small indeed, and no radiation injuries resulted.

The most common type of incident of concern involving a nuclear reaction would be the disruption of the cooling system for the reactor core of nuclear fuel. Loss-of-coolant accidents (LOCAs) can result in failure to cool a reactor core, allowing it to reach temperatures at which the nuclear fuel and associated assembly melts (hence the term 'meltdown'). The cause may be a pipe break, valve failure or pump failure that interrupts cooling. Reactors generally are now designed to avoid an LOCA by automatic insertion of control rods to shut down the reactor before criticality occurs and sets the stage for a 'meltdown'. LOCAs may result in the release of radioisotopes such as srontium-90 (^{90}Sr), ^{137}Cs and iodine-131 (^{131}I), to name a few (Jarrett, 1999; Christensen *et al*., 2008b; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004). Medical management of workers or other individuals near the site of a reactor incident with release of radioactive materials may require immediate care for medical conditions, surgical conditions and thermal burns. If a plume were allowed to escape the reactor facility and containment structure, it would drift with the current wind conditions direction. Airborne, ground, environmental, animal and human contamination could occur in the plume's path, as with a nuclear weapon detonation. The impact from Chernobyl as a result of the plume effect reached into Scandinavia and beyond.

The Chernobyl reactor incident resulted because several safety systems were bypassed, while a set of experiments with the reactor were performed. There were two explosions, with fires and meltdown of the reactor core, leading to serious widespread contamination of the environment.

The early phase of the accident had the following results (Jarrett, 1999; International Atomic Energy Association (IAEA), 2009b; The Chernobyl Forum 2003–2005, 2009; World Health Organization, 2009):

- 237 persons were hospitalized
- 134 persons had acute radiation syndrome (ARS)
- 28 persons died within the first three months
- Two persons were killed in the initial explosion
- One person died of heart failure
- 250 000 persons were permanently evacuated from the area.

The primary radioactive isotopes responsible for health problems were ^{137}Cs and ^{131}I. Considering the gravity of the accident, it is commendable that the response-team actions led to low overall mortality.

2.1.4 Improvised Nuclear Device

An IND, if successful, could produce a nuclear yield similar to that of Hiroshima and Nagasaki, with release of radiation, blast and thermal pulses, together with significant radioactive fallout. In reality, a terrorist organization might be able to produce a partial yield, producing less effect. The conventional explosive would detonate and blow the device apart, resulting in environmental contamination with weapons material, such as plutonium or uranium (McFee and Leikin, 2005; Jarrett, 1999; Leikin *et al*., 2003; Walter *et al*., 2000; Christensen *et al*., 2008b; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004).

A review of the data suggests that the mean lethal dose (LD) of whole-body radiation necessary to kill by 60 days 50% of people exposed (LD50/60) is between 3.25 and 4 Gy, without supportive medical care. Survivors of Hiroshima had estimated doses of less than 3 Gy.

Construction heretofore of such a device has been considered highly difficult because of the sophisticated engineering and expertise required. More recent studies conducted by Harvard University and projects assessing the threat of nuclear terrorism have come to the conclusion that a capable, well funded and organized group could make, deliver and detonate at least a crude nuclear bomb capable of incinerating the centre of any major city in the world, *if* the necessary fissile materials were obtained.

For a crude 10 kilotonne weapon (two thirds that of the Hiroshima bomb) detonated at Grand Central Station—a major transportation hub located in Manhattan, New York City—it is estimated over 500 000 would be killed immediately and hundreds of thousands more would be injured. Depending upon wind direction, Manhattan would have to be evacuated—the mass exodus creating more injuries. Much of the island would be destroyed. Environmental impact and direct costs would exceed $1 trillion. The psychological impact would be incalculable (Kristoff, 2004).

2.1.5 Nuclear Weapons

Today's nuclear weapons are far more sophisticated than the kilotonne bombs detonated over Hiroshima and Nagasaki, with destructive power in the megatonne or higher category (McFee and Leikin, 2005; Jarrett, 1999; Leikin *et al*., 2003; Walter *et al*., 2000; Christensen *et al*., 2008b; NTI and The Center for Nonproliferation

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Studies at the Monterey Institute of International Studies, 2004).

Nevertheless, detonation of such devices in populated areas could result in tens, even hundreds of thousands of deaths. Physical trauma and thermal burns are the immediate hazards to life and limb. *Immediate deaths would not be the result of exposure to ionizing radiation* (*IR*). Patients not immediately near the epicentre who might survive may require treatment for physical injuries, thermal injuries, as well as radiation-induced injuries and illnesses (Christensen *et al*., 2008a; 2008b).

Recognize that a nuclear weapon, as with all explosions, creates enormous blast forces, which are the primary destructive force, along with thermal energy and radiation energy.

There are three forms of blast injury: primary, secondary and tertiary (Basic Disaster Life Support (BDLS) Course, 2004).

- Primary blast injuries involve the direct blast waves through overpressure forces, which are especially dangerous to gas-filled organs such as ears, lungs and the gastrointestinal (GI) tract. The brain can also be affected, and concussions can occur with seemingly no external injury. Bear in mind, if a victim has suffered from a tympanic membrane rupture, communications will be compromised, confounding the medical response. Also pneumothorax, pneumomediastinum, 'shock lung' and other air-membrane interfaces can be affected, some of which can result in significant medical/surgical attention, if not death.
- Secondary blast injuries result from flying debris that is now travelling at projectile velocity, resulting in blunt and penetrating injuries.
- Tertiary blast injuries result in the patient becoming the projectile. Numerous injuries are possible.

In addition to the blast effect would be significant thermal injuries. These burns, immediate from the explosion and some evolving from the radiation effect, require highly specialized burn and radiation infection-control measures.

Medical management of such a scenario would require extensive radiological and medical triage of patients to ensure appropriate and efficient utilization of public health and emergency medical resources.

While the probability of stealing a sophisticated nuclear weapon in the Western world is considered by many to still be a remote exigency because of high security, others are less optimistic (Graham and Talent, 2008; Christensen *et al*., 2008b; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; Basic Disaster Life Support (BDLS) Course, 2004).

However, there are two situations warranting concern. First, among the nuclear nations, at least two are politically and/or militarily unstable and pose a security risk in the region, and perhaps globally if their governments fail to control their weapons—North Korea and Pakistan. Second, and widely supported as worrisome, both Vladimir Putin and members of the Russian general staff, as well as security officers who have defected to the West, have stated publicly that several (estimates range from a handful to 50) suitcase nuclear weapons with a one kilotonne rating are unaccounted for in the former Soviet Union. These weapons are potential 'suitcase bombs', and represent an increasing threat, especially on the black market (McFee *et al*., 2004; Graham and Talent, 2008; Christensen *et al*., 2008b; International Atomic Energy Association (IAEA), 2009b; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; Basic Disaster Life Support (BDLS) Course, 2004).

The consequences within the first minute of detonation of a one kilotonne nuclear weapon are as follows (Jarrett, 1999; Nuclear Threat Initiative (NTI), 2009; Samuel and Dolan, 1977):

- Blast range would reach 400–500 yd
- Thermal radiation would reach approximately the same distance as the blast
- Nuclear radiation, that is, gamma particles and neutrons, would reach half a mile
- Radioactive fallout could produce high exposure rates up to half a mile.

Regardless of the nature of the threat, clearly the most serious scenario results in patients exposed to high level, high dose, acute whole-body or even partial-body gamma irradiation. As evident in **Table 1**, numerous radionuclides considered a military/security threat are gamma emitters. As will be discussed in the next section, gamma rays require special shielding, are high energy and potentially lethal.

Whether an IND, nuclear accident or nuclear weapon, widespread human, animal and agricultural impact from airborne, and environmental contamination are likely (Christensen *et al*., 2008b).

Since radioactive iodine (^{131}I) will be a likely threat, prophylactic thyroid-blocking therapy with potassium iodide (KI) will need to be initiated. KI supplies are stockpiled within a 10 mile radius of nuclear power plants. This will be discussed in Section 5.4 on Antidotes (International Atomic Energy Association (IAEA), 2009a; Christensen *et al*., (2008a; 2008b); Basic Disaster Life Support (BDLS) Course, 2004).

The National Council on Radiation Protection and Measurements (NCRP) Report Number 65 also contains an in-depth overview for dosages and methods of delivery (NCRP, 1979). When considering upgrading facility preparedness, it is important to become familiar with NCRP reports (Christensen *et al*., 2008b). Identification and quantification of internal contamination with various radionuclides is needed to guide chelation and/or other

decorporation therapies. Recognize there will be disruption of public infrastructure that will require mobilization of federal resources, such as the Federal Radiological Monitoring and Assessment Center (FRMAC), a multi-agency response contingency managed by the National Nuclear Security Administration (NNSA) of the US. For preparedness purposes, The Radiation Emergency Assistance Center/Training Site (REAC/TS, 2009) is a valuable consulting resource. If you are not located in the United States, identify the national and regional authorities in your country that would provide similar medical, security, environmental and resource services.

3 RADIOACTIVITY AND IONIZING RADIATION: A PRIMER

3.1 Radiation Chemistry

The periodic table of elements contains over 100; these are the building blocks for all substances on earth. Each element has an atomic structure consisting of a nucleus, electrons, neutrons and protons. Elements may occur in several forms called isotopes that differ in their nuclear properties (McFee and Leikin, 2005; Timins and Lipoti, 2003; United Nations, 2000; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Walter *et al*., 2000; Christensen *et al*., 2008a; 2008b; World Health Organization, 2009).

Isotopes may be either stable or unstable; the latter are referred to as radioisotopes because of the radioactive decay occurring in the basic structure which underpins the instability. There are literally thousands of radioactive sources.

Radioactive chemicals or isotopes within the element can also demonstrate toxic properties beyond radioactivity. There are forms of caesium and compounds including that element that can cause burns, or explode on contact with water (McFee and Leikin, 2005; US Environmental Protection Agency, 2009). Of note, unlike traditional chemical toxicants, radiation cannot be diluted with water to neutralize the toxicity. Water may create distance or pose limited shielding for relatively weak particles, but it cannot detoxify radiation. It is effective, especially with soap, in decontamination procedures to wash off particles from patients (Jarrett, 1999; Leikin *et al*., 2003; Christensen *et al*., 2008a; 2008b).

Knowing the decay rate, energy, amount and type of radiation associated with a particular isotope (radioisotope) is necessary to characterize the level of risk that a weapon or source hazard poses to human health.

Decay rate is usually expressed as the *half-life,* which is the amount of time it takes for half of the radioactive sample to decay. In notation it would appear as $t_{1/2}$. For example, after one half-life, 50% of the material is gone; after two half-lives 25% of the material remains, and so forth with each subsequent half-life. The range of possible $t_{1/2}$s for radioactive sources varies from seconds to thousands of years! The latter clearly has the potential to pose an environmental challenge (Leikin *et al*., 2007; McFee and Leikin, 2005; Timins and Lipoti, 2003; United Nations, 2000; Jarrett, 1999; Christensen *et al*., 2008a; 2008b).

Energy emission is isotope specific and measured in mega electron volts. In notation it would appear as MeV. The higher the MeV, the deeper the penetration into tissue, for example (McFee and Leikin, 2005; Timins and Lipoti, 2003; United Nations, 2000; International Atomic Energy Association (IAEA), 2009a; Christensen *et al*., 2008a; 2008b).

Amount of radiation is characterized by the number of nuclear transformations (disintegrations) per time period (usually a second), referred to by the conventional (US) unit of measure the curie (Ci) named after the discovering chemist and pioneer in radiation studies, Marie Curie, or the Système International (SI) term becquerel (Bq). One Bq = 1 disintegration per second; one Ci = 3.7×10^{10} Bq or disintegrations per second. In practical terms, what is the significance of the Ci for human health? Consider the banana—considered a good source of potassium in the diet. Each banana contains the radioisotope potassium-40 (^{40}K), making bananas a radiation emitter! However each banana contains 10^{-11} Ci. Compared to a radioactive cobalt pellet (^{60}Co) found in radiotherapy units to treat certain forms of cancer, which is 2 Ci; the banana is one billionth the emitter of Co^{60} (McFee and Leikin, 2005; Timins and Lipoti, 2003; United Nations, 2000; Christensen *et al*., (2008a; 2008b); Goans, 2007).

Either term (Bq or Ci) can be used to refer to the amount of radioactive material released into the environment. It is estimated that 81 million Ci of radioactive caesium was released into the atmosphere during the Chernobyl disaster.

Radiation is the emission and propagation of energy through a medium or space in the form of waves or particles; there are a variety of types of radiation within the electromagnetic spectrum, most of which do not have the energy to cause ionization. Radioactivity occurs because the nucleus of the atom is unstable, resulting in emission of energy (Leikin *et al*., 2007; McFee and Leikin, 2005; Timins and Lipoti, 2003; United Nations, 2000; International Atomic Energy Association (IAEA), 2009a; 2009b; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009).

Radiation can be measured in terms of emission from a radioactive source, absorption by a person or risk that a person might suffer health effects—the biological risks (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; Timins and Lipoti, 2003; United Nations, 2000; Thomas and Walter, 2008; Christensen *et al*., 2008a; Goans, 2007;

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Ricks *et al*., 1990; REAC/TS, 2009; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009). Depending on the aspect of radiation under discussion, different units of measurement are used. A release in the form of radiation is in proportion to the number of disintegrations of radioactive atoms in a radioactive material over a period of time. Radioactivity is a naturally occurring phenomenon; we are exposed to small amounts on a daily basis (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; Timins and Lipoti, 2003; United Nations, 2000; Thomas and Walter, 2008; Christensen *et al*., 2008a; Goans, 2007; Ricks *et al*., 1990; REAC/TS, 2009; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009). When a person is exposed to radiation, energy is deposited in the body. Radiation dose refers to the absorption of radiation energy per unit mass of absorber. The amount deposited per unit of weight, using the US conventional term is called the rad or radiation absorbed dose; the basic unit of measuring exposure dose is defined as the deposition of 0.01 J of energy into one kilogram of tissue. The Système International (SI) unit of measure is the gray (Gy); 1 Gy = 100 rad. The number of rads a patient has been subjected to allows clinicians to anticipate the potential severity of ARS and plan clinical management accordingly (Leikin *et al*., 2007; McFee and Leikin, 2005; 2009; United Nations, 2000; Harrison *et al*., 2007; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Waselenko *et al*., 2004; Flynn and Goans, 2006; Walter *et al*., 2000; NCRP, 2001; Christensen *et al*., 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; NCRP, 1979; REAC/TS, 2009; Fliedner *et al*., 2001; Gusev *et al*., 2002; Basic Disaster Life Support (BDLS) Course, 2004).

The risk that a person will suffer adverse health effects from radiation is measured using the unit rem (roentgen equivalent in man). The rem quantifies the amount of damage suspected from a radiation exposure. The SI unit is the Sievert (Sv); 1 Sv = 100 rem. The rem is adjusted to reflect the type of radiation absorbed and the likely damage produced (Leikin *et al*., 2007; McFee and Leikin, 2005; 2009; United Nations, 2000; Harrison *et al*., 2007; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Waselenko *et al*., 2004; Flynn and Goans, 2006; Walter *et al*., 2000; NCRP, 2001; Christensen *et al*., 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., (1990; 2002); NCRP, 1979; REAC/TS, 2009; Fliedner *et al*., 2001; Gusev *et al*., 2002; Basic Disaster Life Support (BDLS) Course, 2004).

Key Facts: For the intent and purpose of acute care, roentgens are equivalent to rads which are equivalent to rems.

Type of radiation refers to whether a source is IR or nonionizing radiation (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008a; Ricks and Fry, 1990; Schleipman *et al*., 2004; NCRP, 1979; REAC/TS, 2009; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; World Health Organization, 2009).

3.2 Nonionizing Radiation

Nonionizing forms of energy radiation include microwaves, as well as light—visible, ultraviolet and infrared. These forms of non-IR can still cause tissue damage by creation of heat (Leikin *et al*., 2007; 2003; Christensen *et al*., 2008a; World Health Organization, 2009).

3.3 Ionizing Radiation (IR)

Ionizing radiation is a form of energy that has the potential to remove electrons from other atoms. For example, in IR, by stripping a negative electron from an atom, an 'ion pair' is created—an electron and a positively charged atomic remnant. This process of 'ionization' creates instability in molecules, the most important of which, from a medical perspective, is cellular genetic material—deoxyribonucleic acid (DNA). Ionizing radiation can also damage cells by the hydrolysis of water to form highly reactive 'free radicals' which can propagate tissue destruction by chemical reactions (Leikin *et al*., 2003; 2007; Jarrett, 1999; Walter *et al*., 2000; Christensen *et al*., 2008a; World Health Organization, 2009).

Not all IR is the same. Within this category are several types of IR; the differences among types of ionizing radiation relate to their energy and charge. Their respective properties determine tissue toxicity: deeply ionizing radiation can penetrate cells, tissues or organs as they deposit energy along their tracks.

While the type of IR and resulting range of penetration vary, they also determine the nature of the absorber or barrier necessary to block their respective energy. This is the basis for shielding.

Penetration is determined by the circumstance—tissue/host type, distance from source and shielding, which have implications in terms of the health threat, type of personal protective equipment (PPE) required and prognosis. IR comprises alpha and beta particles, and gamma and X-rays (Leikin *et al*., 2003; 2007; Jarrett, 1999; Christensen *et al*., 2008a; World Health Organization, 2009).

Various technologies are used to characterize, interpret and even identify IR. 'Ionization' is the primary basis for locating radioactivity and radioactive materials. 'Spectrometry' is used to identify the energy of the radiation, allowing it to be compared to a known spectrum,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and is utilized to identify specific radionuclides. Each radionuclide has a unique energy spectrum much like every human has unique fingerprints.

3.3.1 Types of Ionizing Radiation

3.3.1.1 Alpha Particles

Alpha particles are large, charged particles (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; 2008; 2009; Harrison *et al*., 2007; Stather 2007; Jarrett, 1999; Christensen *et al*., 2008a; Ricks and Fry, 1990; Schleipman *et al*., 2004; NCRP, 1979; REAC/TS, 2009; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; World Health Organization, 2009). They are essentially helium nuclei consisting of two protons and two neutrons. They have significant mass and kinetic energy that can cause direct ionization of other atoms or molecules. Because of their size-to-speed characteristics and 2+ charge, they have little penetrating power. Intact skin, clothing, even paper, can stop alpha particles and are effective barriers to penetration. Examples of alpha emitters include americium, plutonium and polonium, which will be discussed later in greater detail. If the radiation source is strictly an alpha emitter, universal precautions are sufficient protection from external danger. However, it is important to recognize alpha emitters are significantly dangerous once internalized—through ingestion, inhalation or percutaneously via insertion/injection or contamination of wounds. IEDs that integrate toxicants, including radioactive materials, can internalize alpha particles into wounds. Intentional poisoning, as with the Litvinenko assassination, demonstrated the deadly nature of internalized alpha emitters (Harrison *et al*., 2007; Stather 2007; McFee and Leikin, 2008; Jarrett, 1999; Leikin *et al*., 2003; Flynn and Goans, 2006; Christensen *et al*., 2008a; Ricks and Fry, 1990; Ricks *et al*., (1990; 2002); REAC/TS, 2009). Once internalized, alpha emitters can cause ARS, and wide range of tissue effects, symptoms and organ damage. These particles pose a contamination risk and must be removed from victims (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; United Nations, 2000; Jarrett, 1999; Christensen *et al*., 2008a; Ricks and Fry, 1990; Schleipman *et al*., 2004; NCRP, 1979; REAC/TS, 2009; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; World Health Organization, 2009).

It is important to make certain *before an event* that radiation detectors can identify alpha particles. Responders should be familiar with the capability and limitations of the detectors. Usually special wands or sensor attachments are necessary and applied in specific ways.

3.3.1.1.1 The Alexander Litvinenko Case: Death by Polonium 210

On 1 November 2006, a previously healthy, athletic, 43-year-old Russian male, who had emigrated to London five years earlier, presented to a North London hospital with acute, severe, progressive GI symptoms (Harrison *et al*., 2007; McFee and Leikin, 2008; 2008; 2009; Stather 2007). As is now well known, he was a former Russian agent before becoming a writer in the UK. Whether Litvinenko intentionally withheld his prior occupational history or it was not initially pursued by clinicians remains unclear. Litvinenko's health rapidly deteriorated: his hair fell out and he developed pancytopenia. His symptoms were consistent with radiation toxicity; physicians obtained urine and blood samples and subjected them to gamma spectrometry. Not surprisingly, the tests came back negative, given that these were inadequate to the task (see following section on testing/management). Subsequently clinicians began searching for other causes of illness, including exotic toxins, biologicals and poisons; the patient's condition steadily declined. Because Litvinenko was not responding to treatment, his urine was sent for more advanced laboratory analysis to Britain's Atomic Weapons Establishment (BAWE), where tests revealed significant amounts of alpha-particle radiation (McFee and *et al*., 2008).

On November 23, Litvinenko died of internal contamination from Polonium-210 (^{210}Po). Twenty-one weeks elapsed between the poisoning and realization that radioactive materials were used, and as of January 2007, at least 12 people have tested positive for contamination. The incidental exposure of these individuals did not appear to pose a risk. However, fears of ^{210}Po contamination led thousands of people to contact the National Health Service's direct helpline, established in the aftermath of the assassination.

3.3.1.1.2 Polonium

^{210}Po is considered one of the most hazardous radioactive materials, but like other alpha emitters, it must be internalized to pose a toxic threat. Patients affected by ^{210}Po do *not* pose a health risk to responders. Intact skin is a good barrier. However, inhalation and ingestion are access points (Harrison *et al*., 2007; McFee and Leikin, 2008; 2008; 2009; Stather 2007).

Polonium was discovered in 1897 by Marie and Pierre Curie; Madame Curie named it after her native Poland. There are more than 20 isotopes of Po; ^{210}Po, the most stable form, is an alpha-particle (5.3 MeV)-emitting radionuclide with a radio-decay half-life ($t_{1/2}$) of 138 days. Unlike other radioactive elements, ^{210}Po is relatively safe to transport. However, if these high-energy particles are inhaled, ingested or inserted into abraded skins or wounds, they can damage tissue.

In the case of alpha emitters, such as ^{210}Po, identifying the source's nature as a contaminant, on the victim or in the area, requires equipment capable of detecting the full range of ionizing radiation types (Christensen *et al*., 2008a). Also, in the case of alpha emitters as toxicants, once inside the patient, especially if the victim

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is not externally contaminated, further investigation to determine the aetiology is recommended on the basis of the clinical picture, because external detection methods are unlikely to be of value for an internal toxicant. Advanced laboratory testing is required to evaluate biological samples and conduct blood tests.

Few human data are available on the health effects of ^{210}Po, but the toxicity of orally administered ^{210}Po appears to be consistent with the amount reaching the blood (bioavailability). Damage to the gut mucosa is a probable contributory cause of death after oral administration. In a Russian case of interest, a male worker accidentally inhaled an aerosol of ^{210}Po. Nine deaths occurred after 13 days (Harrison *et al*., 2007; Scott, 2007). Vomiting was severe at the time of admittance to a clinic, two to three days after the intake. A high fever was reported, but there was no diarrhoea. Thrombocyte counts were 150×10^9 l^{-1} on day 6 and 80×10^9 l^{-1} on day 8. Within minutes of ingesting ^{210}Po, the cells lining the victim's GI tract would begin to die and slough off, which would cause nausea, pain and severe GI bleeding. Other systems would be affected by ^{210}Po, and, unless early decorporative (chelation) treatment is initiated to lower the body burden and other medical interventions were provided, significant morbidity and ultimately death would be anticipated.

The earlier the initial symptoms of radiation poisoning (nausea and vomiting) occur, the more likely it is that it is a severe exposure (Jarrett, 1999; Christensen *et al*., 2008b). Although profound fear response and/or psychological exposure without actual radiation exposure can also cause nausea and vomiting, these don't tend to cause rapid hair loss and disruption of blood counts. In the presence of an actual exposure, persistent GI symptoms within the first two hours of exposure portends a poor prognosis and potentially fatal outcome.

There are other important alpha emitters of concern (**Table 1**) (Jarrett, 1999). These include americium, which can be found in smoke detectors, and plutonium, which is a highly controlled commodity produced from uranium (^{239,238}U) in reactors, often contaminated with americium and used in thermonuclear devices.

3.3.1.1.3 Lessons Learned from the Litvinenko Case

Although Litvinenko's symptoms were consistent with radiation illness, as a result of the initial hospital assessment, which apparently focussed on gamma radiation, radiation was abandoned and other diagnoses were sought. Of note, the Centers for Disease Control and Prevention (CDC) recommend a 24 hour urine collection to assay for the presence of ^{210}Po when suspected; levels in excess of background are suggestive of internal contamination (CDC, 2006). The essential issue is suspecting radiation toxicity early on and employing a full range of testing until it can be ruled out (Harrison *et al*., 2007; McFee and Leikin, 2008; 2008; 2009; Stather 2007; Scott, 2007; CDC, 2006).

3.3.2 Beta Particles

Beta particles (**Table 1**) are identical to electrons, have a negative charge, are very low in mass (1/2000 that of protons or neutrons) and possess a spectrum of energies. High-energy beta emitters can penetrate a few meters through air and a few millimetres into tissue. Like alpha emitters, beta emitters pose an internal hazard. However, beta emitters also pose an external hazard risk (McFee and Leikin, 2005; United Nations, 2000; Jarrett, 1999; Leikin *et al*., 2003; Flynn and Goans, 2006; Berger *et al*., 2006; Goans and Waselenko, 2005; REAC/TS, 2009; International Atomic Energy Association (IAEA), 2009b; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; Oliveira *et al*., 1991a; 1991b; US Environmental Protection Agency, 2009; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009; Hall and Giaccia, 2005).

Caesium-137 (^{137}Cs) is a ubiquitous beta emitter that has demonstrated an ability to cause human illness and has been utilized in SDDs (McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008a; Goans, 2007; Oliveira *et al*., 1991a; 1991b; US Environmental Protection Agency, 2009).

Recall the concept of MeV (McFee and Leikin, 2005; Christensen *et al*., 2008a). ^{137}Cs is a beta emitter (McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008a; Oliveira *et al*., (1991a; 1991b); US Environmental Protection Agency, 2009; World Health Organization, 2009). Beta emitters with just 0.1 MeV of energy emission can penetrate 0.15 cm into human tissue. Severe beta particle burns can occur on skin or the eye with protracted contact (**Figure 2**). Aluminium, tin foil or thick plastic protective clothing is required as an effective barrier. Caesium is a common source for beta particles. Like alpha particles, beta particles pose a significant internal hazard. These particles pose a contamination risk and must be removed from victims.

It is important to make certain *before an event* that radiation detectors can identify beta particles. Responders should be familiar with the capability and limitations of the detectors.

3.3.3 Gamma Rays

Gamma rays, also called 'photons' consist of electromagnetic energy or electromagnetic radiation. These high-energy uncharged particles are similar to X-rays and can readily penetrate most materials and matter, including skin and clothing, depending upon their energy. Gamma rays result in whole-body radiation and can damage multiple organ systems, albeit different tissues exhibit varying degrees of radiosensitivity; at

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

large enough exposures virtually all systems will be affected. Gamma emitters pose both an internal and external hazard (McFee and Leikin, 2005; Jarrett, 1999; Leikin *et al*., 2003; Christensen *et al*., 2008a; Goans, 2007; World Health Organization, 2009).

High-atomic-weight elements are used for shielding—heavy metals such as lead or depleted uranium. Concrete barriers can be used to shield against gamma radiation, usually in concert with heavy metals; in an emergency, setting up makeshift barriers, establishing perimeters that place space between people and gamma sources, and limiting time of exposure in the danger zone may be the most immediate, if imperfect, safety option. Doubling the distance from a source reduces the threat by 75%.

3.3.4 X-rays

X-rays are similar to gamma rays; high energy and able to readily penetrate skin, clothing and most matter. X-rays have longer wavelengths than gamma rays. Again, like gamma rays, special shielding is necessary (McFee and Leikin, 2005; Jarrett, 1999; Leikin *et al*., 2003; Christensen *et al*., 2008a; Goans, 2007; World Health Organization, 2009).

3.4 Radiation: 'Exposed' (Irradiation) and 'Contaminated'

Understanding the difference between these terms is critical to medical management (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; 2008; Timins and Lipoti, 2003; United Nations, 2000; Jarrett, 1999; Flynn and Goans, 2006; NCRP, 2001; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Schleipman *et al*., 2004; NCRP, 1979; Gusev *et al*., 2002; World Health Organization, 2009; Nuclear Threat Initiative (NTI), 2009; Hall and Giaccia, 2005). The 'irradiated' patient is one who has been 'exposed' to ionizing radiation (International Atomic Energy Association (IAEA), 2009a; Christensen *et al*., 2008a; NCRP, 1979; Mettler and Upton, 1995). One can consider it similar to patients who have had diagnostic X-rays. Just like the patient you have sent for an X-ray, purely irradiated or radiation exposed patients are *not* radioactive and pose no risk to others.

On the other hand, patients who are 'contaminated' have radioactive material on them (external contamination) or in them (internal contamination). This would be likely after exploring an SDD, stolen materials, as in the Goiana, Brazil event involving ^{137}Cs, or in the aftermath of a 'dirty' bomb or RDD (ED Management, 2002; Harrison *et al*., 2007; McFee and Leikin, 2008; 2009; Stather 2007; Jarrett, 1999; Thomas and Walter, 2008; Christensen *et al*., 2008a; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; NCRP, 1979; REAC/TS, 2009; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004). Patients are thus likely to have external contamination with radioactive materials on clothing or skin. These patients may pose a risk to others, depending upon the type of IR and quantity present. The proper use of PPE can significantly reduce this risk. Another important strategy: *removal of clothing* in such cases can reduce external contaminants by ~90% (McFee and Leikin, 2005; Jarrett, 1999; Leikin *et al*., 2003; Christensen *et al*., 2008a).

Internal contamination can occur with radioactive materials being inhaled, ingested, as occurred in the Alexander Litvinenko murder using ^{210}Po, penetration or percutaneous absorption (McFee and Leikin, 2005; 2008; 2009; Harrison *et al*., 2007; Stather 2007; Jarrett, 1999; Christensen *et al*., 2008a; 2008b; Goans, 2007; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004). In the event of a radiation-associated explosion, wounds may become contaminated with radioactive materials, which may become embedded in tissue.

Key Facts: The radiation-poisoned patient poses little risk to healthcare workers, especially if proper precautions are taken. Do not delay life-saving care because the patient is a 'radiation victim'. Hospital personnel safely handle patients on a daily basis who have had nuclear medicine scans and who are internally contaminated with injections of radioactive materials.

Enlist the assistance of a radiation health physicist (HP) early, as s/he will be well schooled in the critical science and convergence points of radiation and human health.

3.4.1 Radiation Damage: 'Deterministic' and 'Stochastic' Effects

The amount of damage to an organism is related to the dose, which, in terms of radiation, is the total amount of energy deposited. Traditional tenets of managing the poisoned patient are built upon the notion that the dose determines the difference between harmless and harmful—a 'deterministic' effect. These have a threshold at which an expected effect will appear. Above that threshold, as radiation dose increases, the effects become worse, as will be discussed in Section 4 on Acute Radiation Syndrome (McFee and Leikin, 2005; Christensen *et al*., 2008a; Goans, 2007).

An important linked consideration is the dose rate—the time over which ionizing radiation energy is deposited. The shorter the time period during which the energy is delivered, the greater the effects.

The impact of the dose is also to some degree influenced by the volume of cells or tissues absorbing the dose—the larger the volume of tissue irradiated, the greater the effects.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The type and function of the cells receiving the dose also influences the outcome; some tissues are more radiosensitive at certain doses than others.

Of note is that the schedule of dose delivery has an influence on outcomes as well. If a dose is delivered in smaller divided doses or is *fractionated*, compared to giving the entire dose at one time, more significant effects will be seen with the single acute dose. Fractionation allows some repair of damage between doses.

As with other toxicants, the type and quality of radiation is important.

Host considerations play a role. The young and old are more susceptible to radiation injury and illness than more robust adults. Patients suffering from other injury or illness, for example, combined injuries, defined as radiation injury with trauma and/or thermal burns have increased morbidity and mortality. There are, as can be seen in more traditional illnesses, individual variations in susceptibility. No two persons are alike in their ability to withstand any kind of insult, whether it is a disease or toxic exposure involving radiation, chemicals, biological toxins, trauma or thermal injuries.

'Stochastic effects' have 'no lower threshold' (NLT) at which the effects are seen (Christensen *et al*., 2008a). They are random or probabilistic 'events' rather than 'effects'. In the crudest terms, radiation exposure imposes greater than a zero threat. Put another way, the number of cancers generated, or cancer incidence, increases with increasing radiation dose to a population, but the various types of cancer that develop do not become 'worse'. For purposes of emergency care, a thorough understanding of stochastic effects is not necessary, but will be necessary for patient counselling about the potential for various cancers after an incident.

3.4.2 Tissue Sensitivity

Cells that are less differentiated are generally more radiosensitive than more differentiated cells. Stem cells or precursor cells are generally more sensitive to radiation than more differentiated cells, for example, red blood cells (RBCs), sperm, striated muscle cells or neurons, to name a few. However, at high enough doses, these, too become susceptible to the effects of radiation.

Cells that are actively dividing are generally more radiosensitive than those that are not actively dividing. Haematopoietic cells in bone marrow actively divide and are much more sensitive compared to nervous system tissues that do not rapidly divide (Jarrett, 1999; Christensen *et al*., 2008a; Goans, 2007).

Sensitivity is also determined by life stage. Embryos and the foetus are more sensitive than later development *in utero*. Children are more radiosensitive than adults. Some organs are more radioresistant than others, for example, the thyroid gland is more radiosensitive than the liver.

3.5 Protection Against Radiation

The three primary ways to protect against radiation are time, distance and shielding (Leikin *et al*., 2007; McFee and Leikin, 2005; Jarrett, 1999; Thomas and Walter, 2008; Christensen *et al*., 2008a).

- Time: Exposure and absorption of radiation are dose and time dependent. By limiting the time in a radiation environment, the exposure is limited—one of the bases for rotating medical and response teams, and keeping individual doses to a minimum during victim rescue. No treatment should occur in the exposure or hot zone.
- Distance: Distance reduces the exposure. Keeping the maximum distance possible between yourself and the source is an essential consideration in response, and benefits both the rescuer and the victim. The inverse square law applies: if you double the distance between yourself and the source, the exposure will be reduced to one fourth of its original value. The reduction of exposure is exponential.
- Shielding: Different types of shielding strategies are required, based upon the various ways the different forms of IR behave (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008a). Paper or hospital protective clothing, such as universal precautions will stop alpha particles and external alpha contamination. Beta particles require stronger shielding, which includes aluminium or thick plastic. Universal or standard protective clothing will provide only partial protection. Gamma and X-rays can be attenuated, but not fully stopped, by lead, thick concrete or depleted uranium. Buildings, vehicles or makeshift barriers with heavy materials may provide some shelter in an emergency; limiting exposure time may be the only option.

Recognize that contaminated materials or clothing can pose a threat to the ambulance and crew—ideally removing such materials at the incident site and appropriate storage will enhance responder and patient safety.

3.6 Biological Effects of Radiation

Radioactivity is a naturally occurring phenomenon; we are exposed to trace amounts on a daily basis. Whenever a person is exposed to radiation, energy is deposited in the body. (Jarrett, 1999; Christensen *et al*., 2008a; Goans, 2007; World Health Organization, 2009; Leikin *et al*., 2007; McFee and Leikin, 2005; International Atomic Energy Association (IAEA), 2009a; Hall and Giaccia, 2005).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.6.1 Survival Probable

Patients with exposures less than 100 rad should have very few signs and symptoms if any, although nausea and vomiting are possible, which generally subside in a few hours (Christensen *et al*., 2008a; 2008b).

3.6.2 Survival Possible

Patients exposed to 200–800 rad present with nausea and vomiting that may last 24–48 hours. Reverse isolation, haematology, infectious disease and immunology management are critical. Patients will develop bone-marrow and haematopoietic suppression. Death can occur without strict attention to infection control, the use of blood replacement products and colony-stimulating factors (CSFs). Even antiviral and antifungal agents may become necessary (Jarrett, 1999; Christensen *et al*., 2008a; 2008b).

3.6.3 Survival Improbable

Patients who have received whole-body exposures in excess of 800 rad (some authorities suggest 1000 or above) face a poor prognosis. Even with short-term survival, long-term outcomes are poor. While there have been successfully treated patients who received 800–1200 rad, they often develop severe lung damage a few months later and die (Jarrett, 1999; Christensen *et al*., 2008a; 2008b).

If a mass casualty incident has occurred, patients suspected of receiving very high doses are to be made as comfortable as possible and assigned a non-clinical companion for compassionate care, because survival is unlikely, and resources and clinical manpower limited.

Depending upon the dose, patients are more likely to survive in this era with the development of more effective chemoprophylaxis, infection control, antidotes and intensive care than in prior times.

4 ACUTE RADIATION SYNDROME (ARS)

4.1 Overview

ARS describes a serious pattern of injury that occurs when the body receives a high dose of penetrating radiation over a short period of time (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; 2009; Harrison *et al*., 2007; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Waselenko *et al*., 2004; Flynn and Goans, 2006; Christensen *et al*., 2008a; 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; REAC/TS, 2009; Fliedner *et al*., 2001; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995). The illness follows a predictable clinical course proportionate to the significance of exposure over a few hours to several weeks. The time interval from exposure to symptoms depends upon dose; the higher the dose the shorter the time interval (Leikin *et al*., 2003; 2007; McFee and Leikin, 2009; 2005; Harrison *et al*., 2007; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Waselenko *et al*., 2004; Flynn and Goans, 2006; Christensen *et al*., 2008a; 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; REAC/TS, 2009; Fliedner *et al*., 2001; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995).

High dose, high dose rate, penetrating or whole-body exposure are likely to produce severe, possibly fatal ARS. Host factors can play a part in the illness. Age, pre-existing medical conditions, especially chronic, debilitating disease and genetic considerations are also factors. In terms of clinical considerations, the source of radiation, once ARS occurs, becomes irrelevant. Whether a weapon of mass destruction, an industrial accident or a nuclear reactor, if the dose is high enough, it will produce the same ARS effects.

ARS represents clinical manifestations—a spectrum of radiation-induced illnesses whereby the signs and symptoms associated with a specific range of exposure dosages will appear relatively predictably over time.

For example, at low, survivable doses there may be a delay between time of exposure and time of symptoms for days or weeks and, in some cases, months. ARS, which is divided into subsyndromes—haematological (haematopoietic), cutaneous, GI and cardiovascular/neurovascular syndromes—is characterized by the development of groups of symptoms and signs that are manifestations of acute irradiation of the whole body or significant portions of it.

Living cells are differentially sensitive to radiation, referred to as their 'radiosensitivity' or 'radioresistance' (Christensen *et al*., 2008a). This variable sensitivity is the basis for the constellation of symptoms and signs that will appear as the dose of acute whole-body irradiation (WBI) increases. The reactions of various tissues to radiation exposure depend upon a number of factors, including, but not limited to, dose, dose rate, volume of tissue irradiated, schedule of dose delivery, type and quality of radiation, and host factors such as age, other medical conditions and individual variations, among others.

It is important to recognize that *the time to onset of symptoms and signs becomes shorter as the radiation dose increases* (Leikin *et al*., 2003; 2007; McFee and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008b). The duration of clinical signs and laboratory findings also becomes shorter, that is, the injury or illness progresses more quickly as the dose increases.

Circulating peripheral lymphocytes are among the most radiosensitive. Lymphocytes are highly differentiated (International Atomic Energy Association (IAEA), 2009a; Christensen *et al*., 2008b; Goans, 2007; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003). As they do not undergo mitosis they can nevertheless be killed by radiation during interphase. Many other cells are more sensitive at mitosis. Because of the sensitivity of lymphocytes to radiation injury, loss of these cells can occur relatively quickly—within hours to days. This feature allows clinicians to use lymphocyte depletion kinetics as a biodosimeter.

Stem cells or precursor cells to sperm and blood cells (spermatogonia and myeloblasts) are radiosensitive (Christensen *et al*., 2008a; 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; REAC/TS, 2009; Fliedner *et al*., 2001; Gusev *et al*., 2002; International Atomic Energy Association (IAEA), 2009b; Basic Disaster Life Support (BDLS) Course, 2004; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003). Damage to these cells will not become manifest for some days to weeks after radiation injury. Tissues that are considered 'body barriers', such as skin, mucosal linings of the GI system and respiratory tract, and small blood vessels, are less radiosensitive, especially at low-dose short exposure. Significant damage to these cells appears much later, on the order of weeks to months, and sooner at higher doses. Osteocytes, spermatocytes, mature sperm, mature white blood cells, mature RBCs, fibrocytes, chondrocytes, muscle cells and nerve cells are progressively more radioresistant (Christensen *et al*., 2008a; 2008b; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003). The appearance of damage to these cells occurs over weeks, months or years, and at even higher doses.

It is important to remember two distinct, but important, scenarios:

1. If a known event involving radiation has occurred, practitioners can be expectant of certain systemic illnesses related to radiation exposure
2. If patients present to hospital without a known history of radiation exposure, it is important in the appropriate context of a constellation of symptoms that may not initially seem the result of a 'unifying' infection or pathology, to keep radiation and toxicity within the differential diagnosis. Clearly in the early onset of exposure, especially a low-dose exposure, such patient presentations can be confusing to the unwary clinician. Depending upon the nature and timing of exposure(s), patients may present with mixed symptoms and several signs of ARS.

Key Facts: The notification of a radiation exposure can be worrisome for both the patient and clinician. It is important to remember the following: ionizing radiation at *survivable* doses does not cause the following:

- *Sudden* death
- Incapacitation.

Fairly sudden loss of consciousness, seizures, hypotension and other signs can occur with acute ionizing radiation exposure, but would indicate an LD if the exposure was acute.

Ordinarily, especially in low or survivable doses, loss of consciousness, seizures, hypotension—such severe symptoms and signs will have another aetiology. Even after lethal doses of ionizing radiation, death should not occur for many hours to days, sometimes even months.

Remember—very early, 'non specific' symptoms such as anorexia, nausea, vomiting and low-grade fever may appear with significant *survivable* doses of ionizing radiation AND these are usually *transient*. They are merely a prelude or a prodrome to the phases of ARS to follow.

4.2 Phases of Acute Radiation Syndrome

The evolution of ARS and its various subsyndromes may roughly be divided into four phases: the prodrome, the latent phase, the period of manifest illness and, lastly, the period of recovery or death. The time to onset of each phase and the duration of symptoms and signs is determined by a large number of factors, as discussed above (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; 2009; Harrison *et al*., 2007; International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Waselenko *et al*., 2004; Flynn and Goans, 2006; Christensen *et al*., 2008a; 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; REAC/TS, 2009; Fliedner *et al*., 2001; Gusev *et al*., 2002; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

- Prodromal phase: In the prodrome, any signs and symptoms are generally considered 'non-specific' such anorexia, nausea, vomiting, fatigue and perhaps low-grade fever (Leikin *et al*., 2007; McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008a; 2008b; Goans, 2007; World Health Organization,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

- Latent phase: No clinical signs are apparent at all. Significant doses will result in a more-or-less slow progression of cellular damage that will not be evident until the manifest illness phase (Leikin *et al*., 2007; McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008a; 2008b; Goans, 2007; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).
- Manifest illness phase: Symptoms and signs of damage to specific cells and tissues will begin to appear, based upon their radiosensitivity (Leikin *et al*., 2007; McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008a; 2008b; Goans, 2007; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).
- Period of recovery or death: If the dose absorbed is not too high, recovery can be complete or can be incomplete, with persistent or long-term sequelae (Leikin *et al*., 2007; McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008a; 2008b; Goans, 2007; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

It is important to recognize that, like other clinical conundrums, the greatest challenge to the clinician is to make a diagnosis of acute or chronic radiation-induced injury or illness in the absence of an event history. This difficulty arises because the various constellations of symptoms and signs of radiation illness, especially in the early stages, look much like more common injuries and illnesses.

4.3 Syndromes of Acute Radiation

While the clinical team will be called upon to address radiation injury, it is important to remember these patients may suffer from combined injuries, that is, radiation injury or illness, plus trauma or thermal burns (**Table 3**). Combined injuries significantly increase morbidity and mortality, that is, they significantly lower the radiation LD50/60. The key to treating these patients is understanding the likely progression of physiological damage associated with exposure, and planning treatment rapidly and accordingly (Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007).

4.3.1 Radiation Lethal Dose 50/60 (LD50/60)

In humans, the LD50/60 is approximately 3.5 Gy (350 rads) for acute WBI without treatment. Of a population uniformly exposed to such a dose of ionizing radiation, 50% will die within 60 days if not aggressively treated. The goal is to push the LD50/60 to a higher dose.

Table 3 Acute radiation syndromes and the exposure range associated with them (Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007)

Acute radiation subsyndromes	Exposure range
Subclinical	<0.75–1 Gy (75–100 rad)
Haematopoietic	>1–2 Gy (>100–200 rad)
Cutaneous	>3 Gy (>300 rad)
Gastrointestinal	>6 Gy (600 rad)
Respiratory	>6 Gy (600 rad)
Cerebrovascular/Central Nervous System (CV/CNS)	>30 Gy (3000 rad)
Neurovascular	

Gy = 100 rad.

4.3.2 Subclinical

Most patients who receive below 100 rads (<1 Gy) are unlikely to have significant illness resulting from their exposure. About 10% of patients exposed at this range may still vomit. Nevertheless, the prognosis is good (International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Waselenko *et al*., 2004; Christensen *et al*., 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; Fliedner *et al*., 2001).

The complete blood count (CBC) may be useful in determining the effect of the radiation on the haematopoietic system. The dicentric assay from chromosomal aberration analysis may be necessary to determine doses below 100 rads and guide management.

4.3.3 Haematopoietic Syndrome

The haematopoietic system exhibits the earliest indications of the severity of radiation exposure manifest by the rapid decline of the lymphocyte cell line. This decline leads to immune system dysfunction, increased risk for infectious complications, anaemia, delayed and impaired wound healing and haemorrhage. A whole-body exposure of as little as 100–800 rad will produce the haematopoietic syndrome (Leikin *et al*., 2007; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Waselenko *et al*., 2004; Walter *et al*., 2000; Christensen *et al*., 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; Fliedner *et al*., 2001; Daniak *et al*., 2003).

Infection remains a leading cause of death among radiation-exposed victims resulting from immune-system

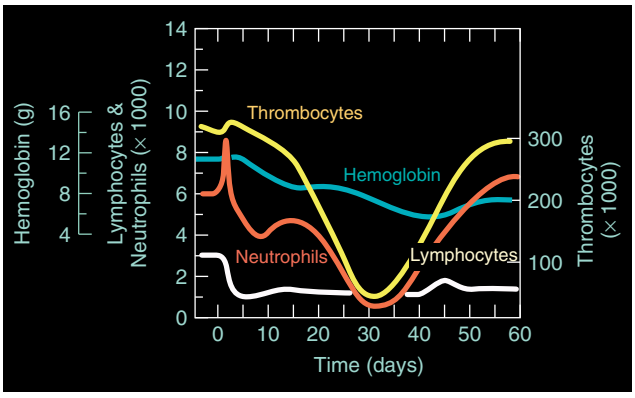

Figure 4 Haematological response to whole-body ionizing radiation at 3 Gy. (Reproduced with permission from International Atomic Energy Agency (IAEA).)

dysfunction. Strict attention to infection control, promotion of host defences through CSFs, nutritional support and chemoprophylaxis is essential.

Acute radiation, or WBI with doses from 1 to 2 Gy (100–200 rad) can cause progressive reduction in cells within bone marrow and peripheral blood as the dose increases (**Figures 3** and **4**; (International Atomic Energy Association (IAEA), 2009a; 2009b).

Stem cells can become depleted. Leucopenia and sometimes pancytopenia may result (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003). Not unexpectedly, the risk of infections in the radiated patient is expected. Other complications include haemorrhage, anaemia and impaired wound healing. The latter requires early surgical consultation in the

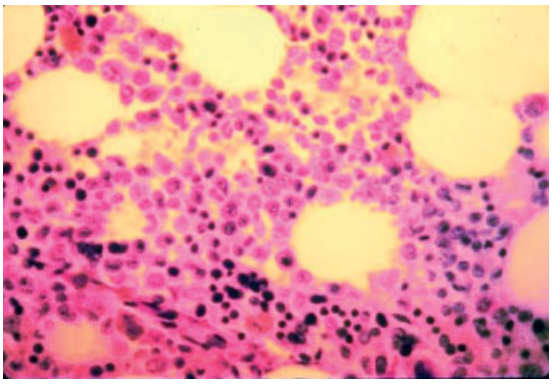

Figure 5 Normal bone marrow. (Reproduced with permission from International Atomic Energy Agency (IAEA).)

event of trauma or injury, since critical decisions when to perform surgery and wound closure must be made based upon the likely and predictable progression of haematological and immune effects associated with radiation illness.

Patients exposed to radiation in the potentially low- to mid-lethal range (2–6 Gy) will experience depression of bone-marrow function with cessation of blood-cell production that will lead to pancytopenia (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

Recall that bone marrow *contains the renewal systems for three haematopoietic cell systems, each with different responses* in terms of their evolutionary/developmental cycles, cellular distribution patterns and post-irradiation responses (**Figure 5**) (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003). These three lines include erythropoietic (red cell), myelopoietic (white cell) and thrombopoietic (platelet) and evolve from the pluripotential stem cells. The bone marrow houses a complex interplay of compartments; each cell-renewal system consists of and depends upon a stem-cell compartment for the production of erythrocytes, leucocytes (lymphocytes, granulocytes, monocytes, etc.) or platelets, a dividing and differentiating compartment, a maturing (nondividing) compartment and a compartment containing mature functional cells.

Because tissue with rapid cell turnover tends to be the most sensitive to radiation exposure, the stem-cell lines of the bone marrow are among the most radiosensitive tissue of the body owing to their high mitotic rate and their high nuclear-to-cytoplasmic ratio (**Figure 6**) (International Atomic Energy Association (IAEA), 2009a; 2009b).

Of note, and important in determining appropriate medical care, is that with an exposure to ionizing radiation, even in the dose range of 2.5 Gy and higher,

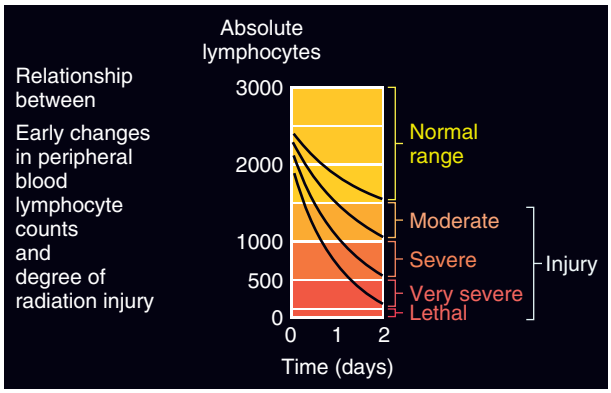

Figure 7 Effect on lymphocyte count after exposure to radiation. (Reproduced with permission from International Atomic Energy Agency (IAEA) and Jacocks, 2003.)

it is likely that a small percentage of the stem-cell population will survive and be capable of continuously expanding progeny (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Leikin *et al*., 2003; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003). Of concern—the surviving stem cells will be tasked with replenishing their own populations—are the committed stem cells and also the vital differentiated precursor blood-line cells. Given the impact on the bone marrow, patients must be supported as the counts of the shorter-lived cell populations drop and it will take time for recovery, assuming the patient survives. The likelihood of cell replenishment and ultimately survival is dependent upon the dose of radiation, host factors, timeliness and aggressiveness of medical care.

Patients exposed at a high enough level to suffer from the haematopoietic syndrome will undergo the various stages of ARS.

Prodromal symptoms include nausea and vomiting, which, compared with those for the other more advanced syndromes (GI and neurovascular), are less severe, of shorter duration (hours) and easier to control. Time of symptom onset from exposure can range from an hour to about 24 hours.

Central nervous system syndrome signs are unexpected, unless a high-dose exposure occurred. One can expect slight if any change in blood pressure, and only mild watery diarrhoea. Fatigue, malaise, anorexia and drowsiness may be observed, but are not consistently correlated to dose received, as are the onset and severity of nausea and vomiting.

The next, or latent phase may last up to a month. During this period, mild symptoms may occur but these usually only include general malaise, tiredness and weakness.

