Basic Elements of Toxicology

Bryan Ballantyne, Timothy C. Marrs and Tore Syversen

CONTENTS

1 INTRODUCTION

Toxicology, essentially addressing the potentially harmful effects of chemicals to living organisms, is now a universally recognized scientific and medical discipline devoted to a large and widespread number of basic and applied issues. Although only generally accepted as a specific and defined area of knowledge and investigation since the early part of the twentieth century, its principles and implication have been appreciated for aeons. Thus, the harmful and lethal effects of certain substances, plants, fruits, insect bites, animal venoms and minerals, have been known since prehistoric times. Indeed, the Greek, Roman and subsequent civilizations knowingly used certain substances and extracts for lethality in hunting, protection, warfare, suicide and homicide. Currently, activities in toxicology are mainly centred around, though not exclusively, determining the potential for chemicals, both naturally occurring and synthetic, to produce adverse effects, and as a consequence to assess hazard and risk from such chemicals to humans and lower animal forms, thus allowing the development of appropriate precautionary, protective, restrictive and therapeutic measures. For example, substances used, or of potential use, in commerce, the home, the environment and medical practice may present variable types of harmful effects, whose nature is determined by many factors, including particularly the physicochemical characteristics of the material, its potential to interact with biological materials and the pattern of exposure.

Toxicology investigations can have far-reaching implications for health-related issues in the workplace, commerce, home and general environment. For man-made and man-used materials, a balanced critical approach may be necessary in order to assess the risk–benefit ratio for their employment in specific circumstances, and to determine what precautionary and protective measures are needed for safe use. Indeed with drugs, pesticides, industrial chemicals, food additive and cosmetic/personal care preparations, mandatory toxicology testing and regulations exist. In the UK, safety evaluation toxicology has been closely associated with pathology and experimental pathology, but in many other countries, including the USA, toxicology has been regarded as a component or branch of pharmacology. However, with the growth of toxicology it has become a major multidisciplinary science with significant overlap into other health-related science.

2 HISTORICAL DEVELOPMENT OF TOXICOLOGY

As noted in Section 1 above, toxicology in formal terms has been regarded as a relatively young science. However, the origins of toxicology are ancient, and it is likely that man, unknowingly, undertook the first experiments in toxicology in searches for an acceptable diet on moving out of the habitat in which he evolved. It is likely that many of these early excursions had an unfortunate outcome. In Greek and Roman periods, poisons, generally of plant origin, were used for murder and suicide, whilst the potential danger of medicinal products and their adulterants has been recognized since Babylonian times. Poisoning for nefarious purposes has remained a problem ever since, and much of the earlier impetus to the development of toxicology had been primarily forensic. Another motivation for the development of toxicology was the careful description of adverse reactions to medicinal products that began to appear in the eighteenth century. Thus William Withering described digitalis toxicity in 1785, and around 1790 Hahnemann, the founder of homoeopathy, carried out toxicological experiments on himself and his healthy friends with therapeutic agents of his time, including cinchona, aconite, belladonna,

ipecacuanha and mercury. The introduction of anaesthesia was followed by formal enquiries into sudden deaths during chloroform anaesthesia in the closing years of the nineteenth century.

During World War I, a variety of poisonous chemicals were used in the battlefields of northern France and Belgium. This was the stimulus for much work on mechanisms of toxicity, as well as medical countermeasures to poisoning, In fact war, or the prospect of war, played as great a part in the development of toxicology as of many other sciences. Much of the basic work on organophosphates (OPs) was stimulated by the discovery of these compounds by the Germans in the 1930s. Although defence considerations stimulated this work, much of it, particularly related to treatment, is applicable to the use in industry and agriculture of OP pesticides. Similarly, chelation therapy, initially studied in relation to organic arsenicals, is now used in the treatment of poisoning by many metals.

Occupational toxicology (see **Occupational Toxicology** and **Occupational Toxicology and Occupational Hygiene within the European Union (EU) Chemicals Regulation**) originated in the late 1600s and early 1700s with the writings of Bernardino Ramazzini, a professor of medicine in the Universities of Modena and Padua, and referred to as the father of occupational medicine. It gained impetus in the nineteenth century as a product of the industrial revolution, with early descriptions of occupational diseases induced by chemicals, such as cancer of the scrotum in chimney sweeps. Although in theory, but much less in practice, affected workers in the past had some remedies at law, major advances in the control of occupationally related diseases of chemical origin came in the period after 1960 with the setting of threshed limit values (TLVs) and occupational exposure limits (OELs). Additionally, in Western countries the increasing wealth of workers and the activities of their Unions have enabled them to make use of existing legal remedies and make representation in respect of needed improvements in occupational litigation. This has resulted in many companies having to take care of their workers and devote greater resources to industrial hygiene and occupational medicine. However, there are still clear needs for improvement in underdeveloped countries and with a few employers in Western countries.

Regulatory toxicology (see **Regulatory Toxicology**) has its origins in the development of the chemical and pharmaceutical industries in the nineteenth and twentieth centuries. The first toxicology regulation is often said to be the Alkali Act of 1863 (UK, 1863), which was intended to control pollution by heavy industry. Regulatory toxicology now accounts for a very large majority of expenditure on toxicology testing and administration. Toxicology has only come of age as a defined scientific discipline over the past few decades, as concern for worker and consumer health, and for the adverse environmental impact of xenobiotics, increased. Additionally, the growth of toxicology has been fuelled by a series of disasters such as Seveso, Bhopal, tri-*ortho*-cresyl phosphate (TOCP) poisoning incidents, methyl mercury incidents and the thalidomide tragedy, which threw up lacunae in knowledge concerning the toxic effects of substances, as well as the inadequacy of testing procedures. One of the earliest of such disasters occurred in the USA in 1937 and resulted in the deaths of 105 individuals from poisoning by an elixir of sulfanilamide containing the solvent diethylene glycol (DEG) (Calvery and Klumpp, 1939). This led to the passing of legislation in the form of the US Federal Food, Drug and Cosmetic Act, forbidding the marketing of new drugs until cleared for safety by the US Food and Drug Administration (FDA). Regulations have been elaborated at national, continental (European Union (EU) and North Atlantic Free Trade Area (NAFTA) and international levels. It is therefore disappointing and frustrating to note that contamination of medicinal formulations with DEG and resultant large-scale outbreaks of poisoning with acute renal failure, often with mortalities, has occurred on several occasions up to the present time, since the original poisoning outbreak in 1937. Most of these have been recorded in children from countries having generally lower standards of human care, and have included the following: Cape Town, 1969 (seven deaths from DEG-contaminated sedative formulations; Bowie and McKenzie, 1972); Bombay, India, 1986 (14 deaths from DEG-contaminated glycerine: Pandya, 1988); Nigeria, 1990 (47 deaths from DEG-adulterated paracetamol (acetaminophen) syrup: Okuonghae *et al*., 1992); Dhaka, Bangladesh, 1990–1992 (236 deaths of 339 children having acute renal failure from DEG-containing paracetamol (acetaminophen) elixir: Hanif *et al*., 1995); Haiti, 1996 (85 deaths in a follow-up group of 87 cases of acute renal failure from DEG-contaminated paracetamol (acetaminophen) syrup: O'Brien *et al*., 1998); Gurgaon, India 1998 (acute renal failure with 33 deaths from contaminated cough expectorant: Singh *et al*., 2001); New Delhi, India (encephalopathy and renal failure in 11 children from DEG-contaminated paracetamol elixir; Hari *et al*., 2006). In Argentina, during 1992, there were 15 deaths of 29 victims of poisoning from the use of DEG-containing propolis syrup (for upper respiratory infection) (Ferrari and Giannuzzi, 2005). A series of 64 Chinese adult patients (Guangdong Province) with severe liver disease received intravenous (iv) Armillarisin-A (3-acetyl-5-hydroxylmethyl-7-hydroxycoumarin) that contained DEG as solvent. Of these, 15 had confirmed DEG poisoning, of whom 12 died; findings in the poisoned patients included metabolic acidosis, acute renal failure and acute renal tubular necrosis with interstitial nephritis on renal biopsy (Lin *et al*., 2008). Subsequently five employees of the Qiqihar No. 2 Pharmaceutical Company of Heilongjiang Province, who

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

were responsible for allowing DEG to be used in the production of Armillarisin A, were jailed for between four and seven years (EAASM, 2008). With respect to all these cases of lethal human DEG poisoning the lessons are clearly there for all, but unfortunately unlearned by many. In some cases the DEG contamination was accidental, but in others was financially driven. DEG, an inexpensive solvent, was more profitable to use than the more expensive propylene glycol or glycerine. Stricter pharmaceutical manufacturing oversight and enforcement is required on a worldwide basis (Wax, 1996).

The main international organizations currently regulating chemicals are the Codex Alimentarious Commission (CAC), and its committees, for food standards, and the Organization for Economic Cooperation and Development (OECD) for the standardization of test methods. The International Conferences on Harmonization (ICH) and the Veterinary International Conferences on Harmonization (VICH) have attempted to harmonize test requirements for pharmaceuticals, both human and veterinary. Because of the tendency for new test methods to be introduced, often without eliminating older tests, regulations have been inclined to become ever more complex, with the result that the cost of laboratory toxicology testing has become a significantly large administrative and economic segment of product development. However, more recently introduced test methods do not always imply added costs; thus the introduction of *in vitro* genotoxicity studies may permit the avoidance of costly and time-consuming long-term *in vivo* carcinogenicity bioassays. However, the complexity of toxicological regulations may imply, not only an effect on the profits of companies developing the chemical or drug, but also loss of potentially useful substances. In some cases this has led to sufficient disquiet for legislative action to be taken. Examples of this are the 'orphan drug' procedure in the USA, and the clinical trials exemption in the UK. Industrial effects of the increasing complexity of regulatory activity have been the need to establish regulatory departments within chemical and pharmaceutical organizations for the interpretation of, adherence to, and oversight of regulations, and to establish discussion channels with appropriate government departments on safety issues related to company products. Also, for reasons of size and costs, many companies have chosen not to develop their own toxicology testing facilities, or abandon or significantly reduce their own 'in-house' facilities. This has resulted in the significant growth of the contract toxicology testing industry.

Organochlorine insecticides probably averted an epidemic of typhus at the end of World War II, but it was the persistence of these compounds in the environment that was probably the greatest stimulus to the evolution of environmental toxicology. A major landmark in the evolution of this branch of toxicology was the publication by Rachel Carson of *Silent Spring* (Carson, 1962).

The past decades have seen a gradual shift in the emphasis of toxicology from its origins in acute toxicity, particularly human, to long-term and nontarget species toxicity. More or less in parallel, stress has changed from studies of natural, usually plant, compounds to products of chemical synthesis. Additionally, in recent years considerable resources have gone into testing for carcinogenic potential, whilst there have been extensive and intensive investigations into *in vitro* alternatives to animal toxicology testing.

Clinical toxicology, concerned with the causation, diagnosis and management of poisoning was originally under the control of general physicians in general hospitals. Much of the impetus for the subsequent development of clinical toxicology came from the activities of government defence research establishments. For example, chelation therapy for heavy-metal poisoning was discovered during searches for a method to treat organic arsenical poisoning during World War II, while oximes for OP poisoning were developed during the 'cold war' in the 1950s and 1960s (see above). As a distinct specialization, clinical toxicology is relatively new domain, having developed as a consequence of the fact that general physicians may not necessarily have access to the information required to treat their patients. Currently clinical toxicology has its own certification requirements, specialized societies and journals specifically devoted to the specialization. Poison information services developed during the 1950s in the USA and UK, and the concept has since spread throughout the world. Thus poisons information centres, which have access to information on thousands of drugs and chemicals that people may become accidentally or deliberately poisoned with, are to be found in major cities in most developed countries. In many cases, units exist, not only to back up clinicians with information and to act as a general advisory service to the general population, but also to carry out hands-on management of poisoning (see also **Susceptibility of Children to Environmental Xenobiotics**; **Ethical, Legal, Social and Professional Issues in Toxicology**).

A recent development was the recognition that differing toxicology requirements may be a barrier to free trade. Within major trading blocks such as NAFTA and the EU it has been necessary to elaborate common toxicological requirements for clearance of materials, while the agreement on the application of sanitary and phytosanitary methods ('SPS agreement', WTO, 1994), achieved after tortuous negotiations in 1994, requires that, in most circumstances, CAC maximum residue levels (MRLs) for food additives, contaminants and pesticides, be accepted for world trade purposes. This inevitably raised the profile of the international expert committees, such as the Joint Expert Committee on Food

Table 1 Major driving forces for the development and increasing specialization of the scientific basis and applications of toxicology

- Exponential increase in the number of synthetically produced industrial and domestic chemicals
- Major increase in the numbers and nature of new drugs, pharmaceutical preparations, tissue-implantable materials and medical devices
- Increase in the number and nature of pesticides and related products
- Growing concern about the number of food-additive materials
- Increasing concern that environmental agents, including pesticides, chemical pollutants and naturally occurring toxins, are contributing to the causation and pathogenesis of diseases, in particular cardiovascular, neurological, pulmonary and neoplastic.
- Mandatory testing and regulation of chemicals and drugs used commercially, domestically and medicinally
- Enhanced public awareness of the potential for adverse effects from xenobiotics and naturally occurring chemicals to man, animals and the general environment
- The potential for interactions between occupational, domestic and environmental exposures and its influence on adverse effects
- Litigation, principally as a consequence of occupationally related illness, unrecognized or poorly documented product safety concerns and environmental harm. Recently, certain lawyers (of the ambulance-chasing type) are inserting advertisements on television to draw attention of the general public to adverse drug effects and offering their services for litigation against companies and prescribers (a practice that will have detrimental implications for future drug development)
- Activities of public awareness and 'watchdog' groups

Additives (JECFA) and the Joint Meeting on Pesticide Residues (JMPR).

Major, extensive and rapid developments in the scientific basis of toxicology and its practical applications have been obvious since the early 1950s. These developments have been a consequence of a variety of reasons, the major elements of which are listed in **Table 1**. Reflecting these developments has been a major proliferation in the number of textbooks and journals devoted to general and special aspects of toxicology; a proliferation of abstracting and information services; the provision of undergraduate and graduate courses and of certification requirements in general and applied toxicology; and the establishment of an industry devoted to toxicology testing and consultation. Along with these has been an increase in the number of professional organizations and certification boards specifically devoted to toxicology. As a consequence of the markedly expanded scope of toxicology, a number of circumscribed differing subdisciplines have emerged, and several major areas of subspecialization have been defined (**Table 2**).

An excellent informative demonstration on milestones in the history of toxicology has been prepared by Dr. Steven W. Gilbert and Dr. Antoinette Hayes, and is reproduced with their kind permission in **Figure 1**.

3 DEFINITION AND SCOPE OF TOXICOLOGY

Definitions of toxicology vary according to the relative importance that the defining author or authority ascribe to the component elements. Most toxicology considerations, and hence definitions, are concerned with the effects from natural or synthetic (man-made) substances, including biological toxins and a wide range of commercial and domestic chemicals. Thus, many definitions hinge around chemical toxicology. The central consideration in toxicology is the potential for the agent(s) under investigation to cause adverse (harmful) effects. Thus, in definitions of toxicology, adverse effects imply those that are detrimental to the survival or normal functioning of living organisms (Ballantyne, 1989). In view of this, some authorities and organizations have suggested that an overall definition should include 'catch all' causative agents that may produce adverse effects in biological materials. This has led to the inclusion of biological and physical agents in some overview definitions. The core of chemical toxicology is that of a discipline concerned with investigating the potential of chemicals, or mixtures of them, to produce harmful effects in living organisms and determining the implications of these effects; in this chemical-limited concept, chemicals cover naturally occurring substances (from plants, animals and microorganisms) and synthetic (man-made) materials, the latter often being referred to as xenobiotics. One overview definition covering the various elements of toxicology is as follows: 'Toxicology is a study of the interaction between chemical, biological and physical agents in biological organisms in order to quantitatively determine the potential for these agents to produce morphological and/or functional injury that results in adverse effects in living organisms, and to investigate the nature, incidence, mechanism of production, factors influencing

Table 2 Major subspecialties of toxicology

Specialty	Major functional components
Laboratory	Design and conduct of *in vivo* and *in vitro* toxicology testing programmes
Regulatory	Administrative function concerned with the development and interpretation of mandatory toxicology testing programmes, and with particular reference to ensuring the safe use, handling and transportation of substances used commercially, domestically and therapeutically, and with the development of product-safety literature and labels
Clinical	The causation, diagnosis and management of poisoning in humans
Veterinary	The causation, diagnosis and management of poisoning in domestic and wild animals
Forensic	Establishing the cause for death or intoxication in humans, by analytical procedures, and with particular reference to legal processes
Occupational	Determining the potential for adverse effects from chemicals and other agents in the occupational environment and the development of appropriate screening procedures and precautionary and protective measures
Product	Assessing the potential for adverse effects from commercially produced chemicals and formulations, and development of recommendations on safe patterns, protective and precautionary measures, and development of relevant literature for users
Pharmacological	Assessing the toxicity of therapeutic agents
Aquatic	Assessing the toxicity to aquatic organisms of chemicals discharged into marine and fresh waters
Environmental	Determining the adverse effects of toxic pollutants, usually at low concentrations, released from commercial, industrial, domestic and natural sources into the immediate environment and subsequently widely distributed by air and water current and by diffusion through soil. It differs from ecotoxicology (see below) in focussing on the effects on individuals
Ecotoxicology	Determining adverse effects and impact from synthetic or natural pollutants on populations, communities, and terrestrial, freshwater and marine animal, vegetable and microbial ecosystems. If differs from environmental toxicology (see above) in that the aim is to integrate the effects at all levels of biological organization from molecular to whole communities, and therefore is a broader discipline.
Toxicology	Determining the toxicity of substances of biological origin, including plants, animals and pathogenic microorganisms

their development, and reversibility of such adverse effects'.

Within the scope of this definition, adverse effects are those that are detrimental to either the survival or the normal functioning of a living organism. Inherent in this definition are the following key elements in toxicology, particularly with respect to chemical toxicology:

1. Chemicals, or their conversion products, are required to come into close structural and/or functional contact with tissue(s) or organ(s) for which they have a potential to cause injury.
2. When possible, the observed toxicity (or an end point reflecting it) should be quantitatively related to the degree of exposure to the chemical (the exposure dose). Ideally, the influence of differing exposure doses on the magnitude and/or incidence of the toxic effect(s) should be investigated. Such dose–response relationships are of prime importance in confirming a causal relationship between chemical exposure and toxic effect, in assessing relevance of the observed toxicity to practical (in-use) exposure conditions, and to allow hazard evaluations and risk assessment.
3. The primary aim of most toxicology studies is to determine the potential for harmful effects in the intact living organism, in many cases (and often by extrapolation) to man.
4. Toxicological investigations should ideally permit the following characterization of toxicity to be evaluated:
   (a) The basic structural, functional or biochemical injury produced
   (b) The dose–response relationships
   (c) The mechanism(s) of toxicity, that is, the fundamental chemical and biological interactions and resultant aberrations that are responsible for the genesis and maintenance of the toxic response
   (d) The factors that may influence the toxic response, for example, route of exposure, species, gender, age, formulation of test chemical and environmental conditions
   (e) The development of approaches and methods for the recognition of specific toxic responses
   (f) The reversibility of toxic effects, either spontaneously or with treatment procedures.

The word 'toxicity' is used to imply the induction of adverse effects and to describe the nature of adverse effects produced and the conditions necessary for their induction, that is, toxicity is the potential for a material to produce injury in biological systems. In some related or subdisciples of toxicology, specific terminology may be used to describe adverse effects; for example, with pharmacologically active and therapeutic agents ('drugs')

description of adverse or nondesired effects is most appropriately undertaken using certain specific terms, as discussed in Section 11.

Toxicity (i.e. the potential to injure) investigations require clear differentiation from the process of hazard evaluation, which determines the likelihood that a given material will exhibit its known toxicity under particular conditions of use.

4 DESCRIPTIVE TERMINOLOGY OF TOXIC EFFECTS

Precision in communication depends on a clear understanding of the definitions of technical and scientific terms in the context of their intended use. This section discusses the derivation and meanings of frequently used expressions in toxicology. A schematic representation of the basis for the general classification of toxic effects is given in **Figure 2**. Before toxicity can develop, a substance must come into contact with a body surface, such as skin, eye or mucosa of the alimentary or respiratory tract; these are, respectively, the cutaneous, ocular, peroral (po) and inhalation routes of exposure. Other routes of exposure, notably in experimental or therapeutic situations, are subcutaneous (sc), iv, intramuscular (im) and intraperitoneal (ip). Harmful effects that occur at the sites where a substance comes into initial contact with the body are referred to as local effects. If substances are absorbed from the sites of contact, they, or products of their bioconversion, may produce toxic effects in cells, tissues or organs remote from the site of exposure; these remote responses are referred to as systemic effects. Many substances may produce both local and systemic toxicity. Also, since the nature and probability of toxicity developing depends on the number of exposures, this forms an additional general means for classifying toxic effects into those developing after a single (acute) exposure or multiple (repeated) exposures. Repeated exposure toxicity can cover a wide timespan; however, it is descriptively convenient to refer to short-term repeated (not more than 5% of lifespan), subchronic (5–20% of lifespan) and chronic (entire lifespan or the major portion of it). Examples of toxic effects classified according to location and to number of exposures are given in **Table 3**.

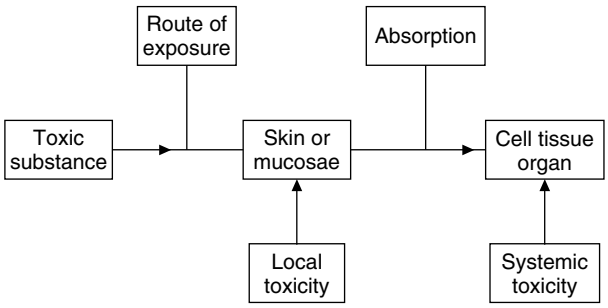

Figure 2 Schematic basis for the general classification of toxic effects.

Additional descriptions of toxicity are by the time to development and the duration of induced effects. Thus they may be described as temporary (reversible or transient) or permanent (persistent). Latent (delayed-onset) toxicity exists when there is a period free from signs following (usually) an acute exposure. Latent toxicity is of particular importance in clinical toxicology since individuals exposed to chemicals of known latency in toxicity should be kept under review in order that any delayed adverse effects may be both promptly recognized and treated. Cumulative toxicity involves progressive injury produced by summation of incremental injury resulting from successive exposures. Examples of toxicity according to the timescale for development and duration of effect are given in **Table 4**. Effects may also be classified, and described, according to the primary tissue or organ forming the target for toxicity, for example, hepatotoxic, nephrotoxic, neurotoxic, genotoxic, ototoxic, immunologic. A description of toxicity from a material requires inclusion of the following: if effects are local, systemic or mixed; their nature and (if known) mechanism of toxicity; organs and tissues affected and condition of exposure resulting in toxicity (including species, route and number or magnitude of exposure).

5 MORPHOLOGICAL AND FUNCTIONAL NATURE OF TOXIC EFFECTS

The nature and magnitude of a toxic effect depend on many factors, amongst which are the physicochemical properties of the substance, its bioconversion, the conditions of exposure, and the presence of bioprotective mechanisms. The last factor includes physiological mechanisms, such as adaptive enzyme induction, DNA repair mechanisms and phagocytosis. Some of the frequently encountered types of morphological and biochemical injury constituting a toxic response are listed below. They may take the form of tissue pathology, aberrant growth processes, altered or aberrant biochemical pathways, or extreme physiological responses.

Inflammation: This is a frequent local response to irritant chemicals or may be a component of systemic tissue injury. The inflammatory response may be acute with irritant or tissue-damaging materials, or chronic with repetitive exposure to irritants or the presence of insoluble particulate material.

Fibrosis: This production and accumulation of fibrous connective tissue may occur as a consequence of the inflammatory process.

Necrosis: Pathologically used to describe circumscribed death of tissues or cells, necrosis may result from

Table 3 Examples of toxic effects classified according to timescale and location

Exposure time	Location	Effect	Substance
Acute	Local	Skin corrosion	Methylamine
		Lung injury	Hydrogen chloride
	Systemic	Kidney injury	Phenacetin
		Haemolysis	Arsine
	Mixed	Lung injury and methaemoglobinaemia	Oxides of nitrogen
Short-term	Local	Skin sensitization	Ethylenediamine
Repeated	Local	Lung sensitization	Toluene di-isocyanate
		Nasal septum ulceration	Chromates
	Systemic	Neurotoxicity	Acrylamide
		Liver injury	Arsenic
	Mixed	Respiratory irritation and neurobehavioural	Pyridine
Chronic	Local	Bronchitis	Sulphur dioxide
		Laryngeal carcinoma	Nitrogen mustard
	Systemic	Leukaemia	Benzene
		Angiosarcoma (liver)	Vinyl chloride
	Mixed	Emphysema and kidney injury	Cadmium
		Pneumonitis and neurotoxicity	Manganese

Table 4 Examples of toxic effects classified according to the time for development or duration of the lesion

Timescale	Effect	Substance
Persistent	Testicular injury	Dibromochloropropane
	Scarring (skin/eye)	Corrosives
	Pleural mesothelioma	Asbestos
Transient	Narcosis	Organic solvents
	Sensory irritation	Acetaldehyde
Cumulative	Squamous metaplasia	Formaldehyde
	Liver fibrosis	Ethanol
Latent	Pulmonary oedema	Phosgene
	Peripheral neuropathy	Anticholinesterase organophosphates
	Pulmonary fibrosis	Paraquat

a variety of pathological processes induced by chemical injury, for example, corrosion, severe hypoxia, membrane damage, reactive metabolite binding, inhibition of protein synthesis and chromosome injury. With certain substances, differing patterns of zonal necrosis may be seen. In the liver, for example, galactosamine produces diffuse necrosis of the lobules (Mehendale, 1987), acetaminophen (paracetamol) mainly centrilobular necrosis (Goldfrank *et al*., 1990) and certain organic arsenicals peripheral lobular necrosis (Ballantyne, 1978).

Enzyme inhibition: This may decrease biological activity in biologically vital pathways, producing impairment of normal function. The induction of toxicity from enzyme inhibition may be due to accumulation of substrate or to deficiency of product or function. For example, OP anticholinesterases produce toxicity by accumulation of acetylcholine at cholinergic synapses and neuromuscular junctions (Ellenhorn and Barceloux, 1988). Cyanide inhibits cytochrome oxidase and interferes with mitochondrial oxygen transport, producing cytotoxic hypoxia (Ballantyne, 1987).

Biochemical uncoupling: Agents capable of biochemical uncoupling interfere with the synthesis of high-energy phosphate molecules, but electron transport continues resulting in excess liberation of energy as heat. Thus, uncoupling produces increased oxygen consumption and hyperthermia. Examples of uncoupling agents are dinitrophenol and pentachlorophenol (Williams, 1982; Kurt *et al*., 1988).

Lethal synthesis: This occurs when foreign substances of close structural similarity to normal biological substrates become incorporated into biochemical pathways and are then metabolized to a toxic product. A classical example is that of fluoroacetate, which becomes incorporated in the Krebs cycle as fluoroacetyl coenzyme A, which combines with oxaloacetate to form fluorocitrate. The latter inhibits aconitase, blocking the tricarboxylic acid cycle and results, particularly, in cardiac and nervous system toxicity (Albert, 1979).

Lipid peroxidation: In biological membranes free radicals start a chain of events causing cellular dysfunction and death. The complex series of events includes

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

oxidation of fatty acids to lipid hydroperoxides which undergo degradation to various products, including toxic aldehydes. The generation of organic radicals during peroxidation results in a self-propagating reaction (Horton and Fairhurst, 1987). Carbon tetrachloride, for example, is activated by a hepatic cytochrome P450-dependent mono-oxygenase system to the trichloromethyl and trichloromethyl peroxy radicals; the former radical probably covalently binds with macromolecules and the latter initiates the process of lipid peroxidation leading to hepatic centrilobular necrosis. The zonal necrosis is possibly related to high cytochrome P450 activity in centrilobular hepatocytes (Albano *et al*., 1982).

Covalent binding: Electrophilic reactive metabolites covalently binding to nucleophilic macromolecules may have a role in certain genotoxic, carcinogenic, teratogenic and immunosuppressive events. Important cellular defence mechanisms exist to moderate these reactions, and toxicity may not be initiated until these mechanisms are saturated.

Oxidative stress: Oxidative stress induces injury to cells by excessive production of reactive oxygen species (ROS) having high reactivity against DNA, lipids and proteins (Pérez *et al*., 2006).

Receptor interaction: Occurs at a cellular or macromolecular level and involves specific chemical structures modifying the normal biological effect mediated by the receptor; these may be excitatory or inhibitory. An important example is effects on Ca^{2+} channels (Braunwald, 1982).

Endocrine disruption: A number of xenobiotics found in both human community and wildlife environments have been shown to have a potential to disrupt endocrine functions. Endocrine disrupting effects of chemicals have a potential to cause reproductive problems and increase the risk for development of endocrine-dependent cancers. Interference with steroid biosynthesis may have adverse effects on sexual differentiation, growth and development (Sanderson, 2006). Additionally, there have been studies on the interactions between xenobiotics and hormone receptors, particularly thyroid hormone, oestrogen and androgen receptors.

Immune-mediated hypersensitivity: Such reactions stimulated by antigenic materials are particularly important considerations for skin and lung resulting in allergic contact dermatitis, respiratory sensitization and asthma (Cronin, 1980; Brooks, 1983; Bardana *et al*., 1992; Isola *et al*., 2008; see also **Cytogenetics**; **Allergic Asthma and Rhinitis: Toxicological Considerations**; **Assessing Impacts of Environmental Contaminants on Wildlife**). Skin-sensitizing potential, a Type VI hypersensitivity reaction, can be investigated by standard *in vivo* studies in laboratory animals, such as occluded patch tests (Buehler, 1965) and the guinea-pig maximization procedure (Magnusson and Kligman, 1969; Magnusson and Kligman, 1970), and by induction of the response by the local lymph node proliferation assay (Gerberick *et al*., 2000; Hilton *et al*., 1998; Kimber *et al*., 1994; 2001; Ryan *et al*., 2008), and where considered necessary confirmed by the human repeat insult patch test. Recently, various changes in epidermal Langerhans cells have been suggested as possibly forming the basis for the development of *in vitro* assays for assessing skin sensitization potential (Ryan *et al*., 2005). Respiratory sensitization, mediated by IgE- and Th2-cell responses, cannot be predicted by conventional repeated inhalation exposure studies, but can addressed by studies such as the mouse IgE test and cytokine fingerprinting (Dearman and Kimber, 2001; Dearman *et al*., 2003; Kimber *et al*., 2002; Holsapple *et al*., 2006).

Immunosuppression: Suppression of the immune system by xenobiotics may have important repercussions with respect to increased susceptibility to infective agents and certain aspects of tumorigenesis.

Neoplasia: Agents stimulating neoplasia cause an aberration of tissue growth and control mechanisms of cell division, and result in abnormal proliferation and growth. This is a major consideration in repeated exposure to xenobiotics. The terms tumorigenesis and oncogenesis are general expressions used to describe overall the development of neoplasms; the word carcinogenesis should be restricted specifically to malignant neoplasms. In experimental and epidemiological situations, oncogenesis may be exhibited as an increase in the total number of neoplasms, an increase in specific types of neoplasm, the occurrence of 'rare' or 'unique' neoplasms or a decreased latency to detection of neoplasms.

Chemical carcinogenesis is a multistage process. Simplistically, the first, and critical, stage is a genotoxic event followed by other processes leading to the pathological, functional and clinical expression of neoplasia. One multistep model that has received much attention is the initiator–promoter scheme (**Figure 3**). The first stage, that of initiation, requires a brief exposure to a genotoxically active material which results in binding of the initiator or reactive metabolite to cellular DNA; there is a low, or no, threshold for this initiation stage. The second stage, that of promotion, permits the expression of the carcinogenic potential of the initiated cell. Promoting agents have the following characteristics:

- They need not be genotoxic
- Pepeated exposure is required after initiation
- They show some evidence for reversibility
- They may have a threshold for promoting activity.

Figure 3 Schematic representation of inter-relationships between initiator and promoter in the two-stage mechanism of carcinogenesis: (A) an initiating dose of a genotoxic carcinogen is not by itself oncogenic; (B) if the initiating dose is followed by multiple applications of an epigenetic promoter, neoplasia results (the classical initiator–promoter relationship); (C) if promotion is delayed following initiation, a neoplastic response occurs indicating a persisting initiating effect; (D) if promoter dosing is infrequent or doses are small, there may not be a neoplastic response or a low tumour incidence, indicating a threshold for the the promoting effect; (E) multiple applications of an epigenetic promoter alone due not result in neoplasia; (F) initiation must precede promotion; (G) a genotoxic carcinogen may act as both initiator and promoter.

Genotoxic initiators may also act in a promotional manner following initiation. Substances causing or enhancing a carcinogenic process may be conveniently described as genotoxic and epigenetic carcinogens; the former are capable of causing DNA injury and the latter exert onocogenic effects by mechanisms (epigenetic) other than direct genotoxicity. Genotoxic materials acting directly with DNA are referred to as primary carcinogens; those requiring metabolic activation are procarcinogens, with the metabolically active electrophile being the ultimate carcinogen. Examples of primary carcinogens include alkylene epoxides, sulfate esters and nitrosoureas; procarcinogens include polycyclic aromatic hydrocarbons, aromatic amines, azo dyes and nitrosamines.

Epigenetic carcinogens include the following differing functional classes: promoters, cocarcinogens, hormones, immunosuppressives and solid-state materials. Cocarcinogens, when applied just before or with genotoxic carcinogens, enhance the oncogenic effect. Various mechanisms may cause enhancement, including increased absorption, increased metabolic activation of procarcinogen, decreased detoxification or inhibition of DNA repair. One group of epigenetic carcinogens are the peroxisome proliferators, which induce liver tumours in experimental rodents. These materials produce hepatomegaly and hepatocyte peroxisome proliferation and induce several liver enzymes, including those of the peroxisomal fatty acid β-oxidation system. Phthalate esters are one class of compound producing peroxisomal proliferation and experimental hepatocarcinogenesis (Rao and Reddy, 1987). A threshold may exist with epigenetic carcinogens, but there is disagreement about the way in which data from studies with epigenetic carcinogens should be analysed for risk-assessment purposes.

5.1 Genotoxicity

Genotoxic chemicals, which interact with DNA and possibly lead to heritable changes, may be conveniently classified as clastogenic or mutagenic.

Clastogenic effects occur at the chromosomal level and are usually visible by light microscopy. They may involve simple breaks, rearrangement of segments, or gross destruction of chromosomes. Severe clastogenic effects may be incompatible with normal function, and cell death occurs. The relevance of chemically induced sublethal cytogenetic effects is not totally understood, but could lead to dysfunction of the reproductive system and other tissues with rapid cell turnover rates (see **Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation**; **Carcinogenesis and Carcinogens that are also Genotoxic**).

Mutagenic effects are focal molecular events in the DNA molecule, which involve either substitution of a base pair or deletion or addition of a base. Base-pair transformations ('point mutations') may occur by direct chemical transformation, incorporation of abnormal base analogues or alkylation. Addition or deletion of a base will result in a disturbance of the triplet code and hence alteration of the codon sequence distal to the addition or deletion ('frameshift mutation'). Intracellular DNA repair enzymes are present, but if the capacity of repair mechanisms is exceeded then abnormal coding will be transcribed into RNA and expressed as altered protein structure and possibly function, depending on the molecular segment affected. As noted above, it is considered that in genotoxic carcinogenesis the molecular DNA event of initiation is fundamental to multistage oncogenesis. There is now considerable evidence showing a good correlation (with some test systems) between carcinogenic and mutagenic potential. Thus, the use of certain mutagenicity tests procedures has become widely accepted as a means of screening chemicals for their carcinogenic potential (Krisch-Volders, 1984; Brusick, 1988; see **Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation**).

Over the past decade there has been considerable interest and major developments in the field of toxicogenomics (Borlak, 2005; Hamadeh and Afshari, 2004; see **Reactive Oxygen Species in the Induction of Toxicity**). Toxicogenomics is concerned with a study of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the complex interactions between the cellular genome, toxic agents, organ dysfunction and the disease state (Gatzidou *et al*., 2007). Following exposure of an organism to a toxic agent there is a cellular response exhibited as an alteration of the gene expression, which through transcription into messenger RNA (mRNA) results in altered protein synthesis and function. A major technical advance relating to defining molecular events in toxicogenomics is that of microarray technology, which permits the simultaneous analysis of the transcriptional expression level for thousands of individual genes under various physiological conditions (de Longueville *et al*., 2004). As a molecular complement, post-transcriptional and post-translational events can be investigated using high-throughput proteomics or wider metabolic aspects by metabolomics (Robertson, 2005). These approaches permit a detailed molecular perspective on how an organism responds to stress or xenobiotics. The applications of toxicogenomics have been broadly classified into two overlapping areas: mechanistic research and predictive toxicology (Cunningham, 2006; Cunningham *et al*., 2003; Gatzidou *et al*., 2007; Pennie *et al*., 2000). Transcript profiling is a major factor for understanding a mode of action and the detection of the induction of patterns of gene expression changes, and is the basis for predictive toxicology. Studies indicate that short-term gene expression profiles are likely to have significant potential for predicting carcinogenicity (Ellinger-Ziegelbauer *et al*., 2004; Fielden *et al*., 2008). Microarray technology has become a powerful tool to explore the expression levels of thousands of genes or even complete genomes after exposure to xenobiotics, but a major current challenge in toxicogenomics is functional interpretation, linking potentially inter-related alterations in gene expression to conventional toxicological end points (Moggs, 2005; Yu *et al*., 2006).

5.2 Reproductive and Developmental Toxic Effects

These aspects of toxicology are concerned with, respectively, adverse effects on the ability to conceive and adverse effects on the structural and functional integrity of the conceptus up to and around parturition.

Adverse effects on reproduction may result from a variety of differing mechanisms on reproductive organs and their neural and endocrine control mechanisms (Barlow and Sullivan, 1982). Developmental toxicity deals with adverse effects on the conceptus from the stage of zygote formation, through the stages of implantation, germ layer differentiation, organ formation and growth processes during intrauterine development and the neonatal period. The most extreme toxicity, death, may occur as preimplantation loss, embryo resorption, foetal death or abortion. Nonlethal foetotoxicity may be expressed as delayed maturation, including decreased body weight and retarded ossification. Structural malformations (morphological teratogenic effects) may be external, skeletal or visceral. The preferential susceptibility of the conceptus to chemical (and other environmental) insults in comparison with the adult state is related to: (i) the small numbers of cells and their rapid proliferation rates; (ii) a large number of nondifferentiated cells lacking defence capabilities; (iii) requirements for precise spatial and temporal interactions of cells; (iv) limited metabolic capacity and (v) immaturity of the immunosurveillance system (Tyl, 1988). There is now considerable awareness that functional, in addition to structural, malformations of development may occur, and this is reflected in the increased monitoring in developmental toxicity studies. Malformation from chemical exposure may result from, amongst other mechanisms: (i) genotoxic injury; (ii) interference with nucleic acid replication, transcription or translation; (iii) essential nutrient deficiency and (iv) enzyme inhibition. The most sensitive period for induction of structural malformations is during organogenesis. Functional teratogenic effects may be induced at later stages, particularly neurobehavioural disturbances (Rodier, 1980).

5.3 Pharmacological Effects

These may be induced by drugs and chemicals generally and usually involve interaction between causative agent and cell receptors resulting in suppression or exaggeration of physiological functions expressed normally by the involved receptor(s). This differentiates pharmacological effects from toxic effects, with the latter being, by definition, adverse in nature. The receptor–agent complex is reversible and thus the induced effects are transient. However, marked (potent) pharmacological effects may cause significant physiological hyper- or hypofunction, and in these cases there are borderline or overlapping considerations with toxicity. Pharmacological effects can be a cause of temporary incapacitation or inconvenience in the occupational environment, as well as side-effects of medication. For example, narcosis from acute overexposure to an organic solvent may clearly be of relevance in safe workplace considerations; such a reversible narcosis needs to be differentiated from central nervous system injury resulting from long-term, low-concentration solvent exposure (World Health Organization, 1985). Another important pharmacological effort, particularly from airborne materials in the workplace, is peripheral sensory irritation. Materials having such effects interact with sensory nerve receptors in skin or mucosae, producing local discomfort and related reflex effects. For example, with the eye there is pain or discomfort, excess lacrimation and blepharospasm. Although such effects are

warning and protective in nature, they are also distracting and thus likely to predispose to accidents. For this reason, peripheral sensory irritant effects are widely used in defining, along with other considerations, exposure guidelines for workplace environments (Ballantyne, 1984; see **The Influence of Temperature on Toxicity**).

6 DOSAGE–RESPONSE RELATIONSHIPS

6.1 General Considerations

A fundamental concept in biology is that of variability. Individual members of the same grouped species and strain differ to variable degrees with respect to their biochemical, cellular, tissue, organ and overall characteristics. Additionally, within a given individual there is a spectrum of variability in certain features, for example, cell size and biochemical function within a particular cell series. The differences between individuals are, at least in part, a consequence of genetic factors and age. Since toxicity is the result of adverse effects on biological systems, or modifications of defence mechanisms, it is not unexpected that the majority of toxic responses will also show variability between individuals of a given strain. Also, because of genetic and biochemical variability, even larger discrepancies in response will be observed between species. It is axiomatic to the toxicologist that, within certain limits and under controlled conditions, there is a positive relationship between the amount of material to which given groups of animals are exposed and the toxic response, and that the response of a given animal may differ quantitatively from that of other animals in the same dosage group. As the amount of material given to a group of animals is increased, so does the magnitude of the effect and/or the number who are affected. For example, a specific amount of a potentially lethal material given to a group of animals may not kill all of them; however, as the amount of material is increased, so the proportion dying increases. This reflects the variability in the susceptibility of the population studied to the lethal toxicity of the test substance. Likewise, if an irritant material is applied to the skin, as the amount is increased over a given area this is associated with: (i) an increase in the number of the population affected and (ii) an increase in the severity of the inflammation. For the two examples given above, death is an 'all-or-none' response (a quantal response), whereas inflammation may be considered from a dose–response viewpoint as having two elements, that is, its presence or otherwise, and the degree of inflammation which represents a continuous (or graded) response. The above considerations, which reflect variability in biological systems, form the basis for the fundamental concept of dose–response relationships in both pharmacology and toxicology, there usually being a positive relationship between dose and response *in vivo* and in many *in vitro* test systems.

It follows from the above discussion that the amount of material to which an organism is exposed is one prime determinant of toxicity. The dose–response relationships for differing toxic effects produced by a given material in a particular species may vary. Thus, as discussed later, dose–response relationships have to be carefully interpreted in the context of the effect studied and the particular conditions under which the information was collected.

The word 'dose' is most frequently used to denote the total amount of material to which an organism or test system is exposed, and 'dosage' defines the amount of material given in relation to a recipient characteristic (e.g. weight). Dosage allows a more meaningful and comparative indicator of exposure. For example, 500 mg of a material given as a po dose to a 250 g rat or a 2000 g rabbit will result in dosages of 2 and 0.25 mg (kg body weight)$^{-1}$, respectively. It follows that comparative dosing studies should be expressed in dosage units. Dose in most reports usually implies the exposure dose, that is, the total amount of material that is given to an organism by the particular route of exposure, or the amount incorporated into a test system. Another expression of dose is absorbed dose, which is the amount of material penetrating into the organism through the route of exposure. Absorbed dose may show a closer quantitative relationship with systemic toxicity than exposure dose, since it represents the amount of material directly available for metabolic interactions and systemic toxicity. A further expression of dose is target-organ dose, which is the amount of material (parent or metabolite) received at the organ or tissue exhibiting a specific toxic effect of interest. This should be expressed (if possible) in terms of the mechanistically causative molecule (parent chemical or reactive metabolite). Clearly, target-organ dose is a more precise quantitative indication of toxicity than exposure dose, since it is a measure of the amount of material at the site of toxicity, whereas exposure dose is total dose to the organism and only a proportion of this (or a metabolite) will ultimately gain access to the target site(s) for the toxic response. However the estimation of target or organ-tissue dose requires a detailed knowledge of the pharmacokinetics and metabolism of the material. For this reason, most information relates to the exposure dose.

The exposure dose is of practical importance since it reflects the amount of material to which the organism is actually exposed and its relationship to the likelihood of the development of a particular toxic end point, and therefore is of particular use for hazard-evaluation purposes. Absolute target-organ doses, on the other hand, allow a more detailed biological evaluation of toxicity in relation to bioavailable chemical, and when related to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

exposure dose may be used for rational risk-assessment procedures.

If a material is capable of inducing several differing types of toxicity, the dose (or dosage) of material required to cause the individual effects may differ, with the more sensitive toxic effect appearing at the lower dosages. The first distinct toxicity, at lower dosages, may not necessarily be the most logically significant effect. For example, with epicutaneously applied materials, local inflammation may appear before more sinister systemic toxicity. Conversely, if the most significant toxicity occurs at lower dosages, then other toxicity at higher dosages may be of lesser interpretive significance.

6.2 Expression of Dosage–Response Relationships

As discussed above, with a given population there is a quantitative variability in susceptibility to a chemical by individual members of that population. Thus, with a genetically homogeneous population of animals of the same species and strain, the proportion exhibiting a particular toxic effect will increase as the dosage increases. This is shown schematically in **Figure 4** as a cumulative frequency distribution curve, where the number of animals responding (as a proportion of the total in the group) is plotted as a function of the dosage given (as a $\log_{10}$ function). In many instances there is a sigmoid curve, with a log-normal distribution and being symmetrical about the mid-point. This is a typical dosage–response relationship, often loosely referred to as a dose–response relationship. There are several important elements to this curve that require consideration when interpreting its toxicological significance:

- The majority of individuals responding do so symmetrically around the mid-point (i.e. the 50% response value). The position of the major portion of the dosage–response curve around its mid-point is sometimes referred to as the potency.
- The mid-point of the curve (50% response point) is a convenient description of the average response, and is referred to as the median effective dosage (ED_{50}) for the effect being considered. If mortality is the end point, then this is specifically referred to as the median lethal dosage (LD_{50}). The ED_{50} is used for the following reasons: (i) it is at the mid-point of a log-normally distributed curve and (ii) the 95% confidence limits are narrowest at this point.
- A small proportion of the population, at the left-hand side of the dosage–response curve, respond to low dosages; they constitute a hypersusceptible or hyper-reactive group.
- Another small proportion of the population, at the right-hand side of the curve, do not respond until higher dosages are given; they constitute a hyposusceptible or hyporeactive group.
- The slope of the dosage–response curve, particularly around the median value, gives an indication of the range of doses producing an effect. It indicates how greatly the response will be changed when the dosage is altered. A steep slope indicates that a majority of the population will respond over a narrow dosage range, and a shallower slope indicates that a much wider range of dosages is required to affect the majority of the population.

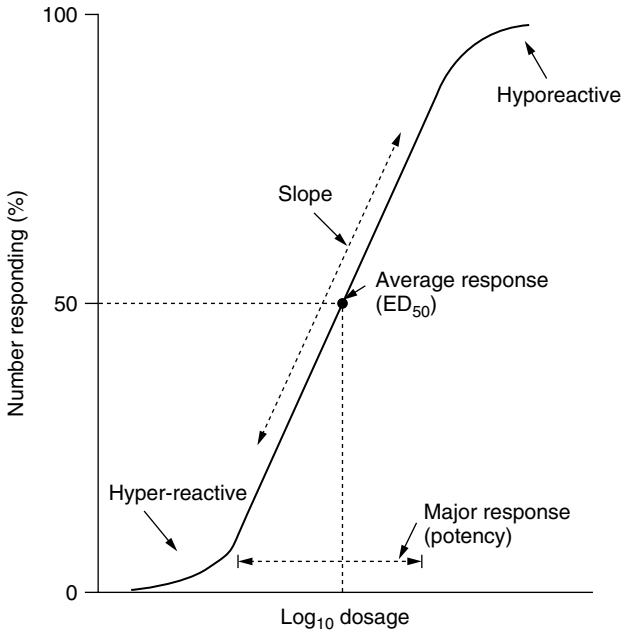

Figure 4 Sigmoid dosage–response curve for a toxic effect plotted as proportionate response against $\log_{10}$ dosage. The curve is typically symmetrical about the average (50% response) point. The major response (potency) occurs around the average response. The slope of the curve is is determined by the increase in response as a function of incremental increases in dosage. Hyper-reactive and hyporeactive individuals in the group are at the extreme left- and right-hand sides of the curve, respectively.

The shape of the dosage–response curve, and its extreme portions, depend on a variety of endogenous and exogenous factors; the former may include cellular defence mechanisms and reserves of biochemical function. Thus, toxicity may not be initiated until cellular defence mechanisms are exhausted, or a biochemical detoxification path is near saturation. Also, saturation of a biochemical process that produces toxic metabolites may result in a plateau for toxicity.

An important variant of the sigmoid dosage–response curve may be seen with genetically heterogeneous populations, where the presence of an usually high incidence in the hypersusceptible area could indicate the existence

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

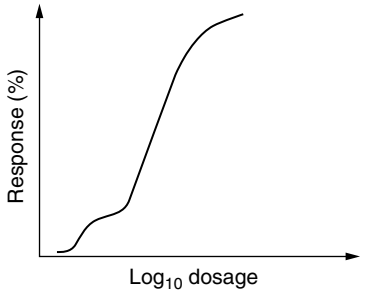

Figure 5 Variant of the sigmoid cumulative dosage–response curve resulting from an enhanced hyper-reactive response. This can represent a genetic variant in a proportion of the population causing an enhanced sensitivity to the toxic effect.

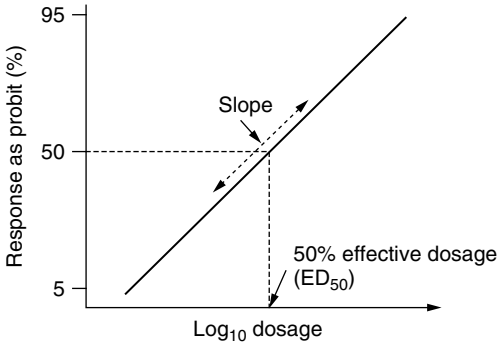

Figure 6 Linear transformation of dosage–response data by log-probit plot.

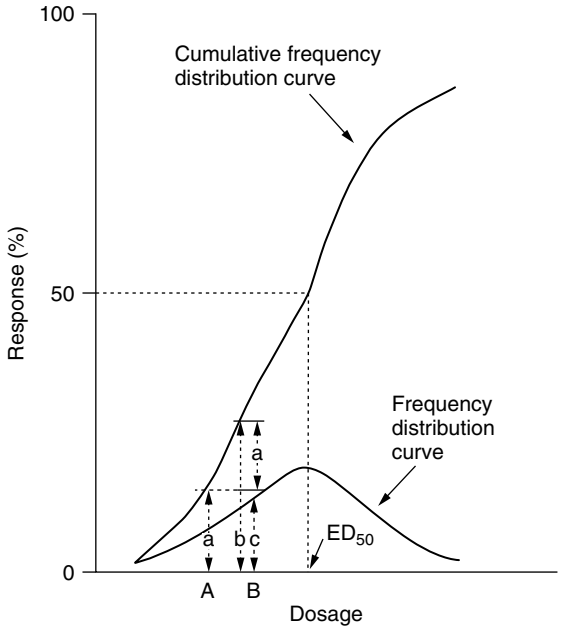

Figure 7 Relationships between a cumulative frequency distribution curve and a normal frequency distribution curve for quantal data. The cumulative frequency distribution curve shows the proportionate response for each dosage, and the expected total response for any given dosage. The normal frequency distribution curve shows the response specific for a given dosage compared with lower dosages. For the normal frequency distribution curve, the response (c) at any given dosage (e.g. at B) is obtained by taking the total response at that dosage (b) and subtracting the response (a) at the immediately lower dosage.

of a special subpopulation that have a genetically determined hypersusceptibility to the substance being tested (**Figure 5**).

Data plotted on a dosage–response basis may be quantal or continuous. The quantal response is 'all-or-none', for example, death. The graded, or variable, response is one involving a continual change in effect with increasing dosage, for example, enzyme inhibition, degree of inflammation or physiological function, such as heart rate. The dosage–response curve is often linearly transformed into a log-probit plot ($\log_{10}$ dose vs. probit response) because it permits the examination of data over a wide range of dosages, and allows certain mathematical procedures (e.g. calculation of confidence limits and slope of response) (**Figure 6**). Quantal data can also be plotted as a frequency histogram or frequency distribution curve; this is done by plotting the percentage response at a given dose minus the percentage response at the immediately lower dose (i.e. response specific for the dosage). This procedure usually results in a Gaussian distribution (**Figure 7**), reflecting the differential biological susceptibility of the test organism to the treatment. In such a normal frequency distribution curve the mean ± 1 standard deviation (SD) represents 68.3% of the population, the mean ± 2 SD represents 95.5% and the mean ± 3 SD is 99.7% of the population. It is important to stress that not only will the incidence of the effect of interest vary with dosage, and determine the dosage–response relationship, but also the severity or magnitude of the effect will change with varying dosage. Thus, for any given dosage producing a particular response incidence, those responding may show a difference in the magnitude of the effect.

The absence of a clear dosage–response relationship in a controlled experiment may indicate a nontoxic or nonpharmacological action of the material. For example, an aminoalkyltrialkoxydisilane given by gavage to rats resulted in the following mortalities (expressed as (number dying/number dosed)): $16\,g\,kg^{-1}$ (4/5), $8\,g\,kg^{-1}$ (0/5), $4\,g\,kg^{-1}$ (3/5) and $2\,g\,kg^{-1}$ (0/5). Clearly, there was no dosage–response relationship in this study. Necropsy of dying rats showed that polymerization of the material had occurred in the stomach, producing a hard, opalescent, solid mass completely occluding the stomach. Hence, the cause of death was a consequence of mechanical obstruction and nutritional deprivation, rather than intrinsic toxicity.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

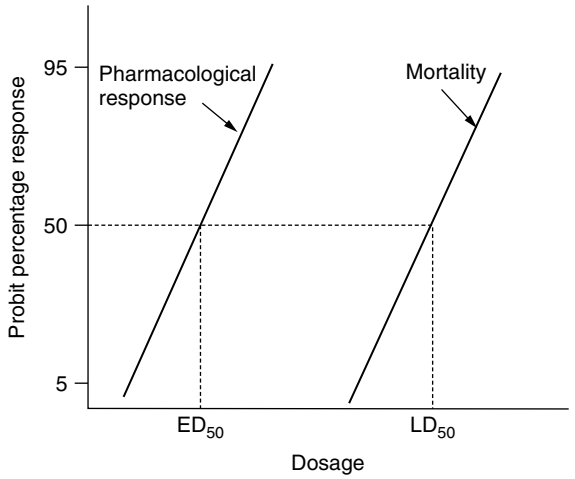

Figure 8 One simplistic method to assess 'safety ratios' for drugs is by comparing the ratio of the therapeutically effective dosage (ED_{50}) to that causing mortality (LD_{50}); the ratio LD_{50}/ED_{50} is referred to as the 'therapeutic index' (TI). For parallel pharmacological effect and lethality dosage–response lines, the TI will be similar over a wide range of dosages, as shown in the figure above. However, nonparallel lines may give misleading conclusions if the TI_{50} is calculated (see **Figure 9**).

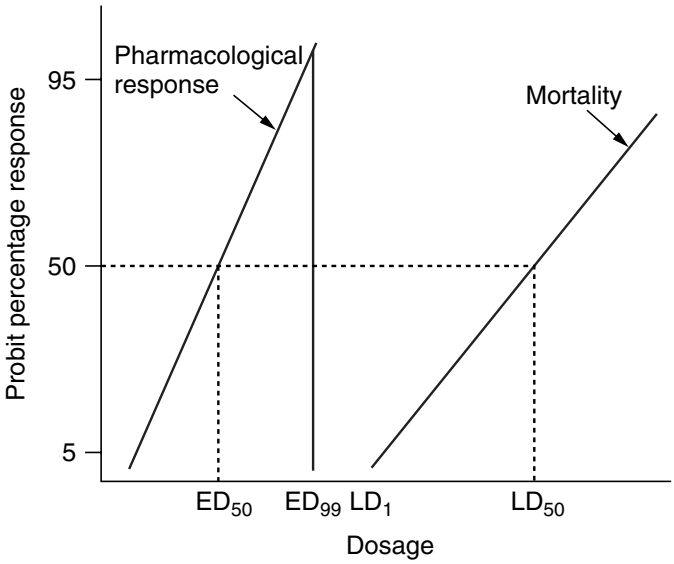

Figure 9 The TI_{50} may give misleading information if the dosage–response lines for pharmacological and lethal effects are not parallel. In the example shown here, there may be a reasonable safety margin based on the LD_{50} and ED_{50} considerations. However, due to the shallower slope of the mortality dosage–response line, the TI will be significantly lower at the 1 and 5% levels, and thus the hyper-reactive group may be at greater risk. In this case a better index of safety will be the ratio of LD_1/ED_{99}, which is referred to as the 'margin of safety'.