Subsequently the patient will be in the manifest illness phase, which is characterized by neutropenia, fevers, systemic and localized infections, sepsis and haemorrhage. Patients are highly vulnerable during this phase.

4.3.4 Specific Blood Lines

4.3.4.1 Red Blood Cells

After exposure to ionizing radiation, there is usually no depression or only a very mild depression of RBCs, unless there is concomitant haemorrhage (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

4.3.4.2 Granulocytes

Lymphocyte counts are usually the first blood counts to drop after exposure to ionizing radiation. A drop in lymphocytes occurs 24–48 hours after the injury (**Figure 7**). The speed and extent of the lymphocyte drop is linearly proportional to the severity of the dose to the bone marrow (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

A minor drop is noted after doses of 0.25–1 Gy. At about 1.5 Gy, the drop is around 50%. At 3 Gy, the count drops to 1000 mm^{-3}; at 4–5 Gy, it drops to less than 500 mm^{-3}. A drop to zero implies a dose of greater than 6 Gy.

The drop in lymphocyte count is a crude, but sensitive, important estimation of severity of injury within 48 hours of exposure. For example, a patient whose lymphocyte count stays above 1500 mm^{-3} after 48 hours may have received a clinically significant dose, but the overall prognosis is quite good. On the other hand, a patient whose count drops to less than 500 mm^{-3} in 24 hours demonstrates a profound life-threatening injury.

Exposure doses >2 Gy can cause an initial paradoxical rise in lymphocyte counts; but this lasts only hours or days and will be followed by a significant drop. The transient rise is caused by demargination of white cells into the circulation. Take caution in interpreting early laboratory results—this is why sequential monitoring is critical. Any CBC taken when the paradoxical rise occurs may be misinterpreted as evidence of infection or even worse, of a good immune system! Patients exposed to moderate doses of radiation are at risk for infection and should be treated within radiation protocols, accordingly.

Doses of 2–5 Gy can cause a second transient rise, which interrupts the initial dramatic drop in counts for several days or a week. This second rise is caused by the products of final differentiation and entry into circulation of marrow polymorphic nucleated cell (PMN) precursor cells, which do not need to undergo further mitotic divisions. The extent and duration of this second rise is variable. Historically it can last for a week and be associated with a rise from about 50% to about 75% of normal. But then, near day 25–35 post-exposure, the neutrophil count continues dropping to a nadir—with levels near 0–20% of normal.

Injury to bone marrow and nucleated blood cells can occur at IR doses as low as 0.25 Gy, but clinical depression of cell counts is usually not noted until a dose of 0.5 Gy.

Key Facts: The lymphocyte count and neutrophil count as biodosimetric tools can be useful for the uncomplicated patient without other injury. With a radiation patient who is also a victim of trauma or has burns—these can cause changes in blood cell counts that will confound interpretation of expected radiation-induced blood-cell kinetics.

4.3.4.3 Platelets

After exposure to ionizing radiation, platelet counts generally drop along with declining neutrophil counts. Unlike with granulocytes, a transient rise in platelet count is not typically expected. Platelet counts drop to zero or near zero with doses that exceed 5 Gy (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

Predictably, the damage to the immune and haematostatic systems emperil the patient. Not only are the number of cells reduced, but the function of those remaining may be altered and thus not fully capable of protecting the patient. Among the few neutrophils and platelets remaining, they are old (senescent) or damaged.

Decrements in RBC and platelet counts occur much later than the decrements of lymphocytes and other leucocytes. Bleeding and anaemia may be significant at higher survivable doses, but do not occur for several weeks after irradiation.

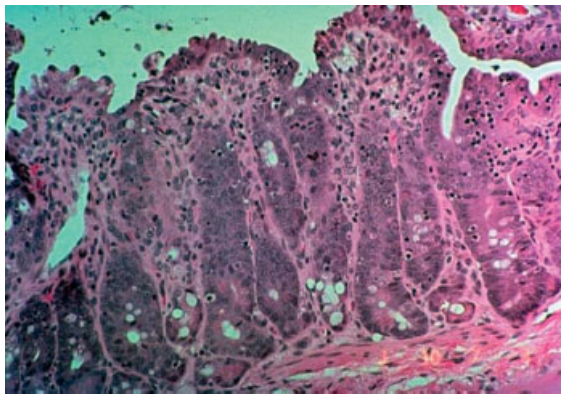

Figure 8 Irradiated gastrointestinal mucosa. (Reproduced with permission from International Atomic Energy Agency (IAEA).)

If, during the 15 day recovery period from the neutropenia, the patient survives neutropenic fever, complications of sepsis and uncontrollable haemorrhage, recovery following the nadir period can be expected.

The goal of clinical management is to lessen the severity of thrombocytopenia and neutropenia, while preventing/minimizing and/or treating infections.

4.3.5 Gastrointestinal Syndrome

The GI tract, like other tissue exhibiting high cell turnover, is very radiosensitive. High-dose exposure can lead to loss of integrity of the cells lining the large intestine (**Figure 8**). Doses of 600–3000 rad (6–30 Gy) will produce this syndrome. The classic symptoms are nausea, vomiting and diarrhoea, as seen in the Litvinenko case (Leikin *et al*., 2007; McFee and Leikin, 2008; 2005; 2009; Harrison *et al*., 2007; Stather 2007; International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

It is worth noting that these symptoms can also occur as a psychological response to a terrorism event. The time from exposure to onset of vomiting and diarrhoea provides an important insight into the potential severity of injury; patients who vomit in the first 2–6 hours likely obtained a very high dose. These symptoms result in significant loss of fluids and can set the stage for opportunistic infections that can lead to sepsis. Persistent high fever and bloody diarrhoea are serious. Death can occur within one to two weeks.

Gastrointestinal injury can occur and become evident after an exposure dose of 6–8 Gy (600–800 rad) WBI. As expected in radiation-related injuries, the signs and symptoms of IR, especially as they pertain to the GI syndrome, can be relatively immediate in the aftermath of significantly high doses or take upwards of two weeks

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

at survivable doses of WBI. Severe anorexia, nausea, vomiting are the initial GI symptoms.

Generally, exposure to a dose range of 8–30 Gy is fatal, since that dose range causes reproductive death of the mucosal crypt stem cell. Loss of these cells eliminates the bowel's ability to replenish the short-lived mucosal cells that normally slough off during routine GI function.

Since the rate of cell turnover is highest in the small intestine, radiation injury is usually most severe in that section of the GI tract. Disruption of neural control of the gut, abnormal release of intestinal neurohormonal peptides, submucosal oedema and engorgement or stasis of the submucosal blood vessels can be expected, especially in greater than low-dose exposures. As a result, dysfunctional bowel motility, resulting in severe bloody diarrhoea, anaemia, ileus, severe electrolyte disturbances and malnutrition.

Denuding of sections of bowel can be problematic and allow the invasion of bacteria normally relegated to the intestinal lumen into the circulation. Loss of fluid and electrolytes, diminished absorptive capability are likely to accompany this level of damage. Gastrointestinal haemorrhage can occur. Clearly disruption of the GI tract will compromise nutrition.

Like the other types of ARS, the GI syndrome involves three phases: prodromal, latent and manifest periods.

- Prodromal period: Within 30 minutes to two hours of exposure, patients who have received radiation doses of 8–30 Gy may experience severe anorexia, nausea, vomiting and occasionally watery diarrhoea with abdominal cramps, which increase in intensity for 4–8 hours and may be difficult to control with antiemetic medications. These symptoms are usually accompanied by drowsiness, malaise and fatigue. Occasionally, the parotid gland is involved and will be painful. Patients have also complained of a metallic taste sensation. During this phase, depending upon the dose and clinical picture, mild hypotension and tachycardia may be present. The prodromal symptoms continue, but diminish over the first 48 hours after exposure.
- Latent (subacute) phase: The patient's symptoms may subside. This relative asymptomatic period may last for hours or days, depending upon the exposure. Nevertheless, the patient will be very tired and weak.
- Manifest phase: This phase sees the return of severe GI symptoms, including vomiting and diarrhoea that will go through stages: diarrhoea with fever, bloody diarrhoea, then possibly shock and death. Aggressive medical intervention may be able to save some patients.

The pathophysiology of the GI syndrome involves the depletion of the epithelial cells lining the lumen of GI tract, which allows the intestinal bacteria to gain free access to the body. As the GI tract is progressively damaged, it will necrose. Haemorrhage through denuded areas will lead to hypotension and shock. If the dose is not sufficient to cause massive disruption, there will, nevertheless, be a loss of absorptive capacity.

Management of the GI syndrome will need to take into account the haematological syndrome as well.

Key Facts: Instrumentation of the GI tract, such as endoscopy is relatively contraindicated, given the potential for perforation.

NB: At about 6 Gy (600 rad) and higher WBI, multi-organ system damage may become evident. Damage to the endothelium of smaller blood vessels is a basis for multiple organ damage or failure. At 6 Gy or higher, these vessels can be expected to occlude. Tissue/organ ischaemia, necrosis and death can occur.

4.3.6 Pulmonary Effects

Radiation doses in the 8–30 Gy range usually cause death from the GI syndrome. However, such doses also produce potentially life-threatening pulmonary effects of respiratory insufficiency, acute respiratory distress syndrome (ARDS) and pneumonitis (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; World Health Organization, 2009).

Pneumonitis is likely to be caused by a complex of factors, including breakdown of vascular permeability, fluid imbalance, free-radical tissue interactions, infectious agents, biological and chemical toxin damage, and inhalation injury from heat, smoke and fumes.

The patient injured by fatal whole-body radiation may die of the GI syndrome before the pulmonary effects become manifest. However, partial-body shielding or other situations may set the stage for pulmonary effects.

4.3.7 Cerebrovascular/Central Nervous System Syndrome

Neuronal tissue is not as radiosensitive as other tissue. Doses of 3000 rad (30 Gy) and above produce this syndrome, which may cause microvascular leaks within the brain. Doses in this range cause significant direct effects, as well as free-radical overload of the cells and basement membranes of the microcirculation system. This leads to, among other damage, massive loss of serum and electrolytes through leakage into the extravascular space, circulatory collapse, oedema, increased intracranial pressure and cerebral anoxia. Acute radiation doses of 30 Gy and above cause death within 72 hours and usually between 24 and 48 hours (Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007).

Early vomiting and increased cerebral pressure occur within minutes. Patients tend to become confused, disoriented. Convulsions, coma and severe hyperpyrexia result; death is within a couple days. Death is imminent and no recovery from this is likely. Comfort measures and compassionate care should be initiated.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Prodrome: In less than an hour and possibly within minutes of exposure, patients receiving these doses begin experiencing prodromal symptoms: a burning sensation within minutes, and severe nausea and usually projectile vomiting within an hour. The symptoms, which are severe and may last more than 24 hours, also include diarrhoea that is occasionally bloody, cutaneous oedema and erythema, hypotension, hyperpyrexia, disorientation, prostration, loss of co-ordination and possibly seizures.
- Latent: Pain may subside. Following the prodromal phase, there may be a brief latent phase of apparent clinical improvement; but this will last for only hours, perhaps a day or two.
- Manifestation: Finally, the victim will succumb to a complex of gross central nervous system dysfunction and total cardiovascular collapse, leading to a relatively prompt and inevitable death.

4.3.8 Cutaneous Syndrome

Radiation injury to the skin, like the other ARS syndromes, has a clinical course with three phases—prodrome, latent, manifest periods (Leikin *et al*., 2007; McFee and Leikin, 2005; 2009; Harrison *et al*., 2007; Stather 2007; McFee and Leikin, 2008; International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Christensen *et al*., 2008b; Berger *et al*., 2006; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009).

- Prodrome: There may be early erythema (**Figure 2**) that may be accompanied by dysesthesias, vague and uncomfortable sensations of heat or pinching.
- Latent: This period, like that of other ARSs, is characterized by the appearance of no clinical change.
- Manifest: The skin injury may ensue with progression of skin damage. Sloughing can occur. Depending upon the extent, it is important to address proper burn management and wound care.

4.3.9 Acute Local Injury

Injuries to smaller or circumscribed areas may result initially or fully as skin damage only. However, it is also possible for more severe and deeper damage, that can include the dermal structures and vasculature, as well as subcutaneous regions. Depending upon the level of exposure, the damage can be profound, requiring aggressive surgical management, even amputation. Surgeons with experience treating immune-compromised patients (cancer patients) or radiation experience are preferred (Leikin *et al*., 2007; McFee and Leikin, 2008; 2005; 2009; Harrison *et al*., 2007; Stather 2007; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; Fliedner *et al*., 2001).

Key Facts:

1. ARS can accompany acute local injury. Clinicians should monitor these patients as with other radiation exposed.
2. Estimating the dose exposure associated with an acute local injury is a complex process; consultation with an HP and/or REAC/TS or other radiation expertise is advised. The delay in appearance of ionizing radiation injury accounts for the difficulty identifying radiation injury and managing these patients.

5 MEDICAL MANAGEMENT OF THE RADIATION-EXPOSED PATIENT

5.1 Initial Response

It is well accepted that a radiation incident could cause a surge of potentially contaminated patients to the ED. Given most HCFs have limited surge capacity and limited experience of handling a hazardous material incident (HAZMAT), let alone a radiation event, one can appreciate the challenge to protecting the staff, HCF and providing rapid, appropriate care (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; NCRP, 2001; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Fliedner *et al*., 2001; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009).

When responding to a radiation victim, the precise source is not critical to initial care, but is important in selecting the most appropriate protective strategies. It is important to recognize historically the provision of healthcare to radiologically inured or ill patients is a low risk activity; no known history of significant exposure to IR has caused serious injury to healthcare providers.

It is important to acknowledge that the presentation of the patient may not be initially recognized as a radiation victim. However, when radiation is suspected, the use of PPE, at a minimum, and disrobing the patient may reduce the risk posed by a potentially contaminated patient. HAZMAT and radiation experts should be consulted immediately upon even suspecting a radiation victim. Most HCFs have a radiation safety officer or HP—a valuable resource in pre-event preparedness planning, as well as in the initial approach to the patient. They should be well known to the ED, prehospital responders

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and others likely to interact with the radiation patient. They have the expertise, equipment and resources to assist the clinician. Moreover, their knowledge should go beyond direct patient care to assisting with environmental, public-health and community-infrastructure concerns.

If the patient is to have a chance of surviving, this is the overview of requisite care:

- Rapid diagnosis
- Address life-threatening injuries
- Administer specific antidotes as soon as possible
- Decorporative (chelators) and other treatments for internal contamination need to be considered early in the clinical course in order to minimize morbidity and mortality
- Standard toxicological treatment
- Symptomatic and supportive care
- Address each of the ARS syndromes rapidly
- Haematological
- Aggressive supportive care
- Antibiotic prophylaxis
- Treatment of bleeding disorders and anaemia
- Cytokines therapy
- Stem-cell transplants must begin early
- Gastrointestinal
- Protect alimentary function
- Prevent infection
- Provide low-microbial nutrition.

5.2 Medical Management of Radiation Patients

The appropriate medical management of the radiation-exposed patient or group of radiation-terrorism victims is predicated upon the following (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; NCRP, 2001; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Fliedner *et al*., 2001; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009; Hughes *et al*., 2002):

- Trained clinicians
- Availability of an HP
- A well-developed and practised response plan
- Key personnel are identified and have worked together on drills
- Well-posted information on REAC/TS and other appropriate resources
- Functional and calibrated radiation-detection technology
- Readily available
- Team is practised on the use
- Capability and limitations of technology are well known
- Availability of radiation-specific
- Equipment
- Disposal materials
- Antidotes.

Considering radiation in the differential diagnosis is essential.

The medical management of radiation/combined injuries can be divided into three stages (International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Leikin *et al*., 2003; Flynn and Goans, 2006; Walter *et al*., 2000; NCRP, 2001; Christensen *et al*., 2008b; Goans, 2007; Schleipman *et al*., 2004):

1. Triage
2. Initial emergency care
3. Definitive care.

Effective, quality care can be provided, both when there are few casualties and a well-equipped facility and when there are many casualties and a functioning worldwide evacuation system. The therapeutic modalities vary according to current medical knowledge and experience. Precisely implemented modalities will depend on the number of casualties, available medical facilities and resources. Recommendations for the treatment of a few casualties may not apply to the treatment of mass casualties because of limited resources.

It is essential to implement good infection-control measures as soon as radiation. Clearly that should be the dictum in all healthcare, given the rising rate of hospital-acquired infections, but no more critically than in an expected immune-compromised patient.

The management of a radiation casualty involves three critically important and inter-related issues (Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Waselenko *et al*., 2004; Flynn and Goans, 2006; Walter *et al*., 2000; NCRP, 2001; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Schleipman *et al*., 2004; REAC/TS, 2009; Fliedner *et al*., 2001; Gusev *et al*., 2002; NTI and The Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003; Hughes *et al*., 2002):

1. Managing severe immune-system compromise
2. Managing/preventing the resulting infectious complications
3. Preventing haemorrhage and severe anaemia due to thrombocytopenia.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Dose exposures in the haematopoietic syndrome range are survivable. The therapeutic goal is to lessen the severity of neutropenia and thrombocytopenia, while minimizing the likelihood of and/or aggressively treating infection.

Look for and treat immediately life-threatening injuries. Recognize that, in addition to clothes, body fluids can be contaminants, as well as necessary to submit for sampling and diagnostic purposes. Recall that removal of clothes has the potential to reduce contamination by upwards of 90%.

Different types of radiation accidents require different resources and management strategies. These range from simple medical attention to highly sophisticated care at specialty HCFs. Although the radiation exposure may pose a serious health risk to the patient, irradiation or exposure is not necessarily a medical emergency or immediately life-threatening. Moreover, the severity or extent of the radiation injury may not be immediately obvious.

The first priority for the radiation victim is consistent with good medical practice—stabilize the patient and attend to life-threatening injuries first. Attend to the 'ABC' basics—Airway, Breathing and Circulation. Airway protection and fluid replacement may be required. Pain management and control of vomiting may also be necessary.

Triage will be based on associated injuries, presenting signs and symptoms. Remember, radiation is rarely *immediately* life threatening. Other injuries—burns and trauma—should be attended to. If radiation is suspected, rendering surgical care and other interventions must be done in consultation with radiation-health expertise, and infectious disease, surgical and haematology specialists. Once the patient is stabilized and decontaminated, more definitive care can be provided.

5.2.1 Patient Triage

If a multiple or mass casualty event has occurred, especially one that may involve radiation, it is important to implement triage—the sorting of patients into classes of injury/disease for the purpose of expediting clinical care and maximizing the available clinical services and facilities (Jarrett, 1999; Flynn and Goans, 2006; Walter *et al*., 2000; NCRP, 2001; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Schleipman *et al*., 2004; Liu and Rodgers, 2008; Kennedy *et al*., 1996; Lai *et al*., 2003; Lanoix *et al*., 2002).

One of the main tasks is to determine the level of emergency care. If the accident produces only a small number of casualties, medical management should not cause major problems in most countries. An accident involving tens or hundreds of individuals exposed, or suspected of exposure, would cause great difficulties, especially in hospitalization.

Preplanning is clearly important, and should be adapted to the system of medical care contemplated for catastrophic event situations.

In a radiation patient, the early clinical symptoms serve for the basis of sorting persons exposed to radiation and deciding upon proper medical care at an individual level. Proper planning, teamwork and the availability of detection technology, expertise and critical resources, including antidotes, will determine the success of response. In subsequent sections detection technology will be discussed.

As will be discussed momentarily in the medical and physiological sections, the most important early clinical signs are onset of nausea, vomiting and diarrhoea. The time from exposure to appearance of symptoms is quite telling in terms of potential severity of illness. Keep in mind the psychological impact of an event; this may also cause mild GI symptoms.

Estimating the degree of radiation exposure and attendant damage is challenging. Ongoing diagnosis and reassessment is required throughout the patient's clinical course (Jarrett, 1999; Christensen *et al*., 2008a; 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Schleipman *et al*., 2004; International Atomic Energy Association (IAEA), 2009b).

Recall there is the prodrome, when symptoms begin within hours of exposure, characterized by GI signs and symptoms, including nausea, vomiting, diarrhoea, fatigue, weakness, fever and headache. These symptoms generally do not last longer than 24–48 hours after exposure, but a vague weakness can persist for an undetermined length of time.

Note that the time of onset, severity and duration of these signs are dose dependent and dose-rate dependent and should be used in conjunction with early biological parameters, such as granulocyte and lymphocyte levels, to determine the presence and severity of the ARS.

Given radiation will affect blood cells, in a dose-dependent fashion, an initial baseline sample should be obtained as early as possible after irradiation. Frequent sampling will increase the reliability of dose estimates. If lymphocytes have decreased by 50% and are less than $1000\,\mu l^{-1}$ within 24–48 hours, the patient has received at least a moderate dose of radiation (International Atomic Energy Association (IAEA), 2009a; Christensen *et al*., 2008b).

At the initial stage of patient evaluation, take into account the physiology of radiation illness, the relationship between exposure dose and symptoms, and have ready the appropriate surveillance equipment, as well as expertise.

From the moment of exposure, the clock is ticking. A likely fatal exposure may experience the following:

Vomiting within the first hour, especially if accompanied by significant, possibly haemorrhagic diarrhoea, is associated with fatal doses. Vomiting, even within the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

first 2–3 hours, is usually associated with a severe radiation dose. Due to the transient nature of these symptoms, it is possible that the patient will have already passed through the initial phase of GI distress before being seen. However, the severity of these symptoms is usually memorable by the patient and should be inquired about.

Casualties who have received a potentially lethal radiation injury show a significant rise in body temperature within the first few hours postexposure. The occurrence of a fever and chills within the first day postexposure is an ominous sign, often associated with a severe and life-threatening radiation dose. Hyperthermia may occur in patients who receive lower, but still serious radiation doses (2 Gy or more).

A person who received a WBI dose of more than 10 Gy, or comparable doses to local body regions, is likely to develop erythema within the first day postexposure, albeit the erythema should be restricted to the affected area. With whole-body doses, lower, but still in the potentially fatal range, erythema is less frequently seen (Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Schleipman *et al*., 2004; World Health Organization, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

A noticeable drop in systemic blood pressure has been reported among victims who received a lethal dose of WBI. Severe hypotension after irradiation is associated with a poor prognosis.

Neurological tissue requires a large dose to develop damage. Virtually all persons who demonstrate clear signs of damage to the central nervous system within the first hour postexposure have received an LD. Symptoms include mental confusion, convulsion and coma. Intractable hypotension as the cardiovascular system becomes involved, along with neuro effects, will probably accompany these symptoms. Despite vascular support, death usually occurs within 48 hours.

In the triage of multiple patients, identifying patients likely to have been exposed is essential to managing patients effectively. The following quick thoughts are likely to assist.

- Unlikely exposure: The patient with unlikely radiation injury demonstrates no more than episodes of nausea and vomiting and usually retains lymphocyte counts above 1500 mm^{-3} in 48 hours.
- Probable exposure: The patient with probable radiation injury has prodromal symptoms that include more pronounced or severe and sustained nausea and vomiting that began within one hour to one day of exposure and last for hours. The lymphocyte count will drop to around 1000–1500 lymphocytes mm^{-3}, but there should be no vascular or central nervous system symptoms.
- Likely severe or fatal exposure: The patient who has received a severe, potentially fatal radiation injury (who may become categorized as 'expectant') in a triage situation presents with uncontrollable nausea and vomiting within one hour after exposure. Those symptoms are frequently associated with explosive, bloody diarrhoea, hypotension, a burning skin sensation and obvious CNS signs.

5.3 General Surgical Considerations

Radiation can complicate wound healing. Therefore surgical procedures should be performed early in the course of a radiological exposure, preferably within 24–36 hours. Surgical procedures performed after 36–48 hours from the time of the radiation injury may be complicated by failure to heal and a variety of infections. Tissue oedema, leakage of fluids and vascular damage make an ideal medium for growth of micro-organisms. The immune compromise associated with radiation-induced haematopoietic damage can also complicate management. Skin grafts, if performed too early in the course of a radiation injury, may not take, especially if there is significant injury to the microvasculature supporting the skin. As in other clinical situations, the risk–benefit ratio must be considered; emergency surgery must be performed in life-threatening situations, taking into account the ongoing evolution of immune and haematology damage. Precautions, including anticipating unexpectedly active bleeding should be part of preoperative planning for the radiation victim (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Leikin *et al*., 2003; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; REAC/TS, 2009; Fliedner *et al*., 2001; Gusev *et al*., 2002; World Health Organization, 2009; Hall and Giaccia, 2005).

5.4 Antidotes

The medical management of acute radiation patients, especially in a high-dose exposure is complex. The use of immune stimulation, infection control/prophylactic chemotherapy and antidotes may all be required (McFee *et al*., 2004; Leikin *et al*., 2003; 2007; United Nations, 2000; International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Waselenko *et al*., 2004; Flynn and Goans, 2006; NCRP, 2001; Christensen *et al*., 2008a; 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Fliedner *et al*., 2001; Gusev *et al*., 2002; Oliveira *et al*., 1991b; Basic Disaster Life Support (BDLS) Course, 2004; CDC, 2006).

There are several antidote classes available: these include decorporative (separate the patient from the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

poison), mechanistic (interfere with the process of toxicity) or other mechanisms (McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007).

Selecting which approach to take requires consultation with toxicologists and radiation experts, as well as haematologists and infectious disease experts (Christensen *et al*., 2008b; Goans, 2007; Daniak *et al*., 2003).

The uptake and/or incorporation of radioactive materials is relatively fast for some of the security-threat or nuclear-accident radionuclides. These include radioiodines and radiocaesium. Recalling the toxicologists axiom 'time is tissue', treatment should begin very quickly—ideally within hours.

'Antidotes' may not be curative (Christensen *et al*., 2008b). Nevertheless, they can often 'buy time' for the body to heal or regroup. Antidotal therapies are generally categorized into the following broad categories:

- Saturation and blocking, for example the use of stable KI to prevent thyroid uptake and incorporation
- Ion binding, for example the use of Prussian blue (ferric ferricyanate or ferric hexacyanoferrate) for radiocaesium as well as both radio- and nonradioactive thallium
- Competitive displacement, for example the use of calcium to compete with radioactive strontium
- Chelation, for example, the use of diethylenetriamine pentaacetate (DTPA or pentetate) for the transuranic radionuclides: americium, curium and plutonium
- Isotopic dilution, for example the use of high intakes of water for tritium that has ^{3}H or is radioactive. Recall the hydrogen in water (H_20) can compete with the 3H in tritium. Caveat—be cautious of fluid status.

5.4.1 Antidotes for Specific Situations

5.4.1.1 Caesium (^{137}Cs)

^{137}Cs is often found in medical radiotherapy and industrial instruments. It was used in a Chechen threat as a component of an SDD deployed in Moscow. It emits both beta and gamma, is completely absorbed by the lungs, from the GI tract and from wounds. Soluble in most forms, metabolically it is a potassium analogue. Following intake, caesium redistributes much like potassium. Radioactive caesium is internalized, transported, metabolized and excreted exactly like nonradioactive caesium. The pathology from internalization of ^{137}Cs is related to its radiological toxicity (McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; Oliveira *et al*., 1991a; 1991b; US Environmental Protection Agency, 2009; Basic Disaster Life Support (BDLS) Course, 2004).

Primary toxicity with ^{137}Cs like other radiation risks is by WBI (Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; Oliveira *et al*., 1991b; US Environmental Protection Agency, 2009; Heyltex Industries, 2009).

Treatment consists of including the full range of clinical care—from dose estimation, to addressing the impact and likelihood of ARS, to providing early administration of Prussian Blue (Radiogardase®) or ferric hexacyanoferrate, which binds radioactive and nonradioactive caesium and thallium toxicants in the GI tract by ion exchange, adsorption and mechanical trapping within the structure; it is used for decorporation of such toxicants (Jarrett, 1999; Christensen *et al*., 2008b; Heyltex Industries, 2009; US Department of Health and Human Services, 2009). This ion exchange binds and helps to prevent the absorption of the toxicant, reducing the biological half-life of radioactive caesium to approximately one-third of normal, which follows an enteroenteric cycle (Christensen *et al*., 2008b; Heyltex Industries, 2009; US Department of Health and Human Services, 2009).

Prussian Blue is available in 500 mg capsules that can be safely opened and mixed with food or beverages to ease administration (CDC, 2009; Heyltex Industries, 2009; US Department of Health and Human Services, 2009). The usual dose for adults, breastfeeding women and children older than two years of age is 3 g, three times a day for at least 30 days. Possible adverse effects include nausea, constipation and bluish teeth or faeces (opened capsules).

5.4.1.2 Cobalt (^{60}Co)

Cobalt is widely used in medical radiotherapy devices, as well as in food irradiators. Most likely this threat will occur from theft or improper disposal of medical/industrial equipment, similar to the Goiano, Brazil event (only this involved caesium). However, with the ready availability in often undersecured locations, Co may be used in an SDD or RDD (Jarrett, 1999; Christensen *et al*., 2008a; 2008b; Goans, 2007; World Health Organization, 2009).

It is rapidly absorbed from the lung; less than 5% is expected to be absorbed from the GI tract. Absorption from wounds is largely understudied or uncharacterized. The primary toxicity is expected from a WBI resulting in ARS.

Although some suggest gastric lavage or other GI decontamination, there are insufficient data to commend this practice without consultation on a patient-by-patient basis with toxicologists and HPs. The US Military suggest the use of penicillamine chelation for extreme cases.

5.4.1.3 Americium (^{241}Am)

Americium is a decay 'daughter' of plutonium, and is an alpha emitter. Found in smoke detectors, as well as industrial instruments, it is easy to acquire. Fallout from the detonation of a nuclear weapon will result in ^{241}Am. It is a heavy-metal poison, but in large amounts can cause WBI. Emission of gamma can be detected through the use of a FIDLER (field instrument for the detection of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

low-energy radiation) detector (McFee and Leikin, 2005; Jarrett, 1999; Christensen *et al*., 2008b; World Health Organization, 2009).

GI absorption is minimal, but inhalation results in 75% absorption, with 10% retained. It may be readily and rapidly absorbed through wounds. Elimination is through urinary and hepatic excretion.

Treatment (see Section 5.4.1.5 on Transuranic Elements) includes chelation with zinc diethylenetriamine pentaacetate (Zn DTPA) and calcium diethylenetriamine pentaacetate (Ca DTPA) with in the first 24–48 hours following pulmonary exposure. EDTA (ethylenediaminetetraacetic acid) chelation can be used until DTPA is available. Consultation with medical toxicologists and HPs is a critical early strategy.

5.4.1.4 Iodine ($^{131-135}I$)

Radioactive iodine will occur after nuclear reactor accidents or their destruction by terrorism. It is a normal fission product in fuel rods. The primary toxicity is via beta rays, with some gamma. The thyroid gland is the most vulnerable organ; uptake of radioactive iodine resembles therapeutic thyroid ablation, especially untreated. Following the Chernobyl disaster, there was a high incidence of childhood thyroid cancer in the region (McFee *et al*., 2004; Leikin *et al*., 2007; McFee and Leikin, 2005; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Flynn and Goans, 2006; Walter *et al*., 2000; NCRP, 2001; National Institute of Occupational Safety and Health, 2009; Christensen *et al*., 2008a; 2008b; Schleipman *et al*., 2004; Basic Disaster Life Support (BDLS) Course, 2004; The Chernobyl Forum 2003–2005, 2009; World Health Organization, 2009; Kristoff, 2004; Nuclear Threat Initiative (NTI), 2009; Samuel and Dolan, 1977).

Administration of KI, ideally within six hours of exposure is essential for those near the site, or downwind of a plume of debris. Adults should receive the 130 mg tablet, while children 3–18 can receive 65 mg, children one month to three years should receive 32 mg and infants up to one month can receive 16 mg daily until the environmental threat subsides. Pregnant women and their infants can take normal doses. Children who weigh 150 lbs (~70 kg) can take the adult dose. Adverse affects may include fever, rash, abdominal pain, nausea and a metallic taste.

Oral propylthiouracil has been suggested, but this should be done in careful consultation with radiation-health experts and endocrinologists.

5.4.1.5 Transuranic Elements: Plutonium, Americium, Californium, Curium

The FDA has approved the use of two heavy-metal chelators, Ca-DTPA and Zn-DTPA for the treatment of internal contamination by plutonium, americium, californium and curium transuranic soluble salts (Food and Drug Administration (FDA), 2009; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; World Health Organization, 2009; US Department of Health and Human Services, 2009).

DTPA is a chelating agent which exchanges either calcium or zinc for another metal with greater binding ability, carrying it to the kidneys where it is excreted in the urine. The chelating efficacy is greatest immediately, or within one hour, following uptake, when the radionuclide is circulating in or available to tissue fluids and plasma.

Ca-DTPA is approximately 10 times more effective within the first 24 hours than Zn-DTPA for chelation of transuranics and therefore should be used whenever larger body burdens are expected. However, after 24 hours, Zn-DTPA is as effective as Ca-DTPA and should be used for protracted therapy because of its lesser toxicity. If Zn-DTPA is not available, or you are treating a pregnant patient, Ca-DTPA is acceptable for the duration of therapy. Monitor for toxicity.

Zn-DTPA is recommended for sensitive populations such as children, pregnant women and patients with known kidney disease or bone-marrow suppression.

The dose of either Ca-DTPA or Zn-DTPA for adults is 1000 mg and for children under 12 years of age 14 mg kg^{-1}, not to exceed 1 g. It should be administered by a 3–4 minute slow intravenous push or dilute infusion in 100–250 ml of dextrose 5%, or 0.9% sodium chloride, or lactated Ringer's solution over 30 minutes. If inhalation was the route of exposure, consider nebulizing either Ca- or Zn-DTPA in a 1:1 mixture with saline or sterile water via a nebulizer. Caution and extra monitoring with asthma patients is recommended, as underlying pulmonary illness can be exacerbated (Christensen *et al*., 2008b; US Department of Health and Human Services, 2009; Food and Drug Administration (FDA), 2009).

Adverse events can include headache, lightheadedness, nausea, metallic taste, pruritis, injection-site discomfort, dermatitis, chest pain, nausea and diarrhoea.

Key Facts: Chelation therapy can have a deleterious impact upon electrolytes. DTPA agents can deplete zinc, magnesium and manganese. Regular monitoring and replenishing electrolytes is suggested.

Follow-up and additional therapy may be continued. DTPA chelating agents are manufactured by Hamelin Pharmaceuticals in Germany.

DTPA should not be used for uranium or neptunium internal uptake.

5.4.1.6 Strontium (^{90}Sr)

Strontium-90 (^{90}Sr) is a fission product and radioactive 'daughter' of uranium. Sr^{90} and its daughters emit beta and gamma rays, as well as pose an external hazard in large quantity. Strontium biologically follows calcium in the body. It is readily absorbed by both the respiratory and GI routes (Jarrett, 1999; Goans, 2007).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Immediately after ingestion, the use of over-the-counter (OTC) antacids such as aluminium phosphate can reduce GI absorption of strontium. Aluminium-containing antacids are the most effective, reducing strontium uptake by 50–85%. In the acute aftermath of radioactive strontium exposure, calcium gluconate 2 g mixed into 500 ml solution can be given intravenously. The use of barium sulfate (300 g po), in the immediate postaccident or exposure setting may block intestinal absorption. Large doses of calcium and acidification can increase excretion.

5.4.1.7 Tritium (^{3}H)

Tritium is a hydrogen with a nucleus composed of two neutrons and one proton. Used in nuclear weapons and luminescent gun sights, it is unlikely to pose a significant threat unless in a closed space, as tritium gas rapidly diffuses. Tritium is a beta emitter. Though not a high-threat irradiation hazard, nevertheless, it equilibrates with body water rapidly and is excreted in urine; samples will be positive within one hour of a significant exposure. Biological $t_{1/2}$ is 10–12 days. Oral hydration should help reduce body burden, but caution should be exercised to not fluid-overload the patient (Jarrett, 1999).

5.4.1.8 Uranium ($^{238,235,239}U$)

Uranium is found in depleted uranium, naturally occurring uranium, fuel rods and as nuclear-weapon-grade material (Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007).

Uranium and its radioactive 'daughters' emit alpha, beta and gamma radiation. Like other toxicants, absorption is determined by the chemical state. Soluble salts, as expected, would be readily absorbed, while the metal isn't. Inhaled uranium compounds can be metabolized and excreted in the urine. Following acute exposure, urinary levels of 100 $\mu g\,dl^{-1}$ may cause renal failure.

Generally, uranium presents a greater chemical than radiological hazard. Alkalize the patient with sodium bicarbonate in order to promote excretion. Alkaline urine forms a nontoxic uranium carbonate complex that is promptly excreted through the kidneys.

Important factors in determining the effectiveness of this method include the chemical form and particle size of the inhaled uranium. Sodium bicarbonate should be administered either orally or intravenously.

Tubular diuretics may be beneficial. Regularly monitor these patients. In addition to the 'standard' radiation-related lab tests, perform a urinalysis, 24 hour urine uranium bioassay, serum BUN (blood urea nitrogen) and creatinine, β2-microglobulin, creatinine clearance and liver studies. Involve a nephrologist, especially one familiar with radiation effects, early in the management of such patients (**Table 3**).

5.5 Haematological Support

5.5.1 Cytokines

Growth factors or CSFs are critical to management of the haematopoietic syndrome. Granulocyte colony stimulating factor (G-CSF), GM-CSF and the pegylated form of GCSF are three cytokines used to treat cytopenias in oncology patients. The rationale for their use in the medical management of patients from radiation incidents is based upon that experience. Cytokines cause proliferation and differentiation of stem cells that lead to increased numbers of circulating blood cells. For optimal efficacy, they need to be administered early, preferably as soon as it is determined that there may have been an acute WBI of >1.5–2 Gy (150–200 rad) (Leikin *et al*., 2007; McFee and Leikin, 2005; 2009; Harrison *et al*., 2007; International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Flynn and Goans, 2006; Christensen *et al*., 2008a; 2008b; Berger *et al*., 2006; Goans and Waselenko, 2005; Goans, 2007; Oliveira *et al*., 1991b; Basic Disaster Life Support (BDLS) Course, 2004; World Health Organization, 2009; Scott, 2007; CDC, 2006; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003; Christensen *et al*., 2008b; Goans, 2007; Scott, 2007; CDC, 2006; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

Cytokines stimulate proliferation and differentiation of haematopoietic stem cells. The following are recombinant forms of stem cells:

- G-CSF (Neupogen, Amgen Inc.)
- GM-CSF (Leukine, Berlex)
- Pegylated form of G-CSF (Neulasta, Amgen Inc.).

Cytokines include GM-CSF, macrophage colony-stimulating factor (M-CSF), G-CSF, termDefstem cell factor (SCF) and the interleukin series (IL-1 to IL-16).

GM-CSF and G-CSF have been available for the treatment of radiation myelosuppression. G-CSF and GM-CSF are currently in widespread clinical use for the treatment of acute neutropenic conditions, and, in turn, the management of infections, following radiochemotherapy of cancer patients.

G-CSF and GM-CSF are valuable tools used that act upon uncommitted stem-cell populations within the bone marrow to increase the mitotic rate and accelerate repopulation, differentiate daughter cells to become committed stem cells, speed the maturation process and improve the function of existing granulocytes. Given that it is likely after a radiation exposure that some stem cells remain, even in damaged bone marrow, these factors can improve the immune function of existing cells, while speeding the recovery of stem-cell populations and reducing the time of immune system compromise. Studies of neutropenic

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cancer patients reveal that use of these cytokines reduces infection rates, admissions and days hospitalized.

GM-CSF and G-CSF confer an obvious advantage: their effect on granulocytes and myeloid stem-cell lines do not come at the expense of other marrow cell lines.

5.5.1.1 Dosing

G-CSF, for example Filgastim (Neupogen/AMGEN) is given at 100–200 mcg m^{-2} day^{-1}. GM-CSF, for example Sargramostim (Leukine/Immunex) is given at 200–400 mcg m^{-2} day^{-1}. Both are given intravenously or subcutaneously and should be initiated promptly upon diagnosis of significant bone-marrow damage and continued until recovery of neutrophil counts is sustained above 800 mm^{-3}.

Key Facts:

- G-CSF and GM-CSF increase rate of haemopoietic recovery in patients after radiation exposure and may obviate need for a bone marrow transplant (BMT), when stem cells are still viable. ILs (IL-1 and IL-3) act in synergism with GM-CSF
- Cytokines were successfully used for radiation victims after Goiânia, San Salvador, Israel, Belarus and Istanbul accidents
- A benchmark absolute lymphocyte count (ALC) of less than 500 μl^{-1} may be considered a threshold for beginning cytokine therapy in the first two days. The therapeutic goal of cytokine application is to minimize the extent and duration of radiation-induced neutropenia, and hence minimize the subsequent risk of infection.
- In order to achieve maximum clinical response, G-CSF or GM-CSF should be started 24–72 hours after exposure. This provides the opportunity for maximum recovery. Cytokine administration should continue, with daily consecutive injections, to reach the desired effect of an absolute neutrophil count (ANC) of 1000 μl^{-1} after the ANC bottoms.

A side effect associated with G-CSF (filgrastim) is medullary bone pain, which may be observed shortly after initiation of G-CSF treatment and again just before onset of neutrophil recovery. G-CSF may exacerbate pre-existing inflammatory conditions.

Side effects from GM-CSF (sargramostim) are fever, nausea, fatigue, headache, bone pain and myalgia. It is not clear whether side effects of G-CSF or GM-CSF differ markedly when conventional doses are administered.

5.5.2 Blood Products

Trauma or thermal burns may require the early use of blood products. If the emergency situation permits, these blood products should be leukocyte-reduced and irradiated to 25 Gy to prevent transfusion-associated graft vs. host disease. Do not withhold life-saving blood products. Packed RBCs and platelets for haematopoietic damage will not be required for several weeks at survivable acute WBI doses (Christensen *et al*., 2008b).

5.5.3 Stem-Cell Transplants

Pancytopenia and depletion of stem cells from higher radiation doses may eventually require stem-cell transplants. There are a number of methods for stem-cell transplantation, however this is not a matter for concern in the ED early in the clinical course. Blood for tissue typing should be drawn in the ED if possible, however. Later consultation with a specialist in haematology/oncology may be required to evaluate the necessity of using the valuable resource (International Atomic Energy Association (IAEA), 2009a; 2009b; Jarrett, 1999; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Schleipman *et al*., 2004; Scott, 2007; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

5.5.4 Immunoglobulin Administration

Immunoglobulins have not been shown to be beneficial for radiation casualties on a general basis. However, their use may be beneficial in specific diseases (International Atomic Energy Association (IAEA), 2009a).

Passive intravenous administration of immunoglobulin (IgG) following acute radiation injury is a therapeutic measure employed to counter the suppressive effects of irradiation on the immune system and to diminish susceptibility to infection or its pathological consequences. The therapeutic strategies for using IgG treatment fall into two, quite distinct, camps. The first, more commonly applied strategy (e.g. in WBI patients receiving bone-marrow transplants) involves periodic blood infusions in an attempt to bolster the diminished IgG blood plasma levels that are critical in combating a variety of infections. The second strategy, which is more experimental in nature and less certain in terms of efficacy, is designed to selectively control the pathogenic responses related to septic shock and associated overexpression of inflammatory cytokines.

5.6 Preventing Infections

Nosocomial infections can be a disaster in radiation casualty cases. The loss of a functional immune system predisposes these patients to severe, potentially fatal infections (International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; Basic Disaster Life Support (BDLS) Course, 2004; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Once the granulocyte count is affected, reverse isolation should be initiated. Nursing and infection control personnel should be forewarned of the need for rigorous environmental and visitor control.

Overall recommendations for management of infection are:

- Initial care of medical casualties with moderate and severe radiation exposure should include early institution of measures to reduce pathogen acquisition, with emphasis on low-microbial-content food, acceptable water supplies, frequent hand washing (or wearing of gloves) and air filtration.
- Early collaboration with infectious-disease and HP expertise.
- A standardized plan for the management of febrile, neutropenic patients must be devised.
- Empiric regimens must contain antibiotics broadly active against gram-negative bacteria, but antibiotics directed against gram-positive bacteria need be included only in institutions where these infections are prevalent.
- No single antimicrobial regimen can be recommended above all others, as pathogens and susceptibility vary with time.
- If infection is documented by cultures, the empiric regimen may require adjustment to provide appropriate coverage for the isolation. This should not narrow the antibiotic spectrum.

5.7 Fever

While the irradiated patient is at severe risk of sepsis, any neutropenic fever should be aggressively evaluated and, unless a specific pathogen is identified, empiric triple antibiotic therapy should be initiated (International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Waselenko *et al*., 2004; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; REAC/TS, 2009; Hall and Giaccia, 2005; Mettler and Upton, 1995; Daniak *et al*., 2003).

Empirical/specific therapy should be maintained until granulocytes exceed $800\,mm^{-3}$. If antibiotics fail to control the fever, or if specific fungal or viral pathogens are suspected on clinical grounds, aggressive use of antifungal and antiviral agents should be considered.

This 'empirical' regimen of antibiotics should be selected, based on the pattern of bacterial susceptibility and nosocomial infections in the particular institution and the degree of neutropenia. Broad spectrum empirical therapy with high doses of one or more antibiotics, avoiding aminoglycosides whenever feasible due to associated toxicities, should be used. Broad-spectrum antibiotic coverage includes double β-lactam antibiotics such as a third-generation cephalosporin and ureidopenicillin, monotherapy with imipenem or a third-generation cephalosporin, and vancomycin plus a third-generation cephalosporin.

Neutropenic fever therapy:

- Survey for possible source, pancultures
- Administer antibiotics for ANC $<500\,mm^{-3}$
- Use-broad spectrum antibiotic coverage
- Add amphotericin for prolonged fever lasting five to seven days after starting standard antibiotics
- Continue antibiotics for duration of ANC $<1000\,mm^{-3}$.

If there is evidence of resistant Gram-positive infection, vancomycin should be added.

Although antibiotics and antibiotic-associated diarrhoea is a well-described, as well as an emerging, hospital-acquired pattern of infection, often caused by *Clostridium difficile*, nonetheless, stool cultures should be examined for *Salmonella*, *Shigella*, *Campylobacter* and *Yersinia* as well as *Clostridium difficile*.

Oral and pharyngeal mucositis and esophagitis suggest herpes simplex infection or candidiasis. Empiric antiviral and/or antifungal therapy should be considered.

Surveillance cultures may be useful for monitoring acquisition of resistant bacteria during prophylaxis and emergence of fungi. A once- or twice-weekly sampling of surveillance cultures from natural orifices and skin folds (e.g. axillae, groin) would be reasonable, but should be modified according to the institutional patterns of nosocomial infections. A chest radiograph should be considered at initiation of empirical therapy. This may aid in definitive diagnosis of a new pulmonary infiltrate obtained during the course of neutropenia. Several principles have been stated that are generally applicable to the febrile neutropenic patient and provide a foundation upon which a specific initial regimen may be selected.

Antifungal coverage with amphotericin B should be added, if indicated, for patients who remain persistently febrile for seven days or more on antibiotic therapy, in association with clinical evidence of infection, or if they have new fever on or after day 7 of treatment with antibiotics.

Loss of peripheral circulating lymphocytes and leukocytes, as well as decrements in marrow stem cells result in an immunologically compromised patient who will be susceptible to an array of infectious events. This phase of the haematopoietic syndrome is almost identical to the clinical course of human immunodeficiency virus (HIV) infection. Infection control is a fairly complicated matter. Haematology/oncology and infectious disease expertise will be needed.

Those patients with doses of $>2\,Gy$ (200 rad) acute WBI should be placed in reverse isolation in a general

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

hospital. Patients with doses of 5–6 Gy (500–600 rad) and those with combined injuries will probably require treatment at a specialty hospital or medical centre.

Antibiotic prophylaxis and specific antidotes will be required. Antibiotic use should be directed towards specific foci of infection in non-neutropenic patients. Control of infections in the neutropenic phase of the haematopoietic syndrome is critical, is the most difficult to manage and is the major limiting factor for a successful outcome in otherwise salvageable patients. Neutropenic patients with an ANC of $<0.500 \times 10^9$ cells l^{-1} should be given a broad-spectrum fluoroquinolone or a fluoroquinolone with coverage for *Streptococci*. A febrile event in the neutropenic patient who has been given prophylaxis, but without other focal evidence of infection should be interpreted as the beginning of Gram-negative sepsis that can be rapidly fatal. Fluoroquinolones should be stopped and treatment of sepsis should begin. This treatment needs to include coverage for *Pseudomonas aeruginosa*, in particular, as well as for organisms known to be opportunists in the particular hospital.

5.8 GI Considerations

The radiation-injured patient endures significant nutritional and metabolic stress. Maintaining the integrity of the GI tract, while attempting to reduce pathogen risk and mechanical injury to the bowel mucosa are challenging. Collaboration with HP and GI disease specialists, especially experienced in radiation-related illness, and nutritional experts are critical, as a health team is necessary to aid the patient to recovery. Some suggest the use of an 'elemental' diet which delivers nutrients directly to surviving mucosal cells, limits mechanical stress to the small intestine, preserves physiological functioning, limits growth of abnormal bowel flora and limits injury of the bowel from pancreatic enzymes and bile acids. Some research has suggested that an increased concentration of glutamine in the diet may help to speed regeneration of crypt-cell populations, but data are lacking to make strong recommendations; a case-by-case approach is warranted (Harrison *et al*., 2007; McFee and Leikin, 2009; 2008; Stather 2007; International Atomic Energy Association (IAEA), 2009a; Jarrett, 1999; Waselenko *et al*., 2004; Leikin *et al*., 2003; NCRP, 2001; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002; REAC/TS, 2009).

5.9 GI Infection

In a situation of severe immunocompromise, as with ARS, a significant source of infection may be pathogenic bacteria that normally inhabit the human colon. The pathophysiological changes that occur during radiation injury, combined with use of antibiotic therapy, significantly alter the normal gut flora and cause many GI pathogens to gain access to the patient's circulation.

Historically and now a subject of some debate in combating this problem is the early selective decontamination of the gut using poorly absorbable oral antibacterial drugs. Quinolones eliminate potentially pathogenic aerobic gram-negative bacilli, prevent colonization and subsequent infection. Preserving anaerobic bacteria, they assist in maintaining digestion of overexposed persons developing the GI syndrome. Other attractive candidates for this purpose are, in order, ciprofloxacin, polymyxin B and trimethoprim-sulfamethoxizole or other sulphur-based oral medications. Some experts advocate performing a sensitivity screen of bowel flora prior to the period of manifest illness to better define a panel of antibiotics to be used if needed, but the possibility of an unscreened pathogen causing illness should still be kept in mind. Antiviral drugs (e.g. acyclovir) should be guided by a positive anti-HSV (herpes simplex virus) antibody test or empirically, if a test is not available.

Other authorities consider gut decontamination no longer beneficial except for patients with abdominal wounds or infection such as *Clostridium difficile* enterocolitis. Neutropenia and immunocompromise will allow mucosal overgrowth of *Candida* species, which may be partially controlled with fluconazole, 400 mg daily. Some *Candida* species, moulds and *Aspergillus* are resistant to fluconazole. The presence of these organisms requires special considerations beyond the scope of this work. Disruption of cutaneous and mucosal barriers also help create a favourable environment for opportunistic infections.

Remember, managing infectious complications of ARS will require specialty consultation. Radiation-induced cellular damage creates an ideal medium for reactivation and growth of quiescent infectious agents such as HSV and cytomegalo virus (CMV). Shortly after the nadir of lymphopenia, HSV reactivation may occur in those patients who have previously been infected. Prophylaxis with acyclovir or one of its congeners will be required. Serologies for HSV are recommended; however, in the presence of mucositis, empirical treatment may be started. Stomatitis from these infections can look like radiation-related stomatitis. Similarly, the presence of *Pneumocystis carinii* pneumonia requires special considerations.

Maintenance of gastric acidity (avoidance of antacids and H2 blockers) may prevent bacteria from colonizing and invading the gastric mucosa and may reduce the frequency of nosocomial pneumonia due to aspiration of these organisms. The use of sucralfate or prostaglandin analogues may prevent gastric haemorrhage without decreasing gastric activity. When possible, an early oral

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

immuno-incompetent diet is preferred to intravenous feeding to maintain the immunological and physiological integrity of the gut.

5.10 Nutritional Support

Surgical implantation of a subcutaneously tunnelled central venous catheter can be considered to allow frequent venous access, but meticulous attention to proper care is necessary to prevent disastrous catheter-associated infections (International Atomic Energy Association (IAEA), 2009a; Christensen *et al*., 2008b; Goans, 2007; Koenig *et al*., 2005; Ricks and Fry, 1990; Ricks *et al*., 1990; 2002).

An area of debate, not just for radiation victims, but in other clinical situations, involves whether and when to use total parenteral nutrition (TPN) vs. an elemental diet delivered orally and/or through a feeding tube. TPN has the advantage of delivering large amounts of carefully and regularly adjusted nutrients to a patient whose GI function may be compromised. Furthermore, if the damage to the GI tract is especially severe or in the case of severe vomiting, ileus or obstruction, TPN is the only option available.

5.11 Psychosocial Effects and Support

Psychosocial concerns, for example widespread panic, may interfere with medical management of patients involved in an radiological/nuclear (R/N) incident. The general lack of knowledge about radiation and radioactive materials, coupled with the generally high level of anxiety, even fear, about all things radiological may result in exaggerated responses (McFee *et al*., 2004; Jarrett, 1999; Christensen *et al*., 2008b).

Psychosocial support professionals need to be identified *prior to* an R/N incident and engaged early following an incident.

Support personnel should include psychologists, pastoral care and social workers, public information officers and others.

Many patients will present to healthcare facilities, who only have the *perception* of significant exposure or contamination and who are really without the need for medical care—their needs will be primarily for reassurance and psychological support.

The real issue for first responders and first receivers is to determine who really has significant irradiation and thus the potential for significant radiation-induced injuries and illnesses.

Planning and preparation for R/N terrorist incidents must take these factors into account in order to communicate with and control patients effectively after an incident.

Key Facts: For healthcare professionals, responding to a mass-casualty incident, with or without radiation, as well as responding to a radiological terrorism event will be stressful even to the most seasoned clinician. Provide appropriate psychological care in the immediate aftermath of the response to staff *and* their families, who may be concerned about radiation threats at home. While that exigency is unlikely, remember information is the best antidote for fear.

6 PREPAREDNESS CONSIDERATIONS AND REQUIRED EQUIPMENT

6.1 Radiation/Nuclear Preparedness

Among the WMD, radiological threat response is rarely emphasized (McFee *et al*., 2004; Leikin *et al*., 2003; 2007; McFee and Leikin, 2005; ED Management, 2002; Jarrett, 1999; Waselenko *et al*., 2004; Walter *et al*., 2000; Christensen *et al*., 2008a; Schleipman *et al*., 2004; REAC/TS, 2009; NTI and the Center for Nonproliferation Studies at the Monterey Institute of International Studies, 2004; Basic Disaster Life Support (BDLS) Course, 2004; Liu and Rodgers, 2008; Kennedy *et al*., 1996; Lai *et al*., 2003).

The deadly explosion in 1986 at Reactor 4 of the nuclear power plant of Chernobyl in the former Soviet Union demonstrated the impact on human health, responders and the environment that radiation events can have. Although rare, this high-profile event demonstrated the potential for multiple casualties and long-term illness. Moreover the threat to those outside the immediate region—as weather patterns spread some of the toxicity as far away as Northern Europe illustrate the danger of radiation when safeguards are bypassed or inadequate. The health effects are still being observed 20 years later.

6.2 Healthcare Facility Preparedness

First and foremost is training (Leikin *et al*., 2003; Walter *et al*., 2000; Christensen *et al*., 2008a; Liu and Rodgers, 2008; Kennedy *et al*., 1996; Lai *et al*., 2003). Having the appropriate medical interventions including antidotes to the radionuclides identified as potentially the most problematic is essential (**Table 4**). Now is a good time to develop or ensure collaborations with regional planners and establish memoranda of understanding with other HCF to optimize the availability of critical medications.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135

Table 4 Radioactive material and the treatments associated with them

Radionuclide	Antidote
Caesium-137	Prussian blue (ferric hexacyanoferrate), which adsorbs caesium in the GI tract. It may enhance elimination.
Iodine-131	KI blocks thyroid uptake.
Plutonium-239	DTPA can be used as a chelator and for wounds. EDTA is also a suitable chelator. Aluminium hydroxide antacids may bind plutonium in the GI tract
Radium-226	Immediate lavage with 10% magnesium sulfate followed by saline and magnesium purgatives. Ammonium chloride may increase faecal elimination.
Strontium-90	Aluminium hydroxide antacids may bind strontium in the GI tract. Aluminium phosphate can decrease absorption by 85%. Ammonium chloride can acidify the urine and enhance excretion. Barium sulfate may reduce strontium absorption. Stable strontium competitively can inhibit the metabolism and increase excretion of radiostrontium.
Tritium	Oral fluids reduce the biological half-life from 12 d to approximately 6 d. Do not overhydrate patients.
Uranium	Sodium bicarbonate renders the uranyl ion less nephrotoxic. Diuretics

6.3 Preparedness Considerations: Equipment

A mass casualty incident can lead to numerous, even contaminated patients presenting to a HCF, especially if it involves chemicals or radioactive materials. Of paramount consideration is the protection of the HCF and personnel. Keeping potentially toxic substances and people contaminated with such materials out of the HCF protects other patients and critically vital staff from becoming ill. Essential to protecting the HCF is ongoing and real- or near-realtime communications between the incident zone and the receiving institutions. Otherwise a facility can be overrun by the sick, injured or worried well—any of which can be contaminated. An index of suspicion is critical, especially if patients self transport from a scene in advance of first responders arriving at the incident, as happened during the sarin nerve agent of the Tokyo subway in 1995. During that time 23% of hospital staff involved suffered acute poisoning symptoms from secondary exposure from nerve agents. Nearly 10% of emergency responders were also affected (Jarrett, 1999; Christensen *et al*., 2008a; Liu and Rodgers, 2008; Kennedy *et al*., 1996; Lai *et al*., 2003).

In addition to an index of suspicion, technology plays an important, but yet incompletely appreciated or defined, role in early detection. Detector technology includes the traditional hand-held Geiger–Muller counter (GC), the radiation detection portal (RDP). In limited situation studies, both technologies were useful, *if* they were used appropriately, calibrated and capable of detecting the potential threat. Not all detectors, especially older models, are able to detect the full range of IR. Often special attachments, such as wands, are needed to allow the GC to detect alpha emissions.

The ability to detect, locate and quantify radioactive materials is a major advantage not universally afforded by other hazards like biological or chemical agents. Biological agent releases are usually surreptitious; unless the event is announced, detecting the pathogen at the point of dispersal or those exposed is unlikely. Bear in mind that there is an incubation period, which is the lag period between exposure and illness. Although a variety of detection technologies are deployed or under development, realtime alert capacity remains largely unrealized. Identification of a biological event, alas, occurs as patients present. Chemical agents, even unannounced incidents, yield symptoms much closer temporally than biological weapons. Moreover, there is likely to be a group of individuals simultaneously exposed, albeit they may present to different facilities. There are numerous detectors that can identify various chemical agents, although false positives remain a challenge. Radiation is a distinctive threat in terms of detection capability. The main challenge for the clinician or responder is considering radiation, not detecting it—with a caveat that all detectors do not necessarily detect all types of radiation.

6.4 Types of Radiation Detectors

- **Geiger–Muller counters (GMC)** (**Figure 9**) or so-called 'Geiger counters' are used to detect ionizations. There are a number of other detectors available, but GMC are the most common and easiest to use.
- **Dose-rate meters** (**Figure 10**) are used to *quantify* radiation levels. They are scaled to read in 'roentgens per hour' or 'milliroentgens per hour' or 'microroentgens per hour'.
- **'Survey meters'** (**Figure 11**) detect radiation; they are used to count ionizations in counts per minutes (cpm).

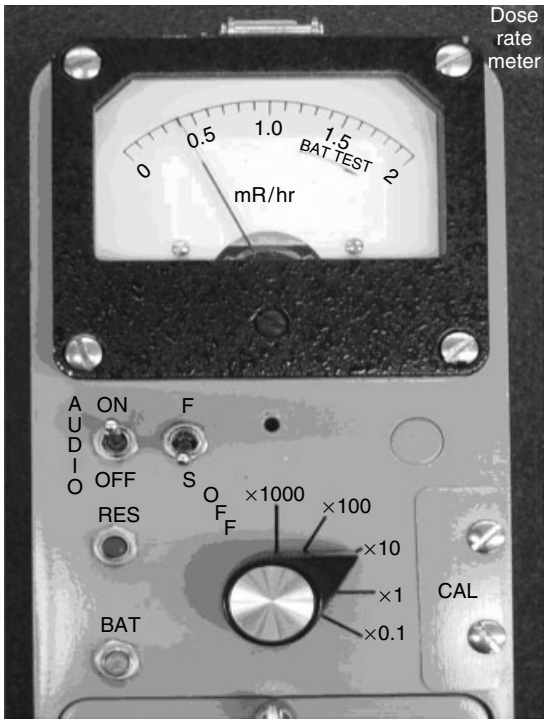

Figure 10 Dose-rate meter. (Reproduced from Christensen 2008a; 2008b, with permission from Radiation Emergency Assistance Center/Training Site (REAC TS).)

Prior to use, remember to check the level of background radiation in the area where patients from a suspected radiological incident will be evaluated and treated (Jarrett, 1999; Christensen *et al*., 2008a; Ricks and Fry, 1990). Background levels vary with geographical area. For example, the background levels in Oak Ridge, TN are in the range of 20–40 cpm. Bear in mind that higher levels may generally be found in areas at higher elevation; however, other factors may impact background levels.

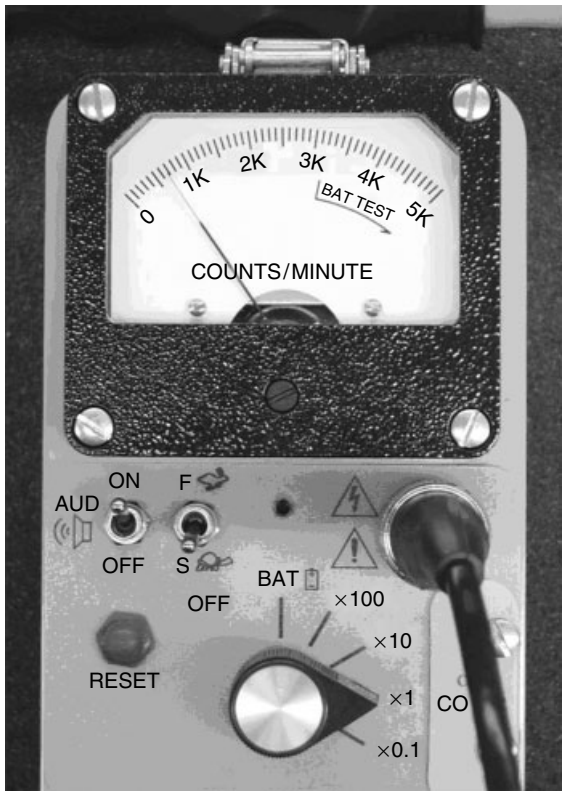

Figure 11 Survey meter. (Reproduced from Christensen 2008a; 2008b, with permission from Radiation Emergency Assistance Center/Training Site (REAC TS).)

First responders in the EMS system and public safety (fire, police) as well as first receivers may unknowingly be exposed to radiation or contaminated with radioactive materials. While increasingly the EMS has a variety of detectors in the field, radiation remains an underpractised area.

The following is a description of the equipment necessary to have ready in advance of anticipated radiation victims. The objective is to facilitate decontamination, safe collection and containment of potentially contaminated clothes and fluids (decontamination run-off and body fluids), create, as necessary, barriers along corridors and floors, staff/medical teams wearing appropriate barrier clothing and utilizing detection technologies to identify the threat.

6.5 Identifying Radioactive Materials

GMC or Geiger Counters (**Figure 9**) can be used to detect and locate radioactive materials, not to *identify* radiation and radioactive sources. Pancake probes can be used to distinguish between alpha, beta and gamma radiation in the appropriate setting and by a trained professional. Identifying the radiation type(s) involved is highly

At the top are 'pen' or 'pencil' or 'pocket' dosimeters from which photon doses can be read directly by looking through the device to see a reading of dose to the dosimeter. At the bottom is a digital direct-reading dosimeter. (Reproduced from Christensen 2008a; 2008b, with permission from Radiation Emergency Assistance Center/Training Site (REAC TS).)

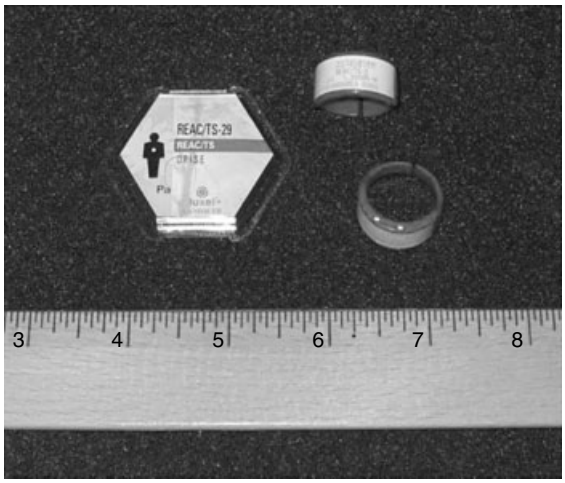

Figure 13 On the left is an optically stimulated luminescence dosimeter (OSLD) usually attached to clothing between the shoulders and the waist. On the right are two views of ring dosimeters. Both types must be 'developed' by a special process to determine dose absorbed in the area where the dosimeter is worn. (Reproduced from Christensen 2008a; 2008b, with permission from Radiation Emergency Assistance Center/Training Site (REAC TS).)

useful in planning medical management (Jarrett, 1999; Christensen *et al*., 2008a; Ricks and Fry, 1990; Salen *et al*., 2007; Gollnick, 2000; Thermo Scientific, 2009).

Identification of radioactive material can be accomplished with a gamma spectrometer. This is a relatively sophisticated piece of equipment that may be located only at fairly specialized research, response or designated radiation response HCFs. However, to effectively prepare for a radiation event, such facilities that can provide critical identification services need to be identified, agreements developed with and then included in the ED response plan *before* an incident. Of note, there are portable spectrometers available on the market, but they may require the expertise of an HP.

Figure 14 Electronic personal dosimeter from Thermo Scientific (NB: this is not an endorsement of any specific product or manufacturer; for illustrative purposes only!). (Reproduced with permission from Thermo Scientific 2009.)

6.6 Dosimeters

Unless an incident has occurred in a known radiation-controlled environment, such as radiological or nuclear industries or laboratories, most victims will come in equipped with 'dosimeters' (**Figures 12–14**). A 'physical' dosimeter is a device that can be used to determine how much radiation is absorbed at the location on the body where the device is worn. These devices are designed to detect some, but not necessarily all, radiations, and they must be properly selected in advance according to likely scenarios and within their performance windows. HPs need to be consulted for decisions about devices to be used in EDs in advance of an incident. In the event the victims are wearing a dosimeter, an HP should be consulted to assist in accurate interpretation (Jarrett, 1999; Christensen *et al*., 2008a; Ricks and Fry, 1990; Salen *et al*., 2007; Gollnick, 2000).

There are a variety of dosimeters available. These include electronic personal dosimeters (EPDs) that are worn much like pagers on waist belts, have audible alarms and can be preset to a variety of alert settings (**Figure 14**). Some electronic devices that will directly report dose rates or radiation doses absorbed by the devices in measurable quantities in realtime.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Others include thermoluminescence dosimeters (TLDs), worn by radiology department personnel, or optically stimulated luminescence dosimeters (OSLDs), which must be developed after the fact by a special process. Dosimeters that must be 'developed' in this way will be of no immediate help with dose assessment. 'Ring' dosimeters may be worn by personnel handling radiation sources with their hands, such as during extraction of a piece of shrapnel or other surgical procedures. Direct-reading 'pen', 'pencil' or 'pocket' dosimeters may be worn by healthcare personnel during management of patients (**Figure 12**). These devices respond to photons, not alphas or betas. They can be read directly after or during patient management. These dosimeters must be 'zeroed' or the reading noted prior to use.

6.7 Hospital Facility Detection

Protecting a facility from surreptitious radiation exposures—hidden SDDs or preventing thefts of radioactive materials—has long been a security vulnerability. A wide range of approaches have been undertaken to develop 'arms-length' detection technology. These include large portal detectors strategically placed at ED entry points, small sensors placed strategically thoughout a facility and linked to integrated computer programs and other products. To date, no universally accepted product has been in widespread use. However, in November 2008, Washington Hospital Center in Washington, DC installed a radiation detection system as part of a pilot programme. The technology places a wide array of sensors that are integrated into an interpretation centre; the information is disseminated in realtime or near-realtime to key personnel. It is designed to identify gamma radiation from dirty bombs (RDD) as well as the theft of medical radiological material, contamination of patients and so on. Whether it has false alarms or the ability to detect during real events, or discriminate in a useful manner other forms of IR, remains to be seen. The 'holy grail' of detection technology that will identify a surreptitious release in the facility, or persons contaminated with or smuggling out (or in) radioactive materials, in realtime, remains to be proven cost-effective and practical for the average HCF.

6.8 Radiation Protection and Contamination Control

Protection from radioactive materials and radioactivity is not much different to protection from biological or chemical agents. It is relatively easier to provide protection from radiological materials because of the ability to detect them. Contamination control is the most important way to prevent exposures. A very basic level of understanding of physics, how radioactive materials behave and how to control radioactive contamination is all that is needed by healthcare providers.

The equipment necessary can be found in **Table 5**. Personnel can help protect themselves by using:

- Universal precautions
- Sterile technique.

6.9 Decontamination

Contamination should be considered as nothing more than dirt with radioactive atoms mixed in, so remove the dirt and the radioactive materials go with it. Decontamination of the potentially radiation-contaminated patient is similar to that for chemically exposed patients, with a few caveats.

First, soap and water is adequate. There is no need for harsh chemicals, shampoos, shaving cream, industrial nonsolvent grease removers and any number of other types of cleansers.

Warning: Degreasers or other solvents should not be used because defatting of the skin may damage it enough to allow percutaneous absorption of radioactive and other potentially toxic materials (Christensen *et al*., 2008a).

Second, be thorough—hair, under the nails, orifices, intertriginous areas—but avoid abrading the skin, which can increase the risk of absorption.

Priorities for decontamination should be given to open wounds first, then body orifices, in particular the nose and mouth, or any other area that may be a portal for radioactive materials to enter the body. A superb reference for decontaminating the potentially contaminated patient with radioactive materials is *http://orise.orau.gov/reacts/guide/procedures.htm*.

Total-body decontamination, like showering, may be necessary, even with the presence of radioactive materials. In many cases, biological or chemical hazards may be more hazardous than radiological materials, therefore management of those contaminants will dictate the best method of decontamination.

Body hair, including beards and eyebrows, should not be shaved, because microabrasions may allow absorption and internalization. Given the deleterious effects of radiation on hair follicles, shaved eyebrows may not regrow.

Decontamination of wounds with intravenous (iv) fluids and a syringe is a very useful technique for wound management. Wound care, irrigation, debridement and repair can generally proceed as usual, but, given the effect on the immune system and healing, consultation with surgeons knowledgeable in treating such patients, along with an HP can greatly enhance medical outcomes. Bear

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 5 Decontamination and radiation response equipment (Leikin *et al*., 2003; 2007; Jarrett, 1999; Christensen *et al*., 2008a; Ricks and Fry, 1990; Liu *et al*., 2008; Kennedy *et al*., 1996; Lai *et al*., 2003; Salen *et al*., 2007; Gollnick, 2000; Thermo Scientific, 2009)

Universal PPE	Hospital greens and surgical gown (waterproof, any openings taped shut)
	Surgical trousers taped to shoes
	Caps (water resistant/water proof)
	Face shield (water resistant/water proof)
	Booties (water resistant/water proof)
	Double glove: inner layer taped to surgical gown
Plastic apron	—
Dosimeters	Pencil dosimeters
	Thermoluminescent dosimeters (TLD)
	Finger TLD
	Survey meters
	QFD + charger
	Electronic readout dosimeter/electronic personal dosimeter (EPD)
	Personal air sampler
Plastic sheeting (polyethylene)	Wall and floor
	Drapes
Ventilation filter paper	—
Plastic bags and large garbage cans	—
Butcher paper	—
Radiation signs and tape	—
Decontamination stretcher	Stretcher should have drainage capability and storage container tank
Lead storage containers	—
Respiratory masks—n95 or greater	—
Radiation detector	Capable of detecting alpha, beta, gamma, X-ray.
Advanced level PPE	Level A, B or C depending upon response role
Neoprene industrial gloves	—

in mind, if a life-saving medical intervention would be necessary on this patient in the absence of radioactive materials, then the intervention can usually be done in the presence of radioactive materials.

6.10 Self-Protection

Key points:

- Minimize *time* spent around or near sources of ionizing radiation
- Maximize *distance* from sources. The inverse square law defines the effect of distance upon dose. If the distance is doubled, the dose will be quartered. If the distance is halved, the dose will be four times higher
- Maximize *shielding* from sources
- Minimize *amounts* of radioactivity.

7 CONCLUSION

The threat of radiation—whether from an industrial or nuclear reactor accident or the intentional use of a weapon, is increasing. With widespread proliferation of radioactive materials, securing these is a daunting task, as is preparing an HCF to address radiation victims, especially in a world of competing demands and financial pressures. Nevertheless, it is the HCP the public looks to as the definitive protector in the event of a radiological event. Given most HCFs, as well as EMSs and clinicians have not seen, let alone treated a radiation victim, greater training is warranted. While most departments would fail to certify a clinician to perform intubation after only practising once a year or less, is it wise to 'certify' or consider a HCF competent to respond to a radiation event when plans are old or nonexistent, drills rarely performed and training has been cut back?

The management of the patient acutely poisoned by radiation is complex and requires a team of experts drawn from a variety of medical and health disciplines. Working together to develop familiarity prior to an event will go far to enhance capabilities when the real thing occurs.

Medical management hinges upon early recognition, which will require awareness, detection technology, treating life-threatening injuries and anticipating the long-term effects of ARS. Such patients will require long-term care and monitoring. Infection control, nutritional and psychosocial care will be necessary.

Given most regions of the industrialized world have nuclear reactors, radiation research and industrial sources of radioactive material, preparedness is worth the effort. A rapid and well-performed response will save lives.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135

8 QUICK REFERENCE: RESPONDING TO A RADIATION POISONED PATIENT

The following is a checklist when radiation/nuclear patients may present. Consider the ability to conduct each section an ersatz list of competencies to which HCPs should be held.

8.1 Essential Tasks

ED/receiving medical personnel should be able to perform initial surveys for radiation and radioactive contamination.

Key Facts: The history (suspected/actual) of a radiological or nuclear incident is as essential as the medical history to the medical diagnosis and management of patients:

- History of the incident—document
- Radiation—yes or possible?
- History of mechanism of injuries—document.
- Radiation injury alone
- Combination trauma/burn/radiation
- History and times of onset and duration of symptoms—document.
- Call for health physics support
- Radiological and healthcare personnel should be identified, trained and integrated into ED processes *prior* to an incident.
- Patient radiation surveys
- Incident history and reconstruction
- Identification of radioactive materials
- Radiation dose estimates—help guide medical management.
- The process of incident history and dose estimation need to be repeated.
- These patients require ongoing re-evaluation to guide medical management.
- Conduct a complete physical examination and document including:
- Vital signs
- Temperature
- Weight
- Skin appearance
- Involve consultation with key specialists early
- Infectious disease
- Haematology
- Surgery
- Call for psychosocial, pastoral and other support
- Psychosocial support personnel need to be identified, trained and integrated into ED processes *prior* to an incident.

8.2 Laboratory Studies

Key Facts: Laboratories and the necessary sampling equipment required to identify and quantify radioactive materials on clothing, dressings or in-body fluids (bioassays) need to be identified *prior* to an incident:

- Save and double-bag contaminated clothing and dressings as samples for further radiological analyses
- Have appropriate secure/safe location for potentially radiation-contaminated materials
- Suspicious incidents are likely to be considered part of a crime scene; the issues associated with chain of evidence can complicate the medical response.

Preparedness planning and practice in advance of an actual radiological or terrorist criminal event will allow greater interoperability and smoother working relationships with law enforcement, preventing the potential for obstructive territoriality. It will also enhance the collection of forensic samples and the need for heightened attention to proper collection, containment and identification with patient name, patient identifier, date and time of collection and name of collector.

- Laboratories that can perform cytogenetic biodosimetry need to be identified *prior* to an incident
- Cytogenetic biodosimetry
- Usually, only one lithium-heparin tube is needed
- Special handling and packaging are required
- Cytogenetic laboratories
- Most of those that perform chromosomal analyses do so for genetic disease diagnosis and counselling rather than dose assessments
- They are *not* typically set up to perform chromosomal analyses for radiation biodosimetry
- Two federally funded cytogenetic biodosimetry laboratories to date are available in the United States
- The Armed Forces Radiobiology Research Institute (AFRRI) in Bethesda, MD
- The Radiation Emergency Assistance Center/Training Site (REAC/TS) at the US Department of Energy's Oak Ridge Institute for Science and Education (ORISE) in Oak Ridge, TN
- Draw all laboratory specimens and perform diagnostic testing as required for other injuries and illnesses
- Laboratory specimens and special studies that may be required for evaluation of radiological injuries:
- Complete blood count (CBC)
- Absolute lymphocyte counts (ALCs) every six hours for the first 24 hours than every 12 hours for two days, then daily
- Absolute neutrophils counts (ANCs) every six hours for the first 24 hours than every 12 hours for two days, then daily

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Check initial urine specimen for radioactivity with a Geiger counter—this is referred to as 'rad urine'on the Radiation Patient Treatment decision support algorithm in **Figure A.1**
- Some high-energy photons from ^{137}Cs might be detected in urine depending upon how soon after an event the initial spot urine is checked.

A negative initial spot urine radiation survey is *meaningless*—only positives that indicate internal contamination are significant.

- Begin 24-hour urine and faecal collections for 'radiobioassays'.
- Such laboratories need to be identified *prior* to an incident.
- Obtain a baseline chest X-ray
- Perform other special studies as needed
- Obtain a serum amylase initially, then at 24 hours
- Significant irradiation of the salivary glands can result in high amylase levels.
- Interpret high amylase levels with caution if the patient has suffered from trauma affecting the face, head, neck, chest or abdomen.
- Obtain blood for typing
- Cross match only if needed for other medical or surgical conditions.
- Obtain blood for HLA tissue typing
- Draw one lithium-heparin tube for cytogenetic biodosimetry
- Culture wounds, blood or other body fluids as indicated.

In severely neutropenic patients, particularly those who are also anaemic, they may not mount a normal inflammatory response. Examples include:

- A urinary tract infection without pyuria
- Pneumonia without chest X-ray infiltrate
- Skin infection without typical cellulitis.

Radiation/nuclear events can cause anxiety and fear. This may result in significantly more patients, families—the worried well—disproportionate to the event. This exaggerated concern response can include healthcare providers. Information is the best cure for fear.

- Expect larger numbers of patients with the *perception* of radiation injury or illness than those who actually may have *real* significant radiation exposures or contamination.

9 APPENDIX A: FAST FACTS

The following 'fast facts' can be photocopied and place strategically in your department to guide your preparedness and response to a potential radiation or nuclear event.

9.1 Enhancing Your Preparedness

First and foremost, every department that will be called upon to respond to a radiation or nuclear event should have the following:

- An updated RAD/nuclear response plan that is practised regularly
- Team members who have received training in RAD/nuclear patient care
- Readily available and key personnel are practised in the use of updated detection and surveying technology
- Have on display *validated algorithms* such as those from REAC/TS (**Figure A.1**).

9.1.1 Basic Considerations

- Most radioactive materials (and radioactivity) are relatively easy to detect with appropriate instruments:
  - If well maintained
  - If they cover the full range of ionizing radiation (IR)—alpha, beta, gamma/X-Ray)
- Once identified, the patient can be managed effectively employing simple and readily applied practices:
  - Universal precautions with appropriate personal protective equipment (PPE)
  - Integrate health physicists early in the process
  - Remember the immediate needs of the patient:
    - Trauma/life threatening illnesses
    - Time is tissue—radiation damage is progressive, but may not immediately be apparent
    - Antidotes and chemoprophylaxis must be initiated early—example of key antidotes and the respective radionuclide can be found in **Table 6**
    - Surgery and other aggressive/advanced interventions must be decided in concert with experts in radiation response, taking into account the potential weakening of immune response and healing response associated with radiation
    - These patients, especially once disrobed and decontaminated (soap and water) do not pose a threat to the HCF, personnel or other patients and thus should not be denied access to conventional diagnostic or other services
- Historically, nonterrorist radiation events have been classified into five categories:
  - *High-level external* radiation—external exposure

Table 6 Radionuclide and suggested antidote/therapy

Radionuclide	*Antidote*
Cesium 137	Prussian blue (ferric hexacyanoferrate), which adsorbs cesium in the GIT. It may enhance elimination.
Iodine 131	KI blocks thyroid uptake.
Plutonium 239	DTPA can be used as a chelator and or wounds. EDTA is also a suitable chelator. Aluminum hydroxide antacids may bind plutonium in the GIT
Radium 226	Immediate lavage with 10% magnesium sulfate followed by saline and magnesium purgatives. Ammonium chloride may increase fecal elimination.
Strontium 90	Aluminum hydroxide antacids may bind strontium in the GIT. Aluminum phosphate can decrease absorption by 85%. Ammonium chloride can acidify the urine and enhance excretion. Barium sulfate may reduce strontium absorption. Stable strontium competitively can inhibit the metabolism and increase excretion of radiostrontium.
Tritium	Oral fluids reduce the biologic half-life from 12 days to approximately 6 days. Do not overhydrate patients.
Uranium	Sodium bicarbonate renders the uranyl ion less nephrotoxic. Diuretics

- Late systemic symptoms (two to three weeks) including neutropenia and sepsis
- Similar industrial and accidental events have occurred with, but not limited to:
- Caesium-137
- Cobalt-60
- Iridium-192

- *Low-level external* radiation—external exposure
  - Normal clinical examination without physical damage expected
- *Local injury*
  - Usually to an extremity or specific area of the body
  - Systemic symptoms unlikely unless unrecognized/untreated high level of local radiation resulting in infection, necrosis
- *Internal—inhalation or ingestion*
  - Depending upon the dose internalized these exposures can range from nontoxic to fatal
  - The initial physical examination may be normal
  - Subsequently the patient may develop symptoms referable to radiation exposure, depending upon the dose
- *Iatrogenic/hospital/treatment* associated
  - Cancer and other radiation treatment
  - Brachytherapy
  - Nuclear medicine studies
  - *Caveat:* Radiation pericarditis is often overlooked

- Healthcare professionals (HCPs) can decrease their risk by:
  - Disrobing the patient (removes ~90% of contamination)
  - Decontaminating patient (soap and water)
  - Realizing patients do not pose a significant risk to HCPs.

9.1.2 Radiation-Related Terrorism

- May or may not be announced or heralded by explosion
- If associated with explosion it is important to recognize there may be four types of injuries:
  - Blast
    - Patients may have serious internal damage without obvious external signs
    - Tympanic membranes, lungs and hollow organs are highly sensitive to blast injuries
  - Burn
  - Radiation injury
  - Psychological trauma
- Clinical acumen and index of suspicion will be critical to assess the various clinical clues; include radiation in the differential diagnosis. Time is tissue; delayed diagnosis can be costly
- Victims of a radiation terrorism event involve three critical considerations:
  - Surgical care
    - Radiation can confound wound healing—surgical evaluation in consultation with infectious disease, haematology and radiation specialists is critical to determine the optimal time to consider surgery
  - Medical care
    - Radiation terrorist events may result in traumatic injuries, as well as exposure to radioactive materials
    - Always treat life-threatening injuries first
  - Radiological care
    - Radiation-related effects may not manifest for hours if the exposure is significant; most likely it will take days to weeks before clinical evidence of radiation sickness occurs

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- While treating trauma, surgical and other medical issues it is important to determine the estimated dose each patient received
  - Collaborating with a health physicist or other radiation expertise is essential to determine the exposure as the course of acute radiation syndrome is largely based upon the dose received and the underlying health and clinical situation of the patient.
  - The lethal dose for 50% of persons receiving whole-body irradiation or exposure to die in 60 days (LD50/60) is ~3.5–4.0 Gy (350–400 rad) with supportive care only. Some texts use the LD 50/30 signifying survival to 30 days
  - The LD 50/60 with aggressive expert medical care may be upwards of 6 Gy. Some suggest 8 Gy is survivable under these conditions. Greater than 10 Gy exposures carry a poor prognosis
- Once the exposure dose is estimated, the patient can be triaged into the categories of acute radiation syndrome (ARS) given in **Table 3**
- Acute radiation syndrome (ARS)
  - Symptoms vary by
    - Type of radiation
    - Individual radiation sensitivity
    - Amount absorbed
  - ARS is a time-phased illness
    - Prodromal phase—relatively rapid symptoms
    - Latent phase—dose dependent
    - Radiation illness
  - ARS radiation illness
    - Haematopoietic
    - Gastrointestinal
    - Neurovascular
- Initiate appropriate management of radiation illness, including:
  - Antidotes
  - Colony-stimulating factors
  - Infection prophylaxis
  - Other interventions

9.1.3 Challenges to Effective Response

- Lack of training persists among all healthcare professions concerning radiation
- Least emphasized of all preparedness threats—natural, industrial or intentional
- Radiation may not be considered at the first-responder level
- There may be a delay between recognizing that an event occurred and the patients who present—radiation events may be surreptitious or lack warning signs typical of other threats, such as explosives or chemicals.
- Radiation is rarely considered in the differential diagnosis
- Lack of familiarity with radiation detection equipment
- Lack of familiarity with critical resources including expertise, such as
  - Radiation Emergency Assistance Center/Training Site (REAC/TS) in Oak Ridge Tennessee (Emergency phone ask for REAC/TS: **865.576.3131** or **865.576.1005** or online at *http://orise.orau.gov/reacts/* (accessed 29 April 2009)).
  - Armed Forces Radiobiology Research Institute (AFRRI) in Bethesda, Maryland
  - Local HAZMAT
  - Healthcare facility radiation physicist
  - Regional poison information centre.

9.1.4 Opportunities to Enhance Preparedness

- Enlist expertise to assist your healthcare facility
- Collaborate *before* an event with local and regional responder groups to become accustomed to working with different performance cultures
- Conduct regularly scheduled training and update sessions
- Test your plans with drills, scenarios and table-top exercises
- Check your radiation response equipment regularly
- Ensure your facility has the appropriate countermeasures
  - Collaborate with regional preparedness, especially for chemotherapeutics
    - Antidotes—certain radiation appropriate medications may need to be acquired from the government
  - Personal protective equipment
  - Decontamination equipment
  - External resources—mutual aid agreements
  - Other medical interventions.

9.2 Radiation Terrorism Response: Fast Medical Facts

Make certain your department has an updated response plan and everyone on the team is aware of it, has practised it and has critiqued it.

9.2.1 Arrival

- The management of patients who are *irradiated only* and who are *not contaminated* requires no special area within the treatment facility.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat135
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Removing the victim's clothes is likely to eliminate ~90% of the external contamination threat to clinicians and responders
  - Using appropriate hazardous waste disposal procedures is critical
- Prepare a special area for receipt, evaluation and treatment of contaminated patients.
- *Priorities for decontamination*
  - *Open wounds*
  - *Body orifices*
  - *Intact skin*
- Decontamination must be accomplished to prevent/minimize internal contamination
- As soon as possible after medical and surgical conditions have been stabilized survey and collect using swabs or other testing materials as suggested by your radiation health physicists the following areas:
  - Face
  - Mouth
  - Nose
  - Open wounds
  - Don't forget intertrigonous areas.

9.2.2 Treatment

- Perform a patient assessment, keeping in mind the possibility of radiation
  - The initial survey should include appropriate detection technology
- Use a Radiation Patient Treatment algorithm
- *Treat trauma first: surgical and medical emergencies are a priority*
  - Remember to look for burns and blast injury
  - Combined injuries are defined as radiation injuries/illnesses *plus* trauma and/or thermal burns
    - Combined injuries significantly increase morbidity and mortality
  - Radiation-related illness may take hours, days or weeks to manifest

NB: Morbidity and mortality from radiation injuries and illnesses will usually be delayed, unlike some traumatic and thermal injuries

- A good history is essential; especially if there was no explosion and the patient may be the index case
  - Determining if radiation is a potential cause, especially in an unannounced event is a significant challenge for the clinician
  - Taking into account the patient is a good biological dosimeter by virtue of the relative radiosensitivity of tissue types can guide the clinician in determining if ARS is present and to what extent
- If radiation is considered, enlist the assistance of radiation HPs *early* in the management of the patient
  - *Estimation of dose will be essential to guide medical management*
  - Begin specific antidotes for some radioactive materials.

Depleted Uranium: Toxicology and Health Consequences

Alexandra C. Miller

CONTENTS

1 INTRODUCTION

Advances in metallurgy and weapons design in the past several decades have led to new munitions whose effectiveness has provided tactical advantages on the battlefield and consequently, saved the lives of military personnel. Depleted uranium (DU) kinetic energy penetrators are perhaps the best-known example of these advanced munitions, primarily because of their outstanding, well-publicized performance against enemy armour in the 1991 Persian Gulf War. DU munitions were again used in NATO military actions in Bosnia-Herzegovina (BiH) (1995) and Kosovo (1999), and, more recently, coalition actions in Iraq.

DU munitions were initially used only by Coalition forces during the 1991 Gulf War, but that use led to DU fragment injuries among Coalition forces as a result of friendly fire incidents. Other personnel may have been potentially exposed via inhalation/ingestion after working around vehicles struck by DU munitions. Such exposures were not considered especially dangerous at the time, because numerous epidemiological studies of uranium miners and millers working with natural uranium had shown few concrete health effects from exposure and DU is chemically the same as natural uranium, with the difference being the uranium isotopic concentrations. However, the exposure of wounded personnel to uranium as embedded fragments had no medical precedent, so the earlier studies, dealing primarily with inhalation or ingestion exposures in miners, were of uncertain utility. As a result, questions were soon raised as to whether it was wise to leave in place fragments possessing the unique radiological and toxicological properties of DU, especially when considering that exposures might extend as long as the 40–50 years remaining in the individuals' lives. As these treatment questions were being addressed,

Table 1 Transformation of human osteoblast cells: comparison of DU, tungsten alloy, nickel and beryllium

	Transformation: biological properties of transformed HOS cells					
	Untreated	DU (soluble)	DU (insoluble)	rWNiCo (insoluble)	Beryllium (insoluble)	Nickel (insoluble)
Transformation frequency (per survivor $\times 10^{-4}$)	4.4 ± 1.1	49.6 ± 4.8	71.2 ± 4.8	37.6 ± 5.1	31.4 ± 4.4	39.5 ± 3.1
Morphology	Flat	Transformed	Transformed	Transformed	Transformed	Transformed
Saturation density ($\times 10^5$ cells)	2.6	6.9	6.6	6.1	6.3	7.1
Soft-agar colony formation (plating efficiency %)	3	47	56	34	31	28
Tumorigenicity (mice tumours/mice inoculated)	0/82	9/20	14/20	8/20	7/20	6/20
Kras expression (densitometric analysis; relative to actin)	0.5	8.1	7.3	6.9	7.0	5.7
pRb phosphorylation (densitometric analysis)	6.1	1.0	1.2	4.0	4.6	1.1

Cells were exposed to DU, tungsten alloy, nickel or beryllium and assessed for neoplastic transformation. The transformation frequency was determined. A comparison of cell morphology, transformation frequency, saturation density, soft-agar colony formation, tumorigenicity, *Kras* expression, pRb phosphorylation was done.

a growing public concern about the long-term health and environmental impact of using a radioactive metal like DU on the battlefield fuelled forceful national and international efforts to ban the use of DU in munitions. The impact of DU on civilian populations and the environment was unknown as well.

This chapter aims to summarize the current status of knowledge about the potential health effects of DU, based on cellular, animal and limited human studies. Toxicological assessments have been conducted using cultured cells and animal models and have attempted to answer questions relating to toxicity, carcinogenicity and the involvement of radioactivity. Additional information and research is still needed to provide a more complete understanding of DU human health effects.

2 BACKGROUND

2.1 Uranium

An understanding of DU requires a review of the element uranium. Uranium was discovered in the mineral pitchblende in 1789 by the German chemist Martin Heinrich Klaproth. Uranium possesses a unique role in radiation science, since a sample of uranium was used by the French physicist Henri Becquerel in his discovery and formulation of the concept of radioactivity in 1896. Uranium does not exist in pure metallic form in nature because it is quickly oxidized in air and occurs most commonly as U_3O_8, uranium oxide, in ores such as pitchblende. Refined uranium metal used in reactors is in the form of UO_2, uranium dioxide.

Natural uranium has three predominant natural isotopes, ^{234}U, ^{235}U and ^{238}U, all of which are radioactive; other uranium isotopes such as ^{236}U can be produced artificially in a reactor. **Table 1** shows the relative contributions of the uranium isotopes to DU and natural uranium. Uranium isotopes are alpha-particle emitters; alpha particles are positively charged ions composed of two protons and two neutrons. Due to physical characteristics, alpha particles lose their kinetic energy quickly and have little penetrating power because of their charge and relatively large size. The range of an alpha particle is approximately 4 cm in air and considerably less (20–32 μm) in tissue (ATSDR, 1999a). Therefore, uranium is primarily an internal radiation hazard, since an alpha particle will only penetrate the outermost layer of skin. Thus, alpha particles represent little hazard when on the surface of the skin, but are potentially a significant hazard if inhaled or ingested, whereupon they come into close contact with sensitive tissues (Hartmann *et al*., 2000). In the decay process, beta and gamma radiation are emitted, radiations which are significantly more penetrating than alpha particles requiring the necessity of providing shielding for DU when it is not being used (ATSDR, 1999b). Uranium isotopes decay to other radioactive elements that eventually decay to stable isotopes of lead (ATSDR, 1999b). The half lives of the isotopes are: 2.44×10^5 years for ^{234}U, 7.10×10^8 years for ^{235}U and 4.5×10^9 years for ^{238}U, and their composition in natural

Comparison of the relative contribution of Uranium isotopes[a] (Natural and Depleted)

Isotope	Specific activity (μCi g^{-1})	DU SA by WT% (μCi g^{-1})	Natural uranium SA by WT% (μCi g^{-1})
^{238}U	0.333	0.332	0.331
^{236}U (not naturally occurring)	63.6	0.0001	0
^{235}U	2.2	0.0044	0.051
^{234}U	6200	0.093	0.310
Total		0.4295	0.692

[a]Contribution of daughter products is not include.

Figure 1 Comparison of relative contributions of isotopes of uranium (natural and depleted). The specific activities by weight of natural and depleted uranium are shown and the contribution of each uranium isotope is shown.

uranium by mass is: 0.005% ^{234}U, 0.711% ^{235}U and 99.284% ^{238}U. The isotopes of uranium have the same chemical properties because they all have the same number of protons, 92. Like all other elements, variation in the number of neutrons gives the isotopes different radiological properties. The radioactivity of isotopes can be compared using specific activity, a measurement of the number of nuclear transformations (disintegrations) per second per unit mass. The most abundant naturally occurring uranium isotope, ^{238}U, has the lowest specific activity (0.33 μCi g^{-1}) (Squibb *et al.*, 2005). The high specific activity of ^{234}U (6200 mCi g^{-1}) contributes to more than half of the radioactivity of natural uranium, even though by weight its percentage is extremely small. Enriched uranium is quantified by its percentage of ^{235}U (specific activity 2.2 μCi g^{-1}) which can range from 2% to more than 90% (US AEPI, 1995). A comparison of DU to natural uranium is shown in **Figure 1**. This chart quite simply shows that DU has an approximately 50% lower specific activity than natural uranium.

Considering the isotope half-lives and their mass percentages, it can be calculated that 48.9% of the radioactivity of natural uranium is derived from the isotope ^{234}U, 2.2% from ^{235}U and 48.9% from ^{238}U (ATSDR, 1999a). Thus, ^{234}U contributes as much to the radioactivity of natural uranium as does ^{238}U, despite the fact it is 20 000 times less abundant. Natural uranium has a low specific activity of about 0.68 μCi g^{-1} or 1.8 $\times$ 10^7 Bq, which means natural uranium is considered only a weakly radioactive element. However, chemically, uranium is categorized as a heavy metal (i.e. any metal with a specific gravity of 5.0 or greater) and like other heavy metals, that is, nickel and arsenic, has a significant chemical toxicity. Similar to those heavy metals, the chemical toxicity of a uranium compound varies depending on the nature of the compound, its solubility, and its route of exposure, different to that of natural uranium.

2.2 'Depleted Uranium'

The use of uranium as nuclear fuel or in nuclear weapons requires enrichment of the fissionable isotope ^{235}U. The enrichment process concentrates ^{235}U in the metal to specific activities required to sustain nuclear reactions. The by-product of enrichment is uranium with reduced levels of the ^{235}U isotope, or 'depleted' uranium. The Nuclear Regulatory Commission considers the specific activity of DU to be no more than 0.36 μCi g^{-1}, but more aggressive enrichment processes can drive this value slightly lower ($\sim$0.33 μCi g^{-1}) (ATSDR, 1999b). This means DU has roughly 50% of the radioactivity of natural uranium. Even though DU has less specific activity than natural uranium, it retains all of its chemical properties. The large-scale production of enriched uranium for nuclear weapons and fuel over the decades has resulted in an abundance of cheap DU, a factor that has played a role in its use in a wide variety of applications (e.g. radiation shielding, compact counterweights, armour, kinetic-energy weapons). The properties of DU that make it useful as an armour-penetrating munition are its density (1.68 times that of lead) and the ability to engineer into it a molecular structure that facilitates entry into a hardened target by 'shedding' outer layers of the metal during penetration. The chemical and physical properties of DU are ideal for many military and commercial uses. It is 65% more dense than lead (with a density of 18.9 g cm^{-3}), has a high melting point (2070°F, 1132°C), is highly pyrophoric (it ignites when it fragments), has a tensile strength comparable to most steels and is chemically highly reactive (Kirk and Machalowski 1982).

2.3 Depleted Uranium Exposures

Beginning with the 1991 Persian Gulf War, US weapons systems have utilized DU (frequently alloyed with 0.75% titanium by weight to reduce oxidation) for offensive and defensive purposes (Parkhurst *et al.*, 1995; OSAGWI, 1998). Heavy armour tanks have a layer of DU armour to increase protection. Offensively, DU increases the penetration effectiveness of the kinetic-energy cartridges and ammunition rounds used by the Army (105 and 120 mm tank ammunition), Air Force (armour-piercing munitions for the Gatling gun mounted on the A-10 aircraft), Marine Corps (Harrier aircraft and tank munitions) and Navy (rounds for the Phalanx Close-in Weapon System) (OSAGWI, 1998). The Army used an estimated 9500 DU tank rounds during the 1991 Gulf War, for both training and practice purposes (OSAGWI, 1998). The use of DU munitions in further military operations includes NATO military actions in Bosnia-Herzegovina (1995) and Kosovo (1999), and, more recently, coalition actions in Iraq.

Known exposure of US personnel to DU during the 1991 Gulf War occurred as the result of friendly fire incidents, cleanup operations and accidents (including fires). DU-containing projectiles struck 21 US Army combat vehicles (15 Bradley Fighting Vehicles and six Abrams tanks) (US AEPI, 1995). After the war, assessment teams and cleanup and recovery personnel (including explosive ordnance disposal, battle damage assessment and radiation control teams and salvage personnel) may have had contact with DU-contaminated vehicles or DU munitions. In July 1991, a large fire occurred in Camp Doha near Kuwait City. This site housed a number of combat-ready vehicles, and the series of blasts and fires damaged or destroyed vehicles and munitions including M1A1 tanks and DU munitions. Troops at the scene and those involved in cleanup efforts may have been exposed to DU residue. Other troops may have been exposed through contact with vehicles or inhalation of DU-containing dust. It is difficult to assess the exposure of Iraqi soldiers and other nonmilitary personnel during military operations.

A range of DU concentrations have been measured within struck vehicles in test firings of large-calibre DU rounds (US Department of Defense, 2004), and inhalation intakes of DU oxides for surviving crew have been estimated to be about 10–20% greater in an Abrams tank with DU armour, compared to one with conventional armour, and about three times greater in a struck tank than in a less heavily armoured Bradley Fighting Vehicle. In one test firing the activation of the tank's ventilation system reduced the concentration and hence the estimated inhalation intake of DU by about 90% (Capstone Report, 2004), but in friendly fire incidents in the Gulf War it is not clear whether ventilation systems were active, and assessment of risks in most studies are based on the cautious assumption of no ventilation. Those surviving within, or close to, a tank struck with a DU round will inhale DU oxides in the impact aerosols, and may also receive DU shrapnel wounds, and are therefore believed to be at highest risk from DU, although a broader view of the risks to soldiers on the battlefield is required (Miller, 2006; Spratt, 2006). Radiation risks to military personnel of handling DU rounds, and to tank crews from the DU rounds stored within tanks, are considered to be very low, as exposure levels can easily be monitored and managed. A discussion of civilian populations and the environment with regard to DU is found later in this chapter.

Most studies of the hazards of DU munitions have focussed on battlefield exposures, but there are also concerns about longer-term exposures to local populations who live in, or return to, areas where DU munitions were deployed. In the Gulf War, the conflicts in the Balkans and in Iraq, the great majority of the total mass of DU that was deployed was small calibre DU rounds (30 mm; ~300 g of DU), fired in strafing runs by attack aircraft, with only a small proportion being large-calibre tank rounds (mostly 120 mm; ~4.5 kg of DU). Most of the DU penetrators in strafing runs miss their intended targets and end up embedded several feet in the ground, where they corrode (UNEP, 2002). In the years following a conflict, the local population may also be exposed to DU by inhalation of resuspended soil containing DU oxides, unless careful clean-up procedures are used (UNEP, 2002).

Understanding the exposure pathways of most significance for soldiers and local populations, and the resulting risks to health, requires estimates of intakes of DU for a number of different scenarios. Exposures on the battlefield have usually been considered in one of three categories (US Department of Defense, 2004), an approach that provides a useful framework for considering the potential intakes and risks, and which was used in the Royal Society, Capstone and Sandia reports.

- Level I includes soldiers surviving in a vehicle struck by a DU penetrator(s), or first responders entering the struck vehicle to rescue the occupants. Intakes are likely to be dominated by inhalation of DU particulates and, for surviving crew, by DU shrapnel wounds.
- Level II includes those who work within struck vehicles for substantial periods, at some time after the impact, and who may be exposed to inhalation of DU oxides resuspended within the contaminated vehicle.
- Level III includes all others on the battlefield who may be exposed from being downwind of struck vehicles or from briefly entering struck vehicles.

Identification and health monitoring of soldiers who are believed to have received Level I and II exposures has been the main priority for veterans of the Gulf War and subsequent conflicts. The number of soldiers

who are known to have received Level I exposures is relatively small. For example, after the 1991 Gulf War, approximately 100 United States soldiers known to have been involved in friendly fire incidents were assessed as being in this category (McDiarmid *et al*., 2006 and 14 United Kingdom soldiers were assessed as having received Level I exposures in the Iraq conflict during 2003 (UK Ministry of Defence, personal communication; (Spratt, 2006). However, there are likely to be larger numbers of Iraqi soldiers from the 1991 Gulf War who had Level I exposures, but no data appear to be available. Exposures for soldiers categorized as Level III are likely to be much lower than for those in Level I or II, but, as this group is potentially very much larger, estimates are required of the range of exposures (and health risks) for soldiers and support personnel who were on or near the battlefield where DU munitions were deployed.

3 URANIUM ABSORPTION

Previous studies on uranium absorption, retention and excretion have been done almost exclusively following an acute uranium exposure and are very different from the chronic DU exposure scenarios that were discussed above. The amount of uranium that the body absorbs depends largely on the route of exposure and the solubility of the uranium compounds to which the individual is exposed. Absorption of uranium can occur in three ways, through inhalation, ingestion and wounding.

Following inhalation of uranium, insoluble uranium compounds may remain within the pulmonary tissues, especially the pulmonary lymph nodes, for a long time and thus constitute a localized radiological hazard. In contrast, uranium is less readily absorbed from the intestinal tract than from the respiratory tract, resulting in lower doses per unit intake. Chemical toxicity, characterized predominantly by renal dysfunction as a consequence of acute exposure to soluble uranium, and lung injury potentially caused by the ionizing radiation from uranium decay isotopes are the best-characterized consequences of acute exposure to uranium compounds. However, the chemical and radiological properties of uranium could act cooperatively to cause tissue damage, and therefore, it cannot be assumed that excess cancers would be due solely to the radiological effects of uranium or that organ damage is exclusively due to its heavy-metal properties.