For drugs, one convenient indication of 'safety' often used is the ratio of the median effective dose causing death to that producing the desired therapeutic response (i.e. LD_{50}/ED_{50}); this is frequently referred to as the therapeutic index (TI_{50}). In general, the higher this ratio, the greater is the degree of safety with respect to lethality. However, very considerable caution is needed in applying this information. For example, if the slopes of the dosage–response curves for drug effectiveness and lethality are parallel, then the assumption of an equal therapeutic ratio over a range of dosages and to a majority of the population is justified (**Figure 8**). If, however, the dosage–response curve for lethality is shallower than that for the therapeutic response (**Figure 9**), then there will be a decreasing TI at the lower dosages, and the hyperreactive groups may be at greater risk. One approach which can be used to take into account differences in slopes is to calculate the ratio between the dosage causing a 1% mortality (LD_1) and that producing near maximum therapeutic efficacy (ED_{99}). This ratio, LD_1/ED_{99} is referred to as the 'margin of safety' (**Figure 9**). A complete appraisal of safety-in-use, of course, also requires considerations on sublethal and long-term toxicity, and at therapeutic dosages the likelihood of side effects and idiosyncratic reactions.

The slope of the dosage–response relationship, particularly around the mid-point, can be of value for more precisely assessing hazard or potential for overdose situations. Thus, for example, in considering lethality, a steep slope indicates that a large proportion of the population will be at risk over a small range of doses. Likewise, with a material producing central nervous system depression, a steep slope implies that a small incremental increase of dosage may result in coma rather than sedation.

In most cases of acute lethal toxicity, the dosage–response curve is a log-normal cumulative frequency distribution or Gaussian frequency distribution. In a few cases, however, there may be two definite peaks in the frequency-distribution curve; this is distinct from an increase in hyper-reactive groups at the left-hand side of the dosage–response curve and is known as a bimodal distribution; it may reflect different modes of toxicity possibly with differing latencies. Such a bimodal distribution may reflect different modes of lethality toxicity possibly with differing latency. Earlier deaths at the lower dosages, producing the first phase of the bimodal distribution, represent a quantitatively more potent toxicity; those surviving the first phase toxicity may succumb to the higher dosage latent toxicity. For example, with op anticholinesterase, the first deaths are due to the cholinergic crisis resulting from acetylcholinesterase inhibition, and late toxicity may result from delayed-onset peripheral neuropathy. In some cases, log-probit plots will allow the determination of ED_{50} values for each subgroup in the bimodal distribution.

For many toxic effects, except genotoxic carcinogenesis, there is a dose below which no effect or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

response can be elicited; this corresponds to the extreme left-hand side of the dosage–response curve. This dosage, below which no effect occurs, is referred to as the 'threshold dosage'. The threshold concept, a corollary of the dosage–response relationship, is important in that it implies that it is possible to determine a 'no-observable effect level' (NOEL), which can be used as a basis for assigning 'safe levels' for exposure.

6.3 Applications of Dosage–Response Information

It is important to reiterate that conclusions drawn from dosage–response studies are valid only for the specific conditions under which the information was collected. Within this constraint, dosage–response information allows at least the following:

1. Confirmation that the effect under consideration is a toxic (or pharmacological) response to the chemical or therapeutic agent. Thus, a positive dosage–response relationship is good evidence for a causal relationship between exposure and the development of toxicity or pharmacological effects.
2. Quantitative dose–response information allows the determination of an average (median) response, gives the range of susceptibility in the population studied, and indicates where the dosage for hypersusceptible groups is expected.
3. The slope of the dosage–response curve gives information on the range of effective dosages and the differential proportion of the population affected for incremental increases in dosage. With a shallow slope the range of effective doses is widespread; the proportion of the population additionally affected by incremental increases in dosage is small. In contrast, a steep slope implies that the effective dose for the majority of the population is over a narrow range, and there will be a significant increase in the proportion of the population affected for small incremental increases in dosage.
4. The shape of the left-hand side of the dosage–response curve may indicate the existence of an unusually high hypersusceptible proportion of the population. This may, for example, indicate a genetically determined increased susceptibility to the chemical or pharmacologically active substance studied.
5. Quantitative comparison for a specific end point may be made between different materials with respect to average and range of response, particularly if the information has been collected under similar conditions.
6. The data may allow conclusions on 'threshold' or 'no-effect' dosages for the response or the determination of those concentrations or doses that do not result in the appearance of any effects due to exposure to the substance tested (NOEL) or do not cause the development of effects regarded as potentially biologically harmful (no observed adverse effect level (NOAEL)). Recently there has been the development of a concept of benchmark dose (BMD) as an alternative to the NOAEL, or compromise between the NOAEL and the lowest observable adverse effect level (LOAEL). The BMD concept, introduced by Crump (1984), is the dose of a material that is required to achieve a predetermined response of a toxicological effect. For quantal data, the BMD involves fitting a dose–response curve to bioassay data, and the dose (or lower bound on the dose) corresponding to a given low-level response on the fitted curve (e.g. a 5 or 10% elevation in incidence over background: BMD_{05}, BMD_{10}) selected as a characterization of the dose level at which a detectable increase in the measured effect of interest occurs (Sand *et al*., 2008; Rhomberg, 2005). Also cited are the lower 95% confidence limits on the BMD; for example, $BMDL_{05}$.

For continuous data, it has been standard to define the BMD as corresponding to a percentage change in response relative to background (Sand *et al*., 2008). Also, for continuous dose–response data, Sand *et al*. (2006) proposed an approach that defines the BMD as the dose at which the slope of an S-shaped dose–response relationship changes the most in the low dose region. The dose is in a transition region where the sensitivity to chemical exposure may start to change noticeably. After the application of appropriate uncertainty factors (UFs), the BMD is used for the determinations of certain safe dose values, such as acceptable intakes or reference doses (RfDs). The fact that the BMD approach involves uncertainty analysis has been cited as a major improvement over the NOAEL approach (Sand *et al*., 2008). Another frequently cited dose is the reference dose (RfD), which is an estimate of a daily exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime (Barnes, 2000). In general, the RfD is calculated from the NOAEL, derived from animal studies, with the application of UFs and a modifying factor (MF):

$$\text{RfD} = \text{NOAEL}/\text{UFs} \times \text{MF} \quad (1)$$

In the simplest case, the NOAEL is divided by two Ufs of 10 each, in order to address extrapolation from animal to human and the sensitivity within the human population respectively; in such cases an MF of 1 is used:

$$\text{RfD} = \text{NOAEL}/10 \times 10 \times 1 \quad (2)$$

As noted above, the derivation has generally involved the application of a 100-fold safety factor to a measure of the threshold for toxicity, such as the NOAEL or BMD. This 100-fold factor is composed of two 10-fold factors allowing for human variability and species differences. It has been proposed that the 10-fold factors can be refined with a chemical-specific adjustment factor (CSAF) when suitable data are available (WHO, 2001). Such refinements would emphasize pathway-related factors associated with variability in kinetics, and derived from databases that quantify interspecies differences and human variability in Phase I metabolism, Phase II metabolism and renal excretion (Dorne and Renwick, 2005).

The above considerations are briefly illustrated in the following section for acute lethal toxicity.

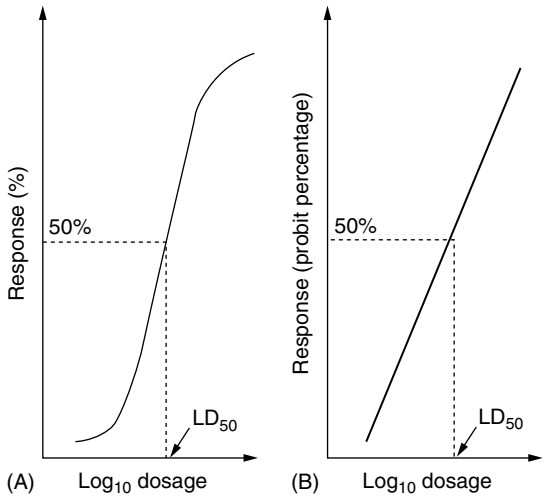

Figure 10 Dosage–mortality data plotted (A) as a cumulative frequency distribution curve (% response versus $\log_{10}$ dosage) and (B) linearly transformed by log-probit plot.

6.4 Dosage–Response Considerations for Acute Lethal Toxicity

Death, a quantal response, is an end point incorporated in many acute toxicity studies, and often used for the calculation of LD_{50} values. Acute lethal toxicity studies involve giving differing dosages of the test material to groups of laboratory animals of the same strain by a specific route of exposure and under controlled experimental conditions, e.g. with respect to diet, caging, temperature, relative humidity and time of dosing. Mortalities at each dosage are recorded over a specified period of time, usually 14 days. By epicutaneous or respiratory exposure, the exposure time should be stated, since the degree of local injury and the potential for systemic toxicity are a function of this time, as well as the exposure dosage. For routes other than inhalation, the exposure dosage is usually expressed as mass (or volume) of test material given per unit of body weight, for example, ml (kg body weight)$^{-1}$ or mg (kg body weight)$^{-1}$. For inhalation, the exposure dose is expressed as the amount of test material present per unit volume of exposure atmosphere: mg m^{-3} or ppm. Dose–response information collected for differing concentrations of an atmospherically disposed material should be over similar periods of time in order to allow the most meaningful comparisons to be made. Alternatively, the effect of differing inhalation exposure doses can be made by exposing different groups to the same concentration of test substance for various exposure periods; this may allow the calculation of a median time to death (50% response rate) for the population exposed to a specific atmospheric concentration of test material (LT_{50}). By using both of these approaches it is possible to reach conclusions on the differential sensitivity of a population to varying concentrations for a specified period of time, or to differing exposure periods for a given concentration.

Dosage–mortality data usually conforms to the sigmoid cumulative frequency distribution curve (**Figure 10A**), which may be converted to a linear form using a log-probit plot (**Figure 10B**). Lethal toxicity is usually initially calculated and compared at a specific mortality level; most frequently used is that causing 50% mortality in the population studied, since this represents the midpoint of the dosage range about which the majority of deaths occur and usually with a symmetrical distribution. This is the median lethal dose for 50% of the population studied (LD_{50}), that is, that dose, calculated from the dosage–mortality data, which causes death of half of the population dosed under the specific conditions of the test. This concept of the LD_{50} was introduced by Trevan (1927). By inhalation, the reference is the lethal concentration$_{50}$ (LC_{50}) for a specified period of time (i.e. x h LC_{50}). Other values calculated include the LD_5 and LD_{95}, which give statistical indications of near-threshold and near-maximum lethal toxicity, respectively, and the range of doses over which a lethal response may occur.

Since the LD_{50}, for economical and ethical reasons, is usually conducted with only small numbers of animals, there is a UF associated with the calculation of the LD_{50} (or LC_{50} or LT_{50}). This is estimated from the 95% confidence limits; that is, the dosage range for which there is only a 5% chance that the LD_{50} (or other LD value) lies outside. The 95% confidence limits are narrowest at the LD_{50} (**Figure 11**), which is a further reason why this is an appropriate point for the comparison of acute lethal toxicity.

The LD_{50}, by itself, is an insufficient index of lethal toxicity, particularly if comparisons are to be made between different materials. The whole of the dosage–response information should be examined,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

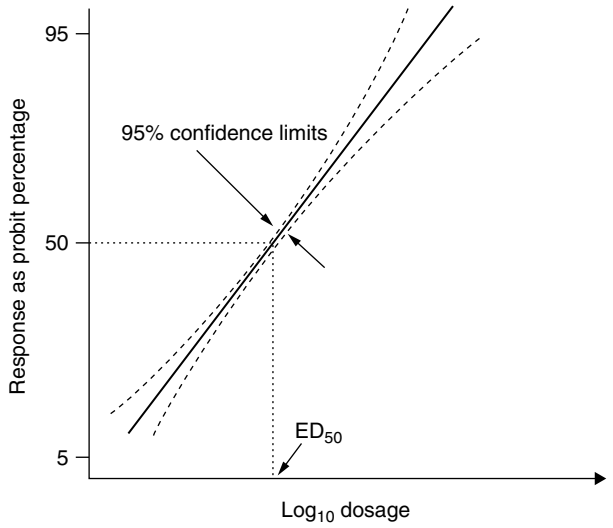

Figure 11 Dosage–mortality curve fitted with 95% confidence limits. The limits are closest at the ED_{50} and diverge at the extremes of the dosage response.

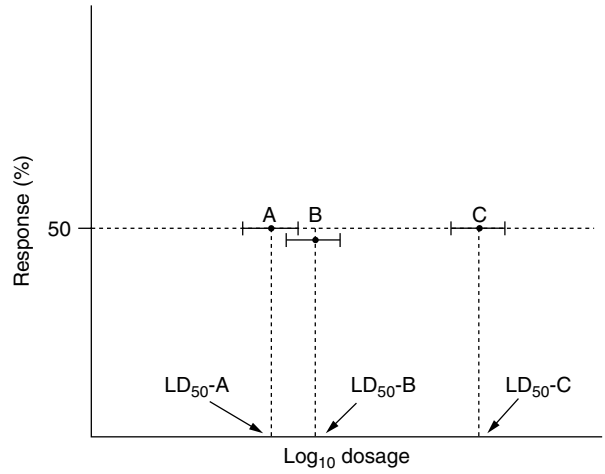

Figure 12 Comparison of the acute lethal toxicity for three compounds based on LD_{50} data alone. Compounds A and B have overlapping 95% confidence limits, and therefore have comparable acute lethal toxicities. Compound C has 95% confidence limits that are numerically separate from those of A and B, and is thus significantly less lethally toxic than either A or B, based on LD_{50} considerations.

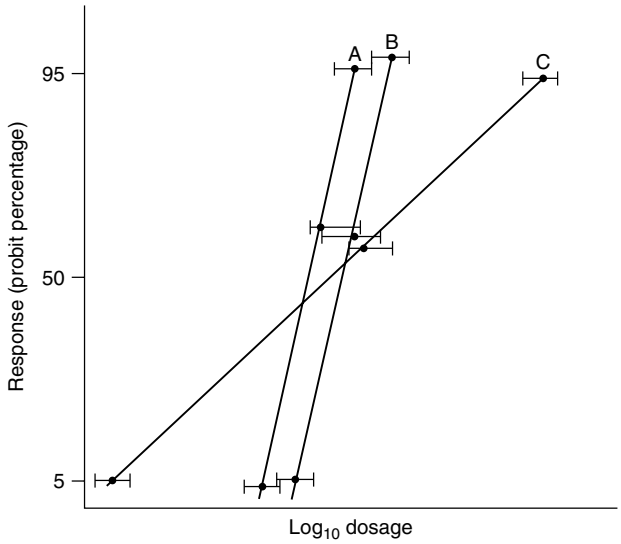

Figure 13 The influence of the slopes of dosage-mortality plots on the interpretation of LD_{50} data. All three illustrative materials (A, B and C) have overlapping 95% confidence limits at the 50% response level, and are therefore of comparable LD_{50}. Materials A and B have parallel dosage–response lines and overlapping 95% confidence limits at the 5 and 95% levels; therefore, these two materials are of comparable acute lethal toxicity over a wide range of dosages. Material C, in contrast, has a shallower slope and significantly different LD_5 and LD_{95} values, and therefore over a wide range of dosages C has a differing lethal toxicity to A and B. With materials A and B, because of the steep slope of the dosage–mortality line, a much larger proportion of the population will be affected by small incremental increases in dosage. With material C, there may be a greater risk for the hyper-reactive group since the LD_5 lies at a much lower dosage than for A and B.

including the slope of the dosage–response line and 95% confidence limits. For example, two materials with differing LD_{50} values, but overlapping 95% confidence limits are not regarded as being of significantly different lethal toxicity, since there is a statistical probability that the LD_{50} of one material will be within the 95% confidence limits of the other. However, when there is no overlap of 95% confidence limits, then the materials are considered to have significantly different lethal toxicity at the LD_{50} level (**Figure 12**). A particularly important consideration is that of the slope of the dosage–response curve (**Figure 13**). For example, if two materials have similar LD_{50} values with overlapping 95% confidence limits and identical slopes on the dosage–response lines (and therefore statistically similar LD_{10} and LD_{90} values), they are lethally equitoxic over a wide dosage range (A and B, **Figure 12**). However, materials having similar LD_{50} values but differing slopes (and hence significantly different LD_{10} and LD_{90} values) may not be considered to be lethally equitoxic over a wide dosage range (A or B versus C, **Figure 13**). Thus, materials having a steep slope (A or B, **Figure 13**) may affect a much larger proportion of the population by incremental increases in dosages than is the case with materials having a shallow slope; thus, acute overdose may be a more serious problem affecting the majority population for materials with steeper slopes. In contrast, materials having a shallower slope

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(C, **Figure 13**) may present problems for the hyper-reactive groups at the left-hand side of the dosage–response curve, and may occur at significantly lower dosages than for hyper-reactive individuals associated with the steep slope group. It follows from the above that a proper interpretation of acute lethal toxicity information should include examination of LD_{50}, 95% confidence limits, slope and extremes of the dosage–response curve.

It needs to be stressed that dosage–response information requires to be interpreted in terms of the conditions by which it was obtained; the following few examples are used to illustrate the care necessary:

1. The numerical precision of the LD_{50} lies only in the statistical procedures by which it is calculated. If an experiment to determine LD_{50} is repeated at a later time, slightly different dosage–response data may be obtained because of biological and environmental variability, resulting in a different numerical value for the LD_{50}. Therefore, LD_{50} values should be regarded as representing an order of lethal toxicity under the specific circumstances by which the information was collected.
2. An important consideration in interpreting the acute hazard from a chemical is the time to toxic effect. Thus, materials of similar LD_{50}, but differing times to death may present different hazards. For example, with substances having similar LD_{50} and slope values, those having more rapid times to death can be considered as presenting a greater acute hazard. However, those substances with longer latency to effect may have a potential to produce cumulative toxicity by repeated exposure. For example, the acute po LD_{50} of 2,4-pentanedione in the rat is $0.58\,g\,kg^{-1}$ and that of 2,2-bis(4-aminophenoxyphenyl)propane (BAPP) is $0.31\,g\,kg^{-1}$, with respective times to death of 2–5 hours and 13–14 days; on this basis, 2,4-pentanedione would be regarded as presenting a greater acute potential hazard than BAPP (Tyler and Ballantyne, 1988).
3. A more complete interpretation of the significance of LD_{50} data may require consideration of the cause of death. If differing potentially lethal toxic effects are produced, it is important to know if this can lead to a multimodal dosage–response curve, and thus to differing hazards by immediate or latent mortality or morbidity. Clearly, latency is of importance in clinical toxicology for decisions on immediate medical management and observations and treatment for latent toxicity. For example, *tert*-butyl nitrite given by acute ip injection to mice has a 30 minute LD_{50} of $613\,mg\,kg^{-1}$ and a seven day LD_{50} of $187\,mg\,kg^{-1}$. The earlier deaths were probably related to cardiovascular collapse and methaemoglobin formation, whereas later deaths were due to liver injury (Maickel and McFadden, 1979).
4. Acute LD_{50} data may not be a direct guide to defining lethal toxicity by multiple exposures. Thus, with a material producing significant cumulative toxicity, the acute lethal dose (and dosage) may be significantly higher than that producing death by multiple smaller exposures. For example, the four hour LC_{50} for trimethoxysilane is 47 ppm (rat); however, for rats given 20 exposures, each of seven hours over four weeks, the LC_{50} was 5.5 ppm for that time period (Ballantyne *et al.*, 1988). Thus, the potentially lethal vapour concentration of trimethoxysilane for repeated exposure is significantly less than that by acute exposure.

Any investigation into lethal toxicity should attempt to allow the maximum amount of usable information to be obtained. For this reason, acute toxicity studies should be designed not only to determine lethal toxicity, but also to monitor for sublethal and target organ toxicity; this is possible by incorporating into the protocol observations for signs, body weight, haematology, clinical chemistry, urinalysis, gross and microscopic pathology and other specialized procedures as considered appropriate for the material under test. In this way a significantly greater amount of relevant information can be obtained, and the most useful and meaningful information collected to allow a comparative evaluation of acute toxicity and potential hazards, and the potential for cumulative toxicity (Zbinden and Flury-Roversi, 1981).

Detailed discussions on dosage–response relationships and their toxicological and pharmacological relevance have been written by Sperling (1984), Tallarida and Jacob (1979) and Timbrell (1982).

7 FACTORS INFLUENCING TOXICITY

With animal studies and human poisoning, the nature, severity, incidence and probable induction of toxicity depend on a large number of exogenous and endogenous factors. Some of the more important are as summarized as follows.

7.1 Species and Strain

Species and strain differences in susceptibility to chemical-induced toxicity may be due, to variable extents, to differences in rates of absorption, metabolic conversions, detoxification mechanisms and excretion. In some cases animal studies may give underestimates,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and in other instances overestimates, for acute po toxicity to humans. For example, the acute po LD_{50} of ethylene glycol has been determined in several laboratory mammals to range from 4.7 to 7.5 g kg^{-1} (Sweet, 1985–1986a) and that for methanol to range from 5.63 to 7.50 g kg^{-1} (Sweet, 1985–1986b); however, these chemicals are significantly more lethally toxic to humans, with both having a minimal lethal dosage in humans around 0.5–1.0 g (kg body weight)$^{-1}$.

7.2 Age

With some substances age may significantly affect toxicity, probably mainly due to relative differences in metabolizing and excretory capacities. In one extensive compilation of LD_{50} values for drugs to neonatal and adult mammals (Goldenthal, 1971), the ratio (LD_{50} adult) /(LD_{50} neonate) varied from <0.02 (for amidephrine) to 750 (for digitoxin).

7.3 Nutritional Status

Nutritional status may significantly influence the level of cofactors and biotransformation mechanisms important for the expression of toxicity, and in this way diet can affect toxicity (Rao and Knapka, 1998). Moreover, diet may markedly influence the natural tumour incidence in animals and modulate carcinogen-induced tumour incidence (Grasso, 1988). Khanna *et al.* (1988) studied the effect of protein deficiency on the neurobehavioural effects of acrylamide in rat pups exposed during the intrauterine and early postnatal stages. They found acrylamide to be more toxic in protein-deficient hosts, owing to a significant decrease in dopamine and benzodiazepine receptor binding. Based on a two-year study, Hubert *et al.* (2000) found that a dietary restriction of around 25% is appropriate for Sprague–Dawley rats in toxicity and carcinogenicity assays to improve survival without an impairment of growth and routine clinical chemistry monitors. Feeding is an important factor in the design and interpretation of acute po toxicity studies. For example, Kast and Nishikawa (1981) compared the acute po toxicity of several anti-gastric-ulcer drugs and β-adrenoceptor agonists and blockers; the ratio (LD_{50} fed)/(LD_{50} fasted) for rats and mice ranged from 1.3 to 1.47, indicating a higher toxicity in the starved animals. The authors concluded that the greater acute toxicity in the starved animals was due to accelerated gastric emptying and intestinal absorption. The importance of dietary factors in toxicity has been reviewed by Angeli-Greaves and McLean (1981) and Grasso (1988).

7.4 Time of Dosing

Diurnal and seasonal variations in toxicity may relate to similar variations in biochemical, physiological and hormonal profiles. Examples of temporal variations in biological activity include circadian dependence of metabolic adverse effects of cyclosporin (Malmary *et al.*, 1988), toxicity of methotrexate (Marks *et al.*, 1985) and seasonal variations in gentamicin nephrotoxicity (Pariat *et al.*, 1988). Circadian toxicology is discussed in **Chronotoxicology**.

7.5 Environmental Factors

A variety of environmental factors are known to influence the development of toxicity, including temperature, relative humidity and photoperiod. The influence of temperature may vary between differing chemicals and the effects investigated. For example, colchicine and digitalis are more toxic the higher the temperature (Lu, 1985); in contrast, studies on the behavioural toxicity of the anticholinesterase soman suggest that the lower the temperature, the greater the susceptibility (Wheeler, 1987). The influence of temperature on toxicity is clearly an important consideration for materials used in arctic and tropical areas. The influence of temperature on toxicity is discussed in **The Influence of Temperature on Toxicity**.

7.6 Dosing Characteristics

The nature, severity and likelihood of inducing toxicity are influenced by the magnitude, number, frequency and profiling of dosing. Thus, local or systemic toxicity produced by acute exposure may also occur by a cumulative process with repeated lower-dosage exposures; also, additional toxicity may be seen with the repeated exposure situations. For example, acute exposure to formaldehyde vapour causes peripheral sensory irritant effects and (with sufficiently high concentrations) injury and inflammatory change in the respiratory tract; short-term repeated vapour exposure can result in the development of respiratory sensitization; longer-term vapour exposure may cause squamous metaplasia and nasal tumours (Wartew, 1983). The relationships for cumulative toxicity by repetitive exposure compared with acute exposure toxicity may be complex, and the potential for repeated exposure cumulative toxicity from acutely subthreshold doses may not be quantitatively predictable. For example, the LC_{50} for a four hour exposure to trimethoxysilane vapour is 47 ppm; by repeated exposure over a four week period (seven hours a day, five days a week) the LC_{50} is 5.5 ppm (Ballantyne *et al.*, 1988). In contrast, acute

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

exposure to benzene vapour for 26 hours (95 ppm) or 96 hours (21 ppm) produced severe bone marrow cytotoxicity, whilst a similar exposure dose given over a longer period of time (95 ppm for 2 hours a day for two weeks) produced little toxicity (Toft *et al*., 1982).

For repeated exposure toxicity, the precise profiling of doses may significantly influence toxicity. For example, with formaldehyde in a four week vapour inhalation study, it was determined that exposure of rats to 10 or 20 ppm by interrupted exposure over eight exposure periods produced more nasal mucosal cytotoxicity than did continual exposures (Wilmer *et al*., 1987). In a four-week inhalation study with carbon tetrachloride, it was found that interruption of a daily six hour exposure by 1–5 hour periods of nonexposure caused more severe hepatotoxicity than with continuous exposures, but five minute peak loads superimposed on a steady background only slightly aggravated the hepatotoxic effect of carbon tetrachloride vapour (Bogers *et al*., 1977).

7.7 Formulation and Presentation

For chemicals given perorally or applied to the skin, toxicity may be modified by the presence of materials in formulations that facilitate or retard the absorption of the chemicals. With respiratory exposure to aerosols, particle size significantly determines the depth of penetration and deposition in the respiratory tract (see **Neurotoxicology**).

7.8 Miscellaneous

A variety of factors in addition to the above may influence the nature and exhibition of toxicity, depending on the conditions of the study; for example, housing conditions, handling and dosing volume. Variability in test conditions and procedures may result in significant interlaboratory variability in results of otherwise standard procedures; for example, LD_{50} determination (Griffith, 1964; Hunter *et al*., 1979).

All the above factors need to be taken into consideration during risk assessments for xenobiotic exposures in order to more accurately predict human responses (Aldridge *et al*., 2003).

8 BIOHANDLING AS A DETERMINANT OF SYSTEMIC TOXICITY

The induction of systemic toxicity results from a complex inter-relationship between absorbed parent material and conversion products formed in tissues, their distribution in body fluids and tissues, binding and storage characteristics and their excretion. Some of these factors are considered below (see also **Figure 14**).

8.1 Absorption

The absorption of a substance from the site of exposure may result from passive diffusion, facilitated diffusion, active transport or the formation of transport vesicles (pinocytosis and phagocytosis). The process of absorption may be facilitated or retarded by a variety of factors, which include elevated temperature, that increases percutaneous (pc) absorption by cutaneous vasodilation, and surface-active materials, that facilitate penetration. The integrity of the absorbing surface is important; for example, the acute PC LD_{50} for HCN (solution) is 6.89 mg kg^{-1} for rabbits with intact skin, and 2.34 mg kg^{-1} if the skin is abraded (Ballantyne, 1987).

8.2 Biodistribution

Following absorption, materials circulate either free or bound to plasma protein or blood cells; the degree of binding, and factors influencing the equilibrium with the free form, may influence availability for metabolism, storage or excretion. Within tissues there may be binding, storage, metabolic activation or detoxification; binding may produce a high tissue/plasma partition and be a source for slow titration into the circulation following the cessation of environmental exposure. Examples of storage sites include fat for lipophilic materials (e.g. chlorinated pesticides) and bone for fluoride, lead and strontium. The relationship between exposure dose and release rate may be complex; for example, volatile lipophilic materials are generally more rapidly desorbed than nonvolatile lipophilic substances. Permeability of tissues may be modified by tissue-specific barriers; for example, the blood–brain barrier and placenta. This may affect differential toxicity within classes of compounds, for example, neurobehavioural effects produced by organomercurials and, to a lesser degree, with inorganic mercury compounds (Lu, 1985).

8.3 Biotransformation

Metabolism of substances is conveniently classified under the following two major headings (Williams, 1959):

Phase I reactions: A functional group is introduced into the molecule by oxidation, reduction or hydrolysis.
Phase II reactions: There is conjugation of an absorbed material or its metabolite with an endogenous substrate.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

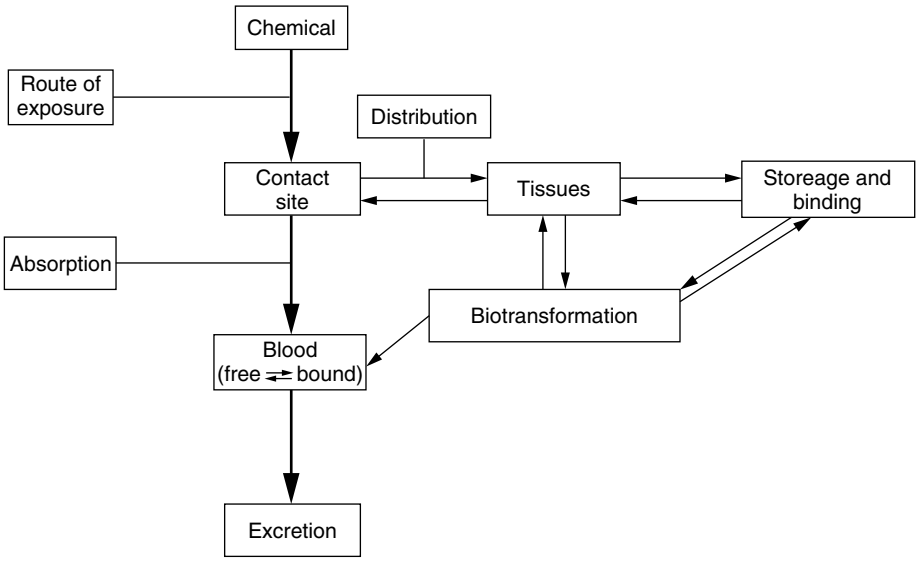

Figure 14 Possible pathways for the fate of a chemical absorbed from the route of exposure.

For many materials there is an initial Phase I reaction to produce materials which are conjugated by Phase II processes. In other instances, only a Phase II process may be utilized. Reactions of a Phase I type include oxidation, reduction and enzymatic hydrolysis; Phase II reactions include conjugation with glucuronic acid, sulfate, glycine and glutathione, and acetylation and methylation. Phase I reactions, particularly, may result in the formation of toxic metabolites from relatively innocuous precursors, that is, metabolic activation. Phase II conjugates are generally more water-soluble than the parent compound or Phase I metabolites and hence usually more readily excreted. With toxic parent compounds, or toxic metabolites, there may be conversion to less toxic products; that is, detoxification has occurred. Examples of metabolic activation and detoxification are given in **Table 5**. Many activation reactions are catalysed by a cytochrome-P450-dependent mono-oxygenase system, which is particularly active in the liver. Clearly, a major determinant of the likelihood of toxicity developing, and its severity, is the overall balance between the absorption rate of a chemical, its metabolic activation and detoxification, and the excretion of toxic species (see **Toxicokinetics**).

8.4 Excretion

Substances may be excreted as parent compound, metabolites and/or Phase II conjugates. A major route of excretion is by the kidney, and in some cases the urinary elimination of parent compound, metabolite or conjugate, may be used as a means for assessing absorbed dose. Some materials may be excreted in bile and thence in faeces; in such cases there may also be enterohepatic cycling. Certain volatile materials and metabolites may be eliminated in expired air. The excretion of materials in sweat, hair, nails and saliva is usually quantitatively insignificant, but these routes may be of importance for a forensic or industrial diagnosis or confirmation of intoxication (Paschal *et al*., 1989; Randall and Gibson, 1989). Materials excreted in milk may be transferred to the neonate.

Table 5 Examples of the metabolic transformation of chemicals

Biotransformation	Chemical	Conversion
Detoxification	Cyanide	Enzymatic conversion to less toxic thiocyanate
	Benzoic acid	Conjugation with glycine to produce hippuric acid
	Bromobenzene	3,4-Epoxide reactive metabolite is enzymatically hydrated to the 3,4-dihydrodiol or conjugated with glutathione
Activation	Carbon tetrachloride	Microsomal enzyme metabolic activation to hepatotoxic trichloromethylperoxy radicals
	2-Acetylaminofluorene	*N*-Hydroxylation to more potent carcinogen *N*-Hydroxyacetylaminofluorene
	Parathion	Oxidative desulfuration to the potent cholinesterase inhibitor paraoxon

8.5 Biohandling Interactions

The probability of adverse effects developing in response to chemical exposure depends particularly on the magnitude, duration, frequency and route of exposure. These will determine the amount of material to which an organism is exposed (the exposure dose), and hence to the amount of material which can be absorbed (the absorbed dose). The latter determines the amount of material available for distribution and toxic metabolite formation, and hence the likelihood of inducing a toxic effect. Opposing absorption and metabolite accumulation is elimination. Hence, for a given environmental exposure situation, the probability of inducing toxicity, and its magnitude, depend on the relationship between rate of absorption, metabolism (activation and detoxification) and elimination of parent material and metabolites.

The amount of a material in contact with the absorbing surface is one of the principal determinants of absorbed dose. In general, the higher the concentration, the greater is the absorbed dose. However, if mechanisms other than simple diffusion across a concentration gradient are operating, a simple proportionate relationship between concentration and absorbed dose may not be present. In such instances, a rate-limiting factor could result in proportionately smaller increases in absorbed dose for incremental increases in concentration at the absorption site. Also, and in particular when there is absorption by active transport, there may be saturation of the absorption process and a ceiling value.

When there is repeated exposure, the relative amounts of biotransformation products, and the distribution and elimination of metabolites and parent compound, may be different from that following an acute exposure. For example, repeated exposure may induce and enhance mechanisms responsible for the biotransformation of the absorbed material, and thus alter the relative proportions of parent molecules and metabolites (activation and detoxification), and hence the probability for target-organ toxicity. Also, if there is slow detoxification, storage and/or slow excretion, repeated exposures may lead to the accumulation of toxic species and hence a potential for cumulative toxicity.

9 ROUTES OF EXPOSURE

The primary tissue or system by which a material comes into contact with the body, and from where it may be absorbed in order to exert systemic toxicity, is the route of exposure. The usual circumstances of environmental exposure are by ingestion (po), inhalation and skin (epicutaneous/pc) or eye contact. Also, for investigational, therapeutic and certain forensic purposes, im, iv and sc injections may be routes of exposure.

The relationship between route of exposure, biotransformation and potential for toxicity may be complex and also influenced by the magnitude and duration of dosing. Materials that undergo hepatic activation are likely to exhibit greater toxicity when given po than if absorbed across the lung or skin, owing to the high proportion of material passing directly via the portal vein following po dosing. In contrast, materials that undergo hepatic detoxification are likely to be less toxic perorally than when absorbed pc or across the respiratory tract. However, in determining the relevance of route to biotransformation and toxicity, both the magnitude and timescale for dosing should be considered. Thus, when a single, large dose (bolus) of a metabolically activated material is given po, its rapid metabolism may result in the immediate development of a severe acute toxicity. However, if the same material is given po at much lower rates (e.g. by dietary inclusion), then there will be slow and sustained absorption, and in such circumstances the rate of generation of the toxic species may approach that resulting from continuous exposure by other routes. With materials that are detoxified by the liver, a slow continuous alimentary absorption will result in an anticipated low toxicity, compared with other routes of exposure. However, a po bolus may result in the detoxifying capacity of the liver being overwhelmed, and unmetabolized material may enter the circulation to initiate. A few comments on specific routes of exposure follow.

9.1 Peroral

If a material is sufficiently irritant or corrosive, it will cause local inflammatory or corrosive effects on the upper alimentary tract. This may lead to, for example, fibrosis, dysphagia and perforation with mediastinitis and/or peritonitis and the complications thereof. Additionally, carcinogenic materials may induce tumour formation in the alimentary tract. The gastrointestinal tract is an important route by which systemically toxic materials may be absorbed (see **Peroral Toxicity**).

9.2 Cutaneous Contact and Percutaneous Absorption

Skin contact is an important route of exposure in the occupational and domestic environments, and can result in local and/or systemic toxicity. Local effects may include acute inflammation and corrosion, chronic inflammatory responses, immune-mediated reactions and neoplasia. The PC absorption of materials can be a significant route for the absorption of systemically toxic materials (Billingham, 1977; Bronough and Maibach, 1985; see **Cutaneous Toxicology**), and indeed is now a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

means for the systemic titration of pharmacologically active materials (Woodford and Barry, 1986). Factors influencing the PC absorption of substances include skin site, integrity of skin, temperature, formulation and physicochemical characteristics, including charge, molecular weight and hydrophilic and lipophilic characteristics (Billingham, 1977; Dugard, 1977; Stuttgen *et al*., 1982; Kemppainen and Reifenrath, 1990). In addition to enhancing pc absorption by topical epicutaneous contact, some materials may also do so following systemic absorption. For example, ethanol can act as a topical penetration enhancer through solubility and skin-disrupting actions (Cornwell and Barry, 1995; Walters *et al*., 1997). Also, Brand *et al*. (2006) demonstrated that ethanol dosed acutely to rats by gavage increased the pc absorption of epicutaneously applied paraquat, *N,N*-dimethylformamide, and *N,N*-diethyl-*m*-tolbutamide.

Although it is well appreciated that pc absorption of materials may occur when they contaminate the skin as liquid or solid, it has been shown that pc absorption can also result from exposure of the skin to vapour. In the majority of situations, absorption by the inhalation route is generally regarded as being significantly greater than by pc absorption from the vapour phase (McDougal *et al*., 1986; Jacobs and Phanprasik, 1993). When controlled studies are conducted in humans, difference of conduct and interpretive opinion may exist, particularly with the need for artefact-free techniques. For example, Johanson and Boman (1991) conducted a comparative study on human volunteers who were exposed for two hours mouth-only to 50 ppm 2-butoxyethanol, followed by one hour of no exposure, followed by a further two hours of skin-only exposure to 50 ppm 2-butoxyethanol. Using areas under the curve for concentrations of 2-butoxyethanol in finger-prick blood samples, they calculated that approximately 75% of the total uptake of 2-butoxyethanol vapour was absorbed through the skin. Subsequently, Corley *et al*. (1997) criticized this approach, mainly on the basis that the finger-prick sampling was compounded by locally high concentrations of 2-butoxyethanol at the site of absorption. They conducted a study involving exposure of one arm of human volunteers subjected to 50 ppm [$^{13}C_2$]-2-butoxyethanol vapour (50 ppm) for two hours. Blood samples were taken by finger-prick from the exposed arm and by catheter from the unexposed arm, and analysed for 2-butoxyethanol and its major haemolytic metabolite, butoxyacetic acid. They found the concentration of 2-butoxyethanol in the finger-prick blood samples to be almost 1500 times those taken by catheter from the unexposed contralateral arm. Blood butoxyacetic acid concentrations were found to be within a factor of four of each other for the two sampling techniques, and it was considered that the metabolite was a better indicator of absorption into the systemic circulation. In a physiologically based pharmacokinetic model of a 'worst case' scenario (100% body exposure) of an eight hour exposure to 25 ppm vapour, they calculated that only 15–27% of the total uptake of 2-butoxyethanol would be by pc absorption. In contrast, with styrene, measurement of urinary metabolites in workers showed no significant pc absorption of styrene (Limasset *et al*., 1999).

9.3 Inhalation

The likelihood of toxicity from atmospherically dispersed materials depends on a number of factors, the most important of which include physical state, physicochemical properties, and concentration, time and frequency of exposure. The water solubility of a gas or vapour influences the depth of penetration of a material into the respiratory tract. As water solubility decreases, and lipid solubility increases, there is more effective penetration towards the alveoli. Water-soluble molecules, such as formaldehyde, are more effectively scavenged by the upper respiratory tract.

The penetration and distribution of fibres and particulates in the respiratory tract are determined principally by their size. Thus, in general, particles having a mass medium aerodynamic diameter (MMAD) greater than 50 μm do not enter the respiratory tract; those of diameter >10 μm are deposited in the upper respiratory tract; those having a range of 2–10 μm are deposited in the trachea, bronchi and bronchioles; and only particles whose diameter is <1 μm reach the alveoli. Thus, larger insoluble particles are more likely to cause local reactions in the upper respiratory tract, and the potential for alveolar injury is greater with smaller diameter particles. Fibres have aerodynamic characteristics such that those having diameters >3 μm are unlikely to penetrate the lung. In general, fibres having a diameter <3 μm and length <200 μm will enter the lung. Fibres of diameter >10 μm may not be removed by normal clearance mechanisms. Several studies have indicated that fibres of diameter >1.5 μm and length <8 μm have maximum biological activity (Asher and McGrath, 1976; Stanton *et al*., 1981). Dust may be a significant cause of lung disease (Conference, 1990).

The likelihood that inhaled substances will produce local effects in the respiratory tract depends on their physical and chemical characteristics (particularly volatility), reactivity with lining fluids, reactivity with tissue components and site of deposition. Depending on the nature of the material, conditions of exposure and biological reactivity, the types of response produced include acute inflammation and injury, chronic inflammation, immune-mediated hypersensitivity reactions and neoplasia. The degree to which inhaled gases, vapours and particulates are absorbed and, hence, their potential to produce systemic toxicity, depend

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

mainly on molecular weight, solubility in tissue fluids, metabolism by lung tissue, diffusion rate and equilibrium state.

A relatively recent, but rapidly expanding area relating mainly, though not exclusively, to the inhalation route of exposure is nanotoxicology. This subject area is concerned with assessing toxicity related to particles in the 10^{-9} m size. More specific definitions indicate that the size is $\leq$100 nm in one dimension, or a range of 1–100 nm (Borm and Kreyling, 2004). Nanoparticles currently in use have been made from transition metals, silicon, carbon and metal oxides (zinc dioxide and titanium dioxide) (Dreher, 2004), and in many cases engineered nanoparticles exist as nanocrystals (Murray *et al*., 2000). Nanoparticles are of technological interest because, for a given particle-type, as the particle size is decreased within the nanoscale range, certain fundamental physicochemical characteristics change, resulting in the development of new and different properties; for example, change from electrically insulating to conducting or insoluble materials becoming soluble (Warheit *et al*., 2000). Manufactured nanoparticles have physicochemical properties that result in their having unique electrical, mechanical, thermal and imaging properties that are highly desirable in the commercial, medical and environmental areas (Dreher, 2004; EPA, 2003). There are indications from pulmonary toxicology studies that nanoparticles cause enhanced toxicity in comparison with larger-sized particles of similar chemical composition (Donaldson *et al*., 2001; Lam *et al*., 2004; Oberdörster, 2000). A substantial proportion of inhaled nanoparticles are likely to deposit in the respiratory tract; ~30% to >90%, depending on breathing rate and particle size. They readily reach the deep lung, and the alveolar region is the primary site of deposition for nanoparticles in the range 10–100 nm. In addition to compartmentalization within the respiratory tract, dissolution is probably another relevant factor in determining the fate and effects of nanoparticles (Borm *et al*., 2006). There are indications that these materials may pose a hazard locally to the lung through oxidative stress, inflammation, and tumorigenesis, and also cause systemic effects by redistribution to other organs following pulmonary deposition (Donaldson *et al*., 2005; 2006). Translocation from lungs has been shown for brain, liver, kidney and spleen (Elder *et al*., 2006; Geiser *et al*., 2005), and the rate depends on the physicochemical properties of the nanoparticles, including size, chemical nature, shape and charge (Oberdörster *et al*., 2002; Kreyling *et al*., 2006). Studies with nanoparticles require that the material tested has detailed characterization (Murdock *et al*., 2008), and a suggested prioritized list for physicochemical characteristics is as follows (Warheit, 2008): particle size and distribution (wet state) and surface area (dry state); crystal structure; aggregation status; composition/surface coatings; surface reactivity; method of nanomaterial synthesis; sample purity. Currently many resources, particularly in the USA, Europe and Japan, are being devoted to the development of risk and safety evaluations of nanomaterials, environmental fate, human health effects, workplace and environmental monitoring, and precautionary measures (Stern and McNeil, 2008; Thomas and Sayre, 2005; Thomas *et al*., 2006a; 2006b). A detailed review of nanotoxicology is given in **Nanotoxicology-The Toxicology of Nanomaterials**.

9.4 Eye

Local and systemic adverse effects may be produced by ocular contamination with liquids, solids and atmospherically dispersed materials. Local effects include transient inflammation, permanent injury and hypersensitivity reactions. Penetration may lead to iritis, glaucoma and cataract. Also, with pharmacologically or toxicologically potent materials, systemically active amounts of material may be absorbed from periocular blood vessels and/or nasal mucosa following passage down the nasolachrymal duct (Shell, 1982; Ballantyne, 1983; see **Ophthalmic Toxicology**).

10 EXPOSURE TO MIXTURES OF CHEMICALS

Circumstances involving exposure to several xenobiotics can result in prior, coincidental or successive exposure to these chemicals, and the nature of the toxicity may vary considerably depending on the conditions of exposure. Thus, an evaluation of the hazards from exposure to multiple chemicals can be much more demanding than is the case for a single chemical. In assessing toxicity from mixtures it is important to consider: (i) chemical and/or physical interactions of the individual materials, (ii) the effect that one chemical may have on the absorption, metabolism and pharmacokinetic characteristics of another and (iii) the possibility for interaction between parent compound and metabolites (Ballantyne, 1985). One longstanding descriptive classification for effects produced by binary mixtures of chemicals is as follows:

Independent effects: Substances qualitatively and quantitatively exert their own toxicity independently of each other.

Additive effects: Materials with similar qualitative toxicity produce a response that is quantitatively equal

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to the sum of the effects produced by the individual constituents.

Antagonistic effects: Materials oppose the toxicity of each other, or one interferes with the toxicity of another; a particular example is that of antidotal action.

Potentiating effects: One material, usually of low toxicity, enhances the expression of toxicity by another; the result is more severe injury than that produced by the toxic species alone.

Synergistic effects: Two materials, given simultaneously, produce toxicity significantly greater than anticipated from that of either material alone; the effect differs from potentiation in that each substance contributes to toxicity, and the net effect is always greater than additive.

In assessing the toxicity of mixtures, the following need to be taken into consideration:

- Possible physical and chemical interaction, which may result in the formation of new substances or groupings, or influence bioavailability
- Time relationships of the exposure for the various components
- Route and conditions of exposure
- Physical and physiological factors affecting absorption
- Mutual influence of materials and metabolites on biotransformation, pharmacokinetic characteristics and target organ doses of toxic species
- Relative affinities of the target sites
- Potential for independent, additive, antagonistic and interactive processes between the various chemical species.

Mixtures may be complex and contain unreacted parent materials, major reaction and degradation products, contaminants and trace additives. It is important to be aware that small quantities of high-toxicity materials may have equal, or greater, significance with respect to adverse health effects than major components. For example, serious consideration needs to be given to repeated exposure toxicity from small quantities of monomer residuals in polymeric materials; for example, ethylene oxide, propylene oxide, vinyl chloride and formaldehyde (Ballantyne, 1989). The contribution to toxicity by trace materials is well illustrated by, for example, the presence of trialkyl phosphorothioate or phosphorothionate impurities in op anticholinesterases (Hollingshaus *et al*., 1981) such as malathion (JMPR, 1998), and the presence of 2,3,7,8-tetrachlorodibenzodioxin in chlorophenols (Kimbrough *et al*., 1984).

Many instances of enhancement of toxicity by specific routes are known. Thus, by skin contact, the systemic toxicity of a material may be enhanced by other materials that facilitate pc absorption. For example, the presence of a surface-active material may result in a carrier function, and the presence of a primary irritant may produce local erythema resulting in increased skin blood flow. If the viscosity of a material is increased, this may enhance local or systemic toxicity due to persistence on the skin.

The inhalation exposure dosage of chemicals may be modified by, for example, the presence of sensory irritants or HCN, which can alter the rate and depth of breathing. Some substances may cause anosmia and hence remove an olfactory warning for other inhaled materials. Particulates may absorb other materials that, if inhaled, cause an increased local burden. When trace quantities of highly volatile and toxic materials are present in a substance, they may, depending on the condition of air movement, have a significant influence on toxicity and hazard. For example, if materials containing trace amounts of acrolein are handled in stagnant air conditions, then potentially toxic vapour concentrations of acrolein may develop; in contrast, when there is free airflow, the acrolein vapour concentration may remain low (Ballantyne *et al*., 1989a). Thus, the degree of ventilation of a space may significantly influence the toxicity of the atmosphere resulting from vapourization of the individual constituents of a liquid mixture.

The endogenous determinants of overall toxicity resulting from exposure to a mixture of chemicals can be very complex. For example, toxicity may be modulated by prior or simultaneous exposure, resulting in enhancement or suppression of metabolic activation or detoxification pathways. The potential for toxicity may depend on the equilibrium state, although this may be continually fluctuating. Modification of toxicity can also result from modulation of pharmacokinetic characteristics, variation in the biodistribution of absorbed materials and metabolites, modifying elimination of the toxic species, and competition for binding sites or receptors. All the above factors will influence the relative and absolute concentration of toxic species at target sites for toxicity. For complex mixture situations, such as environmental considerations, the extremely large number of potential chemical combinations (constituents and concentrations) limit the usefulness of standard toxicity testing for establishing hazard, and modelling approaches have been employed. Most of these models have been constructed on no-interaction assumptions, and rely on concentration-addition or response-addition approaches. Concentration addition is based on an assumption that mixture components contribute to toxicity through a common mechanism of action and an additive effect is obtained from the individual components of the mixture, and thus is regarded as a 'toxic equivalency' approach (Altenburger *et al*., 2000; Safe, 1990). Response addition models are used when mixture constituents have different mechanisms of action, and the combined effects of the constituents are based on the probability that individual constituents

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

will affect the exposed organism (Backhaus *et al*., 2000; Walter *et al*., 2002). Combined concentration addition and response addition models can be built into a comprehensive model for noninteracting mixtures (Altenburger *et al*., 2005; Olmstead and LeBlanc, 2005; Teuschler *et al*., 2004). However, the concentration-addition and response-addition models have limited application to complex mixtures, since they do not address the problem of component interactions. Toxicokinetic interactions between chemicals result in one chemical altering the effective concentration of another, and toxicodynamic interactions can occur in which one chemical influences the response of the organism to another chemical (Anderson and Dennison, 2004). In order to integrate interactions into models for mixture toxicity, Rider and LeBlanc (2005) developed a mathematical model that combines concentration addition, response addition and toxicokinetic interaction into the toxicity assessment of chemical mixtures. Haddad *et al*. (2001) developed a physiologically based pharmacokinetic (PBPK) model for the assessment of health risks from chemical mixtures based on an approach to take into account the influence of multichemical pharmacokinetic interactions at a quantitative level.

Detailed discussions on the toxicity and hazard evaluation of mixtures of substances have been presented by the World Health Organization (1981), Murphy (1983), Ballantyne (1985), Bhat and Ahangar (2007) and the National Research Council (1988) (see also **Evaluation of Toxicological Interactions for the Dose-Response Assessment of Chemical Mixtures**; **Toxicology of Chemical Mixtures**).

11 TOXICOLOGY OF DRUGS

11.1 Undesirable Effects

It has been estimated that in the USA adverse dug reactions affect somewhere in the region of two million patients, and are lethal to about 100 000 individuals annually (Nakamura, 2008). Drugs and medicinal products can produce adverse effects in the usually defined manner of toxicity and, additionally, they can cause prolongation or exaggeration of the known pharmacological effect(s) of the substance and in this respect cause the adverse inconvenience of pharmacological activity. Undesirable and unwanted effects can be classified and described according to the following schemes:

1. One system divides them into two types: *Type A*, which are the results of an exaggerated, but otherwise normal, pharmacological action of a drug, such as bleeding induced by anticoagulant drug or hypoglycaemia induced by diabetic drugs; *Type B,* which are totally aberrant effects not expected from the known pharmacological mode of actions of a drug, such as deafness from streptomycin.
2. A second system divides them into three groups: *dose dependent*, as in Type A above, *dose independent*, which are of an allergic nature involving antigen–antibody reactions, and *pseudoallergic* reactions, where allergic reactions are mimicked by mediator release due to direct action of the drug or its metabolite on mast cells.
3. In this approach, specific terms are used to describe grouped effects of an apparently common aetiological factor. They are usually characterized as follows:
   - Side effects: undesirable effects which result from the normal pharmacological actions of the drug.
   - Overdosage: implies that toxicity will occur by dosing in excess of that recommended for the desired pharmacological effect.
   - Intolerance: implies that the threshold dose to produce a pharmacological effect is lowered; this may be a consequence of a genetic abnormality.
   - Idiosyncrasy: an abnormal reaction to a drug due to an inherent, frequently genetic, anomaly.
   - Secondary effects: those arising as an indirect consequence of the pharmacological action of a drug.
   - Adverse drug interactions: adverse effects produced by a combination of drugs, but not seen when the drugs are given separately at the same dose.

Some of the terms used in this third scheme are difficult to define, and particular reactions may difficult to classify into a single one of them. Also, there is clearly bridging with some descriptive classes, notably intolerance and iodiosyncrasy with respect to genetic influences. Amongst the potential causes for adverse drug reactions, genetic variants are a likely large reservoir, and this has given rise to the study of pharmacogenomics (Huang *et al*., 2006; Nakamura, 2008). This specialization has as its main objectives investigation of the influence of genetic variability on bioresponse to drugs, identification of the gene loci responsible for adverse drug reactions and the design of screening procedures for identifying susceptible individuals. Genes currently known to be associated with adverse drug reactions have been classified into three major categories: drug-metabolizing enzymes, drug transporters and human leucocyte antigens (HLAs); those in the first two categories influence pharmacokinetics and those in the latter may possibly influence cellular immune response (Wilke *et al*., 2007). Illustrative examples are as follows. Antituberculosis drugs, including isoniazid, are known to be hepatotoxic, and it has been proposed that the production and elimination of toxic metabolites is dependant on the activities of several enzymes, including *N*-acetyl transferase 2, cytochrome P450 oxidase (CYP2E1) and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

glutathione S-transferase. There is evidence that polymorphisms at the loci for these enzymes could modify the activities, and hence the risk for hepatotoxicity. The prevalence of polymorphisms varies geographically, and correspondingly the risk for hepatotoxicity differs in populations; thus, knowledge of the polymorphisms at these loci might be useful in evaluations for, and in controlling, hepatotoxicity (Roy *et al*., 2008). Decreased drug metabolism and clearance can increase the body load of a drug or metabolite to a toxic level, and thus result in an adverse reaction. For example, genetic variants in the genes encoding thiopurine-*S*-methyl transferase and uridine diphosphate glucuronosyl transferase 1A1 are known to reduce the enzymatic conversion of azothioprine and irinotecan, respectively, and increase the risk for myelotoxicity associated with therapy (Nakamura, 2008). HLA molecules may involve interaction between a certain HLA molecule and a drug, or metabolite, and trigger a cellular immune repose. For example, there is a strong association in Han Chinese between HLA-B 1502 and the Stevens–Johnson syndrome induced by carbamazepine (Chung *et al*., 2004).

11.2 Factors Influencing Drug Toxicity

Factors influencing dose-dependent drug toxicity include formulation, route of administration, pregnancy, age, genetic polymorphism of metabolism, environmental influences on metabolism, renal and hepatic excretion, disease, drug interactions and patient compliance. Genetic factors have been considered above in Section 11.1 Nutritional status can affect both dosing efficacy and toxicity (Thomas *et al*., 1998). Additionally, certain common foods or drinks may interact with drugs or metabolites or modify their metabolism. One well-known example is the interaction of monoamine oxidase inhibitors with food rich in tyramine, causing systemic accumulation of amines and hypertensive crises (Lloyd, 1991). Another, but as yet not as widely appreciated, finding is drug interactions with grapefruit juice (Fuhr, 1998). A major factor in this interaction is suppression of the cytochrome P450 enzyme CYP3A4 in the wall of the small intestine, resulting in diminished first-pass metabolism with higher bioavailability and increased maximum plasma concentrations of the drug substrates. The P-glycoprotein pump, found in the brush border of the intestinal wall, transports many of the cytochrome P450 3A4 substrates, has also been noted to be inhibited by grapefruit juice. A consequence of inhibiting these enzyme systems is an alteration in the pharmacokinetics of several drugs leading to an elevation of their plasma concentrations (Kiani and Imam, 2007). The inhibition of intestinal CYP3A4 was, apparently, was first noted in an interaction study of felodipine with ethanol, where grapefruit juice was used to 'blind' for the administration of ethanol (Bailey *et al*., 1989). It was noted that felodipine concentrations were considerably higher than those previously reported for the dose used. In addition to increasing the bioavailability of drugs, grapefruit juice may prolong the metabolic elimination of some drugs (Fuhr *et al*., 1993; Bailey *et al*., 1994). The interaction between drugs and grapefruit juice is marked for felodipine, nimodipine and saquinavir, for which there are marked increases in the area under the curve (AUC) and/or maximum plasma concentrations greater than 70% of controls (Fuhr, 1998). Major drugs implicated in grapefruit interactions include dihydropyridine calcium antagonists, verapamil, terfenadine, cyclosporin, ethinyloestradiol, 17β-oestradiol, prednisone, midazolam, triazolam, quinidine and saguinavir; all these materials share the property of having significant first-pass metabolism by cytochrome P450 AL/5, predominantly in the gut wall, resulting in Phase I metabolites (Fuhr, 1998). It has been suggested that psoralens, principally 6′,7′-dihydrobergamottin, are major inhibitors, with a possible contribution from naringenin (Edwards *et al*., 1996; Runkell *et al*., 1997). It is proposed that patients be advised to refrain from drinking grapefruit juice when taking a drug that is extensively metabolized, unless a lack of interaction has been demonstrated (Fuhr, 1998).

In many countries, evidence of adverse drug reactions is sought in normal volunteers and patients in all phases of clinical trial leading up to licensing and marketing of a new product. Postmarketing surveillance (PMS) is then carried out to assess long-term safety in thousands of patients in order to detect low-frequency reactions that were not recognized in the relatively small number of patients studied in premarketing trials. There are a variety of PMS schemes, including voluntary reporting of possible cases of drug reaction, while standard epidemiological techniques, such as retrospective studies, prospective cohort studies and case–control studies may be useful.

12 NATURE, DESIGN AND CONDUCT OF TOXICOLOGY STUDIES

12.1 General Considerations

Toxicology studies should permit, within the constraints of the time period studied, a quantitative determination of the potential for a chemical, or mixture of chemicals, to produce local and systemic adverse effects and allow a determination of factors that may influence the nature, severity and possible reversibility of effects. Specific features that any toxicology testing programme should allow are as follows:

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- The nature of any adverse effects
- Relationship of the adverse effects to in-use and practical situations
- Dose–response relationships (average, range, hyper-reactive groups, no-effects and minimum-effects concentrations or dosages)
- Modifying factors
- Effects of gross acute overexposure
- Effects of repeated exposure (short and long term)
- Definition of allowable and nonallowable exposures
- Definition of monitoring procedures
- Guidance on protective and restrictive procedures
- Guidance on first aid and medical management
- Definition of 'at-risk' populations (e.g. by sex, pre-existing disease, or genetic susceptibility).

Information necessary for the above purposes can be obtained only from carefully designed and conducted studies. In some cases, it may not be economically possible to undertake a complete range of toxicology studies, and in such circumstances it is necessary to carefully consider the most appropriate investigational approaches based on known physiochemical properties, existing and suspected toxicology, and anticipated conditions of use. The relevance and credibility of a toxicology study can be no better than its design and conduct permit. For the purposes of hazard evaluation, there is a need to emphasize exposure conditions that may exist under practical conditions of use.

Toxicology testing programmes generally start with single-exposure *in vivo* or *in vitro* studies and progress to investigations evaluating the effects of long-term repeated exposures. Studies having specific end points, such as teratology and reproductive effects, are conducted as the emerging toxicology profile and end-use exposure patterns dictate. Toxicology testing procedures can be conveniently subdivided into general and specific. General toxicology studies are those in which animals are exposed to a test material under appropriate conditions, and are monitored for all types of toxicity that the monitoring procedures permit. Specific toxicology studies are those in which exposed animals, or *in vitro* test systems, are monitored for defined end point(s).

12.2 General Toxicology Studies

These are usually conducted as a programme in the sequence of acute, short-term repeated, subchronic and chronic. Ideally, the protocol for general studies should include provision for some animals to be kept for a period after the end of dosing in order to determine latency and reversibility, or otherwise, of toxic effects. Acute studies give information on toxicity produced by a single exposure, including the effects of massive overexposure; they also give information of use for setting exposure conditions for short-term repeated-exposure studies. The type of monitoring employed in general toxicology studies will be determined by several considerations, including the chemistry of the test material, its known or suspect toxicology, degree of exposure, and the rationale for conducting the investigation. In general, since multiple-exposure studies are most likely to produce the widest range of toxicity, it is usual to employ the most extensive monitoring in these studies. The monitoring employed to detect functional toxicity and toxicological pathology includes the following:

- Inspection, on a regular basis, for signs of toxic and/or pharmacological effects
- Body weight before dosing and at appropriate intervals during the dosing phase
- Food and water consumption
- Haematology for assessment of peripheral blood and haematopoietic tissue responses
- Clinical (blood) chemistry of various substances and of specific enzyme activities, and appropriate urinalysis
- Gross and microscopic pathology with organ weight measurement
- Special pathological or functional tests may be required on a case-by-case basis.

12.3 Specific Toxicology Studies

Many of these procedures are directed at determining a specific toxic or pathological effect for hazard-evaluation and risk-assessment purposes, but others are employed as 'screening' or 'short-term' tests to assess the potential of a substance to induce chronic effects or toxicity with a long latency. Some of the most frequently employed special toxicology methods are listed below.

12.3.1 Primary Irritation

These studies are designed to determine the potential of substances to cause local inflammatory effects, notably in skin and eye (see **Ophthalmic Toxicology**; **Cutaneous Toxicology**). In order to reduce the use of animals for eye irritancy testing, a variety of alternative procedures have been proposed, which include the use of enucleated eyes, various *in vitro* cell or tissue cultures, and the noninvasive measurement of corneal thickness (Nardone and Bradlaw, 1983; Shopsis and Sathe, 1984; Ballantyne, 1986; Borenfreund and Borrero, 1984).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

12.3.2 Peripheral Sensory Irritation

Methods to assess the potential to cause eye or respiratory tract discomfort with associated reflexes are particularly useful to perform, notably with respect to occupational toxicology, since such effects may be distracting (Owens and Punte, 1963; Ballantyne *et al*., 1977; Ballantyne, 1984; see **Peripheral Chemosensory Irritation: Fundamentals, Investigation and Applied Considerations**).

12.3.3 Immune-Mediated Hypersensitivity

Allergenic materials may produce hypersensitivity reactions by skin contact or inhalation, and several methods are available to determine the potential for chemicals to produce allergic contact dermatitis or respiratory sensitization (Goodwin *et al*., 1981; Maurer *et al*., 1984; Karol *et al*., 1985).

12.3.4 Neurological and Behavioural Toxicity

To confirm the existence, nature, site and mechanism of toxic injury to the central and/or peripheral nervous system, a variety of approaches with varying degrees of sophistication are available (see **Neurotoxicology**; **The Role of Behavioural Toxicity in Risk Assessment**). These include observational test batteries (Gad, 1982), light and electron microscopy (Spencer *et al*., 1980), selective biochemical procedures (Abou-Donia *et al*., 1987), electrophysiological, pharmacological, tissue culture and metabolism techniques (Dewar, 1981; Mitchell, 1982). The potential to produce delayed polyneuropathy, carried out in hens and sometimes in rodents, and used in the toxicological assessment of OPs and some other neurotoxic substances, has been increasingly refined (Veronesi, 1992; OECD, 1995).

12.3.5 Developmental Toxicity

Most studies are directed at assessing the potential for chemicals to induce structural defects of development, and essentially involve administering the test material to the pregnant animal during the period of maximum organogenesis (Tuchmann-Duplessis, 1980; Beckman and Brent, 1984; Tyl, 1988). However, there has been increasing interest in the development of test methods to assess possible adverse functional effects resulting from exposure of the foetus both during gestation and in the early neonatal period; for example, developmental neurobehavioural toxicology and immunotoxicology (Zbinden, 1981; Vorhees, 1983; see **Developmental Toxicology**; **Developmental Neurotoxicity**).

12.3.6 Reproductive Toxicity

Reproductive studies are conducted to assess the potential for adverse structural and functional effects on gonads, fertility, gestation, foetuses, lactation and general reproductive performance. Exposure to the chemical may be over one or several generations. In view of the necessarily comparatively low doses used during these long-term studies, they may not be sufficiently sensitive to detect most potentially teratogenic materials. The basis for these reproductive studies has been reviewed (Mattison, 1983; Baeder *et al*., 1985; Rao *et al*., 1987; see **Reproductive Toxicology**).

12.3.7 Metabolism and Pharmacokinetics

These studies may be of very considerable importance in the interpretation of conventional toxicology studies, in helping determine the mechanism of toxicity, in assessing the relationship between environmental exposure concentration and target organ toxicity, and in the design of additional studies to elucidate mechanisms of toxicity. Metabolic studies should yield information on the biotransformation of a material and the nature of the products, the sites at which this occurs and the mechanism of biotransformation. Pharmacokinetic studies should allow a quantitative determination of the rate of uptake, the absorbed dose, the biodistribution, tissue binding and storage, and the routes and rates of excretion of test material and metabolites (Oehme, 1980; Gibaldi and Perrier, 1982).

12.3.8 Genotoxicity

A number of tests, both *in vitro* and *in vivo*, are available to assess the mutagenic or clastogenic potential of chemicals (see **Mutagenesis**; **Cytogenetics**; **Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation**; **Short-term Tests for the Determination of Genotoxic and Carcinogenic Potential of Xenobiotics**). A positive genotoxic result is not necessarily a directly usable end point *per se*, but may assist in defining a potential for adverse health effects or be used in screening for potential longer-term toxicity. Thus, materials with clear mutagenic activity may be suspected of being genotoxic carcinogens, and appropriate further studies may be required; clastogenic materials may be suspect of reproductive or haematological toxicity.

The most widely used *in vitro* mutagenicity test has probably been that described by Ames (1982) and which utilizes histidine-dependent mutants of *Salmonella typhimurium*. The bacteria are incubated in a medium deficient in histidine; if the added test chemical is genotoxic it causes a reverse mutation to the histidine-independent state, which permits bacterial growth. Since the introduction of this bacterial assay, there have been a host of other mutagenic tests developed, including the use of other strains of bacteria and a variety of *in vitro* cell-line cultures. For example, a commonly used test system is a forward gene mutation assay in Chinese hamster ovary (CHO)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cells with a strain which is deficient in the enzyme hypoxanthine-guanine phosphoribosyl transferase (HGPRT), which confers resistance to toxic purine analogues such as 6-thioguanine and permits growth of the cells in a medium containing such substrates. The presence of a mutant chemical will restore sensitivity to the presence of purine analogues, and this may be used to assess mutagenic potential quantitatively. Clastogenic potential can be assessed *in vitro* by exposing cultured cells and subsequently examining them by light microscopy for chromosome damage. *In vivo* tests for clastogenicity involve direct approaches by examining cell preparations from dosed animals for chromosomal damage (cytogenetic studies) or indirect approaches of detecting products from damaged cells such as micronuclei in erythrocytes.

It is usual to conduct *in vitro* genotoxicity studies in the presence and absence of a metabolic activation system in order to assess the possible influence of metabolism on the genetoxic potential of the test chemical. Frequently employed is a homogenate of liver from animals given the polychlorinated biphenyl, arochlor, which induces a broad range of hepatic P450-metabolizing enzymes.

In vivo genotoxicity studies can be conducted in a variety of ways. For example, the specific locus test in mice involves exposure of nonmutant mice to the test substance and subsequently mating them with multiple-recessive stock. Mutant offspring have altered phenotypes such as hair or eye colour, ear length or hair structure. As noted above, clastogenic potential can be assessed *in vivo* by exposure to the test chemical and subsequently examining mitotically active tissue, such as bone marrow, for chromosome injury.

12.3.9 Combustion Toxicology

It has been estimated that 50–75% of deaths occurring within a few hours of being exposed to a fire are the result of inhalation injuries and systemic toxicity (Ballantyne, 1981). The primary aim of combustion toxicology is to determine the adverse effects produced as a result of exposure to heated or burning materials. Although considerable emphasis has been placed on acute effects, there is increasing concern about the long-term consequences of repeated exposure to the products of combustion in occupationally exposed individuals, such as fire fighters. The design and interpretation of appropriate studies may be difficult because of the large number of variables that may affect the nature, concentration and temporal variations of combustion products. The major, though not exclusive, factors that influence the toxicity and hazard from a fire atmosphere include the nature of the material available for heating or burning, the phase of the combustion process, temperature, air flow and oxygen availability, and potential for interaction between the combustion materials generated. All of these factors may be required to be investigated and considered in evaluating the continually changing hazard from a fire. Principal lines of investigation and sources of information about toxicity and hazards from fire atmospheres are as follows:

1. Physicochemical studies to determine the nature of the products of combustion generated under differing conditions of temperature and oxygen availability
2. Animal exposure studies
3. Clinical and forensic observations on fire casualties to determine the nature and cause of morbidity and mortality from exposure to a fire atmosphere.

Although investigations designed to investigate the nature and determinants for materials producing local respiratory or systemic toxicity are of clear importance, it is also necessary to be aware of the presence of materials that may produce sensory irritant or central nervous system depressant effects. Clearly, irritant effects on the eye or narcosis may impede escape from a potentially hazardous situation. Polymers, which constitute a major component of commercial and domestic buildings, provide good examples of the generation of toxic, irritant and neurobehavioural chemical species on combustion (Ballantyne, 1989; see **Combustion Toxicology and Implications for Adverse Human Health Effects**).

12.3.10 Antidotal Studies

In addition to being aware of the likelihood of spontaneous reversibility of toxic injury (i.e. biochemical, physiological and morphological healing), it is of clear practical importance to investigate the induction of reversibility of toxicity by antidotal procedures (Marrs, 1988; see **Antidotal Studies**). Indications for such studies include high acute toxicity (including dose and time to onset of effects); serious (but potentially reversible) repeated exposure toxicity; where there are indications that early treatment may reduce or abolish latent toxicity; suspicions of a potential for antidotal effectiveness based on considerations of mechanism of toxicity and confirmation that antidotal treatment is effective for a new member of a chemical series for which a generic antidote has been established. Examples of chemicals for which specific antidotal treatment has been investigated include cyanides (Marrs, 1987; Meredith *et al*., 1993; Ballantyne *et al*., 2007), ethylene glycol and DEG (Baud *et al*., 1988; Brent *et al*., 1999; Buchanan *et al*., 2008; Velez *et al*., 2007) and OP anticholinesterases (Arena and Drew, 1986; Ellenhorn and Barceloux, 1988; Bismuth *et al*., 1992).

In addition to investigating specific antidotal therapy, it may also be necessary to confirm, or otherwise, if standard methods of management and support are appropriate for particular substances or groups of materials.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

This may include, for example, potential for aspiration hazards, influence of dilution (by giving fluid to drink) and potential for adverse interaction with drugs used to maintain cardiovascular or respiratory homeostasis.

12.3.11 Human Studies

Information resulting from human exposures may be available for certain chemicals, and can be divided into:

1. That generated experimentally, including volunteer studies and clinical trials
2. That resulting from and observing exposed populations using epidemiological techniques.

Investigational exposures of human subjects have been carried out to variable extents with a heterogeneous collection of substances, including medicinal products, cosmetics and body-care products, certain pesticides (JMPR, 1999) and industrial chemicals, food additives and chemical warfare agents (Marrs *et al*., 1996). The types of studies conducted include efficacy determinations with careful detailed monitoring for potential averse effects (clinical studies), pharmacokinetic and metabolism studies, confirmatory (to laboratory animal findings) irritancy and sensitization studies, monitoring of epidemiological studies. Carefully controlled volunteer studies are conducted for the following basic reasons:

1. To confirm the absence of potentially adverse health effects with substances that by the nature of their use patterns are deliberately brought into contact with specific routes of exposure. These may include, as examples, skin irritation or sensitization tests with cosmetic formulations, or phototoxicty/photoallergy studies with materials dosed orally or epicutaneously.
2. To investigate the metabolism and/or pharmacokinetics of a material. This may be important where prior studies have shown species variability in the pharmacokinetic or metabolic behaviour, which can be correlated with the development, or otherwise, of a particular toxic end point. In such cases, human volunteer studies can aid in determining which animal model may best represent the human situation, and hence allow a comparative risk assessment for the use of the particular material for the human population (Wilks and Weston, 1990).
3. To study quantifiable dose–exposure relationships, where a detailed hazard evaluation or risk assessment is required for the in-use application in the human population. One example is with OPs, where an assessment of dose–response and NOEL values are required with respect to cholinesterase inhibition.
4. To meet national and international governmental regulations where specified.

The conduct of human studies has implications for ethical and potential litigation considerations. Although the objective of a human volunteer study is to obtain information relative to human safety evaluation, the prime concern should be for the volunteers and to ensure that they are not exposed to unacceptable risks (van Gelderen *et al*., 1990). Clearly, detailed forethought is required to avoid the production of adverse effects that could lead to harm and possible subsequent litigation. Occasionally, clinical drugs trials in human volunteer subjects have been associated with severe reactions; for example, in a small trial involving the testing of an anti-inflammatory agent, the adverse effects were critical and volunteers required treatment in an intensive care unit (BBC, 2006). In addition to study design in order to obtain the most relevant and meaningful information, detailed attention should be given to professional, ethical, regulatory and legal factors. Sass and Needleman (2004) have noted that human studies with low statistical power are not useful for determining the presence or magnitude of adverse effects from xenobiotics, and that industry-sponsored studies may (knowingly or unknowingly) lead to bias in study design, analysis and interpretation. In 2003, the US National Research Council noted that because of potential bias in industry-sponsored and conducted studies they should receive careful scrutiny. At an expert workshop held during 2002 in New York it was noted that even at that time there were no general ethical guidelines for studies of pesticide toxicity conducted in humans and no governmental oversight. The participants developed several ethical and public policy recommendations regarding human testing of pesticides (Oleskey *et al*., 2004).

In selecting volunteers for human studies it is necessary to ensure their good health, but constraints may be necessary on certain sectors of the population: for example, women of child-bearing age, atopics and those with genetically determined biochemical disorders, such as glucose-6-phosphate dehyrogenase deficiency. Proposals for human volunteer studies should receive the approval of an independent 'ethics committee' or 'institutional review board' (IRB). They hold responsibility for deciding that the proposals are justified, possible to conduct, that the procedures are acceptable and that the study carries the minimum of risk for the participants. The IRB should be subsequently informed of any changes in the project, if there are any early indications of adverse effects or any other significant untoward events. In general, IRB approval mainly centres on risk–benefit relationships and the adequacy of the informed consent processes (Goldman and Links, 2004). The ethical committee or IRB should be totally independent of the institution or organization conducting the study. It has been proposed that the traditional IRB should be supplemented with an environmental

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

health and community review board that would have an extended ethical construct of dignity, veracity, sustainability, justice and community-based issues (Gilbert, 2006).

The major guidelines under which human volunteer studies are permissible are as follows:

1. The reasons for conducting the study have been clearly defined, including an understanding of why the study will give information relevant to hazards evaluation and/or risk assessment in the human that may not be possible by nonhuman studies.
2. The concept in 1 above should be clearly stated in the protocol, which should also contain all technical details, the rationale for the route and mode of exposure, number of volunteer subjects required and monitoring procedures. The protocol should be reviewed and approved by the IRB.
3. A risk–benefit analysis should ideally be carried out in advance of the study; the smaller the direct benefit to the community, the lower should be the risk to individual volunteers.
4. The investigators conducting the study should be appropriately qualified, and this is documented.
5. Compensation to volunteers for participating in a study should be limited to inconveniences and not be an inducement.
6. Informed consent should be obtained from volunteers who must sign an appropriate consent form that should embrace the following: (i) the purpose of the study, the procedures involved and any potential risks have been comprehensively explained to the volunteers (Melnick and Huff, 2004), (ii) there is a right to refuse to participate without penalty and (iii) it is clearly stated that the volunteer can withdraw at any stage of the study.

It is of importance that the publication policies of medical and scientific journals that accept papers dealing with toxicological research involving the participation of human volunteer subjects should stress compliance with ethical, legal and human rights protection aspects. This accords with the clear intent of Article 27 of the Helsinki Declaration: 'Reports of experimentation not in accordance with the principles laid down in the declaration should not be accepted for publication'. This qualification on the publication of toxicological research involving human volunteer participation has been adopted by several professional societies who require documentation of compliance with ethical and regulatory guidelines on submission of manuscripts for publication; for example, the Society of Toxicology (Schwetz *et al*., 2005).

13 REVIEW OF TOXICOLOGY STUDIES

A critical review of toxicology studies requires detailed case-by-case considerations, but attention should be generally directed to at least the following:

- That the laboratory or institution reporting the study has the necessary scientific and/or medical credibility, capabilities, experience and expertise in the areas being investigated.
- The objectives of the investigation should be precisely stated, and the study protocol should reflect this in detail.
- The work should be reported in a clear and unambiguous manner, with all the necessary detail to allow the reader to undertake his/her own assessment and conclusions about the study.
- There should have been adequate quality control procedures, and standards appropriate to good laboratory practices (GLPs) should have been followed.
- The material tested should be precisely specified, including stability and the nature and amounts of any impurities, conversion products or additives.
- It should be confirmed that the methodology that is used for exposure and to monitor the *in vivo* or *in vitro* studies is sufficiently specific and sensitive to allow the various objectives and end points to be determined.
- Studies should be designed to allow a determination of the significance of the results and permit hazard and risk assessment procedures. For example, the number of test and control animals should be sufficient to allow for the detection of biological variability in response to exposure, to allow trends to be appreciated and to permit statistical analyses. There should be sufficient dose–response information to allow decisions on causal relationships and the magnitude of dosages which produce definite and threshold effects and those not producing toxicity.
- Monitoring should allow a determination of whether any injury produced is a direct consequence of toxicity or an effect that is secondary to toxicity at another site. A primary effect is one produced as a result of a direct toxic effect of a chemical, or metabolite(s), on a target organ or tissue. Secondary effects are those occurring, often at another, but nontarget, site, as a consequence of toxicity in the primary tissue or organ. For example, primary pulmonary injury produced by inhaled potent irritant materials may result in significant hypoxaemia and secondary hypoxic injury to other organs, including liver, kidney or brain. Ideally the study should be carefully assessed to allow a conclusion as to whether the toxicity induced is a consequence of the action of parent material or metabolite, for example,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

comparison of routes involving and not involving first-pass effects.

- Detailed assessment is required to determine if the numerical data have been appropriately and correctly evaluated. Thus, although there may be a statistically significant difference between a test group and the controls, this may not be of biological or toxicological significance. Conversely, changes or trends, not of statistical significance, may be of biological and toxicological relevance. Quantitative information should be viewed against the study as a whole, normal biological variability, quantitative changes which imply pathological processes and the magnitude of any changes as they may relate to an adverse effect.

The above considerations demand the careful design of toxicology studies, taking into account all factors that are inherent in the defined and inferred objectives of the investigation. To illustrate the care required in the interpretation of toxicology studies, a few examples are given below of different specific factors that need attention in particular studies:

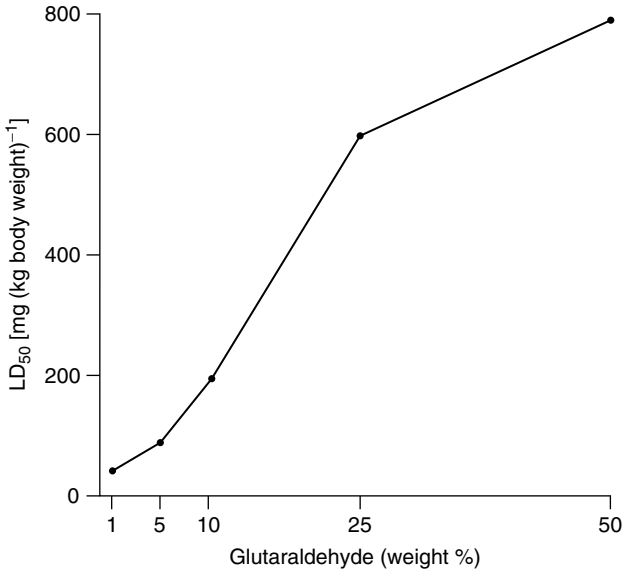

Figure 15 Effect of aqueous dilution on the acute peroral lethal toxicity (as LD_{50}) of glutaraldehyde to rats. As dilution increases the LD_{50} becomes smaller; that is, greater toxicity. (Data after Ballantyne and Jordan, 2001.)

- The acute po LD_{50} of the undiluted diethylamine is $<0.25\,ml\,kg^{-1}$, whereas with a 10% aqueous solution the acute po LD_{50} is $1.41\,ml\,kg^{-1}$, illustrating the influence of dilution of the test material on toxicity. A reciprocal relationship has been demonstrated with glutaraldehyde (**Figure 15**); in this case, acute po toxicity (as mg active material per kg body weight) increases with dilution within the confines of the study.
- Materials with similar LD_{50} values may have differences in acute toxicity shown by other monitors of their toxicity. For example, 2,4-pentanedione has an acute po LD_{50} (rat) of $0.58\,g\,kg^{-1}$, similar to that of BAPP at $0.31\,g\,kg^{-1}$; however, times to death were 2–5 hours with 2,4-pentanedione and three to four days with BAPP, indicating a more serious potential hazard with the former.
- With inhalation studies, the method of generation of the test material in the atmosphere may be a highly important consideration, as indicated by the following three illustrative examples:
  - For acute vapour inhalation studies, and in tests concerned with defining the effects of saturated vapour atmospheres, the vapour may be generated by static or dynamic methods. Static methods involve placing a sample of the test material in the exposure chamber and allowing the atmosphere to equilibrate for an appropriate period of time; thus, all volatile components accumulate to vapour saturation in the chamber. Dynamically generated atmospheres are produced by passing air through the test material and transferring the atmosphere so generated into and through the chamber in a continuous manner; this results in components of the test material being present in the atmosphere in proportion to both their concentration in the test material and volatility. Thus, trace contaminants of highly volatile toxic materials will be present in much higher concentrations with static, as opposed to dynamic, conditions. For example, methoxydihydropyran (MDP), containing 0.037% acrolein, when generated dynamically did not produce mortalities with rats for a four hour exposure period (MDP vapour concentration 7748 ppm; acrolein, trace). However, when the same material was used in a static exposure system there were mortalities due to the accumulation of acrolein vapour in the atmosphere (MDP vapour concentration 8044 ppm; acrolein, 240 ppm); acrolein has a four hour LC_{50} of 8.3 ppm (Ballantyne *et al.*, 1989a).
  - The relative humidity of the chamber atmosphere may influence inhalation toxicity with hydrolysable materials. For example, when tris(dimethylamino) silane (TDMAS) was generated as a vapour with moistened air, a four hour LC_{50} of 734 ppm was determined (female rat), which accords stoichiometrically with toxicity due to dimethylamine formed by hydrolysis of TDMAS. However, when the vapour was generated under dry air conditions, a four hour LC_{50} of 38 ppm was calculated from the exposure–mortality data, indicating

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

a highly significantly greater intrinsic toxicity for the TDMAS molecule (Ballantyne *et al*., 1989b).
- A marked difference in toxicity may be obtained for the same material generated in different modes of exposure or different physical states. For example, short-term repeated exposure to vapour from 2-methacryloxypropyltrimethoxysilane does not produce any respiratory tract injury. However, when generated as an aqueous respirable aerosol it produces laryngeal granulomas (Klonne *et al*., 1987).
- The use conditions of the test material may influence toxicity. Thus, the potential for cutting oil to induce cutaneous neoplasms is significantly enhanced after its industrial use, possibly owing to the generation of polycyclic aromatic hydrocarbons (Agarwal *et al*., 1986).

14 HAZARD EVALUATION AND RISK ASSESSMENT

Toxicology is concerned with determining the potential for materials to produce adverse effects, whereas hazard evaluation is a process to determine if any of the known potential adverse effects will develop under specific conditions of use. Thus, toxicology is but one of the many considerations to be taken into account in the hazard evaluation process. The following are some of the other factors that need to be considered in defining whether a specific use of a material will be hazardous, and are discussed in detail by Tyler and Ballantyne (1988):

- Physicochemical properties of the material
- Use pattern
- Characteristics of the handling procedure
- Source of exposure and route of exposure, both normal and possible misuse
- Control measures
- Magnitude, duration and frequency of exposure
- Physical nature of exposure conditions (e.g. solid, liquid, vapour, gas, aerosol)
- Variability in exposure conditions
- Population exposed (e.g. number, sex, age, health status)
- Any experience and information derived from exposed human populations.

The general approach used to assess hazards is as follows:

1. A search for all available health-related information on the substance and, if appropriate, substances of close chemical structure. This may include information on physicochemical properties, *in vivo* and *in vitro* toxicology, epidemiology, known occupational and domestic incidents, case reports, monitoring and use patterns. Mention should be made of the use of structure–activity relationships (SAR) for the prediction of toxicity. Basically this generally involves a computer-based modelling approach to relate chemical structure to (adverse) biological activity and, where sufficient information exists, to develop quantitative structure–activity relationships (QSAR) of biological potency. These approaches may yield valuable information that can be used in the planning of toxicology studies and, within the limits of the methodology and its assumptions, supply interim predictive statements on potential hazards. When used for hazard-evaluation purposes, it should clearly be stated that the information has been derived by SAR methods. Although a useful approach in the absence of 'hard' information, it has been noted that given the large range and variability of possible interactions of chemicals in biological systems, it is highly unlikely that SAR models will ever achieve absolute certainty in predicting toxicity, particularly with respect to the whole-animal system (McKinney *et al*., 2000).
2. Detailed impartial review of all information obtained, emphasizing those studies conducted by credible scientific standards and by relevant routes of exposure.
3. Interpretation of the credible and relevant literature in order to define toxicity and, if possible, mechanism, dose–response relationships and factors influencing toxicity (endogenous and exogenous).
4. Conclusions regarding potential adverse effects from the substance under specific conditions of use.
5. Determination of acceptable handling or in-use conditions and acceptable exposure to the substance with respect to immediate and long-term conditions of use.
6. Determination of the management of overexposure situations.

The process and understanding of hazard evaluation, and its scientific basis, are now at a level where reliable interpretation and prediction can be made. A less reliable and scientifically limited evaluation process is that of risk assessment, which is an important developing component of regulatory and occupational toxicology. It is the objective of risk-assessment processes to assess the probability that adverse health effects will develop from known, or suspect, xenobiotics in the environment (e.g. drinking water or air) or workplace. Such quantitative risk assessments are most frequently conducted for work-time or lifetime exposure to low concentrations of xenobiotic. They are based on extrapolating dose–response relationships from animal studies, or occasionally human

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

epidemiological data to: (i) determine risk at known or anticipated ranges of occupational or environmental exposure dosages or (ii) to assess 'risk-free' dosages. The approaches most frequently employed are to assess risk from carcinogens, teratogens, reproductively active substances and genotoxic materials.

With most materials there is usually insufficient information on mechanisms of toxicity for particular materials to allow scientifically valid, appropriate mathematical models to be developed for a specific toxic effect. The methods of extrapolation often make many, often biologically unreasonable, assumptions which include: (i) the existence (or otherwise) of thresholds for specific toxic end points; (ii) linearity of dose–response relationships; (iii) comparability of metabolism and pharmacokinetic parameters between species; (iv) the interaction between xenobiotics and biological systems at low concentrations and (v) the statistical reliability and biological variability resulting from the relatively small numbers of animals that may technically and ethically be incorporated into animal studies. Thus, with current mathematical approaches to data extrapolation, quantitative risk assessments should probably be regarded as 'best guesses' for environmentally safe exposure dosages. The findings from quantitative risk assessment may result in risk-management measures being undertaken (Hallenbeck and Cunningham, 1986). This involves the development and implementation of regulatory action, taking into account additional factors such as available control measures, cost–benefit analyses, 'acceptable' levels of risk, and taking note of various policy, social and political issues. More specific and mechanistically reliable estimates can be obtained from the process of 'biological risk assessment', which allows a more rational risk analysis based upon incorporation of metabolism and pharmacokinetic findings, including interspecies differences, mechanisms of toxicity and influence of physiological variables (Clayson, 1987; National Research Council, 1987).

15 SPECIAL CONSIDERATIONS IN HUMAN HAZARD EVALUATION

By the very nature their intended design, laboratory toxicology studies are conducted under highly controlled conditions using healthy animals often of a particular weight range. The extrapolation of such information to a heterogeneous human population, with differing lifestyles and variable states of health, needs to be undertaken with considerable caution, taking into account all possible known and predictable variables. The possible interactions of multiple exposures to a variety of chemicals or drugs has been discussed earlier in this chapter. Other illustrative examples are presented below.

15.1 Personal Habits

Many personal habits, including diet and the taking of medicinal products, may influence the response to a toxic chemical. Two factors that have received special attention are cigarette smoking and excessive alcohol consumption. Cigarette smoking may lead to increased body burdens of many of the combustion products found in smoke, in particular carbon monoxide. Owing to the significantly increased carboxyhaemoglobin concentrations in smokers, they may be at greater risk in the occupational environment from carbon monoxide and carbon monoxide-generating materials, such as methylene chloride. Other materials in cigarette smoke that may increase the exposure burden include hydrogen cyanide, hydrogen sulfide, acrolein and polycyclic aromatic hydrocarbons. In some instances, there are clear indications of significantly enhanced toxicity, for example, synergism between cigarette smoking and asbestos (Hammond and Selikoff, 1973) or radon (Archer *et al*., 1972). Heavy alcohol consumption may lead to chronic progressive liver injury and fibrosis, and thus increase susceptibility to hepatotoxic substances and impair detoxification pathways.

15.2 Coexisting Disease

Individuals with certain illnesses may be at greater risk from particular drugs or industrial chemicals. For example, those with established cardiovascular disease may be at increased risk from exposure to carbon monoxide or methaemoglobin-generating substances, since both may compromise the available oxygen supply to the myocardium. Inhalation of irritant materials may aggravate chronic progressive pulmonary disease.

15.3 Genetically Susceptible Subpopulations

Individuals with genetically determined biochemical variants may be at greater risk from certain drugs and chemicals than those with normal biochemical features. Some examples are as follows:

- Individuals with hereditary methaemoglobinaemia may generate significant amounts of methaemoglobin at exposure doses of nitrites or aromatic amines that cause only minor methaemoglobin concentrations in the normal population.
- It is well known that slow acetylators are significantly more susceptible to the neurotoxic potential of isoniazid, whereas fast acetylators are more

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

likely to develop liver injury, since hepatotoxicity is caused by the metabolite acetylhydrazine (Breckenridge and Orme, 1987). Another aspect of acetylator status relates to the potential of arylamines to induce bladder cancer. Slow acetylators may be more susceptible to arylamine-induced bladder cancer (Cartwright *et al*., 1982), possibly related to a higher urinary excretion of free arylamine (Derwan *et al*., 1986).

- Individuals with glucose-6-phosphate dehydrogenase-deficient erythrocytes may be at increased risk from haemolytic effects of oxidants because of the inability of the erythrocyte to generate sufficient NADPH and maintain an adequate concentration of reduced glutathione, resulting in haemolysis (Calabrese *et al*., 1987). However, animal studies suggest that haemolytic effects occur only on exposure to otherwise toxic concentrations (Amoruso *et al*., 1986).
- Exposure of persons with inherited uroporphyrinogen decarboxylase deficiency to dioxin can cause latent chronic hepatic porphyria to develop into porphyria cutanea tarda (Doss and Columbi, 1987).

Other genetically determined variants that have been implicated as causing increased susceptibility to chemicals include α1-antitrypsin deficiency (emphysema), aryl hydrocarbon hydroxylase deficiency (lung cancer), pseudocholinesterase variants (anticholinesterase toxicity) and thalassaemia (lead). An interaction between environmental factors and specific genotypes has been suggested as being involved in the aetiology of a number of diseases, including parkinsonism (Menegon *et al*., 1998; Cummings, 1999). Genetic screening of workers or prescreening for the identification of susceptible subpopulations to occupational exposure has raised several issues of ethical and social concerns (Christiani *et al*., 2008), and it has been proposed that workers and/or their representatives should be involved in deciding when and where genetic testing in the workplace is done (Holtzman, 2003).

16 PROFESSIONAL AND ETHICAL ISSUES

The right to search for truth implies also a duty. One must conceal any part of what one has recognised as true.

(Albert Einstein)

16.1 General Comments and Principles

There is no utopia with respect to the protection of the human population and the environment against xenobiotics, and it is thus of prime importance that the toxicologist and professional colleagues should be acutely and constantly aware and certain of the ethical and professional foundations of their work and its potential implications, and that they should give opinions in a credible, transparent and professional manner. All professional branches of science and technology have in common the objectives of high standards of learning, practice, personal and professional conduct, and visibility, in addition to more specific considerations relevant to the individual specialization. As a consequence many have developed codes of conduct and guidance note on ethical practices; for example, the Institute of Biology (2005) and the Royal Society of Chemistry (1995). However, codes of conduct and ethics should allow for constructive communication between scientists and the community. This sometimes falls short of expectations, as did the UK Council for Science and Technology 'Universal Ethical Code for Scientists' which was a series of awkwardly worded exhortations and platitudinous rules (Editorial, 2006). Members of the profession of toxicology should also follow the demands of ethical integrity as dictated by their individual conscience and the guidance of representative professional organizations. By their very nature and intended applications, toxicology investigations can have far reaching implications for health-related issues in the workplace, commerce, home and general environment. The same consideration applies to the application and expression of specialist knowledge by the toxicologist in his/her professional capacity. There are, as a consequence, many ethical issues associated with the practice of the science of toxicology and the practical applications of toxicology information. Whereas morality often involves a distinction between what is right and what is wrong, professional ethical considerations may not have such a clear distinction and individual experience, lifestyle, mental orientation and professional outlook are contributing factors. Against these considerations, various competing factors may have an opposing and possibly detrimental effect on the ethical values, and the value of ethical practices, by an individual; these include biases, motivations and potentially conflicting attitudes within a group organization. Thus, toxicologists working in commerce/industry and government service may find themselves in the midst of situations with the potential for group or organization self interest and expectations for bias in attitude and interpretation which could conflict with professional and personal ethical standards, and lead to difficult, strained and possibly inharmonious relationships. Such situations may lead to problems associated with community values, where the behaviours that govern moral and ethical conduct depend on a multiplicity of considerations, principal amongst

which are majority viewpoints of the general population, the existing background of accepted general concepts and principles of moral and ethical values, and what are considered by the majority of a democratic society to the advantage of society relative to health, welfare and harmonious coexistence. Professionals often find that their ability to maintain and adhere to ethical standards is often undermined and enforceably questioned by others with self interests outside the professional field; these may include financial, commercial, economic and politically motivated considerations. All of these may result in significant influences to bias or attempt to manipulate the interpretation and implications of scientific observations, including iconoclasm of credible findings. Some professional society codes of conduct clearly recognize these potential employer–employee conflicts. For example, the Institute of Biology advises employees that—'In serving the interests of their employer in good faith and to the best of their ability, always keep in mind the obligation to serve the public interest and maintain and enhance the reputation of the profession' (Institute of Biology, 2005, p. 5).

Current society is experiencing an unfortunate, disturbing and widening gap between democratic societal moral and ethical values and what constitutes legal dictates. This is particularly noticeable in the adversarial society, notably in the USA; in dictatorial truth denials by commercial and political organizations; as a consequence of the decreasing separation of government and dictatorial religious dogma and in the distorted and smear tactics employed by corporations and government against those with ethical, reasoned arguments for causation.

From a practical standpoint and on the basis of the above considerations it is not unexpected to find in some situations that the design, conduct and reporting of toxicology studies as well as the interpretation of the findings and their implications with respect to human health and the environment, may be adversely influenced by considerations of a political, economic, personal, security or other self-interest nature. In many circumstances such factors may result in biased interpretation (in some cases deliberate) of otherwise credible experimental findings and thus a distortion or even suppression of findings and of the truth. Additionally, as noted by Golberg (1982), it is not unusual to see uncritical acceptance of adverse conclusions drawn from poor data. It follows that toxicologists should not only focus on the credibility and scientific significance of their work, but also within ethical and professional perspectives on the practical use(s) to which to which scientific discovery and knowledge can (or will) be used and for its general societal repercussions or misapplications. This is not, and should not be, the prerogative, as claimed, of those having hierarchical wider political and commercial interests. There is no universal scheme or consensus approach to ensure that all health-related information be made generally available to the scientific, medical and other interested communities, but this is not only a highly desirable, but indeed regarded by many of us as a necessary feature of all research and development activities having implications with respect to human health and the environment. However, self-interest by various individuals, groups, organizations, on a national or global basis, implies that no such utopia of knowledge is ever likely to exist.

Toxicologists can and do, at various times, become involved in legally orientated situations and their consequences. In cases involving litigation, the professional toxicologist should anticipate that his/her credibility will be questioned and should be appropriately prepared for critical evaluation (Furst, 1997; Furst and Reidy, 1999). On a more routine work basis, other major areas where the toxicologist may become involved in processes interfacing with national and international laws and regulations include the following: animal welfare; conduct and reporting of laboratory studies; regulatory test requirements; mandatory reporting of potential adverse health effects, as, for example, under Section 8(e) of the Toxic Substances Control Act (TSCA); human volunteer studies. Ethical aspects of human volunteer studies has been reviewed above (see Section 12.3.11), and several other aspects of ethical–legal interactions in toxicology are briefly discussed below.

16.2 Conduct of Laboratory Studies

Before there was formal regulatory control of the conduct of toxicology laboratory studies in the USA, some commercial and industrial in-house laboratories conducted studies without due regard to the development and adherence to specific protocols, kept poor records of findings and often only reported selected findings in a study. Although such badly conducted studies were rampant in only a few laboratories, instances of lesser unacceptable procedures and practices were not infrequent in many laboratories. Following enquiries by the FDA into deficiencies, inaccuracies and fraudulent data contained in reports, legislation was introduced in 1979 to ensure integrity and reproducibility of studies, in the form of GLP. Following introduction of the FDA GLP regulations, several other countries recognized the need for such legislation, and now most countries have programmes with a GLP core in operation that deal with laboratory facilities and personnel, protocols, reports and archives (summarized by Ballantyne, 2005).

16.3 Animal Welfare

The use of animals can be an emotive subject, and has been the subject of deep and extensive augments,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat001
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

public demonstrations, the use of violence by activists, legislation and the introduction of alternative methodologies (Ballantyne, 2005; Edmunds, 2005). Legal controls on the use of animals in biomedical research lie with government. The most extensive and demanding legislation has been in the UK, where a bill was passed through the British parliament in the nineteenth century (Animal Cruelty Act of 1876), and was updated in 1986 by the Animals (Scientific Procedures) Act. The legislation requires detailed licensing of research facilities and of research scientists, annual returns on animal usage and random audits by the Home Office inspectorate. In the USA, animal welfare became an integral component of conducting sound studies with the adoption of the EPA GLP regulations. As a consequence of the activities of credible animal rights groups and concerns by ethically motivated scientists, there have been considerable efforts to reduce animal discomfort and use *in vitro* toxicology research. These have included reduction in the numbers of animals used, refinement of *in vivo* procedures including improved and noninvasive monitoring procedures, and the development of *in vitro* alternatives. Partly because of the increased activities of animal welfare groups, and associated media reporting, several professional organizations have issued guidance documents for good animal welfare practices; for example, the (American College of Toxicology, 1988, Academy of Medical Sciences, 2007, Society of Toxicology, 2005). These, however, should only be regarded as itemized guidance notes, and not be used as a replacement for a carefully developed individual institutional programme. Continual individual and institutional vigilance is necessary in order to remain within the ethical and legal boundaries of animal care and handling. In-depth reviews on the legal and ethical aspects of animal usage in are to be found in **Chemical Terrorism**.

16.4 Regulatory Activity

The professional activities of many toxicologists will be influenced by the requirements of governmental regulatory agencies. Also, the toxicology community and the general population should be aware of the biased, and possibly misleading, influence that extensive lobbying of political organizations by industry for economic reasons (Loewenberg, 2006). Regulatory activities are to be found principally in relation to the production and in-use aspects of pesticides, industrial chemicals, pharmaceutical preparations, veterinary drugs, food additives, food contact materials, medical devices and cosmetics. The structure of regulations, their precise requirements, and whether statutory or voluntary, varies with the nature of the material regulated and the geographical location of the authority.

Toxicologists in commerce should have responsibility for advising on the scientific aspects of conforming to regulatory requirements, and on study design, conduct and the interpretation of findings. Regulatory agencies themselves have had impact on these aspects of toxicology studies, being obvious from the introduction of GLP principles. There have been phases when the attitude has been 'studies conducted to meet regulatory requirements', and during these phases this has resulted in a fragmentation of intellectual approaches to regulatory-based toxicology. Thus, some toxicology testing requirements that have been proposed by regulatory agencies are too specific for the intended purpose(s) and may contain fine detail that does not permit the flexibility necessary to undertake a vital hazard evaluation procedure. This has, at times, led to an attitude that some mandated regulatory toxicology testing is conducted merely to 'satisfy regulations' rather than to undertake a well-designed study to determine toxicity and permit objective evaluation of hazards. Clearly such attitudes may be conducive to inappropriate toxicology practices, excess use of *in vivo* procedures, and result in documentation that does not allow reasonable assessments of in-use hazards. Such a less than satisfactory and scientifically delinquent approach has resulted in reference to 'cook book' regulatory practices. A rationalized toxicology testing programme requires that for any particular material there is an in-depth consideration of a multitude of factors that may be unique to the material being tested and to its intended use. In no way can a generic protocol substitute for a scientifically reasoned approach to study design. In many cases, however, a scientifically relevant testing programme can be developed in collaborative discussions with regulatory agencies. The current complexities, tardiness and almost incomprehensibility of regulatory toxicology activities, including attempts at global harmonization, has been, to a not inconsiderable extent, a consequence of increasing bureaucracy with excesses of committee structures, permanent and advisory staffing, with personnel lacking the necessary educational and experience backgrounds, infiltration with legislative language and the uncontrolled misuse of meaningless synthetic management and legal language. Attempts at international harmonization, often marred by national interests, have on occasion resulted in flagrant disregard of credible scientific truths, concepts and criteria (Ballantyne, 2005). It is important that competent regulatory agencies who review data for classification and regulatory purposes should have access to credible independent and professionally qualified advisors and advisory committees that do not have vested interests in the economics of any submitting commercial organizations. Advisors should have documented national and international respect for their professional knowledge and integrity (Ballantyne and Marrs, 2004).

16.5 Publications

It is a core belief and value of many of us that the privilege of being allowed to conduct medical and scientific research, and to search for truth, is inseparable from the duty that no part of the truth is withheld. Implicit in this belief is that knowledge is the property of civilization and as such should not be subject to suppression by political agendas or commercial interests. In addition to the manipulation and suppression of the truth for political, commercial, economic and other limited interest reasons, it is clear in some cases that unethical and unprofessional practices in the conduct of basic and applied research are often associated with willful aberrations in the communication of scientific and medical information. Whilst the majority of full-length publications in respected scientific, medical and technical journals are of the highest credibility and significantly add to our knowledge and understanding, some are less desirable. The reasons for manipulating and/or fabricating information in publications are usually the same as those for deviant conduct in the research process. Malpractices have included the publication of fictitious data (Lock, 1995), manipulation of data to support a predetermined viewpoint, data modified to achieve a desired statistical significance and misquoting others (often cited as 'unpublished data'). Editors and referees should be constantly vigilant to detect unprofessional activity in submitted manuscripts. A further unfortunate trend is for some workers to duplicate publication, in which the same, or a marginally altered, paper is published in different journals. It is very unlikely that this is a desire on the part of the author(s) to ensure that the widest audience has access to the information, but more likely the motivation is related to publication proliferation in research-restricted or competitive environments. Those who see such unethical duplication of information, often against the stated objective of the journals, should make this known to the appropriate editor(s). With the objective of preventing, or minimizing, publication of papers containing biased protocols and containing falsified or manipulated data, many journals and scientific societies have developed guidelines and codes of practice for the publication and presentation of scientific information. Editors should ensure that their referees act with professional scientific integrity and impartiality when reviewing manuscripts, and do not attempt to impose their opinions on the subjective interpretation of the findings. Indeed it is reprehensible for a referee to insist that the author's interpretation of findings be amended to accord with the viewpoints of the referee, a situation which some of us have encountered on occasion. In such circumstances the author(s) should formally complain to the journal editor and publisher. The major functions of journal editors and referees should be to ensure, as far as is possible, that experimental design is appropriate for the stated objective of the study, and the information submitted in the manuscript represents a true, complete and unbiased record of the methods and findings.

As a component in the process of ensuring credible reporting and interpretation of information, most toxicology-orientated journals now require that the author(s) include a disclosure statement, for publication, of any possible conflicts of interest that could result in misrepresentation of the facts and opinions expressed. Also, many journals also require that participants in the peer review process must disclose, to the editor, any conflict of interest(s) that could result in reviewer bias of the manuscript (Lehman-McKeeman and Peterson, 2003; Maurissen *et al*., 2005).

Peer review of manuscripts by credible scientific journals is an integral component of codes of practice to ensure quality and integrity of publications. It involves the scrutiny of an author's manuscripts by others who are recognized experts in the same field, and to render an opinion as to the suitability of the submitted paper for publication in a particular journal. In an international survey of 3040 academics with respect to their attitudes to the peer-review process, it was generally concluded (90% of those surveyed) that the process helps scientific communication and, in particular, improves the quality of published papers (Ware, 2008). The major findings were: peer review is widely supported by academics; it improves the quality of published papers; double-blind review is preferred and most effective and postpublication review may be a useful supplement to formal peer review. Although peer review of manuscripts submitted to scientific and medical journals is a well-established and accepted process, there have been attempts to question the value and integrity of this standard practice. The motivations of these moves against the standard practice of peer review are variable, but in many cases have a commercial interest. For example, in May 2007 the *New England Journal of Medicine* was served with a subpoena from Pfizer's lawyers demanding that the *Journal* produce peer review and other editorial documents concerning several of their products. Apparently, Pfizer required the documentation not only for defence in product-liability litigation, but also to discover 'flaws in methodology' in the research that might have been noted by the *Journal*'s peer reviewers. The request was refused, and in January 2008 Pfizer's attorneys filed a motion to compel the production of the required documents. The journal again refused and filed with the court an Opposition and Motion for Protective Order, on the basis that reviewers had been promised confidentiality and that to provide the requested information would hamper the *Journal*'s ability to serve the medical community. The motions were heard in federal court on 13 March 2008, where the judge concluded that 'the *New England Journal of Medicine's* interest in maintaining the confidentiality of the peer-review process is a very significant one, especially in the light of its non-party status, and tips the scale in favour of the *New England of Medicine*'. He also noted that 'the batch

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

or wholesale disclosure by the *New England Journal of Medicine* of the peer review comments communicated to authors will be harmful to the *New England Journal of Medicine's* ability to fulfil both its journalistic and scholarly missions' (Curfman *et al*., 2008b). Pfizer also issued similar subpoenas on the *Journal of the American Medical Association* and *Archives of Internal Medicine*, who both argued the sanctity of the peer-review process, and both had similar progression to that of the *New England Journal of Medicine*. In a 14 March 2008 ruling in federal court in Chicago, the judge concluded, '... given the strong policy behind preserving confidentiality in the peer review process, the Court finds any probative value would be outweighed by the burden imposed on the Journals in invading the sanctity of that process' (DeAngelis and Thornton, 2008; Keys, 2008). Also relevant to the peer-review process is the possibility for breach of reviewer confidentiality by the reviewer communicating review-related information to parties other than the journal for whom a review was conducted (Editorial, 2008). There should be provision for declaration of any conflicts of interest by reviewers that might prohibit confidentiality of the process.

There have, from time-to-time, been proposals from some societies and journals that research sponsored by certain commercial organizations should not be accepted for publication because of possible self-interest bias and possible effect of this on credible reporting and interpretation of information. For example, the American Thoracic Society decided that no longer would it accept medical research sponsored by the tobacco industry in its peer-reviewed journals (Rutter, 1995). Decisions of this nature could be interpreted as journals or societies having a political agenda and exhibiting censorship (Roberts and Smith, 1996), a practice that, if uncontrolled, could extend into research sponsored by other organizations such as pharmaceutical and other industries, or even in-house research activities. One effective control approach is by drawing the attention of the reader to potential ethical and professional issues through the mechanism of disclosure of interests, with particular reference to sources of funding (Landrigan, 1995). Disclosure of interest would be by the inclusion in the published paper of a statement recording source(s) of funding and any vested interest(s) of the author(s) in the work conducted for the sponsoring organization (Lehman-McKeeman and Peterson, 2003). The need for disclosure has been stressed by the recently created nonprofit foundations housed in academic institutions, but organized for the benefits of individual investigators and funded by industry sponsors (Schwartz *et al*., 2008). Although such foundations may be helpful in providing needed research funds, the foundations may not be required to publically disclose details of their funding sources. Funding disclosure in published papers is one critical factor in transparency of biomedical research and its implications for the public health. Perhaps the extreme of industry funding and its potential implications with respect to totally credible and unbiased medical science is afforded by the fact that bioethicists and academic bioethics centres have sought and accepted funding, particularly from pharmaceutical and biotechnology industries (Elliott, 2005).

16.6 General Legal–Ethical–Professional–Employer Interfaces

16.6.1 Overview

By the very nature of their activities, professional toxicologists may find themselves in conflict situations resulting from pressures exerted by others (individuals and organizations) to engage in, or condone, decisions and/or actions that do not accord with personal and professional integrity and ethical principles. Whilst the majority of toxicologists have a high level of ethical and professional standards in the practice of their specialization, a small proportion have lower standards with respect to these qualities; the proportion is about the same as for any other profession (Ballantyne, 1988). In some instances the actions and consequences of lower standards may clearly be illegal and unethical, but in other cases whilst there may not be a direct conflict with the law there is clearly professional misconduct; there is a spectrum of malpractices between these two extremes. Although the majority of toxicological research is undertaken and published against a background of scientific impartiality and integrity, some investigations are conducted with preconceived considerations for the outcome, and in this respect the investigators may design, conduct and interpret the study towards obtaining the desired outcome. The reasons for such professional dishonesty may be multiple, and extend from an individual investigator to a whole organization. They include, but are not limited to, economic considerations, including profit margins, competitive activity within a given production line, product registration, attraction of funding, enforced direction from management, political motivation and career objectives. Malpractices include biased protocol development, nonstated deviations from the protocol, data falsification and fabrication, and omission of data that do not further a preconceived bias. On an organizational basis, instances of lack of scientific integrity, malpractices and professional dishonesty have been noted at times with industry, government and academia, and in some disgraceful distances there have been indications of collusion. For example, in the UK, the Institute of Professionals, Managers and Specialists obtained evidence for concern amongst scientists working for government quangos or for newly privatized laboratories who reported that they were asked to adjust their research

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

conclusions and/or resulting advice. This included 17% who were asked to change their conclusions to suit the customer's preferred conclusions, in some cases this was to obtain further contract work (Ballantyne, 2005). Other examples are almost beyond understanding, since it is clear that the deceit will almost certainly become known. One reprehensible instance in the USA was that of the EPA giving misleading information about health effects to New York citizens from debris, dust and smoke in the air around the World Trade Center following the terrorist attacks on 11 September, 2001. Another example of possible government-department withholding of health-related information is by the Centers for Disease Control (CDC) delaying a report indicating greater health risks for people living in some areas around the US Great Lakes areas (Bristol, 2008). The adverse influences on public health issues by some dishonest business organizations, lobbyists and corrupt political administrations are transparently evident on a continuing basis. At the other end of the spectrum of professional dishonesty is misconduct by individuals or small groups, whose motivations include pressure to publish, the need for funding, financial gain and promotion. In order to limit biased or fraudulent activities in studies conducted for commercial organizations by contact, there should be a clear recorded formal agreement that should include the following: ownership and access to data, study design according to credible scientific principles, conduct, auditing, publication rights and indications for project termination (Paris, 1996). One reason for apparent professional and organizational misconduct may stem from the unfortunate trend, seen in both industry and government service, to appoint 'managers', not on the basis of qualifications, knowledge and relevant experience, but on their tenacious 'team player' attitude for the organization, often in the face of obvious truth and credibility. This has resulted in the direction of work being steered towards what is politically or economically desirable by senior organizational management. It has been 'reasoned' that such an organizational structure of lay management with side lining of experienced professionals permits 'the various factors to be viewed in their widest perspective', whilst in fact it is planned to obtain the 'desired interests' of the organization. The ramifications of lay control of professional activity and expression argue for independence of expression without repercussions (see Section 16.6.5). Under research activities, professional malpractice may include the undertaking of work in a clandestine manner for 'reasons' of national security or commercial advantages, and for similar reasons the suppression or manipulation of data. For example, studies may be undertaken confidentially and with no intentions to make the findings publicly known for commercial (monetary) and deceptive business practices, as identified with the tobacco industry, who have studied the relationship between smoking behaviour and product design (Hammond *et al*., 2006). Strategies resulting from these confidential internal studies relate to exploiting the limitations of toxicology testing and to concealing from consumers and regulatory agencies the potential health dangers of products. This underlines the greed and blatant disregard for pubic health by the tobacco industry, and their current advantage in the USA that there is no (at the time of writing) regulatory activity by the FDA with regard to tobacco products (Curfman *et al*., 2008a).