4 URANIUM TRANSPORT, RETENTION, EXCRETION

Following acute uranium exposure, absorbed uranium forms soluble complexes with bicarbonate, citrate or proteins in the plasma (Pellmar, 1999a; Stevens *et al*., 1980; Cooper *et al*., 1982). Estimates show that approximately 47% of blood uranium forms a complex with bicarbonate in plasma, 32% of uranium binds to plasma proteins and 20% binds to erythrocytes (Chevari and Likhner, 1968). The retention time and excretion of the bicarbonate complex of uranium depends on the pH of the solution and differs in various bodily compartments (Berlin and Rudell, 1986). The low-molecular-weight bicarbonate complex passes through the renal glomerulus and is excreted in the urine at a rate that depends on urinary pH. At high pH, small amounts of uranium are retained within the walls of the tubular lumen of the kidney. At low pH, bicarbonate–uranyl (and citrate–uranyl) complexes dissociate. The uranyl ion forms complexes with proteins on the surface of cells lining the tubule. In contrast, protein-bound uranium is more likely to remain in blood since little protein passes through the glomerulus.

Based primarily on animal studies, the rate of deposition and clearance of inhaled uranium particles from the lung depends on their chemical form and particle size. Larger particles are transported by mucociliary action from the respiratory system to the pharynx, where they are swallowed and then eliminated in the faeces. The clearance of the smaller particles that are deposited in the lungs depends on the solubility of the compounds. Particles that contain the more soluble forms of uranium are more rapidly absorbed into the bloodstream and excreted in urine within one to five days (Damon *et al*., 1984), while smaller particles of less soluble forms can be retained for up 30 months (Leach *et al*., 1973). It is again important to consider the differences between acute and chronic uranium exposure when considering uranium kinetics. An example of the differences between acute and chronic uranium exposure and uranium retention can be observed by examining the contrasting studies of Lang and Raunemaa (1991) and Pellmar *et al*. (1999a). After administering high dose UO_2 to rats by an intragastric tube, no significant uranium was detected in liver, kidney, muscle, bone, brain, blood and urine within 48 hours post ingestion. In contrast, Pellmar *et al*., using embedded DU pellets (chronic exposure 1–18 months) in rodents, demonstrated that bone and kidney were the primary reservoir for the uranium that had dissolved from embedded DU fragments. Uranium also localized within the central nervous system (CNS), lymph nodes, testes and spleen (Pellmar *et al*., 1999a). Low levels of uranium were noted in the serum at all time points.

5 DU TOXICITY: *IN VITRO* RESEARCH APPROACHES

The earliest studies on DU effects involved using cellular model systems and were initiated and conducted

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

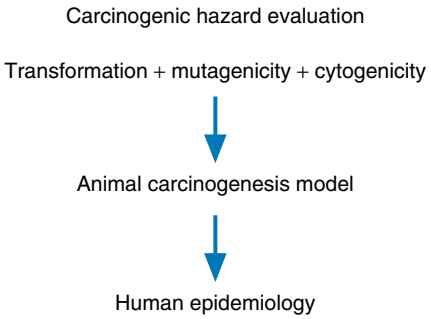

Figure 2 The process of carcinogenic hazard evaluation. The standard approach to assess carcinogenicity is to use cellular end points initially, followed by animal carcinogen studies. Human epidemiology studies contribute to the evaluation of carcinogenesis, if available.

at the US Armed Forces Radiobiology Research Institute, beginning in the mid 1990s. A strategic research approach, involving the progression from cellular studies to animal models and finally to human epidemiology considerations, was used by Dr. Miller and colleagues (**Figure 2**). Using this multistep approach, an immortalized human cell line was used to examine multiple end points, including neoplastic transformation, genomic instability, genotoxicity and radiation-induced damage. First the carcinogenic potential of soluble and insoluble forms of DU was evaluated using the neoplastic transformation model approach (**Figure 3**). In this approach, human cells were exposed to the test material, processed and analysed for cell colony formation. An evaluation of the colony morphology is used to define the state of transformation of the exposed cells. These were the first studies to demonstrate that DU could transform human cells into the malignant phenotype. A comparison to other heavy metals, like nickel and tungsten alloy, was also done. Neoplastic transformation of human osteoblast (HOS) cells to a tumorigenic phenotype after exposure to both uranyl chloride, a soluble DU compound, and uranium dioxide, an insoluble DU compound, was observed (Miller *et al.*, 1998b). These malignant (DU-treated) cells also demonstrated anchorage-independent growth, increased levels of the *k*-ras oncogene and decreased levels of the Rb tumour-suppressor protein. The latter changes are associated with the malignant phenotype in other heavy-metal-exposed cells. A comparison to insoluble DU (uranium dioxide), and other nonradioactive heavy metals was done to enable a comparison of DU-induced effects to those of better-known carcinogenic heavy metals, like nickel. Transformation rates of DU-exposed cells were 9.6 times those of untreated controls, and transformed cells formed tumours in nude mice. The results from all these transformation studies are compiled in **Table 1**. A comparison of the transformation values indicates that DU can neoplastically transform human cells similar to other better-known heavy metals and at a similar magnitude. These results were the first indication that DU could be carcinogenic; however, as is the case for any determination of carcinogenicity, *in vivo* studies would be necessary to more fully understand DU's potential as a carcinogen. Not only was the human-cell model excellent as a means to study DU, but the same model was later used to evaluate additional carcinogenic, mutagenic and genotoxic end points, providing a continuity in assessing the results.

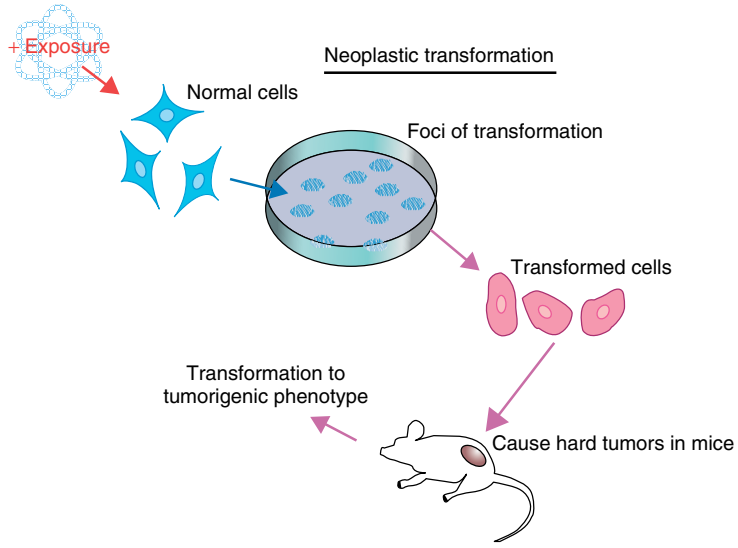

Figure 3 Neoplastic transformation assay. The neoplastic transformation assay is an *in vitro* assay used to assess the phenotype of cells following exposure to the suspected carcinogen. Cells are plated onto petri dishes, incubated for cell growth and assessed after the appropriate growth time for colony formation. Colonies are counted and individual colonies are expanded to a cell line. Cells are then injected into immunocompromised mice to evaluate tumorigenicity.

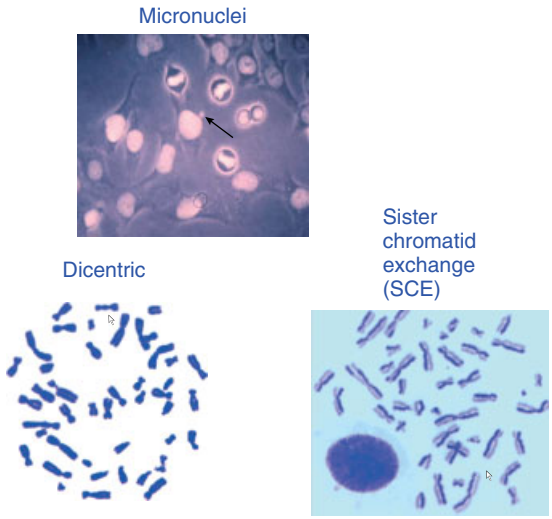

Figure 4 Examples of genotoxic damage. Chromosomal measures of genotoxic damage include micronuclei, dicentric chromosomes and sister chromatid exchanges.

In vitro studies demonstrated that DU was genotoxic by measuring the induction of sister chromatid exchanges, micronuclei and dicentric chromosomes in the same human-cell model used to study neoplastic transformation. Three examples of chromosomal damage measured in these studies are shown in **Figure 4**, including micronuclei, dicentric chromosomes and sister chromatid exchanges. Studies examining the effect of DU exposure on the induction of these chromosomal changes revealed that DU (in both soluble and insoluble forms) could induce an increase in genotoxic damage in comparison to control levels (**Table 2**). Experiments with cultured rodent cells have also demonstrated the capacity of DU to induce genotoxic changes. Lin (1993) showed that uranyl nitrate increased frequencies of micronuclei, sister chromatid exchange and chromosomal aberrations in Chinese Hamster Ovary (CHO) cells. The results describing the development of dicentric chromosome damage were the first studies to demonstrate that DU could induce a radiation-specific marker, a dicentric chromosome. The nonradioactive heavy metals, like nickel, which were genotoxic, causing sister chromatid exchanges and micronuclei formation, did not induce dicentric chromosomes; therefore, these data also suggest that DU causes genotoxic damage via a radioactive mechanism. This finding led to additional studies addressing the potential role of alpha-particle radiation in damage caused by DU exposure.

Inhalation studies in a rodent model showed that exposure to DU by inhalation resulted in DNA strand breaks in bronchoalveolar lavage (BAL) cells and in an increase of inflammatory cytokine expression and production of hydroperoxides in lung tissue, suggesting that the DNA damage was in part a consequence of the inflammatory processes and oxidative stress (Monleau *et al*., 2006a). The observed effects, which seemed to be linked to the DU doses, were independent of the solubility of DU compounds and correlated with the type of inhalation. Repeated inhalations resulted in a potentiation of the effect in both BAL and kidney cells. Measurement of DNA damage by the Comet assay in neutral conditions revealed that DNA damage in BAL cells was composed partly by double-strand breaks. Since double-strand DNA breaks are associated with radiation-induced, but not chemically induced damage, the results suggest that radiation could have contributed to the DU genotoxic effects observed *in vivo*. In contrast, the formation of uranium–DNA adducts and mutations in mammalian cells after *in vitro* exposure to another DU compound, uranyl acetate, were not associated with the generation of free radicals. These results suggest that chemical effects played a significant role in the DU-induced DNA damage (Stearns *et al*., 2005; Yazzie *et al*., 2005).

To more definitively address the question of the role of alpha-particle radiation and DU, Miller *et al*. (2002a) showed that incubating HOS cells with uranyl nitrate solutions at a fixed uranium concentration, but increasing specific activity, resulted in increasing transformation rates (**Figure 5**). These results demonstrated that uranium toxicity can result from both chemical and radiological toxicity. Previously it was thought that DU caused its effects through chemical effects alone, since the radioactive contribution was calculated to be low. The results from the uranium-isotope study have indicated that the role of radiation in DU's cellular effects cannot be discounted (Miller *et al*., 2002b). Further support of DU's radiation effects includes a

Table 2 Heavy-metal genotoxicity of human osteoblast cells. Cells were exposed to DU, tungsten alloy, nickel, or beryllium and assessed for genotoxic damage. Genotoxic measures used were micronuclei, dicentric chromosomes, sister chromatid exchanges and DNA double-strand breaks

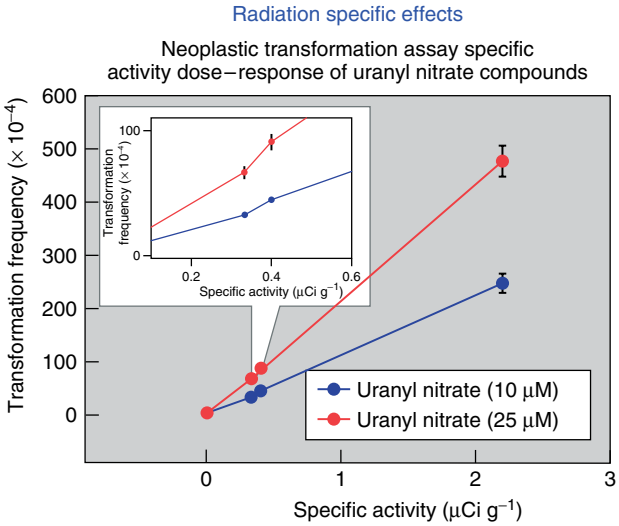

Figure 5 Radiation specific effects. To determine if DU induces radiation-specific damage, human osteoblast cells were exposed to equal concentrations of uranyl nitrate compounds (DU, specific activity (SA) 0.43 μCi g^{-1}; 238U, SA 0.33 μCi g^{-1}) that had different specific activities. Neoplastic transformation frequency was assessed. (Reproduced from Miller *et al.*, *Radiation Protection Dosimetry*, **90**, 4, 2002.)

recent mutagenicity study. Mutagenicity at the hypoxanthine (guanine) phosphoribosyltransferase (*hprt*) locus was measured by selection with 6-thioguanine. There was a dose-dependent increase in mutagenic response following DU exposure (10.50 μm); the average increase in mutagenicity above background ranged from 2.54 ± 1.19 to 8.75 ± 1.8 ($p < 0.05$). Using the same concentration (25 μM) of two uranyl nitrate compounds that have different uranium isotopic concentrations and, therefore, different specific activities, the effect on *hprt* mutant frequency *in vitro* was examined. Results showed that at equal uranium concentration, a 1.33-fold increase in specific activity resulted in a 1.27 ± 0.11-fold ($p < 0.05$) increase in *hprt* mutant frequency. Taken together, these data support earlier results showing that radiation can play a role in DU-associated mutagenicity *in vitro*.

Since evidence has shown that radiation can induce a transmissible persistent destabilization of the genome, studies were done to evaluate the involvement of genomic instability in the mechanism of DU-induced effects (Miller *et al.*, 2003). This means that damage to cells that are irradiated is transmitted over time to offspring cells. A variety of end points can be used to assess genomic instability, including cell survival, neoplastic transformation and genotoxic damage. One study has demonstrated the yields of cell lethality and DNA damage measured immediately, or at delayed times after DU, Ni and gamma-radiation exposure in a human cell model. Micronuclei yields were also measured in clonal progeny of surviving DU-exposed cells. Following the initial concentration-dependent acute response for both end points, data demonstrated that there was *de novo* genomic instability in the surviving progeny. Delayed reproductive death was observed for many generations (36 days, 30 population doublings) following cellular exposure to DU, Ni or gamma radiation. Delayed production of micronuclei was observed at times up to 36 days post DU exposure. There was also a persistent increase in micronuclei in all clones isolated from individual cells which had been exposed to nontoxic concentrations of DU. Cell clones isolated from gamma-irradiated individual cells (at doses equitoxic to the DU exposure) and Ni-exposed cells, did exhibit an increase in micronuclei frequency. From this investigation, it appears that DU exposure *in vitro* resulted in genomic instability manifested as delayed reproductive death and micronucleus formation. These studies confirm previous results demonstrating that heavy metals, like cadmium and Ni, could induce genomic instability *in vitro* similar to that observed with radiation (Coen and Mothersill, 2001; Mothersill and Seymour, 1998). Since there are also extensive data showing that alpha particles can induce a persistent instability in the genome of progeny of irradiated cells, it is difficult to determine whether the alpha particle or metal component of DU is responsible for the induced genomic instability. There have been no published studies determining whether the mechanism of genomic instability associated with DU exposure involves radiation, is exclusively chemical or involves both effects.

In conclusion, the *in vitro* studies examining cellular effects of DU compounds demonstrate that the DU compounds tested are neoplastically transforming, genotoxic, mutagenic and can induce genomic instability. Cellular damage following DU exposure is caused in part by radiation effects, but the contribution of chemical vs. radiation effects is still not known. These findings strongly support the hypothesis that DU is carcinogenic. In the next section of this chapter we will review what the limited carcinogenesis *in vivo* studies have shown regarding the question of DU carcinogenicity in animal models.

6 DU TOXICITY: *IN VIVO* RESEARCH APPROACHES

6.1 Solid Tumours in Laboratory Animals

Experiments with laboratory animals have expanded our understanding of the carcinogenic potential of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat136

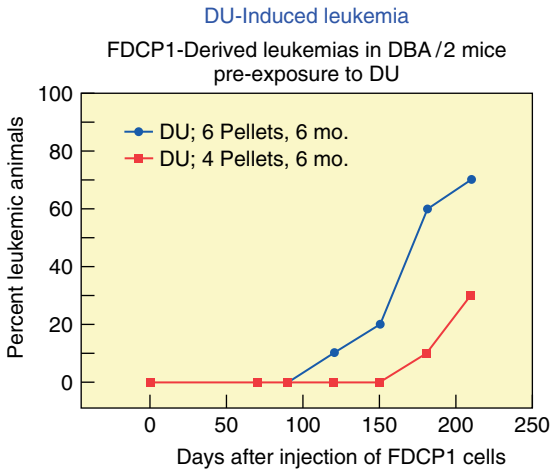

Figure 6 DU-induced leukaemia *in vivo*. Rodents were chronically exposed to implanted DU pellets for three months. The animals were then injected with haematopoietic progenitor cells and monitored for leukaemia development for 225 days. Leukaemia was determined by white blood counts and verified by necropsy.

uranium and DU. Not long after the 1991 Gulf War, in an effort to understand more about the potential health effects in personnel wounded in that conflict by DU shrapnel, Pellmar *et al.* (1999a) carried out a toxicological investigation using Sprague–Dawley rats implanted with various numbers of DU pellets (cylinders 1 mm in diameter and 2 mm long) to mimic shrapnel injuries in humans. Although cancer was not specifically designed as an end point in these studies, necropsies of subject rats showed no increased number of tumours in DU-implanted rats compared to tantalum-pellet-implanted controls. The interpretation of that data was confounded by the high levels of spontaneous tumour development typical of Sprague–Dawley rats and the lack of a statistically relevant number of rats. In similarly designed studies with appropriate numbers of rodents, Hahn *et al.* (2002) implanted male Wistar rats with either pellets or thin foils (1 × 2 or 2 × 5 mm) of DU in their hind limbs. This study showed that DU pellets of sufficient size were associated with soft-tissue tumours; the types of tumours included malignant fibrous histiocytoma, fibrosarcoma and osteosarcoma (Hahn *et al.*, 2002). All tumours were in the soft tissues of the hind legs directly associated with the implanted DU. In some tumours, black shards, particles of implanted fragments could be seen scattered through most of the tumour tissues. These histologic findings lend further credence to the association of the implants with the tumours. An increased tumour incidence was observed in the rats with the largest DU implants when compared with the sham or foreign-body (Ta) controls. In addition, increased tumour incidence was related to increased fragment size in the DU-treated rats. The response could not be explained by physical surface area alone because the tumour incidence with the Ta implants of similar size was much lower. There was a correlation with the initial alpha-particle radioactivity on the pellet surface. However, radiography demonstrated that the physical shape of the DU fragments changed prior to tumour development and therefore the surface alpha radioactivity changed with time as the shape of the implants changed, making it difficult to determine to what extent radioactivity was involved in the development of DU-associated tumours. In comparison, in experiments assessing the carcinogenic potential of DU and a tungsten alloy proposed as a surrogate for DU in armour-penetrating munitions, Kalinich *et al.* (2005) demonstrated DU pellets (1 × 2 mm cylinders) implanted into the leg muscles of Fisher 344 rats for 18 months caused no tumour development. These conflicting results have not provided a clear answer as to whether chronic exposure to embedded DU causes solid tumours, but highlight the usual confounding problems in heavy-metal carcinogenesis research. These confounding factors include the relevance of size-dependent tumour formation, heavy-metal solubility and species/strain selection.

6.2 Leukaemia in Laboratory Animals

While studies using rat models showed that DU caused a solid-state induction of solid tumours, other results indicated that DU implants could induce leukaemia in a mouse model. Recent studies from Miller's laboratory demonstrated that internalized DU could be a carcinogenic risk by causing leukaemia in laboratory mice (Miller, 2005). To better assess this risk, they developed an *in vivo* leukaemogenesis model using murine haematopoietic cells (FDC-P1) that are dependent on stimulation by granulocyte-macrophage colony-stimulating factor. Although immortalized, these cells are not tumorigenic on subcutaneous inoculation. As shown in **Figure 6**, intravenous injection of FDC-P1 cells into DBA/2 mice was followed by the development of leukaemias in 76% of all mice implanted with DU pellets In contrast, only 10% of control mice developed leukaemia. Karyotypic analysis confirmed that the leukaemias originated from FDC-P1 cells. The full impact of these results is not understood, since human studies have not shown the development of leukaemia in DU-exposed individuals; however, it appears that a DU-altered *in vivo* environment may be involved in the pathogenesis of a DU-induced leukaemia in an animal model. Further studies are necessary to determine how the DU-altered environment enhanced the development of leukaemia in mice.

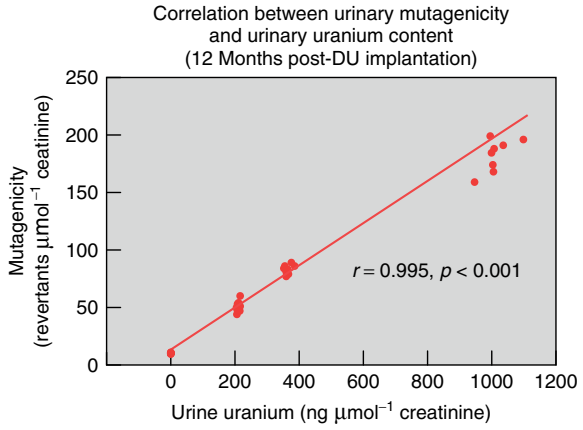

Figure 7 DU-induced mutagenicity *in vivo*. Rodents were chronically exposed to implanted DU pellets for 3–18 months. Urine was collected periodically and assayed for mutagenicity using the Ames test. (Reproduced from Miller *et al.*, *Mutagenesis*, **13**, 643–648, 1998.)

6.3 Uranium Genotoxicity/Mutagenicity

There have been very few studies evaluating uranium exposure in humans with genotoxic end points. Such studies are relevant because destabilization of the genome can indicate an increased susceptibility to cancer development. Martin *et al.* (1991) reported that levels of chromosomal aberration, sister chromatid exchange and dicentrics measured in nuclear-fuel workers increase proportionally with uranium exposure. McDiarmid *et al.* (2004), in their 10 year follow-up of 39 veterans exposed to DU in friendly fire incidents during the 1991 Gulf War, reported that study participants exposed to the highest levels of DU showed a statistically significant increase in chromosomal aberrations compared to the low-exposure groups. HPRT mutation frequencies were also significantly higher in the high-DU groups, but sister chromatid exchanges were not.

The consistent observation of uranium-induced genetic changes remains a cause for concern since they are known to precede cancer development. Hu and Zhu (1990) injected uranyl fluoride into the testes of mice and showed that chromosomal aberrations in spermatogonia and primary spermatocytes are dependent on the amount of injected uranium. In experiments in which rats were implanted with pellets of DU and/or the biologically inert metal tantalum, urine mutagenicity levels increased in a DU dose-dependent manner (Miller *et al.*, 1998a). **Figure 7** demonstrates that DU internalization results in the excretion of a mutagen which is assumed to be uranium.

6.4 Nephrotoxicity

The review by Hodge (1973) of uranium toxicity prior to the Manhattan Project (1942) shows that it has long been known that uranium is toxic to humans, animals and other living things. Kidney toxicity of uranium was first recognized in animals around the middle of the nineteenth century, and kidney toxicity remains the primary basis for the regulation of uranium exposure. Limits for inhalation and ingestion of uranium are aimed at not allowing uranium content in the kidney to exceed a set value, which for most countries is set at a maximum of 3 µg of uranium per gram of kidney tissue; effects caused by exposure of the kidneys at these levels are considered to be minor and transient.

The pharmacokinetics and pharmacodynamics of uranium and, therefore, DU are well established (Wrenn *et al.*, 1985; Leggett, 1994; Taylor and Taylor, 1997; ICRP, 1995; Leggett and Pellmar, 2003). There have been many studies that have investigated the results of uranium exposure in laboratory animals (Morrow *et al.*, 1982; La Touche *et al.*, 1987; Ortega *et al.*, 1989; Wrenn *et al.*, 1989). Once absorbed it circulates in the blood, primarily as the stable uranyl ion UO_2^{2+} bound to bicarbonate, albumin or proteins (Diamond, 1989; Kocher, 1989; Leggett, 1989). In the kidney, uranium is filtered through the glomerulus and most is excreted within 24 hours. Renal kidney toxicity occurs when residual uranium is subsequently taken up by the proximal tubules and causes damage by forming complexes with phosphate ligands and proteins in the tubular walls, thereby impairing kidney function (Blantz, 1975).

Pellmar *et al.* (1999a) showed that DU from pellets implanted in muscle of rats can be measured in their urine within one day after pellet implantation. Over the course of the 18 month experiment, kidney uranium content reached levels well above 5 µg g^{-1} of kidney tissue, a concentration that, if reached in an acute exposure, would normally prove lethal to the animal. The findings suggested that the kidney adapted to the high levels during the chronic exposure. This aspect of DU exposure has not been fully examined and the potential for adaptive responses to DU remains an intriguing possibility.

6.5 Bone Effects

Bone is a major site of uranium deposition. Neuman and colleagues, in a series of early articles designed to understand how uranium interacts with normal bone metabolism, published the first observation demonstrating that bone has a high affinity for uranium. Of a toxic dose, 20–30% of intravenous uranium could be found in the bones of male rats within 2.5 hours after administration, and 90% of the uranium retained by the body

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat136
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

after 40 days was in bone (Neuman *et al*., 1948a). They showed that young growing rats or rats deficient in dietary calcium incorporated greater amounts of uranium than controls (Neuman *et al*., 1948b). They also showed that uranium is preferentially incorporated in areas of active calcification and becomes more refractory to resorption as new calcification covers areas of uranium deposition (Neuman and Neuman, 1948).

Uranium incorporates itself into the bone matrix by displacing calcium to form complexes with phosphate groups in the matrix (Domingo *et al*., 1992; Guglielmotti *et al*., 1989). Bone-bound uranium establishes equilibrium with uranium in the blood, and as the circulating uranium is excreted by the kidneys, bone-bound uranium slowly returns it to the circulation over time (Wrenn *et al*., 1985). Pellmar *et al*. (1999a) demonstrated that DU from implanted pellets rapidly distributes throughout the body and accumulates at high levels in the bone, though histological examination showed no bone lesions as a result.

6.6 Neurological/Behavioural Effects

The neurophysiological effects of uranium exposure have been investigated for many decades. Among the early findings was the observation that uranyl ions potentiate the twitch response of frog sartorious muscles by prolonging the active state of contraction. The fact this effect was reversed by administration of phosphate ions suggested that uranium prolongs the action potential (Sandow and Isaacson, 1996). In a study of uranium workers, Kathren and Moore (1986) showed individuals excreting up to 200 µg U per l urine manifested abnormal mental function. High doses of oral (210 mg kg^{-1}) or subcutaneous (10 mg kg^{-1}) uranyl acetate caused tremors in rats (Domingo *et al*., 1987). It was also shown that uranium applied at high concentrations to the ileal longitudinal muscle of guinea-pig (Fu and Lin-Shiau, 1985) and mouse phrenic nerve–diaphragm preparation (Lin *et al*., 1988) enhanced muscle contraction.

In a study investigating the toxicology of embedded pellets of DU in rats to mimic shrapnel wounds in wounded 1991 Gulf War veterans, Pellmar *et al*. (1999b) demonstrated that DU crosses the blood–brain barrier and accumulates in the hippocampus, where electrophysiological changes were observed. Briner and Murray (2005) tested behavioural effects and brain lipid peroxidation in rats exposed to various concentrations of uranyl acetate in drinking water for two weeks or six months. Open-field behaviour was altered in male rats receiving the highest dose of DU after two weeks of exposure; female rats demonstrated behavioural changes after six months of exposure. Lipid peroxidation levels increased in the brain and correlated with some of the behavioural changes, but the correlation was ambiguous. Barber *et al*. (2005) sought to determine the kinetics of uranium content in the brains of rats following a single intraperitoneal injection of uranyl acetate (1 mg kg^{-1}). They found that uranium content in all areas of the brain tested increased rapidly after injection and remained elevated for seven days post-injection. Interestingly, rats stressed by daily forced swimming before uranium injection accumulated less uranium in their brains and had lower levels than unstressed animals, seven days after exposure.

Additional models have been used to evaluate neurotoxicity. The neurotoxicity of DU-uranyl acetate in *C. elegans*, using various neuronal green-fluorescent-protein reporter strains to visualize neurodegeneration, was studied (Jiang and Aschner, 2007). Results demonstrated that DU-uranyl acetate had low cytotoxic potential, did not result in significant changes in cellular energy metabolism, thiol metabolite oxidation or lipid peroxidation. Furthermore, the *C. elegans* studies did not show any significant neurodegeneration following DU-uranyl acetate exposure. Together, these studies suggest that DU, in the form of uranyl acetate, has low neurotoxic potential.

Studies employing enriched uranium have also been conducted to evaluate the functional neurological effects of accumulation of uranium in the brain, Houpert *et al*. examined the effects of chronic exposure to enriched uranium in the drinking water of rodents (Houpert *et al*., 2007). Concomitant with significant accumulation of uranium in the hippocampus, enriched uranium exposure altered the spatial working memory capacities of rodents and this effect was correlated with previously described accumulation of uranium in the hippocampus, which is one of the cerebral areas involved in this memory system.

Limited studies have been done to assess behavioural effects of DU exposure and the results have been conflicting. An evaluation of the effect of implanted DU in rats indicated that DU did not have a significant negative impact on their general health or neurobehavioural capacities, when assessed after long-term DU exposure (Arfsten *et al*., 2005). In contrast, repeated inhalation of DU resulted in uranium uptake in several brain tissues and an associated decrease in spontaneous locomotion activity and spatial working memory in exposed rodents (Monleau *et al*., 2006b).

6.7 Reproductive/Developmental Effects

Despite nearly a century of studies of uranium toxicity, there were few detailed studies of uranium reproductive and developmental toxicity until the late 1980s (Domingo, 1995). In most exposure scenarios, the chemical toxic effects from uranium compounds appear to occur at lower exposure levels than radiological toxicity

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat136
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Hartmann *et al*., 2000), and this is thought to be the case for reproductive effects as well (Domingo, 1995). In the early 1980s, Domingo and his colleagues began extensive investigations of uranium reproductive toxicity, and they have provided most of our current knowledge on the subject to date. These studies, however, involved acute high-dose exposures to uranium and are very different from the chronic exposures examined in recent DU investigations. There are a few recent studies investigating the reproductive and developmental health effects of DU specifically. It is beneficial, however, to review the information regarding acute high-dose uranium exposures for comparison.

Early studies (Maynard and Hodge, 1949) identified uranium as a possible reproductive toxicant in rats. Male and female rats fed diets containing 2% uranyl nitrate hexahydrate for seven months, followed by normal diets for five months produced fewer litters, with fewer pups per litter, than control rats (Maynard and Hodge, 1949). However, it was difficult to determine in these experiments whether uranium toxicity or nutritional effects arising from retarded weight gain in the uranium-fed rats caused the decreased reproductive success. In follow-up studies, rats fed diets containing 2% uranyl nitrate hexahydrate for a single 24 hour period after weaning also produced fewer litters with fewer pups per litter than control rats, with no signs of maternal toxicity (Maynard *et al*., 1953), an observation that strengthened the connection between uranium exposure and reproductive toxicity.

Llobet *et al*. (1991) showed that male mice continuously receiving water containing uranyl acetate dihydrate and mated with untreated females resulted in a significantly decreased, but dose-unrelated, pregnancy rate, but testicular function and spermatogenesis were unaffected. Domingo *et al*. (1989) showed that pregnant female mice given uranyl acetate dihydrate ($0.05–50\,mg\,kg^{-1}\,day^{-1}$) by oral gavage from gestational day (GD) 13 through postnatal day (PND) 21 demonstrated no significant decrease in litter frequency, litter size and pup viability except at the highest dose ($50\,mg\,kg^{-1}$; about one-fifth of the oral LD_{50}). On the other hand, injection of 1/40 to 1/10 of the subcutaneous LD_{50} dose ($20\,mg\,kg^{-1}$) into pregnant female mice between gestational days 6–15 produced both maternal and foetal toxicity (Bosque *et al*., 1993). Some of the malformations noted in pups could have occurred as a result of maternal toxicity, but defects such as cleft palate and certain other variations are not known to be associated with maternal toxicity and were interpreted to be the result of uranium developmental toxicity (Domingo, 2001).

Recent studies have been conducted to examine the potential reproductive effects of chronic DU exposure. Using a Sprague–Dawley rat model, Arfsten and colleagues showed that internalized exposure to DU pellets (150 days total exposure), did not significantly affect the concentration, motion and velocity of sperm isolated from DU-implanted animals, in comparison to sham surgery controls (Arfsten *et al*., 2006). Reports of the health status of military veterans of the 1991 Gulf War have provided certain insights into the possible reproductive health effects of DU as well. A follow-up examination of DU-exposed individuals (via embedded DU fragments and/or inhaled DU dust) showed that there were no significant differences in semen and sperm characteristics among veterans with high- or low-DU urine concentrations (McDiarmid *et al*., 2000; 2004). Data from animals chronically exposed to DU pellets (seven months), however, have demonstrated a DU-dose dependence on the induction of sperm DNA damage measured by the Comet assay (Merlot and Miller, 2007) suggesting that DU exposure could have a deleterious reproductive effect in exposed males. Limited studies examining the reproductive effects on female rodents exposed to DU have been done as well. Oestrogen receptor-dependent responses in female mice were observed following long-term exposure (>120 days) to DU in drinking water (Raymond-Whish, 2007). These oestrogenic responses included selective reduction of primary follicles, increased uterine weight, greater uterine luminal epithelial cell height, accelerated vaginal opening and persistent presence of cornified vaginal cells. Indicators from this study that DU is an endocrine-disrupting heavy metal may have implications for reproductive health in females exposed to DU, but there are no data on human females and DU exposure to answer this question.

The impact of diminished reproductive parental health on offspring following parental DU exposures has been addressed in limited studies and, in general, the results demonstrate a DU dose- and time-dependent effect. Investigations on the involvement of DU exposure and offspring effects have been conducted using several model systems including Sprague–Dawley rats and C57/BL Big Blue transgenic mice. Short-term exposure (90 days) of Sprague–Dawley rats to embedded DU pellets did not have a negative impact on P1 reproductive success, survival, or body-weight gain (Arfsten, 2005). Furthermore, there were no statistically significant differences in F1 birth weight, survival and litter size at PND 0, 5 and 20 and no gross physical abnormalities were identified in the offspring (Arfsten, 2005). In contrast, long-term, high-dose DU-pellet exposure (seven months; eight pellets) in a 'Big Blue' transgenic mouse model, caused a significant reduction in F1 birth weight ($>12.3 \pm 1.1\%$) and litter size ($>22.4 \pm 2.0\%$) (Miller and McClain, 2007). Previous studies have demonstrated that paternal preconceptional exposure to radiation or heavy metals like cadmium can induce cancer in unexposed offspring (Lord, 1999; Dubrova, 2003; Nomura, 2004). The paternal transmission of genetic damage in offspring of male rodents carrying embedded DU pellets, using a transgenic mouse model, was examined. In this system λlacI gene mutation frequency in multiple tissues obtained from progeny of exposed

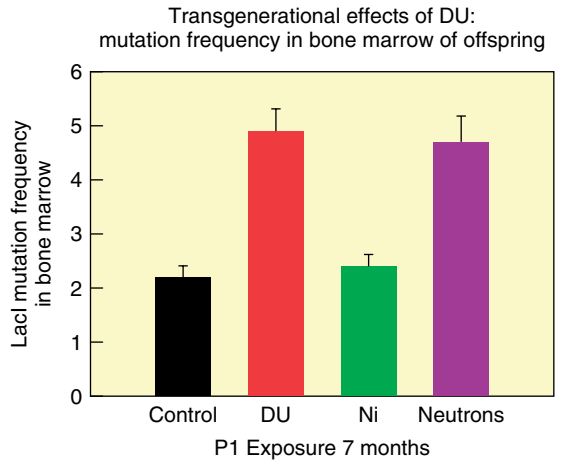

Figure 8 Transgenerational effects of DU: mutation frequency in bone marrow of offspring. An evaluation of preconceptional paternal exposure to DU was done. Male 'Big Blue' C57BL/6 mice which are genetically engineered to carry the *LacI* gene were chronically exposed to embedded DU for seven months. They were mated with nontransgenic unimplanted female C57Bl mice. The offspring were tested for *LacI* inheritance and offspring that carried the *LacI* gene were further tested for *LacI* mutagenicity (bone marrow). A comparison to implanted nickel and neutrons (1 Gy; 0.55 Gy min^{-1}) was done.

fathers is assessed by employing a λ*lac*I shuttle vector carried by cells of a transgenic mouse (Big Blue: strain C57BL/6 hemizygous mice containing 40 copies of a λ*lac*I shuttle vector per cell). Male rodents were internally exposed to implanted DU (high and low dose) and the mutation frequencies in testes and bone marrow were then measured. Offspring from exposed male parents were genotyped and those positive for the λ*lac*I gene were assessed for transmission of genetic damage in bone-marrow tissue. Data demonstrate that offspring from DU-exposed (high-dose) male parents exhibited a significant increase in the mutation frequency of the λ*lac*I gene in their bone marrow (2.4-fold elevation) in comparison to offspring from control or nickel-exposed fathers (**Figure 8**). The *LacI* mutation frequency in progeny from neutron-irradiated fathers was also significantly increased above control levels. The results from this study indicate the possibility of transmission of genomic instability from male parents carrying embedded DU to the somatic cells of their offspring. Paternal occupational exposures, including metals, (Tomatis, 1994) have been associated with an increased risk for a variety of childhood malignancies and transgenerational carcinogenesis has been shown in several rodent models with a spectrum of exposures, including chemical, metal and radiation (Cheng, 2004). Therefore, the possibility that DU exposure may be relevant to offspring health needs to be considered. This conclusion is further supported by results demonstrating that parental exposure to enriched uranium induced a delayed hyperactivity in rat offspring, suggesting that offspring studies should not be restricted to effects observed in young rodents (Houpert *et al.*, 2007) and that offspring effects are not related to carcinogenic possibilities, but include behavioural modification as well.

As of 1999, 50 of the Gulf War veterans in the McDiarmid studies had fathered 35 children since the conflict, and none had birth defects (McDiarmid *et al.*, 2001). The relatively small number of individuals involved in these studies and the end points that were possible limit their contribution towards fully understanding reproductive health effects and the studies were unable to address late effects in offspring.

7 EPIDEMIOLOGICAL STUDIES—DU EXPOSURE

A series of significant epidemiological studies of nuclear-industry workers and uranium miners and millers carried out since the mid-1960s have added a wealth of data to the uranium health-effects database. Several investigations of uranium millers (Wagoner *et al.*, 1965; Archer *et al.*, 1973; Waxweiler *et al.*, 1983), workers whose occupation exposes them to uranium dust inhalation in the workplace, used death certificates and, in some cases, health records to investigate cancers and other diseases (e.g. renal) as a cause of death. These studies failed to clearly identify a link between uranium exposure and any specific health effects, including cancer. Studies have also been carried out on workers at the Y-12 nuclear processing plant in Oak Ridge, Tennessee (Dupree *et al.*, 1995; Loomis and Wolf, 1996). The studies, which often included controls for age, race, gender, radiation dose, other chemical exposures and medical history (when available) showed no association between cancer and occupational exposure to radiation from external and internal sources. The relatively small sizes of these epidemiological studies, uncertainties about the amount of uranium workers were exposed to, and the impact of confounding factors, such as parallel exposures to agents such as radon, silicates and other toxic metals (e.g. arsenic), lead to large statistical errors in the results, so caution should be exercised in overinterpreting the results of such studies.

As discussed earlier, in the 1991 Gulf War, an unknown number of personnel were exposed to DU aerosols (primarily uranium oxides) after being in vehicles that were struck by DU munitions, rescuing personnel in struck vehicles, reclaiming or investigating struck vehicles or moving through areas where DU dust was left in the environment. Even though satisfactory exposure models exist for such personnel, it is generally considered that the brief exposures to DU dust experienced by personnel would have been far below

exposures experienced by uranium miners and millers in earlier studies, so no cancers would be expected by any route of exposure. McDiarmid *et al*. (2004) calculated radiation dose estimates for personnel carrying DU shrapnel in their bodies as a result of fragment injuries. Whole-body radiation counting, using the International Commission on Radiological Protection (ICRP) 30 biokinetic model for uranium, yielded an upper dose limit of 0.1 rem per year, a dose is not considered particularly dangerous.

The fact that human uranium epidemiology studies continue to remain controversial as to whether uranium exposure by any route is associated with cancer (IOM, 2008; ATSDR, 1999a) the *in vivo* results from the DU studies are significant, and only serve to strengthen the relevance of *in vitro* experiments showing genetic changes consistent with cancer development. The BEIR IV report (BEIR IV, 1988) on radon and other alpha-particle emitters states that large statistical uncertainties in most of the epidemiological studies looking for cancer in uranium workers may be hiding small populations of adversely affected individuals; it cautions against minimizing the risk until more studies are available. The same is probably true for DU exposure.

8 DU ASSESSMENTS IN THE BALKANS

8.1 Background

Since DU has been used by the US military and Coalition forces in Kuwait (1991) and Iraq (2003–present), and by NATO in military operations in the Balkans (1995, 1999), there has been concern among the civilian populations in those regions as to their potential exposure to DU. To evaluate potential environmental contamination by DU in the individual countries where it was used, the United Nations Environmental Programme (UNEP) and the French Defense Radiological Protective Service (Service de Protection Radiologique des Armées (SPRA)) have conducted studies. The UNEP has conducted studies: (i) in Kosovo in 1999; (ii) in Serbia and Montenegro in 2001; (iii) in BiH in 2002 and (iv) in Kuwait, with the International Agency on Atomic Energy (IAEA) in 2003; (v) the French SPRA conducted a radiological assessment in Kosovo in December 1999 to evaluate DU exposure in the environment as well. To assist UNEP, in 2000, the North Atlantic Treaty Organization (NATO) provided UNEP with new information concerning the use of DU during the Kosovo conflict. This information included maps, amount of DU ammunition used and coordinates of the targeted areas. It enabled UNEP to conduct one of the first-ever international assessments on the environmental behaviour of DU following its use in a real conflict situation. The French government was concerned as well, since French soldiers had been stationed very near to specific DU-targeted sites in Kosovo, so they commissioned their own radiological assessment. Since a small number of sites outside Kosovo, in Serbia and Montenegro, had also been targeted with ordnance containing DU during the Kosovo conflict, UNEP decided that they should also be assessed. In 2002, the Council of Ministers of BiH requested UNEP to conduct a similar assessment in BiH related to the use of DU ordnance during the war 1994–1995. UNEP assisted the IAEA in conducting a study in Kuwait in 2002 as well. In the Balkans and during the IAEA Kuwait mission, mainly air-to-ground ammunition of the types 20/25 mm penetrators (Kuwait) and 30 mm penetrators (Balkans) were studied.

As indicated previously in this chapter, natural uranium is found in trace amounts in all rocks and soil, in water and air, and in materials made from natural substances. Therefore, each individual is exposed to a 'background' level of uranium in the environment. Uranium is commonly found in air, soil, drinking water, leafy vegetables, root vegetables and milk products. Natural uranium is incorporated into the human body, mainly through the ingestion of food and water, and the inhalation of air. The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) has estimated that the average person ingests 1.3 μg of uranium per day, corresponding to an annual intake of 0.46 mg or 11.6 Bq, primarily through the consumption of drinking water. Typically, the average person receives an annual dose of less than 116 μSv from exposure to natural uranium via ingestion and inhalation. Most of the uranium ingested is excreted in faeces within a few days and never reaches the bloodstream. The remaining fraction will be transferred into the bloodstream and excreted in urine within a few days, but a small fraction remains in the kidneys and other soft tissue, as well as in bones. All totalled you will probably receive a whole-body internal dose of approximately 116 μSv of natural uranium in a year.

Uranium is not generally transferred effectively along food chains, so in environmental assessments, inhalation is usually the exposure pathway that merits primary attention. Processes, such as migration through the soil, deposition of resuspended material onto crops and transfer to groundwater, might be of greater interest in the longer term. In a combat situation, the main radiological hazard associated with DU munitions is the inhalation of the aerosols created when DU munitions hit an armoured target. Studies carried out at test ranges show that most of the DU aerosols created by the impact of penetrators against an armoured target settle within a short time of the impact and in close proximity to the site, although smaller particles may be carried a distance of several 100 m by the wind. A possible exposure pathway for those visiting or living in DU-affected areas after the aerosols have settled

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat136
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is the inhalation of the DU particles that are resuspended through the action of the wind or human activities. One possible pathway of exposure that merits consideration is the inadvertent or deliberate ingestion of soil, although doses from this exposure pathway were, however, found to be much lower than doses associated with other pathways. Furthermore, exposure of individuals who find and handle unexploded DU munitions via external irradiation, due to the beta particles and gamma rays emitted by the DU, could occur. However, the dose received would be significant *only if* a person were in contact with DU projectiles over a considerable period of time, since the contact dose to the skin from DU is about $2.3\,\mathrm{mSv\,h^{-1}}$. It is therefore unlikely that even prolonged contact with DU would lead to skin burns or any other acute radiation effect. For perspective, the worldwide average annual effective dose from natural background radiation is 2.4 mSv, with a typical range of 1–20 mSv. The most significant contribution to the worldwide average annual effective dose comes from exposure to radon and its decay products (1.15 mSv); exposure to terrestrial gamma rays and cosmic rays accounts for 0.48 and 0.38 mSv, respectively. It is important to keep in perspective, the amount of natural radiation exposure an individual is exposed to each year.

8.2 Results from UNEP Assessments of DU in the Balkans

Results were obtained by the UNEP on the DU assessments that took place in the Balkans and the joint IAEA-UNEP mission to Kuwait. It should be noted that the time between the military conflict and the corresponding assessment in Kosovo was 1–2 years, in Serbia-Montenegro 2–3 years, in BiH 7–8 and 13 years in Kuwait. Since UNEP did not have its own laboratory capacity, it relied on the assistance of several international laboratories to analyse the samples and complete the results. The laboratories involved were the Swedish Radiation Protection Institute (SSI), the Swiss SPIEZ laboratory, the Italian Environmental Protection Agency and Technical Services (APAT) and the University of Bristol, UK.

At the sites investigated by the UNEP DU assessments, where a total of approximately 10 000 penetrators were fired, more than 200 penetrators, fragments and jackets (casings) were found on surfaces, and more than 500 penetrators were discovered buried in the ground. UNEP divided its penetrator assessment analysis into several areas including isotopic concentration, actinides/transuranic contamination and corrosion.

UNEP found that the composition of the DU used for 30 mm ammunition in the Balkans had been constant: ^{235}U ($0.200 \pm 0.005\%$ by mass); ^{234}U ($0.00055 \pm 0.005\%$) and ^{238}U ($0.790 \pm 0.006\%$). A similar value was found on Type 20/25 mm penetrators, analysed by the IAEA from the joint IAEA mission to Kuwait. The presence of ^{236}U, a resulting product from uranium enrichment was confirmed ($0.0028 \pm 0.0002\%$ by mass). UNEP also confirmed the presence of plutonium in penetrators used in the Balkans, but the concentrations were found to be extremely low, ranging from less than 0.8 to $88\,\mathrm{Bq\,kg^{-1}}$ for the sum of ^{239}Pu and ^{240}Pu. From the IAEA Kuwait mission $^{239+240}$Pu was found to be in the range $0.6–6.2\,\mathrm{Bq\,kg^{-1}}$ in the DU penetrators. The values found by UNEP and IAEA were lower compared to the values published by the US Army in January 2000 on DU used as tank armour, ranging from 85 to $130\,\mathrm{Bq\,kg^{-1}}$.

After lying in the ground for over seven years in Bosnia, the penetrators were heavily corroded and intensive pitting (corrosion attack producing small holes) of the DU surface had taken place. Based upon information provided by the US military, it was estimated that the penetrators had lost 34% of their weight due to corrosion (24) and penetrators laying on the ground surface were much less corroded than those buried below the ground surface. While unconfirmed, evidence was observed during the IAEA Kuwait mission that penetrators and fragments showed a similar corrosion pattern under desert conditions as in the Balkans.

Multiple contamination places and types were examined including more than 500 points of contamination by DU, including contamination of ground, buildings, vehicles, air and water. A contamination of the ground surface may be either *localized* or *widespread* over a large area, depending on the properties of the aerosols and the prevailing meteorological conditions. Widespread contamination exists in cases where the contamination can be found over a couple of 100 m from the source of contamination resulting in an large affected area. In general, widespread contamination occurs as a result of initial dispersion in air during the use of DU penetrators and then by dispersion/resuspension of DU by wind. UNEP determined that there were multiple sites of localized ground contamination, but found no evidence of widespread ground contamination by DU.

Contamination of vehicles was not observed by UNEP, since any previously hit vehicles had been removed prior to their assessment. A very comprehensive study on the effects of DU and vehicle contamination has been published by the US Army Center for Health Promotion and Preventive Medicine (2004).

The DU assessments in Kosovo, and Serbia and Montenegro did not find any DU-contaminated buildings. In contrast, fragments and DU dust were found in two buildings which were still in use by the local population or the army in BiH at two sites which reportedly were targeted by A10 aircraft penetrators. Both scratch and smear samples were collected, demonstrating a primary deposition of debris and dust from the initial impact of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat136
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

DU penetrators on the concrete floor inside the buildings. DU contamination inside the buildings ranged between 11 and 1070 mg m^{-2}. Smear samples taken from surfaces of artillery guns and grenade boxes, considered to be secondary contamination, showed a surface contamination of 59–270 μg m^{-2}. The resuspension factor for this building was calculated and found to be 5.2 10 9 m^{-1}. UNEP, using ICRP models, calculated that this contamination constituted a minor radiological risk. Therefore, UNEP recommended several decontamination measures that were to be completed by the local authorities.

Water sampling and analysis in Kosovo, Serbia and Montenegro, and Kuwait showed no contamination of water by DU. However in BiH, DU contamination of groundwater was found at one of the 11 sites investigated. Uranium isotopic analysis of all 11 water samples demonstrated that DU was present in only one source. The concentration of DU in that source was considered low, however, and measures were taken to prevent future water use. Water from that source had been used in farming, but no further action was taken.

As with water samples, measurements on possible contamination of air by resuspended DU from contaminated ground were carried out in Serbia and Montenegro, Kuwait and in BiH. The levels in air in Serbia and Montenegro and Kuwait were insignificant. In the Balkans investigations, several sampling sites demonstrated an increase in uranium concentrations in the air at two sites that sustained more DU munitions usage. Using ICRP models, UNEP calculated that the concentration of DU in air was in the nanograms per cubic metre, 0.05–6.0 ng m^{-3}, range and was classified as low. Normal uranium concentration in the air was also in the nanograms per cubic metre range, 0.08–0.80 ng m^{-3} (radiation dose: 1 μBq m^{-3}). From the radiation-dose viewpoint, UNEP concluded that effective doses from airborne uranium are very small, even if the concentration is several hundred times higher than normal.

In terms of botanical materials, at all sites UNEP primarily sampled lichen. In Bosnia, some lichen showed traces of DU that suggested earlier or ongoing contamination, possibly via resuspension through the air from contaminated ground. No vegetables tested were found to be contaminated by DU. Several farming areas in Kuwait were investigated in detail in the IAEA Kuwait assessment. There was no evidence of the presence of DU in any of the soil samples taken in the farms. However, in some crop samples in Kuwait low concentrations of DU were found; these results are confusing since neither the water taken from the site nor the soil, nor any other vegetables demonstrated any DU contamination. UNEP concluded that a possible cross-contamination had occurred at the time of packaging the samples at the end of the assessment.

Based on UNEP's work to date, they have concluded that the residue of DU munitions does not present a significant risk to the health of the general population in the countries they assessed. On a site-specific basis, the main risks are still considered to be toxicological, based on exposure to a heavy metal. The radiological risks are very small and less than or equal to background natural radiation. However, based on the precautionary principle and on existing scientific uncertainty regarding the environmental behaviour of DU, risk reduction measures, such as access restrictions and clean-up, should be adopted. In addition, UNEP recommends that long-term monitoring of groundwater should be employed and that the authorities should also be active by informing the local residents and workers at such sites of the hazards associated with collecting DU residues and other possible actions.