Toxicologists need to be continually vigilant in order to maintain a credible, ethical and professional approach to their work and its implications. This covers work practices and inter-relationships with others, including advisory functions and employers. Some major areas where caution is necessary are as follows.

16.6.2 Professional Conduct

To ensure that scientific investigations are conducted and communicated in publications in accordance with the highest scientific and ethical standards, several professional societies and journals have developed codes of practice for their membership and contributors. Such codes require thoughtful development against a myriad of challenges (Goodman, 1996). They should not be regarded as static documents for display, but as guidelines that require periodic revision against the changing background of investigational procedures and evolving knowledge. It has been proposed that there are three broad approaches to preventing scientific fraud and misconduct: education, standards and training (Evered and Lazar, 1995). These should be conducted by, demonstrated by and practised by the staff of research and development organizations, academic institutions, government organizations, professional organizations and their society members. When there are accusations of professional misconduct and/or behaviour, these should be dealt with promptly, impartially, by transparent methods and with subsequent access to arbitration and appeal if considered necessary.

16.6.3 Personal Integrity and Denigration

Toxicologists may encounter situations in which there are attempts to degrade their personal integrity and credibility, sometimes due to jealousy, on occasion for financial gain, or because of differing competitive scientific opinion. This may be intradepartmental, conflict between organizations or part of the armamentarium of the legal business. This may be seen at its most unpleasant in some court of law proceedings with so-called expert witnesses making attorney-stimulated derogatory remarks, often with financial incentive, at the opposing expert witnesses, and for which there is often little chance for open rebuttal (Hernberg, 1995).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

16.6.4 Expert Witness

Appearing in court proceedings as an expert witness is, in most cases, a voluntary activity, sometimes carried out for sociopolitical reasons, but usually for financial gain. Acting as an 'expert' witness is now a career with some qualified toxicologists in contract organizations or private practice, and their specialist areas can be found in advertising services online. The toxicologist should be aware that as a voluntary expert witness he will be subject to extensive questioning by opposing lawyers concerning his/her qualifications, professional integrity and motivations, and there will be attempts made to destroy credibility as an expert witness. Before accepting an invitation to become an expert witness, the credible toxicologist should make it clear that he/she will act in an ethical and professional manner and not distort the truth for legal augment.

The toxicologist should be aware of, and wary of, the growing nauseating variant on the 'ambulance chasing' activity of the legal business, who seek to further their finances by taking advantage of adverse effects from drugs and medicinal products. In this practice, most noticeable in the USA, the legal business seeks clients, by the medium of television advertisements, who 'might' have developed averse health effects as a result of being exposed to certain industrial chemicals or having been legally prescribed certain specific and named medications. Clients are invited to have a free legal consultation to determine if they have a case against the manufacturer of the named chemical or drug. These advertisements are seen daily and cover, in the main, asbestos, analgesics, antidepressants, cholesterol-lowering drugs and anti-inflammatory agents. Presumably the legal business conduct regular searches of the medical and pharmacological literature for newly reported adverse reactions to drugs. This practice has recently extended into client litigation for general medical and surgical complications; for example, abdominal aortic surgery, haemodialysis, cardiac pacemakers. This practice will ultimately result in significant suppression of new drug developments.

16.6.5 Conflict and Hounding

Leading a credible and ethical professional lifestyle can, if the employee discovers malpractices by his management and/or fellow workers, result in hounding, unfair treatment, dismissal or antisocial activities against the employee, if he/she draws attention to unprofessional or unethical behaviour, including suppression or misrepresentation of health-related information. Discrimination against employees based on disclosure of unsafe and/or unethical practices has sometimes been classed as 'whistleblower' activity, based on the employee making public statements about the suppression or misrepresentation of health-related information. Such unethical employer activity has been recorded to occur in industry, government and academia. In the USA, employees in some states are protected by the so-called 'whistleblower' laws. In New Jersey, for example, this legislation is called the 'Conscientious Employee Protection Act' and is intended to protect employees who act in the public interest, possibly against business interests (Soskolne, 1999). In the UK, protection is provided by the Public Interest Disclosures Act, 1998, which became law on 1 January 1999. It provides that where employees disclose certain types of wrongdoing inside or outside the company or organization they are protected from any form of discrimination or dismissal by their employer (Faculty of Occupational Medicine, 1999). The Act covers situations where a worker reasonably believes that he/she has credible and supportable information and evidence that there has been, or continues to be: (i) the commission of a criminal offence; (ii) failure to comply with a legal obligation; (iii) a miscarriage of justice; (iv) a danger to the heath and safety of any individual; (v) damage to the environment and (vi) the deliberate concealment of information supporting a conclusion of the preceding. 'Whistleblowers' (a demeaning term for ethically and professionally motivated individuals), should be aware that the vicious Mafia-like tactics adopted by industrial and government organizations are likely to persist, and that they will continue to face continued career suicide, economic and emotional deprivation, victimization and personal abuse (Yancy, 2000). Thus, in a survey of 87 'whistleblowers' from public service and industrial organizations in the USA, all but one experienced retaliation (Sockon and Sockon, 1987). There is doubt as to whether protection by legislation is supported by some political administrations; this includes the US Federal Executive Branch from 2000 to 2008 who had a clear industry/commerce financial-motivated approach. The public community should be grateful to those who risk their careers and well-earned reputations by drawing attention to employing organizations who covertly undertake malpractices and misinformation for political, commercial and financial motivations, particularly if the issues involved are health-related matters. The increasing recognition of the value of 'whistleblower' activities and the protection they should be afforded is emphasized by the formation of a National Whistleblowers Center based in Washington DC, which has an extensive informational web site (*http://whistleblower.org*) and several publications, such as Kohn *et al.* (2004).

There is a clear need for greater emphasis to be placed on the utmost importance of professionalism and ethical approaches in toxicology, particularly because of its wide implications for public health. These need to be infused into the early stages in the training of toxicologists at graduate and postgraduate levels. Educationalists need to draw attention to the social responsibility of the toxicologist and to audits of the practice and standards

Acute Toxicity

David J. Andrew

CONTENTS

1 INTRODUCTION

Historically, the study of toxicology was largely limited to investigations of acute toxicity; the induction of effects within a short time period following the administration of a single dose of an acutely toxic substance having obvious advantages for the investigator and some of the fundamental principles of modern toxicology are based on these investigations. The basic principles of acute toxicity testing have changed little, although testing on unwitting or unwilling humans has been replaced by the use of animal models, and studies are now performed primarily for the purposes of ensuring human safety rather than the converse. However more recently, advances, both in our understanding of the mechanisms of acute toxicity and in scientific techniques, have enabled a further move towards the use of 'alternative' models.

1.1 Definition

Acute toxicity can be defined as the adverse effects resulting from a single (or short) exposure to a chemical substance or repeated exposures within a short period of time (less than 24 hours), and which also occur within a short period of time following exposure. Acute toxicity is typically apparent within a few hours of exposure to the substance, however for the effects of some substances may be manifested within a much shorter period of time (seconds or minutes) or may be much more delayed. While some definitions of acute toxicity refer to effects that occur within 14 days of exposure, this time period probably reflects the standard period over which studies of acute toxicity are performed and it is possible that, for some substances, effects may be delayed beyond this period. The time between exposure and toxicity is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat002

obviously strongly influenced not only by the level of exposure, but also by the kinetic parameters, which are dependent on the route of exposure.

As is also the case for other types of toxicity, acute toxicity results from a combination of the inherent toxicity of the substance and systemic exposure of the tested organism. Obvious exceptions to this are those local effects such as irritation or corrosion which do not require systemic exposure. Systemic exposure can only occur if the substance is absorbed from the gastrointestinal tract, through the skin or from the respiratory tract; all of which provide barriers to absorption of varying effectiveness. Administration of the substance by another, parenteral route (intravenous or intraperitoneal), effectively avoids these physiological barriers to absorption and therefore gives more information on the mechanism of toxicity, although these routes of administration are of limited relevance to most classes of substance. A combination of acute toxicity studies using a parenteral and another route of administration can be used to indicate the extent of absorption (bioavailability) by this route, however it is important to note that other factors such as metabolic deactivation (such as the first pass effect following oral exposure) may also have a major effect on toxicity.

For a large proportion of substances, the toxic effects resulting from a single exposure are distinct from those seen following repeated exposures over a longer period of time. This may simply reflect the fact that acute toxicity studies generally use much higher doses than those used for repeated dose (sub-acute, sub-chronic or chronic) toxicity studies. Thus acute toxicity studies performed with benzene will identify depression of the nervous system typical of hydrocarbon solvents as the major toxic effect, whereas longer-term studies will identify adverse effects on the bone marrow. Those substances that are rapidly absorbed will tend to be more acutely toxic, however distinct, delayed toxic effects may also be seen. The toxicity of rapidly absorbed and eliminated substances which cause rapidly reversible effects is likely to be similar following acute and chronic administration: an example of this is the toxicity of carbamate compounds which cause the inhibition of acetylcholinestesterase activity in the peripheral and central nervous system (see **Toxicology of Pesticides**). Recovery from sub-lethal doses of carbamates is essentially complete due to the rapid reversibility of the critical effect and further exposures are tolerated without enhanced sensitivity. The repeated dose toxicity of these compounds can therefore be compared to a series of acute doses. Conversely, for substances whose toxicities are not totally reversible within a short period of time, the toxicity following repeated dosing will be greater (and potentially much greater) than that seen following acute administration.

While it is possible for teratogenic or carcinogenic effects to result from a single exposure to a substance, the longer latency periods mean that these types of effect are not classified as acute toxicity. Delayed toxicity following an acute exposure is also known for some compounds, one of the best-known examples being the organophosphate tri-orthocresyl phosphate (TOCP), where the characteristic clinical and histopathological effects of neuropathy are typically not apparent until 10–20 days following administration (see **Neurotoxicology**).

1.1.1 Threshold of Toxicity

For all chemicals—even the most potently toxic—there is a level below which adverse effects will not occur or will not be apparent. This concept of the threshold of toxicity is based on the assumption that adverse effects will not occur until a sufficient number of molecules of the toxic substance have interacted with their target within the body, or that at low levels of exposure endogenous defence mechanisms will deactivate the substance or otherwise prevent it interacting with its target.

The acute toxicity of carbon monoxide results from the critical interaction of the carbon monoxide molecule with haemoglobin to form carboxyhaemoglobin which effectively prevents the release of oxygen from the erythrocyte into the tissues. However, there is a threshold for carbon monoxide toxicity equivalent to approximately 10% carboxyhaemoglobin, below which there are no apparent acute toxic effects. The minor paracetamol metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI) is highly reactive and is capable of causing damage by binding to hepatocyte macromolecules. At therapeutic levels of paracetamol, NAPQI is effectively deactivated by binding to glutathione, however at high dose levels, increased NAPQI production results in a depletion of glutathione levels. Glutathione levels may drop to a critical point at which NAPQI is not deactivated and it is able to cause hepatocellular damage.

2 HISTORY

The toxic actions of naturally occurring substances have been studied for millennia; the earliest observations recorded approximately 5000 years ago by Shennong, reputed to be the father of traditional Chinese medicine. The ancient Egyptian Ebers papyrus (circa 1550 BC) and Sumerian texts (circa 1400 BC) also include references to poisonous substances. However it was probably the ancient Greek philosophers and physicians (including Homer, Socrates, Theophrastus, Aristotle, Hippocrates and Mithridates) who first systematically studied the action of toxins and their antidotes—often on prisoners—a practice which was continued by Cleopatra (69–30 BC). Paracelsus (1493–1541) defined the dose-response relationship, one of the basic principles of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

modern toxicology at a time when others (including Rodrigo and Cesare Borgia, and Catherine de'Medici) utilized poisons primarily for political and monetary gain. Again the more acutely toxic substances were used to produce the desired effect and it is reputed that Medici also conducted experiments on the poor and sick in order to refine her assassination techniques.

2.1 The LD_{50}

The formal testing of substances for acute toxicity has been carried out for nearly a century: the important concept of the LD_{50} (the median lethal dose) was first defined by Trevan (1927), and was used as a biological assay for measuring and standardizing the content of digitalis extracts, diphtheria toxin and insulin. Intra-individual differences in susceptibility to a given substance result in a range of sensitivity within a population and plotting the frequency of a quantal response, such as death, against dose gives a bell-shaped curve; plotting the cumulative frequency against dose results in a characteristic sigmoidal dose-response curve characteristic for the compound administered and the species investigated. These dose-response curves were used to estimate the dose lethal to 50% of the animals tested, which was designated the LD_{50}. Mathematical transformation of the sigmoidal curve into a linear function allows more accurate derivation of the LD_{50} and its associated confidence intervals. The use of probit values was introduced later to allow for uncertainty resulting from the use of fewer animals and dose levels (Bliss, 1935), however this method is less effective for studies including groups with 0 or 100% responses. A simplified graphical procedure of calculating LD_{50} values and their associated confidence limits has been defined by Litchfield and Wilcoxon (1949); more recently, computer programs for calculating LD_{50} values have been developed.

The median lethal dose is therefore the statistically derived amount of a substance found or estimated to be lethal to 50% of a tested group of animals. The acute oral LD_{50} of a substance is the most frequently used indication of comparative toxicity and is conventionally expressed in terms of milligrams of substance per kilogram bodyweight: this also enables some estimation of the lethal dose for species other than that tested. Other less commonly used measures of acute toxicity include the LD_1 (the dose level of a substance calculated to be lethal to 1% of a population), the LD_{99} (the dose calculated to be lethal to 99% of a population) and the LD_{lo} (the lowest dose level causing lethality). LD_{50} values are relevant to exposure routes (e.g. dermal, intravenous) other than the inhalation route, for which the analogous measurement LC_{50} (the atmospheric concentration of a substance estimated to be lethal to a group of animals) is used.

2.1.1 Measurement of the LD_{50}

The LD_{50} value is conventionally expressed with its 95% confidence limits to give an indication the uncertainty in its derivation. Separate values may be expressed for males and females and for the sexes combined. While slight differences in LD_{50} values calculated for the two sexes are common and most often to reflect biological variation, more marked differences between the two sexes may reflect a greater sensitivity of one sex.

Considerable effort has, in the past, been expended in precisely measuring the LD_{50} value for substances in an individual study. This approach necessitates the use of a large number of experimental animals: a classical LD_{50} study can use as many as 200 animals (10 animals per sex at 10 different dose levels). However such precise measurements are of limited value as biological variation and other factors can have major influences on the measured LD_{50}, meaning that the results of these studies are very difficult to replicate. This is particularly the case for compounds of moderate or low toxicity. Parameters that can influence the LD_{50} include the age, strain, sex, nutritional status and housing conditions of the animals. It has been recognized for some time that LD_{50} values have poor reproducibility (Griffith, 1964), and multilaboratory trials have showed variation in the LD_{50} value of 3–11 times for the same substances (Hunter *et al.*, 1979).

2.1.2 Use of the LD_{50}

With a few exceptions, such as the use of the mouse intraperitoneal LD_{50} to standardize preparations of very toxic substances such as botulinum toxin, LD_{50} values are primarily used to compare or rank the toxicity of a group of chemicals for purposes such as hazard classification. The use of studies designed to precisely define the LD_{50} have therefore received considerable criticism both for scientific reasons and for reasons of animal welfare. Over recent years, a number of alternative methods to estimating the LD_{50} have been developed, which both reduce the numbers of animals used and also reduce the reliance on lethality as an endpoint.

3 ACUTE TOXIC EFFECTS

Other than death—the most obvious and most frequently measured effect in acute toxicity studies—a single exposure to a toxic substance can potentially have any number of acute effects. Toxicity may occur as a result of an effect at the organ, tissue, cellular or biochemical level and may be reversible or irreversible. The reversibility of a given effect will be governed by its precise nature as well as its severity: for example, the length of time required to synthesize an irreversibly inhibited enzyme or for the cells of a particular organ or tissue to regenerate to replace those lost through cytotoxicity. Irreversible toxicity may result from damage to cells with little or no

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat002
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

regenerative capacity. The severity of an effect may also be influenced by factors such as species, age, sex and genetic susceptibility.

The acute toxicity of a chemical may be highly specific in that it targets a single enzyme, cell type or organ; or it may be nonspecific and targets a large number of organ or tissue types. Specific toxicity can result from the inherently greater sensitivity of an organ or tissue or from relatively high exposure. An example of the former is the toxicity to the nervous system of sarin; an example of the latter is the toxicity of paraquat to the lung. The liver is a common target of acute toxicity for orally ingested substances as a consequence of physiology: the hepatic portal vein ensures that the absorbed substance is transported effectively to the liver, thereby achieving relatively high tissue levels, which can exceed the detoxification, cellular defence or repair capacities of the organ. Similarly, high dose levels of substances excreted predominantly in the urine may cause acute renal toxicity as a consequence of their concentration by the kidney.

The acute toxicity of chemical substances covers a very large range, with LD_{50} values reported over many orders of magnitude from the essentially nontoxic to the exquisitely toxic (**Table 1**). The substances most acutely toxic to humans are naturally occurring; the reported LD_{50} value for botulinum toxin is in the order of 1 ng kg^{-1} bw. Among the most acutely toxic synthetic substances are those used as chemical weapons including the nerve agents such as sarin and VX (for which the human lethal dose is estimated to be 10 mg by dermal exposure). It is notable that some of the most acutely toxic compounds known are naturally occurring rather than manmade: this runs counter to the common public misconception that natural substances are less harmful than synthetic chemicals.

3.1 Routes of Toxicity

The potential of a substance to cause acute toxicity following different routes of exposure not only depends on its inherent toxicity and toxicokinetic factors, but also its physical form. Acute toxicity via the inhalation route is clearly only relevant for substances where exposure by this route is possible; the respiratory tract can be considered to be a relatively poor barrier to absorption, particularly for those substances reaching the deep lung. Acute dermal toxicity is generally lower than acute oral toxicity as the skin provides a much more effective barrier to absorption, however it is also possible that detoxification may be not be as rapid following dermal administration in the absence of a first-pass effect.

3.2 Acute Toxicity in Humans

Acute poisoning incidents resulting from dietary exposure to food contaminants and from the deliberate or accidental administration of plant or mineral toxins have occurred throughout history. In modern societies, the production of synthetic chemicals has resulted in a large increase in the exposure of populations to toxic chemicals. Whilst exposure to most of these substances is tightly regulated to ensure the absence or to minimize

Table 1 The acute oral toxicity of selected substances

Chemical	Acute oral LD_{50} value (mg kg^{-1}bw)	Chemical	Acute oral LD_{50} value (mg kg^{-1}bw)
Ascorbic acid	11900	Paraquat	150
Ethanol	7060	Methyl isocyanate	69
Cimetidine	6000	Amphetamine	60.5
Paracetamol	3700	Nicotine	53
Sodium chloride	3000	Strychnine	16.2
Ibuprofen	1600	Arsenic pentoxide	8
Aspirin	1500	Sodium cyanide	6.44
Morphine	905	Fluoroacetic acid	2.5
Lithium chloride	751	Mercury (II) chloride	1
Phenobarbital	660	Sarin	0.165
Codeine	542	2,3,7,8-TCDD	0.02
Amitriptyline	530	Tetrodotoxin	0.01
Caffeine	200–400	Polonium 210	0.00001
Warfarin	323	Botulinum toxin	0.000001

the likelihood of acute toxicity, it is perhaps inevitable that incidents of acute toxicity continue to occur.

Figures from US Poison Centres for 2006 (Bronstein *et al.*, 2007) show a total of over 2.4 million reported poisoning incidents, of which just over 50% were defined as paediatric (i.e. those involving children of $\leq$5 years old). The majority of these reported exposures resulted in no effect or only minimal toxicity; 'major effects' were reported for less than 1% and death for 0.1% of the cases. The most commonly involved substances were analgesics (11.9% of the reported incidents), with cosmetics (8.9%) and household cleaning substances (8.9%) also important causes. It is perhaps of note that the large majority of the reported incidents (92.6%) occurred within the home, with only 2.1% occurring in the workplace. Figures for the UK (HES, 2007) show a similar pattern, with analgesic poisonings [particularly involving paracetamol and nonsteroidal anti-inflammatory drugs (NSAIDs)] accounting for a large proportion of cases and hospital admissions. The most recent mortality statistics available for the UK are for 2005 [Office for National Statistics (ONS), 2007] and show that, while poisoning deaths account for only a very small proportion (<0.5%) of the total mortalities, the deaths of over 2000 people in that year were attributed by the coroner to poisoning **(Table 2)**. The majority (approximately 75%) of the deaths attributed to poisoning were due to drugs (pharmaceuticals and drugs of abuse), whereas a smaller proportion resulted from exposure to 'nonmedicinal' substances. A larger proportion of deaths were classed as 'accidental' (of which most were overdoses of prescribed pharmaceuticals or drugs of abuse) rather than 'deliberate' and only a very small proportion of the intentional mortalities were classed as homicidal.

Mass human poisoning incidents are relatively rare, but have occurred following the catastrophic failure of chemical manufacturing plants with the release of large amounts of chemical at Seveso (1976) and, with far more severe consequences, at Bhopal (1984). While occupational exposure to chemicals in the developed world may be controlled by the use of protective equipment, exposure limits and other industrial hygiene measures, relatively minor health effects such as headache, nausea and local irritation may still occur. Fortunately, fatal acute poisonings are rare, such as the death due to cyanide poisoning of five employees of an electroplating plant in Auburn, Indiana in 1988.

Mass poisonings resulting from the contamination of food are also well documented and include Minamata disease (Japan, 1956 and 1965); amnesic shellfish poisoning (first reported in Eastern Canada in 1987); toxic oil syndrome (Spain in 1981) and the deliberate adulteration of wine with diethylene glycol in Austria in 1985. The outcomes of such incidents vary widely from minimal acute toxicity to large numbers of fatalities.

Acute toxic effects following the correct therapeutic administration of a pharmaceutical agent can be classified as either an exaggerated pharmacological response, a recognized side effect or an idiosyncratic reaction with an immune system involvement. The potential for acute toxicity following the correct use of any given pharmaceutical will be influenced by its therapeutic index; severe effects (including death) occur with a much greater frequency following accidental or deliberate (suicidal) overdose.

Acute toxicity resulting from exposure to pesticides occurs more frequently in those applying products in the field, as the exposure levels encountered by this group are generally higher, however poisoning incidents account for only a relatively small proportion of the total incidents reported (4% in the USA; Bronstein *et al.*, 2007). There is a risk of acute toxic effects in the consumer resulting from the consumption of treated produce where the crop or produce has been treated with an unlicensed product or treated inappropriately (for example at a higher application rate or

Table 2 UK poisoning deaths (2005)

Category			Number of deaths		
			M	F	Total
Deaths due to poisoning	Drugs, medicinal substances	Heroin	118	20	138

closer to harvest) with a licensed product. Incidents are more frequently reported in countries where pesticide use is less tightly regulated and often involve the more acutely toxic organophosphate and carbamate compounds.

Deliberate poisoning incidents in humans (suicidal or homicidal) most commonly involve chemicals known to be acutely toxic; paraquat, methanol, ethylene glycol and paracetamol are examples. Homicidal poisonings have become relatively rare in recent times, possibly as a result of increasingly sophisticated and powerful chemical analytical techniques, and are consequently well-publicized when they do occur. Recent cases include the 1994–1995 Japanese terrorist attacks using the nerve agent sarin, the alleged dioxin poisoning of Viktor Yuschenko and the assassination of Alexander Litvinenko with polonium 210.

4 ACUTE TOXICITY AND REGULATION

The safety testing of drugs in experimental animals became mandatory following the introduction of the USA Federal Food, Drug and Cosmetic Act in 1938 following the deaths of more than 100 patients (mostly children) following the use of diethylene glycol in a sulfanilamide preparation. Similar requirements were subsequently introduced in other countries and for other groups of substances, including industrial chemicals, food additives and pesticides.

The various pieces of legislation require the manufacturers, suppliers or importers of chemical substances to appropriately classify the substance to reflect the acute toxic hazard and to show this classification on the packaging of the substance. The precise classification and terminology used to reflect the toxic hazard varies according to the country, the group of substance and the relevant legislation; however, the general principles are similar and follow the assignment of the substance to a particular category of toxicity. For acute oral, dermal and inhalation toxicity, the classification category to which the substance is assigned depends on the estimated LD_{50}/LC_{50} value. The most acutely toxic substances are variously classified as 'Very Toxic', 'Highly Toxic' or 'Extremely Toxic'; substances are typically assigned to this category if the acute oral LD_{50} value is less than $50\,mg\,kg^{-1}$ bw. Less acutely toxic substances (for example those with oral LD_{50} values of between 50 and $200\,mg\,kg^{-1}$ bw) are assigned a classification such as 'Toxic' or 'Hazardous'; those less acutely toxic still (for example those with oral LD_{50} values of between 200 and $2000\,mg\,kg^{-1}$ bw) are assigned a less severe classification such as 'Harmful' or 'Slightly Hazardous'. Substances of little or no acute toxic hazard (generally considered to be those with an oral LD_{50} value of $>2000\,mg\,kg^{-1}$ bw) do not generally require labelling. The classification category to which a substance is assigned also governs the hazard symbol to be used on the label.

Companies are therefore obliged to perform assessments of acute toxicity in order to establish the toxic hazard of their products, to meet legislative requirements regarding safe transportation and to ensure (as far as possible) the safe use of the substance. The results of the acute toxicity studies also define the risk phrases, safety phrases, instructions for safe use and appropriate medical/first aid treatment which appear on the material safety data sheet (MSDS), an important component of product stewardship and occupational safety and a legal requirement under most legislation.

4.1 Industrial Chemicals

The 1976 USA Toxic Substances Control Act (TSCA) was enacted in order to give the Environmental Protection Agency (EPA) the ability to assess the estimated 75 000 industrial chemicals used in the USA. The act requires manufacturers to provide toxicity data for new chemicals and also gives the EPA the authority to require chemical manufacturers to test existing chemicals. The toxicity data requirements are governed by the nature of the chemical and the quantity produced, however the basic toxicity data requirements include acute toxicity studies. In the European Union (EU) there is a harmonized approach to the classification and labelling of industrial chemicals under the Dangerous Substances Directive (Directive 67/548/EEC). The 'base-set' toxicity data requirements for any new chemical produced in quantities of $\leq 100\,kg\,yr^{-1}$ is acute toxicity via the oral and one further exposure route (the choice of second route being governed by the physicochemical properties of the substance and its intended use), skin and eye irritancy, and skin sensitization. Similar data are required for existing chemicals produced or imported at levels of 10 tonnes yr^{-1} or greater. More recent EU legislation on the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) has updated the data requirements, but testing for acute toxic effects remains an important part of the hazard characterization (see **Occupational Toxicology and Occupational Hygiene within the European Union (EU) Chemicals Regulation**, **Regulatory Toxicology**, **Risk Assessment of Chemicals**, **Basic Toxicological Issues in Product-Safety Evaluations**).

4.2 Pesticides

Acute toxicity studies (acute oral, dermal and inhalation toxicity studies, skin and eye irritation studies, skin sensitization study) form part of the basic data

requirements for pesticide active substances under the USA Federal Insecticide, Fungicide and Rodenticide Act (FIFRA, 1947), the Canadian Pest Control Products Act (PCPA, 1985) and (in the EU) Directive 91/414/EEC. Acute toxicity studies are also required for pesticide products under the relevant legislation, however in the EU pesticide products are covered by the Dangerous Preparations Directive (see below) and studies may not be necessary. In the USA the results of the acute toxicity studies are used to categorize the product for general or restricted use depending on its acute toxic hazard; the hazard is indicated on the product label using the words 'Danger', 'Warning' or 'Caution'. In the EU, the indicators of acute toxic hazard are 'Very Toxic', 'Toxic', 'Harmful' or 'Irritant'; the severity of the classification influences the protective equipment and medical information on the product label and certain classifications for acute toxic effects may preclude the use of the product in a domestic situation.

The different classification categories for pesticide products in the USA and EU are shown in **Table 3**; there is a risk that the use of different categories may result in studies of acute toxicity being repeated to satisfy the requirements of the different regulatory agencies. One of the aims of the United Nations (UN) Globally Harmonised System (GHS) of Classification and Labelling of Chemicals, implemented during 2008, is to eliminate such duplication.

4.3 Pharmaceuticals

The USA Food and Drug Administration (FDA) requires that the acute toxicity of a pharmaceutical be tested in two mammalian species (rodent and nonrodent) prior to the first human exposure in clinical trials. Studies are usually performed using two routes of exposure: the route of intended administration to humans and intravenously. Similar data requirements apply in the EU under Directive 2001/83/EC. While acute toxicity studies performed with pharmaceuticals are currently a regulatory requirement, a recent report from a workshop involving the pharmaceutical industry and regulatory agencies highlights that the data from these studies is little used. The report highlights the fact that findings from acute toxicity studies are never used to identify target organs or to set the starting dose for studies in man (Chapman and Robinson, 2007). It was also highlighted that the studies would not be performed if they were not a regulatory requirement.

5 ACUTE TOXICITY TESTING

Acute toxicity studies are, in most cases, the first studies performed with a substance of unknown toxicity. The results of these studies are used in hazard identification, to provide information on the mechanism of toxicity and therefore the likely treatment regimes for accidental overexposure to the substance when in use. The results of the acute toxicity studies are also used to inform the dose selection for longer-term toxicity studies, where these are required by the relevant regulatory regime.

As is the case for other types of toxicity studies, the choice of animal model should ideally be informed by its relevance to humans both in terms of general physiological and biochemical comparability and also in terms of the pharmacokinetics and pharmacodynamics of the substance being investigated. The use of a representative animal model enables the experimental response to be extrapolated to humans with a greater degree of confidence. The species most commonly used for acute toxicity testing—the rat—is widely accepted as a relevant model, however the response of the animal model may be more or less than in humans and, in some cases, the model may have a completely different response. A general principle of chemical risk assessment is the precautionary assumption that humans will respond in the same way as the most sensitive animal species tested. Following this assumption, therefore, testing for acute toxicity in a number of different animal species is preferable and may also reduce some of the uncertainty

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat002

associated with interspecies extrapolation, as observing a common response in a number of different animal models increases the likelihood that the response will also be seen in humans. Despite the potential advantages, acute toxicity testing is most commonly performed in a single species for reasons of convenience, ethics, economics and the extensive background data. While interindividual variation in the test species is minimized by the use of inbred strains and by minimizing variations in age, bodyweight and general health, the potential remains that relying on a single species may considerably under- or overestimate the acute toxicity of a compound.

As the extent of absorption of any given substance appears to be relatively consistent between species, differences in sensitivity are therefore due largely to other toxicokinetic parameters such as metabolism, distribution and excretion, and toxicodynamic factors, which show more marked interspecies variability. Although the expression of the LD_{50} value in terms of $mg\,kg^{-1}$ bw enables some estimation of toxicity in other species, this is not entirely reliable. Better estimates can be made using the linear relationship between the log of the bodyweight and the log of the LD_{50} value, both within a species and between different species (Morrison *et al.*, 1968) or using allometric scaling, however these approaches assume that the kinetics of the substance and the toxic response are the same. More recently, more accurate interspecies extrapolation has been made possible by physiologically based pharmacokinetic (PBPK) modelling, which takes into account differences in kinetic parameters.

5.1 Principles of Acute Toxicity Testing

Most acute toxicity tests are conducted for hazard identification purposes, therefore the principles of study design are relatively unsophisticated. A single large dose of the chemical is administered to a group of animals, which are then observed for a relatively short period of time—typically up to 14 days. The results of an acute toxicity study can indicate the critical toxic effect, the target organ or tissue, can inform the choice of dose levels for longer-term, repeated-dose toxicity studies and indicate the likely effects of accidental or deliberate oral exposure in humans. Well-designed acute toxicity studies are unusual in that groups of animals are dosed sequentially with increasing dose levels of the substance; the time interval between administration of the dose levels should be sufficient for the full effects of the previous dose level to be manifested.

5.1.1 The Limit Dose

The fundamental concept of toxicology—first stated by Paracelsus—that all chemicals are toxic if administered in high enough quantities, clearly has the potential result that test animals are administered unreasonably large dose levels which have no relevance to human exposure scenarios. This potential for the use of very high dose levels of chemicals of limited toxicity is clearly undesirable, not least for reasons of animal welfare. The use of excessive doses may be scientifically unreliable, as very large quantities of a foreign compound may cause purely physical effects which may be misinterpreted as direct toxicity. There is therefore a point at which it should be concluded that a test material is of intrinsically low toxicity and does not pose any hazard with regard to acute lethality. This point is defined as the limit dose and, depending on the relevant legislation is defined as a dose level of 2000 or 5000 $mg\,kg^{-1}$ bw.

5.1.2 Observations

The observations and measurements made in a study of acute toxicity are typically limited and will include periodic observations of clinical signs and behaviour (most frequently during the 24 hours immediately following dosing), and measurement of bodyweight. The observations should therefore provide information on the time course of the acute toxic response, including the rate of recovery and, where more than one dose level is used, information on the dose-response relationship. Terminal investigations are also limited to macroscopic observations of major organs and tissues. Experience indicates that acute toxicity is, in the majority of cases, due to a general biochemical effect rather than any specific effect and is not associated with any visible change in tissue or cell structures (Gad and Chengelis, 1988). The most common causes of death in acute toxicity studies generally involve the nervous, cardiovascular or respiratory systems (DiPasquale and Hayes, 2001) and may not be readily identified by gross necropsy or histopathology. Histopathological investigations may be useful in identifying the smaller proportion of chemicals causing death as a result of specific toxicity to other organs such as the kidney or liver, but are rarely performed as part of a regulatory acute toxicity study. However, if acute toxicity studies are to provide the primary safety data for a pharmaceutical substance supporting single-dose safety and/or kinetic studies in humans, the acute toxicity studies should incorporate investigations of clinical pathology and histopathology. These parameters are assessed at an early time point (i.e. at maximum effect) and at termination (to assess recovery) [Centre for Drug Evaluation and Research (CDER), 1996].

Modern test methods place increasing emphasis on clinical signs, with less reliance on death as an endpoint. However, while some clinical signs (or combinations of signs) are characteristic of a mode of toxicity (e.g. interaction with a specific receptor, inhibition of a particular enzyme) or target organ, most are nonspecific and it is clear that most chemicals cause death by nonspecific actions following acute administration. Clinical

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat002
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

signs—for example, those associated with the inhibition of a specific enzyme—may be rapidly reversible; others—for example, those associated with functional or structural damage to an organ or tissue—may be less rapidly reversible or irreversible within the period of the study.

The liver is a common target of acute toxicity as a consequence of its role in the metabolism and excretion of xenobiotics. For chemicals administered orally and transported by the hepatic portal system, the liver is often the primary target of toxicity. Clinical signs of hepatotoxicity are largely nonspecific and difficult to distinguish by cage-side observation. Early detection of liver damage requires clinical chemistry investigations, which are not performed as part of acute toxicity studies, however gross changes to the organ at necropsy may indicate hepatotoxicity. The kidneys are a common target of acutely toxic chemicals as they receive a large proportion (circa 25%) of the cardiac output. The role of the kidney in xenobiotic excretion may also result in the concentration of toxic chemicals and/or toxic metabolites in this organ. Clinical signs, such as polyuria and haematuria, seen in acute toxicity studies may indicate nephrotoxicity, however prolonged or repeated exposure may be required for renal effects to be lethal. Pulmonary injury is clearly much more frequent in acute inhalation toxicity studies and may result from local irritation or tissue damage. Clinical signs of pulmonary injury include various effects on the rate, depth and regularity of breathing and are readily detected. However, certain compounds, such as paraquat, may target the respiratory tract regardless of the route of administration. The nervous system is a common target for acute toxicity due to its complexity, high metabolic activity and relatively low regenerative capacity. Relatively nonspecific clinical signs may result from a general stimulation or depression of the nervous system, however the activation or inhibition of a neurotransmitter receptor or the inhibition of a specific enzyme may result in a characteristic effect (Straub tail) or syndrome (cholinesterase inhibition). Chemicals causing effects on the cardiovascular system may not produce any signs other than general nonspecific signs. Chemicals causing effects on the haematopoietic system may cause pallor or cyanosis; haematuria may also be cause by haemolytic agents.

Table 4 illustrates clinical signs observed in acute toxicity studies; it is apparent that many of the clinical signs are nonspecific and are of little value in indicating a target or mechanism of toxicity.

5.2 Acute Oral Toxicity

Investigations of acute oral toxicity are the most fundamental and therefore the most commonly performed toxicological studies *in vivo*. The study forms part of the

Table 4 Signs of toxicity

Clinical sign	Target of toxicity	Clinical sign	Target of toxicity
Piloerection Hypoactivity Ataxia Prostration Loss of coordination Abnormal gait Chromodacryorrhoea Exophthalmos	Non-specific	Lacrimation Salivation Rhinorrhoea Aggression Passivity Resistance to handling Vocalization Hyperactivity	Autonomic nervous system Nervous system/ nonspecific

basic data requirements for most (if not all) groups of substances and the results may be used: (i) for hazard identification purposes; (ii) for classification and labelling purposes and (iii) to inform the dose levels to be used in subsequent animal studies or in clinical studies with pharmaceuticals.

Administration of the test substance is most commonly by gavage dosing, although capsule administration may be used in some species. The rat is the most commonly used species, although the testing of acute oral toxicity in additional rodent or nonrodent species may be required under some regulatory regimes. If rats are used they are fasted overnight, which allows a larger volume of the dosing vehicle to be introduced into the stomach and also eliminates any variation in absorption resulting from the presence of food in the stomach, or variation in response resulting from differences in nutritional status. Shorter periods of fasting are recommended for smaller species such as the mouse as these have greater energy requirements and prolonged fasting can influence the result of the study.

Liquid substances are administered either undiluted or diluted in a suitable dosing vehicle such as water or corn oil. If more than one dose level is used, either the volume of the test material will vary (if it is administered undiluted) or will be constant for each dose level (if a dosing vehicle is used). The vehicle itself should be of known low toxicity and should not directly influence the toxicity of the test compound. Solid substances are either dissolved in a suitable solvent or suspended homogeneously in an aqueous vehicle; suspending agents such as methyl cellulose may be used to ensure homogeneity. The nature of the dosing vehicle and the physical state of the substance in the vehicle can influence the rate and/or extent of absorption from the gastrointestinal tract and hence its systemic availability and toxicity. The acute oral toxicity of lipophilic substances has been shown to be higher when dissolved in a suitable solvent compared to suspension in an aqueous dosing vehicle. Toxicity is also known to be influenced by the size of particles administered as a suspension: fine milling of a solid substance to produce small particles has been shown to increase toxicity compared to coarser particles, presumably due to the increased rate or extent of oral absorption. Corn oil, a vehicle commonly used for substances insoluble in aqueous vehicles, is of low toxicity, but can increase gastrointestinal motility and may result in reduced absorption of the test substance.

The Organisation for Economic Cooperation and Development (OECD) guideline 401 was deleted in 2002, but was the standard international method for many years. This guideline described a more limited version of the classical acute toxicity test and included the concept of the limit dose. Thus it became possible for chemicals of relatively low toxicity to be administered to a single group of five animals at the limit dose of $2000\,mg\,kg^{-1}$ bw if no mortality resulted. If mortality was seen at the limit dose, then testing proceeded in a sequential manner at set dose levels of 500 and $50\,mg\,kg^{-1}$ bw. The results of the study gave an approximation of the LD_{50}, but provided sufficient information to allow the substance to be assigned to a classification category. A number of alternative methods are now available to assess acute oral toxicity.

5.2.1 Fixed-Dose Procedure

This method, proposed by the British Toxicology Society, was validated in an international study involving 20 reference chemicals (Van den Heuvel *et al.*, 1990), and subsequently adopted as OECD guideline 420. The concept behind the design of the method is again that the results of the test are used simply to assign the chemical to a classification category.

The objective of the study is to identify 'evident toxicity', without requiring mortality as an endpoint. Groups of a single sex are administered the test material at one of four fixed dose levels (5, 50, 500 and $2000\,mg\,kg^{-1}$ bw). If mortality occurs, the test is repeated at a lower dose level; if there is no evident toxicity, the test is repeated at the next higher dose level. Testing is not required at dose levels below $5\,mg\,kg^{-1}$ bw or greater than $2000\,mg\,kg^{-1}$ bw and the choice of initial dose level should be informed by any data available on the acute oral toxicity of related compounds in order to reduce the number of animals used. The use of females is preferred, as, if there are marked differences in sex sensitivity, females are generally shown to be the more sensitive sex (Lipnick *et al.*, 1995).

5.2.2 Acute Toxic Class Method

Unlike the fixed-dose procedure, the acute toxic class method (Roll *et al.*, 1986) uses lethality as the primary endpoint, however it does potentially use fewer animals. The method is based on a sequential dosing procedure with the use of a minimum number of animals (three) in each step. The substance is administered sequentially to groups animals at four defined dose levels (5, 50, 300 and $2000\,mg\,kg^{-1}$ bw). The absence or presence of compound-related mortality is used to determine the next step: either no further testing is needed, three additional animals are administered the same dose or dosing proceeds to the next higher or the next lower dose level. This method is reproducible and gives sufficient information on the acute toxicity of the test substance to assign it to an appropriate classification category.

5.2.3 The Up and Down Method

This method (Bruce, 1985), which has been adopted as OECD guideline 425, again uses mortality as an endpoint, but uses fewer animals. LD_{50} values derived from this method have been shown to correlate well with

DOI: 10.1002/9780470744307.gat002
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

more conventionally derived values. The test involves the administration of a dose, estimated to be a step below the LD_{50}, to a single animal, with the choice of subsequent dose level (usually a factor of 3.2 lower or higher) informed by the mortality or survival of this animal at 48 hours. The method is therefore most appropriate for those chemicals causing relatively rapid death and is less suitable for those causing more delayed effects. The LD_{50} and its confidence interval are calculated based on the status of all dosed animals at termination.

5.3 Acute Dermal Toxicity Testing

Dermal exposure is the major route of exposure for most chemicals encountered in the workplace; the assessment of the toxic hazard is therefore a regulatory requirement for this group. In common with studies of acute oral toxicity, the species of choice is the rat, however studies in rabbits may also be encountered. Although the pig is increasingly being used for investigations of dermal toxicity due to the close structural similarity of pig skin to human skin, this species is not used for acute dermal toxicity studies where the primary aim is hazard characterization and assignment of a substance to a classification category.

The general design of the study is that the test substance is applied to the skin of five animals of each sex per dose level used. Prior to application, the skin of the test animals is shorn to allow the test substance to come into close contact with the surface of the epidermis. The applied substance is covered with an occlusive or semi-occlusive dressing in order to maximize contact over the exposure period; the dressing also prevents any loss by run-off, evaporation or oral ingestion by the test animal. Solid substances are commonly ground to a fine powder and applied to moistened skin in order to maximize contact and therefore the potential for dermal penetration and systemic exposure. Older study designs may include investigations of comparative toxicity following application to abraded and intact skin; however dermal abrasion is of less relevance and is additionally now considered to be undesirable for reasons of animal welfare. Modern studies therefore investigate toxicity using intact skin only. Test guidelines specify an exposure period of 24 hours; exposure is terminated by washing the exposure site with water, an aqueous solution of mild detergent or (less frequently) another solvent. Following the termination of exposure, animals are observed for a period of time—typically 14 days. Signs of toxicity will be assessed at regular intervals on the day of exposure and daily during the remainder of the study; the site of exposure is also assessed for local irritant effects. Other investigations are typically limited to weekly measurement of bodyweight and gross necropsy at the end of the study; in some instances more detailed histopathology may be performed on the exposed skin, however this is not a standard guideline requirement.

Mild clinical signs such as chromodacryorrhoea and reduced weight gain observed in the initial stages of an acute dermal toxicity study may be a consequence of the dressing used to apply the test material and not to direct toxicity of the substance, however it can be difficult to definitively identify the cause. A number of dose levels may be used in order to provide an estimation of the LD_{50}; a limit dose of 2000 mg kg^{-1} bw can be used for substances suspected to be of low toxicity (OECD guideline 402).

When compared to acute oral toxicity, it is notable that there are no alternative methods for the assessment of acute dermal toxicity which would reduce the numbers of animals used and/or reduce reliance on lethality as an endpoint. However, a draft method (OECD guideline 434) analogous to the fixed-dose procedure for acute oral toxicity has been proposed. There is also increasing criticism of the routine requirement in some regulatory regimes for an acute dermal toxicity study. Analysis of a large number of studies performed in support of applications for pesticide approval in the EU has shown that the acute dermal toxicity study almost never provides any useful additional information (Thomas and Dewhurst, 2006). Instead it has been proposed that the requirement for an acute dermal toxicity study is not a default, but is triggered by specific criteria, such as marked acute oral toxicity and/or evidence for significant dermal absorption. Similar criteria are applied for other regulatory systems such as the EU biocides system, recognizing that significant toxicity by the dermal route is unlikely in the absence of inherent toxicity of the test material and/or significant systemic exposure.

5.4 Acute Inhalation Toxicity Testing

Acute toxicity may result from the inhalation of a substance in the form of a gas, vapour, aerosol or small solid particle (dust). The assessment of acute inhalation toxicity is therefore a regulatory requirement for a number of substance types, where exposure via this route is possible. Inhalation exposure will only occur if the substance is encountered in an inhalable form, which is determined primarily by particle size. For substances in the form of a solid or nonvolatile liquid, this is generally accepted to mean particles of size $\leq 5-6\,\mu m$ and extensive technical measures are undertaken in the test laboratory in order to generate atmospheres containing particles within this range. Exposure to particles of between 1 and 4 μm is generally considered to be most appropriate in an acute toxicity study, as this is likely to ensure the deposition of particles in all areas of the rat respiratory tract. In the absence of any information on the area of the respiratory tract likely to be most sensitive to the test material, this approach ensures most effective testing. OECD guidance (OECD, 2004) states that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat002
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

testing should be performed if it is likely that exposure to particles of respirable size will be encountered under the normal conditions of use. Additionally, exposure may not be expected to occur (and testing is not required) if particles of respirable size cannot be generated under laboratory conditions.

The generally accepted 'acute' exposure period for inhalation toxicity is four hours, and the species most commonly used is the rat. Five animals of each sex per concentration level are exposed to artificially generated atmospheres containing the test material in an inhalable form, such as a vapour or aerosol (for a test material in the form of a liquid) or as a solid aerosol or dust (for solid test materials). Concentration levels are expressed in terms of $mg\,l^{-1}$, or less commonly $mg\,m^{-3}$. A number of concentration levels may be used in order to provide an estimation of the LC_{50} value; a limit concentration of $5\,mg\,l^{-1}$ can be used for substances suspected to be of low toxicity by this route. A maximum concentration of below $5\ mg\,l^{-1}$ may also be used for those substances for which it is technically not possible to generate atmospheres containing a concentration as high as $5\,mg\,l^{-1}$. The test animals are generally restrained during exposure, with only the snout in the exposure chamber (nose/snout-only exposure). Whole body exposure—where the animals are present in the exposure chamber—has been used in the past; this method is less desirable, as exposure of the animals to the test substance results from a combination of inhalation, dermal and oral (resulting from grooming behaviour) and is consequently less representative.

Observations are made during the exposure period (although these may be limited for restrained animals), immediately following exposure, at regular intervals on the day of exposure and daily for the remainder of the study period. Clinical signs may indicate systemic toxicity or local irritation of the respiratory tract, however restraint of the animals during snout-only exposure can result in mild clinical signs that may be mistaken for toxicity. Terminal investigations are generally limited to gross necropsy, although more detailed investigation of the respiratory tract including measurement of lung weight may be made. A comparison of 'wet' and 'dry' lung weights can identify those compounds causing pulmonary oedema. In some laboratories, measurement of core (rectal) temperature is made during or immediately following exposure. While this effect is thought to be specific to the rat, it can give an indication of the potential of the test material to cause respiratory irritation in exposed humans (Pauluhn and Mohr, 2000). This response also has the potential to markedly reduce the systemic exposure of the tested animals to highly irritant chemicals. An alternative fixed-concentration procedure (OECD 433) has been proposed for acute inhalation toxicity testing which is analogous to the oral fixed-dose procedure.

5.5 Dermal Irritation and Corrosion

In addition to acute systemic toxicity, dermal exposure to chemical substances also has the potential to cause local effects (irritation or corrosion) at the site of exposure. Dermal irritation refers to the production of reversible local damage to skin at the site of exposure, Effects appear shortly after exposure and are characterized by the some or all of the signs (erythema, oedema, pain and swelling) typical of an inflammatory response. Irritant chemicals are able to penetrate the stratum corneum and are cytotoxic to the underlying layers of the epidermis. Dermal corrosion is a more severe effect involving full thickness destruction of skin tissue, which may be irreversible. In contrast to skin sensitization (discussed below), dermal irritation and corrosion are nonimmunogenic responses.

Substances of a number of classes, including cosmetics, household products, pesticide products and industrial chemicals, clearly have the potential to come into contact with the skin as a result of deliberate application or accidental exposure. Assessment of the potential for local irritant effects at the site of contact is therefore an integral part of the hazard assessment for these groups. Substances with the potential to cause severe dermal irritation or corrosivity should be identified on the basis of structure–activity relationship (SAR) analysis or physicochemical properties such as pH, and not tested *in vivo*. Regulatory guidelines also specify sequential testing using *in vitro* methods prior to investigation *in vivo*, for reasons of animal welfare. The irritant potential of a substance may also be predicted from data available for related substances or from the findings of the acute dermal toxicity study, and additional testing is not required.

Studies of dermal irritation *in vivo* are performed in the rabbit—the use of albino strains facilitates the observation of irritant effects. Regulatory guidelines specify the use of either three or six animals. A single animal is initially exposed and the study discontinued if severe reactions are observed. A standard exposure time of four hours is used and dermal contact with the test material is maintained by covering the application site with a dressing. Exposure to the test material is terminated by washing the application site either with water or with a solution of mild detergent. Local dermal reactions at the application site are assessed at specified time points, generally within one hour of application and subsequently at 24 hour intervals. Observations are continued for 72 hours or until the irritant reactions have resolved if these are still present at 72 hours. Irritant reactions (erythema and oedema) are scored using standardized scales. Assignment of the substance to a classification category depends on the regulatory regime and is dictated by a combination of the severity and reversibility of the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

reaction. The testing of coloured substances can be problematic, as staining of the skin at the application site may interfere with the assessment of erythema.

5.6 Eye Irritation and Corrosion

Eye irritation is defined as the production of changes in the eye following the application of a test substance to the anterior surface of the eye; corrosion is defined as the production of irreversible tissue damage to the eye. In common with the strategy for dermal irritation/corrosion testing, investigations *in vivo* should not be undertaken until relevant information, such as physicochemical properties (e.g. pH) and data from related substances have been considered. Testing should then be performed sequentially, with an initial screen *in vitro* included to detect those substances likely to be corrosive or severe irritants *in vivo*.

Studies of ocular irritation *in vivo* are performed in the rabbit; this species is preferred for a number of reasons, despite some concerns regarding the reliability of the extrapolation of irritant effects to man due to structural and functional differences. The response of the rabbit eye to a chemical is often more severe than the primate eye (Buehler and Newmann, 1964) and alternative methods, such as the low volume eye test (LVET) have been shown to produce a degree of irritation more consistent with that following human exposure.

The substance (0.1 ml of a liquid; 0.1 ml or 100 mg of a solid) is instilled into the inferior conjunctival sac of one eye of three or six rabbits (following initial testing in one animal); the other eye of each animal remains untreated and acts as a control. It is commonly recommended that solid test materials are ground to a fine powder prior to testing. The test material may be washed from the treated eye with saline or water. The treated eyes are examined at intervals up to 72 hours following instillation of the test material; observations may continue for up to 21 days (or until the reversibility of effects is demonstrated). Ocular reactions (including conjunctival erythema and oedema, iritis and conjunctival opacity) are graded using various schemes, such as that defined by Draize *et al.* (1944). The irritation seen for solid substances may result from a combination of physical and chemical effects. The test substance is assigned to a classification category; the category is governed by a combination of the severity and reversibility of the reaction.

5.7 Skin Sensitization

For regulatory purposes, testing for skin sensitization—the ability of a substance to cause delayed contact hypersensitivity—is usually grouped with other aspects of acute toxicity. Although a sensitization response can be induced by one exposure to a substance, prior exposure to that substance is required for the establishment of the immune memory required to elicit the response (see **Immunotoxicology**). The immune system of the mouse has been better characterized than that of other species, however it is the guinea pig that has been the species of choice for skin sensitization studies for several decades. Guinea pig tests for sensitization can be divided into two general categories: those using injection of an adjuvant to potentiate sensitization and test that do not use adjuvant. Of the numerous tests developed, the Buehler test (Buehler, 1965)—a nonadjuvant method, and the maximization test (Magnusson and Kligman, 1969)—an adjuvant method, are the methods specified by regulatory guidelines. The guinea pig tests are similar in that they consist of two phases: an induction phase, during which an immune response to the test substance may develop, and a challenge phase, during which the immune response is expressed as an allergic dermal reaction. In order to increase the sensitivity of the studies, the concentration of the test substance used for induction should be the minimum irritant concentration; the concentration used for challenge should be the maximum nonirritant concentration. It is important in this type of study for the investigator to be able to distinguish between irritant and hypersensitivity reactions, therefore the study designs include control animals which are only exposed to the test substance during the challenge phase. The incidence of sensitization reactions following challenge exposure is used to assign the chemical to a classification category.

More recently, the mouse local lymph node assay (LLNA) has been validated as an alternative to the guinea pig methods (Basketter *et al.*, 1996), and is the preferred method under some regulatory regimes. The principle underlying the LLNA is that skin sensitizers cause lymphocyte proliferation in the lymph nodes adjacent to the site of application. The test substance is applied in a suitable solvent to the ears of groups of female mice at three concentrations; groups of positive and negative control animals are also used. The immune response to the application of the test substance is assessed by the incorporation of tritiated thymidine in the lymphocytes of the local draining (auricular) lymph nodes compared to control animals, and is expressed as the stimulation index (SI). An SI value of three or greater is considered to represent a positive response for purposes of classification.

6 ALTERNATIVE METHODS IN ACUTE TOXICITY TESTING

In the UK in 2006, approximately 420 000 animals were used in studies performed for toxicological purposes; a relatively large proportion (circa 34%) of these animals were used in tests of acute toxicity (Home Office, 2007). Acute toxicity testing is an easy target for those opposed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat002

to animal testing and it is increasingly being argued by those within toxicology that the existing *in vivo* studies of acute toxicity are outdated and unsophisticated, and while the more recently developed methods for acute oral toxicity study methods use fewer animals and do not all depend on mortality as an endpoint, similar refinements have not yet been adopted for acute dermal and inhalation toxicity.

From a regulatory standpoint, the primary use of acute toxicity data is for the classification and labelling of chemicals to allow their safe transport and to ensure the protection of the end-user. The relevance of the results of animal studies to humans can be criticized due to the potential for marked species differences in response, and, while it is claimed that similar information could be obtained from studies *in vitro*, these alternative methods also have their own limitations; until alternative procedures have been validated and accepted, conventional *in vivo* methods will continue to be used.

It may be possible to estimate the acute toxicity of a substance by using information available for a structural analogue or analogues; this approach (also known as read-across) is mainly used for the prioritization of untested substances. The EU Dangerous Preparations Directive (Directive 99/45/EEC), which applies to products containing mixtures of substances, adopts a pragmatic approach with regard to acute toxicity testing. Classification of the product can be addressed by a method involving calculation based on the levels and classification of substances within the product. The aim is therefore to reduce the acute toxicity testing required for the large number of products covered by this Directive.

Quantitative structure–activity relationship (QSAR) analysis for predicting acute toxicity is being used increasingly and may be useful for the prioritization of chemicals within a group, but is limited in its ability to predict the response of an animal which is a complex system of numerous different cell and tissue types. The Danish Environmental Protection Agency has made extensive use of QSARs to predict the toxicity (including the acute toxicity) of chemicals; QSAR models are also by the US EPA and other US regulatory agencies to predict acute toxicity for regulatory purposes (Cronin *et al.*, 2003). Available models are used to predict acute oral LD_{50}, skin irritation/corrosivity, eye irritation/corrosivity and skin sensitization. Progress in terms of the training sets and improved predictability is being made constantly.

6.1 *In Vitro* Alternatives

In addition to the refinements to *in vivo* tests described above, significant research has also been carried out into *in vitro* alternatives to animal studies in all areas of acute toxicity testing (see **Alternatives to In Vivo Studies in Toxicology**).

6.1.1 Acute Toxicity

In vitro models of acute toxicity should ideally use human rather than animals cells in order to eliminate interspecies variations in those cellular factors potentially affecting toxicity. The theory that cytotoxicity *in vitro* may be correlated to acute toxicity to an intact animal *in vivo* is based on the premise that the mechanism of toxicity for most chemicals is relatively nonspecific and involves those biochemical processes that are common to all cells; however this is clearly not the case for all substances. The MEIC (multicentre evaluation of *in vitro* cytotoxicity) programme was designed to assess the potential application of *in vitro* assays based on cultured mammalian cells in predicting acute toxicity and, for the chemicals selected, a good correlation was found between cytotoxic concentrations *in vitro* and lethal human blood concentrations. However, simple cell culture models do not take into account the rate or extent of absorption of the substance, for example from the gastrointestinal tract or through the skin. The complete assessment of the acute toxicity of a chemical *in vitro* is therefore dependent on an understanding of its toxicokinetics, including factors such as the rate and extent of absorption, tissue distribution, metabolism and the rate and route(s) of excretion. Subsequent initiatives have therefore also investigated the development of additional *in vitro* tests capable of detecting additional (more specific) mechanisms of toxicity and the incorporation of toxicokinetic parameters. A tiered approach to *in vitro* testing for acute toxicity has also been recommended (Seibert *et al.*, 1996; Botham, 2004). The first tier of this approach involves a combination of basal cytotoxicity tests and physicochemical data on the chemical in question, the second tier involves metabolism *in vitro* in cultured liver cells and the third tier involves the assessment of toxicity to target organs or tissues using (for example) cells of renal, hepatic or nervous system origin. Of relevance to acute oral toxicity testing is the ability to predict the absorption of a chemical from the gastrointestinal tract using physiochemical properties (primarily the octanol/water partition coefficient) or by using cultured human cells such as Caco-2. Validated *in vitro* models using human skin (removed during surgical procedures) have been developed to assess the rate and extent of dermal penetration, however the values obtained from this model are generally higher than those expected *in vivo*. Other *in vitro* assays are available to assess the influence of plasma protein binding on toxicity. Alternatively, kinetic parameters may be modelled using PBPK models, however the majority of these techniques have similarly not been validated to regulatory standards.

6.1.2 Dermal Irritation and Corrosion

The mechanisms by which chemical substances cause dermal irritation are well characterized and therefore

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat002
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

significant progress has been made in this area over a number of years. Organotypic models consisting of epidermal keratinocytes of human origin, cultured to form multilayered and highly differentiated models of the epidermis are routinely used as screens for corrosive substances, prior to testing *in vivo*. The SkinEthic™ and Epiderm™ models measure cell viability [as assessed by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction] and have been validated by the OECD for the assessment of dermal corrosion. Other OECD-validated methods are the transcutaneous electrical resistance (TER) assay, an ex vivo method which measures the integrity of the stratum corneum and the Corrositex™ assay which measures the time taken for the test substance to degrade a barrier consisting of a hydrated collagen matrix (Fentem *et al.*, 1998). In the EU, the *in vitro* EPISKIN™ model has recently been validated as a stand-alone alternative to the rabbit skin irritation test (Botham, 2007). This human skin model is constructed using multiple layers of viable human keratinocytes, and has a functional stratum corneum supported on a collagen matrix. Test substances applied to the epidermal surface are considered to have the potential to cause dermal irritation if they are able to penetrate the stratum corneum and cause toxicity to underlying cells. Cytotoxicity is assessed by a simple MTT assay and by measuring the release of the inflammatory mediator interleukin-1α.

6.1.3 Eye Irritation and Corrosion

There are currently no validated *in vitro* test systems for the assessment of eye irritation. However, a number of *in vitro* models are available and are used routinely as part of a sequential testing strategy to screen chemicals for severe ocular irritation and corrosivity, and to eliminate the need for the assessment of ocular irritation *in vivo*. The rabbit enucleated eye test (REET) assesses effects on the cornea including thickness, opacity and integrity; similar endpoints are assessed in the chicken enucleated eye test (CEET) or isolated chicken eye test (ICET). The hen's egg test-chorioallantoic membrane (HET-CAM) can also be used as a model of mucous membrane irritation.

6.1.4 Skin Sensitization

There are currently no validated *in vitro* tests for the assessment of skin sensitization. However, the mechanisms of sensitization *in vivo* are relatively well characterized and therefore significant efforts have been made towards the development of sufficiently sensitive *in vitro* assays. Current research is focussing on the expression of surface markers and the release of cytokines by dendritic-like cells (Basketter and Maxwell, 2007). Concurrent progress in the development of QSARs for skin sensitization and the prediction of protein binding means that it is likely that future approaches to testing will involve a combination of *in vitro* and in silico methods (Patlewicz *et al.*, 2007).

7 CONCLUSION

Investigations of acute oral toxicity are the most fundamental and therefore the most commonly performed studies *in vivo*: acute toxicity has been investigated for centuries and formal testing is a regulatory requirement for many classes of substances in order to ensure human safety. The relatively simple nature of acute toxicity studies makes them candidates for replacement by alternative methods and, while progress continues to be made in this area, regulatory acceptance of these methods is presently limited. The assessment of acute toxicity should follow an intelligent, integrated approach utilizing all available methods including (where available) read-across from chemical analogues, QSAR analysis and *in vitro* data. *In vivo* testing should only be performed when necessary and, where studies are required, study design should be considered with regard to the relevance of the endpoint being investigated, and also the principles of reduction and refinement.

Repeated Exposure Toxicity

Bryan Ballantyne

CONTENTS

1 BACKGROUND

The amount of detail and usable information on potential adverse health effects that can be obtained from general toxicology studies depends on a multiplicity of factors including, although not limited to, route of exposure, species, total dosage, formulation and purity of test material, the general and specific monitors employed and the timescale for exposure. In order to appreciate the importance of repeated-exposure studies in overall health hazard assessments, it is useful to compare the differences in approaches and resultant findings for acute studies with those for repeated-exposure investigations. This is discussed in outline below.

1.1 Acute Studies as Preliminary to Repeated Exposure

Acute (single-exposure) studies are conducted along the following defined lines for the usual routes of exposure. Perorally (po), the dose is given by bolus gavage or by divided doses over 24 hours; percutaneously (pc), the dose is by skin contact (usually occluded) for a specified period (often 4 or 24 hours); respiratory exposure is by a single inhalation dose for a specified period (to various atmospheric concentrations), or for different variable periods of time to a specific test agent concentration. Other routes of dosing, such as intravenous (iv), intraperitoneal (ip) and intramuscular (im), usually employ bolus dosing. Observations are often conducted over a 14-day postdosing period. Acute studies include provision for observation for signs of toxic and/or pharmacological effects. A major end point is often for mortality, with subsequent calculation of the dose that kills half (50%) of the animals tested (LD_{50}) or the timed concentration that does so (LC_{50}). Most studies also incorporate observations for nonlethal signs, body weights and gross pathology by necropsy of animals that die and survivors sacrificed at the end of the 14-day postdosing observation period. Many acute studies are conducted as screens for toxicity, to obtain information on potential overexposure situations and/or to satisfy regulatory requirements. Because of this, and sometimes for reasons of economy, most acute studies do not include provision for physiological, biochemical or histological monitoring. Although

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat003
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

adding cost, in selected cases much more information related to potential adverse health effects can be obtained by the use of limited haematology, clinical chemistry and histology. Within the constraints of the limited monitoring usually conducted, acute toxicology studies are useful with respect to the following:

1. Give information on potential local and systemic toxicity (and thus permit hazard assessments) by acute overexposure to the material tested.
2. Give information which may be important in determining the acute lethal toxicity, or lack thereof, of the material. In the absence of other information, this is often used as a basis for assuming lethal toxicity in humans, in spite of the difficulties associated with the extrapolation of such data. In a number of cases, acute mortality data obtained from small laboratory animals may be significantly misleading, because of species differences in absorption, pharmacokinetics and metabolism. A notable case is with ethylene glycol: the rat acute peroral LD_{50} is $8.54\,ml\,kg^{-1}$, whereas estimates from human lethal poisoning cases suggests a lethal dose around $1.0\,ml\,kg^{-1}$ (Tyler and Ballantyne, 1988).
3. Permits a comparative evaluation, often based on LD_{50} or LC_{50} data, of the toxicity of materials. However, comparison of such data should not be based solely on the LD_{50} or LC_{50} values, since they may result in misleading conclusions with respect to population hazards. An evaluation of all data, including 95% confidence limits, slope on the dose–mortality regression lines, and times to death, is required.
4. Acute studies, if adequately monitored, may give information on the potential for long-term adverse health effects; for example, delayed-onset peripheral neuropathy from overexposure to organophosphates (Johnson, 1992).
5. Give information needed to meet the requirements of regulatory authorities with respect to classification into categories for use in various activities such as handling, transportation and labelling. Although there are geographical differences in the definition of the various classification bands, there is much activity to attempt to reach harmonization of classification standards on an international basis.

Additionally, and when the available information is sufficient, acute exposure studies may give a limited indication of the potential of a substance to cause local and/or systemic toxicity by repeated exposure. For example, local cutaneous or respiratory tract irritant (inflammatory) effects caused by acute exposure may be anticipated to occur also by repeated exposure to lower concentrations. However, the potential for materials to produce systemic toxicity by acute exposure must be carefully interpreted, as also must the extrapolation of such findings to repeated-exposure conditions. For example, a dose–response relationship for liver injury when the test substance is given perorally may strongly suggest a potential for cumulative hepatotoxicity by lower dose repeated exposure, for example with organic arsenicals (Ballantyne, 1978). In other instances, however, specific acute organ injury may be a secondary effect; for example, renal tubular necrosis in acute inhalation studies with irritant materials may be a consequence of hypoxaemia secondary to lung injury (Ballantyne and Callaway, 1972). A proper evaluation of the potential for toxicity by repeated exposure requires that repeated-exposure studies be conducted. Only in this way can reliable no-observed-effect levels (NOELs) and no-observed-adverse-effect levels (NOAELs) be established. For hazard evaluation purposes it is also useful to have information on the threshold for induction of adverse effects (lowest observed adverse effect level: LOAEL).

1.2 The Need for Repeated-Exposure Studies

Although, as noted above (Section 1.1), in a limited number of cases acute studies may give an indication of the potential for substances to produce toxicity by repeated exposures, this is generally limited to inflammatory effects and clear dosage-related direct organ toxicity. Since many potential toxic effects are not detected in acute studies because of the need for cumulative toxicity to develop or because of a long latency to exhibition of toxicity, reliable evaluations of the potential for toxicity by repeated-exposure conditions requires that studies be conducted by an appropriate route for a sufficient number of exposures. It is generally necessary to conduct repeated-exposure studies initially over a limited period of time in order to determine the development of toxicity as a function of exposure concentration or dose. The initial concentrations or doses chosen will be determined by findings from acute studies, when these permit the detection of toxicity. When acute studies do not exhibit toxic effects then doses may sometimes be chosen on the basis of comparison with findings from the same chemical class of material, or failing this from short-term high-dose studies. The findings from well-conducted and appropriately monitored short-term repeated-exposure studies are used to determine concentrations or doses for longer-term studies. Such longer-term repeated studies may ultimately need chronic (lifetime) studies if malignant or extreme and potent toxicity are suspected. The major goals of repeated-exposure studies are as follows, particularly when used for hazard evaluation and safety confirmation purposes:

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat003
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1. To determine the incidence and nature of potentially adverse biological effects by recurrent exposures, and their dose/concentration dependency, including characterization of the shape of the dose–response curve. In general, the longer the period over which exposures are conducted, the lower the individual doses/concentrations that are needed to induce toxicity.
2. To determine the dependency and severity of development of toxicity as a function of the exposure conditions.
3. For the determination of those concentrations or doses which do not result in the appearance of any effects due to exposure to the substance tested (NOEL) or do not cause the development of effects regarded as potentially biologically harmful (NOAEL). Recently there has been the development of a concept of benchmark dose (BMD) as an alternative to the NOAEL, or compromise between the NOAEL and the LOAEL. The BMD involves fitting a dose–response curve to all bioassay data, and the dose (or lower bound on the dose) corresponding to a given low-level response on the fitted curve (e.g. a 5% elevation in incidence over background: BMD05) is selected as a characterization of the dose level at which a detectable increase in the measured effect of interest occurs (Rhomberg, 2005). After the application of appropriate uncertainty factors, the BMD is used in determinations of certain safe dose values such as acceptable intakes or reference doses.
4. To determine the threshold for induction of potentially adverse effects based on observable toxicity; the LOAEL.
5. With the shorter-term repeated-exposure studies, to give sufficient reliable information to permit the design and dosage/concentration choices for more expensive longer-term studies.

2 DETERMINANTS FOR REPEATED-EXPOSURE TOXICITY

As noted previously (Section 1.1), acute studies may show a potential for repeated-exposure local and systemic toxicity, providing the effects are not secondary to some marked disturbance of normal physiology and if they are dose-related. However, in most acute studies the test material is given by bolus dosing, which results in the rapid development of high circulating concentrations of parent material and metabolites if the dosed material is readily absorbed by the route of exposure. In these circumstances, the threshold to induce toxicity may be exceeded and toxic effects exhibited. With repeated-exposure conditions, however, the individual doses given are usually much smaller than those employed in acute studies, and probably subthreshold for the induction of toxicity by acute dosing. In such circumstances there may be an incremental increase in body load of the material (and/or metabolite) with increasing sequential cumulative exposures, and there may be an associated latency to the onset of toxicity by repeated-dose procedures (Ballantyne, 1989). Many factors are associated with the likelihood for toxicity by repeated exposures, and its nature, the most important of these being as follows:

1. **Period of repeated exposures:** As noted above, there may be latency to the development of body loading with parent material (or metabolite) that is sufficient to initiate the toxic effect. Clearly, in addition to the absolute individual doses, the number of exposures will be a determinant of the likelihood of reaching the threshold body load of toxic material and thus for the development of toxicity.
2. **Dosing characteristics:** The precise profiling of exposure doses may have a significant influence on the development of toxicity, which may not be predictable from acute toxicity information. For example, with benzene vapour a 24 hour exposure to 95 ppm or a 96 hour exposure to 21 ppm both produced severe bone marrow toxicity, but in a repeated-exposure study involving exposure to 95 ppm vapour for 2 h day^{-1} for two weeks there was little toxicity (Toft *et al*., 1982). The precise influence of profiling of dosing may vary depending on chemical nature of the test material. For example, in a four-week inhalation study with formaldehyde, 8 hours of continuous exposures were compared with 8 hour intermittent exposures (Wilmer *et al*., 1987). The findings suggested that concentration rather than total dose was the major determinant of toxicity. Thus, interrupted exposures of rats to 10 or 20 ppm formaldehyde vapour induced more cytotoxicity in the nasal mucosa than did continuous exposure to 5 or 10 ppm. In a four-week inhalation study with carbon tetrachloride, interruption of a daily 6 hour exposure by 1–5 hour periods free of carbon tetrachloride produced a slightly more severe hepatotoxicity, whereas 5 minute peak loads superimposed on a fixed background exposure only slightly enhanced the hepatotoxicity of carbon tetrachloride (Bogers *et al*., 1987).
3. **Pharmacokinetics and metabolism:** Given by repeated exposure, the time available for compensatory biological responses is longer, in particular for the induction of biotransformation mechanisms, including metabolic activation and detoxification. Depending on the route of exposure (including any first-pass involvement), the development of toxicity and its severity will depend on the relative balance of the induction of activation and detoxification processes.

3 DURATION OF REPEATED-EXPOSURE STUDIES

Repeated-exposure studies are usually conducted for a variable combination of the following reasons:

1. To determine the potential for non-oncogenic cumulative or long-term toxic effects.
2. To determine the *in vivo* oncogenic potential of a material.
3. To determine threshold or no-observed-adverse-effect dosages, particularly when the results are to be used to protect populations, for example, establishment of workplace exposure guidelines or acceptable daily intakes.
4. To meet the requirements of regulatory authorities for activities such as product registration.

Depending on the reason(s) for conducting the investigations, and the stage in the assessment of toxicity, repeated-exposure studies vary in length from a few days to a lifetime of exposure. It is convenient to subdivide these into short-term, subchronic and chronic studies, as follows:

3.1 Short-term Repeated Studies

These vary in length from a few (5–9) days to 28 days. The shorter studies, around 7 days, have sometimes been referred to as subacute studies. Although the individual daily dosages employed may be less than acute doses, the total duration and total number of exposures is greater, and not below (sub) that for the acute exposures. The term 'subacute' is not a preferred descriptor. The choice of duration for a short-term repeated-exposure study will depend on a number of factors, including the reason for conducting the study, but they are often conduced as preliminaries to subchronic studies to determine appropriate exposure doses/concentrations.

3.2 Subchronic Studies

These studies involve exposing the test species for 15–20% of their lifespan. Thus, for most laboratory species used in subchronic tests (e.g. rats and mice), exposures will extend over a period of about 90 days. These studies are usually conducted in order to determine the potential for non-oncogenic adverse effects, and their threshold LOAEL and NOAEL. Additionally, and to ensure an appropriate choice of dosing, subchronic studies are also conducted in advance of chronic toxicology studies.

3.3 Chronic Studies

Such studies involve exposing the test species to the test material for their lifespan, or the greater part thereof. Although a primary aim of many chronic studies is to investigate the *in vivo* potential for oncogenicity, the majority are usually conducted as combined chronic toxicity/oncogenicity studies. Because of the high cost of such studies, in the region of, or more than, a million dollars, depending on the route of exposure, decisions on the need for, and design of, such studies requires very careful consideration.

It is clear that repeated-exposure studies of varying duration should be carried out in sequence, with the shorter studies being conducted initially to give guidance on the types of adverse effects to be anticipated (and monitors for them), and also to allow for decisions on appropriate dosing for the longer studies.

4 GENERAL DESIGN FEATURES

Details concerning animal use and care and statistical considerations for toxicological studies are given in **Statistics for Toxicology** and **Animal Welfare in the Toxicology Laboratory**, respectively. The following comments give an overview of the major considerations in the development of protocols for repeated-exposure studies.

4.1 Generic Issues in Experimental Design

During the design of any repeated-exposure toxicity study, a multiplicity of differing factors needs to be taken into account in developing a protocol. Failure to give adequate thought with respect to all, including minor, details might result in the conduct of an unsatisfactory study, or cause the introduction of artefacts, which can complicate interpretation of the findings. Some of the more important relevant considerations are briefly discussed below.

4.1.1 Animals

In order to ensure comparability of groups, and to avoid complications from outlier animals, those that are used in a study are often selected to be of closely comparable age at the start of the study and within a restricted weight range, usually within two standard deviations of the batch mean weight for each sex. To ensure that the animals to be used in a particular repeated-exposure toxicity study are healthy, a randomly selected subgroup from the test batch of animals should be checked for health status before the start of the study; this procedure

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat003
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

involves, at least, examination by a clinical veterinarian, blood sampling for limited clinical chemistry and viral antibodies, examination for faecal parasites, necropsy for gross pathology, and histology of selected tissues and organs (to include respiratory tract, gastrointestinal tract, liver, kidney, lymph node and spleen).

4.1.2 Environmental Conditions

To minimize the possible effect of environmental influences on both animal welfare and induced toxicity, factors such as environmental temperature and relative humidity should be maintained within accepted optimum conditions. Significant variations from the recommended range of animal-house temperatures can increase susceptibility to infection, impair general health and cause a variation in response to toxic chemicals (WHO, 1978). Changes in temperature may elicit homeostatic changes in various physiological and biochemical systems, and alter rate-determining physiological processes for the absorption and action of toxic chemicals. Also, because of the influence of circadian factors on toxicity (see **Chronotoxicology**), a constant photoperiod should be used.

The positioning of animals in holding rooms can influence certain physiological and pathological processes, and hence the requirement for randomization and periodic rotation of the position of individual cages at least weekly. It has also been advised (Ecobichon, 1992) that 'sentinel' animals be included in the longer-term studies. These animals are not part of the definitive study, but placed in the same room as the test and control animals and periodically monitored for the appearance of bacterial or viral infections, test agent-induced toxic changes due to contamination of the facility, or changes in environmental conditions. These animals should be subjected to periodic haematology, clinical chemistry and bacteriology/virology checks.

4.1.3 Caging

Toxicity can be influenced by a number of factors related to the manner of caging, including type of caging, grouping and bedding material. For example, the toxicity of isoprenaline (isoproterenol) was greater in rats caged singly for more than three weeks than in rats caged in groups (Hatch *et al*., 1965). In a study of the influence of housing conditions in skin oncogenicity bioassays, DePass *et al*. (1986a) showed that differences in housing conditions can influence both the latency and incidence of local neoplasms resulting from chronic cutaneous application of a carcinogen. Multiple caging can result in unique identification problems, and trauma from bites. Additionally, with multiple housing, the susceptibility to transmissible diseases is increased, and if mortalities occur there may be cannibalism. Also, multiple caging does not permit individual animal food consumption values to be obtained, and thus does not allow any correlations between individual weight changes and food consumption to be established. When dosing is by incorporation of test material into the diet, multiple caging does not permit the calculation of individual animal test-agent consumption. For these reasons, it is generally recommended that for repeated-dose toxicity studies animals should be caged singly (Wilson and Hayes, 1994).

The type of cage employed, metal or plastic, solid floor or suspended, requires careful consideration during protocol design (Stevens and Mylecraine, 1994). For example, solid floor caging requires bedding which may create dust, and certain sawdust and chips may induce hepatic mixed function oxidase activity. Suspended wire cages, on the other hand, may result in trauma, especially to the feet and legs. Shoebox-type cages may cause problems associated with stasis of the air in the cage.

Most repeated-exposure studies with rodents are generally conducted using suspended wire cages with the animals housed singly. This eases clinical examinations and allows information to be obtained on food and water consumption.

4.1.4 Diet

It is well appreciated that both the degree and type of nutrition may affect laboratory animal lifespan, expression of toxicity and the pattern of carcinogenicity in control and test-agent animals (Allaben and Hart, 1998; Haseman, 1998; Leakey *et al*., 1998; Turturro *et al*., 1998). Of particular importance in chronic studies is the marked influence that diet may have on natural tumour incidences, and also on modifying carcinogen-induced tumour incidence (Grasso, 1988). For example, Tucker (1979) demonstrated that Charles River mice on a 20% dietary restriction developed fewer liver tumours than mice fed diet *ad libitum*. Conybeare (1980) found that the incidence of liver tumours in mice was reduced from 47 to 12% by restricting food intake to 75% of the normal amount. Benson *et al*. (1956) found that a higher incidence of spontaneous mammary adenocarcinomas developed in rats when olive oil was added to the diet, and Chan and Dao (1981) noted a higher incidence of mammary tumours in rats on a semisynthetic diet containing 16% corn oil. Both the protein and fat content of diets may influence the induction of tumours by carcinogens. High-fat diets enhance mammary tumour incidence caused by dimethylbenzanthracene in rats (Carroll and Khor, 1975), hepatocellular carcinomas in rats caused by *p*-dimethylaminoazobenzene (Miller and Miller, 1953), colon cancer by 1,2-dimethylhydrazine (Reddy *et al*., 1976) and pancreatic adenocarcinomas by azaserine (Roebuck *et al*., 1981). In the rat, a high protein diet enhanced hepatocellular carcinoma development from aflatoxin (Madhavan and Gopalan, 1968),

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and colon carcinoma from 1,2-dimethylhydrazine (Reddy *et al*., 1976).

Diet should ideally be kept constant over the study period and be of known composition and nutritional status. Diets should be used that have been assayed for contaminants such as pesticides, heavy metals and mycotoxins. They should not be used beyond expiratory dates, and stored to prevent contamination.

4.1.5 Test Material

The material to be tested should be of known purity and its chemical identity confirmed. Test material purity, and possible degradation products, should be measured before the start and at the end of the study to ensure stability. With the longer repeated-exposure studies, interim analyses may be required. If a dosing matrix, such as drinking water or diet, is used, then stability of the test material and homogeneity of distribution in the matrix are required. Ideally a single batch (lot) of the test material should be used over the study period to ensure an absence of effects due to possible changes and inconsistencies from batch to batch. This, of course, may not be possible with chronic studies, where there should be detailed attention to analyses and to documentation. Also, with materials to be used commercially, the test material should be as close as possible to that intended to be used or marketed.

4.2 Choice of Species

Most repeated-exposure studies are conducted using rats or mice, with some regulatory agencies also requiring the (additional) use of a larger species (e.g. dog), particularly for subchronic studies. The choice of test species is an important consideration, particularly where there is reason to suspect that species variation in the toxic response may occur, qualitatively or quantitatively. An example is that of butadiene, where the toxic (carcinogenic) potential is greater in the mouse than the rat (Melnick *et al*., 1990). Since it has been demonstrated that the metabolism of butadiene in the rat is more like that in the human than in the mouse, the rat appears to be a more appropriate model for repeated-exposure studies (Bond *et al*., 1995; Himmelstein *et al*., 1997; Anderson, 1998). Also, there may be significant differences between different strains for a given species. For example, Wistar rats are more sensitive to ethylene glycol renal toxicity than Fischer 344 rats; the respective NOAELs were $200\,mg\,kg^{-1}\,day^{-1}$ for male F-344 rats (DePass *et al*., 1986b) and $71\,mg\,kg^{-1}\,day^{-1}$ for male Wistar rats (Gaunt *et al*., 1974). Subsequent toxicokinetic studies (Cruzan *et al*., 2004) showed that the strain differences in renal toxicity were related to differences in the ability to clear ethylene glycol and its metabolites, notably oxalate. Criteria for the selection of a species include:

1. The requirements of regulatory agencies.
2. The material should have similar pharmacokinetic and metabolic features in both the test species and humans. For the majority of substances, with the possible exception of therapeutic agents, this information is either sparse or not available. Therefore, from a practical viewpoint, this criterion can seldom be applied.
3. Use of the most sensitive species (and strain) to the known or suspect toxicity of the test material, on the basis that this represents the most conservative approach in extrapolating toxicity in the test species to humans. Again, such information may not be available at the start of repeated-exposure testing, and acute toxicity information may not be a reliable guide to cumulative or long-term toxicity.
4. Experience of the laboratory and the existence of a good historical control database. Although concurrent control animals should be used in repeated-exposure studies, in some instances comparison with the treatment groups may yield equivocal results, and in such cases reference to the historical database may be of use.
5. The use of primates, even if considered appropriate on investigational scientific grounds, is limited by cost considerations and animal welfare legislation.

In view of the fact that there is species variability in the response to toxic chemicals, and since no one species is a perfect surrogate for the human, several regulatory agencies require the use of two species, often citing a rodent and a nonrodent. Often the choice of a species is based on considerations that include experience with that species, animal size, ease of handling, databases, accommodation and economics. However, from the viewpoint of obtaining relevant useable information from a well-designed study, attention should be paid to information on physicochemical characteristics, known toxicity, and any available pharmacokinetic and metabolism data of the test material.

4.3 Dosing Procedures

The route of exposure will be determined principally by the intended use of the test material and the likely route by which the user will be exposed. In some instances there could be a need for study by more than one route of exposure. For example, with pesticides the applicator may be exposed cutaneously or by inhalation, whereas the consumers of treated crops will be exposed through the peroral route. In most cases the appropriate route can be used in repeated-exposure studies, but in a very

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat003
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

few instances because of physical or technical problems an alternative route may be required. An example is provided by ethylenediamine (EDA), for which the respiratory tract is a potential route of exposure. However, generation of the vapour for a long-term study presents difficulties, as do the sampling and analyses of the chamber atmosphere; also, EDA reacts with water and carbon dioxide. These problems hamper the conduct of a chronic inhalation study with EDA. In a comparative pharmacokinetic and metabolism study, EDA was given by oral, iv and endotracheal dosing. The equivalency of the fate of EDA by the peroral and endotracheal routes was demonstrated (Yang and Tallant, 1982). Based on these findings, a chronic toxicity/carcinogenicity study was successfully completed in the rat by incorporation of EDA into the diet (Hermansky *et al*., 1999).

By the peroral route, a multiplicity of dosing procedures are available, the choice of which will depend on the intended use of the test material, physical and chemical characteristics, likely exposure patterns by the user, stability of test material, and the test species. In some instances the material may be given by gavage. This procedure ensures that relatively precise daily pulses of chemical are given, but carries the disadvantage that intubation trauma and dose misplacement may occur. Many peroral repeated-dosage studies are conducted by incorporating the test material into diet or drinking water, resulting in a slower titration of the material into the gastrointestinal tract. There may well be differences, therefore, between the absorption pharmacokinetics of test material depending on whether it is given by gavage or dietary/drinking-water incorporation. This factor needs consideration in the design and interpretation of studies. When given by inclusion in the diet, it is essential to conduct tests to ensure homogeneity of distribution and stability in the diet, and also to conduct extraction procedures to preclude binding to the diet that will significantly reduce bioavailability. When test material is incorporated into the diet for dosing, it is common practice to adjust the dietary concentration of test material periodically (usually weekly) to achieve constancy of the target daily doses against a progressively changing body weight. Mean projected dietary concentration is calculated from the preceding body weight gain, and the dietary test material concentration is adjusted to achieve constancy of dosing. Feeding at a constant concentration during a study has also been conducted, but this results in loss of control of constant dosage and may modify toxic response and interpretation of the findings from the study (Wilson and Hayes, 1994). As with dietary incorporation studies, when test material is dissolved in drinking water, homogeneity of distribution and stability needs to be confirmed. Also, the test material should not be so unpalatable as to reduce food or water consumption significantly. In special circumstances the test material may require to be dosed using capsules or by an encapsulation procedure; this is particularly useful for highly volatile materials or to mask objectionable taste. Microencapsulation involves uniformly coating the test material with a degradable but impervious material (Melnick *et al*., 1987; Yuan *et al*., 1991).

By inhalation, the study design will depend on whether exposure is to gas, vapour or aerosol. The principles of ensuring constancy of exposure dose and avoiding artefacts are similar to those by other routes of exposure. The details of generation, distribution, sampling and analysis of the atmosphere should follow the guidance given in **Inhalation Toxicity**. If whole body exposures are undertaken then the possibility for some percutaneous absorption, and, more significantly, swallowing of material due to grooming, should be kept in mind, particularly during interpretation of the findings. This can be avoided by the use of nose-only exposures. For example, in a developmental toxicity study with an ethylene glycol aerosol in which rats and mice received daily 6-hour exposures by whole body exposure over gestational days 6–15 inclusive, maternal toxicity and terata were produced in mice (Tyl *et al*., 1989; 1995a). In simultaneously exposed mice, ethylene glycol was analytically detected on fur after exposure, which could have accounted for between 65 and 95% of the total dose, and be available for absorption percutaneously or orally following grooming. When mice were exposed to ethylene glycol aerosol by a nose-only procedure this prevented most of the maternal and developmental toxicity observed as a result of whole body exposure (Tyl *et al*., 1995b). Measures should be in place to avoid exposure of the laboratory worker or contamination of the animal facility after the end of an exposure period. This will include keeping the animals in a stream of fresh air for a period after the exposure has been completed. The direct instillation of test material into the trachea has been used in some studies as a procedure to investigate toxic and toxicokinetic aspects of pulmonary exposure. Intratracheal dosing has been employed for a variety of differing reasons including its comparatively low cost, simplicity, to ensure the delivery of a well-defined dose, or technical problems with generation of an appropriate test atmosphere for standard inhalation studies (Driscoll *et al*., 2000). Whilst this can be a useful and cost-effective dosing method in certain circumstances, the relevance of the procedure and the findings need to be carefully considered against the background of the reason for the study and significance relevant to in-use situations. The uses and limitations of intratracheal instillation as an exposure route for the evaluation of respiratory tract toxicity have been reviewed by Driscoll *et al*. (2000) and Porter and Hubbs (2006).

Repeated-exposure skin contact studies are labour intensive. Again, prevention of secondary route of exposure by licking the test site should be avoided by choosing an appropriate remote application site and/or covering the application site. Based on screening or prior definitive studies, care should be taken to avoid the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat003
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

development of cumulative local skin irritation or injury that could lead to a premature termination of the study.

Repeated-exposure studies have been conducted using parenteral routes such as intravenous, intramuscular, intraperitoneal and subcutaneous. Such labour-intensive studies require special careful attention to the dosing techniques in order to avoid trauma associated with the injection process. Alternative parenteral dosing procedures for continuous dosing by slow release have included the use of implanted material or implantable osmotic minipumps (Dey *et al*., 1982; Ray and Theeuwes, 1987).

4.4 Exposure Groups

A prime consideration in the design of repeated-exposure studies is the number of groups of animals to be used. Although group size should be dictated primarily by the desired statistical power, it is often decided by the guideline protocol which is being adhered to for studies used for regulatory submission. A minimum of three groups should be used for exposure to differing concentrations or dosages of the test material. This allows the demonstration of a dose–response relationship, essential for confirmation of a toxic process. Also, and by careful choice of dosages, by using three groups this should allow for one which exhibits toxicity (top dose), one showing a marginal effect or LOAEL, which should be the intermediate dose, and a NOAEL or NOEL at the lowest dose. This information is used principally in two ways: first, in using the dose–response information for the purposes of defining safety margins in hazard evaluations and assigning permissible exposures (e.g. the threshold limit value (TLV) or acceptable daily intake (ADI)), and second, in setting exposure concentrations or doses for longer-term repeated-exposure studies. In the latter case, and particularly when using information derived from a subchronic study conducted prior to a chronic study, one prime determinant is the establishment of a maximum tolerated dose (MTD). This is a dose which is usually defined as causing no more than a 10% decrease in body weight, does not produce mortality, and produces effects that will not shorten the lifespan and jeopardize the study, but nevertheless produce some toxicity (Sontag *et al*., 1976; Haseman, 1985). The MTD is mostly used as a basis for assigning the highest dose for a chronic study.

The numbers of animals used per treatment group requires careful planning. There should be sufficient to allow for valid statistical analyses, but not in excess of the numbers dictated by good animal welfare practices. Depending on the length of the study, basic group size (from start to end of dosing) often ranges from 5 to 20 animals per sex. For subchronic and chronic studies, 20 per sex per group is a reasonable basic group size. Additional animals may be included if 'recovery' groups are required to assess reversibility, or otherwise, of induced toxicity after the end of the dosing period. This is a useful group to have for interpretive purposes, particularly with subchronic studies. The use of 'recovery' animals in the shorter-term repeated-exposure studies should also be considered. These 'recovery' animals are most frequently added to the high-dose and control groups. Additionally, and in order to study the onset and progression of induced toxicity, many studies also add extra animals for interim sacrifice at predetermined times during the exposure period. These groups also may yield valuable information useful in assessing dose–response relationships.

An untreated control group, equal in size to a dosing group (including interim sacrifice and 'recovery' animals), is of course necessary for primary comparative purposes against the treatment groups. Such a concurrent control group not only serves for the comparison of statistical and dose–response relationships of induced lesions, but may also indicate the presence of any nontreatment and environmental effects. Where the test material has to be given in a vehicle (solvent or suspending agent), some investigators suggest the need to confirm an absence of effects by the vehicle by inclusion of a vehicle control group. It will have been previously confirmed that the inert vehicle does not react with the test agent and the preparation has stability. The requirement for a vehicle control group will depend on the length of the study, physicochemical properties of the vehicle, and the extent to which it has been investigated toxicologically.

An important consideration in planning and protocol development is the development of criteria for decisions on when, and how, to euthanize animals that become moribund during the dosing period. These criteria should be in accord with Good Laboratory Practice (GLP) (see **Quality Assurance in Toxicology Studies**), the practices of the laboratory conducting the study, and national/federal, and/or state animal welfare regulations (see **Animal Welfare in the Toxicology Laboratory**).

4.5 Monitoring for Toxicity

Repeated-exposure toxicity studies are costly, in part because of their labour-intensive nature. It therefore follows that the maximum amount of toxicological and usable information should be obtained from them by appropriate extensive monitoring for toxic and other possible treatment-related effects. In this way, a repeat of the study can be avoided because of unexpected secondary findings indicating a primary toxicity not detected *per se*. Extensive monitoring is employed in the longer-term (subchronic and chronic) studies in order to define, as far as possible, evidence for structural and functional injury to tissues and organs. Whilst the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat003
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

shorter-term (five to nine day) studies are often conducted as screening (preliminary) for the longer-term studies, and used to set dosages for such longer-duration studies, it is wise to undertake some specialized monitoring to assess potential target organs and tissues by short-term repeated exposure, and also aid in the planning of detailed monitoring in the longer-term study. The 28-day studies should certainly be well monitored, as for a subchronic study, particularly if they are to be submitted to a regulatory agency. For the longer-term studies (subchronic and chronic), very detailed monitoring should be planned to include, as a basis, well-recognized monitors for the general detection of potentially adverse effects, and also specific techniques to assess sites of toxic response in particular organs and tissues.

Routinely, and discussed in more detail with subchronic studies (Section 6), the major overall monitors should include at least the following:

- Clinical observations for signs of toxic and/or pharmacological effects.
- Periodic measurement of body weight.
- Food and water consumption.
- Peripheral blood haematology.
- Blood biochemistry (clinical chemistry).
- Urinalysis.
- Necropsy for signs of gross pathology.
- Organ weights.
- Processing of tissues and organs for histological examination.

It is important to compare clinical pathology findings from treatment groups to those of the concurrent control groups, for which blood has been collected under identical conditions. For example, Walter (1999) compared clinical pathology values for blood collected from the orbital sinus of rats anaesthetized with either pure (100%) carbon dioxide or an oxygen/carbon dioxide mixture (34, 66%) with the values for blood from unanaesthetized rats. Small, but statistically significant, differences were found for several values; thus, for the carbon dioxide groups there were smaller values for calcium, and higher values for leukocyte counts, lymphocyte counts and glucose. A larger proportionate difference was found for creatine kinase and aspartate aminotransferase activities, with values being highest in the unanaesthetized group. This was attributed to the physical activity in this group of animals. When it is necessary to review study findings by comparing with laboratory historical control values, as for example in studies where the chemical pathology findings are borderline, equivocal, or inexplicable, then the comparisons should be made with great care because of the influence of various factors on measured values; for example, mode and site of collection of blood samples, whether they are taken from anaesthetized, unanaesthetized or sacrificed animals, and the analytical methods employed.

For haematology, clinical chemistry and urinalysis, the choice of individual measurements may vary from laboratory to laboratory, often based on their experience, but certain core measurements are necessary in all studies (see **Clinical Chemistry in Toxicity Testing: Scope and Methods** and **Haematology and Toxicology**). In some studies, viewed on a case-by-case basis, additional specialized monitoring may be considered necessary based on information already available or suspect toxicology resulting, for example, from structure–activity considerations. Thus, in the planning of the protocol, there is a clear need to consider the requirement for additional ('nonstandard') monitors. For example, with 5-ethylidene-2-norbornene (ENB), and based on older studies (Kinkead *et al*., 1971), there was some evidence to suggest a possible effect of ENB on the thyroid gland. Thus, in more recently conducted studies on the repeated-exposure toxicity of ENB, provision was made for measurement of thyroid hormones and TSH in serum, and for detailed histology of the thyroid gland including morphometry (Ballantyne *et al*., 1997). In a National Toxicology Program (NTP) study on the subchronic inhalation toxicology of glutaraldehyde, additional monitors included sperm morphology, vaginal cytology and histoautoradiographic evaluation of respiratory tract cell replication rates in the nasal mucosal epithelium (NTP, 1993). These are but two examples, of many, in which additional monitoring was added to clarify any suspect toxicity. It is becoming more common for additional monitoring to be added to repeated-exposure studies to detect effects, some not anticipated, in order to take advantage of the exposure conditions. For example, some regulatory agencies now advise adding monitors for male fertility to repeated-exposure studies (e.g. sperm morphology, counts, motility). Thought should be given to the use of histochemical, ultrastructural, neurotoxic, respiratory function and genetic toxicology methods in repeated-exposure studies when considered appropriate and based on known or suspect toxicology.

Noninvasive procedures (e.g. observations for clinical signs, body weights, food and water consumption) should be conducted before exposure and then sequentially during the treatment and recovery periods. This allows for the detection of any general factors that may indicate the onset of toxicity, or effects secondary to factors not related to test-material dosing. Haematology, clinical chemistry and urinalysis need to be conducted as a minimum at the end of the dosing period. Where there are provisions for interim sacrifices, then chemical pathology should be undertaken at these times in order to detect any early changes. It may also be possible to collect blood and urine samples at interim periods during the dosing phase even if interim sacrifices are not planned. Decisions on whether to conduct chemical pathology on 'recovery' animals in the post-treatment survival groups may depend on whether there are definitive or equivocal changes in the immediate post-treatment

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat003
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

sacrificed animals. Because of the automated nature of most chemical pathology investigations, it is recommended that measurements be undertaken on all control and treatment groups, and in the same period of time, to allow valid statistical comparisons. Observations for gross pathology at necropsy and removal of organs for weighing should be conducted on all animals. Organs and tissues showing gross pathological changes, together with those from a predetermined list, should be removed and processed for histological examination. The number of tissues removed will be determined, in part, by the reason for conducting the study and regulatory requirements, but in most cases it is advisable to remove as many as possible and at least keep those not to be examined in fixative in case of the need for examination of them in the future. It is usual in both subchronic and chronic studies to undertake light microscopic examination of all removed tissues from the high-dose and control groups. Decisions on whether to examine tissues from the lower-dose and recovery groups will depend on the findings from the control and high-dose groups.

5 SHORT-TERM REPEATED-EXPOSURE STUDIES

As noted previously, these studies extend over a period of 5–28 days. They are conducted to obtain an initial indication of the potential for adverse effects by recurrent exposure to the test material, and also as a preliminary to obtain guidance on appropriate doses for a subchronic study. For the latter purpose, it is common to use studies of 7–9 days duration. Since there is a greater likelihood for toxicity to be manifested with increasing time of exposure, 28-day studies may be accepted by some regulatory agencies as meeting the requirements for assessing non-oncogenic toxicity by repeated exposure. Detailed monitoring, equivalent to that for a subchronic study, should be incorporated into the 28-day protocol. However, even with the shorter periods, monitoring should ideally be more than signs, body weight, food and water consumption and gross pathology. There should, at least, be some limited haematology, clinical chemistry and histology. In this way a better indication of the potential for toxicity will be obtained, and permit a more reliable guidance for the design of subchronic studies. Detailed biochemical monitoring even of 7-day studies can yield significant information of relevance to target organ toxicity; for example, chloral hydrate in drinking water (Poon *et al*., 2000).

6 SUBCHRONIC STUDIES

These are usually carried out by exposure for 15–20% of the lifespan of the test species. Thus for most common laboratory animals they will be of about three months duration with respect to the dosing period. Such studies allow a determination of the potential non-oncogenic toxicity of the test material, allow the determination of definitive, threshold and no-effects dosages, including a MTD, and are essential for the successful planning of a chronic study. Many aspects of the design of these studies (species, housing conditions, mode of dosing, etc.) have been discussed earlier in this chapter.

Subchronic studies should have at least three test chemical treatment groups, together with untreated controls and, if necessary, vehicle controls. It is always advisable to add a recovery group of animals to determine the reversibility, or otherwise, of induced toxicity. The need for interim sacrifice or monitoring groups will be determined by the nature of the test agent and its known toxicology.

It is necessary to incorporate into the study design procedures that may permit the detection of unsuspected toxicity, latency to onset, and reversibility. Monitoring procedures should allow for the sensitive detection of early indications of toxicity, latency to toxicity, and reversibility of induced toxicity. They should allow for the detection of structural and functional indications of general toxic effects and of specific organ and/or tissue lesions. Standard lists of recommended procedures for monitoring are available in published texts and regulatory guidelines. However, investigators should add, as routine, methods usually conducted in follow-up tests to confirm specific toxic effects; for example, the inclusion of α_{2u}-globulin measurements in urine to biochemically confirm a hyaline droplet nephropathy.

Monitoring for subchronic studies should include the following to ensure the optimum conditions to detect non-oncogenic toxicity:

1. **Clinical observations:** Animals should be examined twice daily for overt signs of toxicity and for mortality, and examined in detail on a weekly basis with particular respect to skin and fur condition, eyes, mucosae, respiratory, circulatory and nervous system functions and general behaviour. These are standard to most profiles. Many subchronic studies do not have provision for detailed examination of the eye, and some ophthalmic toxicology may be overlooked. It is useful to have, as a minimum, expert examination of the eyes by an ophthalmic veterinarian using biomicroscopy at the start and end of dosing. Other detailed ophthalmic investigations are discussed in **Ophthalmic Toxicology** and by Peiffer *et al.* (2000). There is also frequent use of a functional observational battery (FOB) as a screen for the potential of a chemical to produce neurotoxicity (Eapen *et al*., 2007; see also **Neurotoxicology**, **The Role of Behavioural Toxicity in Risk Assessment**).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2. **Body weight:** Body weights should be measured before dosing and at least weekly during the dosing and recovery periods. Body weight changes for the interweighing periods should be calculated. Body weight and body weight changes are sensitive indicators of the condition of the animals. Changes (usually loss) can be a consequence of alterations in food or water consumption, specific toxic effects or disease processes.
3. **Food consumption:** This is a useful monitor if measured over three-day or weekly intervals. Appropriate containers are needed to limit errors due to spillage. Food consumption data may be useful in the interpretation of body weight changes, and is of course essential if dosing is by incorporation in the diet in order to calculate consumed dosages.
4. **Water consumption:** This measurement, over three- or seven-day intervals, requires the use of individual water bottles for its determination. The information can be of considerable use in assessing body weight or urine volume changes.
5. **Haematology:** Details of the use and application of peripheral blood haematology tests are given in **Haematology and Toxicology**. The following are typical measurements undertaken:
   - haemoglobin concentration;
   - erythrocyte count;
   - packed red blood cell volume (PCV);
   - calculated values: mean corpuscular volume (MCV), mean corpuscular haemoglobin (MCH), mean corpuscular haemoglobin concentration (MCHC);
   - leukocyte count—total and differential;
   - platelet count;
   - reticulocyte count;
   - activated partial thromboplastin time.
6. **Biochemical disturbances:** For detecting general biochemical disturbances (e.g. electrolytes) or to indicate specific organ/tissue damage, a multiplicity of tests is available (see **Clinical Chemistry in Toxicity Testing: Scope and Methods**). The following measurements are typical for subchronic studies:
   - glucose
   - urea nitrogen
   - creatinine
   - total protein, albumin and globulin (often with protein electrophoresis)
   - bilirubin (total, conjugated and unconjugated)
   - phosphorus
   - Ca^{2+}, Na^{+}, K^{+}, Cl^{-}, HCO^{-}
   - aspartate aminotransferase
   - alanine aminotransferase
   - creatine kinase
   - sorbitol dehydrogenase
   - γ-glutamyl transferase
   - alkaline phosphatase
   - glutamate dehydrogenase
   - ornithine carbamyltransferase
   - special studies (e.g. with organophosphates, measurement of acetylcholinesterase and butyrylcholinesterase).
7. **Urinalysis:** Analysis of urine can yield valuable information not only on renal and urinary tract integrity, but also on acid–base balance and certain organ dysfunctions. Specimens should be collected separately, ideally using metabolic cages, over a specifically timed period (usually 16 hours). Typical measurements and observations include the following:
   - volume
   - appearance
   - microscopy
   - pH
   - osmolality
   - protein
   - occult blood
   - glucose
   - ketones
   - bilirubin and urobilinogen
   - creatinine
   - α_{2u}-globulin
   - N-acetyl-β-D-glucosaminidase.
8. **Necropsy and organ weights:** Necropsy examination with detailed inspection for gross pathology is required on all animals; this includes those dying on study and sacrificed survivors at the interim, immediate post-treatment and recovery periods. Organs removed for weighing usually include brain, liver, kidneys, lungs, heart, spleen, thymus, adrenal glands and gonads. Whilst organ weights relative to body weight are often calculated, interpretation of the results should be undertaken cautiously since if changes in body weights have occurred these relative organ weight values may be misleading. For this reason it is also advisable to calculate organ weights relative to brain weight, since this is less variable and test materials that lead to a change in body weight do not generally affect brain weight.
9. **Histology:** Light microscopic examination of all tissues and organs showing gross pathology should be undertaken. Many studies examine other (no gross pathology) tissues only from the high-dose and control groups. Should histopathology be seen in the high-dose group, it is then necessary that tissues from the other treatment groups should be examined. Decisions on the need to examine tissues from recovery group animals will depend on the findings from the immediate postdosing sacrifice group. It is wise to remove as many tissues and organs as possible and keep them in fixative. Those to be examined are listed in standard texts and regulatory guidelines, but investigators

should carefully consider the needs for histology based on these and the nature of the study. Tissues not prepared for histology should be kept in fixative in case a subsequent need arises for their examination. Special staining techniques may be required based on the findings of the study overall (see **Pathological Techniques in Toxicology**); for example, myelin stain with suspect neurotoxicity, and Mallory Heidenhain stain for hyaline droplet nephropathy (Kim *et al*., 1997).

10. **Special studies:** Based on findings from prior well-conducted, short-term repeated-exposure studies, from other investigations on the test chemical, or structure–activity relationship (SAR) considerations, there may be a requirement for special investigations related to detection, quantitation, and mechanisms of morphological and/or functional elements of a specific nature (e.g. ocular toxicity) or of a system (e.g. neurotoxicity, immunotoxicity). Special investigations may also be determined by the exposure nature of the test material, such as route and/or physical nature. An example of the latter is in studies of the potential for adverse effects from inhalation exposure to particulates, which require not only special monitoring of the atmosphere for concentration and particle size, but also biological considerations such as pulmonary retention, determination of induced pulmonary injury, and functional changes in pulmonary physiology (Ballantyne, 2006). Retention and elimination of particulates can be undertaken chemically by sequential removal of lungs at various times and analysis for the specific material; this permits estimation of cumulative processes and elimination rates (Sun *et al*., 1987). Lung injury and inflammation can be estimated by biochemical and cytological studies on bronchoalveolar lavage (BAL) specimens (Duniho *et al*., 2002; Sciuto, 2006). Cytology includes macrophage and neutrophil quantitation, and biochemical measurements include lactate dehydrogenase, acid and alkaline phosphatase, β-D-glucuronidase, glutathione reductase, cathepsins B and D, and total protein. Developing pulmonary fibrosis can be followed histologically and/or by measurement of total lung tissue collagen and of BAL fluid hydroxyproline (Pickrell *et al*., 1983). Components of respiratory function tests that may be studied include compliance, total lung capacity (TLC), functional residual capacity (FRC), forced vital capacity (FVC), resistance, CO diffusion capacity, and intrapleural pressure (Kimmel, 2001; Sun *et al*., 1987). The selection of special studies required depends on the nature of the known or suspect toxicity, and can vary from the addition of a single chemical or physical monitor to a multiple series of additional procedures.

7 CHRONIC TOXICITY STUDIES

A chronic study is conducted with the objective of exposure to the test material for the lifespan of the test species, or a significant proportion of it. Therefore, with the small laboratory animals conventionally used, the dosing extends over a period of about two years. The majority of these studies are conducted with the objective of determining the carcinogenic potential of the test material, and only in a relatively few cases is it necessary to extend a subchronic study into a chronic study based on the non-oncogenic toxicity potential of the test material. Nevertheless, most chronic studies are carried as combined chronic toxicity and carcinogenicity studies, since this allows a more definitive assessment of threshold and no-effects levels for known non-oncogenic effects. In this respect they give a more reliable estimate of safety margins in risk assessment procedures and the assignment of permissible exposure levels where there is long-term human, but controllable, exposure; for example industrial chemicals, pesticides, food additives and food contaminants. With respect to determining the carcinogenic potential of a material, this may be exhibited in one of several ways, or a combination of them. These include:

- a direct comparison with the controls
- a decrease in latency to occurrence of tumours also found in the controls
- an increased incidence of tumours of the types seen in the controls
- the development of tumours not seen in controls
- an increase in the multiplicity of tumours in individual animals.

Dose–response relationships and statistical significance compared with the untreated controls are important interpretive considerations. Based on the results of long-term carcinogenicity bioassays there is evidence that developmental combined with adult exposure to carcinogens produces an overall increase in the incidence of malignant neoplasms and an increased incidence of specific neoplasms related to exposures to given carcinogen (Soffritti *et al*., 2008). This has led to proposals that carcinogen bioassays should start with prenatal exposures. Additionally, it has been noted that in conventional chronic oncogenicity bioassays there is a progressive decrease in survival and that this can result in too few surviving animals at terminal sacrifice to permit adequate pathological evaluations. There have thus been proposals that the duration of chronic studies should be shortened to allow a larger number of surviving animals for pathological and other evaluations. However, investigations by Kodell *et al*. (2000) have shown that stopping chronic studies at 18 months is associated with a substantial and unacceptable reduction in the statistical power to detect chemical carcinogens. The majority of combined

oncogenicity/chronic toxicity studies are still of two years duration with terminal sacrifices at 24 months.

A decision to conduct a chronic study clearly requires a detailed analysis of the need for, and advantages of, the study. This will include considerations on the use and exposure pattern of the test material, findings from other toxicology studies, known dose–response relationships and their relevance to in-use situations, and the demands of regulatory agencies. For example, a material of well-established non-oncogenic toxicity potential with positive findings in genetic toxicology studies will have a higher priority for chronic testing than a material of known non-oncogenic toxicity potential but shown not to be mutagenic or clastogenic in a number of genetic toxicology studies. In view of the duration, labour-intensive nature and high cost of chronic toxicology studies, it is of the greatest importance that they be planned in fine detail to ensure that the objectives for conducting the study are met, including monitoring procedures, and that there is the maximum likelihood for survival over the test period of those animals not affected by known toxicity (e.g. detailed considerations on animal welfare standards and the exclusion of factors that would cause morbidity and mortality for reasons unconnected with the test material). The widest representation of views should be obtained in the planning phase, including those of pathologists and statisticians, and with possible discussions involving the relevant regulatory agencies (national and international). As stated by Stevens and Mylecraine (1994): 'Doing the study right therefore requires that we concern ourselves with the demands of science and society—they need not be mutually exclusive.'

Detailed considerations for the conduct of chronic toxicology studies have been given (WHO, 1978; Stevens and Mylecraine, 1994). There should be at least three treatment groups and a control group. The control group should be at least equal in size to that of one of the treatment groups. Some investigators have used two (separate) control groups against which statistical comparisons can be made. In many cases the use of two control groups, with separate statistical evaluation, has led to interpretive complications due to, at least in part, random differences in tumour and non-oncogenic pathology incidence between the two control groups. It may be better, for comparative statistical purposes, to have a large-size single control group, possibly equal in numbers to the combined treatment groups. Essential to a study of latency is the use of several interim sacrifice groups; as a minimum these should be at 6, 12 and 18 months. However, others suggest a larger number of interim sacrifices, starting at 3 months. In this manner a comparison can be made between the first interim sacrifice and the findings from a previously conducted subchronic study, with respect to the quantitative aspects of the toxicity potential of the test material. Group size should be adequate for both survival considerations and subsequent detailed statistical analyses. At least 20 per sex per group should be used for the final sacrifice (two year) group. Dose selection is usually based on an MTD defined by the subchronic study, which requires careful interpretation against the objectives and conditions for the chronic study. Monitoring for non-oncogenic end points is normally at least the same as for the subchronic study, but with additional procedures based on the findings from the subchronic study, and other known toxicology.