9 SUMMARY AND CONCLUSIONS ON DEPLETED URANIUM HEALTH EFFECTS

Since internalization of uranium in any form will result in a combined chemical and radiation exposure, there exists the potential for subtle differences in health effects between DU and uranium. Recent developments in cell-biology technology and understanding are providing more sensitive approaches towards understanding those differences (Miller *et al*., 2007; 2001). Furthermore, since there are conflicting results regarding the carcinogenicity of chronic DU exposure, (negative solid tumour results vs. positive leukaemia results), the question still remains whether chronic DU exposure is a significant toxicological threat.

Toxicology and Disasters

H. Paul A. Illing

CONTENTS

1 INTRODUCTION

Disasters ('great or sudden misfortunes'—Concise Oxford Dictionary, 1990) occur from time to time. Because they are portrayed and analysed extensively in the news media and subjected to careful examination in subsequent public enquiries, they become entrenched in everyone's mind. Unfortunately, the ideas on how to handle or prevent potential disaster situations occurring have often been developed from the lessons learnt through analysing previous disasters. In many cases, disasters can be avoided and the effects of accidents minimized by careful planning. In addition, by examining how to handle the consequences of an accident once it has occurred, it should be possible to mitigate the effects. It is these thoughts that have led to legislation aimed at considering the safety aspects of certain hazardous situations at an early stage in order to minimize the likelihood of their becoming disasters.

Disasters may be naturally occurring, as with earthquakes and volcanoes. They may include the incidental results of human activity, as with incidents involving food supplies or industrial plant. Although fortunately rare, they may also be the intentional results of human activity, as with terrorist incidents. Some disasters are the consequences of a toxicant entering a biological system and creating a damaging perturbation to that system. These effects may be largely environmental (e.g. the consequences of an oil ranker spill in coastal waters) or they may affect human health, either directly (through ingestion of contaminated drinking water or inhalation of a toxicant as it is dispersed in air) or indirectly (e.g. via uptake into food species). Hence, a knowledge of the effects of toxicants can be important when examining disasters and potential disaster situations.

In this chapter, concepts involved in planning to prevent disasters occurring are discussed first. This is followed by an evaluation of different types of disaster or serious incidents involving toxicants. Although purely environmental effects should not be ignored, the examples chosen are all associated with human health effects. Subsequently, approaches to the planning associated with presenting disasters due to toxicants, and mitigating their effects, are discussed.

2 THEORETICAL CONSIDERATIONS

Many of the concepts used in analysing major hazards and minimizing their potential for causing disasters have their origin in engineering concepts associated with the design of military equipment, aircraft and nuclear plant. As a consequence, different national and international organizations have developed definitions for aspects of this work, and these definitions need examining, especially as difficulties can ensue if toxicologists and engineering-based risk assessors employ different interpretations of the same words. Although 'hazard' and 'risk' are interchangeable terms to the general public, they have separate meanings in the context of risk assessment, so their definitions will be examined carefully.

2.1 Hazard

Hazard is an intrinsic property of a substance or situation. The Royal Society Study Group (1992) defined hazard as 'a situation that could occur during the lifetime of a product, system or plant that has the potential for human injury, damage to property, damage to the environment or economic loss', and the Institution of Chemical Engineers called it 'a physical situation with a potential for human injury, damage to property, damage to the environment or some combination of these' (Jones, 1992). The most recent toxicological definition from the joint Organisation for Economic Co-operation and Development (OECD)/International Programme on Chemical Safety (IPCS) project on the harmonization of hazard/risk assessment terminology (OECD, 2003) calls hazard 'the inherent property of an agent or situation having the potential to cause adverse effects when an organism, system or (sub) population is exposed to that agent'. A chemical hazard was further defined by the Institution of Chemical Engineers (Jones, 1992) as 'a hazard involving chemicals or processes which may release its potential through fire, explosion, toxic or corrosion effects'. A major hazard is an imprecise term: the Royal Society Study Group called it 'a large scale hazard which may have severe consequences'. The Institution of Chemical Engineers calls a major hazard 'an imprecise term for a large-scale chemical hazard, especially one which may be released through an acute event'. Given that a major accident is 'an occurrence (including, in particular, a major emission, fire or explosion) resulting from uncontrolled developments in the course of the operation of any establishment and leading to serious danger to human health or the environment, immediate or delayed, inside or outside the establishments, and involving one or more dangerous substances' (The Control of Major Accident Hazards, 1999), it can be concluded that a major hazard is a hazard having the potential that, if realized, could constitute a major accident. Both of these latter definitions use a narrower remit to excluded natural hazards, hazards from the use of nuclear power and terrorist hazards.

For chemicals or radiation to represent toxic hazards, they must be present in sufficient quantities to exert toxic effects on the individual. If they are to be major hazards, they must be present in quantities which, if released or dispersed, could result in effects being seen in many people.

2.2 Risk

Risk differs from hazard, as it involves a consideration of the probability or likelihood of a consequence occurring as well as what the consequence might be. The Royal Society Study Group (1983) defined risk as 'the probability that a particular adverse event occurs during a stated period of time or results from a particular challenge'. The Institution of Chemical Engineers Working Party (1985) and Jones (1992) extended the statement to 'the likelihood of a specific undesired effect occurring within a specified time or in specified circumstances'. They go on to say that 'it may be either a frequency (the number of events occurring in unit time) or a probability (the probability of a specified event following a prior event), depending on circumstances'. The OECD (2003) definition is 'the probability of an adverse effect in an organism, system or (sub) populations caused under specified circumstances by exposure to an agent'. If risk is quantified, it is a statistically based parameter.

2.3 Relationship between Hazard and Risk

In engineering terms, the risk to the individual is obtained by identifying possible events associated with the release and dispersion of significant amounts of a toxic substance, and/or by analysing potential failure mechanisms which would allow the release to take place (Health and Safety Executive, 1989; 1992). Likely frequencies and sizes of releases can then be calculated. The hazard is a quantitative statement of the exposure conditions associated with a specified level of harm ('harm criterion').

For major hazards, risk associated with a failure includes identification of a geographic area for which, following dispersion, exposure matches or exceeds the harm criterion; that is, the risk is risk of the initiating event. In contrast, occupational and public health toxicologists and epidemiologists often think of risk in terms of likelihood of end effect occurring for a given level of exposure (the risk of end effect arising at the exposure level defined as the harm criterion). To the engineering risk assessor, this is 'uncertainty in defining the hazard'.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

For the purposes of this chapter risk will be taken as risk associated with the initiating event and dispersion pattern.

2.4 Individual and Societal (Population) Risk

There are two principal types of risk which can arise from major hazards: individual risk and societal (or population) risk. The Health and Safety Executive (1988a; 1992) has called the individual risk associated with major industrial hazards 'the risk to any particular individual, either a worker or a member of the public'. A member of the public is considered to be 'either anybody living within a defined radius from the establishment or somebody following a particular pattern of life'. Societal risk (or 'risk giving rise to societal concerns'; Health and Safety Executive, 2001) was 'the risk to society as a whole, as represented, for example, by the chance of a large accident causing a defined number of deaths and injuries'. It is expressed numerically as a frequency (F) that there will be a disaster harming more than a particular number of people (N), and the criteria for acceptability of societal risk can be aggregated in the form of an F–N curve (**Figure 1**). Although the individual risk remains the same for each person, the societal risk is governed also by the number of people likely to be affected. The individual risk of living 1 km from a major hazard (industrial or natural) remains the same irrespective of whether the hazard is located in an unpopulated area or in it city, but the societal risk is very different! The term population risk is used for environmental purposes, where usually it is the risk to the species or habitat, rather than to the individual organism, that matters.

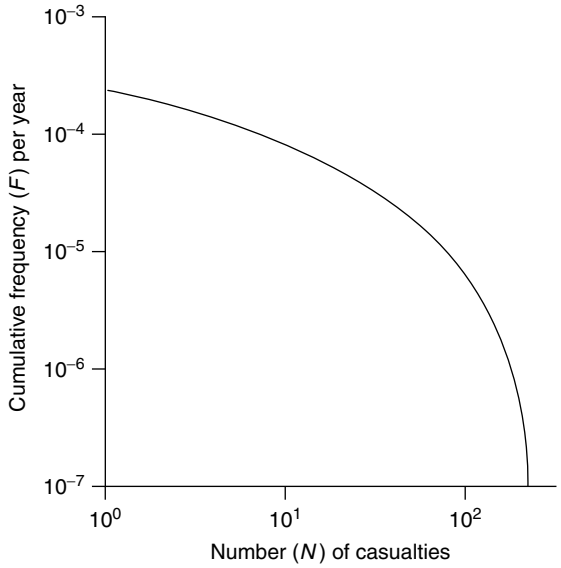

Figure 1 An F–N curve for societal risk. In assessing societal risk, a particular actuarial or estimated curve must be compared with a criterion curve. Actuarial curves (based on historic data) are usually only available for high-frequency—low-number events. Curves for low-frequency—high-number events are normally estimated.

2.5 Risk Assessment, Management and Perception

The concepts of hazard and risk are fundamental to analysing the causes of disasters and to preventing their recurrence. However, these concepts must be contained within a framework of analysis, management and communication if they are to be applied usefully to a given situation. In practice there is a multistage process involved in handling any hazard (**Figure 2**), and most of the people analysing and managing hazards from industrial plants have engineering or chemistry backgrounds. Their specialisms cover plant design and failure rates, event and fault tree analyses, dispersion modelling for releases of clouds of substances and rates of combustion and so on, for explosions and burning gasses (Wells, 1997; Mannan, 2005). Geologists are often the principal people interested in the causes of natural disasters involving toxicants. These are 'overt' disasters where a clear point source can be identified readily.

Only when the substance released is a toxicant or is transformed into a toxicant will any toxicological input become important. This input will largely be in defining the hazard; it will be concerned with identifying whether the agents present are toxic, and defining the combination of exposure size and duration likely to produce a given toxic effect. Clinical toxicologists are also able to advise on the treatment of victims following an incident; that is, they can have a role in the event of an incident occurring.

'Disseminated' disasters are those which only become apparent because of evidence of effect. Identifying the cause when the effect is ill health may require persistent, painstaking research. If the suspected cause is noninfective, the investigation team will need the assistance of toxicologists in identifying the agent responsible.

Often risk can be managed in more than one way. The aim of risk management is to reduce the risk, both in terms of the frequency of an event and in terms of the nature of the potential consequences, to an acceptable or tolerable level (see **Table 1** for definitions of acceptable and tolerable risk). This involves choices as to what chemical physical agents are usable by society and in what circumstances, and on selecting which processes to employ when manufacturing, using or disposing of these agents and their waste products (general risk management). It also involves choices on where to site the major hazards (including waste sites)

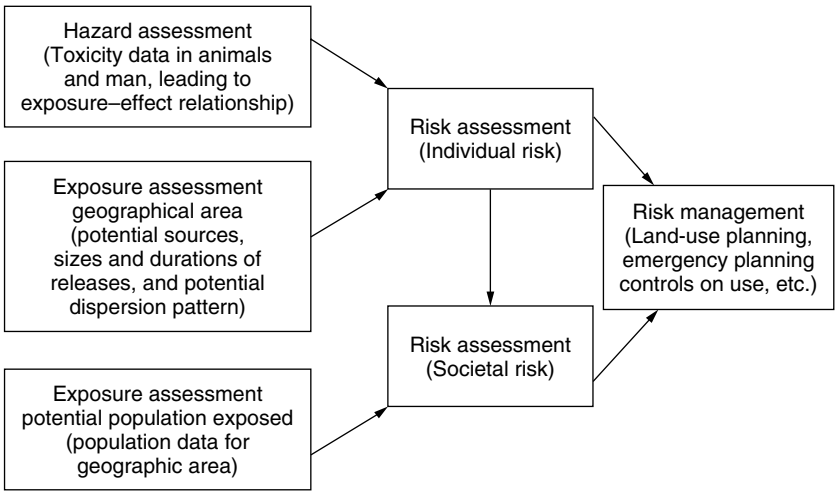

Figure 2 Block diagram illustrating the processes involved in risk assessment and risk management.

Table 1 Various aspects of risk

Objective, actual or statistical risk	A statistically calculated risk evaluation
Perceived risk	The combined evaluation that is made by an individual of the likelihood of an adverse event occurring in the future, and its consequences
Acceptable risk	An acceptable risk is one which, on objective criteria, should generally be regarded as not worth worrying about by those exposed to it
Tolerable risk	A tolerable risk is one which society is prepared to live with in order to have certain benefits
Accepted risk	People tend to accept the risks which they have experienced, but are less prepared to accept new risks, even though, on 'objective' criteria, the risks are similarly acceptable. The new risk is regarded as worse
Voluntary and involuntary risk	Certain risks are accepted willingly by choice (e.g. in sport) by individuals but are not accepted (even by the same individuals) if they are unable to choose to accept the risk
Risk and benefit	Costs occur in reducing risks, either directly or indirectly. For example, many drugs used to treat cancers carry a significant risk that they will cause cancer in that patient at some future time; whooping cough vaccine may prevent severe illness and possible death in most recipients but can cause severe damage in a very few recipients. Risks to nonbeneficiaries are regarded as worse than risks to beneficiaries

Based on Royal Society Study Group (1983), Lovell (1986) and Health and Safety Executive (1988a; 1988b).

and whether to permit housing and other developments around major hazards (land use planning). In addition, risk management is concerned with examining how to handle the consequences of an untoward event at a particular site (emergency planning).

How risks are perceived is also important. The Royal Society Study Group (1983) called perceived risk the combined evaluation that is made by an individual of the likelihood of an adverse event occurring in the future and its likely consequences. In the introduction to the chapter on risk perception in the 1992 report of the Royal Society Study Group, the study group wrote that 'risk perception (from the perspective of the social sciences) involves peoples' beliefs, attitudes, judgements and feelings, as well as the wider social or cultural values and dispositions that people adopt towards hazards and their benefits'. Ultimately, Government (on behalf of society) decides whether a societally regulated risk is generally acceptable or tolerable. What is an acceptable, or at least a tolerable, risk is a problem which depends on a number of factors, some of which are listed in **Table 1**. Individuals or groups of individuals may attempt to vary the decision as it relates to their specific circumstances and perceptions. For this reason it is essential that those evaluating risks and benefits seek to maintain the confidence ('trust') of the general public in their decisions. This includes communicating the issues involved in risk assessment and management and the basis of the evaluations as well as the outcomes in a manner that can be understood by society as a whole. Clear, effective and consistent communication between all parties ('stakeholders') is seen more and more as essential if risks are to be managed satisfactorily. This is a multidirectional process, and requires the

technical specialist to understand the views of individuals and society as well as explaining his or her assessment to the general public. In the final analysis, risk acceptability revolves around personal and political decisions.

3 DISASTERS AND SERIOUS INCIDENTS INVOLVING TOXICANTS

Many disasters are the result of major hazards fulfilling their potential for harm. They are part of a continuous spectrum of possible consequences, which can arise from the accidental release of chemicals at a point source. These consequences range from minor difficulties through serious incidents until, in the worst cases, they become disasters. Most of these disasters are not due to toxicants. Their primary effects are physical in nature, and include crush injuries and burns. Other disasters may be due to the ordinary exposure associated with covenanted releases of potential toxicants. This may be the result of failure to set and meet adequate exposure standards. Failure to set appropriate standards may be because the appropriate knowledge was not available or the criterion against which the knowledge was set was unsuitable. In either case the resulting standard can be inadequate. Alternatively, it may be because of some accidental or, as with terrorist attacks, intentional deviation from the standard. Classification of disasters is given in **Table 2**. This classification is based on the type of event that caused the disaster or serious incident.

Health effects due to toxicants may result from inhalation or from absorption through skin or gastrointestinal tract. Inhaled toxicants may be gases, liquids (aerosol mists) or solids (dusts, fumes). Particle size is important when particulate material is inhaled since, if inhaled, a particle may be deposited in the lung alveoli or—as a result of the 'tracheobronchial escalator'—it may be swallowed. An inhaled toxicant may cause injury to the lung, it may restrict the transfer of oxygen (asphyxiation), or it may act systemically in a particular organ (including skin). Skin and eye effects are often phenomena of surface contamination.

Gastrointestinal absorption may contribute to the overall toxicity of inhaled material. However, it is the main route of entry for those toxicants which are transmitted to humans in food or drinking water.

Examples of different types of disaster or serious incident with the potential for disaster now follow.

3.1 Natural Disasters

Disasters due to natural causes include phenomena caused by the movement of the earth's crust and also the consequences of abnormal weather. In general, these types of disasters cause injuries due to physical effects, or disease due to infective organisms. Toxicants are rarely involved, and then usually secondarily (e.g. due to water contamination), except in the cases of volcanoes, and gas emission from lakes. Asphyxiation can be caused as a consequence of an emitted gas or irritant dust causing respiratory dysfunction, bronchial obstruction and pulmonary oedema.

3.1.1 Volcanoes

Volcanic eruption can be divided into two types: explosive and effusive. Each type may present different health hazards. In a volcanic eruption, magma (molten rock and associated dissolved gas below the earth's surface) is extruded to the surface. When it reaches the surface it may appear as liquid (lava), fragments (pyroclastic debris) and exsolved gasses. In effusive eruptions these flows are usually slow moving. Gas releases are steady and most of the limited amount of dust produced is nonrespirable. Explosive eruptions tend to be more dangerous, the principal toxic hazards being hot ash release and gas emission. Volcanoes may change their nature from one type to the other.

Table 2 Classification of types of disasters involving toxic agents

Cause of disaster	Type	Example
Natural	Volcanic	Vesuvius, AD 79; Mount St. Helens, 1980
	Nonvolcanic	Lake Nyos, 1986
Human-made	Plant failures	Seveso, 1976; Bhopal, 1984; Chernobyl, 1986
	Fire	Manchester Airport, 1985; Kings Cross, 1987
	Food and drink adulteration	Ginger paralysis, 1930; toxic oil, 1981
	Accidental contamination	North Cornwall, 1988; Epping jaundice, 1966
	Environmental contamination	Minamata and Niigata, 1951–1974
Interaction of humans and nature	Shipping	MV Braer, 1993
	Mines and tunnels	Tokyo subway, 1995
	Waste disposal	Love Canal, 1960s; Minamata and Niigata, 1951–1974

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat137

The gas emitted by volcanoes is principally steam, but includes carbon dioxide, carbon monoxide, hydrogen sulfide, sulfur dioxide, hydrogen chloride and hydrogen. Plumes normally disperse by dilution in the atmosphere and are carried on the wind above human settlement. However, sulfur dioxide, hydrogen chloride or hydrogen fluoride may occasionally be present in sufficient quantities to contaminate air within settlements, water supplies and animal feedstuffs. Denser-than-air gases, principally carbon dioxide and hydrogen sulfide, can flow into valleys and low-lying basins, and displace oxygen, giving rise to asphyxiation. A nuée ardente (a cinder cloud carrying trapped gases) can flow rapidly down slopes and may also endanger life.

Pyroclastic debris (tephra) and ash products vary in size. Blocks and bombs are large (over 64 mm), lapilli vary between 2 and 64 mm, and cinders and ashes are smaller particles. Lapilli and ash, when released to the atmosphere, rise in a hot convection cloud which may be transmitted widely (several hundred kilometres) downwind. Eventually they fall to earth and blanket large areas. Finer particles are deposited further away. The particles have the ability to cause darkness during daylight hours. Ash products include respirable particles containing significant levels of crystalline silica (quartz and cristobolite). Volcanic ash can affect the respiratory tract and eyes. Severe tracheal injury, pulmonary oedema and bronchial obstruction can occur, leading to death from pulmonary injury or suffocation. Ash may also act as a respiratory tract and eye irritant. Irritation and inflammation of the upper and lower respiratory tract may persist if low-level chronic exposure occurs.

Lava is molten rock, the liquid product from the volcano. Lava is derived from the molten magma, but differs from it because the dissolved gases in the magma escape with the reduction of pressure that occurs as the material approaches the surface.

Debris flows occur when loose rock mixes with surface water or groundwater and flows as a mass of rock, mud and water.

This description of volcanoes is inevitably very short and much simplified. More detailed information can be found in Sheets and Grayson (1979) and Newhall and Fruchter (1986).

3.1.1.1 Vesuvius, Italy, AD 79

Perhaps one of the best-known historic volcanic eruptions is that of Vesuvius in Italy in AD 79. A contemporary description of the eruption and its effects on one victim was provided by Pliny the Younger in two 'letters' to Tacitus (Radice, 1969). More detailed information on the eruption and its consequences has been obtained during archaeological investigation of the sites at Pompeii and Herculaneum, both of which were buried in the eruption (Jashemski, 1979; Sigurdsson *et al*., 1985).

Vesuvius had been quiescent for many centuries before the eruption of AD 79. The first sign of its reawakening was an earthquake in AD 62 which damaged almost all the buildings in Pompeii. Then came the eruption of AD 79. There were three phases to this eruption. The first stage was expulsion of the vent plug on 24 August. This was followed by expulsion of ashes. There were six surges and pyroclastic flows during the last eruption.

Both Plinys were at Misenum when Vesuvius erupted, together with Pliny the Elder's sister (Pliny the Younger's mother). Pliny the Elder, who was in command of the Roman fleet at Misenum, gave instructions that a ship should be made ready so that he could investigate the phenomenon. However, by the time the ship got under way with the elder Pliny on board, he changed the mission to one of attempting to rescue the people living along the shore of the bay at the foot of Vesuvius (see **Figure 3**). Pompeii and Herculaneum were probably being buried at this time, the former from deposition of

lapilli and ashes and the latter from a mud and tephra flow. Pliny found his mission impossible because of the falling debris near the shore, and eventually made port at Stabiae, where he stayed the night. During the night the courtyard of the house in which he was staying filled with ashes and debris. On the morning of 25 August it was still dark at Stabiae after dawn. Pliny the Elder went to the shore to investigate the possibility of escape by sea, and died. Pliny the Younger described the death as because 'the dense fumes choked his breathing by blocking his windpipe, which was constitutionally weak and narrow and often inflamed'. In modern terms this might he described as asphyxiation.

The crew of the ship later successfully got away, and the younger Pliny and his mother were evacuated from Misenum on 25 August as ashes started falling there. Both survived. Although the 'letters' only describe ash and lapilli, there was also a lava flow on the north side of the volcano. The results of excavations at Pompeii suggest that at least 2000 people died. Presumably many more deaths went unrecorded. Most deaths in Pompeii and Herculaneum were probably due to asphyxiation caused by inhalation of the hot ash material in the first surge of the ash eruption (Sigurdsson *et al*., 1985). Recent studies on 80 skeletons unearthed of a group of 300 people who had taken shelter in the boat chambers at Herculaneum indicate that they probably died from thermal shock, not suffocation (Mastrolorenzo *et al*., 2001).

3.1.1.2 Mount St. Helens, USA, 1980

A much more recent volcanic eruption was that of Mount St. Helens in the Cascade Range in the west of North America. Premonitory earthquakes started on 20 March and, towards the end of April, a bulge developed in an area to the north of the summit (Buist and Bernstein, 1986). On 18 May a major earthquake occurred, the roof of the bulge slid downhill and an explosive blast took place. Large quantities of ash, super-heated steam and gas were released. There were five additional explosions over the following five months, and ash falls accompanied four of these eruptions. The dispersion pattern is shown in **Figure 4**. The main land areas covered by the vented material lay in a northeasterly direction from the volcano.

There were 35 known deaths and at least 23 people missing without trace following the eruption (Baxter *et al*., 1981; 1983; Buist and Bernstein, 1986). Asphyxiation was the cause of death in 18 of the 23 victims autopsied. Ash probably acted as an irritant to the respiratory tract and eye, causing tracheal injury, pulmonary oedema and bronchial obstruction in those dying. The irritation of the respiratory tract continued as the result of chronic low-level exposure to ash, but there appeared to be few long-term sequelae. However any potential pneumoconiotic effect from the single massive exposure to silica could not be detected because of the short time span since the eruption. Interview studies of patients with pre-existing chronic lung disease showed that the ashfall exacerbated the condition in these patients. There were dose-related increases in the prevalence of three psychiatric syndromes associated with disaster stress and generalized anxiety, major depression and post-traumatic stress (Shore *et al*., 1986). The duration of effect was related to the level of disaster stress suffered by the subject.

The toxic effects seen in the victims of the Mount St. Helens eruption were largely those due to the nature of the ash deposited. Fortunately, the toxic gases that were emitted were vented to the atmosphere and diluted to nontoxic levels through dispersion.

3.1.2 Other Natural Disasters

3.1.2.1 Lake Nyos, Cameroon, West Africa, 1986

Volcanoes are not the only natural phenomenon which can cause major disasters due to toxic substances. On 21 August 1986 there was a catastrophic release of gas from Lake Nyos, Cameroon (Freeth and Kay, 1987; Kling *et al*., 1987; Baxter *et al*., 1989b). The cloud of gas was lethal at distances up to 10 km from the source. About 1700 people, 3000 cattle and many other animals died, mostly from asphyxiation. An earlier, smaller release from Lake Monoun, also in Cameroon, had resulted in 37 deaths, presumably from similar causes.

The generally accepted cause of the disaster is that because of the geochemical and geophysical characteristics of the Cameroon rocks and the geological conditions in the Lake Nyos area, waters rich in carbon dioxide developed. The gas accumulated in the lake to near-saturating conditions. Although the trigger mechanism for the release is unknown, a small disturbance would have been sufficient to cause degassing in the form of a large release of the carbon dioxide. The gas cloud produced was denser than air and dispersed through the river valleys. Simultaneously, a water surge resulted in the loss of about 200 000 tonnes of water from the lake. That release was heard as a series of 'rumbling sounds' lasting 15–20 seconds, and one observer reported seeing a white cloud rise from the lake.

Many people lost consciousness rapidly, and survivors woke 6–36 hours after the event, weak and confused. Cutaneous erythema and bullae were present in about 19% of survivors treated in hospital. Very limited pathological investigations on those dying suggested that carbon dioxide was the toxicant, as it appeared that the potential toxicants, carbon monoxide, cyanide or hydrogen sulfide were not relevant to the cause of death. Reports of the odour of sulphur compounds were probably a result of the sensory hallucination due to exposure to high levels of carbon dioxide.

Respiratory symptoms and peak expiratory flow in survivors have been compared with nonexposed subjects living in the same area (Afane Ze *et al*., 1996). There were no differences in the frequency of dyspnoea, cough, sputum production and peak expiratory flow at 55 months postincident, suggesting that there were no long-term respiratory consequences among survivors.

This disaster was a consequence of the special geology of the area. Therefore, although a rare event, it does illustrate that natural disasters involving toxicants are not confined to volcanic releases.

3.2 Human-Made Disasters

3.2.1 Plant Failures

Plant failures are a well-known cause of major disasters. Those involving the release of toxic chemicals or radioactivity are relevant to toxicologists, and some examples are examined here.

3.2.1.1 Seveso, Italy, 1976

An escape of toxic substances occurred at an industrial plant at Seveso, Italy, in 1976. The circumstances surrounding the escape and the potential health effects caused by the escape were investigated by a Parliamentary Commission of Enquiry (Orsini, 1977). Both the engineering and the chemical aspects of the incident have been reviewed (Marshall, 1987; Skene *et al*., 1989). Recent work has been published on potential long-term and reproductive effects. The incident was important because of its influence on European Community legislation (the 'Seveso' Directives) concerned with major industrial chemical hazards.

The plant produced trichlorophenol by reaction of tetrachlorobenzene with sodium hydroxide (**Figure 5**). Following the reaction, the solvent (ethylene glycol–xylene) was partially vacuum-distilled off by the end of shift, at which time the heating and agitation were switched off. Some 7.5 hours later a safety plate on the reactor vessel burst and there was a consequent venting of the reaction mixture, including approximately 2–3 kg of the impurity dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin) to the atmosphere.

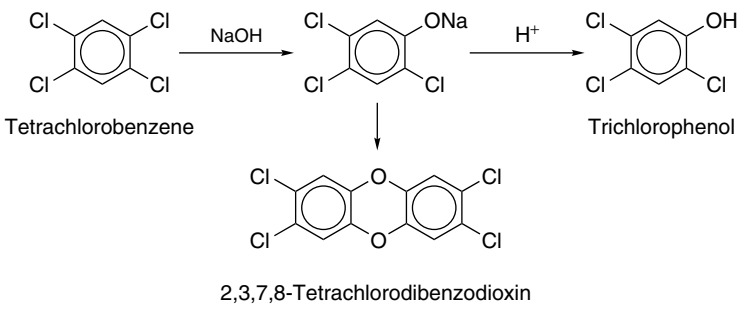

Figure 5 Reaction scheme for the formation of dioxin from tetrachlorobenzene. The condensation to form dioxin is a minor reaction compared with that of synthesizing trichlorophenol.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat137
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

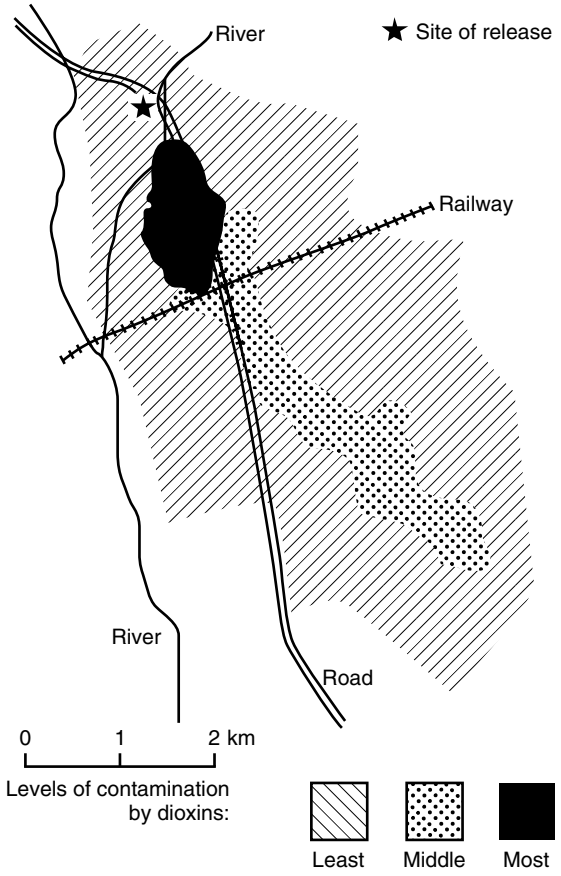

Figure 6 Sketch map of Seveso, showing areas of most, middle and least contamination by dioxin. (Based on Marshall, 1987.)

Once in the atmosphere, the dioxin was spread over a wide area downwind of the plant and settled on fields and houses. Three major zones were identified according to the levels of dioxins present in the vegetation and soil (**Figure 6**). The resident populations in the zones were 733, 4800 and 22 000 people in the most contaminated, middle and least contaminated areas, respectively. A medical surveillance programme was undertaken on these people.

Apart from burns arising directly from contact with the caustic reaction products, the other major effect was chloracne. This was reported some six weeks after the accident, with a frequency correlating approximately to the levels of dioxins in the soil. By the end of 1978 the chloracne had disappeared. Repeated-dose animal studies suggested that dioxin could cause porphyria and was hepatotoxic. In animal studies on reproductive effects, dioxin was a potent foetotoxin and teratogen. Hepatocarcinogenicity has also been established in animal studies. Therefore, these effects were examined in the follow-up to the single acute exposure at Seveso.

Studies on liver effects, including porphyria, in 700 children, failed to identify significant illness, although two indicators of liver dysfunction, γ-glutamyl transferase and alanine aminotransferase, were slightly elevated in boys from the most contaminated zone.

A birth defects register was set up after the disaster. There were no birth defects that could be unequivocally linked to dioxin exposure among the limited number of births to residents of the high-exposure zone. In addition, although there were wide variations in the spontaneous abortion rate between zones, these could not be ascribed to dioxin. Examination of chromosomes in aborted tissue following artificially induced abortions suggested that there might have been a higher frequency of chromosomal aberrations in foetuses from mothers potentially exposed to dioxins, but it was not possible to establish whether these aberrations would have led to adverse reproductive outcomes.

The influence of dioxin exposure from Seveso on endocrine hormone disruption and semen quality has been examined in men 22 years postincident (Mocarelli *et al*., 2008). The study concluded that exposure to dioxin in infancy resulted in permanently reduced sperm concentration and motility, with an opposite effect being seen when exposure occurred during puberty. For both exposures, permanent reductions in oestradiol and increases in follicle stimulating hormone were claimed. These effects were claimed to occur at concentrations of less than 68 ppt (parts per trillion). The biological importance of these findings is, at present, unclear. Examination of women aged 20–40 and not using oral contraceptives at follow-up (20 years postincident) gave no clear indication of ovarian dysfunction in those exposed to high levels of dioxin in the most contaminated and middle zones (Warner *et al*., 2007).

Perhaps the greatest long-term worry from the Seveso incident was cancer. Mortality has now been followed up for 25 years (Consonni *et al*., 2008). Risks of deaths from certain individual cancers and from circulatory disease were elevated. There are excesses of lymphatic and haematopoietic tissue neoplasms in the most exposed zone (six deaths, rate ratio 2.23; 95% confidence intervals 1.00–4.97) and intermediate zone (28 deaths, rate ratio 1.59; 95% confidence limits 1.09–2.33). The small increases in numbers of premature deaths due to certain specific causes seem to suggest that there have not been the feared large-scale increases in the overall numbers of deaths from cancer.

The half-life of dioxin has been determined in blood samples collected up to 16 years postincident for 20 male and 25 female Seveso children (those less than18 years in July 1976) from the high-exposure zone (Kerger *et al*., 2006). The study demonstrated that children and adolescents have shorter dioxin half-lives than adults and this effect is augmented at higher body burden.

The Seveso incident illustrates how an accidental release of a chemical may be perceived by the general public as a major disaster. So far, relatively few human deaths have resulted from the single-dose exposure to dioxin. Those suffering chloracne or burns recovered.

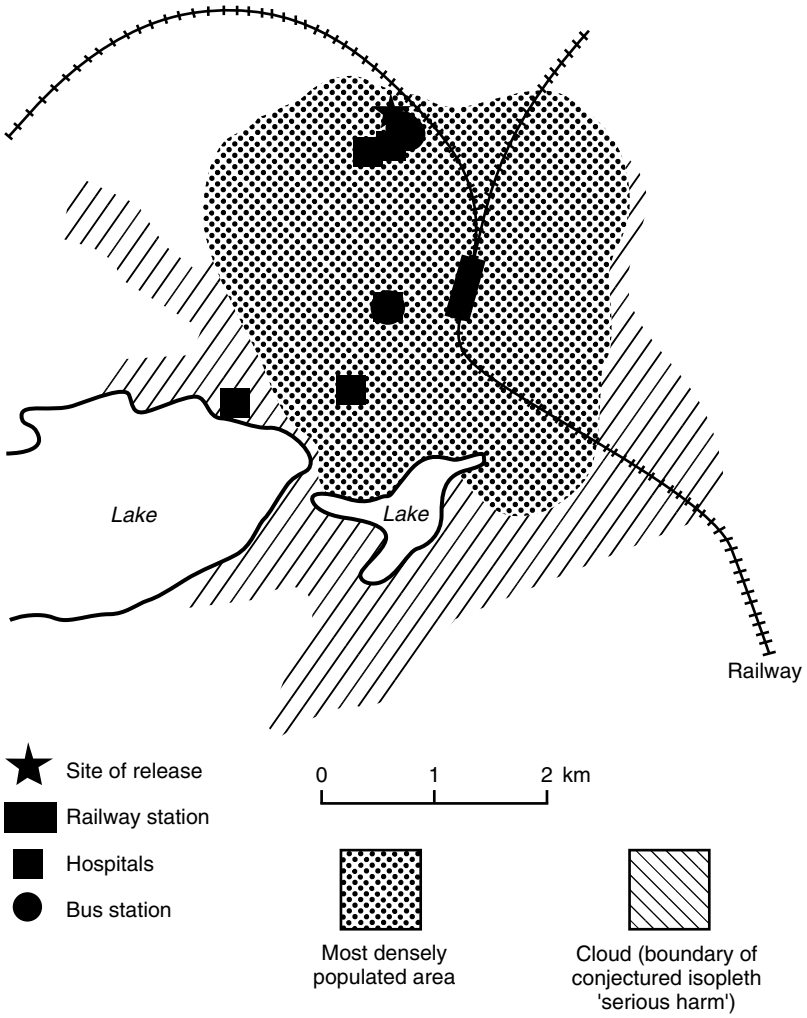

Figure 7 Sketch map of Bhopal, showing overlap between populated area and the approximate boundary for receiving serious harm from the vapour cloud. (Based on Marshall, 1987.)

Fears of large numbers of people being severely affected by potential long-term and reproductive effects have not been confirmed. Nevertheless, the Seveso incident is important, as it raised the general awareness of the potential that for ill health following major plant failure, and was a major factor leading to the European Union (EU) legislation concerning the control of major industrial accident hazards.

3.2.1.2 Bhopal, India, 1984

Methyl isocyanate is a toxic substance that was responsible for a major disaster at Bhopal, India in December 1984, at a factory manufacturing the pesticide carbaryl. The cause of the accident was the introduction of water into a storage tank containing methyl isocyanate. This resulted in the production of carbon dioxide:

$$CH_3NCO + H_20 \longrightarrow CH_3NH_2 + CO_2 \qquad (1)$$

The combination of rising temperature, due to a runaway exothermic reaction, coupled with gas evolution led to a build-up of pressure which caused about 27 tonnes of methyl isocyanate to be vented to the atmosphere in a 1–2 hour period (Dhara and Dhara, 2002). The venting occurred during the night and the cloud dispersed over a densely populated area (**Figure 7**).

In 1994 an International Medical Commission was set up with the aim of assessing respiratory, neurological and other health effects attributable to exposure to the vapour released at Bhopal. Until then investigations had been relatively piece-meal. Many of the studies suffered from limitations associated with study design, bias and exposure classification.

Initial estimates of the number of deaths which resulted front the release vary between 1700 and 55 000, with up to 60 000 people being seriously injured (Bucher, 1987; Andersson *et al*., 1988). Dhara and Dhara (2002) indicate that, although some uncertainty exists in the number of disaster-related deaths, independent agencies had estimated that by 2002 the estimate was between 15 000 and 20 000. Survivors reported that the vapour cloud gave off considerable heat and had a pungent odour.

Acute irritant effects on eye and respiratory system were the major findings following this incident (Dhara and Dhara, 2002). Initial lung effects (oedema, focal atelectasis) were probable causes of death and led, in survivors, to more persistent changes in lung function, and possible fibrosis and inflammation. Persistent small-airway obstruction, attributed to exposure to the vapour, was still present in survivors 10 years after the incident (Cullinan *et al*., 1997). Although severe eye effects, including temporary blindness, were seen in many survivors, they did not persist (Andersson *et al*., 1988). However, there was evidence of persistent eye watering in some cases and tear secretion deficiency in others, suggesting that the exposure had led to a chronic inflammatory process which might have been exacerbated by the very poor housing conditions in Bhopal slum areas (Dhara and Dhara, 2002).

Epidemiological surveys suggested that miscarriages and infant mortality were high in women living near the plant at the time of the release (Varma, 1987; Dhara and Dhara, 2002). Similar foetotoxic effects were seen in mice treated with methyl isocyanate (Schwetz *et al*., 1987; Varma, 1987).

Psychological and neurobehavioural effects were also manifest (Dhara and Dhara, 2002). These included post-traumatic stress syndrome, pathological grief reactions, emotional reactions to physical problems and exacerbation of pre-existing psychiatric problems.

The Bhopal incident illustrates many important points. The reasons for the water entering the methyl isocyanate tank were never clearly identified. However, the consequences were made substantially worse than they need have been because several of the design safety features had been rendered unusable and because there were substantial numbers of shanty houses right up to the factory fence. Also, there was a paucity of toxicological data on methyl isocyanate prior to the incident, which has now been partly rectified by undertaking substantial studies in animals as well as by following up the victims (Bucher, 1987). At the time of the incident there was only one substantial published report on the toxicity of methyl isocyanate, and that was restricted to an animal study on the acute effects following a single exposure (Kimmerle and Eben, 1964).

3.2.1.3 Chernobyl, Former USSR, 1986

Chernobyl (Chornobyl when transliterated from the Ukrainian), 80 km north of Kiev, Ukraine was the site of probably the worst accident to have occurred at a nuclear plant. In April 1986, a test was being conducted on a reactor during shut-down for routine maintenance (Henderson, 1987; Bertazzi, 1989; Wells, 1997). However, the planning of the test was poor and safety devices were deliberately switched off to allow the test to proceed. By the time it was realized that something was wrong, uranium oxide fuel elements in the upper part of the core had probably started to disintegrate because of the high temperatures. Explosions followed, which released considerable quantities of radioactivity to the atmosphere, much of which was dispersed over the former Soviet Union and western and northern Europe.

After the accident, the people in the area around Chernobyl were evacuated. They have not been allowed to return and the area was converted to a national park where human activity, including farming, was banned.

By one year after the event only 31 people had died as a result of it; they died in the immediate aftermath of the accident, from acute radiation sickness.

The Chernobyl Forum (the International Atomic Energy Agency (IAEA), the World Health Organization (WHO), the United Nations Development Programme (UNDP), the Food and Agriculture Organization of the United Nations (FAO), the United Nations Environment Programme (UNEP), the United Nations Office for the Coordination of Humanitarian Affairs (UNOCHA), the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), the World Bank Group, Belarus, Russian Federation and Ukraine) second report (Chernobyl Forum, 2006) includes information on 20 years of follow-up from the accident. Apart from a small number of emergency and recovery workers, exposures of emergency and recovery workers and of residents in areas designated as 'contaminated' were to relatively low whole-body doses of radiation, not much higher than those due to natural radiation.

Although not apparent for the first three years after the accident, by the end of 1994 a clear increase in childhood thyroid cancer had been seen in children from the surrounding areas in Belarus and Ukraine (Likhtarev *et al*., 1995; Stsjazhko *et al*., 1995). The Chernobyl Forum reports that more than 4000 cases of thyroid cancer were diagnosed between 1992 and 2002 in children and adolescents (0–18 at the time of the accident). A cohort study conducted on childhood thyroid cancers in Ukraine concluded that exposure to radioactive iodine was strongly associated with increased risk of thyroid cancer among those exposed as children and adolescents (Tronko *et al*., 2006). It should be pointed out that this is a treatable cancer.

An International collaborative population-based case–control study on childhood leukaemia in Belarus, Russia and the Ukraine indicated that there might be a significant increase in leukaemia risk associated with increasing radiation dose to the bone marrow (Davies *et al*., 2006). There was a lack of significant dose-responses in Belarus and Russia. The large and statistically significant dose-response in the Ukraine might be accounted for, at least in part, by an overestimate of risk. However, it is unclear as to whether the results are due to a true radiation-related excess, a sampling-derived bias in the Ukraine, or some combination of the two. The authors conclude that the study provides no convincing evidence of an increased

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

risk of childhood leukaemia as a result of exposure to Chernobyl radiation.

The Chernobyl Forum 2006 also indicated that there was an increase in psychological problems among the affected population, compounded by insufficient communication about radiation effects and by the social disruption and economic depression that followed the break-up of the Soviet Union. The Forum also suggests that radioactivity levels in the area surrounding the reactor have declined several hundredfold since the incident because of natural processes and countermeasures. The majority of the 'contaminated' territory is now safe for settlement and economic activities, but restrictions on land use in the Chernobyl exclusion zone and some other limited areas will need to be retained for decades to come.

The radioactivity from the accident was washed from the skies and entered food chains, notably in areas of high rainfall. In the UK this led to the banning of the sale for human consumption of sheepmeat from the badly affected areas for over one year.

This disaster is one in which future illness and premature deaths are the primary effects on humans. It is this fear of the future effects of radiation which has made the nuclear industry so heavily regulated in comparison with other industries.

3.2.2 Fire

Thermal injuries, heat stress and physical trauma from collapsing structures are obvious problems in major fires. However, fire statistics indicate that deaths consequent to being overcome by smoke are the most common type of death (Committee on Fire Toxicology, 1986). Such deaths and incapacitations are due to the evolution of toxic combustion products. As toxicants are likely to be funnelled upwards and diluted to nontoxic levels in unconfined fires, major fire disasters usually occur in confined spaces when it is not possible to escape from the effects of the toxic combustion products.

Smoke includes all airborne products from the pyrolysis and combustion of materials (Committee on Fire Toxicology, 1986). Full oxidation of substances present in fires would result in products such as carbon dioxide, water (steam), nitrogen dioxide, sulfur dioxide and chlorine. However, complete combustion rarely occurs and other products such as carbon monoxide, soot (particles), hydrogen cyanide, hydrogen chloride, hydrogen fluoride, acrolein and other organic materials are often present. The toxicity of fires therefore arises from the evolution of smoke (including gases, dust/fume and aerosol) containing irritants and asphyxiants and, potentially, carcinogens. Those most at risk will normally be the fire-fighters in close proximity to the fire, and thus near enough to inhale undispersed toxic smoke and gasses. Potentially, risks from acute health effects of dispersed combustion products may occur in warehouse fires such as that at Brightside, Sheffield (Health and Safety Executive, 1985) or large oil terminal fires such as that at Buncefield, Hertfordshire, UK in December, 2005 (Aus *et al*., 2006). At Brightside, onlookers who were in close proximity to the fire may have acquired sore throats and chest symptoms due to effects from the fire. However, potential combustion-product toxicants were dispersed to levels thought too dilute to pose a risk to the general population within very short distances. Asbestos roofing materials were dispersed widely in this fire, but the longer-term health effects for people exposed to single doses of dispersed fire products were considered to be minimal. At Buncefield, some effects were reported by police officers at the front line, but evacuation of damaged houses and workplaces and advice to 'go in, stay in' to those under the plume of smoke ensured that there were no serious health problems for the general public (Aus *et al*., 2006). Two examples of disasters in which the evolution of toxic combustion products from fires contributed significantly are given below. In both examples most of those who died were incapacitated by the effects of inhaling toxic smoke and gases in relatively confined spaces, and thus became unable to move to less polluted atmospheres.

3.2.2.1 Manchester Airport Crash, UK, 1985

One area where there is a potential for disasters due to toxic hazards is aircraft fires. An example of such a catastrophe was the Manchester (UK) Airport crash of 1985 (Air Accidents Investigation Branch, Department of Transport, 1989).

On 22 August 1985 a British Airtours Boeing 737 aircraft hound for Corfu (Greece) was taking off from Manchester International Airport when the left engine suffered an uncontained failure which punctured a wing fuel tank access panel. The leaking fuel ignited and burnt as a large plume of fire trailing directly behind the engine. The crew abandoned take-off and cleared the runway by turning on to a taxiway as they stopped. A light wind carried the fire on to and around the rear fuselage (**Figure 8**). After the aircraft stopped, the hull was penetrated rapidly and smoke and possibly flames entered through one of the cabin aft-doors, which had just been opened. Fire subsequently developed inside the cabin and generated a dense black toxic/irritant smoke. Despite prompt attendance by the airport fire services the aircraft was destroyed and 55 people (53 passengers and 2 crew) died, one after six days in hospital. All those who died on board the aircraft had general congestion and oedema of the lungs with carbon particles in the air passages, consistent with inhalation of smoke. The cause of death was inhalation of smoke for 48 people and direct thermal injury (burns) for only 6 passengers.

Of those engulfed by smoke, only 38 (47%) survived. The survivors reported that a single breath of the cabin atmosphere was burning and painful, immediately

causing choking. They experienced drowsiness and disorientation. Eight survivors actually collapsed, but recovered sufficiently to get out from the plane. Most of the deaths due to incapacitation might have been prevented if the people concerned had been protected from smoke or if external assistance had been more quickly available. All except one of the survivors of the immediate accident made their exit within 7 minutes of the aircraft stopping. The only survivor recovered by firemen was taken out after 33 minutes. He died six days later from severe pulmonary damage and associated pneumonia.

The thermal decomposition products of cabin materials included toxic or irritant gases, such as carbon monoxide, hydrogen chloride and hydrogen cyanide. Some fluorinated materials (used as decorative films) yielded hydrogen fluoride. It was probably the combined effects of toxic combustion products that caused death. Elevated levels of carbon monoxide and cyanide and the metabolic product of cyanide, thiocyanate, were found in all except 6 of those dying on board the plane. Individually lethal levels of carbon monoxide were found in 13, and of cyanide in 21 of these people (9 had levels of both substances, either of which could have been lethal); for the remainder, the sum effects from the total amounts of toxic materials present probably caused death.

This aircraft accident is an example of a disaster where many of those who died might, in other circumstances, have been rescuable. One element that played a part in the disaster was disablement by the smoke from a fire in a confined space before exit from that space could be achieved. This has encouraged investigations into the potential for placing smoke-hoods of suitable design on aircraft for passenger use in this type of emergency, the investigation into possible 'in-cabin' fire-fighting systems and provision of low-level lighting systems to indicate the route to fire exits. So far, only the last of these has been implemented.

3.2.2.2 *Kings Cross (London) Underground Station, UK, 1987*

Thirty-one people died and many more were injured in an escalator fire at Kings Cross Underground Station. The fire took place in the evening at an extremely busy Underground station where four lines cross (**Figures 9** and **10**). Access to the three deep lines (Piccadilly, Victoria and Northern) is from the ticket hall below the mainline station forecourt. The ticket hall is approached by subways from Kings Cross and St. Pancras mainline stations and from street level. According to the Inquiry

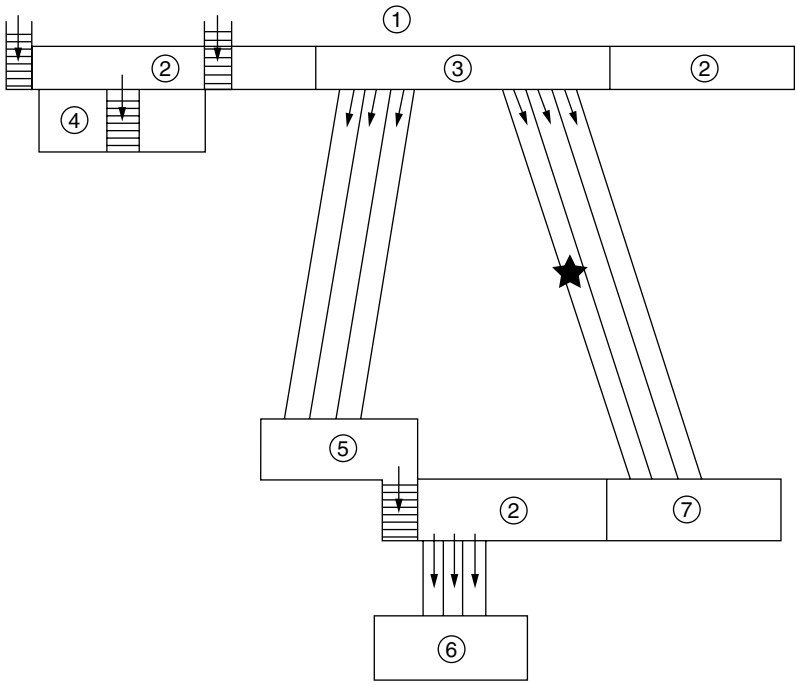

Figure 10 Sketch map of the levels of the components of Kings Cross Underground station. 1—Surface level (Kings Cross mainline station forecourt); 2—subways; 3—ticket hall; 4—Metropolitan and Circle Lines; 5—Victoria Line; 6—Northern Line; 7—Piccadilly Line. Star indicates escalator on which fire started.

Report (Fennel, 1988), the fire started in the Piccadilly line escalator, among an accumulation of grease and detritus (dust, fibre and debris) on the running tracks, possibly as a result of a lighted match passing through the skirting board. This fire preheated the balustrades and decking, which were wooden. As a consequence of a 'trench' effect, the fire initially burnt cleanly and then produced dense, black smoke. 'Flashover' occurred as the fire erupted into the ticket hall. The deaths all occurred among people in the ticket hall at around the time 'flashover' occurred.

The inquiry did not pursue in detail the question of cause of death for the 31 people who died, but concluded that many deaths were due to the toxic effects of the smoke rather than to burns. In the report the Inspector says:

After hearing expert evidence about the role of toxic gases in the fire and the findings of pathologists on post-mortem tests, I determined that the cause of death in individual cases could not be pursued any further in this investigation. On the evidence available to me no reliable assessment could be made of the relative importance of various materials present in the station to the production of toxic fire fumes or to the sources of toxic materials found in the bodies. Although separate statutory Coroner's Inquests were held, the Coroner decided not to take the matter further.