The results from repeated-exposure studies clearly require to be interpreted in terms of metabolic and pharmacokinetic considerations, such as incremental increases in body or organ/tissue load required to initiate a toxic process, biostorage of parent material and/or metabolites and their rate of release from storage sites, development of repair processes, and the balance of induced metabolic activation and detoxification mechanisms. The mode of dosing may influence the toxic response, including route of exposure which will determine the overall rate of absorption and the potential for relative and absolute metabolic activation and detoxification. Also, the pharmacokinetic characteristics and potential for toxicity may depend on whether dosing is by repeated boluses (e.g. gavage) or continuous administration (e.g. in drinking water or food). With the former, intermittent fluctuating high body loading is likely to be attained, and retention of parent material and metabolites will depend on their route(s) and rate of excretion. With sustained dosing, the attainment of a body and tissue/organ load to initiate and sustain a toxic process will be determined by the dynamic equilibrium between absorption, biodistribution, storage and excretion. The same daily dose delivered by bolus or alternatively by sustained dosing may result in differences in the quantitative expression of toxicity, and in some cases the nature of the toxic response. Additionally, and in contrast with acute studies, with the longer-term repeated-exposure studies there may be changing tissue sensitivity with increasing age, altered physiological and metabolic capacities, and the development of spontaneous disease processes. Thus, the interpretation of the findings from long-term repeated-exposure studies should be against not only the apparent toxicity produced, but also against the possible influence of various changing biological parameters.

Biotransformation of Xenobiotics

John A. Timbrell and Timothy C. Marrs

CONTENTS

1 INTRODUCTION

Xenobiotics which are absorbed into biological systems by passive diffusion across membranes are usually lipid soluble and consequently not ideally suited for excretion. For example, very lipophilic substances, such as the polychlorinated biphenyls are very poorly excreted and, hence, may remain in the mammalian body for many years. After a xenobiotic has been absorbed into a biological system, it may undergo biotransformation to products which are rapidly excreted and therefore elimination of the compound from the animal is facilitated. However, biotransformation may also change the biological activity of the substance. Hence, the metabolic fate of the compound can have an important bearing on its toxic potential, the disposition of the compound in the body and the excretion of the compound.

The products of metabolism are usually more water soluble than the original compound. Indeed, in animals, biotransformation seems directed at increasing water solubility and, hence, excretion. For example, the analgesic drug paracetamol (acetaminophen) has a renal clearance value of $12\,ml\,min^{-1}$, whereas one of its major metabolites, the sulfate conjugate, is cleared at the rate of $170\,ml\,min^{-1}$. Facilitating the excretion

of a compound means that its biological half-life is reduced and, hence, potential for toxicity is kept to a minimum. Metabolism may also affect the biological activity of a foreign compound. For example, the drug succinylcholine causes muscle relaxation, but its action lasts only a few minutes because metabolism cleaves the molecule to yield inactive products (**Figure 1**). However, in some cases metabolism increases the toxicity of a compound. There are many examples of this (see below) which have been documented, but a relatively simple case is ethylene glycol. This is metabolized to oxalic acid, which is partly responsible for several of the toxic effects (**Figure 2**). Biotransformation is therefore an extremely important phase of disposition, as it may have a major effect on the biological activity of the compound, and by increasing polarity and so water solubility, thereby increase excretion.

Rarely, metabolism may decrease water solubility and so reduce excretion. For example, acetylation decreases the solubility of some sulfonamides in urine and this may lead to crystallization of the metabolite in the renal tubules, causing tissue necrosis.

Very many different reactions and pathways can be involved in biotransformation (**Table 1**). The processes can generally be simply divided into Phases 1 and 2, although further metabolism of conjugates has been termed Phase 3. However, this terminology is becoming unfashionable amongst some toxicologists. Phase 1 is the alteration of the original foreign molecule so as to produce a functional group which can then be conjugated in Phase 2. This can best be understood by examining the example in **Figure 3**. The xenobiotic is benzene, a highly lipophilic molecule which is not readily excreted from the animal except, as it is volatile, in the expired air. Phase 1 metabolism converts benzene into a variety of metabolites, but the major one is phenol. The insertion of a hydroxyl group allows a Phase 2 conjugation reaction to take place with the polar sulfate group being added. Phenyl sulfate, the final metabolite, is very water soluble and is readily excreted in the urine. Some foreign molecules, such as phenol, already possess functional groups suitable for Phase 2 reactions and therefore simply undergo a Phase 2 reaction.

Biotransformation is almost always catalysed by enzymes and these are usually, but not always, found most abundantly in the liver in animals. The reason for this location is that most foreign compounds enter the body via the gastrointestinal tract and the portal blood supply from this organ goes directly to the liver (**Figure 4**). However, it is important to remember that: (i) the enzymes involved with the metabolism of foreign compounds may be found in many other tissues as well as the liver (Krishna and Klotz, 1994); (ii) the enzymes may be localized in one particular cell type in an

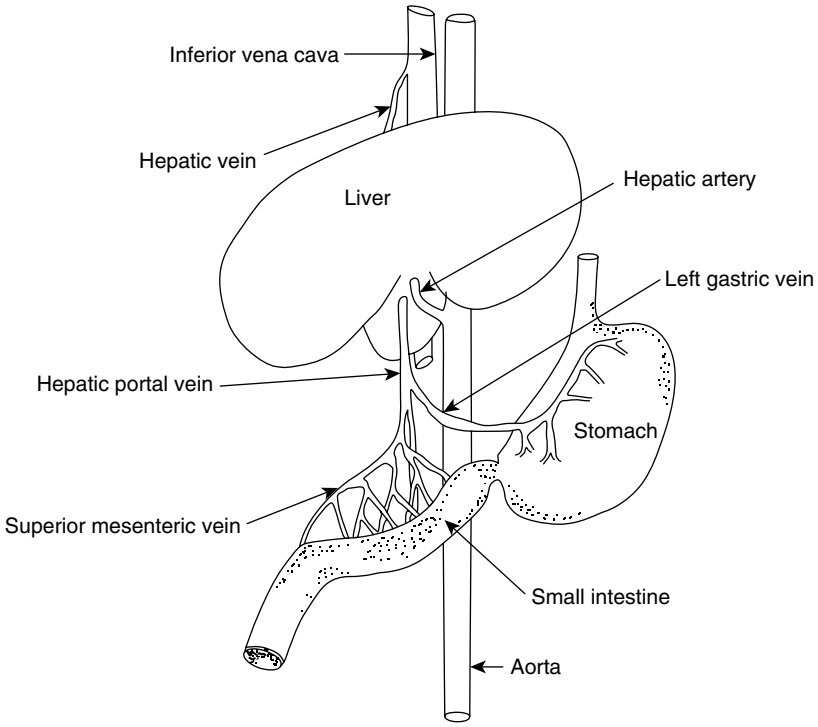

Figure 4 Blood supply to the liver. (Drawn by C. J. Waterfield.)

organ; (iii) unlike the enzymes involved in intermediary metabolism, those involved in the biotransformation of xenobiotics are generally nonspecific and consequently are not always very efficient; (iv) enzymes normally involved in intermediary metabolism may catalyse the biotransformation of a xenobiotic if the chemical structure happens to be suitable and (v) a xenobiotic may undergo many different biotransformations, and the relative importance of each of these may be affected by many factors.

The enzymes involved in biotransformation also have a particular subcellular localization: many are found in the endoplasmic reticulum, some are located in the cytosol and a few are found in other organelles such as the mitochondria.

This chapter focusses on biotransformation in mammals, with particular reference to humans. However, it is important to remember that humans can be exposed to the products of biotransformation in other organisms. For example, in products derived from plants to which agrochemicals, especially pesticides, have been applied, plant metabolites of these products may have been generated and these may be found in food. The same is true of veterinary medicines and animal products: in the case of mammals, metabolism is often, but not always, similar to that in humans. In poultry and fish products, consideration of avian and piscine biotransformation products may be important. In environmental toxicology, metabolism in a wide array of organisms is important and may result in human exposure and, of course, bacterial metabolism in bacteria is important in the mammalian gut.

2 PHASE 1 REACTIONS

2.1 Oxidation Reactions

The majority of oxidation reactions which xenobiotics undergo are catalysed by one enzyme system, the cytochrome P450 mono-oxygenase system (Guengerich, 1991; 1994; 2007; 2008). However, there are a number of other oxidative enzyme systems whose importance in the biotransformation of xenobiotics is increasingly being recognized, and these will be discussed later in this chapter.

2.1.1 Cytochrome P450

Cytochrome P450 is a membrane-bound enzyme system located primarily in the smooth endoplasmic reticulum of the cell, although some forms of cytochrome P450 may be located in other organelles such as the mitochondria. These enzyme systems are called cytochromes P450 because they are coloured proteins, which absorb light at wavelengths near 450 nm when the haem iron is reduced (usually with sodium dithionite) and complexed with carbon monoxide. After homogenization and fractionation of the cell, the enzyme system is isolated in the microsomal fraction. Frequently nowadays, cytochromes

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat004
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

P450 are known as CYPs and they are found in all forms of life. For a discussion of the evolutionary aspects of CYPs see Lewis and Ito (2008).

In mammals, the liver has the highest concentration of CYPs, although they can be found in kidney, lung, adrenal, gonads, brain, skin and most other tissues and organs (Seliskar and Rozman, 2007). The reactions catalysed by cytochromes P450 also require NADPH and molecular oxygen and the overall reaction is

$$SH + O_2 + NADPH + H^+ \longrightarrow SOH + H_2O + NADP^+$$

where S is the substrate.

The sequence of metabolic reactions is shown in **Figure 5** and involves six distinct steps: (1) addition of substrate to the enzyme; (2) donation of an electron; (3) addition of oxygen and rearrangement; (4) donation of a second electron and (5) loss of water. These steps are followed by (6) loss of the oxidized substrate.

The cytochrome P450 system is actually a collection of enzymes, all of which possess an iron atom in a porphyrin complex. These catalyse different types of oxidation reactions and under certain circumstances may catalyse other types of reaction, such as reduction. There are three main gene families important in xenobiotic metabolism: CYP1, CYP2 and CYP3. CYP4 is involved in fatty acid metabolism. Within these there are subfamilies. These may be further divided into genes coding for single distinct enzyme proteins such as CYP1A1 and CYP1A2 (Nelson *et al*., 1993). Thus with CYP1, there are three subfamilies and three genes and one pseudogene (CYP1A1, CYP1A2, CYP1B1) and with CYP2, 13 subfamilies, 16 genes, 16 pseudogenes (CYP2A6, CYP2A7, CYP2A13, CYP2B6, CYP2C8, CYP2C9, CYP2C18, CYP2C19, CYP2D6, CYP2E1, CYP2F1, CYP2J2, CYP2R1, CYP2S1, CYP2U1, CYP2W1). With CYP3, there are one subfamily, four genes, two pseudogenes (CYP3A4, CYP3A5, CYP3A7, CYP3A4). For a list of CYPs see Nelson (2007).

One important feature of the cytochrome P450 enzyme system is its broad and overlapping substrate specificities, which reflect the enormous variety of chemicals that may be potential substrates. Furthermore, one substrate may be metabolized to more than one product by different

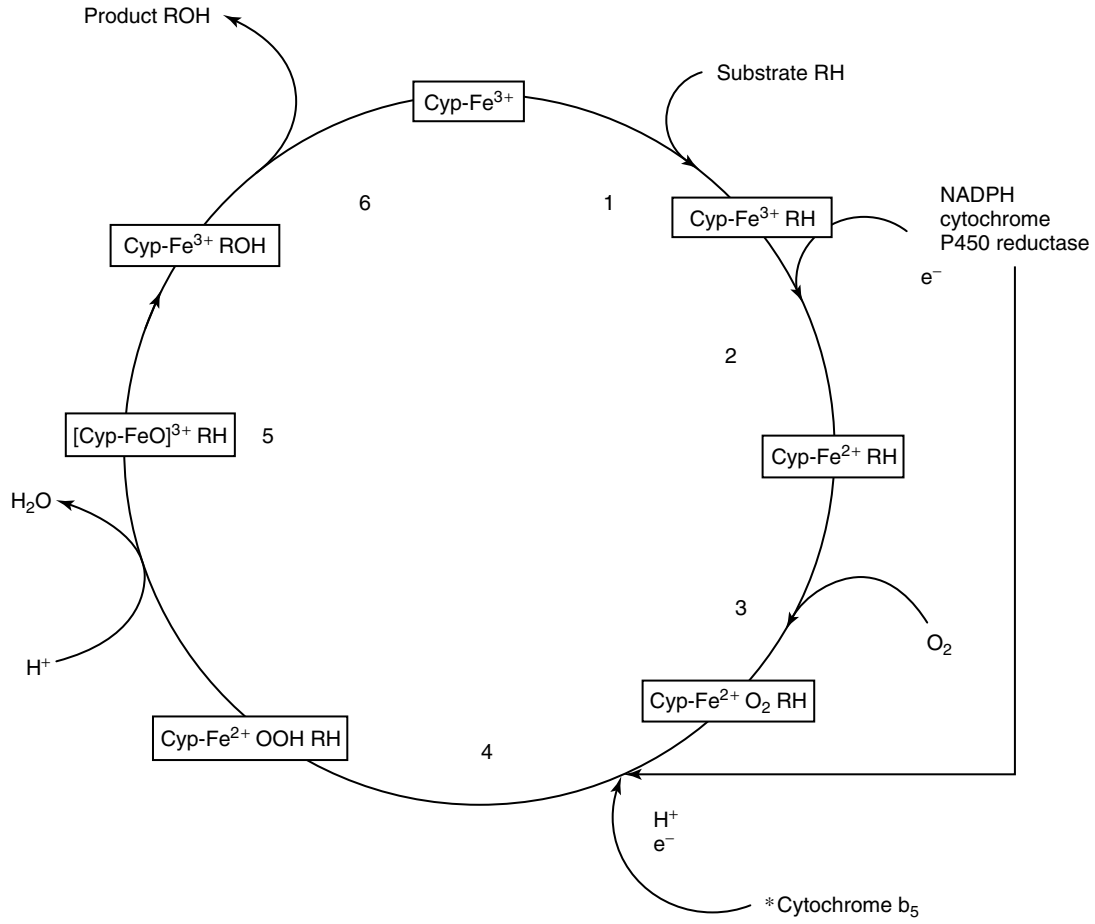

Figure 5 The catalytic cycle of the cytochrome(s) P-450 mono-oxygenase (mixed function oxidase) system. (Adapted from Parkinson A. (2001). Biotransformation of xenobiotics in Klaassen, C. D. (Ed). Cassarett and Doull's Toxicology, 6th Edition, McGraw Hill, Chapter 6. Cyp:- cytochrome P450.)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat004
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

forms of cytochrome P450. For example, the drug propranolol can be metabolized by CYP2D6 and CYP2C19 to 4-hydroxypropranolol and naphthoxylacetic acid, respectively. Sometimes the same form of cytochrome P450 may metabolize one drug to more than one product. For example, the drug methoxyphenamine can be metabolized by CYP2D6 either by *O*-demethylation or hydroxylation at the 5-position.

Another important feature of the CYP enzyme system is its inducibility (Okey *et al*., 1986; Whitlock, 1989; Okey, 1990; Batt *et al*., 1992; Pelkonen *et al*., 2008). Thus, treatment of an animal with certain substances may lead to an increase in the synthesis of one or more isoenzymes of cytochrome P450, leading to an apparent increase in overall activity with respect to a particular substrate. There are now a large number of known inducers of different isoenzymes of cytochrome P450. Exposure of an animal to these substances clearly may have an effect on the metabolism of a compound and can influence its toxicity (this is discussed in more detail later in the chapter).

The major types of oxidation reaction catalysed by the cytochrome P450 system may be subdivided into aromatic hydroxylation of carbon, aliphatic hydroxylation of carbon, alicyclic hydroxylation of carbon, heterocyclic hydroxylation, epoxidation, N-, S- and O-dealkylation, N-oxidation, N-hydroxylation, S-oxidation, desulfuration, dehydrogenation, cleavage of esters and deamination.

2.1.1.1 Aromatic Hydroxylations

Aromatic hydroxylation, such as occurs with benzene (**Figure 6**), is a very common reaction for compounds containing an unsaturated ring. The initial products are phenols, but catechols, quinols and further hydroxylated products may be formed. One of the toxic effects of benzene is aplastic anaemia. This is believed to be due to an intermediate metabolite, possibly the hydroquinone, which may be formed in the bone marrow, the target site. Aromatic hydroxylation usually proceeds via an epoxide intermediate, also called an oxirane ring or arene oxide (**Figure 7**), which involves the addition of oxygen across the unsaturated double bond. The formation of this intermediate may have important toxicological implications, for example the hepatotoxicity of bromobenzene (discussed in detail later in the chapter). Epoxides are often chemically reactive and fairly unstable. They may give rise to positively charged intermediates (electrophiles). The products formed *in vivo* will depend on the reactivity of the particular epoxide and they therefore may form a number of other metabolites, either phenols by chemical rearrangement or, following further metabolism, dihydrodiols, glutathione conjugates and catechols. Destabilized epoxides, for example, will tend to form phenols by chemical rearrangement.

The reactivity of metabolic intermediates may well determine the toxicity of the compound in question.

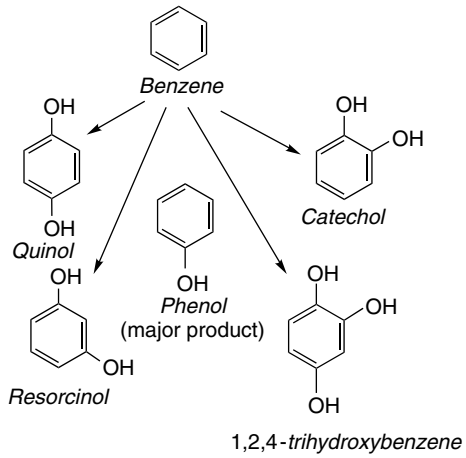

Figure 6 Routes of hydroxylation of benzene.

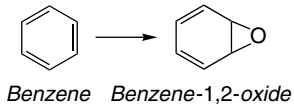

Figure 7 Oxidation of benzene to an epoxide.

However, extremely reactive intermediates are likely to react with many cellular constituents in the close proximity of their formation. Less reactive intermediates may travel to distant sites within or even outside the metabolizing cell and react with more critical cellular targets (Monks and Lau, 1988; Nelson and Pearson, 1990) (see below). Also, aromatic hydroxylation is influenced by the substituents on the ring. Thus, a nitro or other electron-withdrawing group will tend to direct hydroxylation to the *meta* and *para* positions, whereas an electron-donating group such as an amino group will be *ortho*- and *para*-directing.

2.1.1.2 Aliphatic Hydroxylations

Hydroxylation of unsaturated aliphatic compounds may also proceed with the formation of an epoxide across the unsaturated bond. For example, the toxic industrial intermediate vinyl chloride (**Figure 8**) undergoes such a biotransformation catalysed by CYP2E1 to yield chloroacetaldehyde. When the epoxide opens, there may be a shift in the chlorine atom to the adjacent carbon (Hathway, 1984). The active intermediate chloroethylene oxide, which reacts with nucleic acid bases, is thought to be the cause of the mutagenic and carcinogenic potential of vinyl chloride (Bolt, 2005; Bolt and Roos, 2008). Hydroxylation of a saturated aliphatic moiety, such as that in propylbenzene may occur at one of three positions (**Figure 9**). Further metabolism will yield the aldehyde and then the acid from the 3-phenylpropan-l-ol. These further biotransformations may be catalysed by enzymes other than cytochrome P450. Fatty acids such as lauric

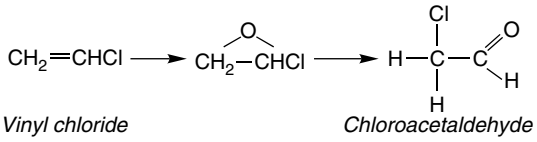

Figure 8 Oxidation of vinyl chloride to an epoxide.

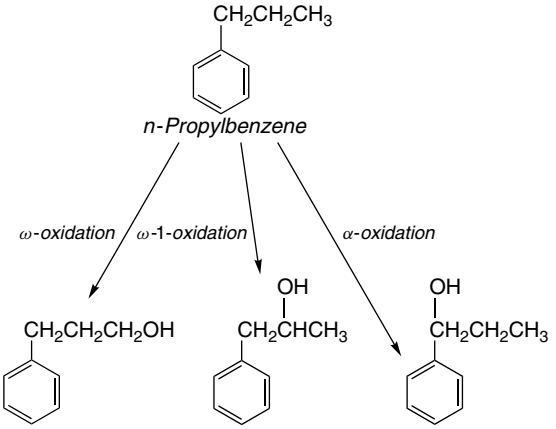

Figure 9 Hydroxylation of propylbenzene.

acid are hydroxylated at the terminal (ω) and penultimate (ω-1) carbon (Shet *et al*., 1996).

2.1.1.3 Alicyclic Hydroxylations

Alicyclic rings may also undergo hydroxylation catalysed by cytochrome P450. For example, cyclohexane may be oxidized to cyclohexanol and then further to the *trans*-l,2-diol. Similarly, heterocyclic rings, such as that in the drug hydralazine may be hydroxylated (see **Figure 19** below). However, other enzymes may also be involved in this type of oxidation, such as the xanthine oxidases (see below).

2.1.1.4 N-, S- and O-dealkylations

Alkyl groups attached to N, O or S atoms are removed by dealkylation reactions, which involve oxidation of the alkyl group. The intermediate hydroxyalkyl compound may be unstable and rearrange with loss of the respective aldehyde (**Figure 10**). Sometimes stable hydroxyalkyl products are produced, for example when dimethylformamide undergoes metabolism (**Figure 11**). S-dealkylation may also involve a factor from the cytosol and so may not be a straightforward microsomal reaction. The chain length will have a bearing on whether dealkylation or oxidation of the alkyl group occurs. The longer the chain length, the more likely is oxidation of the terminal carbon atom to occur.

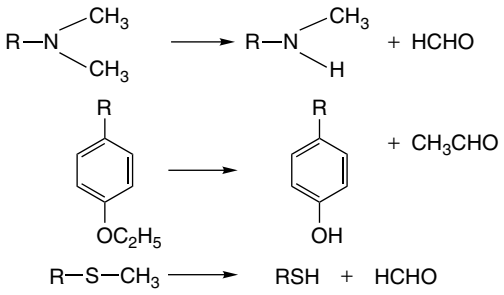

Figure 10 Dealkylation reactions.

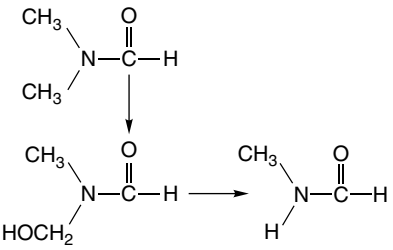

Figure 11 Dealkylation of dimethylformamide via a stable hydroxymethyl intermediate.

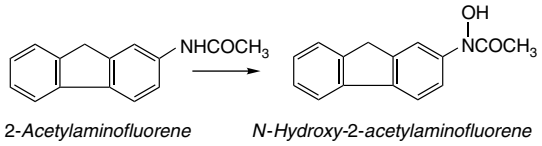

Figure 12 N-Hydroxylation of acetylaminofluorene.

2.1.1.5 N-hydroxylation, S-oxidation, Deamination and so on

Nitrogen atoms in primary arylamines, arylamides and hydrazines may undergo hydroxylation, which is catalysed by cytochrome P450 (**Figure 12**). This reaction may result in a metabolic activation and so be responsible for toxicity (see also below). Nitrogen atoms in xenobiotics may also be oxidized by other oxidases (see below).

Sulphur atoms can also be oxidized by microsomal mono-oxygenases to yield S-oxides and sulfones, such as in the pesticide aldicarb (**Figure 13**). Sulphur atoms may also be removed oxidatively and replaced by oxygen, such as in the metabolism of the insecticide parathion (**Figure 14**). This is a very important general activating pathway for insecticides containing a P=S bond (phosphorothionates); the phosphorothionates have very low anticholinesterase activity, whereas the equivalent phosphates (oxons) are very toxic. Good examples include malathion (FAO/WHO, 1998), chlorpyrifos and fenitrothion (FAO/WHO, 2000), which are converted to their oxons, respectively malaoxon, chlorpyrifos oxon and fenitrooxon. Buratti *et al*. (2005) found that malaoxon formation was catalysed by CYP1A2 and, to a lesser

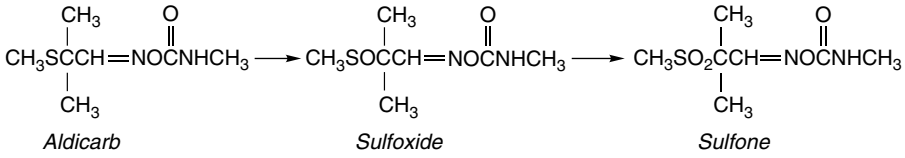

Figure 13 Oxidation of the pesticide aldicarb (Temik) to sulfoxide and sulfone metabolites.

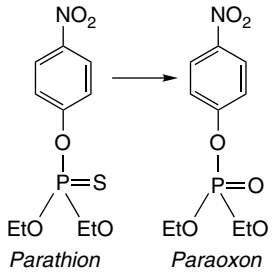

Figure 14 Oxidative desulfuration of parathion.

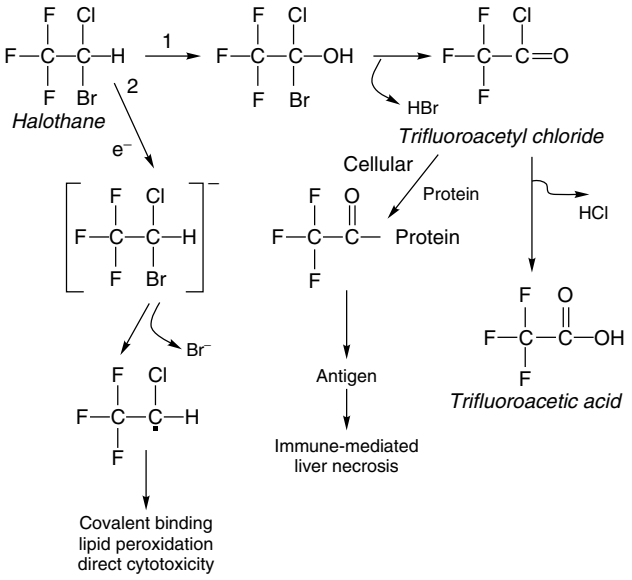

Figure 15 Metabolism of the anaesthetic halothane showing both oxidative (1) and reductive (2) pathways and their role in toxicity.

extent, CYP2B6, whereas CYP3A4 was only important at high malathion levels. Similarly, halogen atoms may be removed via oxidative reactions, as shown for the metabolism of the anaesthetic halothane to trifluoroacetic acid (**Figure 15**).

Amine groups can also be removed oxidatively via a deamination reaction, which may be catalysed by cytochrome P450. For example, in the rabbit, amphetamine is metabolized in this way to phenylacetone (**Figure 16**). However, the initial attack is probably on the carbon atom to yield a carbinolamine, which can rearrange to the ketone with loss of ammonia, as

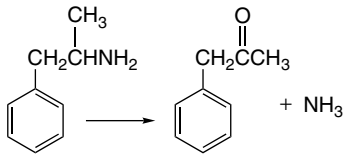

Figure 16 Deamination of amphetamine.

shown. Alternatively, the reaction may proceed via phenylacetone oxime, which has been isolated as a metabolite and for which there are several possible routes of formation. The phenylacetone oxime is hydrolysed to phenylacetone. N-Hydroxylation of amphetamine is also believed to take place and may also give rise to the observed metabolite, phenylacetone. The mechanism underlying the oxidative deamination of amphetamine has been a source of speculation and controversy, but it illustrates that there may be several routes of biotransformation to yield a particular metabolite (Gorrod and Raman, 1989; Kraemer and Maurer, 2002).

2.1.2 Non-Cytochrome P450-Dependent Oxidations

Certain oxidation reactions are catalysed by enzymes other than the cytochrome P450 mono-oxygenase system, such as the microsomal flavin, flavin adenine dinucleotide (FAD)-containing mono-oxygenases (Damani, 1988; Ziegler, 1993; Benedetti and Dostert, 1994; Cashman, 1995). This is responsible for the N-oxidation of tertiary amines such as dimethylaniline and trimethylamine (**Figure 17**). Another example is the N-oxidation of the pyrrolizidine alkaloid senecionine, found in common ragwort (*Senecio jacobaea*). In guinea-pig liver, lung and kidney, oxidation of senecionine is carried out largely by FAD-containing mono-oxygenase (Miranda *et al.*, 1991). The enzyme requires NADPH and molecular oxygen, and proceeds in six steps. Substrate specificity also includes secon-

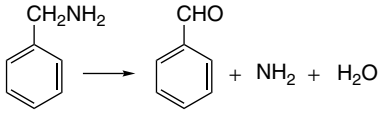

Figure 20 Oxidation of benzylamine by monoamine oxidase.

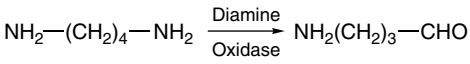

Figure 21 Oxidation of putrescine by diamine oxidase.

dary amines and sulfides, thioethers, thiols and thiocarbamates, and even organophosphates (OPs).

Alcohols, both aliphatic and aromatic, may be oxidized by alcohol dehydrogenase (ADH) (**Figure 18**). This cytosolic enzyme requires NADH. The products from primary alcohols are aldehydes, whereas ketones are formed, more slowly, from secondary alcohols. The oxidation of an alcohol may result in a toxic metabolite such as that from allyl alcohol, where acrolein is formed (**Figure 18**). Increased ADH activity is thus associated with enhancement of allyl alcohol hepatotoxicity (Rikans and Moore, 1987). A microsomal ethanol-metabolizing system has also been demonstrated. This is known to be involved in the metabolism of ethanol and methanol. Aldehydes may be further oxidized to acids by aldehyde dehydrogenase (ALDH), another enzyme which requires NAD (see review by Marchitti *et al*., 2008). There are both cytosolic and mitochondrial ALDHs, and some people of eastern Asiatic descent have a dominant mutation in one of their gene for the mitochondrial ALDH2, making the enzyme less effective. In those affected, acetaldehyde accumulates after drinking alcohol, leading to symptoms such as flushing of the skin, and increased heart and respiration rates (Xiao *et al*., 1996).

Other enzymes may also be involved in the oxidation of aldehydes, such as aldehyde oxidase and xanthine oxidase. These are cytosolic enzymes which contain molybdenum and require flavoprotein cofactors (Beedham, 1988; Garattini *et al*., 2008). There is some evidence that aldehyde oxidase (EC 1.2.3.1) is the same as the 'neonicotinoid nitroreductase' which reduces the neonicotinoid insecticide imidacloprid, at its nitroguanidine moiety (Dick *et al*., 2005; 2007). Xanthine oxidase also catalyses the oxidation of nitrogen heterocycles, such as the purine, hypoxanthine, and also of phthalazine to phthalazinone (**Figure 19**). Aldehyde oxidase will also catalyse the latter reaction. Some amines, such as tyramine, are substrates for the monoamine oxidases, which are mitochondrial enzymes found in a variety of tissues, including the liver. The oxidative deamination of amines via the monoamine oxidases yields an aldehyde product (**Figure 20**). The reaction to cheese with monoamine oxidase inhibitor therapy is discussed in Section 5.2. There are other circumstances whereby the action of monoamine oxidases may give rise to toxic products, such as acrolein in heart tissue produced by the oxidation of allylamine (Biagini *et al*., 1990; Sklar *et al*., 1991). Diamines, such as putrescine and histamine, are metabolized by the soluble enzyme diamine oxidase to dialdehyde and monoaldehyde products (**Figure 21**). Secondary and tertiary amines are less readily oxidized by these enzymes, dealkylation to the primary amine being a preferred pathway (see review by Sessa and Perin, 1994).

Another group of enzymes which are involved in the oxidation of xenobiotics are the peroxidases (Eling *et al*., 1983; Larsson *et al*., 1988). There are a number of these enzymes in mammalian tissues: prostaglandin synthase, found in kidney, lung, intestine and spleen; lactoperoxidase, found in mammary glands; myeloperoxidase, found in the liver Kupffer cells and neutrophils, where it is thought to be responsible for the oxidation of drugs such as hydralazine and procainamide (Uetrecht, 1992). The enzyme is also found in bone-marrow cells, where it may be involved in the metabolic activation of benzene metabolites and therefore in the toxicity of benzene (see reviews by Smith, 1996; Ross, 1996). Uterine peroxidase has been suggested as being involved in the metabolic activation and toxicity of diethylstilbestrol (Metzler, 1984). The overall peroxidase-catalysed reaction may be summarized as follows:

$$\text{peroxidase} + H_2O_2 \longrightarrow \text{compound I}$$

$$\text{compound I} + RH_2 \longrightarrow \text{compound II} + \bullet RH_2^+$$

$$\text{compound II} + RH_2 \longrightarrow \text{peroxidase} + \bullet RH_2^+$$

Among the most important of these enzymes are the prostaglandin synthases (see review by Degen *et al*., 2002). These are known to catalyse the oxidation of *p*-phenetidine, a metabolite of the drug phenacetin, a process which may be involved in the nephrotoxicity of the drug. The prostaglandin-synthase-catalysed oxidation of this compound gives rise to free radicals which may be

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

responsible for binding to DNA (Andersson *et al*., 1982). Horseradish peroxidase will also catalyse the oxidation of this compound (Fischer *et al*., 1986).

2.2 Reduction

Reduction may be catalysed by either mammalian microsomal or cytosolic reductases and by the gut bacteria, which also possess reductases. The latter are clearly important for substances taken orally, where contact with gut microflora is likely. Apart from the gut flora, azo and nitro reduction are catalysed by enzymes in the liver, cytochrome P450 or NAD(P)H quinone oxidoreductase (DT diaphorase). Reduction takes place under anaerobic conditions and utilizes NADH or NADPH. FAD may also be involved, possibly as a nonenzymic electron donor. The most commonly encountered types of reductive reaction are the reduction of nitro and azo groups (see review by Zbaida, 2002). However, aldehydes, ketones, disulfides, sulfoxides, quinones, N-oxides, alkenes, halogenated hydrocarbons and certain metals may also be reduced *in vivo*. The reduction of azo groups such as those present in the drug prontosil (**Figure 22**), often in gut bacteria, is a two-step reaction involving first reduction to a substituted hydrazine, followed by a second reduction and cleavage to yield the amine (Gingell and Bridges, 1973). Reduction of azo dyes can give rise to aromatic amines of increased toxicity.

Reduction of nitro groups is an important route of biotransformation, such as for the compound nitrobenzene (**Figure 23**). Again this involves several steps, producing first a nitroso derivative, then a hydroxylamine and finally an amine. Reduction of nitro groups may be associated with toxicity. Nitrobenzene is haematotoxic in rats when given orally, causing methaemoglobinaemia and haemolysis (see review by Beauchamp *et al*., 1982), whereas given intraperitoneally or to rats without gut flora it is devoid of this toxicity (Reddy *et al*., 1976). This is due to reduction of the compound in the gut to yield the nitroso and hydroxylamine metabolites, which are responsible for toxicity to haemoglobin. Another example is nitroquinoline N-oxide, which is reduced to a hydroxylamine (**Figure 24**), which is believed

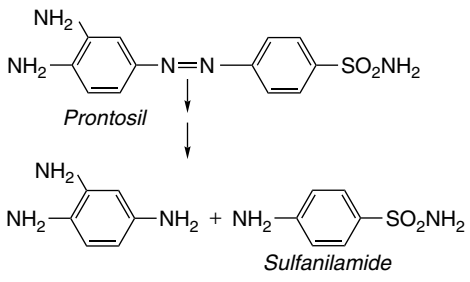

Figure 22 Reduction of the azo bond in prontosil.

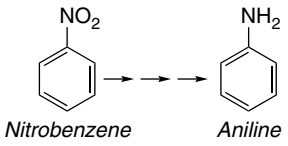

Figure 23 Reduction of nitrobenzene.

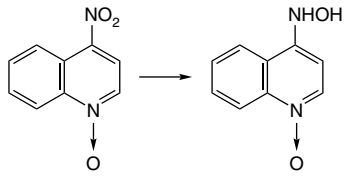

Figure 24 Reduction of the carcinogen nitroqinoline-*N*-oxide.

to be carcinogenic (see review by Bartsch, 1981). Less common reduction reactions include reduction of aldehyde and keto groups, epoxides and double bonds, and may involve other enzymes such as ADH and carbonyl reductase, both of which are found in the liver cytosol, as well as other tissues. Reduction of quinones involves DT diaphorase (quinone reductase Type 1) and disulfides, glutathione reductase and glutathione (see Dinkova-Kostova and Talalay, 2000; Watanabe *et al*., 2004).

Reductive dehalogenation, catalysed by the microsomal enzymes, may also occur in the metabolism of halogenated compounds, such as carbon tetrachloride and the anaesthetic halothane (see **Figure 40** below and **Figure 15**) (Raucy *et al*., 1993). The reductive route is believed to be responsible for the acute toxicity of halothane in rats when the oxygen tension is low. The reactive radical metabolites produced by the reductive pathway will bind covalently to liver protein and this may lead to toxicity. However, the oxidative pathway is probably more important in man under normal conditions of anaesthesia. This also gives rise to a reactive metabolite, trifluoroacetyl chloride (Kenna *et al*., 1988). Both the oxidative and reductive pathways involve cytochrome P450. In the reductive mode, the enzyme donates an electron to the substrate, which then loses a bromide ion, and a second electron is donated, producing a radical species, which may either react with protein or rearrange to other metabolic products (see review by Gut *et al*., 1993). Similarly, reductive dechlorination is also involved in the toxicity of carbon tetrachloride. Here, again, cytochrome P450 donates an electron under reductive conditions and the products are a chloride ion and the trichloromethyl radical (see **Figure 40**, below). This may then react further with oxygen to form the trichloromethylperoxy radical species, which is believed to cause damage to lipids in cell membranes (Mico and

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Pohl, 1983). Alternatively, the trichloromethyl radical may abstract a hydrogen atom from any of a variety of sources (such as glutathione), resulting in the production of chloroform and another radical (such as the glutathionyl radical).

2.3 Hydrolysis

Esterases such as those which hydrolyse carboxylic acid esters and thioesters are seen in a variety of tissues. Esterases are usually found in the cytosol of cells, but microsomal esterases and amidases have also been described; some are also found in the plasma and carboxylesterases are also present in red blood cells. Unfortunately the nomenclature of esterases is confusing, so the Enzyme Commission (EC) numbers are given below. Esterases have been classified as type A, B or C on the basis of activity towards phosphate triesters, the terms A and B esterases having been introduced by Aldridge ((1953a; 1953b), see also Aldridge, 1993c) on the basis of inhibition characteristics. A esterases can hydrolyse OPs without being inhibited (see Walker and Mackness, 1987) and include paraoxonase (PON). B-type esterases are all inhibited by paraoxon (the active metabolite of parathion, an insecticide) and they have a serine residue at the active site; consequently they are also known as serine hydrolases. However, there are a number of different enzymes within this group with different substrate specificities and inhibition characteristics, including the cholinesterases, neuropathy target esterase and the carboxylesterases.

Esterases have been intensively studied in relation to OP esters, which include the OP insecticides and the chemical-warfare agents (see **Toxicology of Chemical Warfare Agents**; **Toxicology of Pesticides**). The phosphohydrolases, (fluorohydrolases, DFPase, EC 3.1.8.2) hydrolyse diisopropyl phosphorofluoridate (DFP), which technically is not an ester but an acid anhydride (see review by Ahmad and Forgash, 1976), as well as fluorine-containing G-type nerve agents, and possibly tabun (see Kasai *et al*., 1992; Noort *et al*., 2002; Benschop and de Jong, 2001; Marrs, 2007). The products of the reaction are hydrofluoric acid and a phosphonate, isopropylmethylphosphonic acid (IMPA), and methylphosphonic acid in the case of sarin. Phosphotriester hydrolases include enzymes that hydrolyse paraoxon to diethylphosphate and 4-nitrophenol; since this involves the loss of the leaving group, the reaction is a detoxication (Edwards, 2001). These enzymes, known as paraoxonases (EC 3.1.8.1) (see also above), can hydrolyse OP esters other than paraoxon, including both insecticides and chemical-warfare agents (see reviews by Dauterman, 1982; Kasai *et al*., 1992; Tang *et al*., 2006; Costa *et al*., 2006). PON is a high density lipoprotein (HDL)-associated enzyme, which seems

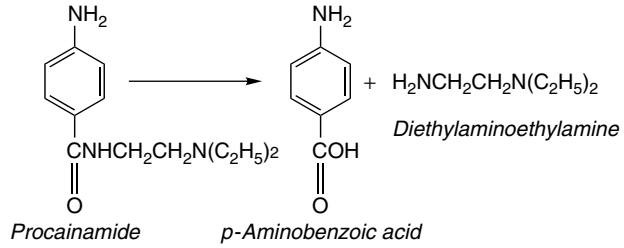

Figure 25 Hydrolysis of an amide, procainamide.

only to be found in mammals (Zech and Chemnitius, 2002). The enzyme exhibits several polymorphisms (Geldmacher-von Mallinckrodt *et al*., 1973), which have been shown to affect the expression and/or the activity level of the enzyme (Costa *et al*., 2003). PON1 exhibits a substrate-dependent activity polymorphism, as well as a large variability in plasma levels among individuals. The PON1 activity polymorphism is determined mainly by a glutamine(Q)/arginine(R) substitution at position 192 of PON1. There is one additional polymorphism in the coding region at L55 M and others in the regulatory and untranslated regions (Furlong *et al*., 2002). Many have sought to connect PON1 polymorphisms and sensitivity to OPs, but it should be remembered that PON has substrates other than OPs (Draganov *et al*., 2005), has important roles in lipid metabolism (Mackness *et al*., 2002) and is implicated in the prevalence of vascular disease (Reddy *et al*., 2008), and that is there is heterogeneity of health outcomes, even without exposure to OPs. Carboxylesterases (EC 3.1.1.1) comprise another important group of esterases. As discussed above, they are B esterases with a broad range of substrate specificity, including many xenobiotics (see review by Satoh and Hosokawa, 1998). There are a number of isozymes which have been characterized with varying substrate specificities (Hosokawa and Satoh, 2006).

A typical amidase reaction is shown in **Figure 25**. Amidases hydrolyse amides; further, hydrazides and carbamates may also be hydrolysed by amidases. Amidases have an important role in the toxicity of the drugs isoniazid (Thomas *et al*., 1981) and phenacetin, where hydrolysis is an important step in the metabolic activation (see **Figure 44** below). Esterases may also have amidase activity and vice versa, and so these two activities may be part of the same overall activity. Amides are generally hydrolysed more slowly than esters. However, electron-withdrawing substituents will weaken the amide bond, making it more susceptible to hydrolysis.

2.4 Hydration

Alkene epoxides and arene oxides, which are three-membered rings containing an oxygen atom, may be

Benzene-1,2-*oxide* *Benzene*-trans-1,2-*dihydrodiol*

Figure 26 Hydration of an epoxide.

reactive metabolic intermediates, although this is not always the case, as stable epoxides exist. They may undergo hydration catalysed by the enzyme epoxide hydrolase. There are several forms of this enzyme, two of which are located in the smooth endoplasmic reticulum, conveniently near to the cytochrome P450 system which produces the epoxide, and one cytosolic enzyme. Indeed, most tissues contain enzyme activity and in the liver and lung, for example, this may parallel the distribution of cytochrome P450 activity. Like the latter enzyme, epoxide hydrolase is also inducible. The reaction can normally be regarded as a detoxication reaction, as the dihydrodiol products are usually much less chemically reactive than the epoxide (**Figure 26**). The products are *trans*-diols. However, there are examples where the diol is further metabolized to a more toxic metabolite, such as benzpyrene-7,8-dihydrodiol. Both aromatic and aliphatic epoxides may be substrates for the enzyme (see Seidegård and Ekström, 1997; Arand *et al*., 2003).

2.5 Other Phase 1 Reactions

Sometimes the enzyme responsible for observed biotransformations is not known or has not been investigated. An example is the N-hydroxylation of aminophenones. 4-Aminopropiophenone is thought to be metabolized to 4-(N-hydroxy)aminopropiophenone, which is a powerful methaemoglobin producer (Marrs *et al*., 1991; Wood *et al*., 1991) and has been considered for use as a cyanide antidote.

3 PHASE 2 REACTIONS

Phase 2 reactions, also known as conjugation reactions, involve the addition of a readily available, polar endogenous substance to the foreign molecule. This polar moiety is conjugated either to an existing group or to one added in a Phase 1 reaction. The polar moiety renders the xenobiotic molecule more water soluble and therefore more readily cleared from the body, and less likely to exert a toxic effect. The endogenous compounds used in Phase 2 reactions are numerous and include carbohydrate derivatives, amino acids, glutathione and sulfate. The mechanism involves formation of a high-energy intermediate: either the endogenous compound is activated as a high-energy derivative (Type 1) or the substrate is activated (Type 2).

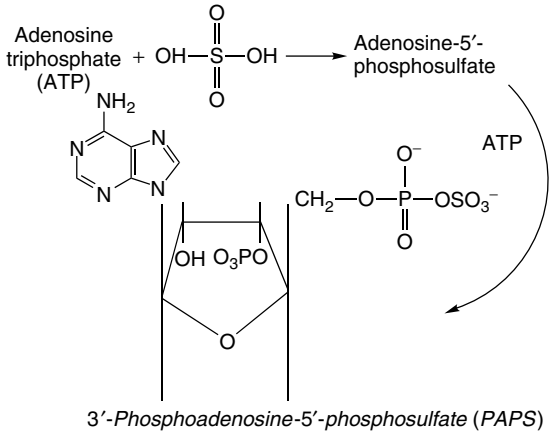
3.1 Conjugation Reactions

3.1.1 Sulfation

The addition of the sulfate moiety to a hydroxyl group is a major route of conjugation for foreign compounds, and also endogenous compounds, such as steroids, may also undergo sulfation. The reaction is catalysed by cytosolic sulfotransferase enzymes found particularly in the liver, gastrointestinal mucosa and kidney. The reaction also requires the coenzyme 3′-phosphoadenosine-5′-phosphosulfate (PAPS). This coenzyme is produced from inorganic sulfate ions and adenosine triphosphate (ATP) in a two-stage reaction (**Figure 27**). Other anions may replace sulfate in the first reaction, but the products are unstable. This may lead to toxicity by the depletion of ATP. The available inorganic sulfate in the body may also be depleted by large doses of compounds such as paracetamol (acetaminophen) which are conjugated with sulfate (see below). There are a number of different sulfotransferases, classified by the particular type of substrate, and some of these exist in multiple forms. The product of sulfate conjugation is an ester which is very polar and water soluble. Both aromatic and aliphatic hydroxyl groups may be conjugated with sulfate, as may N-hydroxy groups and amino groups (**Figure 28**) (see review by Glatt, 2002). Sulfate conjugation may be involved in the metabolic activation of compounds such as the carcinogen acetylaminofluorene (Mulder *et al*., 1988) (see below).

3.1.2 Glucuronidation

In the mammal, glucuronidation is one of the most important Phase 2 metabolic pathways. The addition of



3′-*Phosphoadenosine*-5′-*phosphosulfate* (*PAPS*)

Figure 27 Formation of the sulfate donor PAPS.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

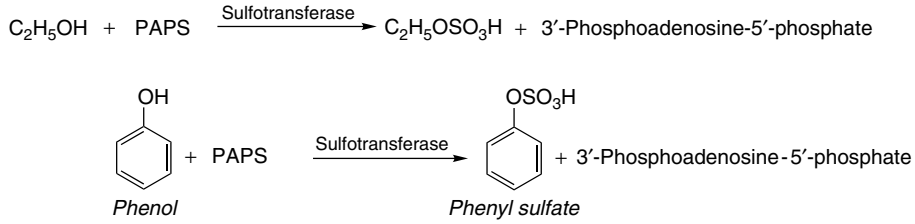

Figure 28 Conjugation of aromatic and aliphatic hydroxyl groups with sulfate.

glucuronic acid, a polar and water-soluble carbohydrate molecule, to hydroxyl groups, carboxylic acid groups, amino groups and thiols is a major route of Phase 2 metabolism. Uridine diphosphate glucuronic acid (UDP glucuronic acid) is the cofactor which donates glucuronic acid and, as with sulfation, the moiety added, glucuronic acid, is in a high-energy form as UDP glucuronic acid. UDP glucuronic acid is synthesized from glucose-1-phosphate in the cytosol in a two-step reaction (**Figure 29**). The addition of the glucuronic acid to the xenobiotic molecule is catalysed by one of a number of glucuronosyl transferases, which are present in the membrane of the mammalian endoplasmic reticulum. Glucuronosyl transferase activity is also seen in creatures other than mammals, such as fish, birds and insects. Additionally, glucuronosyl transferases are found in bacteria, yeast and plants. In humans there are many isoforms, which are grouped into two subfamilies, UGT1A and UGT2B. The enzymes are inducible in animals treated with compounds such as phenobarbital (phenobarbitone) (Burchill and Coughtrie, 1992).

The reaction involves nucleophilic attack by the recipient atom (oxygen, sulphur or nitrogen) at the C-l carbon atom of the glucuronic acid. This displacement reaction involves an inversion of configuration resulting in the product being in the β-configuration (**Figure 30**). As with sulfation, glucuronidation, although generally a detoxication reaction, may occasionally be involved in increasing toxicity, as with the conjugation of a metabolite of acetylaminofluorene (see below) (see review by Bock, 2002). Many xenobiotics are glucuronidated, examples being the pesticides tecnazene (FAO/WHO, 1995) and fenhexamid (FAO/WHO, 2006). Abnormalities in the glucuronosyl transferase system may cause hyperbilirubinaemias such as Crigler–Najjar syndrome and Gilbert's disease (Costa, 2006). Affected individuals may show abnormalities in xenobiotic metabolism, including that of drugs (Maruo *et al*., 2005).

3.1.3 Conjugation with Glucose and Other Sugars

Other carbohydrates may also be involved in conjugation, such as glucose, which is utilized by insects to form glucosides (Yu, 2008). Ribose and xylose may also be used in conjugation reactions. Conjugation with carbohydrates other than glucuronic acid seems uncommon in mammals, but does exist (e.g. Chmela *et al*., 2001). Savage *et al*. (2008) identified a glucosylsulfate as a metabolite of 3,4-dihydro-2,2-dimethyl-2H-naphtho[1,2-b]pyran-5,6-dione (ARQ 501, β-lapachone) in humans.

3.1.4 Glutathione Conjugation

This group of reactions involves the addition of glutathione to a molecule, usually with the subsequent removal of two amino acids to leave a cysteine conjugate. This is then acetylated to yield a mercapturic

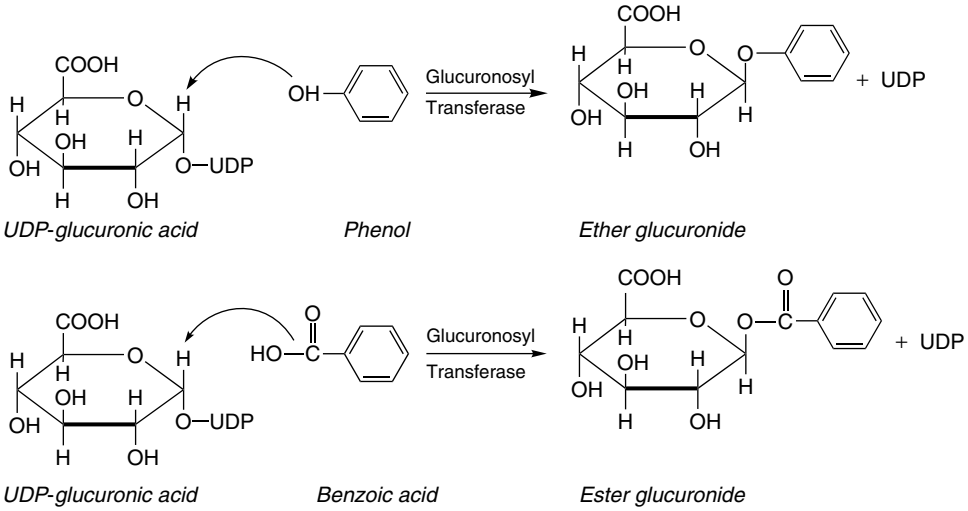

Figure 30 Formation of ether and ester glucuronide conjugates.

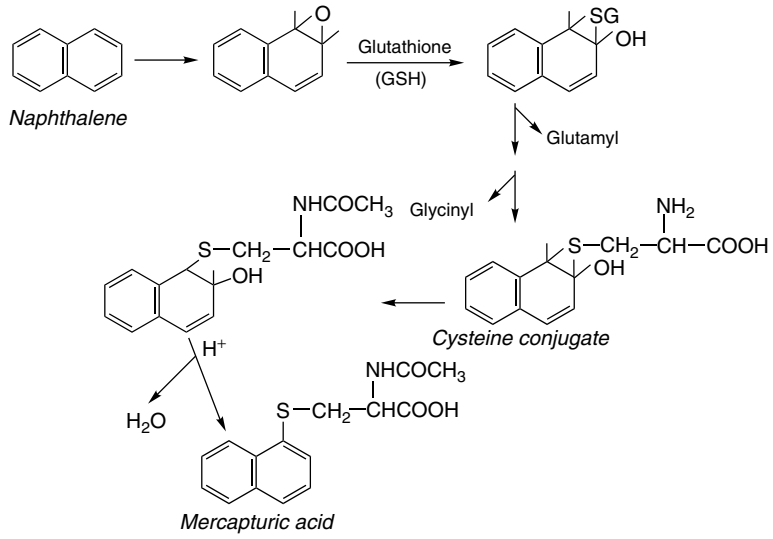

Figure 31 Metabolism of naphthalene to an *N*-acetylcysteine conjugate.

acid or *N*-acetylcysteine conjugate (**Figure 31**). Glutathione is a tripeptide (glutamylcysteinylglycine) found in most mammalian tissues, but especially the liver. Glutathione has a major protective role in the body, as it is a scavenger for reactive compounds of various types (Reed and Beatty, 1980) (see **Glutathione and Glutathione-S-Transferase in Detoxification Mechanisms**). The sulfydryl (SH) group reacts with the reactive part of the foreign compound. Glutathione conjugation is a particularly important route of Phase 2 metabolism from the toxicological point of view, as it is often involved in the removal of reactive intermediates. But this route has also been shown to be the cause of some toxic reactions (Van Bladeren *et al*., 1988; Monks *et al*., 1990; Dekant and Vamvakas, 1993) (see below).

Normally the SH group of glutathione acts as a nucleophile and either displaces another atom (e.g. Cl) or group (e.g. nitro), or attacks an electrophilic site (**Figure 31**). Consequently, glutathione may react either chemically or in enzyme-catalysed reactions with a variety of compounds which are reactive/electrophilic metabolites produced in Phase 1 reactions (Ketterer, 1982). The reactions may be catalysed by one of a group of glutathione transferases (Armstrong, 1997; Sherratt and Hayes, 2002). These are widely distributed enzymes in both the animal and plant kingdoms, and their phylogeny has been studied (Pearson, 2005). In mammals there are two superfamilies of glutathione transferases. Those located in the soluble fraction of the cell are divided into a number of families designated by nonsequential Greek letters. Glutathione transferases that are present in the microsomal fraction are also known as membrane associated proteins in eicosanoid and glutathione metabolisms (MAPEGs) (Jakobsson *et al*., 2000). In recent years there have been major advances in the understanding of the structure of MAPEGs

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat004
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Hebert and Jegerschöld, 2007). The substrates include aromatic, heterocyclic, alicyclic and aliphatic epoxides, aromatic halogen and nitro compounds, alkyl halides and unsaturated aliphatic compounds. Although the specificity is not high for the xenobiotic, there is high specificity for glutathione. The glutathione conjugate which is produced typically undergoes further metabolism, which involves first a removal of the glutamyl residue, catalysed by γ-glutamyl transferase, then loss of glycine, catalysed by cysteinyl glycine dipeptidase and finally the cysteine moiety is acetylated to give an *N*-acetylcysteine conjugate or mercapturic acid (**Figure 31**). The *N*-acetyltransferase (NAT) which carries out this reaction is a microsomal enzyme found in liver and kidney, but is not the same as the NAT which catalyses the acetylation of xenobiotic amine groups (see below). This further metabolism of conjugates, such as illustrated for glutathione conjugates and cysteine conjugates (see below) has been termed Phase 3 metabolism. Glutathione conjugates, or the cysteinylglycine conjugate which results from them, may be excreted directly into the bile and further metabolism may take place in the gastrointestinal tract.

There are numerous examples of xenobiotics being conjugated with glutathione, the earliest to be described being 1,2-dichloro-4-nitrobenzene (Booth *et al*., 1961) and bromosulfophthalein (Combes and Stakelum, 1960). A more recent example is the mammalian detoxication of 1,3-dichloropropene (Stott *et al*., 2001), a substance used to control parasitic plant nematodes.

3.1.5 Cysteine Conjugate β-lyase

This enzyme is responsible for the further metabolism of cysteine conjugates before they are acetylated. Only nonacetylated cysteine conjugates are substrates. The result is a thiol conjugate of the xenobiotic, pyruvic acid and ammonia. The thiol conjugate which results may, in some cases, prove to be toxic (see below) (see review by Cooper and Pinto, 2006).

3.1.6 Acetylation

Acetylation is an important route of metabolism for aromatic amino compounds, sulfonamides, hydrazines and hydrazides (**Figure 32**). The enzymes involved are acetyltransferases and are found in the cytosol of cells in the liver, gastric mucosa and white blood cells. The enzymes utilize acetyl CoA as cofactor. The mechanism of the acetylation reaction involves first an acetylation of the enzyme, followed by addition of the substrate and then transfer of the acetyl group to the substrate. There are two enzymes (NAT 1 and NAT 2) in humans, rabbits and hamsters which differ markedly in activity and substrate specificity. NAT 1 is located in the liver and gut, whereas NAT 2 is found in most tissues (see review by Levy and Weber, 2002). In humans, the possession of a particular mutant isoenzyme in NAT 2 is genetically determined and gives rise to two distinct phenotypes known as 'rapid' and 'slow' acetylators. The acetylator phenotype has an important role in the toxicity of a number of drugs such as hydralazine, isoniazid and procainamide. These examples illustrate the importance of genetic factors in toxicology (Evans, 1992; 1993; Grant *et al*., 1992; Kalow, 1992; Sim *et al*., 2008).

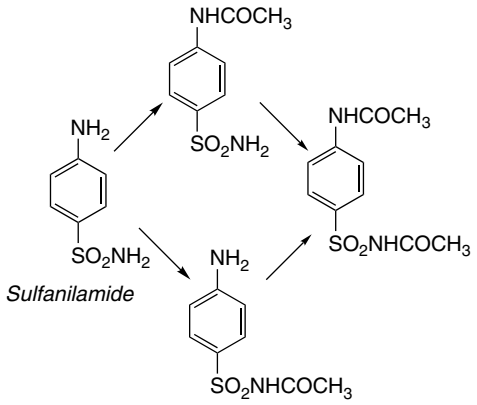

Figure 32 Acetylation of amino and sulfonamido groups.

A related reaction is N,O-transacetylation. This reaction applies to arylamines, which first undergo N-hydroxylation and then the hydroxylamine group is acetylated to yield an arylhydroxamic acid (see **Figure 45** below). This may transfer the acetyl group to another amine molecule or to the hydroxy group, to yield a highly reactive acyloxyarylamine which is capable of reacting, after a rearrangement, with proteins and nucleic acids (King and Weber, 1981) (see below). The enzyme involved, an N,O-acyltransferase, is a cytosolic enzyme.

3.1.7 Amino Acid Conjugation

This is the second type of acylation reaction, but in this type the xenobiotic itself is activated. Organic acids are the usual substrates for this reaction, with conjugation with an endogenous amino acid, or similar substances such as taurine (1-aminoethane sulfonic acid). The first amino-acid conjugation reaction to be described was the reaction that produces hippuric acid (benzoylglycine). This was found in horse urine in 1829 by Liebig and human urine in 1842 by Keller, in both cases the hippuric acid being derived from benzoic acid (Conti and Bickel, 1977). The production of benzoylglycine results from the conjugation of benzoic acid with glycine. However, the particular amino acid utilized depends on the organic acid and the species concerned, and possibly also the availability of amino acids and therefore the diet. Species within a similar evolutionary group tend to utilize the same amino acid. In mammals, glycine

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

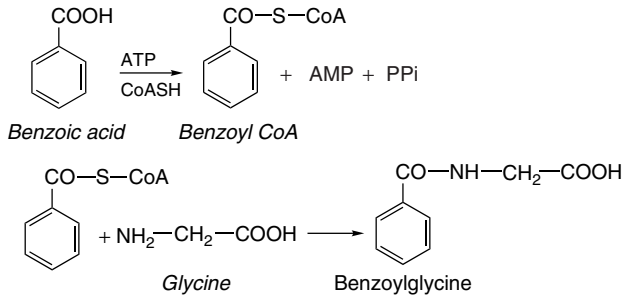

Figure 33 Conjugation of an aromatic acid with glycine.

is the most common amino acid used, but taurine, glutamine, serine, alanine and aspartic acid also take part in conjugation reactions. Ornithine is important in some avian species (Idle *et al*., 1976) and a variety of reptiles (Smith, 1958). The foreign carboxylic acid group is first activated by reaction with coenzyme A in a reaction which requires ATP and is catalysed by a mitochondrial ligase enzyme. The S–CoA derivative then reacts with the particular amino acid (**Figure 33**). This second reaction is catalysed by an acyltransferase enzyme which is found in the mitochondria (see review by Steventon and Hutt, 2002).

3.1.8 Methylation

Hydroxyl, amino and thiol groups in both exogenous and endogenous compounds may be methylated by one of a large number of methyltransferases (**Figure 34**). These enzymes are normally found in the cytosol, although a microsomal O-methyltransferase and an S-methyltransferase have been described. For virtually all methyltransferases, the cofactor required is S-adenosylmethionine, which is the methyl donor, the S-adenosylmethionine being formed from ATP and L-methionine by condensation catalysed by ATP:L-methionine S-adenosyltransferase (see review by Creveling, 2002). As with acetylation, the methylation reaction tends to decrease rather than increase the water solubility of the molecule. A number of metals, such as mercury may also be methylated by micro-organisms, a reaction which changes both the toxicity of mercury and its physicochemical characteristics and, hence, the environmental behaviour of the metal (see review by Boening, 2000).

4 OTHER BIOTRANSFORMATION REACTIONS

There are other reactions which a foreign molecule may undergo. An important point, however, is that although a molecule is foreign to a living organism, it may still be a substrate for an enzyme involved in normal metabolic

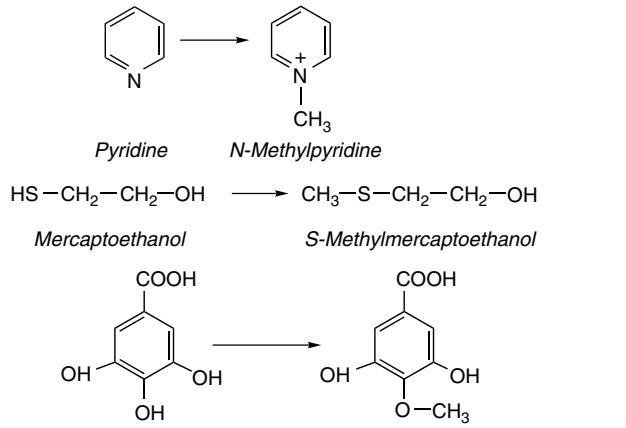

Figure 34 Methylation reactions.

pathways, provided that its chemical structure is appropriate. For example, a foreign compound which is a halogenated fatty-acid derivative may be metabolized by the β-oxidation pathway, but might potentially interfere with that pathway. The possible involvement of enzymes of intermediary metabolism therefore widens the scope of potential metabolic reactions. Foreign compounds can be metabolized by a number of different enzymes simultaneously in the same animal and so there may be many different metabolic routes and metabolites. The balance between these routes can often determine the toxicity of the compound. Some detoxication reactions, for example formation of thiocyanate from cyanide by sulphur transferases *inter alia* rhodanese (cyanide: thiosulfate sulphur transferase; E.C. 2.8.1.1) do not really fall into the classification into Phases 1 and 2 (Isom and Johnson, 1987; Bhatt and Linnell, 1987; Saidu, 2004).

For more information on the metabolism of foreign compounds, the reader should consult the more detailed texts given in the Further Reading section.

5 FACTORS AFFECTING METABOLISM

Factors which affect metabolism may often affect the toxicity of a compound, by changing the rate of removal of the parent compound, by changing the rate of activation or by altering the pattern of metabolism. Different species will often metabolize compounds differently, and so show differences in toxicity. Environmental factors, such as dietary constituents and drugs taken by humans may influence the metabolism, and so alter the toxicity of a particular substance (Shimada *et al*., 1994). In man, genetic factors may play an important role in drug effects (Meyer, 1998) and in determining which metabolic pathway is utilized and therefore whether a compound is toxic or not (Weber, 1987; Sitar, 1989; Alván, 1991; Evans, 1992; Kalow, 1992; Meyer, 1994; Testai, 2001).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

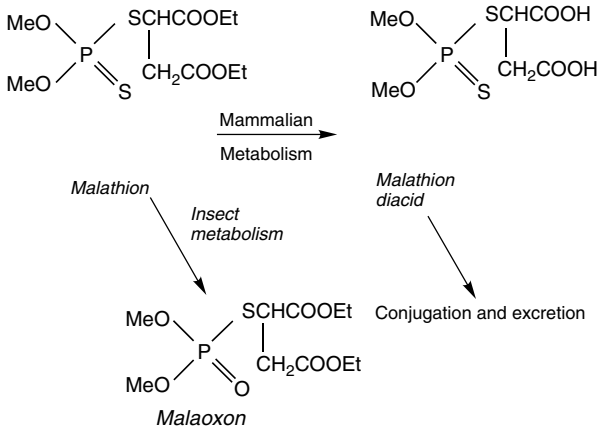

Figure 35 Metabolism of malathion.

The multiple forms of cytochrome P450 may underly many of the observed species differences in metabolism (Berthou *et al*., 1992; Martignoni *et al*., 2006), and may be relevant to the effects of age, sex, nutrition, strain and genetic differences, although any of these factors can affect virtually any Phase 1 or 2 reaction. Different tissues may contain different isoenzymes and, hence, possess different susceptibility to toxic compounds.

5.1 Species

Different species are utilized in the safety evaluation of chemicals and, in the environment, widely different species may all be exposed to a chemical. These species may react very differently to xenobiotics. Indeed, this difference in sensitivity is exploited in pesticides. Insecticides such as organophosphorus compounds and dichlorodipheyltrichloroethane (DDT) are often much more toxic to insects than to humans and other mammals. In the case of malathion and some other phosphorothionates this is due to a metabolic difference (see also above) (**Figure 35**). There are many species differences in metabolism which have been documented (Caldwell, 1980), but this section will mainly concentrate on those which are significant as far as toxicity is concerned. In general, the more closely related the species, the more likely it is that metabolism, including biotransformation, will be similar: thus Smith and Caldwell (1977) found that the rhesus monkey (*Macaca mulatta*) was a good metabolic model for man in about three quarters of the cases they studied, whereas rats and other nonprimates were good models in a far smaller proportion of cases.

5.1.1 Phase 1 Reactions

There are often quantitative differences between species in oxidation reactions, but qualitative differences are perhaps less common. It is difficult to find a species pattern in these differences. These differences may often be the result of differences in cytochrome P450 enzymes. The aromatic hydroxylation of aniline has been shown to vary between various species (**Table 2**), and those species such as the cat (*Felis catus*), which produce more *o*- as opposed to *p*-aminophenol, are more susceptible to the toxicity. The trend in this case is for carnivores to favour *ortho*- rather than *para*-hydroxylation. Another example of quantitative differences in metabolism between species is in the metabolism of ethylene glycol to oxalate (**Figure 2**). The toxicity is partly due to the oxalic acid produced by the oxidative pathway and the toxicity correlates with the production of oxalate. Here again the cat is the species most susceptible to the toxicity, producing the most oxalate, followed by the rat, with the rabbit producing the least (see review by Beasley and Buck, 1980).

Table 2 Species differences in the hydroxylation of aniline

Species	% of dose excreted	
	o-Aminophenol	*p*-Aminophenol
Gerbil	3	48
Guinea pig	4	46
Golden hamster	6	53
Chicken	11	44
Rat	19	48
Ferret	26	28
Dog	18	9
Cat	32	14

Data from Parke (1968).

The N-oxidation of paracetamol (see below) also shows quantitative differences in metabolism between species, which accounts for species differences in hepatotoxicity. Thus, the rat (*Rattus* sp.) is relatively resistant to the toxicity and metabolizes less via the toxic pathway, whereas the hamster (*Mesocricetus auratus*) is very susceptible (Tee *et al*., 1987; Miller *et al*., 1993). In contrast, the rat is well able to carry out N-hydroxylation of acetylaminofluorene (**Figure 12**), a step which is necessary for the compound to exhibit carcinogenicity (Verna *et al*., 1996) (see also **Figure 45** below).

In the metabolism of the drug hexobarbital (hexobarbitone) there are striking differences between species, which correlate with the pharmacological effect (**Table 3**). The overall metabolic rate tends to decrease as the size of the species increases, and this would be expected to have some bearing on drug metabolism. In this example this is approximately true, apart from the rat and rabbit being transposed.

Another Phase 1 reaction which shows a striking species difference that is a cause of selective toxicity is hydrolysis. Thus, the insecticide malathion, which has nugatory acetylcholinesterase activity *per se,* is readily hydrolysed in mammals, but in the insect the carboxylesterase enzyme is absent and oxidative metabolism is the major route (**Figure 35**). This route

leads to the production of malaoxon, which is very toxic because it is a powerful anticholinesterase. The net effect is that malathion is an effective insecticide with low mammalian acute toxicity (FAO/WHO, 1998). This also seems to be true of fenitrothion (FAO/WHO, 2001).

5.1.2 Phase 2 Reactions

A number of Phase 2 reactions also show well-characterized species differences. For example, the metabolism of phenols in most mammals, and also birds, amphibians and reptiles, but not fish, usually involves conjugation with either glucuronic acid or sulfate, depending on the species, but most species utilize a mixture of these two routes. An example is umbelliferone (7-hydroxy coumarin), where differences have been identified between humans, monkeys, dogs and rats in glucuronidation and sulfation reactions (Wang *et al*., 2005; 2006). The domestic cat, however, does not readily conjugate some compounds with glucuronic acid that are conjugated in other species. This phenomenon is important because it renders cats very sensitive to certain xenobiotics, including paracetamol and means that, with certain drugs, the therapeutic dose in cats is much lower than in other pet animals and, indeed, humans. The evolutionary basis of this has been studied; whereas UGTIAI is expressed in the liver, UGT1A6 in cats has stop codons and deletions, which make it unlikely to function as an enzyme. Thus UGT1A6 is a pseudogene in the domestic cat and it has been suggested that the cat can tolerate this because it is exposed to fewer toxins than many animals because of its totally carnivorous diet (Hirom *et al*., 1977; Court and Greenblatt, 2000; Bock, 2002). Like cats, the ferret (*Mustela putorius furo*) liver glucuronidates paracetamol relatively slowly. However, unlike cats, there are no defects in the ferret UGT1A6 gene which could account for the low activity (Court, 2001). It should be noted that cats can glucuronidate some xenobiotics, including apparently nonsteroidal anti-inflammatory drugs (Magdalou *et al*., 1990). Pigs (*Sus scrofa scrofa*) do not conjugate some substrates with sulfate which are so conjugated by other mammalian species (Capel *et al*., 1974; Guhe *et al*., 1996). There are also clear differences in the conjugation of organic acids. Carnivores favour glucuronic acid conjugation, herbivores favour amino-acid conjugation, whereas omnivores utilize both (Calabrese, 1983). Which amino acid is utilized also varies, and although glycine is the most common, glutamine and taurine may be used, and reptiles and some birds utilize ornithine, whereas insects utilize arginine (see also Section 3.1.7).

5.2 Strain of Animal

Different inbred strains of the same animal may show variations in metabolism, just as different species may vary in their response to toxic compounds and in the way they metabolize them. For example, different strains of mice vary widely in their ability to metabolize barbiturates and consequently the magnitude of the pharmacological effect varies between these strains (**Table 4**). Differences can extend to both Phase 1 and Phase 2 metabolism (Stott *et al*., 2004). Similarly, variations between human individuals may also occur, but will be considered separately in this chapter (see below).

5.3 Sex

There can also be variation in the responses between males and females due to metabolic and hormonal differences. Males in some species metabolize compounds more rapidly than females, although this difference is not found in all species. The difference in susceptibility to chloroform-induced liver damage between male and

Table 4 Strain differences in the duration of action of hexobarbitone (hexobarbital) in mice

Strain	Numbers of animals	Mean sleeping time ± SD (min)

female rats is an example of a sex difference which has a metabolic and hormonal basis, thought to be due to the effects of testosterone on liver microsomal enzyme activity. Thus, treatment of females with testosterone decreases the median lethal dose (LD_{50}) and treatment of males with oestradiol increases the LD_{50} of chloroform. Similarly, there is a sex difference in the nephrotoxicity of chloroform in mice, with male mice being more susceptible. This difference can be removed by castration and restored by administration of androgens to the males. It may be that testosterone is increasing the microsomal enzyme-mediated metabolism of chloroform to toxic metabolites (Pohl, 1979). Other examples are the metabolism of ethylmorphine and hexobarbitone (hexobarbital), which are clearly under hormonal control in the male rat. Castration of the animals significantly reduces the metabolism of both compounds. However, the normal rate of metabolism can be restored by the administration of androgens to the castrated animals. Another example is the methaemoglobin-forming cyanide antidote 4-aminopropiophenone, which is active only after metabolic activation *in vivo*, and exhibits a sex difference in (male) beagle dogs and bitches. Bitches produced more methaemoglobin for a given dose of *p*-aminopropiophenone (PAPP) than male dogs. The probable reason for this difference was a lower rate of N-hydroxylation in male dogs (Bright *et al*., 1987). For a review of sex differences in relation to drugs see Wang and Huang (2007).

5.4 Genetic Factors

Genetic variation in metabolism within the human population probably underlies much of the variability in response of that population to the toxic effects of foreign compounds (Meyer, 1994; 1998; Tucker, 1994) and polymorphisms of PON have been briefly discussed in Section 2.3. There are now many examples of toxic drug reactions which occur particularly in individuals who have a genetic defect or genetic difference in metabolism. Many of these are due to nonsynonymous single nucleotide polymorphisms (SNPs). Perhaps the best known example of genetic variability in man is the acetylator phenotype (Weber, 1987; Evans, 1992; Grant *et al*., 1992). In this example the acetylation reaction (see Section 3.1.6) shows genetic variations which are due to the presence of mutations in the gene coding for NAT 2. These mutations give rise to enzymes with differing activities and result in two distinct populations, the rapid and slow acetylator phenotypes, and evidence suggests that NAT 1 may also show bimodal variation. The slow acetylator phenotype, which occurs to a variable extent in the population, depending on the racial origin (**Table 5**), is an important factor in a number of adverse drug reactions (**Table 6**). For example, the lupus syndrome induced by the drug hydralazine only occurs in slow acetylators. The metabolism of the drug is influenced by the acetylator phenotype, with more being metabolized by an oxidative pathway in slow acetylators (Timbrell *et al*., 1984). It is not yet known whether this is responsible for the toxic effect, but Uetrecht (1992) speculated that oxidation by myeloperoxidase in neutrophils was involved (see reviews by Sim *et al*., 2008; Ladero, 2008).

Table 5 Acetylator phenotype distribution in various ethnic groups

Ethnic group	Rapid acetylators (%)	Drug
Eskimos	95–100	INH
Japanese	88	INH
Latin Americans	70	INH
Black Americans	52	INH
White Americans	48	INH
Africans	43	SMZ
South Indians	39	INH
Britons	38	SMZ
Egyptians	18	INH

INH: isoniazid; SMZ: sulfamethazine
Data from Lunde *et al*. (1977).

The acetylator phenotype is also believed to be a factor in isoniazid toxicity (see below) and bladder cancer, which occurs in workers exposed to aromatic amines. Thus, there is an increased incidence of the cancer in slow acetylators. This is postulated to be due to the decreased ability of slow acetylators to detoxify the aromatic amines by acetylation (Cartwright *et al*., 1982; Mommsen *et al*., 1985; Kadlubar, 1994). However, one study did not find any evidence that the slow acetylator phenotype was more susceptible to benzidine-induced bladder cancer (Hayes *et al*., 1993), and there is some evidence with benzidine of a protective effect from slow-acetylator status (Carreón *et al*., 2006) (see review by Sanderson *et al*., 2007).

Another genetic factor in metabolism is polymorphism in the hydroxylation of debrisoquine. This was discovered by Mahgoub *et al*. (1977) during a human volunteer study (**Figure 36**). This was further characterized and the heterogeneity in oxidation was shown for a number of other drugs, such as phenytoin, sparteine and phenformin (Gonzalez *et al*., 1988; Eichelbaum and Gross, 1990; Llerena *et al*., 2009). Again there are two phenotypes, designated poor metabolizers and extensive metabolizers. Unlike the acetylator phenotype, however, the poor metabolizer phenotype is relatively uncommon, only occurring in about 5–10% of a Caucasian population. In some cases, toxic reactions are associated with the poor-metabolizer status. The difference between poor metabolizers and extensive metabolizers is believed to be due to differences in the isozymes of cytochrome P450 present in the particular subject. It has been shown

Table 6 Toxicities related to the acetylator phenotype

Xenobiotic	Adverse effect	Incidence
Isoniazid	Peripheral neuropathy	Higher in slow acetylators
Isoniazid	Hepatic damage	Higher in slow acetylators
Procainamide Hydralazine	Lupus erythematosus	Higher in slow acetylators
Phenelzine	Drowsiness/nausea	Higher in slow acetylators
Aromatic amines	Bladder cancer	Higher in slow acetylators

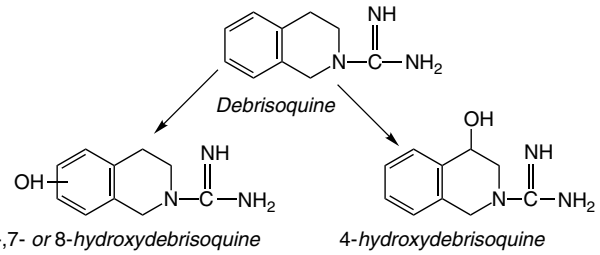

Figure 36 Metabolism of debrisoquine.

(Gonzalez and Meyer, 1991) that poor-metabolizer individuals have a deficiency in activity of liver cytochrome P450 2D6 and this results from various mutations in the CYP 2D6 gene. The poor metabolizer phenotype is known to be caused by two null alleles leading to absence of functional CYP 2D6 protein. There are also CYP 2D6 alleles with low, but definite, activity which produce intermediate metabolizers and individuals with multiple copies of CYP 2D6, who have high activity (see review by Zanger, 2008). It is interesting that there is some evidence that this polymorphism may influence personality type (González *et al*., 2008).

5.5 Environmental Factors

Exposure of animals to chemical substances via the environment, such as in the diet, air or water, may influence the metabolism and therefore the toxic response to the chemical of interest. Humans may be receiving medication with several drugs when exposure to an industrial chemical occurs, for instance. The intake of one drug may affect the metabolism of another. For example, overdoses of paracetamol are more likely to cause serious liver damage if the victim is also exposed to large amounts of alcohol or barbiturates. Both of these drugs influence drug-metabolizing enzymes and thereby increase the metabolism and, in turn, the toxicity of paracetamol (see below).

The diet contains many substances, such as the naphthoflavones found in certain vegetables, which may influence the enzymes involved in drug metabolism. Cigarette smoking is also known to affect drug metabolism.

5.5.1 Induction

One way in which a particular substance may influence the metabolism of another is by increasing the apparent activity of the drug-metabolizing enzymes. This is known as induction. The induction of the microsomal mono-oxygenases, as well as a number of other enzymes, is now a well-known phenomenon and is caused by a large variety of compounds, including many phytochemicals (Batt *et al*., 1992; Murray, 2008). The phenomenon occurs in many species. The different inducers may induce different cytochrome P450 enzymes and are therefore of importance for different types of substrates.

The first type of microsomal enzyme inducer to be described was the barbiturate phenobarbital. When animals are exposed to repeated doses of this compound, there are a number of changes which can be observed. The liver of the animal exposed increases in weight, there is an increase in liver blood flow and the smooth endoplasmic reticulum proliferates. These changes are accompanied by an increase in the total amount of cytochrome P450 in the liver. The activity of other enzymes found in the endoplasmic reticulum also increases.

The effect of enzyme induction is that the metabolism of certain foreign compounds is increased. At the molecular level there is an increase in protein synthesis and underlying this an increase in messenger RNA (mRNA) synthesis. Since the initial discovery that phenobarbital induced the enzymes responsible for its own metabolism, many other inducers have been discovered and studied, and some of these have been found to be different types of inducer. These different inducers induce different isoenzymes of cytochrome P450 and do not necessarily cause all the changes observed with phenobarbital induction, such as the increase in liver weight and blood flow. The inducers currently known can be divided into five types: (i) the barbiturate type; (ii) the polycyclic aromatic hydrocarbon type; (iii) the isoniazid type; (iv) the steroid type, typified by pregnenolone carbonitrile and (v) the clofibrate type. Each of these induces a different form or forms of the enzyme. These can, in some cases, be distinguished and detected on the basis of catalytic activity *in vivo* or *in vitro*, as well as increased amounts of protein. There are also inducers which have a broader inducing ability, such as the compound arochlor 1254, which may be both a barbiturate type and a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

polycyclic hydrocarbon type of inducer. Some of the enzymes induced may be constitutive, whereas others induced by some of these compounds may represent only a small proportion of the total cytochrome P450 present in the uninduced animal. In this case, the induction may cause a large shift in the metabolic profile rather than a simple increase in the overall rate of metabolism. Thus, for the polycyclic hydrocarbon type of inducers, the form of cytochrome P450 induced normally only represents about 5% of the total enzyme, whereas after induction, the amount may be increased by a factor of 16. Furthermore, induction is not confined to the hepatic enzymes, those in other tissues may also be induced. The effect of different inducers on the metabolism of different compounds can be seen from the data in **Table 7**. Clearly, although all these compounds are inducers of cytochrome P450, the effects on different substrates for the enzyme are different. These differential effects even extend to different isomers (**Table 8**). This can be rationalized by the fact that there are many different isoenzymes and that these are induced by different compounds.

In addition to influencing the metabolism of foreign compounds, enzyme induction may have effects on the metabolism of endogenous compounds and so disrupt normal physiological processes.

The mechanisms underlying induction are not all entirely clear but it is known to be a cellular response, which can be studied, for example in isolated hepatocytes. Indeed, the mechanisms seem to vary between the different types and may involve transcriptional activation (e.g. CYP 1A1) or enzyme stabilization (CYP 2E1). The synthesis of new protein is involved, as the induction process can be prevented by inhibitors of protein synthesis. Synthesis of RNA is required, but not of DNA, and so it seems that the effect is at the level of transcription. For the polycyclic hydrocarbon type of inducer, studied using tetrachlorodibenzodioxin (dioxin), which is an exquisitely potent inducer, it seems that there is a cytosolic receptor which binds the inducer. The inducer–receptor complex is then transported to the nucleus and there enhances transcription of the CYP 1A1 gene and other genes such as CYP 1A2, glutathione transferase and glucuronosyl transferase. This causes mRNA coding for cytochrome P450 1A1 and other enzymes to be synthesized. This then allows increased synthesis of the particular cytochrome P450 enzymes for which the mRNA is coded. This involves inducer-dependent derepression and activation of gene expression (Okey, 1990; Waxman and Azaroff, 1992; Whitlock, 1993). However, to date, no receptor for the barbiturate type of inducer has been found, although evidence suggests that the induction may involve inducer-dependent depression and activation of gene expression as for the polycyclic hydrocarbon type. The peroxisome-proliferator (clofibrate) type of induction (CYP 4A) also involves a receptor (Muerhoff *et al*., 1992).

5.5.1.1 *Consequences of Induction*

Induction of drug-metabolizing enzymes may lead to an alteration in the metabolism of a compound, which may then result in the toxicity being either increased or

decreased. Prediction of which will occur is possible only with a knowledge of the metabolism and mechanism of toxicity of the compound in question. In some of the examples at the end of this chapter the effect of inducers will also be discussed.

5.5.2 Inhibition of Metabolism

Just as some of the enzymes involved in biotransformation may be induced, so these enzymes may also be inhibited, and this can have major consequences for toxicity (Netter, 1987; Halpert *et al*., 1994). Such inhibitions are sometimes of major importance clinically, with the interaction between drugs probably more important than induction effects. Inhibition generally requires only a single dose of a compound rather than the repeated doses which are required for induction. The environmental impact of inhibition is, however, probably less than that of induction. Inhibition also may be relevant to the toxic effects of substances encountered in the workplace. For example, workers exposed to the solvent dimethylformamide seem more likely to suffer alcohol-induced flushes than those not exposed, possibly owing to the inhibition of alcohol metabolism (Lyle *et al*., 1979).

There are many different types of inhibitor of the microsomal mono-oxygenase system. Thus, there are inhibitors which appear to bind as substrates and are competitive inhibitors, such as dichlorobiphenyl, which inhibits the O-demethylation of *p*-nitroanisole. There are those inhibitors which are metabolized to compounds which bind strongly to the active site of the enzyme, such as piperonyl butoxide, which probably acts by forming an inactive complex with cytochrome P450, which becomes irreversibly inhibited (Franklin, 1976). There are indeed many compounds which form such inhibitory complexes with cytochrome P450, including some commonly used drugs, such as triacetyloleandomycin. Some inhibitors destroy cytochrome P450, such as carbon tetrachloride, cyclophosphamide, carbon disulfide and allylisopropylacetamide. Finally, there are those which interfere with the synthesis of the enzyme, such as cobalt chloride, which inhibits cytochrome P450 *in vivo* by interfering with the synthesis of the haem portion of the enzyme.

Other toxicologically relevant enzymes involved in biotransformation which also may be inhibited are certain esterases, which are inhibited by organophosphorus compounds (see Section 2.3). Inhibition of monoamine oxidases by drugs such as iproniazid used to treat depression is important clinically, because such treatment results in a decreased metabolism of naturally occurring amines such as tyramine, typically found in cheese, which may be ingested in the diet. These amines may thereby accumulate and can have profound physiological effects such as causing an increase in blood pressure, which in some cases may be fatal (see Strolin Benedetti and Tipton, 1998).

5.5.3 Pathological State

The influence of disease states on metabolism and toxicity has not been well explored. Diseases of the liver might be expected to affect metabolism, but in practice, different liver diseases can influence metabolism differently (Hoyumpa and Schenker, 1982; Howden *et al*., 1989; Kraul *et al*., 1991). Indeed, some metabolic pathways are unaffected by liver damage. For example, the glucuronidation of paracetamol, morphine and oxazepam was found not to be affected by liver cirrhosis in human subjects. Conversely, the oxidation of a number of drugs such as barbiturates, antipyrine and methadone, and the conjugation of salicylates with glycine were all depressed by cirrhosis. Disease states such as influenza are also known to affect drug-metabolizing enzymes, possibly via the production of interferon in response to the infection (Azri and Renton, 1991). Drugs, including complimentary medicines, especially herbal medicines, used to treat disease states, may affect the metabolism of other xenobiotics (see Section 5.5.5).

5.5.4 Age

In general, animals at the extremes of age—neonates and geriatrics—are less able to metabolize foreign compounds than are adult animals between these extremes (Besunder *et al*., 1988; Kinirons and Crome, 1997). However, the development of drug-metabolizing ability is complex and depends on the particular substrate and species, and is also influenced by sex (Horbach *et al*., 1992). For example, in the rat, Phase 1 metabolic activity may develop only after weaning for some demethylation reactions, but the N-hydroxylation of aniline develops from birth. With Phase 2 reactions, again, some are low at birth, such as glucuronidation, whereas acetylation and sulfation are at adult levels and, in the guinea pig, the former is present even in the foetus (Sonawane, 1982). In rats, mono-oxygenase activity begins to decline when the animals reach one year of age. These effects on drug metabolism may be translated into differences in toxicity, but it is not always the young animal which is more susceptible. For example, paracetamol is less hepatotoxic in young mice than in adults. This may be due to the fact that the development of the cytochrome P450 system required to activate paracetamol (see below) reaches maximum, adult levels more slowly than hepatic glutathione levels (Hart and Timbrell, 1979).

5.5.5 Diet

In Section (5.5.1), it was mentioned that phytochemicals can affect induction of metabolic enzymes, and they can also act as inhibitors. This means that constituents of the diet may affect metabolism. Although there is a paucity of information in this area, it is clear that dietary deficiencies can affect the metabolism of foreign

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat004
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

compounds by altering the enzymes involved (Gibson and Skett, 1994). Thus, a low-protein diet will generally decrease the activity of the monoxygenases and decrease the content of cytochrome P450. For example, rats fed a low-protein (5%) diet show 50% of the *in vitro* microsomal enzyme activity of rats fed a normal diet (20% protein). The effect occurs within 24 hours and the enzyme activity is minimal after four days. *In vivo* findings are in agreement with these observations. The decrease in microsomal enzyme activity due to a low-protein diet may result in reduced toxicity. For example, carbon tetrachloride hepatotoxicity is less in protein-deficient rats than normal animals. However, other changes may occur which have the opposite effect, and so paracetamol is more hepatotoxic in protein-deficient animals, possibly owing to decreased hepatic glutathione levels. As with protein deficiency, a dietary deficiency in lipids, such as linoleic acid, also tends to decrease levels of cytochrome P450. Changes in carbohydrate seem to have few effects on drug metabolism, although an increase in glucose intake seems to decrease hepatic cytochrome P450 and inhibit barbiturate metabolism. The effects of starvation seem to be variable, with some microsomal enzyme activities being increased and others decreased. Deficiencies in vitamins in general also reduce the activity of the mono-oxygenases, although there are exceptions to this. The effects of malnutrition on drugs, *inter alia* their metabolism, has been reviewed (Mehta, 1990).

A notable example of the interaction between a particular dietary constituent and drugs is grapefruit juice. Grapefruit juice can markedly augment oral drug bioavailability by reducing presystemic metabolism, the mechanism being down-regulation of cytochrome CYP3 A4 expression in the intestinal wall; grapefruit juice does not appear to affect hepatic CYP 3A4 expression. This phenomenon can affect a number of drugs, including the calcium-channel antagonist, felodipine, and terfenadine, the latter being a formerly widely used antihistamine (Benton *et al*., 1996; Bailey *et al*., 1998; Bressler, 2006).

A related problem is herbal medicine/drug interactions. A number of these are known and the subject has been reviewed (Mills *et al*., 2004; Hu *et al*., 2005; Nekvindová and Anzenbacher, 2007). Examples include preparations made from St John's wort (*Hypericum perforatum*) (Di *et al*., 2008).

5.5.6 Chiral Factors in Metabolism

The importance of chiral factors in metabolism and toxicity has been recognized only relatively recently. The presence of a chiral centre in a molecule, giving rise to isomers, may influence the routes of metabolism and toxicity of that compound. Alternatively, metabolism may yield a specific isomer as a product from a molecule without a chiral centre. For example, it has now been found that only the glutaminic acid derived from the *S*-(−)-enantiomer of thalidomide is embryotoxic, and not that formed from the *R*-(+) enantiomer (Blaschke *et al*., 1979; Heger *et al*., 1994) (see **Effects of Chirality on Toxicity** for *inter alia* a discussion of nomenclature in relation to chirality).

Benzo[a]pyrene is metabolized stereoselectively, by a particular cytochrome P450 isozyme, to the (+)-(7*R*,8*S*)-oxide, which, in turn, is metabolized by epoxide hydrolase to the (−)-(7*R*,8*R*)-dihydrodiol. This metabolite is further metabolized to (+)-benzo[a]-pyrene-(7*R*,8*S*)-dihydrodiol-(9*S*,10*R*)-epoxide, in which the hydroxyl group and epoxide are *trans* and which is more mutagenic than are other enantiomers. This diol-epoxide metabolite is not a substrate for epoxide hydrolase and consequently is not detoxified by this route, and is highly mutagenic (see Levin *et al*., 1980; Jernström and Gräslund, 1994). The (−)-(7*R*,8*R*)-dihydrodiol of benzo[a]pyrene is significantly more tumorigenic than is the (+)-(7*S*,8*S*)-dihydrodiol. It was felt that in this case the configuration was more important for tumorigenicity than the chemical reactivity.

The hydroxylation of the drug bufuralol (**Figure 37**) in the 1-position only occurs with the (+)-isomer, whereas for hydroxylation in the 4- and 6-positions, the (−)-isomer is the substrate. Glucuronidation of the side-chain hydroxyl group is specific for the (+)-isomer (Francis *et al*., 1982). A further complication in human subjects is that the 1-hydroxylation is under genetic control, being dependent on the debrisoquine hydroxylator status. The selectivity for the isomers in respect of the hydroxylations is virtually abolished in poor metabolizers (Dayer *et al*., 1986). In addition to cytochrome P450, other enzymes are specific for or form specific isomers. Thus, epoxide hydrolase forms *trans*-dihydrodiols from cyclic epoxides and glutathione transferases are also stereospecific enzymes. It should be noted that stereospecific metabolism can have

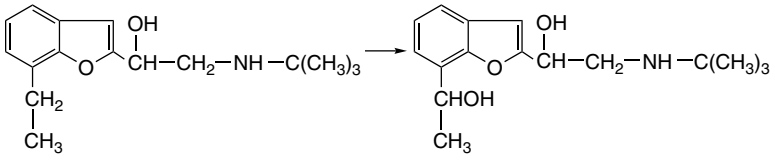

Figure 37 Stereoselective hydroxylation of bufuralol.

regulatory implications (Srinivas *et al*., 2001; Battershill *et al*., 2004).

6 TOXICATION VS. DETOXICATION

The biotransformation of foreign compounds is often regarded as detoxication because it usually converts compounds into more water-soluble, readily excreted substances. This tends to decrease the exposure of the animal to the compound and so tends to decrease the toxicity. However, in some cases the reverse occurs and a metabolite is produced which is more toxic than the parent compound. There are many factors which affect this, such as the dose, availability of cofactors and the relative activity of the various drug-metabolizing enzymes. There may also be several, competing pathways of metabolism—some leading to detoxication, others to toxicity. Factors which alter the balance between these competing pathways will alter the eventual toxicity. This balance between toxication and detoxication pathways (**Figure 38**) is very important in toxicology and underlies some of the factors which affect toxicity (Nelson and Harvison, 1987; Monks and Lau, 1988; Nelson, 1995). Although in many cases the toxic metabolites are generated by the enzymes involved in Phase 1 pathways, there are now a number of examples where Phase 2 conjugation reactions are involved in toxication, as opposed to detoxication, processes. Thus glutathione conjugation of the cyanide antidote 4-dimethylaminophenol (DMAP) does not necessarily lead to inactive Phase 2 metabolites, but reactive glutathione conjugates of DMAP can generate methaemoglobin (Ludwig and Eyer, 1995).

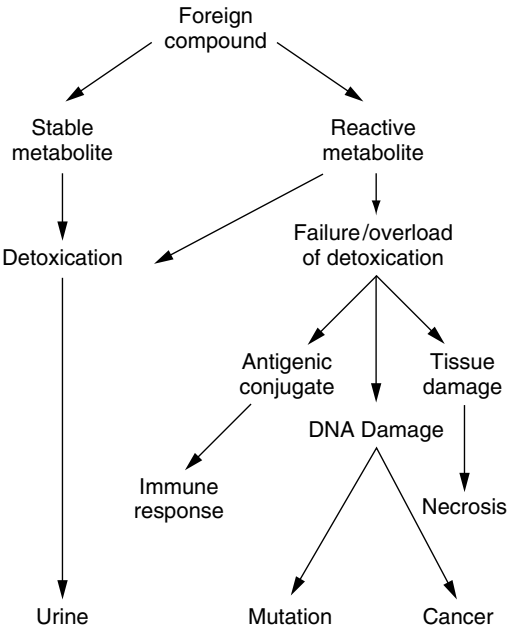

Figure 38 Some of the various consequences of biotransformation.

7 METABOLISM OF SPECIFIC SUBSTANCES

7.1 Paracetamol

A prime example of the role of competing metabolic pathways in toxicity and the importance of endogenous cofactors is afforded by the drug paracetamol (acetaminophen) (Monks and Lau, 1988). This widely used drug is sometimes taken in overdose, generally with suicidal intent. Such overdoses cause centrilobular hepatic necrosis in man and experimental animals, and a wealth of research has revealed that this toxicity is due in part to metabolism of the drug.

There are three pathways of metabolism for paracetamol (**Figure 39**), of which the two most important, quantitatively, are sulfate and glucuronic acid conjugation. The third, resulting in conjugation with glutathione, only represents a few per cent of the dose in humans. This last pathway involves an initial reaction catalysed by cytochrome P450, producing a reactive metabolite which is normally detoxified by conjugation with glutathione. The resulting glutathione conjugate is then further metabolized to a cysteine conjugate

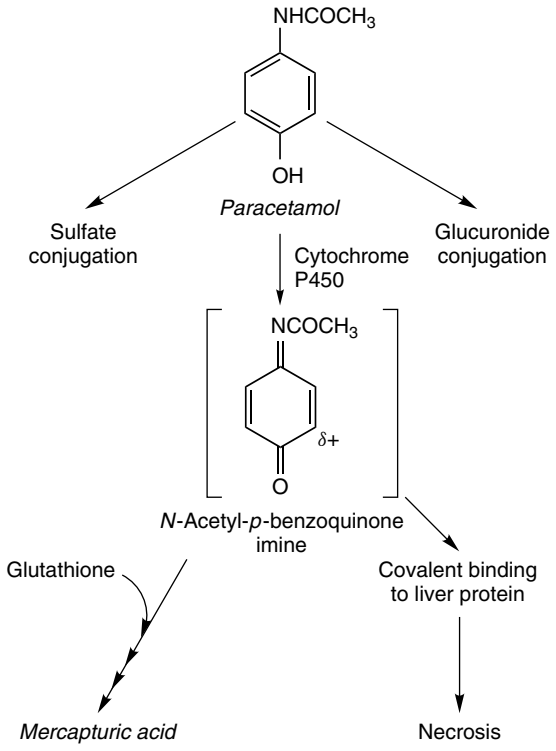

Figure 39 Metabolism of paracetamol.

which is acetylated and excreted as an *N*-acetylcysteine conjugate or mercapturic acid.

Hepatotoxicity ensues when a sufficiently large dose of paracetamol is taken to deplete the liver of the majority of the glutathione (to 20% or less in experimental animals). This means that the reactive metabolite is able to react with cellular macromolecules, such as proteins, covalently bind to these macromolecules and cause hepatic necrosis. The nature of the reactive metabolite has received much attention, but seems to be a quinoneimine (*N*-acetyl-*p*-benzoquinoneimine (NAPQI)), although the exact mechanism of formation is not certain (Nelson, 1995) (see review by James *et al*., 2003).

In liver microsomal incubations both *in vitro* and *in vivo,* radiolabelled paracetamol binds covalently to protein, and the major adduct isolated from these protein conjugates is 3-cystein-5-yl-4-hydroxyaniline. A number of protein targets have been isolated, in particular a 55–58 kDa cytosolic protein and a 100 kDa protein, which is *N*-10-formyltetrahydrofolate dehydrogenase. Arylation of this protein correlates with loss of enzyme activity (Pumford *et al*., 1997). Mitochondrial protein targets such as glutamate dehydrogenase have also been identified. Again, arylation is associated with loss of enzyme activity (Pumford *et al*., 1997). The loss of enzyme activity may contribute to the development of toxicity, such as the detoxication of ammonia. However, as yet unidentified targets such as a 58 kDa protein may also play a role in the development of the toxicity and it is likely that a number of separate events are involved (Cohen and Khairallah, 1997).

It seems, however, that an electrophilic metabolite is involved in some way in the hepatotoxicity. It is clear that the NAPQI is a cytotoxic, reactive metabolite of paracetamol, produced via an oxidation reaction catalysed by one of several cytochrome P450 enzymes, including CYP 1A1, CYP 1A2, CYP 2E1, CYP 3A1 and CYP 3A2. Evidence suggests that Kupffer cells and nitric oxide (NO) are also involved in the metabolic activation (Pike *et al*., 1998; Ito *et al*., 2004). The reactive metabolite produced will react with glutathione. It reacts with glutathione in two ways: (i) by forming a conjugate and (ii) by oxidizing glutathione and being itself reduced back to paracetamol. NADPH can also reduce NAPQI back to paracetamol in a reaction which may involve glutathione reductase. The reactive metabolite can also react with cysteine residues in proteins via either arylation or oxidation of the cysteine SH.

Deacetylation of paracetamol can also occur, giving rise to *p*-aminophenol and subsequent metabolites; *p*-aminophenol is a known nephrotoxin, and this might account for the nephrotoxicity seen after overdoses of paracetamol and occasionally reported with chronic administration.

There are two main detoxication pathways for paracetamol: conjugation with (i) glucuronic acid and (ii) sulfate. The oxidative pathway(s) leading to mercapturic acid accounts for about 5‰in man. The deacetylation pathway is also presumably minor. However, this balance may be altered in a number of ways. Large doses of paracetamol may deplete animals of sulfate, as well as glutathione. Metabolism may thereby be diverted through the oxidative pathway catalysed by the cytochrome P450 enzymes and more will be conjugated with glucuronic acid (**Figure 39**). Factors which affect the activity of the microsomal enzymes, such as inducing agents will also alter this balance. For example, pretreatment of animals with phenobarbital will increase the hepatotoxicity in some species (rats) by increasing the amount metabolized via the cytochrome P450 pathway. However, this pretreatment will also increase the activity of glucuronosyl transferase and in some species (hamsters) this effect will decrease the hepatotoxicity. In the hamster the oxidative pathway is quantitatively of greater importance than in the rat, a factor which underlies the large difference in susceptibility to the hepatotoxicity between these two species.

7.2 Carbon Tetrachloride

Carbon tetrachloride is a potent hepatotoxin which has been studied extensively. The major toxic effect carbon tetrachloride causes is centrilobular hepatic necrosis, which is dependent upon metabolism via the cytochrome P450 system (CYP 2E1, CYP 2B1 and/or CYP 2B2). However, the enzyme system is acting as a reductase in this instance (reductive dehalogenation). Cytochrome P450 donates an electron to the carbon tetrachloride molecule and thereby allows the homolytic cleavage of a carbon–chlorine bond (**Figure 40**). This yields the trichloromethyl radical and a chloride ion. The trichloromethyl radical may then react with oxygen to give the trichloromethylperoxy radical. Alternatively, the trichloromethyl radical can abstract a hydrogen atom from polyunsaturated lipids and thereby form a lipid radical and a stable product, chloroform. The lipid radical

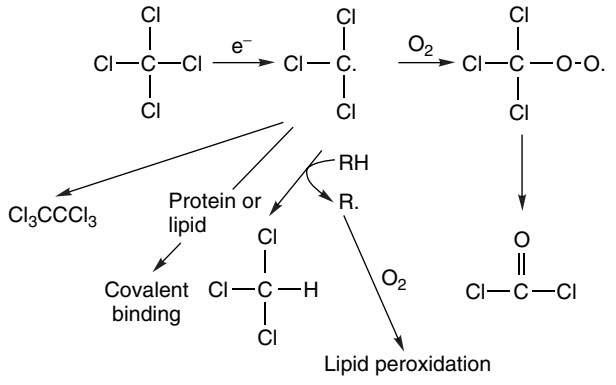

Figure 40 Metabolism of carbon tetrachloride.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat004
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

can then proceed to react with other cellular constituents and cause a cascade of disturbances within the cell. Tumour necrosis factor α, NO and transforming growth factors α and β are activated. Also, the trichloromethyl radical can react covalently with lipids and proteins and it is believed that the trichloromethylperoxy radical is the reactive metabolite responsible for lipid peroxidation (see reviews by Weber *et al*., 2003; Manibusan *et al*., 2007).

The oxygen concentration is important for the formation of the trichloromethylperoxy radical and lipid peroxidation. Elevated oxygen concentrations *in vitro* and *in vivo* reduce lipid peroxidation and hepatotoxicity. Burkhart *et al*. (1991) suggested that oxygen, including hyperbaric oxygen, might have a role in carbon tetrachloride poisoning. As carbon tetrachloride is metabolically activated by cytochrome P450 in the smooth endoplasmic reticulum, the reactive radicals formed are able to react with the enzyme itself and the lipids of the endoplasmic reticulum. The result is that cytochrome P450 is destroyed by carbon tetrachloride. Consequently, if animals are given a small dose of carbon tetrachloride ($0.05\,\mathrm{ml\,kg^{-1}}$), a subsequent larger dose is less toxic than the same dose administered to a control animal (Glende, 1972). This is because the form of cytochrome P450 which activates carbon tetrachloride is destroyed. Carbon tetrachloride is thus hepatotoxic only when it can be metabolically activated (Sesardic *et al*., 1989).

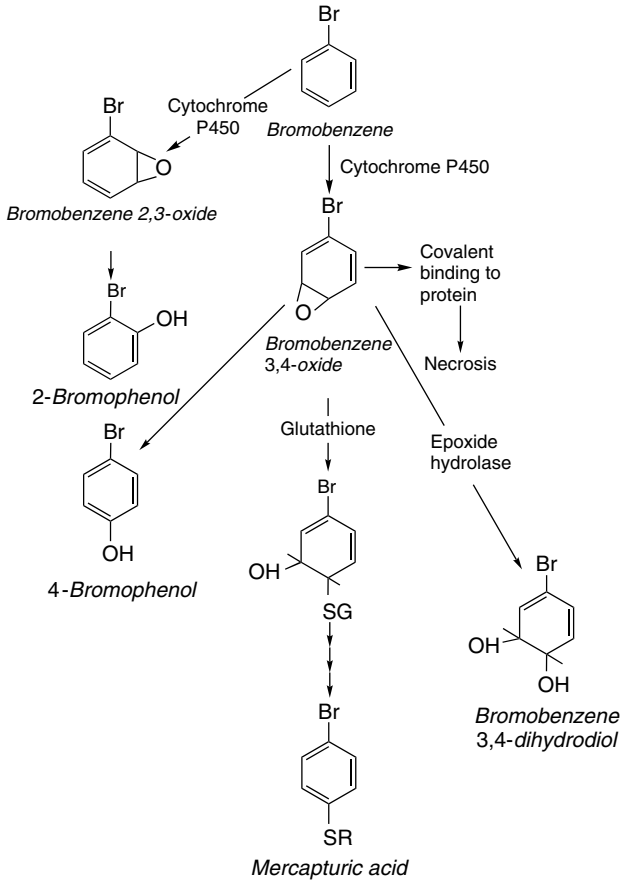

Figure 41 Some of the metabolic pathways for bromobenzene.

7.3 Bromobenzene

Bromobenzene is another hepatotoxic compound, but one which may also damage the kidneys, and the involvement of metabolism in these two toxic effects is different. Bromobenzene metabolism affords an interesting example of the importance of competing pathways of detoxication vs. toxication and of the way in which metabolic pathways may be switched by inducers. The metabolism of bromobenzene is complex, proceeding via two different epoxides and involving multiple reactive intermediates (Lau and Zannoni 1979; 1981; Beyhl and Mayer, 1980; Lau *et al*., 1984).

Bromobenzene is metabolically activated by oxidation, catalysed by cytochrome(s) P450 (CYP 2B) (Harauchi and Hirata, 1994), to yield an intermediate 3,4-epoxide (**Figure 41**). This epoxide is chemically reactive but may be detoxified in two ways. The first involves conjugation with glutathione (**Figure 41**), eventually giving rise to a mercapturic acid conjugate which is excreted in the urine (Thor *et al*., 1979). Cytosolic glutathione transferases seem to be involved in the conjugation of the epoxide with glutathione rather than the microsomal glutathione transferases or a direct chemical reaction with glutathione; moreover bromobenzene adducts to cytosolic glutathione transferases have been isolated (Aniya *et al*., 1988; Koen *et al*., 2006). The second route of detoxication is metabolism to the dihydrodiol mediated by epoxide hydrolase (Monks *et al*., 1984). Just as with paracetamol, a sufficiently large dose of bromobenzene will deplete the liver of glutathione and, hence, the reactive epoxide will bind to tissue macromolecules, a process which seems to underly the liver necrosis.

There is another oxidation pathway, however, also catalysed by cytochrome(s) P450, which gives rise to another epoxide, the 2,3-epoxide, which is believed to be nontoxic. The evidence for this comes from the effect of inducers on the toxicity and metabolism, and illustrates switching of metabolic pathways. Pretreatment of animals with phenobarbitone increases metabolism via the 3,4-epoxide pathway and increases the toxicity. Conversely, pretreatment with 3-methylcholanthrene increases metabolism via the 2,3-epoxide pathway, as indicated by an increased excretion of *o*-bromophenol, and decreases the toxicity (**Table 9**). Also, mice that have the cytochrome P450 isoenzyme, which catalyses the formation of the 3,4-epoxide, show greater hepatic damage after doses of bromobenzene than do those that who do not. *In vitro*, the 3,4-epoxide binds to microsomal protein and seems to prefer to bind to histidine residues, whereas the 2,3-epoxide binds to

haemoglobin and prefers to bind to the cysteine residues. It is suggested that the 2,3-epoxide is less reactive and more stable than the 3,4-epoxide, and therefore reacts with a different target protein (Lau and Zannoni, 1981). However, the 3,4-epoxide was detected in both blood *in vivo* and hepatocyte incubation medium *in vitro*, when animals or hepatocytes were exposed to bromobenzene. Clearly the reactive intermediate has sufficient stability to move within the hepatocyte and even leave the cell. There would seem to be an optimum reactivity for the epoxide in order for it to be toxic and react with critical sites on macromolecules. Reactive metabolites which are chemically too reactive will tend to interact with biological molecules indiscriminately and may never reach critical target molecules. Further metabolism of the bromophenols may also occur, to give bromoquinols and bromocatechols. 2-Bromohydroquinone will deplete glutathione in both liver and kidney, but only causes pathological damage in the kidney. It is believed that the diglutathione conjugate of bromohydroquinone (**Figure 42**) is the nephrotoxic agent (Monks *et al*., 1991). The metabolism of halogenated benzenes has been reviewed (den Besten *et al*., 1994).

7.4 Methanol and Allyl Alcohol

Methanol is a widely used and readily available solvent, which is often found in combination with ethanol. Consequently, it sometimes features in poisoning cases (see reviews: International Programme on Chemical Safety, 1997; International Programme on Chemical Safety, 2001; Barceloux *et al*., 2002). The toxicity of methanol illustrates the role of metabolism in toxicity where a

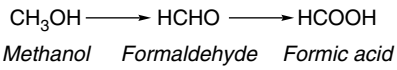

Figure 43 Metabolism of methanol.

chemically reactive metabolite does not seem to be involved. Also, a species difference in detoxication is revealed. It also illustrates the importance of understanding the mechanism of toxicity in order to treat the poisoned patient in a rational way. Methanol is toxic mainly as a result of metabolism to formic acid (**Figure 43**). This is a two-step reaction, with metabolism to formaldehyde being catalysed by either ADH or catalase. The second metabolic step to give formic acid is catalysed by either ALDH or formaldehyde dehydrogenase, an enzyme which requires glutathione.

The formic acid damages the optic nerve, seemingly by inhibiting the mitochondrial enzyme cytochrome oxidase and, hence, reducing the level of ATP available to the nerves (see **Ophthalmic Toxicology**). Humans and certain other primates are much more susceptible than are rodents to the toxicity of methanol; consequently nonhuman primates have been used as a model for human poisoning with methanol (Martin-Amat *et al*., 1977), and indeed are probably the only animal models of poisoning in man that can be used to study antidotes (Blomstrand and Ingemansson, 1984). The differences between primate and rodent susceptibility seems due, at least in part, to the accumulation of formic acid in the former to a greater degree than the latter. Because the metabolism is clearly important in the toxicity, treatment of the poisoning involves blocking the first step in the metabolic pathway by using ethanol as a competitive inhibitor of ADH. An alternative inhibitor of alcohol oxidation, 4-methyl pyrazole (fomepizole) has also been studied as an antidote to methanol (McMartin *et al*., 1980; Blomstrand and Ingemansson, 1984; Flanagan and Jones, 2001).

Another alcohol which is metabolized via ADH, leading to toxicity is allyl alcohol. This compound causes periportal liver necrosis when administered to animals (Badr, 1991; Atzori *et al*., 1989). This is believed to be due to oxidation to allyl aldehyde (acrolein, 2-propenal) catalysed by ADH (**Figure 18**). Allyl aldehyde is reactive and may cause toxicity by reacting with critical macromolecules in the cell. Glutathione conjugation is likely, as an *N*-acetylcysteine conjugate is excreted in the urine. Elegant work using deuterium-labelled allyl alcohol showed that oxidation was necessary for the toxicity (Patel *et al*., 1983).