A major part of the inquiry focussed on the procedures by which London Underground dealt with escalator fires. It was clear that, at the time, the Underground lacked an adequate approach to safety in terms of their attitudes to safety matters, their attention to staff training in safety and their equipment, and procedures to be used in emergencies. The lack of preparedness led to an emergency becoming a disaster. Regulations made subsequent to the report also led to the replacement of wooden escalators in subsurface Underground stations with metal ones, mandatory installation of automatic fire sprinklers and heat detectors in escalators, and fire safety training.

3.2.3 Food and Drink

Mass poisonings due to contamination of food or drink may be considered disasters. Many episodes of this type of mass poisoning are the consequences of bacterial or fungal contamination of foods consumed by the victims. If the causative agent is pathogenic, then health can suffer. However, a portion of such poisonings is due to the introduction of a chemical toxicant into the consumed material, either directly or via a food chain.

Because of the indirect way in which the contamination affects humans, it can be difficult to demonstrate cause and effect. Ill health may occur indirectly, in a species (humans) remote from that (e.g. wheat) to which the toxicant was administered, possibly after transmission through a food chain (fed to farm animals, and so on) or directly (in bread). It may be some time before the toxicant accumulates sufficiently for the victim to exhibit symptoms of ill health, or for the ill health to be

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat137

manifest following ingestion. Consequently, considerable detective work may be needed in order to identify the cause of ill health, and on occasion it may never be properly characterized.

A series of examples of incidents involving contamination of food or water follow. Further examples can be found in Aldridge (1987).

3.2.3.1 *Adulteration of Food or Drink*

Adulteration (debasing by adding other or inferior substances: Concise Oxford Dictionary, 1990) of foodstuffs and deliberate poisonings by admixture in food have gone on from time immemorial. Adulteration for commercial reasons was rife in the eighteenth and nineteenth centuries (see Smullen, 1989). Bread from bakers often contained chalk, lime, lead salts or even bone to make it look white. Leaves of hawthorn, sloe or ash were used to dilute tea. With hindsight, several of these adulterants were toxic chemicals and may have had disastrous consequences for the recipients. Deliberate adulteration, when it occurs, is still capable of causing major disasters.

3.2.3.1.1 Ginger Jake Paralysis, Midwest and Southwest USA, 1930

During prohibition in the USA, the Prohibition Bureau ruled that the US Pharmacopeia (USP) fluid 'extract of ginger' was a nonpotable beverage, an alcoholic patent medicine, and its sale was not restricted (Baum, 2003). This beverage was an alcoholic extract of material from the ginger plant (obtained from Jamaica—hence the 'Jake') and was freely drunk. An adulterated 'fluid extract of ginger' entered circulation through dealers (nonpharmacists), mainly in Ohio and Tennessee early in 1930s. Cases of paralysis started to occur in mid February. Adult men (typically those living alone in cheap rooms, unemployed or employed on a menial job) were the principal victims, and those showing symptoms seemed to do so some 10 days to three weeks after drinking the suspect ginger extract (Smith and Elvove, 1930). Ultimately some 50 000 people were affected (Morgan, 1982).

The paralysis first appeared as soreness of the muscles of the arms and legs, with occasional numbness in the fingers and toes. Foot and wrist drop and weakness of the fingers developed. The symptoms were found in distal parts of the limbs and were more marked in the feet and legs. This neuropathy was a primary axonopathy caused by demyelination and dying back from the distal end of the long nerves. In some cases recovery was very limited (Aldridge, 1987).

In a very detailed piece of work, the causative agent was identified chemically as tri-*o*-cresyl phosphate (**Figure 11**) (Smith, 1930; Smith and Elvove, 1930). Both the adulterated ginger extract and the presumed adulterant, tri-*o*-cresyl phosphate, were found to cause the symptoms of neuropathy in calves, chickens and, to a much less marked degree, rabbits, but had little effect on monkeys or dogs following oral ingestion.

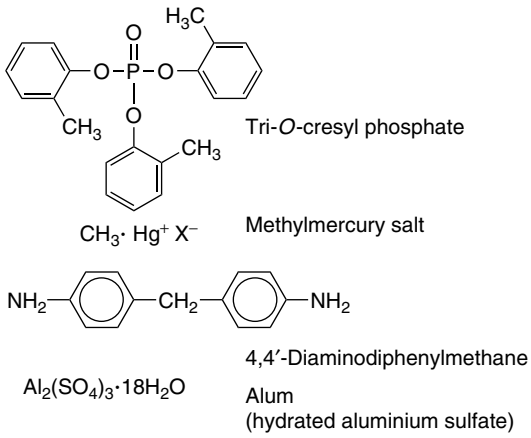

Figure 11 Structures of chemicals implicated in disasters mediated through food or water supplies.

3.2.3.1.2 Toxic Oil Syndrome, Spain, 1981

Toxic oil syndrome was a previously unknown disease syndrome which appeared in Spain in May 1981, principally in Madrid and the northwest provinces (World Health Organization, 1984; Aldridge, 1985; 1987; Gelpi *et al*., 2002). The epidemic was at its peak in mid June and faded away thereafter. By March 1983, 340 deaths had occurred and over 20 000 cases had been recorded. To the end of 1997 there has been no subsequent excess of deaths in those exposed to toxic oil.

The disease developed in two phases. In the acute phase, a pleuropneumonia sufficient to cause respiratory distress and death in severe cases. This pleuropneumonia did not respond to antibiotic treatment and about 20% of survivors did not recover completely. A chronic phase of the disease, a sensorimotor peripheral neuropathy of variable appearance, developed together with sclerodermal-like skin changes. There was little evidence of central nervous system involvement. Although initially thought to be due to an infective agent, the syndrome was rapidly associated with the consumption of an oil sold for food use in 51 cans by itinerant salesmen. The oil was rapeseed oil, denatured with aniline, intended for industrial use. In most cases the oil had been re-refined, mixed with other seed oils, animal fats and poor-quality olive oil or chlorophyll, but in the cases of a small number of victims in the Seville area (well away from the main outbreak) the re-refined oil had not been further processed. Recent studies have suggested that the disease is strongly associated with the consumption of oils containing the fatty acid esters of 3-(*N*-phenylamino)-1,2-propanediol (Gelpi *et al*., 2002). Whether these esters are simply markers for the toxicity of the oils or have the capability to induce the disease has not been determined, in part because of a lack of suitable animal models for the syndrome.

3.2.3.2 *Accidental Contamination*

As opposed to deliberate addition of materials to foodstuffs or drinks, accidental addition of toxicants can also occur. If the toxicant is sufficiently effective and affects a large number of people, a major disaster could result.

3.2.3.2.1 Pollution of Drinking Water in North Cornwall, UK, 1988

Mass intoxications, in theory at least, could occur due to contamination of drinking-water supplies. That this is not such a remote possibility was demonstrated in 1988, when the South West Water Authority found that a truck load (20 tonnes) of alum (aluminium sulfate; **Figure 11**) had accidentally been released into the drinking-water supply to Camelford, a small town in Cornwall, and the surrounding district (Lowermoor Incident Health Advisory Group, 1989; Lowermoor Incident Health Advisory Group, 1991; COT, 2005). The material was delivered into the treated-water reservoir at Lowermoor Treatment Works. The pH of the water dropped below 5 and aluminium levels were raised to over $10\,mg\,l^{-1}$, considerably above the $0.2\,mg\,l^{-1}$ set on aesthetic grounds (potential discolouration) in the European Community Drinking Water Directive. Although initial advice from local sources suggested that little ill health would occur, newspapers reported considerable acute health symptoms and speculated that there were potential long-term effects. The expert assessment was that the early symptoms of gastrointestinal disturbances, rashes and mouth ulcers were probably due to the incident, but these would be short-lived. Up to 400 (out of a population of about 12 000) attributed continuing effects to the incident. Later complaints included joint and muscle pain, malaise, fatigue and memory problems. The 1991 report ascribed these symptoms to a heightened awareness provoked by the incident and subsequent events. Media coverage ascribed further symptoms, including shedding of toenails, to the incident, although these symptoms could not be confirmed from reliable sources. In the 2005 report, additional concerns were voiced concerning cancer and thyroid disease. The Lowermoor Incident Advisory Group concluded that there was no reason to predict any late consequences, but it could not categorically exclude them. Its recommendations included a follow-up study monitoring hospital discharges. This study of hospital-discharge rates up to the fifth anniversary of the incident indicated a continuing significantly higher level of hospital admissions arising from the Camelford area. However, despite examining diagnoses by cause, the authors were unable to identify a statistical excess likely to be linked to aluminium exposure (Owen and Miles, 1995). Compared with deaths in Cornwall over the period 1988–1997, mortality in the area of water pollution was lower than expected (standardized mortality ratio 81.6), and compared with England and Wales it was still lower (77.7) (Owen *et al*., 2002).

There was a higher level of talipes in foetuses from mothers exposed to the aluminium sulfate (four cases, one control, $p = 0.01$), but, because of the low numbers involved (88 exposed mothers) and the likely general under-reporting of positional talipes, the importance of this finding is unclear. The only conclusion drawn was that there was no evidence from the study of major problems apparent at birth (Lowermoor Incident Health Advisory Group, 1991; Golding *et al*., 1991).

The incident is a sufficient reminder of the possibility of a disaster occurring as a result of contaminated water supplies. It also illustrates the difficulties which occur in allaying fears when the affected population receives initial advice which was, to quote the conclusions in the first report of the Advisory Group, 'contradictory, confusing and sometimes inappropriate', and when media reports claiming further health effects continue. The 1991 report suggests that many of the longer-lasting symptoms and complaints arising from the Lowermoor incident would be expected as a consequence of psychological reactions. They cite evidence that, even when the victims concerned have suffered no direct physical damage, then worry, anxiety, depression and 'post-traumatic stress syndrome' may follow a major accident or disaster and can produce real mental and physical symptoms. The Committee on Toxicology report of 2005 also identified that many of the claims associating possible longer-term effects with the incident were for effects occurring at similar levels to those in the unexposed population, although in some cases, they recommended that further studies be undertaken.

3.2.3.2.2 Contamination of Food during Storage—Epping Jaundice, UK, 1965

Epping jaundice was an outbreak of jaundice which affected at least 84 people in the Epping area of London during February, 1965 (Kopelman *et al*., 1966a; 1966b). It was traced to ingestion of wholemeal bread made from flour contaminated with 4,4′-diaminodiphenylmethane (**Figure 11**). The chemical had spilled from a container on to the floor of a van, which was carrying flour as well as chemicals.

In most of the cases, severe, intermittent pains in the upper abdomen and lower chest areas of the body preceded jaundice and liver enlargement. Normally, these pains were of acute onset (50 patients), but sometimes onset was insidious (27 patients). Of the 57 patients further investigated, most had raised serum bilirubin, alkaline phosphate and aspartate aminotransferase levels. Needle biopsies were performed on four patients within three weeks of the onset of symptoms; all showed considerable evidence of portal inflammation and bile duct cholestasis, and evidence of hepatocyte damage. The lesion was reproducible in mice given 4,4′-diaminodiphenylmethane (Schoental, 1968). The patients slowly recovered over succeeding weeks.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat137
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

One feared outcome has been cancer. Of the 83% of the group that have been followed up over 38 years postincident, 37 deaths were recorded (Nichols, 2004). Mortality from all causes was close to expectation (observed 25, expected 26.7, standardized mortality ratio (SMR) 82) in females, and below (observed 12, expected 26.7, SMR 45) in males. There were no observed deaths from cancer of the liver or from nonmalignant liver disease.

The jaundice was the result of an accidental, undetected (until too late) contamination of a foodstuff because it was stored during delivery adjacent to chemicals which were insufficiently securely contained within the packaging. The chemicals were absorbed by the flour through the sacking and, following baking, were present in the bread.

3.2.3.3 Poisoning due to Consumption of Foodstuff Not Intended for Human Consumption

3.2.3.3.1 Methylmercury Poisoning in Iraq 1971–1972

An outbreak of organomercurial poisoning due to the consumption of treated grain by farmers and their families occurred in Iraq in 1971–1972 (World Health Organization, 1976). There were 459 deaths and 6000 further cases admitted to hospital.

Poisoning cases started to appear in hospitals in late December. Farming families only were affected, and the cause of the poisoning was identified as consumption of home-made bread, an important element of their diet, made from wheat treated with seed dressing. There was a latent period of up to 60 days from first consumption to the appearance of signs and symptoms of poisoning, and in many cases consumption of contaminated grain ceased before the symptoms occurred.

Symptoms included speech disturbances, abnormal behaviour, loss of auditory and visual acuity, and ataxia. The severity varied from minimal effects to severe disability and death. Most of those showing only mild or moderate symptoms were symptom-free two years later, although symptoms were still present in severe cases. Mercury levels in hair were found to be good indicators of the dose of mercury received.

Organomercurials, such as the methylmercury (**Figure 1**) involved in this episode are fungicides, the methylmercury being used as a seed dressing to prevent wheat bunt and other crop diseases. Grain dressed with methylmercury was distributed to farmers between mid September and early December, 1971. Although much of the wheat had been consumed before a cause–effect relationship had been established, surplus treated grain was withdrawn to storehouses once the cause of the outbreak was known. The problem arose because wheat intended as seed for next year's crop was eaten by the farmers and their families rather than used for its intended function.

3.2.3.3.2 Environmental Pollution—Minamata and Niigata, Japan, 1951–1974

The examples of major disasters arising from toxic substances so far discussed arise from contamination of the foodstuff. It is also possible for contamination to arise indirectly as a result of an environmental pollutant entering a food chain. Two examples of this occurred in Japan, at Minamata and Niigata (Tsubaki and Irukayama, 1977).

Over the period 1951–1974 there were over 700 recognized cases and 80 deaths due to 'Minamata disease', and over 2000 other people had applied for recognition as Minamata disease patients. The principal geographical areas affected were in two prefectures, Kumamoto and Kagoshima, which border Minamata Bay. The disease occurred mainly in fishermen and their families who consumed large quantities of locally caught fish containing high concentrations of mercury. The patients' nervous systems were affected, with symptoms of sensory, motor and visual involvement. These neurological signs have continued for at least 30 years following cessation of exposure (Ekino *et al*., 2007). Domestic cats (presumably also largely fed fish) exhibited similar clinical signs, and abnormal behaviour occurred among crows in the affected areas. Congenital effects also occurred.

The outbreak of poisoning at Niigata was first identified in 1965, with over 520 patients being identified by the end of 1974. The epidemic was also apparent in the domestic animal population.

In the Minamata outbreak, the effects were due to organically bound mercury present in sludges from industrial plant. The mercury was used as a catalyst. Mercury from the sludge or from the waste-water outlet entered food chains and was bioconcentrated in both shellfish and fish. Humans eventually consumed these foodstuffs. At Niigata, river fish from the lower reaches of the Agano River were the main foodstuff consumed which contained organic mercurial compounds. The source of the mercury was an industrial plant waste-water discharge containing low concentrations of mercury (**Figure 11**). Methylation took place in sediments, and considerable bioconcentration occurred in the fish, as evidenced by the much higher levels of mercury in the fish when compared with the river water.

At both sites, consumption of contaminated fish had gone on for a considerable time before the causes of the disease were identified. This points to the great difficulties involved in deriving a cause–effect relationship when the effect is remote from the source of the causative agent.

Although the particular examples chosen to illustrate this effect related to human health, another species may be the final consumer in a food chain. The story of the consequences of spraying persistent organochlorine insecticides, their bioconcentration in the food chain and

their disastrous effects on raptor populations because the concentrations reached were sufficient to cause eggshell thinning and failure to reproduce effectively, summarized by Smith (1986), is well known.

3.3 Interactions of Humans and Nature

This section includes a miscellaneous collection of disasters in which human activity and natural events have interacted. It includes disasters involving tide, current and weather, in addition to those due to human activity on (in) the land.

3.3.1 Shipping Disasters

The classic shipping disaster involving toxic effects is the spilling of oil from wrecked oil tankers. Most of the consequences are environmental, but there is also potential for indirect or direct effects on the human population.

3.3.1.1 Wreck of the MV Braer, Shetland Isles, Scotland, 1993

On 5 January 1993, the oil tanker MV Braer grounded in the Shetland Isles (off the north coast of Scotland) in bad weather (Ritchie and O'Sullivan, 1994; Topping *et al*., 1997; Whittle *et al*., 1997). The cargo of 8500 tonnes of a biodegradable light crude oil was released over the next seven days. This oil was dispersed by the severe weather; dispersants were not used because of these weather conditions.

Human health effects from direct (airborne) exposure were minimal and were confined to headache, throat irritation and itchy eyes (Campbell *et al*., 1993). There was some evidence for self-reported somatic symptoms, anxiety and insomnia, based on a general health questionnaire (Campbell *et al*., 1994).

Although the principal toxic effects were environmental, there was a potential human health problem arising from the food chain (Topping *et al*., 1997; Whittle *et al*., 1997). The area contaminated was a fishing ground and it included several salmon farms. Because of potential human health problems, an exclusion order under the Food and Environment Protection Act 1985, banning the harvesting for market of fish, shellfish and farmed salmon from within a designated zone around the wreck was made on 8 January. On 27 January, that zone was extended in order to ensure that all areas where contamination took place were included. **Figure 12** shows the approximate area covered by the zone. The order was lifted for fish on 23 April 1993, on crustaceans on 30 September 1994 and on molluscs in February 1995. The farmed salmon usually remain in sea cages for two winters. Both the 1991 and 1992 fish (date is year of transfer of the salmon smolts (young fish) to sea cages) were destroyed, but smolts transferred in early spring 1993 were marketed. The basis of the decision to allow marketing depended on analysis of polycyclic aromatic hydrocarbons present in the fish and taint analysis. Because no formal limits for acceptable levels of these contaminants in foodstuffs were available, chosen were:

1. Fish and shellfish caught within the zone should not contain taint associated with crude oils and petroleum fractions.
2. Concentrations of aliphatic and polycyclic aromatic hydrocarbons should fall within the background range of values for fish and shellfish from outside the exclusion tone.

This approach to the potential problem of contamination of the food chain was successful, in that it upheld the reputation of the Shetland Isles seafood industry, prevented entry of contaminated food into the chain and provided public reassurance concerning the wholesomeness of marketed fish and seafood. However, it did little to alleviate the direct environmental effects of the release of oil.

3.3.2 Mines and Tunnels

People have died as a result of lung cancer due to exposure to radon in mines or pneumoconiosis caused by exposure to coal dust or silica, but the exposure to these agents was a consequence of inadequate working conditions rather than specific accidental exposures. Fire is a potential problem in mines and tunnels. For this reason, when there was an underground coal mining industry in the UK, very strict precautions were developed to prevent fires starting underground. These included testing and certifying machinery for use underground and strict prevention of miners taking potential ignition sources underground.

In general, toxicants are unlikely to be a primary cause of a specific mining disaster, as the conditions causing ill health are unlikely to develop suddenly. Historically, particularly before the use of forced ventilation, disasters due to asphyxiation or the release of toxic gases did occur. Canaries were taken underground to act as fail-safe biological monitors for these effects ('when the singing ceased ...'). Disasters can also occur in tunnels used by the public as a result of the deliberate release of toxic agents. The Kings Cross disaster, already examined, is a demonstration of the potential for disaster that can result from fire occurring in a confined space.

3.3.2.1 Terrorist Attack on the Tokyo Subway, 1995

The dramatic effects of deliberately releasing a toxic agent in a confined space were demonstrated in a terrorist attack in the Tokyo subway in 1995 (Masuda

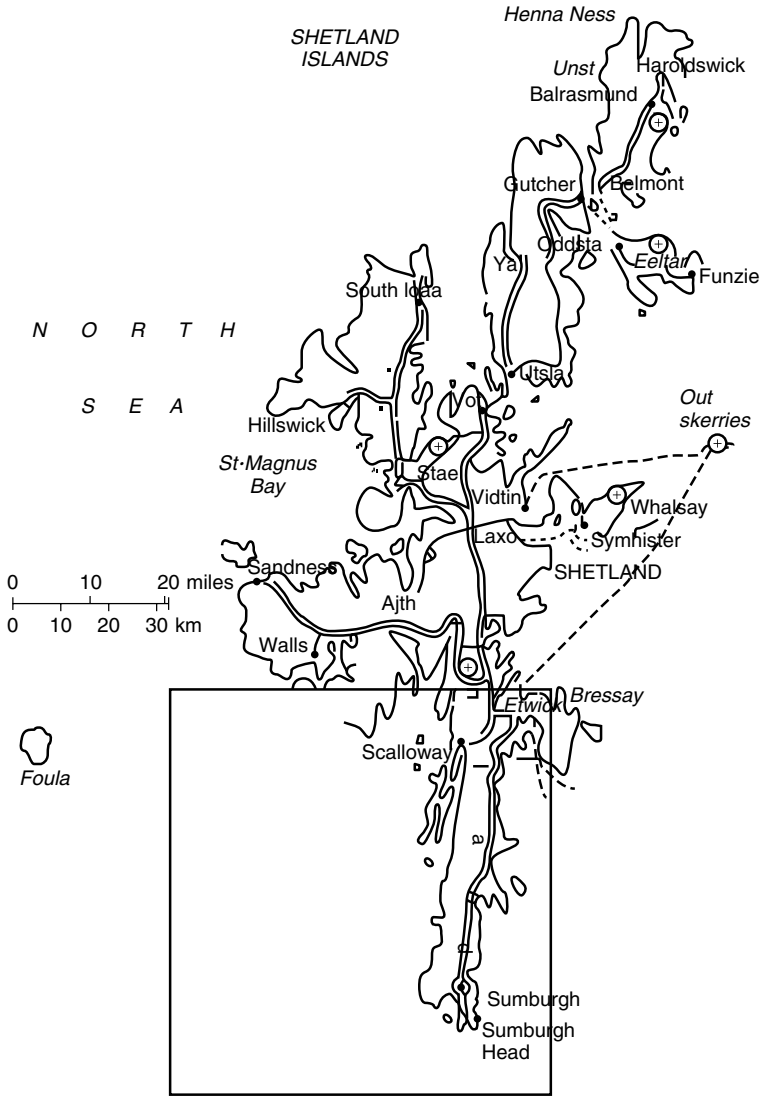

Figure 12 Map of Shetland Isles showing exclusion zone.

et al., 1995; Nozaki and Aikawa, 1995; Nozaki *et al*., 1995; Suzuki *et al*., 1995; Miyaki *et al*., 2005). Sarin, an organophosphorus nerve agent, was released. Twelve people died and over 5000 were poisoned by the attack. Classical symptoms of organophosphorus poisoning were exhibited. Atropine and pralidoxime iodide administration were the principal treatments employed. However, it was claimed that the atropine was of limited value as it is effective against muscarinic dominant responses, and sarin was thought to have produced principally nicotinic dominant responses. It was reported that, as a group, those exposed exhibited a chronic decline of psychomotor function and memory function seven years post incident (Miyaki *et al*., 2005).

3.3.3 Waste Disposal

Inadequately thought-out or poorly controlled disposal of wastes may cause disasters. Love Canal was one such incident.

3.3.3.1 Love Canal, USA

Love Canal was a waste disposal site, which contained municipal and chemical waste disposed of over a period of 30 years up to 1953. Homes were built on the site during the 1960s. Leaching became a problem in the late 1960s, when chemical odours were detected in basements. These were followed by fears of potential ill health which led to considerable psychological stress. Dibenzofurans and dioxins were identified in the organic phases of leachates and were presumably derived from the disposal of waste products of the manufacture of chlorinated hydrocarbons. Animal studies conducted on the organic phase of the leachate indicated that there could be risks of immunotoxic, carcinogenic and teratogenic effects (Silkworth *et al*., 1984; 1986; 1989a; 1989b). Low birth weights have been found in the offspring of residents of Love Canal, together with a higher proportion of female offspring and higher rates of congenital malformations (Vianna and Polan, 1984; New York State

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

Department of Health, 2008). No causal link has been established for exposure to chemicals and cancer in humans (Janerich *et al*., 1981; New York State Department of Health, 2008).

Serious social and psychological consequences have resulted from the use of the site for houses and the initial lack of understanding of the fears of residents concerning the toxic properties of the chemicals dumped at the site (Holden, 1980).

Love Canal is important because it was a key incident leading to the US 'Comprehensive Environmental Response Compensation and Liability Act' (CERCLA) of 1980, and its amendment, the Superfund Amendments and Reauthorization Act (SARA) of 1986, commonly known as 'Superfund'. These provided broad US Federal authority to respond to releases or threatened releases of hazardous substances that may endanger public health or the environment. They also created a tax on the chemical and petroleum industries (which continued to 1995), which went into a trust fund for cleaning up abandoned or uncontrolled hazardous waste sites when no responsible party could be identified. The trust funds ran out in 2003, since when such clean-ups have been paid for from general taxation.

3.3.3.2 *Minamata and Niigata*

The mercury poisonings at Minamata and Niigata, already described, were caused by the disposal of industrial wastes in such a manner that the toxicant was concentrated to dangerous level, in a food chain in the aqueous environment.

3.4 Conclusions

Toxicants, whether derived from nature or the chemical plant, can cause disasters. Identifying the cause is relatively easy when the toxicant is airborne and the ill health occurs during or shortly after exposure. It is usually more difficult if the effect is mediated via the food or water supply and/or if the effect is not immediately apparent. The former have been called 'overt' disasters and the latter 'dilute' disasters (Bertazzi, 1989). As 'dilute' implies some diminution of effect, it might be better to refer to the latter type of disaster as a 'disseminated' disaster.

In overt disasters due to airborne toxicants, there is usually a primary event such as volcanic eruption or a plant failure. This is followed by dispersal of the toxicant, which depends on the buoyancy of the material released and the meteorological conditions at the time of release. Any immediate dose received by humans will depend on the level and duration of the exposure. Only very simple post-event preventative measures can be used to minimize the dose received. Although usually ill health is immediate, long-term effects such as carcinogenicity can occur. However, they are difficult to link to a primary event. Toxic material can be deposited on to surfaces, and ill health due to the consequent continuing lower-level exposures may be prevented by segregation (e.g. collection and containment of the contaminated material and/or banning public access to it).

Most known airborne toxicants involved in major disasters affect the respiratory tract. Irritation, asphyxiation (chemically induced by binding of toxicant, or physically induced by blockage of the respiratory tract) and pulmonary oedema are common (Schwartz, 1987). Cancers are possible effects, although they have been better characterized for radiation, and only recently has it been possible to detect cancers following chemical exposures epidemiologically. Other toxic effects may occur in organs away from the respiratory system, although this appears to be rare. When airborne, the toxicant reaches the lung and respiratory system first: consequently, these appear to be the most frequently affected organ systems.

When transport and dispersal of a toxicant are in water, then buoyancy, flow rates and ability to be taken up and released by sediment or biota become important determinants of the concentration present. Transport of toxic substances deposited on land depends, in large part, on the weather. In dry conditions, air dispersal of the material absorbed on particles is possible; in wet weather, dispersal will be along the same routes as those followed by the rainwater. Soil adsorption and uptake by plants and animals may also occur. Waterborne (or soil-borne) toxic substances may affect human health as a result of direct intake as drinking water or via foodstuffs contaminated with the toxic substances. This type of dispersal may result in 'overt' disasters when the source is readily apparent, or in 'disseminated' disasters when the source of the toxic substance is not obvious.

The causes of 'disseminated' disasters are frequently more difficult to identify and these disasters are often identified initially by end effect. Tracing the cause may take a considerable time, particularly as there may be a significant time delay between exposure occurring and ill health taking effect, and transfer between environmental compartments may have occurred. In consequence, withdrawal of the food, and so on, containing the toxicant, although desirable, may not be possible until it is too late to be an effective post-event preventative measure.

One consistent complicating factor in major accidents and disasters is the possibility of psychological reactions being considered as physiological responses to exposure to a particular agent. Long-lasting consequences, including severe worry, anxiety, depression and 'post-traumatic syndrome', were identified following the Mount St. Helens eruption, Bhopal, the Lowermoor and Love Canal incidents. Although not toxicological responses *per se*, these effects can be real, distressing and disabling. In the absence of sufficient authoritative and accurate information, popular speculation generally favours the worst possible outcomes,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

however improbable. This is likely to worsen psychiatric consequences of the event and to complicate the emergency response. The provision of timely, accurate advice in an understandable form is one need that must be considered when examining how to handle the consequences of a serious incident.

4 DISASTER PREVENTION AND MITIGATION

One role of industry, individual governments and international organizations is to develop and implement procedures for preventing or minimizing the effects of potential or actual disasters. In most countries governments develop a series of legislative requirements in order to provide a framework of regulation within which to work. Rather than compare different national frameworks, this section will concentrate on conceptual approaches to handling the risks arising from major hazards.

Assessment of potential hazards and assessment and management of the likely consequences are the key elements in any process for dealing with major hazards. In the case of toxic hazards, one aspect of the hazard evaluation is an examination of the likely toxicity of the materials involved in the potentially disastrous situation, including the prediction of the amounts of toxic materials likely to cause these effects. Procedures can then be adopted for the assessment of the risks associated with the various uses. These procedures of risk management differ fundamentally according to the type ('overt' or 'disseminated') of potential disaster envisaged.

4.1 Judging Risk

'Is it a risk?' is usually the first question asked when a potential hazard is being examined. Once the concept of risk has been explained, two questions will follow: 'What is the risk?' and 'Is it acceptable/tolerable?' (see **Table 1** for definitions). This involves trying to define general criteria for acceptable or tolerable risk. These criteria should be based on societal judgements, but judgements are often made by the technical expert on behalf of society as a whole. Once criteria for acceptability (tolerability) have been defined, a method is needed in order to compare the risk for the particular problem under study with the relevant criterion for acceptable risk. That method may be qualitative, of the form 'acceptable'/'unacceptable', based on a judgement of the data available against broadly defined criteria. However, for many purposes, including much engineering-based risk assessment for an initiating event, quantitative, numerical approaches are adopted. These numerical approaches are called quantified risk analyses. These quantitative analyses render decision-making easier, especially when choosing between options, as they give a clearer indication of the magnitude of a risk or of the relative risks for different options. However, because these decisions depend, in the final analysis, on societal judgements concerning acceptability, they may be unacceptable to certain individuals or groups within that society. Major reports on risk management and standard setting have emphasized that both communication between technical experts and key 'stakeholders' (acting on behalf of society) and transparency of decision taking process are essential if decisions taken on behalf of society are to be accepted by society (Presidential/Congressional Commission on Risk Assessment and Risk Management, 1997; Royal Commission on Environmental Pollution, 1998). Public (or 'stakeholder') involvement should be included in strategy formulation rather than solely in consultation on already drafted proposals, and may be accomplished using 'focus groups', citizen juries, consensus conferences and deliberative polls as well as by more traditional means.

When considering the risk of an event leading to an end effect, a surrogate for that end effect, a 'dose' or exposure–time combination (a 'harm criterion') is often used. Uncertainty in the relationship between this surrogate and the end effect (normally considered 'risk' by toxicologists and epidemiologists) is regarded, in this context, as uncertainty in defining the hazard.

Judging the acceptability of a human health harm criterion depends on three factors: the frequency level (the frequency with which the end effect is likely to occur), the definition of the biological effect (death, serious injury, etc.) and the status of the receiving individual (a 'normal' or a 'vulnerable' individual).

What constitutes a major accident to the environment is more difficult to define and the definition may involve subjective judgements. Generally loss of populations or loss of habitats, rather than loss of individuals is required when considering nonhuman species. The more extensive the areas of natural or seminatural resources damaged, the longer the effects are likely to last. And the more intense or severe these effects are, then the more likely it is that the event will be regarded as a major accident to the environment. Moreover, if the land is designated for nature conservation purposes (and especially Natura 2000 or Ramsar sites (Ramsar sites are named after the place in Iran where the Convention on Wetlands was signed in 1971)), then the event is likely to be regarded as a major accident at lower thresholds than those that apply to other designated areas, amenity areas, the wider countryside or the more common types of agricultural land. One set of definitions for the types of effects for a major accident to the environment is that the incident:

- Poses knock-out threats to human health by contamination of food or drinking water or impact on sewage treatment works.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat137
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Affects large areas of land designated for conservation, amenity or planning purposes. (Note that this may include extensive agglomerations of fragmented habitats.)
- Results in long-term or persistent damage and/or inhibits natural processes of regeneration.
- Results in significant, permanent or long-term damage to the ecosystem (direct, indirect or knock-on), such as reducing breeding success of protected species, or reducing biodiversity of protected habitats (including local or national extinctions of protected species), or destroying/reducing the quality of a significant portion of a rare habitat.

(Department of the Environment, Transport and the Regions, 1999).

4.2 Framework for Risk Assessment

There are several levels of risk (either of initiating event or of end effect) that can be elaborated. At one level there is the 'trivial', 'negligible' or 'completely acceptable' risk. At the other extreme there is the 'intolerable' or 'unacceptable' risk. In between lies a range of risks which are tolerable under certain circumstances and/or provided they are minimized (**Figure 13**). In between the upper and lower bounds of acceptability lies a region where risks from known hazards should be reduced as far as is reasonably practicable. This means that the cost of reducing the risk should not be disproportionate to the level of risk encountered. A small reduction in an already low risk may not be justified if it is very expensive.

4.2.1 Harm Criteria for 'Acceptable Risk' (Human Health)

When comparing risks, the risk of end effect, and not of initiating event, is being examined. It is necessary to ensure that the particular end effect (e.g. 'death'; in reality foreshortening of life, often to the extent that death occurs during or shortly after the event occurring) for which the likelihood is being calculated is the same for all the likelihoods being examined, in terms of both the biological event and the type of recipient (usually a 'normal' individual). Criteria for assessing this 'risk of death' to the individual have been obtained by comparisons with everyday risks associated with various activities (Royal Society Study Group, 1983; Health and Safety Executive, 1988a; Health and Safety Executive, 1988b; Health and Safety Executive, 1989). For major hazards risk, the acceptable 'risk of death' for exposure to the given agent has to be converted to a 'harm criterion' (exposure concentration–time relationship) for inclusion in the calculation of the overall risk arising from the initiating event.

A likelihood of about 1 in 10^6 per year that the exposure will result in the individual concerned dying from a given cause appears to be generally regarded in the UK as the boundary between tolerable and acceptable (Royal Society Study Group, 1983; Health and Safety

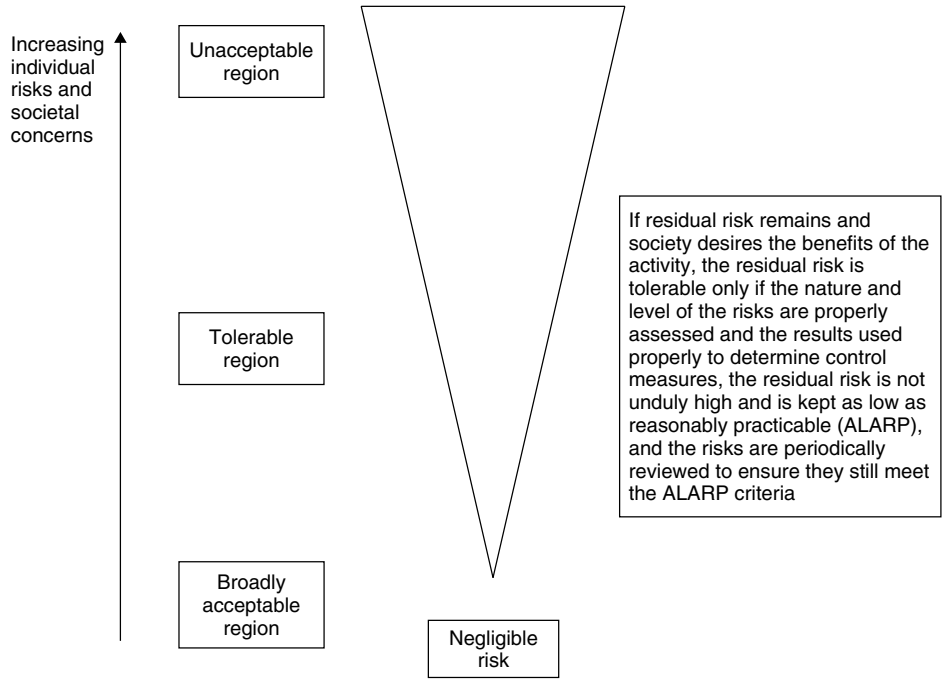

Figure 13 Outline of the Royal Society approach to risk management/tolerability of risk framework. (Based on Health and Safety Executive, 2001.)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

Table 3 Comparisons of risk of death from various causes

Cause of death	Risk (as annual experience) (per year)	Year of statistic	Risk (as annual experience) (per year)	Year of statistic
Cancer	2.8×10^{-3}	1985	2.58×10^{-3}	1999 (England and Wales)
Deep sea fishing	8.8×10^{-4}	1984		
All accidents and external causes			2.46×10^{-4}	1999 (UK)
Quarrying	3.0×10^{-4}	1985		
Coal extraction, manufacture of solid fuels	1.1×10^{-4}	1986–1987		
Mining and quarrying (energy producing material)			1.09×10^{-4}	1996–1997 to 2000–2001 (GB)
Agriculture	8.7×10^{-5}	1986–1987	5.81×10^{-5}	1996–1997 to 2000–2001 (GB)
Construction	9.2×10^{-5}	1986–1987	5.88×10^{-5}	1996–1997 to 2000–2001 (GB)
Road accident	1.0×10^{-4}	1985	5.95×10^{-5}	1999 (UK)
Gas incidents	1.8×10^{-6}	1981–1985	6.62×10^{-7}	1996–1997 to 2000-2001 (GB)
Lightning	1.0×10^{-7}	Average over several years	5.35×10^{-8}	1995–1999 (England and Wales)

Data on industrial accidents are based on accidents to the employee; data on deaths from other causes are averaged over the general population.
Compiled from Health and Safety Executive (1989; 2001). The data from the 1980s were used by the Health and Safety Executive when defining the criteria of 'risk of death'. Note how the data underlying the criteria have improved over time.

Executive, 2001). This was justified by considering the death rates for different activities considered 'safe' (see **Table 3** for some comparative 'risks of death'). The 'risk of death' for workers in recognized dangerous occupations in the 1980s was of the order of 1 death per 10^3 per year; this is considered the highest bound of 'tolerable' risk for a lifetime risk. Any higher level is considered intolerable and unacceptable at all times. Because working in a 'risky' industry is, at least to some extent, voluntary, the individual risk just tolerable for a member of the general public living in the neighbourhood of a hazard is considered to be 10-fold less (1 death per 10^4 per year) (Health and Safety Executive, 1989; 2001). This is approximately the risk from death in a road traffic accident and less than the risk of developing any form of cancer. All of these likelihood criteria relate to individual risk of end effect for the average individual. As risk levels associated with industrial accidents decrease, it could be argued that the criterion value for tolerable/unacceptable risk for workers should be adjusted to reflect more recent statistics.

The type of population being considered may differ according to circumstances. Rather than examining the frequency of achieving a given biological effect in terms of the event occurring in an average individual in a 'normal' population, it may be that the consequence should be considered for an individual from a population containing a large number of particularly vulnerable (or susceptible) individuals. A frequency of 3.3 in 10^7 per year for when there is a high proportion of 'highly susceptible' people receiving a 'dangerous dose' has been proposed in place of the 1 in 10^6 per year for an individual from a population containing a normal balance of 'highly susceptible' individuals (Health and Safety Executive, 1989). The identity of the 'highly susceptible' people will depend on the effects seen, and the proportion will differ according to effect. Homes for the elderly, caring institutions and long-stay hospitals are considered to contain a high proportion of 'highly susceptible' people. However, the choice of the ratio of 3.3 : 1 (a half-order of magnitude) is a pragmatic decision.

A more conservative approach has been elaborated in the Netherlands (Versteeg, 1988). It depends on the frequency of deaths from natural causes and is based on the idea that industrial activity should not increase the background mortality by more than 1%. An upper bound of 10^6 deaths per year has been derived with a lower bound of 10^8 per year being considered trivial. If the biological effect being looked at changes, and/or the type of individual being examined is different, then the numerical value of any harm criterion ought also to be altered. When quoting a harm criterion it is therefore necessary also to mention the effect and the type of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat137
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

recipient. Although these types of numerical comparisons have been made for individual likelihoods associated with severe end effects, such as death, other end effects may be more important for evaluating the potential toxic effects of chemicals for disaster prevention and mitigation. Risks for events leading to more minor ill health may be the evaluation required, and the risk may be societal (or population) risk. Although attempts have been made to consider what frequencies of end effect should be applied for many of these circumstances (e.g. Illing, 1991; Calman, 1996), consensus is absent.

Although descriptive criteria as to what constitutes a major disaster to the environment have been developed for environmental incidents (Department of the Environment, Transport and the Regions, 1999), these descriptions have not been related to predictive information. Thus judgement has to be used.

4.2.1.1 'Overt' Disasters

Risk of the initiating event is the risk being examined. The aim of the risk assessment is therefore to examine the likelihood of events resulting in a release of a chemical or chemicals of a size and type that results in the harm criterion being exceeded in a given geographic location. Potential 'overt' disasters can be averted or minimized by a combination of land-use planning and emergency planning. Good land-use planning can minimize the potential of a release (a catastrophic failure of plant, etc.) leading to a disaster by restricting the size of any interaction of event and consequence. A hazardous process or a large store of hazardous material can be sited well away from large numbers of people (or, for environmental effects, away from important buildings or sensitive wildlife habitats). Potential developments involving significant numbers of members of the public can be sited away from natural or human-made major hazards.

There will remain a residue of risk after appropriate land-use planning has been achieved. Occasionally there will be the situation where inappropriate combinations of people and major hazards occurred prior to the time when the need for appropriate land-use planning became apparent. In addition, other considerations, such as a need for local employment, may mean that other factors were decisive when the planning decision was made. The consequences, should the event occur, can still be substantially reduced, provided that appropriate emergency planning has been undertaken. This includes both enabling potential victims to survive better prior to treatment, and making available appropriate treatment sufficiently rapidly. It also involves protecting water and food supplies intended for human consumption.

Generally, owners (or prospective owners) of potential major hazard installations will prepare 'safety cases' or 'safety assessments' for those sites. These often include assessments of the risks and consideration of the administrative and other arrangements for minimizing risks and for handling emergencies.

4.2.1.1.1 Land-Use Planning

For land-use planning in the UK, the 'Dangerous Toxic Load' (DTL) describes the exposure conditions, in terms of airborne concentration and duration of exposure, that would produce a particular level of toxicity in the general population (Health and Safety Executive, 2008).

The 'Dangerous Dose' is a harm criterion, a description of the exposure conditions producing a specified level of toxicity (SLOT) where (Health and Safety Executive, 1989; Fairhurst and Turner, 1993):

1. Severe distress will be caused to almost everyone in the area.
2. A substantial fraction of the exposed population will require medical attention.
3. Some people are seriously injured and require prolonged treatment.
4. Any highly susceptible people may be killed.

This type of criterion reflects that there is a range of individual ill-health effects and imprecision in the estimate of overall effect seen in the population.

Another DTL is that for the significant likelihood of death (SLOD; a DTL relating to 50% mortality in a normal exposed population) (Health and Safety Executive, 2008).

Some ratios have been enunciated for the relationships between the harm criterion for exposure conditions leading to 'death' (SLOD) and 'dangerous dose' (SLOT; taken as 1% mortality in Health and Safety Executive, 2008) in the same population. Such a value will depend on the LC_{50} (lethal concentration expected to cause 50% mortality) for different durations of exposure and the slopes of the dose–response lines for both the SLOD and the SLOT. Comparisons for chlorine, ammonia, hydrogen fluoride and sulfur dioxide give the relationship:

$$\text{Risk of } LD_{50} = \frac{(\text{Risk of Dangerous Dose})^{1.12}}{2.97} \qquad (2)$$

(Franks *et al*., 1996).

In this exercise, LD_{50} (LD—'lethal dose') is an amount of a substance, a combination of concentration and time. When there are insufficient data to derive a relationship between SLOD and SLOT (or LD_{50} and Dangerous Dose), the Health and Safety Executive (HSE) takes a default factor of 4 and divides the LC_{50} (for a given exposure time) by this (Health and Safety Executive, 2008).

4.2.1.1.2 Emergency Planning

Emergency planning is essentially concerned with mitigating and recovering from the consequences after an

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat137
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

event has occurred. This has very wide application, and includes preparedness for chemical, biological, radiological or nuclear hazards, including those arising from terrorist activity. In the UK, emergency preparedness for non-'Control of Major Accident Hazards Regulations' (COMAH) sites is covered by the Civil Contingencies Act 2004, and guidance has been published (HM Government, 2005). In the USA it is dealt with by the Department of Homeland Security. For certain industrial hazards, the COMAH Regulations (The Control of Major Accident Hazards, 1999) apply. There is a need to cover both 'on-site' and 'off-site' planning, including immediate ('emergency') shutdown, responses of emergency services, the medical management of the immediate and long-term health effects, and the management of food and drinking-water supplies and potential environmental effects (OECD, 1994). Such planning is concerned with a much wider range of biological effects than death. For immediate effects on human health, these include the 'severe health effect' (disability, requiring hospital treatment), and 'mild health effect' (discomfort or distress), as well as the 'detectable but not a true health effect' (nuisance) (Baxter *et al*., 1989a; Illing, 1989). Both the European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC), through their 'emergency exposure indices' and the US National Research Council, through their 'acute exposure guideline levels' (AEGLs) have defined three harm criteria for airborne concentrations for exposures lasting up to a specified time (ECETOC, 1991; National Research Council, 2001). These are criteria above which direct toxic effects are likely to lead to one of the outcomes: death/permanent incapacity, disability or discomfort. Although hospital treatment may be essential for recovery from the severe health effects, it will usually have little influence in the case of milder effects (discomfort). It may also be necessary to consider longer-term health effects, protection of food and drinking-water supplies (by withdrawing affected foods and water from the supply chain), and possibly protection (if feasible) of the environment. There is also a need to plan for an appropriately sized event. One proposal categorizes three types of release: small but likely accidents, severe but reasonably foreseeable events, and large, unlikely events (Baxter *et al*., 1989a). If the severe, reasonably foreseeable event is chosen for planning purposes, then it should be possible to scale up or down the response for an individual event.

4.2.1.2 'Disseminated' Disasters

Essentially, 'disseminated' disasters should only occur as a result of failure of a regulatory system resulting in exposure to a toxicant. The risk should be that of the initiating event, the failure of the regulatory system. That failure may be because a new effect was uncovered by the disaster; alternatively, a known effect might have occurred because of nonadherence to existing regulatory requirements. The primary means of control has to be preventative, ensuring that, under normal conditions of exposure, the frequency of even minor ill health is acceptably low. A sufficiently rigorous enforcement system is needed in order to ensure that failures of control which result in higher frequencies of ill health or more severe ill-health effects do not occur. This type of approach is based on the conventional no-effect level and safety factors, leading to such concepts as maximum 'acceptable daily intake' and 'occupational exposure limits' (Royal Society Study Group, 1983). Where carcinogenic or other stochastic effects are concerned, the approach will be to minimize exposure as far as is reasonably practicable.

4.2.2 Determining Risk Levels

Determination of the risk levels associated with likely release sizes and dispersion patterns is required for airborne overt hazards. There are essentially similar processes for determining risk levels for land-use planning and emergency planning (Health and Safety Executive, 1989; ECETOC, 1991). The process can be divided into seven steps (Health and Safety Executive, 1989):

1. Identification of possible hazardous release events.
2. Identification and analysis of the failure mechanisms which would allow a release.
3. Estimation of rates and durations of the release.
4. Estimation of the frequencies of releases using the analysis of failure mechanisms.
5. Estimation of the injury consequences of releases, taking account of mitigating factors.
6. Combination of the frequencies and consequences to determine the overall risk levels.
7. Judgement of the significance of the risk levels (by comparison with appropriate criteria).

Although this process was described for land-use planning in the vicinity of major industrial hazards in the UK, it can also be used more generally. Essentially, it can be described as three elements—a description of a source, a model for looking at the dispersion of the substance, and a means of entering into the dispersion model parameters describing the conditions which will give a biological effect.

Models have been developed for airborne dispersion. Models are also available for dispersion through surface and groundwaters and soils and sediments, and for dispersion through food chains.

The source term for inputting into the dispersion model can be obtained by 'fault tree' analysis of the frequency of events (failure rates), by 'event tree analysis' leading to an estimate of failure rates, or by engineering judgement based on historical event frequency. The actual method(s) chosen will depend on the type of release being

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

studied and the available data. The sizes and durations of the postulated/actual releases are also examined (Health and Safety Executive, 1989). For land-use planning there is a continuum of event frequency and size of release. Usually, sets of release sizes and durations are selected from the continuum and assigned appropriate frequencies. However, for emergency planning the process can be simplified by using the 'severe, but reasonably foreseeable event' as the appropriate basis on which to plan (Baxter *et al*., 1989a). This event was exemplified as a large hole in, or fracture of, a liquid chlorine pipe, or of a road tanker delivery coupling at a chlorine installation. Scaling a response up or down should then be possible when an event actually occurs if the plan is sufficiently flexible. The modelling then required is concerned with the dispersion of the toxic cloud in air or the toxic material through surface or groundwaters or in soils and sediments. Several models for airborne dispersion have been described (see McQuaid, 1989; Brighton *et al*., 1994). In general, these models require a knowledge of the buoyant density of the cloud under different weather conditions. The dispersal conditions need to be combined with a function describing the combination of exposure concentration and time, resulting in a defined frequency of a specified effect. For example, one concentration–time combination may be described as the 'dangerous dose' for land-use planning, while a different combination could be used for the outer boundary for 'discomfort' for emergency planning. When combined with the information on the source, the model is then used to calculate 'isopleths'. These are boundaries of areas within which, at a point in time, the concentration–time combination of exposure to the toxic substance would exceed that expected to give the identified biological effect. An overall isopleth envelope can then be calculated for a given set of release conditions by combining the individual isopleths for each time point post-event. Similar approaches can be used for dispersion in river systems and for groundwater dispersion.

The information on the various isopleth envelopes for different types of release and meteorological conditions, when combined using knowledge of the frequencies with which these conditions occur, gives a generalized 'contour' for all source terms and dispersal conditions. This contour is a risk statement for individual risk for a person within the specified boundary. An estimate of societal risk can then be obtained if data on the distribution of people within the geographic area are input. In view of the complexity of these systems, computer programs have been developed to carry out the calculations associated with the models. The aim of the toxicologist is to find appropriate information on which to base a function describing the concentration–time relationship for a particular biological effect or combination of effects.

4.2.2.1 Contribution of Human Health Toxicology to Hazard and Risk Assessment

The most likely direct hazards arising from a major accidental release of a toxic substance are the biological consequences of short-term exposure during dispersal of the toxicant. Longer-term or delayed effects should be considered in addition to those more immediately apparent. Indirect consequences due to contamination of food or water supplies or to inhalation of dusts following settlement and subsequent disturbance are potentially important, but less immediate problems, and should be amenable to post-event measures aimed at preventing significant exposure.

4.2.2.1.1 The Data Available

In theory, at least, the ideal assessment of toxicity of a potential major hazard substance or agent would be based on accurate observations of the appropriate effect in humans. Reliable reports on severe effects in humans are, fortunately, few, and mainly as a result of accidental exposure or exposure in wartime. Controversy often surrounds the exposure levels associated with such studies (Withers and Lees, 1987; Marshall, 1989) or the sources of the information (MHAP Toxicology Working Party, 1993). Results from studies on sublethal effects in humans may be more plentiful. Nevertheless, the data on most substances are restricted to accidental exposures, often affecting only one or two people and rarely containing accurate exposure information. Except for radioactivity, human evidence concerning long-term effects of single exposures to most agents and substances is virtually nonexistent. Further studies which require deliberate exposure of men (or women) to dangerous levels of a substance or agent are unethical.

As a consequence of the limited human data, heavy reliance has to be placed on animal and other experiments in attempting to predict the adverse effects in the human population. Often these animal data are confined to short-term effects (sometimes only lethality) following single exposures. For example, prior to Bhopal, the information available on the toxicity of methyl isocyanate was confined to a single published paper (Kimmerle and Eben, 1964) on short-term effects following acute exposure (Bucher, 1987). Also, many animal studies on the types of substances which might constitute major hazards were performed a long time ago and the data are, by modern standards, of poor quality. In view of the very variable nature of the toxicity information, it is essential to evaluate this information critically and to understand the uncertainties introduced as a consequence of the nature and quality of the data (Illing, 1989; Marshall, 1989; ECETOC, 1991; Fairhurst and Turner, 1993). This means that assessments will normally be conducted using the original reports or published papers.

As the information may be required for quantitative risk analysis associated with an initiating event, where

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat137
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

possible it will need to be described in numerical terms. Uncertainty has to be handled by sensitivity analysis. By inputting various potential values for particular effects into the risk assessments, it is possible to discover the differences that variation of the input parameter will have in terms of outcome, the areas of map covered by the contour envelope related to a particular risk value. This sensitivity analysis is an essential part of the overall risk assessment.

Usually there are few, if any, data on the immunological, carcinogenic or reproductive effects likely after single exposures to major hazard substances/agents. Indirect effects mediated through food chain uptake and bioconcentration, or disturbing settled material also need to be considered. If data are available, they should be evaluated. However, that evaluation will normally be descriptive as, except for the effects of radioactivity, there is currently no satisfactory way of obtaining the data in a form suitable for more quantitative approaches.

4.2.2.1.2 Problems of Extrapolation

The difficulties encountered in extrapolating from data in animals in evaluating the hazard to humans are similar whatever the nature of the hazard being examined. Four principal problems—extrapolation for different exposure times, interspecies variation, population heterogeneity (interindividual variation) and route-to-route extrapolation—are particularly relevant when data for major hazard substances are examined.

Extrapolation for different exposure times is considered under 'modelling the toxicity information'.

Interspecies variation in biological effects is an important area of uncertainty in the evaluation. In the absence of suitable alternatives, the 'default option' is to use the most sensitive relevant species, that is, after excluding those species for which mode of action or other data clearly suggest they are inappropriate models for humans. Toxicokinetic and toxicodynamic relationships between species, together with information on the relevant biochemical parameters in humans, can lead to a better understanding of the relevance of results in a particular species for humans, but are rarely available.

Extrapolation between species is usually based on allometric scaling. As lung surface area (for absorption) and body weight or body surface area (for effect) can both be scaled allometrically, such scaling is not usually relevant to inhalation studies.

In addition to interspecies variation, it is necessary to consider interindividual variation (or population heterogeneity) and the nature of the population being studied. This is considered further below under 'modelling the toxicity'.

The UK tended to avoid the use of uncertainty factors for interspecies variation (Fairhurst and Turner, 1993). The factor of 4 in moving from SLOD to SLOT (see below) should include an element associated with interindividual variation as well as a component associated with the move from LC_{50} to a low level of deaths. The US National Research Council (2001) recommended use of uncertainty factors of 1–10 to cover both interspecies and interindividual variation, but more recent analysis suggests that these factors may be inappropriate (Bogen, 2005).

Occasionally, toxicity data may be used which were obtained for a different route of exposure from that for which they are being assessed (Pepelco and Withey, 1985; Pepelco, 1987). For example, in the absence of sufficient inhalation data it may be possible, in some circumstances, to make use of oral data and to relate them to equivalent inhalation exposures. However, comparisons cannot be made if there are substantial differences in the toxicokinetics for the two routes. Often, effects on the lung are critical. These can be considered local effects, in which case it is not appropriate to extrapolate from oral data. Great caution is required when extrapolating data from studies using different routes of exposure. Extrapolation of laboratory animal data to other, nonhuman species, although possible, is only done when there is a specific requirement.

4.2.2.2 Modelling the Toxicity Information

The best way of relating exposure level, duration and effect for quantitative risk assessment is probably based on toxicokinetic and toxicodynamic modelling, similar to that used for workplace exposure to inhaled gases and vapours. This has been used for developing AEGL values for trichloroethylene (Boyes *et al*., 2005). However, appropriate data are not usually available, so other, more pragmatic approaches are adopted.

A generally available pragmatic approach is based on the need to obtain (i) a concentration–time relationship, usually based on the midpoint (LC_{50} or EC_{50} (EC—'effective concentration')) of the effect(s) being examined and, if required, (ii) an appropriate set of exposure conditions that are taken to result in a particular level of effect in the population (ECETOC, 1991; Fairhurst and Turner, 1993; Franks *et al*., 1996; Health and Safety Executive, 2008).

As the concentration–time (ct) relationships often have to be based on LC_{50} or EC_{50} data for various times (they are frequently the only data available), they normally refer to midpoint concentration, that is, where the effect is seen in 50% of the population. In general, the values have to be adjusted to yield the boundary between effects (disability with few immediate deaths for 'dangerous dose'; discomfort with few disabled in the case of defining zones where people needing hospital treatment are likely to be located). The dose response may also need to be adjusted to account for differences in the make-up of the populations being examined. It must be emphasized

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat137

that any boundary will be approximate because of the nature of the data and the models being used.

In the early years of this century, studies on the acute inhalation toxicity for a limited number of gases yielded mortality data suggesting the following relationship:

$$ct = \text{constant} \quad (3)$$

where $c =$ concentration and $t =$ time.

(Haber, 1924). This is usually known as the Haber rule. More recent observations have suggested a more general relationship:

$$c^n t = \text{constant} \quad (4)$$

(ten Berg *et al*., 1985; Klimisch *et al*., 1987; Marshall, 1989; Miller *et al*., 2000; National Research Council, 2001). An alternative form of this equation, which can be used to plot data, is

$$n\log c = \log t + \text{constant} \quad (5)$$

(the constant here is the logarithmic value of the constant in Equation 4.)

Although a wide range of values for n have been cited, usually it appears to be close to the integer value of 1 or 2. Where it is possible, the relationship should be derived from experimental data, ideally from a single series of experiments in the same laboratory and using the same strain of animal. If data are combined from different laboratories and different strains or species, the relationship generated may represent interspecies (or interstrain) variation, rather than a genuine concentration–time relationship.

Occasionally, as with data for rats exposed to sarin, a more complex relationship, including an interaction term is required (Mioduszewski *et al*., 2002). This may reflect the toxicokinetic and toxicodynamic influences associated with substances that cause their effects systemically, rather than at the site of administration.

Frequently there are insufficient data to verify the concentration–time relationship, and the 'default' value of $n = 1$ is used. It is probably adequate when extrapolating to longer times where this figure usually overestimates the consequences. However, the Haber rule could seriously underestimate the exposure if data are not available for shorter periods and extrapolation from longer exposure periods is undertaken (Illing, 1989; Boyes *et al*., 2000). Thus the UK Health and Safety Executive works from single, short-term exposures (up to 4 hours duration) and uses a default value of 1 (Health and Safety Executive, 2008). Also, the US National Research Council recommends using a default value of 1 when extrapolating from shorter to longer time points and a value of 3 when extrapolating from longer to shorter times for AEGLs (National Research Council, 2001). Because of underlying assumptions about steady-state toxicokinetics inherent in any of these relationships, they are all likely to be overestimates at, say, less than 5 minutes, while equilibration to some form of pseudo-steady state is taking place.

Usually it is also necessary to define the concentration–time combination for a boundary condition rather than for the midpoint value for an effect (**Figure 14**). Ideally this should be obtained from experimental data. Often it has to be derived from the slope of the dose–response curve. If data on the slope are not available, it may be possible to use Equation 2 (see above), provided that the effects seen and the populations for which the predictions are required are reasonably similar to those used in deriving the equation. The slope of the dose–response curve depends on the type of population being studied (see **Figure 15**). In transferring from LC_{50} to an LC representing the boundary death–disability, it is necessary to consider population heterogeneity. Animal experiments, particularly those performed in recent years, have been conducted using animals specially bred to limit variations in response, and are usually young, healthy individuals. This implies a relatively steep dose–response curve. In many older studies, much less closely defined animals were used. The general human population is more heterogeneous still, containing groups of individuals who must be considered 'highly susceptible' because of age, genetic constitution or disease state. Under these circumstances the dose–response relationship will be much shallower. A default of 4 has been suggested when moving from LC_{50} (the SLOD) to very low mortality (suggested as 1%) for the SLOT (Health and Safety Executive, 2008). This is probably a reasonable overestimate of the allowance for the movement from a tightly defined population variation due to the use of inbred strains to a more heterogeneous population typical of the normal human populace.

As an alternative to the approach to concentration–time relationships outlined above, it is sometimes possible to describe mathematically a line for the boundary conditions of the concentration–time relationship using scatter diagrams, showing all concentrations and times at which the effect occurred (**Figure 16**) (ECETOC, 1991). This approach normally requires access to more detailed data, including, ideally, the results for individual animals. It also can suffer from problems relating to population heterogeneity and interspecies and interlaboratory variation.

4.2.2.3 Additional Points

Whatever information emerges from animal toxicity data must always be compared with any data that are available in the target species (humans). Those from the most sensitive species are normally chosen as representing a conservative approach.

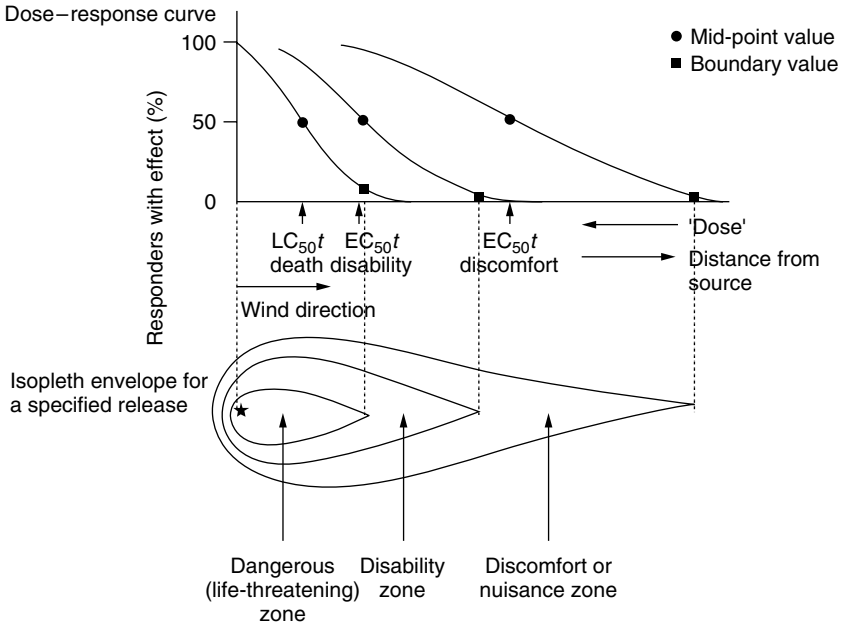

Figure 14 Diagram to illustrate the correlation between response and isopleth envelope. 'Dose' is the combined exposure concentration and duration (time) function for the particular effect. Time after initial event is given as *t*. The isopleth envelope described is that bounding the overall combination of concentrations and durations of exposure for a release, and can be built up from a series of isopleths describing the dispersion at different intervals after the start of the release. A combination of isopleth envelopes becomes a risk estimate when it incorporates the frequencies for different source and dispersion conditions.

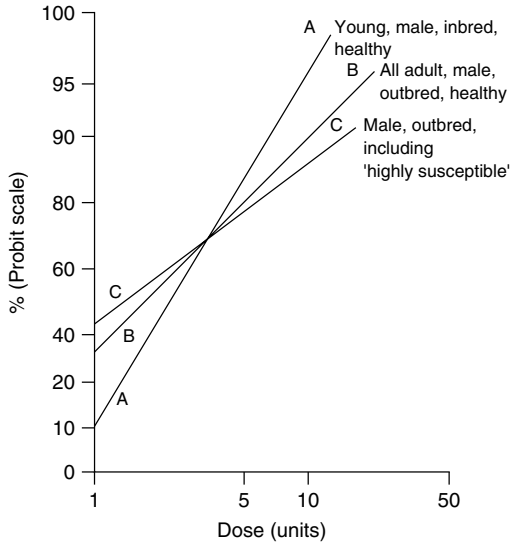

Figure 15 Diagram to illustrate hypothetical dose–response lines for different populations.

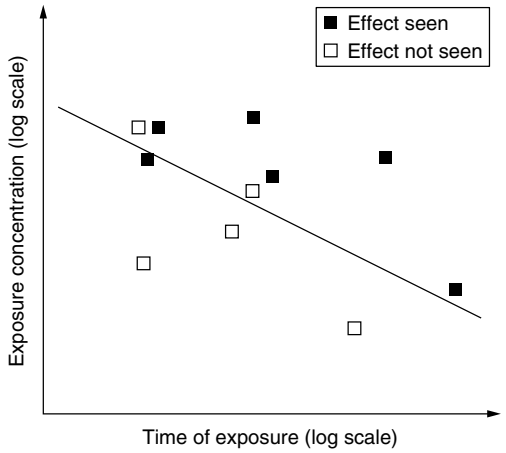

Figure 16 Idealised scatter diagram of the hypothetical relationship for an exposure-time–concentration relationship for an effect. By plotting on logarithmic axes the slope of the boundary line can be used to derive *n*. In the example the slope is $-n$, and $n = 2$.

The data are generally used predictively in order to describe the geographic areas where effects may occur or where the risk levels are associated with particular consequences. Best estimates are therefore usually considered preferable to more 'conservative' values based on the more severe confidence limit for the data. How closely defined the geographic areas affected by the risk analysis are when the toxicity data are limited in quality and quantity needs to be checked by uncertainty analysis in which the more extreme toxicity interpretations can be compared with the best estimate. Great accuracy is not required in view of the approximate nature of the overall evaluation.

4.2.3 Outcomes

The requirements from the overall assessment of the toxic risks are different for land-use planning and for emergency planning.

4.2.3.1 Land-Use Planning

The outcome from a quantitative risk analysis is a risk statement based on a series of isopleth envelopes. This statement can be judged against predetermined criteria to decide whether a risk is acceptable in predetermined 'objective' terms. The risk assessor can recommend that no objection be raised to the proposed development or that the development should not go ahead. Acceptance by the general population may depend on different, often subjective, criteria. There is a political process associated with land-use planning (in the UK, based on the local authority, with access to a planning enquiry on behalf of central government) in order to allow expression of the objective and subjective opinions on the development. A decision has to be taken by the local authority councillors or a government minister on behalf of society as a whole.

4.2.3.2 Emergency Planning

In emergency planning, the aims include delineation of appropriate zones over which to provide public information on the type of hazard and on the protective measures that can be taken to ameliorate the likely damage. They also include delineating ways of tackling the problems likely to emerge post-event, guiding general emergency planning, search and rescue, planning for the medical needs of casualties, including setting permissible exposures for the people involved, planning for the protection of food and drinking-water supplies and planning (when possible) for protection of the environment. Emergency planning and management is an important topic in its own right, and the ways in which emergencies are tackled can vary with the circumstances surrounding the site. For example, the management of an emergency on an oil rig will differ from that for a land-based chemical plant or nuclear reactor. The type of medical planning is also important and is discussed in greater detail elsewhere (Baxter *et al*., 1989a; OECD, 1994; Heptonstall and Gent, 2006).

5 CONCLUSION

Disasters can be caused when large amounts of toxicants interact with a (human) population and cause deleterious effects on that population. They can occur in many forms; some result from natural causes and many from human efforts, accidental or intentional. Describing and understanding past disasters can be the first stage to preventing or ameliorating the effects of potential future disasters.

In general, sites which contain toxicants causing them to be classified as major hazards are so classified because of the amount of toxicant present, and also because of the toxicity of the substance. Both the evidence concerning the toxicity of many of these toxicants and the risk management procedures for managing the hazards and risks they pose have been greatly enhanced in recent years. In addition, there has been recognition of the need to respond to the emergencies that can be caused by terrorist attacks using chemicals, and this has also driven approaches to major incidents involving chemicals. When the first edition of 'General and Applied Toxicology' was published it was easy to bewail the lack of knowledge and procedures. The situation, though not yet ideal, has improved very substantially.

Toxicology of Food Additives

Susan M. Barlow

CONTENTS

1 INTRODUCTION

Evaluation of food additives for safety in use has been continuing for over 50 years, both at the international level and by national regulatory and advisory bodies. In most countries, food additives cannot be marketed unless they have undergone a full safety evaluation. Nevertheless, consumers are often sceptical about the adequacy of toxicological testing of food additives. For example, in a survey conducted in 2005 of over 24 000 consumers from 25 European countries (Eurobarometer, 2006), when asked an open-ended question on what came into their mind when thinking about possible problems or risks associated with food, 7% of those surveyed cited food additives as a problem. It was the sixth most frequently cited issue, with food poisoning being the most frequently mentioned (by 16%) and chemicals, pesticides and toxic substances the second most frequently mentioned (by 14%). When specifically asked about additives like colours, preservatives or flavourings used in food and drinks, 22% said they were very worried, 39% fairly worried, 27% not very worried and 11% not worried at all, a level of concern that was very similar to that expressed by the survey respondents about genetically modified products in food and drinks.

This chapter will consider the history of food additives and discuss the approaches used to test for toxicity of food additives and the way in which such data are used to evaluate safety in use. Examples of how emerging science has affected the regulatory status of some additives that were previously considered to be safe will also be discussed.

2 ORIGIN OF FOOD ADDITIVES

Chemicals have been used to preserve food and to influence the colour and taste of food for centuries. Methods of preservation, such as smoking, salting, pickling, fumigation with sulphur dioxide, and the use of honey and sugar, have long been utilized to extend the wholesomeness of foods gathered in season or in times of plenty, for later use. The use of saltpetre (potassium or sodium nitrate) to preserve meat and fish can be traced back to the Middle Ages. Similarly there is a long history of use of salt (sodium chloride) and vinegar (acetic acid) to preserve fruits and vegetables. When the modern era of processed food manufacture emerged in the twentieth century, the numbers of food additives increased, reaching over 400 by the beginning of the twenty-first century.

Food additives include, not only chemicals that can be synthesized in the laboratory, but also substances that occur naturally, or are synthesized in the laboratory to be nature-identical. In the functional class of colours, for example, there are both synthetic and natural colours. Examples of synthetic colours include quinoline yellow, tartrazine and amaranth. A number of synthetic food colours are azo dyes and were originally (but no longer) derived from coal tar. The azo group (–N=N–) confers intense colouring properties, the hue varying depending on the other structural components of the molecule. Other food colours are derived from natural sources, such as plants, animals and micro-organisms, but are not necessarily from sources that are also used as human food. Examples of natural colours include, beet red from beetroot, lycopene from tomatoes or micro-organisms, anthocyanins from grape skins and other fruits and vegetables, cochineal from insects and chlorophyll from grass, lucerne or nettles.

Examples of other types of food additive that are derived from plant and animal sources are lecithins from soya beans or chicken eggs, which function as both antioxidants and emulsifiers, beeswax from honeycomb produced by bees, which acts as a glazing agent to impart surface shine and prevent food items sticking together, pectins derived from fruit, which act as gelling and thickening agents, and a number of gums and waxes, such as gum arabic, karaya gum and carnauba wax derived from plants, which have a variety of technological actions. Examples of additives derived solely from micro-organisms are gellan gum and xanthan gum. Additives such as ascorbic acid (vitamin C) and citric acid (from lemon juice) can be derived from natural sources, but nowadays may more often be made synthetically.

3 DEFINITIONS OF FOOD ADDITIVES

Various definitions of food additives can be found in advisory and legal texts. Working definitions differ somewhat by region or country, the principle differences being whether food additives are defined solely as those chemicals that are deliberately added to food to exert a technical function, whether certain categories of technical function are excluded from the definition (e.g. the exclusion of flavourings and enzymes under European Union (EU) legislation), and whether substances migrating from food contact materials are regarded as (indirect) food additives, as they under United States (US) legislation, but not under EU legislation.

The Food and Agricultural Organization of the United Nations (FAO) and the World Health Organization (WHO) have played a key role in evaluation of the safety of food additives. The first Joint FAO/WHO Conference on Food Additives proposed the following definition of food additives (FAO/WHO, 1956):

> *Non-nutritive substances added intentionally to food, generally in small quantities, to improve its appearance, flavour, texture, or storage properties.*

Later, this definition was expanded (CCFA, 1965):

> *The term 'food additive' means any substance, not being a food per se, the intended use of which results, or may reasonably be expected to result, directly or indirectly, in it or its by-products becoming a component of, or otherwise affecting the characteristics of a food. The term includes any substance intended for use in producing, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food; and includes any source of radiation intended for any such use.*

In the European Community legislation, a food additive is defined as (European Commission, 1989):

> *Any substance not normally consumed as a food in itself and not normally used as a characteristic ingredient of food whether or not it has nutritive value, the intentional addition of which to food for a technological purpose in the manufacture, processing, preparation, treatment, packaging, transport or storage of such food results, or may be reasonably expected to result, in it or its by-products becoming directly or indirectly a component of such foods.*

In the USA, the Code of Federal Regulations defines food additives as follows (FDA, 2008):

> *Food additives includes all substances not exempted by section 201(s) of the act, the intended use of which results or may reasonably be expected to result, directly or indirectly, either in their becoming a component of food or otherwise affecting the characteristics of food. A material used in the production of containers and packages is subject to the definition if it may reasonably be expected to become a component, or to affect the characteristics, directly or indirectly, of food packed in the container. 'Affecting the characteristics of food' does not include such physical effects, as protecting contents of packages, preserving shape, and preventing moisture loss. If there is no migration of a packaging component from the package to the food, it does not become a component of the food and thus is not a food additive. A substance that does not become a component of food, but that is used, for example, in*

preparing an ingredient of the food to give a different flavour, texture, or other characteristic in the food, may be a food additive.

4 RANGE AND IDENTIFICATION OF FOOD ADDITIVES

4.1 Functional Classes

Food additives perform a variety of technical functions in food (see **Table 1**). They include additives with important functions, such as preservatives, which maintain food in a safe condition free from microbial and fungal contamination. Antioxidants similarly serve an important function to retard or prevent oxidative deterioration of nutritional ingredients such as fats and vitamins. Other additives are essential for some of the technical processes that are used to make processed foods; without them, it would not be possible to manufacture certain foods. They include, for example, emulsifiers that allow the mixing of fat and water in foods such as margarine, sauces and dressings and stabilizers that maintain the stability of such mixtures. Some additives are used to improve the keeping quality of the foods, for example, humectants that maintain moisture levels and softness in foods such as dried fruits and cakes. Other additives are used to affect appearance, taste or texture, such as colours, glazing agents, flavour enhancers, sweeteners and thickeners.

4.2 International Numbering System

Food additives are identified by their technical function or class name, as shown in **Table 1**, and by their individual name and a code number. Code numbering is based on the internationally agreed system adopted by the Codex Alimentarius Commission (CAC) in 1989 and since updated (CAC, 2007). Its purpose is to ensure that there is no confusion between additives with similar names. It also allows additives to be listed on food packaging labels by numbers rather than names so that less space is occupied. In the EU, permitted additives are numbered according to the international coding system, prefixed by the letter 'E', signifying that it has been approved as safe for food use in Europe and is included in positive lists in the relevant legal directives. Each food additive has a separate specification which lays down purity criteria for the additive (FAO, 2006). Labels on processed foods may list additives either by their international code number (or in the EU by the E number) and/or by their common name.

5 EVALUATION OF THE SAFETY IN USE OF FOOD ADDITIVES

5.1 Food Additive Evaluation at the International Level

Evaluation of the safety in use of food additives was initiated at an international level following a joint FAO/WHO Conference on Food Additives, held in Switzerland in 1955 (FAO/WHO, 1956). The conference recommended that an expert committee be convened to address the technical and administrative aspects of chemical additives and their safety in food. In 1956, the first meeting of the Joint FAO/WHO Expert Committee on Food Additives (JECFA) was held and has been convened regularly ever since. The JECFA serves as an independent scientific committee which performs risk assessments and provides advice to FAO, WHO and the member countries of both organizations, as well as to the CAC. While the CAC does not have the same force of law as an EU directive or national legislation, Codex limits are used as a reference point for countries that are looking at revising or creating legislation on food. The requests for scientific advice are, for the main part, channelled through the subsidiary bodies of the CAC in their work to develop international food standards and guidelines under the Joint FAO/WHO Food Standards Programme. The advice to the CAC on food additives is normally provided by the Codex Committee on Food Additives (CCFA), formerly known, between 1971 and 2006, as the Codex Committee on Food Additives and Contaminants (CCFAC) (IPCS, 2008).

5.2 The Principle of the Acceptable Daily Intake

The term 'acceptable daily intake' (ADI) for a food additive was first used by the JECFA. The development of the principles behind the ADI concept began at the first meeting of the JECFA in 1957 (FAO/WHO, 1957) and the first ADIs for additives were elaborated at its sixth meeting (FAO/WHO, 1962). The concept is based on the premise that organisms have some capacity to cope with chemical challenge without the development of adverse effects and only when that threshold capacity is exceeded will toxic effects be manifested. The purpose of the ADI was to act as an acceptable reference value, derived from the available toxicity database, which would be substantially below any level that could be harmful to consumers. It acts as a guide to enable regulatory authorities, where necessary, to set maximum limits for the concentrations of additives in foods and to compare

Table 1 Functional categories of food additives according to the CAC (2007)

Functional classes (for labelling purposes)	Definition	Subclasses (technological functions)
1. Acid	Increases the acidity and/or imparts a sour taste to a food.	Acidifier
2. Acidity regulator	Alters or controls the acidity or alkalinity of a food.	Acid, alkali, base, buffer, buffering agent, pH adjusting agent
3. Anticaking agent	Reduces the tendency of particles of food to adhere to one another.	Anticaking agent, antistick agent, drying agent, dusting powder, release agent
4. Antifoaming agent	Prevents or reduces foaming.	Antifoaming agent
5. Antioxidant	Prolongs the shelf-life of foods by protecting against deterioration caused by oxidation, such as fat rancidity and colour changes.	Antioxidant, antioxidant synergist, sequestrant
6. Bulking agent	A substance, other than air or water, which contributes to the bulk of a food without contributing significantly to its available energy value.	Bulking agent, filler
7. Colour	Adds or restores colour in a food.	Colour
8. Colour retention agent	Stabilizes, retains or intensifies the colour of a food.	Colour fixative, colour stabilizer
9. Emulsifier	Forms or maintains a uniform mixture of two or more immiscible phases such surface as oil and water in a food.	Emulsifier, plasticizer, dispersing agent, surface active agent, surfactant, wetting agent
10. Emulsifying salt	Rearranges cheese proteins in the manufacture of processed cheese, in order to prevent fat separation.	Melding salt, sequestrant
11. Firming agent	Makes or keeps tissues of fruit or vegetables firm and crisp, or interacts with gelling agents to produce or strengthen a gel.	Firming agent
12. Flavour enhancer	Enhances the existing taste and/or odour of a food.	Flavour enhancer, flavour modifier, tenderizer
13. Flour treatment agent	A substance added to flour to improve its baking quality or colour.	Bleaching agent, dough improver, flour improver
14. Foaming agent	Makes it possible to form or maintain a uniform dispersion of a gaseous phase in a liquid or solid food.	Whipping agent, aerating agent
15. Gelling agent	Gives a food texture through formation of a gel.	Gelling agent
16. Glazing agent	A substance which, when applied to the external surface of a food, imparts a shiny appearance or provides a protective coating.	Coating, sealing agent, polish
17. Humectant	Prevents food from drying out by counteracting the effect of an wetting agent atmosphere having a low degree of humidity.	Moisture/water retention agent, wetting agent
18. Preservative	Prolongs the shelf-life of a food by protecting against deterioration caused by micro-organisms.	Antimicrobial preservative, antimycotic agent, bacteriophage control agent, chemosterilant/wine maturing agent, disinfection agent
19. Propellant	A gas, other than air, which expels a food from a container.	Propellant

Table 1 (*continued*)

Functional classes (for labelling purposes)	Definition	Subclasses (technological functions)
20. Raising agent	A substance or combination of substances which liberate gas and thereby increase the volume of a dough.	Leavening agent, raising agent
21. Stabilizer	Makes it possible to maintain a uniform dispersion of two or more immiscible substances in a food.	Binder, firming agent moisture/water retention agent, foam stabilizer
22. Sweetener	A nonsugar substance which imparts a sweet taste to a food.	Sweetener, artificial sweetener, nutritive sweetener
23. Thickener	Increases the viscosity of a food.	Thickening agent, texturizer, bodying agent

assessments of actual exposure to food additives to their respective ADIs.

The ADI is defined as:

> *An estimate of the amount of a food additive, expressed on a body weight basis, that can be ingested daily over a lifetime without appreciable health risk*
>
> (WHO, 1987).

For the purposes of the definition, a standard body weight of 60 kg is assumed. ADIs are expressed in milligrams per kilogram of body weight, as a range from zero to an upper limit, which the JECFA considered to be the zone of acceptability of the substance. Expressing the ADI as a range was designed to encourage the lowest levels of use of an additive that would be technologically feasible.

From its use of the words 'estimate' and 'appreciable risk', it can be seen that the JECFA considered that absolute safety could not be guaranteed. However, by building a suitable margin of safety into the numerical value of the ADI, the committee aimed 'to allow for any species difference in susceptibility, the numerical differences between the test animals and the human population exposed to the hazard, the greater variety of complicating disease processes in the human population, the difficulty of estimating the human intake, and the possibility of synergistic action among food additives' (FAO/WHO, 1958). The derivation of a numerical ADI from the available toxicological studies on a food additive is described later in Section 5.5.

5.3 Current Methods of Safety Testing

5.3.1 Rationale

The purpose of toxicological testing of substances proposed as food additives is to determine whether the substance, when used in the manner and in the quantities proposed, would pose any appreciable risk to the health of consumers. Such testing should provide, not only information relevant to the average consumer, but also relevant to those population groups whose pattern of food consumption, physiological or health status may make them vulnerable, for example, young age, pregnancy, diabetes and so on. Testing of proposed food additives is designed to establish their general toxicological profile, to identify any target organs for toxicity, and to provide a basis for establishing an ADI.

In general, the safety of food additives has been more intensively studied than that of major food components, or natural and environmental contaminants of food (excluding pesticides and veterinary drug residues). Such studies have shown that most food additives have low inherent toxicity since they are designed to perform a technical function in food rather than to have an effect on biological organisms. Toxicity studies are usually carried out in animals or in *in vitro* models, serving as surrogates to be used in risk assessment for humans. Human studies are rarely required by regulatory authorities for approval of food additives, but studies at the preapproval stage are sometimes carried out in human volunteers, for example, to establish gastrointestinal tolerance to bulk sweeteners or to assess the effects of artificial sweeteners on biochemical parameters in humans with diabetes. Similarly, experimental and epidemiological studies may be conducted in humans after a food additive has been marketed.

5.3.2 Range of Recommended Toxicity Tests

Recommendations have been published for the types of toxicity studies that are usually necessary to establish the safety in use of a food additive (see, for example, WHO, 1987; FDA, 2000; SCF, 2001; Barlow *et al*., 2002). A comprehensive range of toxicity studies is usually carried out, including short-term/subchronic repeated-dose tests,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat138
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

long-term chronic toxicity/carcinogenicity tests, genotoxicity tests, reproduction and developmental toxicity tests. In addition to toxicity studies, toxicokinetic (TK) studies of absorption, distribution, metabolism and excretion (ADME) of the additive are also often conducted.

In some cases, a lesser range of toxicity studies may be sufficient to establish safety. Considerations for fewer toxicity studies for a proposed food additive might include one or several of the following:

- If it will be consumed in small amounts
- If it is a substance that is a normal component of the diet
- If it has a structure considered to be of low toxicological potential
- If there is likely to be negligible systemic absorption because of high molecular weight and resistance to breakdown in the gut
- If it is readily metabolized into known innocuous substances or into substances known to be endogenously present in the body.

The US Food and Drug Administration (FDA) has for many years recommended a tiered approach to testing, based on the assumption that the degree of effort expended to reduce uncertainty about the safety of an additive used in food should relate to the likelihood that the additive could pose a risk to human health. This likelihood is based two considerations, the chemical structure of the additive and the predicted daily dietary exposure to the additive. Under this tiered approach, an additive is assigned to one of three levels of concern, low (I), intermediate (II) or high (III), based on information on the toxicological potential of the additive predicted from its chemical structure and an estimate of cumulative human exposure (FDA, 1993) (see **Figure 1**). The minimum set of recommended toxicity tests is related to the Concern Level (I, II or III), to which the additive is assigned (FDA, 2006), as shown in **Table 2**.

In the EU, no fixed programme of testing is laid down, but a general framework describing core tests and other tests is recommended (SCF, 2001). Food additive petitioners are asked to submit the range of studies recommended as a core set and to consider whether any other types of study might also be appropriate. If a study of a type that might be expected is not submitted, then the scientific reasons for that should be provided. The reasons for carrying out any unusual studies should also be explained. The core set of toxicity tests is shown in **Table 3**.

Guidelines and protocols for the conduct of toxicity tests for regulatory submissions have been published by various international and national bodies. The majority of national regulatory systems for food additive approval will accept studies conducted according to the internationally accepted Organization for Economic Cooperation and Development (OECD) guidelines for the testing of chemical health effects (OECD, 2008). The FDA has its own study guidelines in the FDA Redbook (FDA, 2000). OECD and FDA guidelines differ on some points of detail (e.g. in the recommended numbers of animals/sex/dose to be treated), but generally follow closely similar lines on study designs, observations to be made and reporting of results. Studies conducted for regulatory submissions should normally be conducted according to the principles of Good Laboratory Practice (GLP) (OECD, 1998). However, for many food additives already on the market, some for as long as 50 years, toxicity testing may have been conducted at a time when GLP was not a standard requirement.

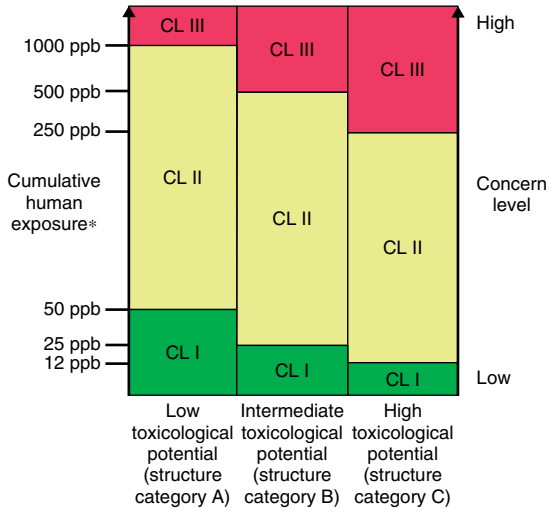

Figure 1 The additive is placed in one of three broad structural categories by comparison with the structures of known toxic substances: Category A is for low toxicological potential, Category B is for intermediate toxicological potential and Category C for high toxicological potential. Within each structure category (A, B and C), estimated human exposure will determine the initial Concern Level to which the additive is assigned. *Cumulative human exposure is expressed as parts per billion (ppb, equivalent to microgram per kg diet) of daily dietary consumption of additives. For conversion of ppb to microgram per kilogram body weight per day, divide by 20, assuming a daily diet of 3 kg. (Reproduced from the FDA, 2006.)

5.3.3 Routes of Administration of Test Substances

The most appropriate route of administration of test substances in laboratory animal studies designed to assess the safety of food additives is the oral route. Administration in the diet or the drinking water most closely simulates the usual conditions of human ingestion of additives in food and beverages. Additives with strong tastes, such as intense sweeteners, may give rise to palatability problems which can limit the maximum amount that may be

Table 3 Core set of toxicity tests recommended by the EU (SCF, 2001)

Toxicity test	Type/species
Metabolism/toxicokinetics studies	Single and repeat-dose, usually in rat
Subchronic toxicity studies	90 day studies in a rodent and a nonrodent
Genotoxicity studies	*In vitro* studies. Positive results *in vitro* should be followed up with *in vivo* studies
Chronic toxicity and carcinogenicity studies	Usually rat (24 months) and mouse (18 or 24 months)
Reproductive toxicity study	Usually rat, two-generation, one litter per generation
Developmental toxicity studies	Rodent and nonrodent, usually rat and rabbit

administered via the diet or drinking water. The solubility of the substance may also limit the amounts that can be administered via drinking water. In the case of reduced palatability of the diet, pair-fed controls can be incorporated into study designs to enable any effects of reduced food intake to be separated from those of any induced toxicity.

Administration by oral gavage is also used to overcome palatability problems and can enable higher amounts of test substance to be administered (e.g. it is often favoured for developmental toxicity studies). Oral gavage may also be an appropriate route for administration of additives that may be consumed in a short timeframe, such as an additive for use in soft drinks, or for additives that are consumed in a single daily ingestion, such as an additive proposed for use in food supplements taken in the form of tablets or capsules. When substances are administered by oral gavage, as a so-called 'bolus' dose, peak concentrations reached in blood may considerably exceed the concentrations that would be reached if the substance were normally ingested via the diet. At high doses, gavage administration may also overwhelm the metabolic capacity to detoxify a substance. These aspects need to be taken into consideration in the interpretation of the likely risks for human health of any observed toxicity.

For a few food additives, such as propellant gases, toxicity studies may only be available using the inhalational route. These studies can be used in risk assessment, provided any necessary adjustments are made for route-to-route extrapolation (see, for example, IGHRC, 2006).

In subchronic and chronic toxicity studies, the test substance is usually given via the diet for practical reasons. The majority of food additives are substances with relatively low molecular weights and thus suitable for testing using protocols such as those developed by OECD for low-molecular-weight substances. They are also usually added to foods in relatively low amounts. However, some types of additive, such as modified starches or celluloses, are high-molecular-weight substances and may be added to foods in higher amounts, for example, as bulking agents. In tests on laboratory animals, it may not be possible to administer these via the diet in high amounts on a milligram per kilogram body-weight basis, because their inclusion may

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat138
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

impact on the nutritional value of the diet. It is generally recommended that the concentration of a test substance that is not a nutrient should not exceed 5% of the diet. This may mean that the highest dose tested may not be much above the likely human intake, expressed on a body-weight basis.

Monitoring of food (and/or drinking water) consumption at regular intervals is an important parameter in all repeat-dose studies on food additives, both as an indicator of palatability or toxicity problems and in order to generate an accurate measure of the amount of the additive that has been ingested on a daily basis.

5.3.4 ADME Studies

ADME studies can give useful information about a proposed food additive, including whether it is broken down in the gastrointestinal tract, the proportion of the administered parent substance (and/or of its gut metabolites) that is absorbed, its metabolic fate following systemic absorption (e.g. whether it may be metabolized by the liver to innocuous products), and how quickly it is cleared from the body by excretion in urine and faeces, and/or expiration via the lungs. ADME studies can thus help, not only in the selection of appropriate doses for subsequent toxicity studies, but also for the interpretation of results of the toxicity studies and for human-risk assessment.

Besides providing information on gastrointestinal absorption and overall elimination rates, they can also reveal any changes in the kinetic behaviour of the substance with repeated administration (e.g. more rapid elimination due to enzyme induction, or increasing body burdens due to accumulation in tissues such as fat). If comparative ADME studies are available, particularly from the laboratory testing species and from humans, they can help in the evaluation of any species differences. They may also provide information on other aspects relevant to toxicity, such as placental transfer, induction or inhibition of metabolizing enzyme systems and reversible or irreversible binding to tissue sites and carrier proteins. *In vitro* studies, employing enzymes, sub-cellular organelles, cell cultures and perfused organs, can also contribute useful information in the investigation of metabolic pathways, mechanisms of toxicity and effects on enzymes.

5.3.5 Acute Toxicity Tests

Acute toxicity tests, utilizing single-dose administration and generally followed by up to 14 days of observation, are considered not essential for the evaluation of the safety in use of food additives. The reason for this is because such tests generally use high doses that are irrelevant to consumer exposure to food additives, which is usually characterized by much lower exposures and ingestion over long periods of time. However, acute studies, if available for other purposes, can aid in the design of subsequent repeated-dose toxicity studies, by providing information on target organs for toxicity that should be particularly scrutinized and information on dose selection for subsequent studies.

The FDA previously only recommended acute oral toxicity studies if they were considered necessary as preliminary tests to further studies (FDA, 1993; 2000). Since 2006, the FDA no longer recommends acute oral toxicity studies for food additives (FDA, 2006). The guidance on food additive submissions for the EU (SCF, 2001) states that acute toxicity studies are not required for evaluation of the safety of food additives, but notes that they may have been conducted for other purposes, such as worker safety, and if such studies are available, they should be submitted, as they may provide useful background information.

5.3.6 Short-Term Toxicity Tests

Short-term toxicity tests are repeat-dose studies generally not exceeding two to four weeks in duration. They are recommended by the FDA for all additives of low concern (FDA, 2006). Such tests, together with genotoxicity tests, may be all that is needed to establish safety in use at Concern Level I (see **Table 2**). At Concern Levels II and III, the FDA only recommends short-term tests if they are needed as a preliminary to further studies.

The EU guidelines do not recommend the use of any short-term, repeat-dose toxicity tests, advising that they are not normally sufficient, by themselves, for evaluation of potential subchronic toxicity. The EU does, however, request that any short-term range-finding studies that have been conducted should be submitted.

5.3.7 Subchronic Toxicity Tests

Subchronic toxicity tests are repeat-dose tests in which the period of administration is around 10% of the animal's normal lifespan. The major objective of subchronic toxicity studies is to determine the general toxicological profile of the test substance following repeated administration. Such studies provide information on the target organs/tissues for toxicity, on the nature and severity of any effects, and on dose–response relationships. They normally include investigations of haematology and clinical chemistry of blood and urine, as well as histopathology of a comprehensive set of tissues. Such studies should allow determination, not only of any adverse effects, but also of the dose at which adverse effects are no longer observed, that is, the no-observed-adverse-effect level (NOAEL). If subchronic studies are conducted according to current protocols (e.g. OECD), they will include parameters that provide an apical screen for neurotoxicity, immunotoxicity and some aspects of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat138
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

reproductive toxicity. Thus they may provide triggers for additional studies on these effects. Subchronic studies may also be helpful for estimating appropriate dose levels for the conduct of chronic toxicity studies.

The FDA recommends subchronic tests in a rodent and a nonrodent for all additives assigned to Concern Level II. For additives assigned to Concern Level III, they are recommended if they are needed as a preliminary to further studies of longer duration (FDA, 2006). EU guidelines recommend that any new additive should normally be tested in subchronic oral toxicity studies in two laboratory species, usually a rodent and a nonrodent, such as a rat and a dog, for a period of at least 90 days, but such studies may be waived if there are longer duration studies available on the same species, with full recording of haematological, clinical chemical and urinalysis parameters, alongside the usual histopathological examinations.

5.3.8 One-Year Toxicity Studies

A one-year toxicity study in a non-rodent and a study in a rodent of a minimum of 12 months are recommended by the FDA for any additive assigned to Concern Level III (FDA, 2006). Such studies are not recommended in EU guidelines.

5.3.9 Chronic Toxicity and Carcinogenicity Studies

Carcinogenicity studies in two species (rat and mouse) are recommended by the FDA for any additive assigned to Concern Level III (FDA, 2006). They further recommend that an *in utero* exposure phase be included in the rat study. The FDA may accept data from a study using a combined chronic toxicity/carcinogenicity protocol, but point out that, because of the *in utero* dosing phase, there are problems in administering appropriate dose levels when the two types of study are combined. Studies in transgenic mice may be accepted as supplemental data, but are not considered by the FDA to be substitutes for two-year carcinogenicity bioassays.

For the EU, chronic toxicity and carcinogenicity studies (using separate or combined protocols) in two species are recommended, with no specific recommendation to include an *in utero* dosing phase. The recommended species (and durations) are rat (24 months) and mouse (18 or 24 months).

5.3.10 Genotoxicity

Genotoxicity studies are recommended by the FDA for all substances proposed as food additives, irrespective of the Concern Level (I, II or III), unless the cumulative dietary exposure is below $1.5\,\mu g\,day^{-1}$, corresponding to a concentration of 0.5 ppb in the daily diet. The recommended battery of tests is: (i) a test for gene mutations in bacteria, (ii) either an *in vitro* test for cytogenetic damage in mammalian cells, or an *in vitro* mouse lymphoma *tk* gene mutation assay and (iii) and *in vivo* test for chromosome damage in mammalian haematopoietic cells. If exposure is below a concentration of 50 ppb in the daily diet, only (i) and (ii) are recommended.

For the EU, any new additive should normally be tested for genotoxicity in order to assess its mutagenic and carcinogenic potential. The recommended battery of tests is: (i) a test for gene mutations in bacteria, (ii) an *in vitro* test for gene mutations in mammalian cells (preferably the mouse lymphoma *tk* assay) and (iii) an *in vitro* test for chromosomal aberrations in mammalian cells. Positive results in any of these *in vitro* tests will normally require further testing for genotoxicity *in vivo*.

5.3.11 Reproductive and Developmental Toxicity Studies

The FDA recommends reproduction and developmental toxicity studies for all Concern Level II and III substances. The recommended reproduction study is a two-generation study, one litter per generation, in which animals in the second (F2) generation are sacrificed at weaning. The study guideline contains optional procedures for including additional litters, additional generations and a test for teratology and developmental toxicity. Developmental toxicity studies are also required on two species, the rat and the rabbit, unless there is information to indicate a different species may be more relevant. They can be conducted either as stand-alone studies or as part of the rat two-generation study.

For the EU, a new additive should normally be tested in reproduction and developmental toxicity studies. A multigeneration reproduction study should be conducted in one laboratory species, usually rat, and comprise at least two generations and one litter per generation. It should include assessment of end points relevant to endocrine disrupter potential. Developmental toxicity studies should be conducted in two laboratory species, usually a rodent and a nonrodent, such as rat or mouse and rabbit. Administration of the test substance should cover, not only the period of embryogenesis, but continue to the end of gestation in order to ensure detection of, for example, endocrine disrupter potential. In order to ensure that a new additive does not affect postnatal development and function, including neurological function and behaviour, the physical, functional and behavioural development of animals exposed from at least the beginning of embryogenesis through to weaning should be studied. This can be done as a separate study or as part of a multigeneration and/or developmental toxicity study.

5.4 Interpretation of ADME and Toxicity Tests

Extensive guidance on the interpretation of toxicity tests on food additives in order to characterize any risk have been published elsewhere (WHO, 1987; Moch *et al*., 1997; Renwick *et al*., 2003). Some key considerations are outlined below.

If ADME studies indicate that a proposed food additive shows evidence of accumulation in the body (for example if it has a long half-life) then it may be considered unacceptable as a food additive or it may be advised that its use should be severely restricted. One such example is the food colour canthaxanthin, which has been shown to accumulate in the eye in humans (SCF, 1989; WHO, 1996). This discovery came, not from its use as a food additive, but from the marketing of canthaxanthin as an orally ingested cosmetic for 'bronzing' the skin. Consequently, it has a very restricted use as a food additive in the EU (permitted only in one type of sausage), but is also permitted as a feed additive for chickens to colour egg yolks and for farmed fish such as salmon and trout.

Whilst the toxicity of food additives is generally low, the effects most commonly observed are effects on growth and body weight, which may often provide the earliest indication of toxicity, or effects on the liver and kidney which, being the major organs of metabolism and elimination, are generally the tissues exposed to the highest concentrations of an additive. Deciding which treatment-related effects are adverse, which are probably not, or which effects are not relevant for human-risk assessment, is a matter for expert judgement and is done on a case-by-case basis, taking into account all the available information. For example, certain hydrocarbon-based compounds induce kidney damage, eventually resulting in tumours in male rats via the accumulation of α-2-microglobulin protein droplets, an effect which is unique to the male rat kidney. Thus if kidney damage can be shown to be due to this mechanism it is not regarded as relevant for human risk assessment (IARC, 1998). However, in the absence of clear knowledge or information to demonstrate that an effect is not adverse or is not relevant for humans, the default assumption for food additives is that it should be taken into account in the risk assessment.

In tests on food additives, the following effects are not uncommon and are usually regarded as toxicologically insignificant, minor or non-dose-related: changes in biochemical parameters without any other indications of toxicity and without evidence of more severe damage to the indicated organ at higher doses; changes in the gut due to administration of high levels of nondigestible substances; adaptive changes, such as liver hypertrophy with enzyme induction due to metabolic overload; staining of tissues with food colours. Occasionally, however, such effects may have human-health implications, as is the case with bulk sweeteners which are not absorbed and can have laxative effects on the gut, sometimes experienced by high consumers.

There are two particular types of toxicological effect which are of special significance in safety evaluation of food additives. These are carcinogenicity and mutagenicity. If a substance is shown to possess genotoxic potential which is expressed *in vivo*, then it will not be approved as a food additive since such effects may be without a threshold and some degree of risk could occur at any level of exposure. If a substance is shown to be a carcinogen in a long-term test then it may not be approved unless it can be clearly demonstrated that the induction of tumours is by a nongenotoxic mechanism, with a threshold at a dose well above the highest likely level of human exposure.

An example of an approved food additive which has a carcinogenic action by a thresholded mechanism is the artificial sweetener saccharin. It causes tumours in the male rat bladder, due to the particular conditions in the bladder of the male rats of high concentrations of sodium ions and elevated urinary pH, which encourages tissue irritation and crystal formation (SCF, 1997). The relevance of such tumours for humans has been questioned, and indeed the JECFA did not base its ADI on that effect (WHO, 1993), although the European Commission's Scientific Committee for Food (SCF) did take it into account (SCF, 1997). Another example is the antioxidant, butylated hydroxyanisole (BHA), which causes forestomach tumours in rodents triggered by early onset hyperplasia and hyperkeratosis. In rodents, food is held for some time in the forestomach, but in species such as humans and other primates there is no forestomach and food passes relatively quickly through the stomach. There is also an indication that at very high doses it causes slight hyperplasia in the oesophagus of animals without a forestomach, such as monkey and pig (Barlow, 1990). BHA is not genotoxic and, although the relevance of forestomach tumours for humans is questionable, an oral dose has been established in rodents at which there is no increase in cell proliferation, as measured by cellular uptake of radiolabelled thymidine. The dose at which no effect was seen on cell proliferation was used to establish the ADI for BHA (WHO, 1989).

Other toxic effects, including teratogenicity, also have demonstrable thresholds, that is, for a given substance there will always be a dose below which no effects occur. Thus, in the absence of genotoxic effects, the various toxicological studies may be assessed to determine an overall no-effect level. The no-effect level is usually termed the 'no-observed-adverse-effect level'. Sometimes the term 'no-observed-effect level' (NOEL) is used to denote that there is an effect observed at a higher dose, but it is not considered adverse, such as induction of a liver enzyme that is indicative of an adaptive effect.

5.5 Derivation of the ADI

Any adverse effects observed in the range of toxicity tests conducted are identified, together with the doses at which they occur (dose–response assessment). All effects that are regarded as adverse and potentially relevant to humans should be considered. When results from two or more laboratory animal species are available, the ADI is based on the most sensitive species, that is, the species that displayed a toxic effect at the lowest dose, unless pharmacokinetic, metabolic or mechanistic data are available to establish that the most sensitive species is not appropriate for human risk assessment. The toxic effect seen to occur at the lowest dose across the range of studies is generally taken to be the critical toxicological effect. Provided the dose at which it occurs does not coincide with the lowest dose utilized in the particular toxicity test under consideration, an overall NOAEL for the additive can be identified.

Long-term toxicity tests, in which the additive is administered for most of the lifespan of the animal, or multigeneration studies generally (though not always) yield the most sensitive effect at the lowest dose in all the tests conducted. Thus the majority of ADIs for food additives are set on the basis of these repeat-dose studies. This is due to the long periods of administration, which often drive the effect and no-effect levels downwards compared with shorter durations of exposure, and the fact that such studies cover a number of critical periods in the lifetime (e.g. pregnancy, neonatal and juvenile periods, ageing).

If there is a comprehensive database, the overall NOAEL is used to derive an ADI. The NOAEL, in milligram per kilogram body weight per day, is divided by a suitable safety factor (see below) to calculate an upper limit (X) for the ADI, which is then expressed as a range ($0–X$ mg (kg body weight)$^{-1}$). Risk managers can then compare estimates of intake of the additive with the ADI to ensure intake is below the ADI for all exposed population groups.

It should be noted that whilst the ADI is generally considered to be applicable to children, it is not applicable to infants under the age of 12 weeks (Walker, 1998). This is because the tissues and organs of young infants may be more biologically sensitive to a chemical on a body weight basis than older children or adults, and because of physiological and metabolic immaturity (Scheuplein *et al*., 2002). Moreover, the usual range of toxicity studies do not adequately mimic the special situation of a baby receiving infant formula (in which some additives are present) as its only source of food in the first weeks of life.

To determine the ADI, a default safety factor (sometimes termed 'uncertainty factor') of 100 is usually applied to the overall NOAEL to provide a conservative margin of safety that takes account of the inherent uncertainties in extrapolating from animal toxicity data to potential effects in humans and variation within the human species. The use of a default factor of 100 is arbitrary, but was first proposed in 1954 by two officials working in the FDA (Lehman and Fitzhugh, 1954). The same default factor of 100 (10 for interspecies differences multiplied by 10 for intraspecies variation) was adopted by the JECFA soon after, which considered it would provide an adequate margin of safety for the consumer, assuming that humans might be up to 10 times more sensitive than the most sensitive laboratory test species and that there might be an additional 10-fold difference in sensitivity range among the human population (WHO, 1987).

Subsequently, studies have been done to investigate whether the use of these arbitrary 10-fold safety factors can be underpinned by supporting scientific data (Renwick and Lazarus, 1998; Renwick, 1998; Walton *et al*., 2001a; 2001b; Dorne *et al*., 2001a; 2001b; 2004; 2005; Dourson *et al*., 2002; Dorne and Renwick, 2005; Dorne, 2007). Renwick (1993) first proposed the use of data-derived safety factors in a scheme, based on comparative information from studies on animals and humans, which allows subdivision of each of the 10-fold components of the 100-fold default safety or uncertainty factor into separate factors for toxicokinetics (TK—fate of the chemical in the body) and toxicodynamics (TD—actions of the chemical in the body). The usual 10-fold factor for interspecies differences is subdivided into a factor of 2.5 for TD and a factor of 4.0 for TK ($2.4 \times 4.0 = 10$), reflecting the fact that there is a greater potential for TK differences than for TD differences between humans and test species. For intraspecies differences, the potential for variability between humans for TK and TD is considered to be similar, and so values of 3.2 are used for both ($3.2 \times 3.2 = 10$). Where appropriate TK or TD data are available for a particular chemical from humans and/or test species, the subdivisions of the default uncertainty values can be replaced with 'correction' factors based on actual data, and these are termed chemical-specific adjustment factors (CSAFs) (WHO, 1994; 2001).

Similarly, if, for example, the critical study for an additive is one involving human subjects, then a reduced default safety factor of perhaps only 10 may be applied, since interspecies differences are no longer relevant. Such is the case, for example, with the food colour erythrosine. This affects the human and rat thyroid, ultimately causing tumours in the rat due to excessive production of thyroid stimulating hormone (TSH). Its mechanism of action is well understood and an NOAEL for increases in thyroid hormone levels in humans has been established and used, in conjunction with a 10-fold rather than a 100-fold safety factor to set the ADI (SCF, 1989).

If the toxicology database is considered complete, then a full ADI will be assigned. Occasionally 'temporary' ADIs may be set when it is reasonable to conclude from the available data that it is safe to consume the

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

additive for the short period of time required to generate some further data which are necessary to complete the safety evaluation. A previously assigned ADI may also be changed to a temporary ADI when new data emerge that appear to call into question the safety of the additive or the assigned value of the ADI. When setting a temporary ADI, a higher safety factor is often used. If new data are provided that show the additive is no longer acceptable for use in food, then the ADI is withdrawn (see Section 5.6 for some examples).

A numerical ADI can be established solely on the basis of toxicological information, without the need for data on intended or actual use(s) or for estimates of dietary exposure. However, in setting ADIs, it may be necessary to know whether particular subpopulations are exposed, since the ADI should be applicable to the whole population. Therefore, general information about exposure patterns should be known at the time of the safety assessment. For example, if a food additive is to be used in foods for infants and young children, then estimates of their daily exposure are essential as they may well be higher than that of adults on a body-weight basis, not because of a higher absolute intake in milligrams per day, but because of their much lower body weights (Ostergaard and Knudsen, 1999).

Occasionally, the toxicity database may not indicate a clear NOAEL in cases where an effect is still seen at the lowest dose tested. If this is the critical effect for the whole database, then a decision has to be made as to whether a change observed can be considered as minor (low incidence, low severity). If so, the dose at which it occurs is called a lowest-observed-adverse-effect level (LOAEL). An LOAEL may be used to derive an ADI, usually incorporating an additional safety factor of 2–3, to allow for the fact that it is not a NOAEL.

If the database cannot be used to derive a numerical ADI, for example, if there is no toxicity observed, even at the highest doses tested, or it is not considered necessary to conduct a full range of toxicity tests (see Section (5.3.2) for circumstances where this may be the case), then the ADI may be expressed as an ADI 'not specified', an approach that has been used by the JECFA. The JECFA defines this term to mean that, on the basis of available data (chemical, biochemical, toxicological and other), the total daily intake of the substance, arising from its use at the levels necessary to achieve the desired effect and from its acceptable background in food, does not, in the opinion of the Committee, represent a hazard to health (WHO, 1987). Alternatively, if a numerical ADI cannot be established, but use of the proposed additive is considered acceptable, then the overall NOAEL for the additive can be compared with the estimates of intake to see whether there is a sufficient margin of safety. This latter approach has been used in the past by the European Commission's Scientific Committee on Food (SCF) and is used now by the European Food Safety Authority (EFSA), when a numerical ADI cannot be derived.

5.6 Removal of Additives with Safety Problems from Approved Lists

Occasionally, new data emerge some time after the approval of a food additive that cast doubt on its safety. When the occurrence of a newly discovered adverse effect is relatively clear, there are two options, either to lower the ADI or, in cases where the continued use of the additive is considered unacceptable, to withdraw the ADI. If lists of approved food additives are consulted according to the international numbering system (CAC, 1989) or European E numbers (FSA, 2007), it is apparent that some numbers in the sequential numbering system are missing. This is because the additives have either been withdrawn by industry or have been removed from the approved list by the regulatory authorities because the ADI has been withdrawn or, in cases where an ADI has not been set, they are considered unacceptable for use.

Some colours, such as butter yellow (toxic to the liver) and Sudan 1 (toxic and later found to be carcinogenic) were banned for food use almost 100 years ago. A number of other colours were banned for food use in the 1950–1970s when they were found to be toxic. Examples include certain colours such as (E) 103, 105 107 and 111 (Alkanet, Fast Yellow AB, Yellow 2G and Orange GGN, respectively), that were used in food many years ago, but have now been withdrawn or banned for such use. In some European countries that are or were outside the EU, many of the azo-containing colours are or were banned.

In the EU, the food colour, Red 2G has been removed from the approved list (European Commission, 2007), following withdrawal of its ADI by the European Food Safety Authority (EFSA, 2007). The information that prompted the withdrawal of the ADI was that Red 2G had been shown to be metabolized into aniline, which is regarded as an animal carcinogen and for which a genotoxic mechanism of action cannot be excluded. EFSA therefore concluded that Red 2G should be regarded as being of safety concern and withdrew the previously established ADI of 0–0.1 mg (kg body weight)$^{-1}$. Up to then, its uses in the EU had been restricted to breakfast sausages and hamburger meat with minimum cereal contents of 6 and 4%, respectively (European Commission, 2007). At the time it was first approved for use in the EU (SCF, 1975), it was not known that it could be extensively metabolized to aniline and it is only relatively recently that a consensus view of the carcinogenicity of aniline has been reached in the EU (EU, 2004).

Another example concerns one of the parabens, propyl paraben. Parabens are antimicrobial preservatives allowed for use in foods, drugs, cosmetics and toiletries. The European Commission's former SCF evaluated the parabens in 1994 and allocated a temporary group

ADI of 0–10 mg (kg body weight)$^{-1}$, for the sum of methyl, ethyl and propyl *p*-hydroxybenzoic acid esters and their sodium salts (SCF, 1996). Following a request from the European Commission, the EFSA Scientific Panel dealing with food additives re-evaluated the toxicology of these substances, including findings from recent studies and the safety of their usage in foods. These findings included the demonstration that several of the parabens had oestrogenic activity *in vitro* and that propyl paraben affected the male reproductive system *in vivo*. The Panel concluded that a group ADI of 0–10 mg (kg body weight)$^{-1}$ could be established for the methyl and ethyl parabens and their sodium salts. However, the Panel considered that propyl paraben should not be included in this group ADI because propyl paraben, unlike the methyl and ethyl forms, showed adverse effects on sperm production at a relatively low dose in juvenile male rats. The Panel was unable to recommend an ADI for propyl paraben because of the lack of a clear NOAEL for this effect (EFSA, 2004).

5.7 Food Colours and Hyperactivity

The question of whether consumption of food additives may be associated with behavioural effects, especially in children, has been a subject of research and debate for many years. Feingold (1975) was the first to suggest that exposure to synthetic food colours and other food additives may be linked to hyperactivity in children. Since then there have been more than 20 human studies that have addressed the 'Feingold hypothesis'. The majority of these have been elimination trials conducted in children considered to be hyperactive or having a diagnosis of attention deficit hyperactivity disorder (ADHD). ADHD is characterized by increased activity, impulsive and inattentive behaviour and it can impact adversely on social interaction and learning. Two more recent studies, both conducted by a research group at the University of Southampton, UK, have differed from previous studies in that the subjects were children selected from the general population and excluded children on medication for ADHD (Bateman *et al*., 2004; McCann *et al*., 2007).

Many of the earlier studies have been reviewed in two meta-analyses (Kavale and Forness, 1983; Schab and Trinh, 2004) and discussed in an opinion of the European Food Safety Authority (EFSA, 2008). Early studies investigated the effects on behaviour of administering a 'Feingold diet' (a diet without synthetic colours and flavours) under double-blind conditions to relatively small groups of hyperactive children. In some studies children identified as possible responders were challenged with food additives in double-blind studies. Several authors reported improved behavioural characteristics (or deterioration on challenge with additives) in some, but not all, children in their study population, while other studies did not provide support for the Feingold hypothesis. The study subjects were generally hyperactive children or children considered to be responsive to food additives, often only small numbers of subjects were studied and parent or teacher ratings of behaviour were used. Mostly, the studies were not designed to address dose–response dependency and did not link the adverse behavioural effect to a specific food additive. The most recent meta-analysis of 15 double-blind, placebo-controlled trials that met the authors' inclusion criteria concluded that, despite the limitations of many of the studies, the results strongly suggested an association between ingestion of artificial food colours and hyperactivity (Schab and Trinh, 2004).

The two more recent UK studies used much larger numbers of subjects than earlier studies (nearly 300 in each study) and administered mixtures of food colours (carmoisine, ponceau 4 R, sunset yellow, tartrazine) and a preservative (sodium benzoate) in drinks in a double-blind, placebo-controlled, crossover design. In the first study on three-year-old children, the authors concluded that there was a general adverse effect of the mixture of food colours and preservative on the behaviour of the children, which was detectable by the parents, but not by clinic assessment (Bateman *et al*., 2004). A detailed review of the study results by a UK government advisory committee, the Committee on Toxicity (COT), noted that the reported effects were small and there were limitations in the study design, concluding that it was not possible to reach firm conclusions about the clinical significance of the observed effects (COT, 2002a). In the subsequent UK study, in which sodium benzoate and the same four colours plus allura red AC were given as two different mixtures to both three- and eight- to nine-year-old children, the authors concluded that artificial colours plus the preservative resulted in increased hyperactivity in both age groups (McCann *et al*., 2007). Behaviour was scored separately by parents, teachers and independent classroom observers. This study has also been reviewed in detail by the COT, which concluded that the study provided supporting evidence suggesting that certain mixtures of artificial food colours, together with the preservative sodium benzoate are associated with an increase in hyperactivity in children from the general population, but noted that the increases in mean levels of hyperactivity observed were small relative to normal interindividual variation, and that changes in behaviour were not evident in all children in any one group and were not consistent across age groups or across the different mixtures used in the study (COT, 2007). The EFSA similarly concluded that this second study provided limited evidence that the two different mixtures of synthetic colours and sodium benzoate tested had a small and statistically significant effect on activity and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat138
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

attention in children selected from the general population, although the effects were not statistically significant for the two mixtures in both age groups and that the clinical significance of the observed effects remains unclear (EFSA, 2008). EFSA also noted that it was largely the parental scores that accounted for the statistical significance of the findings and concluded that, in the context of the overall weight of evidence and in view of the considerable uncertainties in the study, the findings could not be used as a basis for altering the ADI of the tested food colours or sodium benzoate. Subsequently, EU legislators, following the recommendations of the European Parliament, have decided to include warnings in the labelling of products containing any of the five colours tested to the effect that the colours may have an adverse effect on activity and attention in children.

It is interesting to note that none of the studies conducted since the Feingold hypothesis was first proposed have yet provided answers to key questions, some of which were first raised in the 1970s (Lipton *et al*., 1979), concerning the duration and clinical significance of the observed effects, whether the effects can be confirmed by objective laboratory tests, whether specific subpopulations may be affected and whether specific colours are involved. Whatever the role of colours, specialists in the field of ADHD have pointed out that it is a complex, multifactorial condition and that other important risk factors for development of ADHD include genetic factors, maternal smoking during pregnancy, premature birth and institutionalized upbringing (COT, 2007).

5.8 Safety of Additives in Combination

Concern is sometimes expressed about the possible synergistic effects of consuming foods containing several additives, often referred to as the so-called 'cocktail effect'. The testing of all possible combinations of additives that can occur in food for risk characterization is, in practice, impossible, given the large numbers of different combinations that may be present in foods. However, the issue of combined action is amenable to generic research approaches.

In recent years there have been major advances in understanding mechanisms of combination toxicology and a significant theoretical and experimental database has been developed (Ito *et al*., 1995; Jonker *et al*., 1996; 2004; Groten *et al*., 2000; Feron and Groten, 2002; Feron *et al*., 2002). Dose-addition occurs when substances produce toxicity via the same mechanism of action, whereas response-addition occurs when the substances act via different mechanisms. Synergism and antagonism may arise from either TK or TD reasons, but usually requires that each substance is present at active doses or concentrations.

One of the major lessons learned from this research is that exposure to mixtures of chemicals at levels that are nontoxic for each individual chemical generally will not result in a health risk. An important exception to this is when dose addition occurs for a mixture of chemicals with a common mode of action because the summing of a number of essentially inactive doses can give sufficient activity to produce an effect (see, for example COT, 2002b; DVFA, 2003; Kortenkamp, 2007; 2008). Although synergistic interactions can never be fully excluded on theoretical grounds, they are likely to occur only when there is a biologically active dose level of at least one of the chemicals involved.

On food additives specifically, the possibility that structurally unrelated food additives could show either joint actions or interactions has been assessed based on their potential to share common sites and mechanisms of action or common pathways of elimination (Groten *et al*., 2000). All food additives approved in the EU and allocated a numerical ADI were studied, using the data contained in the relevant JECFA reports. In all but a very few cases, the possibility of joint actions or interactions could be excluded on scientific grounds. The exceptions were on the liver (curcumin, thiabendazole, propyl gallate and BHT), the kidney (diphenyl, *o*-phenylphenol and ferrocyanide salts), the blood (azorubine and propyl gallate) and the thyroid (erythrosine, thiabendazole and nitrate). The authors concluded that many of those additives which could not be excluded from showing joint actions or interactions would have low intakes and that joint actions or interactions between additives do not represent a significant health concern.

There are examples in the food additives area of structurally or metabolically related compounds which display similar toxic effects, and for these group ADIs are established that include all members of the group of compounds, in order to limit their cumulative intake. For this procedure to be feasible, each of the substances must of similar toxic potency so that summation of the intakes of the different substances does not have to include a correction for potency. In cases where different substances are converted essentially quantitatively to a common the metabolite, the Group ADI may be expressed on the basis of the common metabolite; a recent example is the ADI for the sweetener steviol and related glycosides, which is expressed as steviol equivalents (WHO, 2005).

The use of a group ADI is also appropriate for compounds that cause additive physiological or toxic effects, even if they are not closely related chemically. For example, it may be appropriate to establish a group ADI for additives such as bulk sweeteners that are poorly absorbed and cause laxation by a common osmotic

mechanism, to ensure that cumulative intake does not exceed the human threshold for undesirable laxation effects.

Safety Assessment of Foods Obtained from Crops Developed Using Biotechnology

Bryan Delaney

CONTENTS

1 INTRODUCTION

1.1 What Are Foods Obtained from GE Crops?

This chapter will describe the methods used to assess the safety of foods obtained from genetically engineered (GE) crops; therefore it is appropriate that the chapter begin by defining just what is meant when these terms are used. For the purposes of this chapter, 'foods obtained from GE crops' refers to products obtained from field crops that are or could routinely be consumed as part of the human or livestock diet. For example, whole maize grain and soya beans may not be considered staples of the human diet, however, corn and soya beans currently constitute the most widely cultivated GE crops. Accordingly, there is a substantial body of literature that has assessed the safety and nutritional quality of milled maize grain from GE corn and processed feed fractions obtained from GE soya beans (e.g. soya-bean meal). Within the context of the current chapter, these substances would be considered as foods obtained from GE crops.

1.2 What is Biotechnology?

Within the context of agriculture, the term biotechnology refers to the modification of field crops for desired traits using methods other than traditional breeding. Biotechnology has also been described as genetic modification or genetic engineering. The process of developing a field crop using biotechnology begins with identification of the desired trait. For the purposes of this chapter, the word 'trait' refers to the genetic factors responsible for a defined biochemical or agronomic property that is not otherwise present in the target crop, though it could also refer to crops developed by selectively increasing or decreasing the expression of endogenous plant molecules using biotechnology. Most currently marketed GE crops are agronomic in nature in that they were developed to increase the yield of field crops by introduction of traits intended to counteract two stressors that consistently result in yield loss from field crops: (i) competition with weeds for environmental resources; (ii) infestation with insect pests.

1.2.1 Herbicide Tolerance

To address the issues of competition with weeds, biotechnology has been used to develop GE crops that are tolerant to application of nonspecific herbicides. The first

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

example of this is RoundUp Ready™ soya beans that were developed by the Monsanto Company. RoundUp Ready™ soya beans were developed following identification of the 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS) gene from *Agrobacterium* strain CP4 (Stallings *et al*., 1991). The nonselective herbicide glyphosate inhibits endogenous plant EPSPS proteins and causes toxicity by inhibiting the synthesis of aromatic amino acids. In contrast, the CP4 EPSPS protein is not inhibited by glyphosate, so that plants in which it is expressed are tolerant to treatment with glyphosate (Padgette *et al*., 1991; 1995). GE crops in which the transgenic CP4 EPSPS protein is expressed have an obvious advantage over crops in which this protein is not expressed, in that they tolerate field application of glyphosate, whereas the weeds competing with the crop do not. The tools of biotechnology have also been used to express the CP4 EPSPS protein in other field crops including corn, cotton and canola.

An alternative method for conferring tolerance to glyphosate in field crops was developed by isolation of the gene for the glyphosate acetyltransferase (GAT) protein found in *Bacillus licheniformis*. This gene was modified using gene shuffling techniques designed to screen for increased activity towards acetylating (and thereby inactivating) glyphosate (Castle *et al*., 2004; Siehl *et al*., 2005). The DuPont Company has developed field crops that are tolerant to glyphosate by expression of the *gat* gene in soya beans and corn under the market name of Optimum® GAT®.

Biotechnology has also been used to produce field crops that are tolerant to the nonspecific herbicidal active ingredient glufosinate ammonium by the Bayer Company. The phosphinothricin acetyltransferase (PAT) protein that was originally isolated from *Streptomyces viridochromogenes* metabolically inactivates glufosinate ammonium by acetylation of phosphinothricin. The gene for this protein has been expressed in field crops under the market name Liberty Link™.

1.2.2 Insect Resistance

Insect pests are also responsible for loss of crop yield, though they may be controlled by numerous classes of chemical pesticides including organophosphates, carbamates and pyrethroids. However, the use of chemical pesticides can result in effects on nontarget insects, development of resistance in target insects, and possible adverse effects from human exposure to residues. The development of insecticidal protein traits in plants, as discussed further below have minimized these effects by reduction of chemical pesticide use.

Farmers of organic foods have used the ubiquitous soil bacteria *Bacillus thuringiensis* (Bt) for insect control for more than 40 years. Biochemical studies have demonstrated that selective pesticidal activity is attributable to the crystalline (Cry) proteins expressed by these bacteria (Höfte and Whiteley, 1989). Biotechnology has been used to transfer individual *cry* or *vip* genes from different strains of Bt into field crops for the purpose of insect control. The particular Cry proteins used in these crops were chosen based on their selective toxicity towards target insect species. For example, the Cry1F and Cry1Ab proteins display a selective toxicity towards European corn borer and other lepidopteran larvae, whereas the Cry3Bb1 and Cry34Ab1/Cry35Ab1 proteins display selective toxicity towards corn rootworm and other coleopteran larvae. The use of GE corn in which Bt Cry proteins are expressed has also been reported to result in decreased concentrations of mycotoxins; an effect that is believed to be attributable to improved health of the plant (Hammond *et al*., 2004a; Wu, 2006).

1.3 Crops Produced Using Conventional Breeding Methods vs. Biotechnology

Traditional or conventional crop breeding has been used for millennia to improve the yield and hardiness of domesticated plants. Selecting and saving seed from the 'best' performers to replant the following season, or crossing (hand-pollinating) a reliable producer with a plant of the same species expressing a new, desirable phenotype are examples of traditional breeding. More recently in the past century, new crop varieties have been created using tools for genetic modification, including forced recombination of entire genomes or chromosomes across species or even genus boundaries (wide-cross hybridization), and the creation of large numbers of random, widespread gene disruptions, by exposing plants to ionizing radiation or mutagenic chemicals (induced-mutation breeding) (National Academy of Sciences (NAS), 2004; Harlander, 2002).

For the past 20 years, plant molecular biologists have been introducing new functionality into cultivated crops using gene isolation and DNA-transfer techniques of modern biotechnology. Recombinant DNA technology, the combining of genes and elements some of which may originate from different organisms, has been used to create new traits of benefit to agriculture. Insect-resistant and herbicide-tolerant corn, soya beans and cotton are some of the first products commercialized using recombinant DNA technology, in which entire coding sequences (genes) with well-characterized functions were stably integrated into the genome of the recipient plant. For these crops, expression of the encoded protein or proteins *in planta* confers the anticipated phenotype. It is also possible to utilize recombinant DNA technology to modulate expression of endogenous plant genes (double-stranded (ds) RNA-induced gene silencing; Kusaba, 2004) or entire biochemical pathways

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat139
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(altered transcription factors; Broun, 2004) for alternative crop phenotypes (e.g. drought tolerance, nitrogen retention). In fact, it is now known that major phenotypic advances in plant domestication using traditional breeding methods were the result of selection for naturally occurring specific transcription factor variants or mutations in cis-regulatory genes (Doebley, 2006; Li *et al*., 2006; Wang *et al*., 2005).

The obvious similarity between recombinant DNA technology and conventional breeding is that the phenotype of the new crop variety is conferred by altering DNA sequence or expression. However, there are two important differences. The first is that in conventional breeding and selection methods, only a proportion of the progeny will express the phenotype of interest. Secondly, most of the progeny will contain additional genetic traits in addition to the intended trait—potentially undesirable qualities that must be bred out by repetitive backcrossing to the parental line. Recombinant DNA technology is more directed than other genetic modification techniques in that only the intended DNA sequence(s) is transferred. It has been documented that considerably greater heterogeneity exists within the genomes, proteomes and metabolomes of conventional varieties of a crop than between a new GE crop and its conventional progenitor (Catchpole *et al*., 2005; Shewry *et al*., 2007; Cheng *et al*., 2008; Ruebelt *et al*., 2006). Within the context of safety assessment, this is curious because regulatory agencies in many countries require safety assessment of crops produced using biotechnology, but little or no safety characterization of crops produced using conventional breeding methods (Harlander, 2002; National Academy of Sciences (NAS), 2004; Parrott, 2006).

The second difference between these methodologies is that recombinant DNA technology eliminates the species barrier across which DNA can be transferred. While the traits imparted into crops from recombinant technology are mediated by genetic modification, just as they are with conventional breeding practices, it is possible that public concern about the safety of GE crops is at least partly attributable to the introduction of foreign genes into a species that would not otherwise have expressed them, since within conventional breeding, forced crosses above the genus level are seldom successful.

2 PRODUCT DEVELOPMENT

Conceptually, the process of product development using biotechnology is relatively straightforward following the identification of the genetic elements responsible for the desired trait. It involves engineering the trait DNA into an expression vector, which is then transferred into the seed germline of the selected crop. At a minimum, the vectors contain DNA responsible for: (i) conferring the desired trait or traits; (ii) the transgenic elements required for their expression and (iii) a selectable marker required to identify transformed plant tissues. The ensuing inheritance and expression of the inserted DNA fragment confers the desired trait to the progeny of the transformed plant. The actual process by which genetically modified (GM) crops are developed is considerably more complicated.

While not typically discussed in the safety assessment of GM crops, it should be noted that the transformation process and selection of efficacious events represent two critical steps in identifying viable candidate plants for product development. Following construction of a transgenic vector, individual transformants are produced by the insertion of the transgenic DNA into the seed germlines. A variety of methods have been used to produce candidates, including particle-based methods (e.g. gene gun) and transfer using nonpathogenic bacteria (Taylor and Fauquet, 2002). The processes used to insert the transgenic DNA into seed germlines are not 100% efficient and do not always result in transfer of functional transgenic DNA. The screening of individual transformants for viability and efficacy is one of the most important steps in product development of GM crops. For example, approximately 10 000 individual transformants were created during the process of development of the corn-rootworm-resistant maize line DAS-59122-7, most of which did not survive the transformation process or produce efficacious events, and only one of which was commercialized (unpublished data).

3 SAFETY ASSESSMENT OF GE CROPS

Assessment of the safety of foods or food components obtained from GE crops is a process that considers numerous factors, some of which relate to the transgenic proteins or other transgenic elements expressed in GE crops, while others focus on assessment of the safety of whole foods obtained from GE crops. The overall goal of the safety-assessment process for any individual GE crop is to determine whether it is *as safe as* its appropriate conventional non-GE comparator, which presumably has a history of safe use. Accordingly, the safety assessment is conducted to determine if the production of the particular GE crop resulted in unintended effects (i.e. pleiotropism) and, if observed, whether the changes are adverse.

The current chapter focusses on assessment of human-health risk from foods obtained from GE crops. A comprehensive safety assessment that would be conducted for a regulatory dossier would also consider a number of additional factors, including environmental effects, such as stability of the trait, possible effects on nontarget insects and, depending on the nature of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

the transgenic event, the potential impact on insect resistance.

3.1 Safety Assessment of Transgenic Proteins

Most dietary proteins are metabolized into individual amino acids and small peptides that are absorbed for nutritive purposes. However, a small number of proteins have been reported to cause two adverse effects: allergenicity and toxicity. The following sections discuss the processes used to assess transgenic proteins for potential to cause allergenic or generalized toxicity.

3.1.1 Allergenicity

Allergenic proteins have been identified in a number of foods and all known allergenic substances identified in foods are, in fact, proteins. Therefore, one of the potential risks that has been identified with the expression of transgenic proteins in GE crops and foods obtained from them is that the proteins could be allergenic, however, this concern appears to be based solely on the fact that they are proteins. During the research phase of one project, a methionine-rich protein from Brazil nuts was transferred into the soya bean seed germline to increase the concentration of sulphur in soya beans for animal nutritional purposes. The safety assessment of the transgenic product conducted early in development determined that the protein that was selected from the Brazil nut was allergenic (Nordlee *et al*., 1996). The product was not commercialized, but it did highlight the need for the assessment of the potential allergenicity of transgenic proteins.

While toxicologists often evaluate the safety of various substances, including proteins, using animal models, there are currently no validated animal models to assess the potential allergenicity of candidate transgenic proteins, even though a number of models have been investigated (McClain and Bannon, 2006; Ladics *et al*., 2003; Helm, 2002; Goodman *et al*., 2008). Nevertheless, guidelines have been developed to assess the potential allergenicity of transgenic proteins by a number of scientific and regulatory authorities (Metcalfe *et al*., 1996; FAO/WHO, 2001; Codex, 2003a). Current guidelines call for a weight-of-evidence approach that considers a number of end points and properties of the transgenic protein (Codex, 2003a).

Assessment of the potential allergenicity of transgenic proteins begins with consideration of the source from which the DNA encoding the transgenic protein was obtained. Sources with a documented history of causing allergic reactions in individuals are considered more likely to contain allergenic proteins than those without a documented history of causing allergic reactions. Many foods have been documented to cause allergic reactions in humans (Hefle *et al*., 1996), but the majority of allergic reactions from foods are attributable to a relatively small number of foods (approximately 200 foods or food groups) including peanuts, tree nuts, seafood, shellfish, egg, milk, soya and wheat. Therefore, mining the sequences of these particular foods for proteins that could be useful in GE crops is typically avoided. However, the known allergenic proteins contained in such foods represent a very small number in the total proteome. Consequently, it should be noted that the proteins or other transgenic elements derived from such commonly allergenic food sources should not necessarily imply that they are allergenic.

Another component in the weight-of-evidence approach for assessing the potential allergenicity of transgenic proteins involves using computer-based bioinformatics tools to determine the similarity of the particular amino acid sequence of the transgenic protein expressed in a GE crop to other known allergenic proteins contained in a database (i.e. AllergenOnline; *www.allergenonline.com*). The AllergenOnline Database is a publically available, peer-reviewed, and curated database that is updated on an annual basis. A variety of bioinformatics tools are available for this application, including FASTA (Ladics *et al*., 2007). According to current guidelines, bioinformatics analyses are conducted to determine if there are any eight contiguous identical amino-acid matches representative of 'theoretical' IgE binding epitopes or an overall sequence identity of greater than 35% over 80 or greater amino acids between the transgenic protein and known allergenic proteins (Codex, 2003a; Silvanovich *et al*., 2006).

Studies have reported that nonallergenic proteins are degraded following *in vitro* exposure to digestive enzymes (Astwood *et al*., 1996). Accordingly, the allergenicity assessment of transgenic proteins also includes an evaluation of their resistance to degradation by digestive enzymes, including pepsin (in simulated gastric fluid) and pancreatin (in simulated intestinal fluid) *in vitro*. The transgenic Bt and herbicide tolerance proteins used in currently marketed GE crops are degraded in these conditions (Herman *et al*., 2003).

It has since been reported that the relationship between digestibility and allergenicity is not absolute, as a number of allergenic proteins were found to be degraded under these conditions and nonallergenic proteins were found to resist digestion under these *in vitro* conditions (Fu *et al*., 2002). Nevertheless, assessment of the *in vitro* digestion of heterologously produced transgenic proteins remains a common component of the protein allergenicity assessment of practically all guidelines.

One example of a transgenic protein that was resistant to digestion under *in vitro* conditions is Cry9C (i.e. Starlink) that was expressed in corn intended to be used for livestock applications. This protein was modified by a one-amino-acid change that made it resistant to digestion

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat139
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and then expressed in corn intended for use in livestock applications. This corn was unfortunately commingled into the human food supply and resulted in a recall of products containing Cry9c from the market (Bucchini and Goldman, 2002). Although the Cry9 C protein was resistant to degradation by digestive enzymes under *in vitro* conditions, a property of some allergenic proteins, there was no indication that exposure to the Cry9 C protein actually resulted in any adverse effects, allergenic or other, in the human population.

In some cases, heat lability of transgenic proteins is also assessed and may be required by some regulatory agencies. This is based on the concept that allergenic proteins would be more likely to remain structurally intact following exposure to heat; however, this relationship has not been clearly demonstrated. Additionally, it should be noted that there are no clear guidelines describing how this particular assessment should be conducted. In cases where this property has been investigated, the data are usually expressed as an activity curve that reports the enzymatic activity at different elevated temperatures (up to 100 °C) relative to that observed at cooler temperatures (for example see Delaney *et al*., 2008c).

When considering the potential for a transgenic protein to cause allergic reactions, the individual components discussed above are considered in a weight-of-evidence approach rather than a check-the-box or flow-chart approach. In other words, there is not always a clear yes–no approach in the assessment for any particular transgenic protein. Rather the individual components discussed above, when considered collectively, give a good indication of whether or not the protein is likely to be allergenic.

3.1.2 Toxicity

A small number of proteins have also been reported to cause mammalian toxicity that is unrelated to allergenicity. The majority of these proteins are bacterial in origin, including shiga toxin, though a number of plant-derived protein toxins are also known to exist, including lectins and antinutrients (e.g. trypsin inhibitor). Because the traits expressed in currently marketed GE crops are proteins, recommendations to determine whether individual transgenic proteins are likely to be toxic have recently been published by the International Food Biotechnology Committee (IFBiC) of the International Life Sciences Institute (ILSI; Delaney *et al*., 2008a). They bear a number of similarities to those used to assess the allergenicity, but are structured in a two-tiered approach rather than a weight-of-evidence approach.

The first tier (potential hazard identification) includes assessing information about the source of the transgenic DNA and whether that source has been documented to cause toxicity in mammalian species. The reasoning for including this particular information is that it is considered that species not known to cause toxicity are less likely to contain proteins that are toxic, than those known to produce protein toxins. This is the reason why transgenic DNA used in GE crops has been obtained from innocuous species such as *B. thuringiensis* rather than from pathogenic bacteria or from plants known to produce protein toxins.

Another piece of information in the first tier is a bioinformatics comparison of the amino-acid sequence of the transgenic protein with that of known protein toxins. In contrast to the bioinformatics assessment conducted for allergenicity, there are currently no internationally accepted standards that constitute a significant sequence or structural match between transgenic proteins and toxic proteins. Further, there are currently no databases where the sequences of toxic proteins are actively maintained. However, these analyses are typically conducted using the same types of bioinformatics tools.

An additional factor to consider in the safety assessment of transgenic proteins is information about their mechanism of action. The more information that is known about the mechanism by which a particular protein acts will aid substantially in the assessment of the safety of that protein. For example, if a transgenic Cry protein obtained from a particular *B. thuringiensis* species interacts with a specific receptor that is only expressed within the target insect, it would be conceptually easier to determine that the protein represents little risk to any other species of insects.

The assessment of transgenic protein resistance to degradation by digestive enzymes conducted under the rubric of allergenicity assessment is also a component of the toxicity assessment. To date, there has been no systematic assessment of whether toxic proteins are more resistant to degradation by digestive enzymes than nontoxic proteins. Nevertheless, the data obtained from the allergenicity assessment is applicable to the toxicity assessment of these proteins, because toxic proteins must remain intact to exert evidence of toxicity. Therefore it is expected that proteins that are degraded by digestive enzymes are less likely to cause toxicity to an organism for the simple reason that they have little or no opportunity to be absorbed intact (reviewed in Delaney *et al*., 2008a).

In many instances, the fundamental elements addressed to assess the toxicity of transgenic proteins in the first tier of the ILSI/IFBiC recommendations alone are adequate to assess the potential for a particular transgenic protein to exhibit toxicity. Nevertheless, a second tier (hazard characterization) was recommended to be considered in the case where the evidence from the first tier is not conclusive. The elements contained within the second tier include considerations for additional general toxicity studies to assess the general safety of the transgenic protein (acute and repeated-dose rodent studies) and, in some cases, hypothesis-based testing.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat139
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

It has been reported that even though most proteins are not toxic, those that are toxic appear to act through acute mechanisms of action (Sjoblad *et al*., 1992). Accordingly, an assessment of the acute toxicity of transgenic proteins is often conducted, though different methods have been used to assess the acute toxicity of transgenic proteins.

In most cases, transgenic proteins were administered to mice rather than rats for practical reasons because the amount of test substance required for mouse studies is substantially lower than that required for rat studies. In some cases the test substance has been administered to mice via oral gavage in accordance with OECD (Organization for Economiic Cooperation and Development) limit dose guidelines (i.e. 2000 mg (kg body weight)$^{-1}$ OECD, 2001b) to assess the potential for adverse effects following oral exposure—the presumed route of exposure to most proteins in foods from crops developed using biotechnology. In other cases, the test substance was administered to mice via alternative routes, including intraperitoneal and intravenous exposure routes. Despite the differences in the methods used to assess the acute toxicity of transgenic proteins, to date there is no evidence that any transgenic proteins used in GE crops exhibit any evidence of acute toxicity (reviewed in Delaney *et al*., 2008a).

Repeated dose (28 day) toxicology studies have been recommended by some regulatory agencies to assess the safety of transgenic proteins used in GE crops. While few studies have been conducted to date, the studies that have been conducted reported no evidence of adverse effects (Delaney *et al*., 2008b; Cerven *et al*., 2008a; 2008b; Mathesius *et al*., 2009; Juberg *et al*., 2009).

The final element of toxicity testing recommended by ILSI/IFBiC is hypothesis-based studies. Conceptually, these types of studies would only be necessary when other studies or information indicated that they would be necessary. One example that has been discussed is that of antifungal protein (AFP; Delaney *et al*., 2008a). Bioinformatics analysis of this particular protein reported sequence similarity between this protein and scorpion toxin. In that case, AFP was isolated and compared to scorpion toxin using electrophysiology methods to demonstrate that it did not possess the same biochemical properties as scorpion toxin, though products containing AFP have not been commercialized to date.

3.1.3 Challenges

One of the problems with conducting allergenicity and toxicity testing with transgenic proteins expressed in GE crops is that of obtaining sufficient quantities of the pure proteins required to conduct these studies. In most cases, the transgenic proteins in GE crops are expressed at low concentrations, making it impractical to isolate them from the crops in which they are expressed to conduct *in vitro* or *in vivo* toxicology studies. Therefore, these studies are typically conducted using heterologously expressed proteins, which necessitate biochemical and analytical studies to demonstrate that, in fact, any studies conducted with heterologously expressed proteins are truly representative of the proteins when expressed *in planta*.

3.2 Safety Assessment of Foods from GE Crops

The fundamental concept for the safety assessment of GE crops is called 'substantial equivalence' and was first proposed by the World Health Organization (WHO) and the OECD (WHO, 1991; OECD, 1993; reviewed in Kok and Kuiper, 2003). This concept was developed because it is not possible to demonstrate that any whole food is absolutely safe, even though countless foods have a long history of safe consumption. Since the original publication, numerous variations have been published by other scientific and regulatory authorities (Codex, 2003b; 2007; EC, 1997; 2003a; 2003b; 2004; EFSA, 2006; 2008; FAO, 1996; FAO/WHO, 2000; ILSI, 1997; 2003b; 2004; OECD, 1997; 2003; WHO, 1995). While there are differences among these different sets of recommendations, in essence, they all recommend using scientific evidence to demonstrate that the only difference between the GE crop and the non-GE counterpart crop is the presence of the transgenic DNA and associated expressed protein or phenotypic trait.

There is controversy regarding DNA and RNA in foodstuffs, but they are both normal components of the human diet and people have been estimated to consume up to 1.0 g day^{-1} of RNA and DNA from the diet (Carver and Allan Walker, 1995; Jonas *et al*., 2001). The DNA present in genetic inserts in foods obtained from GE crops does not differ structurally or in other biochemical properties from the DNA already present in food and represents a very small fraction of the total DNA present within the foods (Parrott *et al*., 2008). Though consumption of both DNA and RNA do not cause adverse effects, it has been recommended that the intake should not exceed 2 g day^{-1}, at least in populations that are sensitive to elevated concentrations of uric acid, such as those with gout (Clifford and Story, 1976). The presence of additional DNA or RNA in the foods obtained from GE crops relative to the DNA present in foods obtained from non-GE foods contributes virtually nothing to the typical daily dietary exposure to either substance.

3.2.1 Characterization of the Genetic Insert

Characterization of the transgenic insertion is normally conducted to determine copy number, integrity, orientation, number of insertion loci, whether the process of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat139
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

transformation resulted in insertion of backbone DNA from the vector, and whether the transgenic DNA was inserted into an endogenous gene. The methods used to conduct these types of analyses have been discussed elsewhere and are beyond the scope of this paper.

3.2.2 Compositional Analysis

In practice, the principle of substantial equivalence has been applied in the comparison of the composition of GM crops with the composition of non-GM crops of closely related genetic lineage (near isogenic) from field trials in which they were both grown under similar conditions. These studies are analytical in nature and are extensive in the number of ingredients that are analysed, including primary nutrients (nutritional proximates), amino acids, fatty acids, vitamins, minerals and antinutrients on a crop-specific basis with known biological importance, either to the plant itself or to their nutritional importance (ILSI, 2003a; OECD, 2001a). Numerous such comparative trials have been published for field crops, including soya beans (Taylor *et al*., 1999; McCann *et al*., 2005), corn (Sidhu *et al*., 2000; Ridley *et al*., 2002; George *et al*., 2004; Herman *et al*., 2003; 2007), wheat (Obert *et al*., 2004) and rice (Oberdoerfer *et al*., 2005). Collectively, these studies have determined that the composition of the GM crops is comparable to the composition of their conventional crop counterparts.

3.2.3 Nutritional Equivalence Studies with Foods Obtained from GE Crops in Livestock Species

In most cases, the information necessary to determine that the foods obtained from a particular GE crop are substantially equivalent to their non-GE comparator can be obtained from characterization of the insert, composition testing and agronomic field studies. However, feeding studies have also been conducted with processed grains and feed fractions from a number of GE crops. To be clear, these are not toxicology studies; however they can provide valuable information about the nutritional quality of the foods obtained from individual GE crops to determine whether adverse pleiotropic effects could have been introduced or expressed from the process of genetic modification that may not have been detected from compositional testing.

Because early generation GE crops were soya beans and corn and a large proportion of the grains obtained from these crops are used as livestock feed, these feeding studies have been conducted in livestock species. These feeding studies have been referred to colloquially as nutritional equivalence studies. Of particular relevance for these types of studies are the feeding studies that have been conducted in broiler chickens. Broiler chickens represent a commercially important commodity that grows rapidly. These animals grow from approximately 40–50 to 2000 g over a 42 day feeding interval, which is the standard lifespan for broiler chickens used by commercial poultry farmers, and nutritional comparison studies conducted in broiler chickens are considered to be very sensitive to nutritionally imbalanced diets (ILSI, 2003c; 2007).

The basic design of these studies is to compare nutritional performance metrics from groups of broiler chickens consuming diets produced with processed (i.e. milled) grains and feed fractions from GE crops (the experimental group) to those observed in groups of broiler chickens consuming diets formulated with corresponding processed grains and feed fractions from non-GE crops. Additional groups are fed diets produced from unrelated commercially available non-GE crop varieties to provide within-study control values for the response variables that are assessed. The response variable typically assessed in these types of studies included body-weight gain, feed consumption, feed-conversion efficiency, and an assessment of commercially relevant carcass traits, including yield of breast, wings and thighs. Numerous feeding studies with processed grains and feed fractions obtained from GE soya beans and/or whole grain from individual and stacked trait GE maize plants have been published though no adverse nutritional effects have been reported to date (Taylor *et al*., 2003a; 2003b; 2003c; 2003d; McNaughton *et al*., 2007a; 2007b).

3.2.4 Subchronic Toxicology Studies with Foods Obtained from GE Crops in Rodents

Subchronic (90 day) rodent toxicology studies have also been conducted with the processed grains and feed fractions obtained from GE crops. These studies were conducted to determine whether the process of engineering the particular crop resulted in adverse pleiotropic effects that were not detected during compositional analyses. These studies were originally designed to assess the health effects of long-term exposure to 'pure' chemicals, using a comprehensive overall health screen in rats, as described in OECD 408 guidelines (OECD, 1998). Subchronic rodent studies conducted with foods from GE crops are similar to subchronic rodent toxicology studies conducted with chemicals or food additives, in that they are the same duration and assess the same growth performance (body weights, feed consumption, etc.) and clinical pathology response variables (serum chemistry, haematology, coagulation, organ weights and organ histopathology).

However, there are differences between the design of subchronic rodent toxicity studies conducted with foods from GE crops and those conducted with food ingredients. The most obvious of these is the dose–response curve, in which the test substance is administered to rodents at tens, hundreds or thousands of times in excess

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat139
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of anticipated human exposure for purposes of quantitative risk assessment. When conducted with whole grains or processed feed fractions from GE crops, these studies represent what is essentially a qualitative safety assessment because they have been designed and conducted to compare the effects of two substances (food from GE crops vs. food from non-GE crops). A variety of study designs have been employed to assess these differences, but it should be noted that the studies themselves are as rigorous as the toxicology studies conducted for quantitative risk assessment of food ingredients (Delaney *et al*., 2008a). When conducting feeding studies with whole foods, whether derived from GE or non-GE crops, it is usually not possible to administer the test substance at levels that are tens of times greater than estimated human exposure. Even if it were physically possible to formulate diets that met these criteria, it would likely result in formulation of nutritionally imbalanced diets that would result in corresponding differences in the response variables evaluated in these studies that are not related to exposure to the particular test substance.

Subchronic rodent feeding studies with processed grains and feeding fractions from GE crops have been conducted by formulating rodent diets according to the specifications of commercially available rodent feed. The experimental diets in these studies typically contain processed grains or feed fractions from GE crops, whereas the control diets are formulated with the corresponding fractions from the nearest isogenic comparator (i.e. near isoline). For example, one commonly used commercial diet in the United States is Purina Mills Certified LabDiet 5002 which contains 33–38% whole maize grain. Subchronic studies with whole corn from GE crops have therefore been conducted by formulating rodent grain-based diets with ~35% GE maize grain in the experimental group and ~35% near-isoline maize grain in the control group.

These studies have essentially borrowed the elements of study design from nutritional comparison studies as conducted in livestock species. They usually compare nutritional performance (body weights, feed consumption) and a more extensive battery of toxicology response variables (haematology, coagulation, clinical chemistry, organ weights and histopathology) between rats consuming diets formulated with the foods obtained from the GE crop and the non-GE control group. The combination of the large number of response variables that are evaluated in these studies and the fact that the primary statistical comparison is between two groups results in a high probability that some statistical differences will be observed between the control and experimental groups. By default, it could be assumed that statistical differences between the two groups are attributed to consumption of the experimental diet. However, it is equally likely that statistical differences could be attributed to deviations in the values observed in the control group. That is, if statistical differences are observed between the control and the experimental group and it can be demonstrated that the values observed in the experimental group fall within the range of anticipated values when the values observed in the control group do not, it is unlikely that the statistical difference represents a biologically significant difference. For that reason, it is common to include additional 'reference' control groups in subchronic rodent feeding studies. The reference groups are fed diets containing the same concentrations of processed grains or feed fractions from genetically unrelated non-GE crops to provide within-study ranges for the response variables typically evaluated in subchronic rodent toxicology studies. It is also common to refer to the values observed in historical control groups to determine whether statistical differences observed between the response variables evaluated in control and experimental groups are within the anticipated ranges to determine whether they are biologically relevant.

In most cases published to date, these types of studies have also included at least three additional groups of rats that were fed diets produced in accordance with commercial standards using commercially available, but unrelated, varieties of non-GE grain fractions (i.e. reference groups). The inclusion of the reference groups has proven useful for statistical analysis of the values in what is essentially a two-group comparison study. Because statistical significance in these studies is typically set at a default of $p < 0.05$ and there are a large number of response variables, it would be anticipated that each independent study would contain a number of statistical differences between the control and experimental groups. In the absence of a true multiple exposure dose–response design it can be difficult to determine whether the statistical differences are biologically meaningful or not. In fact, practically every subchronic rodent feeding study conducted with foods from GE crops to date has reported statistically significant differences between the control and experimental groups for at least one response variable. The data obtained from the concomitant reference groups has therefore been particularly useful in establishing within study ranges for the response variables. Data from historical control groups is also useful for this purpose.

Numerous studies of this design have been reported for corn (MacKenzie *et al*., 2007; Malley *et al*., 2007) and soya beans (Appenzeller *et al*., 2008; Delaney *et al*., 2008b) from GE crops. Some subchronic rodent studies with foods obtained from GE crops have also been conducted using an additional dose group that contains lower concentrations of GE maize grain to construct a dose–response curve, at least with relation to exposure to the test substance (Hammond *et al*., 2004b; 2006a; 2006b; Healy *et al*., 2008). However, it is unclear whether the dose–response design utilized in those studies was useful for quantitative risk assessment, since no differences have been reported among the treatment groups consuming

DOI: 10.1002/9780470744307.gat139
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

different concentrations of the whole foods obtained from GE crops.

Different methods of conducting subchronic feeding studies have also been reported. In some studies, different concentrations of maize grain from GE corn (50 and 70%) were incorporated into experimental diets and fed to rats for 90 days. Control groups were fed diets containing the same concentrations of non-GE, near-isogenic maize grain. The diets in these studies were formulated to meet the guidelines of AIN-93G standards (Reeves *et al*., 1993). Additional control groups were fed commercially sourced AIN-93G diets. The statistical analysis of data obtained from studies of this design have been difficult to interpret, but, to date, studies of this design have not reported biologically significant differences between rats consuming control and experimental diets (He *et al*., 2008).

Subchronic rodent toxicity studies have also been conducted with GE rice. In those studies ground flour from GE rice expressing the Cry1Ab protein or the parental wild-type rice were administered to rats at a dietary concentration of 60% and fed for 90 days. In that study, a number of statistically significant differences were observed between the toxicology response variables of rats consuming the control and experimental diets, but the authors concluded that the differences were not adverse (Schrøder *et al*., 2007). Similar observations were made from a subchronic rodent feeding study conducted with GE rice expressing the insecticidal snowdrop lectin (GNA (*Galanthis nivalis* agglutinin); Poulsen *et al*., 2007a).

In another variation, a recent subchronic rodent toxicity study was conducted, in which rats were fed control (non-GE) or rice that was produced experimentally to express the toxic kidney bean lectin (PHA-E (phytohemagglutinin-E). In this study a third group was included that was fed the PHA-E-expressing rice grain and an additional dietary concentration of 0.1% pure PHA-E (Poulsen *et al*., 2007b). The authors indicated that the intent of designing the study that way was to increase the sensitivity and specificity of the study to detect possible adverse effects. For practical purposes, studies of this design would be difficult to reproduce in many instances because the transgenic proteins and other elements expressed in foods from GE crops are expressed at very low concentrations and it may not be physically possible to obtain the amount of purified test substance that would be necessary to conduct a study according to that type of design.

3.2.5 Other Toxicology Studies with Foods Obtained from GE Crops in Rodents

Toxicology studies other than subchronic have also been conducted using foods obtained from GE crops. For example, multigenerational reproductive studies have been conducted in mice using GE soya beans, maize grain and potatoes, though no evidence of adverse effects were observed (Brake and Evenson, 2004; Brake *et al*., 2004; Rhee *et al*., 2005). Additionally, no adverse effects on the immune system were observed in rats or mice following consumption of GE soya beans (Teshima *et al*., 2000).

4 QUALITATIVE SAFETY ASSESSMENT

The previous sections of this chapter describe the types of studies that are often conducted when assessing the safety of foods or food components from GE crops. What needs to be kept in mind is the overall goal of these studies—to determine if the foods obtained from GE crops are *as safe as* those obtained from non-GE crops (i.e. substantial equivalence). Some typical toxicology studies are included in the assessment, but numerous additional *in vitro, in silico* and analytical studies are also included.

The process of safety assessment of foods from GE crops can therefore be considered as a qualitative safety assessment in that the overall goal is comparative in nature; however, the process itself is certainly no less rigorous than the data considered in the quantitative safety assessment of dietary ingredients (Delaney, 2007).

5 SAFETY ASSESSMENT OF FUTURE GE FOODS

The majority of currently marketed GE crops are relatively simple in nature, in that traits that were engineered into them are mediated primarily by expression of exogenous proteins. The future or GE crops will include new traits intended to confer additional agronomic benefits, such as drought tolerance and nitrogen-use efficiency, and consumer benefits, including modified fatty-acid profiles and altered nutritional properties. It is likely that these effects will not be mediated by expression of exogenous proteins, but rather by the modification of endogenous biochemical pathways of field crops, using such techniques as gene silencing and altered expression of endogenous proteins using transcription factors. Introduction of new traits may also involve more complicated proteins, such as transmembrane proteins that, at least using currently available technology, cannot be isolated in the quantities necessary to conduct safety and toxicology studies such as those described above.

As new molecular and biochemical technologies are developed through scientific research, it will be increasingly important to carefully evaluate these techniques for their utility in safety assessments of GE crops. It has been suggested that 'omics' profiling studies

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(e.g. metabolomics) may be useful in assessing the safety of the next generation of GE crops (Chassy *et al*., 2004; Kok *et al*., 2003; Kuiper *et al*., 2003; Shewry *et al*., 2007). 'Omics' studies provide a large number of data points about expressed genes, metabolites or proteins of GE crops well beyond the analysis of current studies. However, it should be kept in mind that producing additional data alone will not provide greater information about the safety of future GE crops without an understanding of the biological significance of this data and a better understanding of the normal range of variation for the individual components in non-GE crops. For example, many of the components evaluated in current composition analysis studies are based on those for which biological and nutritional properties are known and for which established ranges in non-GE crops have been determined. It is critical to evaluate new molecular and biochemical technologies such that a complete understanding of the biological and safety significance of this data is established. Without this understanding, such techniques have limited utility in the safety assessments of GE crops.

ACKNOWLEDGEMENTS

Special thanks to my coworkers Dave Rice, Brenda Smith, Ray Layton, Ian Lamb, Carey Mathesius, Emily van de Mortel, Sule Karaman, Laura Appenzeller, Greg Ladics, Natalie Weber and Mary Locke, who provided valuable insights and editorial help in the preparation of this chapter.