7.5 Isoniazid

Isoniazid is a first line therapy for tuberculosis, usually given with rifampicin. Isoniazid is a drug which may

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat004
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cause hepatic damage in some patients (see review by Tostmann *et al*., 2008). There are several routes of metabolism, but the most important route is the acetylation reaction (**Figure 44**) (see Section 5.4). The acetyl-isoniazid that results from this is further metabolized by hydrolysis to yield acetylhydrazine and isonicotinic acid. Acetylhydrazine has been shown to be hepatotoxic in experimental animals and this is due to further metabolism via a cytochrome P450-mediated pathway (**Figure 44**). The product is suggested to be an N-hydroxylated metabolite, which, on loss of water, would yield a diazene, which can fragment to a reactive intermediate. This may be either a radical or a carbonium ion, which may react with proteins and cause hepatic necrosis. This pathway is induced by phenobarbital, which also increases the covalent binding of the acetyl group to protein and the hepatotoxicity of acetylhydrazine (Lauterburg *et al*., 1985a; 1985b). However, acetylhydrazine may also be further metabolized by a different route, a second acetylation step, of which the effect is detoxication. Both the primary acetylation step, giving acetylisoniazid, and this second step are influenced by the acetylator phenotype (see above). Therefore, although rapid acetylators produce more acetylisoniazid and therefore more acetylhydrazine, this is then more extensively removed by acetylation to diacetylhydrazine in the rapid acetylator. When the plasma level of acetylhydrazine in human subjects after a dose of isoniazid was determined, it was found that the slow acetylator has a greater exposure to acetylhydrazine. This example illustrates both the importance of competing detoxication and toxication routes of metabolism, and also the influence which genetic factors may have on toxicity (Timbrell *et al*., 1980; Lauterburg *et al*., 1985a; 1985b; Timbrell, 1988).

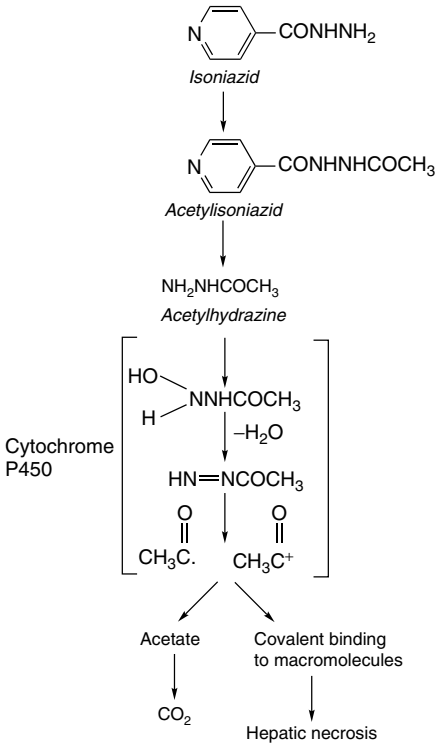

Figure 44 Part of the biotransformation of isoniazid.

7.6 Aromatic Amines

Another example in which acetylation features is the carcinogenicity of aromatic amines (see review by Vineis, 1994). For some aromatic amines, acetylation is a detoxication reaction. For example, 2-naphthylamine and benzidine both cause bladder cancer in man and it seems likely that the acetylation reaction reduces the carcinogenicity. Acetylated derivatives of benzidine are less reactive towards DNA and cause less damage to this macromolecule than does the parent compound. Several studies have shown that the slow acetylator is more at risk than is the fast acetylator from developing bladder cancer, especially those whose work may expose them to aromatic amines, although not all such studies have an increased risk (Evans *et al*., 1983; Miller and Cosgriff, 1983; Ladero *et al*., 1985; Hayes *et al*., 1993; Weistenhofer *et al*., 2008). It has been suggested that aromatic amines and heterocyclic compounds in tobacco smoke may contribute to the elevated risk of bladder cancer in cigarette smokers (Gu *et al*., 2005; Sanderson *et al*., 2007).

However, acetylation may be an activation step, involved in the toxic pathway for some compounds, such as 2-aminofluorene. There are several metabolic pathways involving acetylation and N-hydroxylation yielding *N*-acetoxyaminofluorene (**Figure 45**) and some of the metabolites are mutagenic (Heflich and Neft, 1994). The acetylation steps seem to involve similar, but possibly distinct enzymes, either NAT (see Levy and Weber, 2002), arylhydroxamic acid acetyl transferase (AHAT) and/or N-hydroxy-O-acetyl transferase (NHOAT). 2-Aminofluorene can also be oxidized by prostaglandin H synthase (Degen *et al*., 2002). The *N*-acetoxyaminofluorene may rearrange to yield a reactive nitrenium ion which can react with DNA to give covalent adducts such as *N*-(deoxyguanosin-8-yl)-2-aminofluorene (**Figure 45**). This has been shown both *in vitro* and *in vivo.* Alternatively, *N*-hydroxyacetylaminofluorene may be sulfated on the hydroxyl group and this has also been shown to be an activation step and may be involved in hepatocarcinogenesis, at least in mice. However, using hepatocytes from rabbits which were phenotyped as either rapid or slow acetylators, it was found that the rapid acetylators were more susceptible to DNA damage from aminofluorene, which suggests a role for acetylation. It seems likely that there are several routes for the metabolic activation of acetylaminofluorene in

which acetylation, sulfation and glucuronidation may play a part, with variation in the predominant pathways between organs and species. This example, however, illustrates the role that Phase 2 metabolic pathways may have in metabolic activation.

7.7 Haloalkanes

The toxicity of haloalkanes illustrates the role of glutathione conjugation in metabolic activation, as opposed to detoxication. Several different haloalkanes are known to be metabolically activated by conjugation with glutathione. For example, the compounds 1,2-dichloroethane and 1,2-dibromoethane are both conjugated with glutathione in a reaction catalysed by glutathione transferase (**Figure 46**). The resultant haloethylglutathione conjugate can undergo loss of the halogen and rearrangement to yield a charged episulfonium ion which can react with DNA. Incubation of 1,2-dibromothane with DNA and glutathione transferase gives the adduct *S*-[2-(-*N*-guanyl)ethyl]glutathione. This interaction is believed to be responsible for the mutagenicity of these compounds (see review by Anders, 2004).

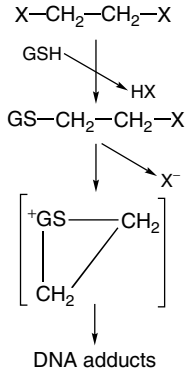

Figure 46 Formation of a reactive metabolite of a haloalkane from a glutathione conjugate.

Some haloalkanes are nephrotoxic and glutathione conjugation has been shown to mediate this toxic effect also. For example, hexachlorobutadiene is conjugated with glutathione, which is then further metabolized to a cysteine conjugate (**Figure 47**). This cysteine conjugate may then undergo further metabolism, either acetylation, deamination or cleavage by the action of the enzyme cysteine conjugate β-lyase. This gives rise to a thiol conjugate which has been shown to be nephrotoxic and is able to bind covalently to protein (Dekant and Vamvakas, 1996; Dekant, 1996).

7.8 Valproic Acid

In addition to enzymes commonly associated with drug metabolism, sometimes enzymes normally involved in intermediary metabolism may be responsible for metabolic activation. Thus, a metabolite of valproic acid (VPA; 2-*n*-propylpent-4-enoic acid) is believed to be involved in the hepatotoxicity sometimes caused by this drug. This metabolite, Δ^4-VPA, irreversibly inhibits enzymes of the β-oxidation system and destroys cytochrome P450. This reactive metabolite may be involved in the hepatotoxicity of the drug. Further metabolism, gives 3-oxo-Δ^4-VPA, which inhibits the enzyme 3-ketoacyl-CoA thiolase, the terminal enzyme of the fatty-acid oxidation system (Li *et al*., 1991; Baillie and Sheffels, 1995). However, recent *in vitro* evidence suggests that reactive oxygen species may also be involved in the toxicity (Tabatabaei *et al*., 1998).

8 CONCLUSION

It can be seen that biotransformation is often a crucial aspect of the toxicity of a compound and may, in a variety of circumstances, be the cause of toxicity rather than a

process of detoxication. It is thus important that the toxicologist study the biotransformation of compounds under study both to understand the nature of the proximate toxicant and to understand what other factors (coadministration of other compounds, the state of the subject, etc.) may affect activation or detoxifying biotransformation pathways. Moreover, for regulated substances such as drugs and pesticides, it is normally required that biotransformation studies be undertaken. With pesticides, such studies are usually done in the rat using radiolabelled (most often using ^{14}C) compounds, as part of studies of absorption, distribution, metabolism and excretion. Such studies can be very useful in the understanding of the toxicity of the test compound. Where metabolism studies are done in more than one species, the studies may help identify which species will most resemble humans in toxic response. A further role of biotransformation studies is in the study of the combined actions of chemicals (Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment, 2002).

Toxicokinetics of Xenobiotic and Metabolite Distribution and Excretion

Mario A. Inchiosa, Jr. and Mario E. Inchiosa

CONTENTS

1 INTRODUCTION

This chapter will focus principally on factors that influence the distribution of xenobiotics and xenobiotic metabolites in the human or animal body, the kinetics of the accumulation of such substances from acute and chronic exposures and the kinetics of elimination from depots that develop with chronic exposure. As part of this chapter, emphasis will be placed on the physicochemical characteristics of xenobiotics that permit them to penetrate potential physical barriers to their absorption into the plasma and their further distribution into anatomic compartments and tissues. Such barriers include, for example, the cellular membranes that constitute the mucosal surface of the digestive tract, the cellular barrier between the pulmonary alveolar space and the pulmonary interstitium and the cell walls of muscle and organs. The potential barrier to absorption and diffusion represented by the structures noted above is primarily related to the lipid constituents of cell membranes. The epidermis is another important barrier to absorption of xenobiotics. However, this represents only a relative barrier because the penetrability of chemicals through the skin can be affected by the degree of hydration of the skin.

2 CELL MEMBRANE BARRIERS

The bimolecular layer of lipids that make up the structure of cell membranes constitutes the principal barrier to the absorption of xenobiotics into the body, as well as the diffusion and distribution within the animal organism. Thus, the degree of lipid solubility of xenobiotics, whether drugs or toxins, substantially determines the ease of penetration of these chemicals through cell membranes. The entire length of the gastrointestinal tract, from the oral cavity to the anus, represents a continuous sheet of cell membrane surfaces, without any effective pores that would allow absorption of xenobiotics into the plasma. There are channels that permit equilibration of water and electrolytes, but their molecular dimensions are too small for significant diffusion of essentially all xenobiotic molecules through pores (Hogben *et al.*, 1959; Creasey, 1979; Bowman and Rand, 1980). Thus, it is known that highly polar drugs such as d-tubocurarine,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

which contains two fixed quaternary nitrogen atoms, and the sugar alcohol, mannitol, are not absorbed when ingested orally. In their clinical use, such drugs must be injected intravenously, and their further distribution in the body is largely limited to extracellular fluid spaces (Bowman and Rand, 1980). The cellular membranes of the epithelial layer in the respiratory alveoli represent the barrier to absorption of polar compounds following inhalation (Taylor and Gaar, 1970; Burton and Schanker, 1974a; 1974b). Likewise, the trophoblastic membrane of the placenta repels the diffusion of polar substances from the maternal to the foetal circulation (Creasey, 1979; Bowman and Rand, 1980; Pratt, 1990).

2.1 Diffusion Across Cell Membranes

It is the intrinsic lipid solubility of some xenobiotics that permits them to diffuse and distribute across cell membranes. However, since the animal body represents a mostly aqueous environment, drugs and other xenobiotics that gain access to the plasma and distribute further are characterized as having both lipid and water solubility. A particularly good example of this is a substance such as ethanol, which is readily soluble in water and distributes through cell membranes to effect an essentially equal concentration in all of the body water.

Although many endogenous mediators, substrates and metabolites are absorbed or distributed in the body by active transport or facilitated diffusion mechanisms, most drugs and other xenobiotics are absorbed and distribute according to the principles of simple diffusion. The important differences among these mechanisms is that active transport and facilitated diffusion overcome the apparent constraints related to lipid solubility for cell membrane transport and, in the case of active transport, may develop concentration gradients for the solute across membrane barriers. Thus, with simple diffusion, a substance will dissolve in one aqueous medium, for example, the interstitial fluid, possess enough intrinsic lipid solubility to dissolve in cell membrane lipids, and then equilibrate across the cell membrane to reach an equal concentration in another aqueous medium, the cell cytoplasm (**Figure 1**).

Another important characteristic of simple diffusion, as compared with active and facilitated diffusions, is that the latter mechanisms show saturation kinetics. That is, as increasing concentrations of solute are presented to one side of a cellular barrier, a point is reached where there is no further increase in the initial rate of diffusion of solute; in this case, all available transport sites are occupied at any given instant. With simple diffusion, there is a linear relationship between solute concentration presented to the diffusion barrier and the initial rate of diffusion (**Figure 2**). This feature is frequently exploited in clinical situations, where it is desirable to have rapid onset of a pharmacological effect, by loading the plasma concentration in order to obtain a rapid rise in an effect compartment, such as the cerebrospinal fluid (CSF).

2.2 Factors Influencing Simple Diffusion

2.2.1 Partition Coefficient

When a drug or a toxicant is a neutral (i.e. nonionizable) chemical, the relative rate of diffusion of this substance across cell membranes can be predicted by its lipid–water partition coefficient (Larson *et al.*, 1962; Pratt, 1990). Various organic solvents, such as chloroform and hexane, have been substituted for actual lipid solutions in the determination of partition coefficients,

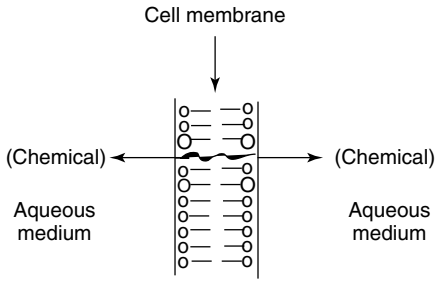

Figure 1 The lipoid barrier presented by the cell membrane.

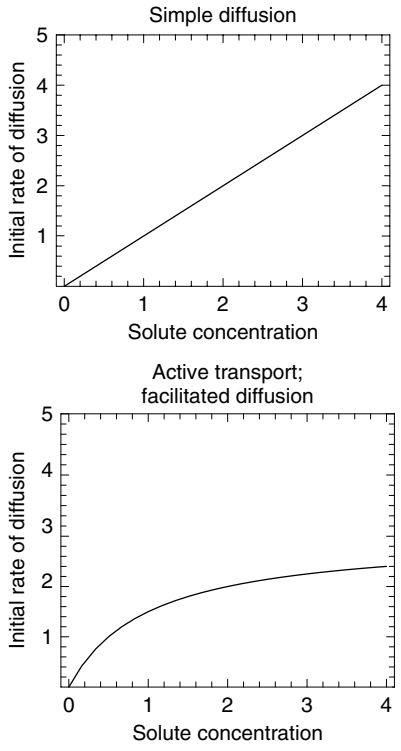

Figure 2 A comparison of the relationship between the solute concentration at the interface with a cell membrane and the initial rate of diffusion, for simple diffusion, and active transport and facilitated diffusion.

although olive oil was commonly used as the organic phase in earlier studies. In fact, the term oil–water partition coefficient is still used. The common standard adopted by most drug and environmental regulatory agencies today is the *n*-octanol–water partition coefficient. It was demonstrated much earlier that the ease of diffusion across the cell membrane did not show a strong dependence on the molecular radius of the solute, but showed a primary correlation with the partition coefficient (Goldstein *et al.*, 1974) (presented in **Figure 3**). This is reasonable, since the solute is expected to dissolve and diffuse through a bimolecular layer of lipid. The contribution of molecular size to the rate of diffusion across the cell membrane would be the relative friction encountered in the lipid medium as size increases. Perhaps this does not become an important factor because of the small path length across this layer. Estimates have placed this in the range of 35–40 Å (Creasey, 1979).

2.2.2 Degree of Solute Ionization

Prediction of the ease and rate of diffusion across cell membranes is more complex when the solute is a weak acid or weak base. And this would represent the vast majority of drugs and toxicants of interest in this discussion. There is an interaction between two principal physicochemical factors that can be used to approximate the rate of diffusion across cell membranes, and the association with the rate of onset of pharmacological or toxic effects. One factor is the partition coefficient of the nonionized fraction of the weak acid or base; the second factor is the percentage of the drug or toxin that is nonionized at the pH of the body fluid at its interface with cell membranes. Since there is a wide variation in the pH of body fluids, the ease of diffusion of a chemical across cell membranes varies widely. If one is considering absorption from the stomach, the pH of stomach contents may be 1.4, and this will influence the state of ionization of a weak acid or weak base. In what is probably the other extreme, anticipating the absorption of a chemical from saliva through the membranes of the oral cavity may require consideration of the degree of ionization at pH 7.8. An example of consideration of an intermediate pH range may relate to the importance of reabsorption of a drug or toxin from renal tubular urine. Although there may be obligatory filtration of a chemical from plasma into tubular urine, as blood perfuses the renal glomeruli, the potential for the reabsorption of the solute into the efferent renal vessels is a function of the percentage of the drug that is nonionized at the pH of the tubular urine (perhaps 5.5) and the partition coefficient of the nonionized molecules. The extent of reabsorption of solute from tubular urine influences the persistence of the drug or toxin in the body and, therefore, its half-time ($t_{1/2}$) of elimination.

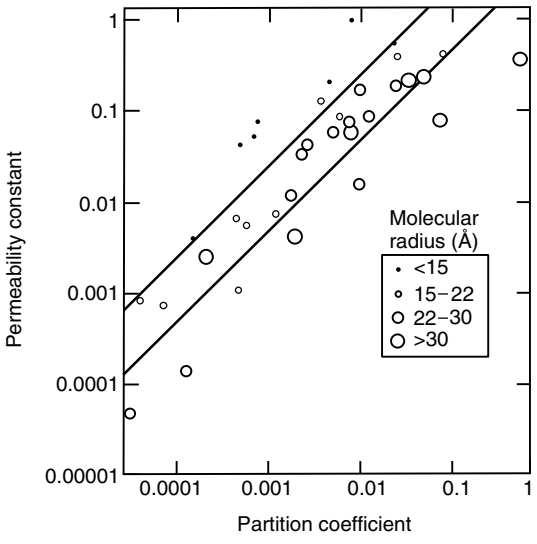

Figure 3 The correlation between the oil-water partition coefficient of a solute and membrane permeability. The lack of an appreciable contribution of molecular size to the relationship is illustrated; relative molecular radii are depicted by the size of the circles. (Reproduced from Goldstein *et al.*, 1974 © John Wiley & Sons, Inc.)

As noted above, a linear relationship between the rate of diffusion of a solute across cell membranes and the partition coefficient of the nonionized form of the solute is expected. The second factor, the percentage of the solute that is nonionized in a particular body medium, contributes substantially to the rate of diffusion that is observed. This nonionized fraction of a weak acid or a weak base, at a particular pH, can be calculated with the Henderson-Hasselbalch equations presented in Appendix A.

The ratios of the concentration of nonionized to ionized forms for weak acids and weak bases, in relation to the differences between the pH and pK_a of the solutes, is presented in **Figure 4**. It is noted that at the pH where there is no difference between the pH of the medium and the ionization constant (pK_a) of the solute, the ratio of the nonionized to the ionized form is 1. In fact, this is the definition of the ionization constant, that is, it is equal to the pH, where there are equal concentrations of the non-ionized and ionized forms of the solute. The figure also shows that this is true for both weak acids and weak bases.

The magnitude of the nonionized fraction is of importance in relation to the ease of establishment of an equilibrium across cell membranes. The nonionized form of the weak acid or weak base is the only form with any degree of lipid solubility. The chemical structure of the solute, that is, the presence of ring structures, long carbon chains, and so on, determines the relative degree of lipid solubility. The ionized fraction of the solute is considered to be completely hydrophilic, and unable to diffuse across cell membranes.

The importance of the ratio between the nonionized and ionized fractions of the solutes at the pH values

DOI: 10.1002/9780470744307.gat006

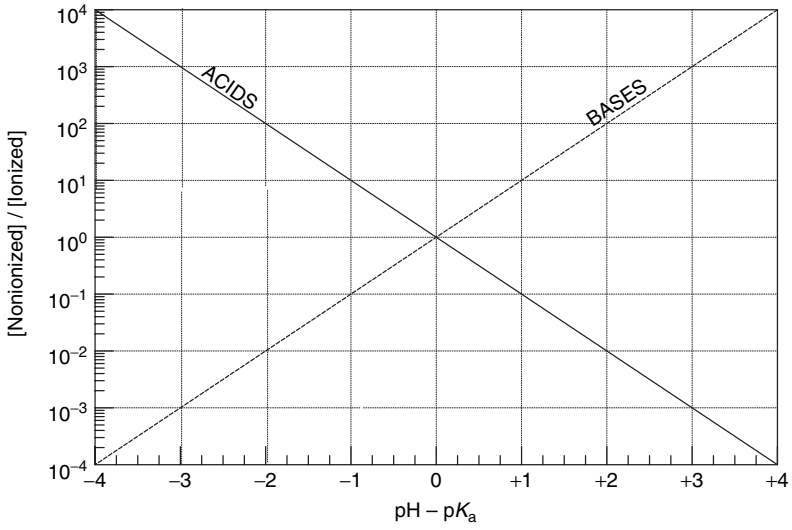

Figure 4 The effect of pH on the state of ionization of weak bases and weak acids. The relationships are only shown for a maximum difference of four units between pH and pK_a, but they can be projected to larger differences.

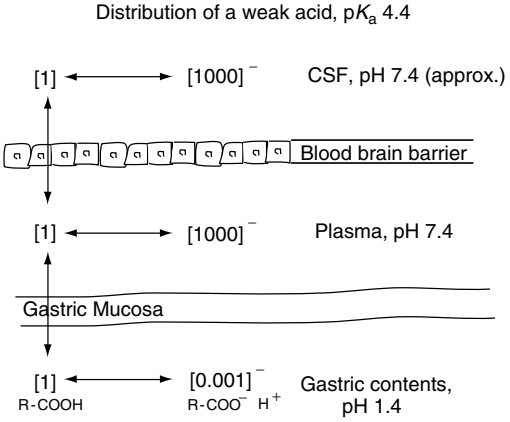

Figure 5 The influence of the pH on the equilibrium distribution of a weak acid, pK_a 4.4, among several anatomic compartments.

in different anatomic compartments can be illustrated by the influence of this ratio on the distribution of the solute across these compartments. **Figure 5** presents a simple example of the contribution of the pH in different anatomic compartments on the final equilibrium distribution of a solute, in this case a weak carboxylic acid with a pK_a of 4.4. (For illustration purposes, only the influence of pH and pK_a are considered in this example.) The nonionized form (the diffusible form) establishes the equilibrium across compartmental barriers. Equilibrium is reached when the diffusible form is at equal concentration in all compartments, and the concentration of the ionized form is appropriate to the pH of the compartment. **Figure 5** demonstrates that, in this example, the drug is at equal total concentration (nonionized + ionized forms) in CSF and plasma, while the total solute concentration in plasma is approximately 1000 times as great as that in the gastric contents. Also, this equilibrium would occur whether the solute had been administered orally or intravenously. It is obvious that even when only a small fraction of the solute is in the nonionized form, in this example approximately 1/10 of 1%, with adequate time this small fraction leads to the drawing of a high concentration of solute into the peripheral anatomic compartment represented by CSF. A therapeutic example where this is important would be in the use of drugs during pregnancy. From the principles that are described, drugs that must be used chronically during pregnancy can be assumed to reach the same concentration in foetal plasma as in maternal plasma. If one considers that the dosing regimen is often directed to maintain a steady-state therapeutic target concentration in the maternal plasma, then there would be ample time to reach equilibrium conditions in the entire body, including foetal plasma and tissues.

The issues of drug treatment during pregnancy also bring up how the state of ionization of drugs and the differences in pH between maternal and foetal plasma influence the risk to the foetus. Some of these considerations are depicted schematically in **Figure 6**. Ethanol would be expected to equilibrate with ease across the trophoblastic membrane of the placenta. This membrane consists of tightly opposed cellular elements that have no effective pores for molecules that are the size of most drugs. The highly polar skeletal muscle relaxant, atracurium, does not diffuse to any extent across the placental barrier. Lidocaine is commonly used as an epidural local anaesthetic for pain relief for both vaginal and caesarean delivery of the foetus. This weak base can show greater concentrations in foetal plasma compared to maternal plasma in conjunction with the relatively more acid conditions that may develop in the foetus in the near-parturient state. This has been termed the 'acid trapping'

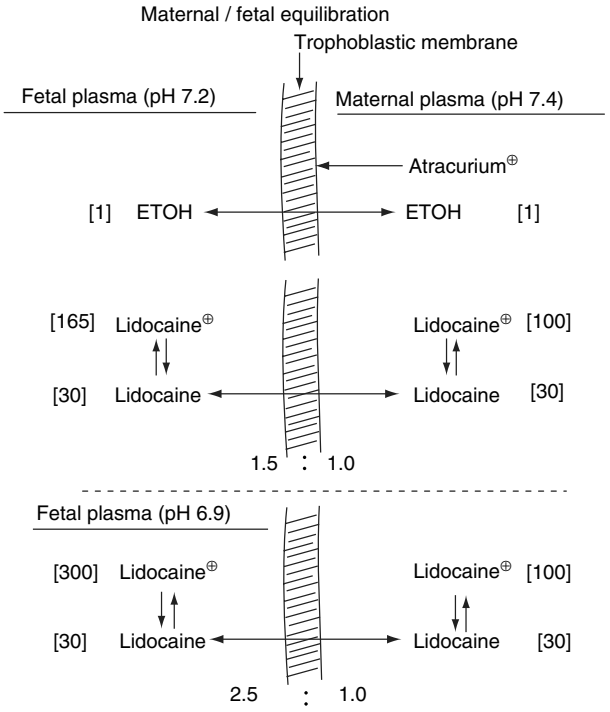

Figure 6 The effects of the pK_a values of several drugs and pH environments on the distribution of drugs between maternal and foetal plasma.

phenomenon of weak bases in acid environments in the body (Millot *et al.*, 1997).

2.2.3 Combined Effects of Partition Coefficient and Ionization

An approximation of the interaction between the partition coefficient of the nonionized form of a solute and the fraction of solute that is nonionized at a particular pH has been termed the 'effective partition coefficient'. Goldstein *et al.* (1974) suggested this term for the arithmetic product of the value for the partition coefficient of one of a series of compounds in a particular immiscible organic solvent-water mixture and the fraction of the drug that is nonionized at a pH of interest. This approach proved to be adequate to establish a rank order of the expected rates of diffusion of a series of weak acids and bases from plasma into CSF (data compiled by Goldstein *et al.*, 1974). A small sample of values from these data compares the effective partition of two clinically important intravenous barbiturates, thiopental and pentobarbital (**Table 1**). These calculations suggest that thiopental would be expected to demonstrate the onset of central nervous system depression approximately 40 times more rapidly than pentobarbital. In fact, these drugs do demonstrate a marked difference in onset of effect when the doses are adjusted to demonstrate their physicochemical properties. We demonstrate this comparison in the medical pharmacology course at New York Medical College. Intravenous injection of 12.5 mg kg^{-1} of thiopental in New Zealand White rabbits results in an immediate surgical anaesthetic state. Injection of the same dose of pentobarbital results initially in only slight impairment of motor function with no loss in consciousness. The motor instability progresses over approximately the next 15 minutes, but the animal never losses consciousness.

Table 1 Effective partition coefficient (expresses the interaction between pK_a and pH). Can be used to rank drugs in relation to onset of effect

	pK_a	Fraction nonionized at pH 7.4 × partition coefficient of non-ionized drug	Effective partition coefficient
Thiopental	7.6	0.61 × 3.3	2.01
Pentobarbital	8.1	0.83 × 0.05	0.04

Another example of the application of the effective partition concept is presented in **Table 2**, which lists the data used in the calculation of the effective partition coefficients in plasma of three narcotic analgesic drugs, and the time for their peak analgesic effects following intravenous bolus injection (Stoelting, 1987). The time to peak analgesic effect ranks inversely with the magnitude of the effective partition coefficient.

The effective partition coefficient was only intended as an approach to rank drugs in order of their expected rates of production of pharmacological or toxicological effects. A more direct approach to predict relative rates of diffusion across cell membranes has been termed the 'overall partition coefficient' (Bowman and Rand, 1980). In this approach, the partition coefficient is determined with the aqueous phase buffered at the pH of interest, that is, pH 1.4 for stomach contents, pH 7.4 for plasma, and so on. For prediction of absorption by inhalation, for example, a relatively neutral pH of the aqueous phase (approximately 7.0) may be chosen to simulate that of the surfactant layer of the pulmonary alveoli (Mason *et al.*, 1977).

Table 2 Effective partition coefficient used to rank time to peak analgesia

	Fraction non-ionized at pH 7.4 × Octanol : H_2O partition coefficient	Effective partition coefficient	Peak analgesic effect (minutes)
Alfentanil	0.89 × 129	115	2
Fentanyl	0.08 × 816	65	6
Morphine	0.23 × 1.4	0.3	20

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat006
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

An equation has been proposed for estimation of the overall partition coefficient, P_0, as follows (Bowman and Rand, 1980):

$$P_0 = \frac{P_n}{\text{antilog } (\text{pH} - \text{p}K_a) + 1} \quad (1)$$

where P_n is the intrinsic partition coefficient for the nonionized form of the solute.

Equation 1 is in the form relevant to calculations for weak acids; the term $(\text{pH} - \text{p}K_a)$ is reversed to $(\text{p}K_a - \text{pH})$ when the equation applies to weak bases.

3 COMPARTMENTS OF BODY WATER

Although this chapter will primarily focus on a discussion of pharmacokinetic 'compartments' in relation to distribution and excretion of xenobiotics, it may be useful to begin the discussion with the dimensions of body water. Although the volume of distribution (V_d) of a solute is always referred to as an apparent V_d, chemicals with clearly defined physicochemical properties may sometimes be accurately predicted to distribute in relationship to anatomic compartments of body water. A classical presentation of these compartments is presented in **Figure 7**. The cross-hatched lines represent the lipoid barriers represented by cell membranes. The interrupted line between the plasma and interstitial spaces relates to the porous nature of this boundary. The importance of binding to plasma proteins on the distribution of xenobiotics, as well as sequestration ('storage') of solutes within tissues, is also illustrated. Filtration of solute from the plasma into the renal tubules is depicted, as well as reabsorption of lipid soluble solute from the renal tubules. It may be noted that all distributions, with the exception of the direction of formation of products of metabolism, are presented as double arrows to represent the equilibration of solute throughout the body.

The relative compartment volumes depicted in **Figure 7** have been found to apply to man and other mammalian species. Ethanol, which has both lipid and water solubility and shows little or no binding to macromolecules, distributes uniformly in all of the body water. It essentially marks the total volume of body water; it has a V_d of approximately 60% of body weight, or 42 l in a 70 kg subject. In another example, inulin is a highly polar substance that is not absorbed by oral administration, must be injected in order to gain access to the plasma, and is found to mark the extracellular fluid compartments, that is, plasma and interstitial fluid. Inulin is completely eliminated by the kidney, and is not metabolized or taken up into cells. It demonstrates a V_d of approximately 20% of body weight, or 14 l per 70 kg of body weight (Guadino and Levitt, 1949). These same properties are shared by the sugar alcohol, mannitol (Bowman and Rand, 1980). Of note, several of the neuromuscular blocking drugs, such as atracurium and pancuronium, which are also polar molecules with fixed positive charges related to their quaternary nitrogen groups, also equilibrate exclusively in extracellular fluid and demonstrate apparent volumes of distribution that approximate 20% of body weight (Shanks, 1986).

As noted above, for illustration purposes, the boundary between the plasma and interstitial fluid compartments in **Figure 7** is presented as a fenestrated line, to represent the porous barrier between these two spaces. These pores are considered to be spaces at the junctions between the endothelial cells at the capillary level. The pores in skeletal muscle capillaries have been estimated to have a radius of approximately 30 Å (Renkin, 1964). Water, electrolytes and smaller water-soluble molecules are able to filter through these pores and equilibrate

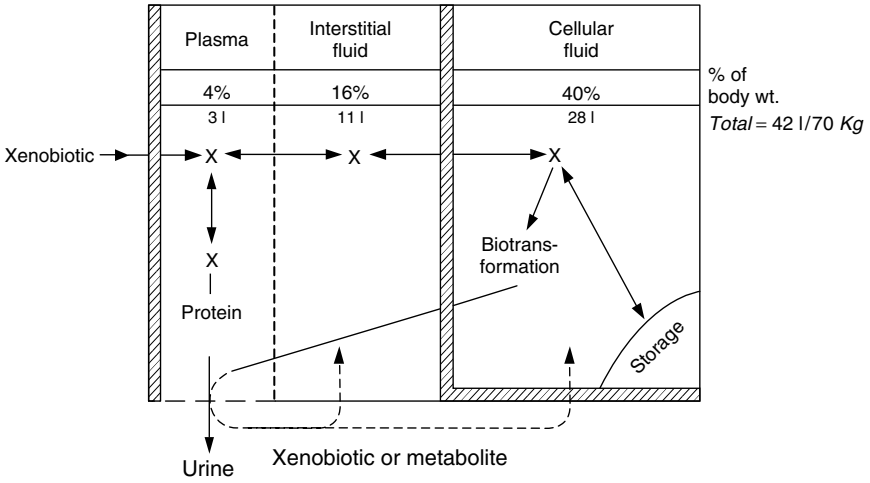

Figure 7 The major anatomical compartments of body water, expressed as both percentages of body weight and as litres in a 70 kg individual. (Reproduced with permission from Inchiosa, 2006. © Taylor and Francis Group.)

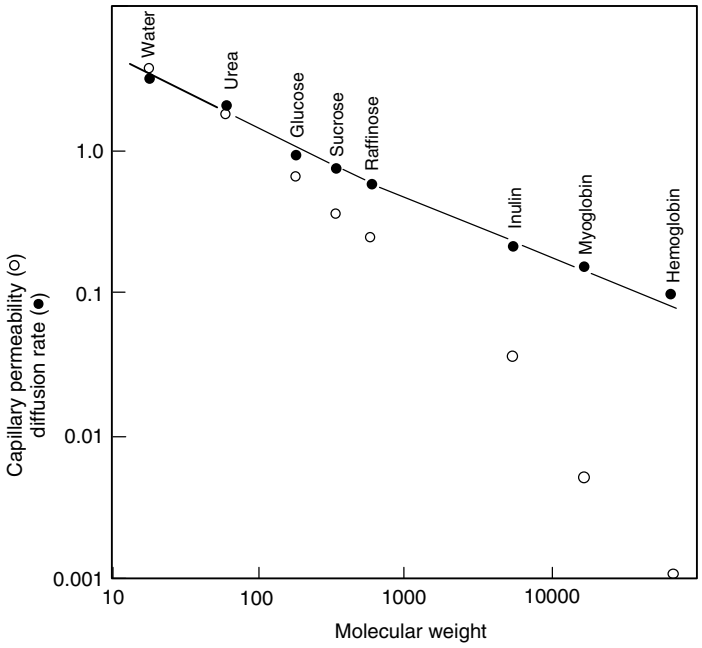

Figure 8 Relationship between molecular weights of several water soluble solutes and their diffusion rates. The filled circles represent diffusion rates ($cm^2\ s^{-1}$) in water at 37 °C, and the open circles indicate the permeability coefficients ($cm^3\ s^{-1}100\ g^{-1}$) across skeletal muscle capillaries. (Reproduced with permission from Inchiosa, 2006. © Taylor and Francis Group.)

between the plasma and interstitial fluid compartments. The relative rate of equilibration is demonstrated by the data in **Figure 8**. The rate of diffusion of raffinose (molecular weight (mol. wt) 594) is markedly more rapid that that of inulin (mol. wt 5500). Large protein molecules are effectively restricted from diffusion across the capillary membrane. Although inulin, with an effective molecular radius of 14.8 Å (Creasey, 1979), is somewhat slowed in its diffusion across the muscle capillary membrane, it is freely filtered from plasma into the kidney tubules across the more porous capillaries of the kidney glomeruli.

It was noted that highly polar substances must be injected in order to gain access to the plasma. Although this is accomplished most directly by an intravenous injection, injections into the interstitial fluid spaces also provide routes to the plasma, since they allow absorption through the capillary membranes into the plasma, in the tissues being perfused (**Figure 7**). Intramuscular, subcutaneous and intraperitoneal routes are examples of injections into interstitial spaces that present no lipoid barriers to the absorption of polar solutes into the plasma.

As noted above, the associations that are possible with certain chemicals between their defined physicochemical properties and their volumes of distribution are almost the exception. For many drugs and other xenobiotics, the influence of macromolecular binding peripheral to the plasma does not permit identification of an anatomic volume in which the solute distributes. The pharmacokinetic 'V_d' of a solute is always designated as an apparent V_d. In the simplest case of a one-compartment pharmacokinetic model, where the solute in the body behaves as though there are no barriers to its distribution and redistribution as the concentration in plasma changes, the formula for calculation of the pharmacokinetic V_d is:

$$V_d = \frac{\text{Dose (mg)}}{\begin{array}{c}\text{Plasma concentration after an initial dose}\\ \text{(or change in concentration from baseline)}\\ (\text{mg l}^{-1})\end{array}} \qquad (2)$$

The calculation simply indicates the 'apparent volume' that the drug must occupy if the concentration throughout its distribution is the same as that in the plasma.

4 EFFECTS OF MACROMOLECULAR BINDING ON DISTRIBUTION

The discussion of xenobiotic distribution in the body to this point has not considered the contribution of the binding of xenobiotics to proteins and other macromolecules to the final equilibrium distribution of the solute. The relative strength of affinity of binding to macromolecules determines the final equilibrium concentration, bound + free, of the solute in plasma and other tissue compartments. These binding forces may greatly influence what is calculated to be the apparent V_d of the solute.

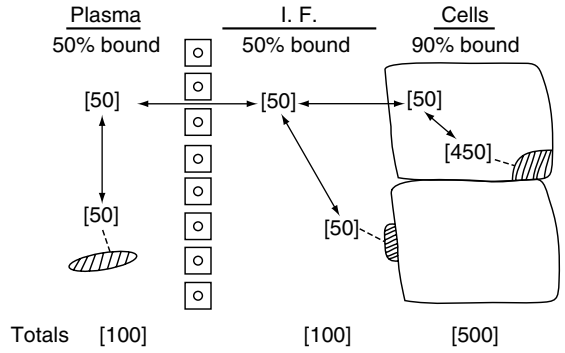

Figure 9 Schematic depiction of the influence of the percentage binding of a solute to soluble proteins, structural entities, organelles and so on, on the equilibrium distribution of the solute in the major anatomical compartments.

The percentage of drug binding to plasma proteins is one of the pharmacokinetic parameters included in most drug compendia. The fraction bound in other anatomic compartments is usually not known. **Figure 9** is presented to illustrate the effect of the competition between plasma protein binding and peripheral binding on the distribution at equilibrium. Reversible equilibrium binding to macromolecules usually represents relatively weak binding forces, such as electrostatic interaction, hydrogen bonding, van der Waals forces, binding of lipophilic molecules to hydrophobic side chains of amino acids in proteins, as well as the partitioning of such molecules into lipid depots. Electrostatic interactions are of particular importance in the interaction between the ionized forms of weak acids and weak bases and their counterions, represented by the charged groups on the side chains of amino acid residues of proteins. For example, the $-COO^-$ groups of aspartic and glutamic acids are particularly plentiful in protein molecules, as well as the $-NH_3^+$ group of lysine (Tanford *et al.*, 1955; Goldstein *et al.*, 1974); these groups will attract the counterions of weak bases and weak acids, respectively.

The number of potential binding sites and their relative affinities contribute importantly to the distribution of solute under equilibrium conditions. Although the percentage of drug binding to plasma proteins is a fundamental pharmacokinetic parameter, it would be of limited application if the percentage of binding varied considerably over the range of therapeutic plasma drug concentrations. In fact, the binding percentage is expected to remain quite constant for most xenobiotic entities. The relationships among the number of potential binding sites, the binding affinity and the percentage binding are presented in **Figure 10**. It can be seen that as the number of binding sites per protein molecule increases, plasma drug concentrations may vary several orders of magnitude without a change in the percentage bound.

It was noted above that the negatively charged side chains of aspartic and glutamic acid are important in the electrostatic interaction with the non-ionized fractions of weak bases. The relationships in **Figure 10** can be placed in perspective by the fact that there is a total of 101 aspartic and glutamic acid residues per molecule of bovine serum albumin. Similarly, there are 57 positively charged side chains of lysine residues per molecule of protein that are available for binding the non-ionized fractions of weak acids (Tanford *et al.*, 1955; Goldstein *et al.*, 1974). As noted above, however, non-ionic binding also takes place between xenobiotic molecules and macromolecules.

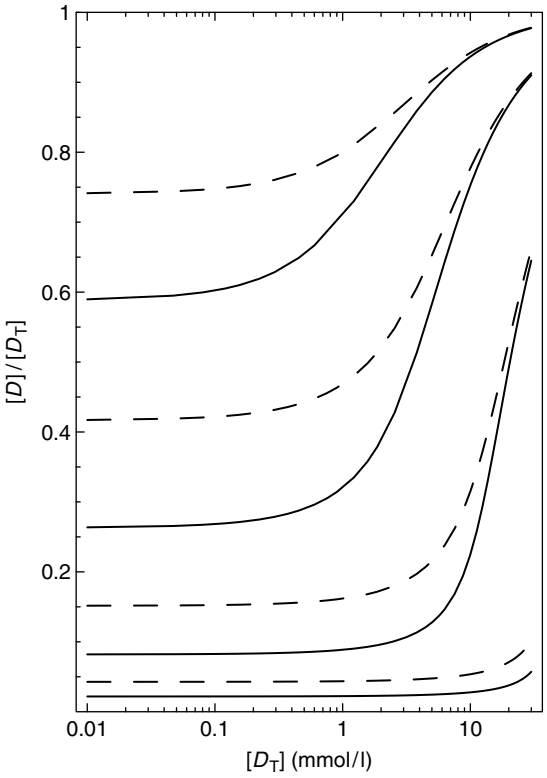

Figure 10 The influence of the potential number of binding sites (n) per molecule of albumin and the dissociation constant for the ligand (K), on the ratio of the unbound concentration [D] to the total solute concentration. The abscissa presents the total drug concentration [D_T] and the ordinate expresses the ratio of unbound concentration to total concentration of drug. The solid lines represent the theoretical results with a K of 1 mmol/l; the broken lines are for a K of 2 mmol/l. The pairs of curves from top to bottom are for n of 1, 4, 16 and 64 binding sites per molecule of albumin. The albumin concentration [P_T] was taken as 0.7 mmol/l. (Modified from Figure 40.9, Bowman and Rand, 1980.) The curves were calculated according to the following formula: $[D] = \frac{1}{2}\left([D_T] - K - nP_T + \sqrt{4D_TK + (-D_T + K + nP_T)^2}\right)$.

Although therapeutic drug concentrations rarely vary over even one order of magnitude, there are clinical situations where patients receiving a large number of drugs may show a competition for available binding sites.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Plasma concentrations of free solute may increase as a result of such competition, and since the free drug may be responsible for receptor interaction, there may be an excessive pharmacologic or toxic effect. This scenario may also occur or be intensified in a patient with hypo-albuminaemia, which may occur in the aged or malnourished patient.

Figure 9 is designed to provide an example of the influence of macromolecular binding peripheral to the plasma on the final equilibrium distribution, that is the V_d of a xenobiotic. The diagram is schematic; the porous cellular barrier depicted between plasma and the interstitial fluid space represents the capillary endothelium. The size of cells of tissues or organs is not drawn to scale relative to endothelial cells; the size was convenient to depict details of xenobiotic concentrations. Macromolecular structures are represented by hatched lines. As shown, this includes soluble plasma proteins, cell membrane structures in the interstitial fluid compartment, and intracellular structures, or perhaps, lipid depots that sequester lipophilic molecules. The presentation in **Figure 9** is only meant to be illustrative of the many possible interactions of xenobiotic molecules that contribute to the measure of the apparent V_d of a solute, and to demonstrate how such binding forces result in unequal concentrations in different body environments.

It was noted above that competition among solutes for available binding sites can result in displacement of solute and increases in the free concentration. If the competition or displacement primarily affects the binding to plasma proteins, thereby allowing more free solute to leave the plasma, the total plasma concentration (bound + free) will decrease. The new equilibrium will show an increase in the apparent V_d of the solute. In comparison, if the competition or displacement primarily results in an increase in the concentration of free solute peripheral to the plasma, this will allow more solute to equilibrate back into the plasma, thereby raising the plasma concentration and causing a decrease in the apparent V_d. This follows from the fact that the calculation of the apparent V_d is determined mathematically from the division of the total amount of the xenobiotic in the body by the concentration in the plasma.

Units of concentration in **Figure 9** are not indicated, since the diagram is only intended to demonstrate relative concentrations as a result of different binding affinities. If we indicate, for example, that the units are $\mu g\,ml^{-1}$, then the free, diffusible form of the solute everywhere in the body would be expected to be $50\,\mu g\,ml^{-1}$. **Figure 9** is intentionally presented to include only free diffusible solute, and solute bound to macromolecules and structural entities, to limit the complexity. The presentation must be expanded to allow for the fact that there may be concentrations of free nondiffusible solute, as well. This may represent, for example, the polar ionized fractions of weak acids and weak bases. **Figure 11**

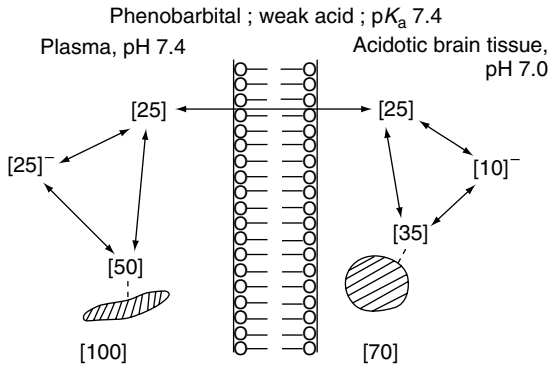

Figure 11 Schematic representation of the equilibrium distribution of a weak acid, phenobarbital, pK_a 7.4, which shows 50% total binding to macromolecular proteins and other structures in both plasma and the central nervous system.

suggests how the equilibrium would be influenced by circumstances where there may be insufficient binding capacity for all of the ionized solute. At equilibrium, the degree of ionization would influence the concentration of solute that is in the diffusible form, but it would be expected to be the same in all compartments. Obviously, different pH environments represented across the lipoid barrier, together with different affinities for macromolecular binding in the compartments, influence the final equilibrium. Phenobarbital was chosen to illustrate these interactions (**Figure 11**). Phenobarbital, a weak acid, provides a convenient starting point for this example, because its pK_a value is the same as the pH of plasma, that is, 7.4 (Holford, 2007). Therefore, phenobarbital would exist in equal concentrations of the ionized and nonionized forms in plasma. Also, the population value for its percentage binding to plasma proteins under normal circumstances is 51% (Holford, 2007). For convenience, the value was taken as 50% binding in both plasma and the tissue compartment, as presented in **Figure 11**. This diagram also suggests, schematically, that there may be binding of the nonionized fraction of phenobarbital to both plasma protein and to structures (organelles) in the tissue compartment. The concentration ratio of ionized to nonionized fractions of phenobarbital in the tissue compartment is calculated with the appropriate Henderson-Hasselbalch equation, noted above. In approximating the various concentrations of ionized and nonionized drug, the bound drug was considered to be in another phase, and not contributing to the proportion of ionized and nonionized molecules. Under these conditions, the concentration ratio of total drug in brain tissue to that in plasma is expected to be 0.7. Of course, it is not common that details of the percentage binding to macromolecules within tissues would be known. However, all of these factors become resolved in the final determination of the apparent V_d of the solute. Determination of V_d in multicompartmental models will be returned to, below.

Table 3 Lack of consistent relationship between the percentage of binding of several drugs to plasma proteins and their apparent volumes of distribution

Drug	Percentage bound to plasma proteins	Apparent V_d per 70 kg body weight (l)
Gentamicin	10	18
Metronidazole	10	52
Metoprolol	11	290
Sulfamethoxazole	62	15
Cloroquine	61	13 000
Indomethacin	90	18
Imipramine	90	1600

The specific contribution of active and facilitated transport mechanisms to the final distribution of xenobiotics, including P-glycoprotein drug efflux pumps (Kurzawski *et al.*, 2007), is beyond the scope of this chapter. These active and facilitated processes may offset or enhance, to varying degrees, the forces associated with simple diffusion, and result in concentrations at equilibrium that are the net result of these forces. Again, however, all equilibrium forces will be encompassed in the final determination of V_d, and the implications of this V_d for the pharmacokinetics of the xenobiotic will be preserved.

The discussion thus far should provide a framework to appreciate why the single pharmacokinetic parameter of percentage binding to plasma protein for xenobiotics is not adequate to predict whether a chemical will have a small or large V_d relative to body mass. Some examples that show the inconsistencies between the apparent V_d of several drugs and their percentages of binding to plasma proteins (Holford, 2007) are presented in **Table 3**. It is obvious that the binding affinities of the solutes to macromolecules and membranes and organelles peripheral to the plasma, in combination with the states of ionization of the solutes and the partition coefficients of their nonionized fractions, result in a distribution at equilibrium that may have little or no relationship to the percentage of binding to plasma proteins.

5 DIFFUSION INTO SALIVA

Some of the principles described above also apply to the distribution of xenobiotics and their metabolites into saliva. Saliva may represent a convenient noninvasive access to monitoring xenobiotic exposure. It has been found that a fairly constant ratio may exist between the concentration of a xenobiotic in saliva and its concentration in plasma. For this reason, saliva measurements have been applied to studies of drug bioavailability, elimination pharmacokinetics and therapeutic monitoring (Matin *et al.*, 1974; Breckenridge *et al.*, 1977; Parsons and Neims, 1978; Inchiosa *et al.*, 1981; Newton *et al.*, 1981; Poland and Rubin, 1982). Matin *et al.* (1974) have expressed the factors involved in predicting the saliva to plasma ratio R in the following equation:

$$R = \frac{1 + 10^{(\mathrm{pHs} - \mathrm{p}K_a)} f_p}{1 + 10^{(\mathrm{pHp} - \mathrm{p}K_a)} f_s} \tag{3}$$

where
R = saliva/plasma ratio
pHs = saliva pH
pHp = plasma pH
f_p = fraction of drug unbound in plasma
f_s = fraction of drug unbound in saliva.

Equation 3 is in the form for solutes that represent weak acids. In calculations for weak bases, the exponent in the numerator is reversed to $\mathrm{p}K_a - \mathrm{pHs}$, and to $\mathrm{p}K_a - \mathrm{pHp}$ in the denominator. Throughout this chapter, it is assumed that the pharmacokinetic principles of distribution and elimination will generally apply to the metabolites of xenobiotic molecules, as well. With knowledge or prediction of the ratio between the saliva and plasma concentrations of a xenobiotic metabolite, saliva measurements may provide a convenient approach to monitoring xenobiotic exposure.

The conceptual utility of Equation 3 can be seen in that if it is applied to the data of **Figure 11**, and the brain tissue compartment is substituted for the saliva compartment in the equation, the ratio of brain concentration to that in plasma is 0.7, as predicted from first principles.

6 ACCUMULATION OF XENOBIOTICS AND THEIR METABOLITES

6.1 Agents with Dose-Independent Pharmacokinetics

With chronic administration or chronic exposure to xenobiotics that are eliminated by first-order kinetics, that is, as a constant percentage per unit of time, one can predict the time course of accumulation in the plasma. In the simplest presentation of this relationship, it is assumed that the elimination half-life ($t_{1/2}$) of the xenobiotic remains unchanged over the range of body burden of the xenobiotic. The same criterion would apply if one were following the rate of accumulation of a xenobiotic metabolite, that is, the metabolite was the entity of interest and its accumulation was being measured. The principle in this simplest presentation is that the solute of interest shows, 'dose-independent pharmacokinetics'. It is observed, then, that the accumulation in plasma proceeds such that in each time interval equal to the terminal $t_{1/2}$ of the solute, the solute attains a concentration that is half the remaining concentration interval to the projected maximum concentration. The maximum concentration, or plateau concentration is conveniently

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

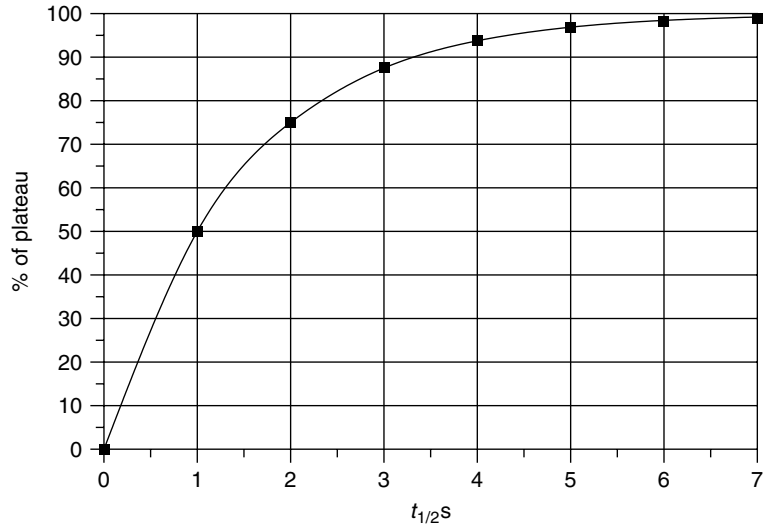

Figure 12 The plasma concentration of a xenobiotic, expressed as a percentage of the projected steady-state plateau concentration, when the xenobiotic is being administered at a constant rate (zero-order rate of administration). The time units of the abscissa are $t_{1/2}$s of elimination of the xenobiotic.

termed the concentration steady state (C_{SS}). The progression of accumulation is presented in **Figure 12**. Note that the legends of the graph are presented in relative units, that is, % of the plateau concentration and $t_{1/2}$s of elimination. The plasma plateau, or C_{SS}, is reached when the rate of elimination of the xenobiotic is exactly equal to the rate of administration or exposure to the xenobiotic. Therefore, the relationship is applicable to all xenobiotics that demonstrate first-order rates of elimination in association with a zero-order rate of administration or intake. The plateau principle is of wide application because the overwhelming majority of xenobiotics usually show first-order rates of elimination in either their therapeutic range for drugs, or from their unintended or unavoidable exposure. The profile of the plasma concentration vs time (normalized to $t_{1/2}$s) in **Figure 12** is typical when there is a zero-order rate of administration, as in the case of a constant intravenous infusion. If the drug, or other xenobiotic, is administered or exposed episodically, the plasma concentration curve will consist of peaks and nadirs in the concentration that relate to the timing of the episodic doses or exposures. However, the 'average' plasma concentration curve will be the same as that associated with the zero-order continuous infusion, provided that the total dose per hour, per day and so on, is the same by both modes of administration or exposure (Buxton, 2006).

6.2 Agents with Dose-Dependent Pharmacokinetics

A therapeutic entity that shows a zero-order rate of elimination (a constant amount of drug per unit of time) would pose an unacceptable risk of continuous accumulation to the extent that the dose exceeds the maximum rate at which the drug can be eliminated. By definition, a half-time of elimination cannot be described for such an entity. There are examples of drugs that may show a transition to dose-dependent kinetics of elimination at the upper limit of their therapeutic plasma concentration, and this may lead to a prolongation of the $t_{1/2}$ of elimination. The antiseizure drug, phenytoin, is a prominent example of this phenomenon (Holford, 2007). This is of most risk for a xenobiotic that has only one route of elimination. This is true of phenytoin, which only demonstrates approximately 2% excretion of the unchanged drug in the urine; 98% undergoes biotransformation before elimination (Holford, 2007). Ethanol is another example of a drug that shows a transition from a first-order to a zero-order rate of metabolism. The rate of metabolism of ethanol is first-order rate at low, essentially noninebriating plasma concentrations, but at blood alcohol levels associated with even moderate consumption, metabolism is functionally saturated and shows a zero-order rate (Fleming *et al.*, 2006).

When the body burden increases to the point where all routes of elimination are saturated, zero-order elimination will take place and the plasma concentration will accumulate linearly. This is presented schematically in **Figure 13**. It can be seen in the figure that if administration/exposure to the xenobiotic is terminated, the plasma concentration will decrease in a linear trend until the biotransformation mechanisms are no longer saturated, and plasma concentrations will again decrease exponentially. Again, it is not expected that any therapeutic entity would be intentionally administered at doses that would result in zero-order rates of elimination.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat006
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

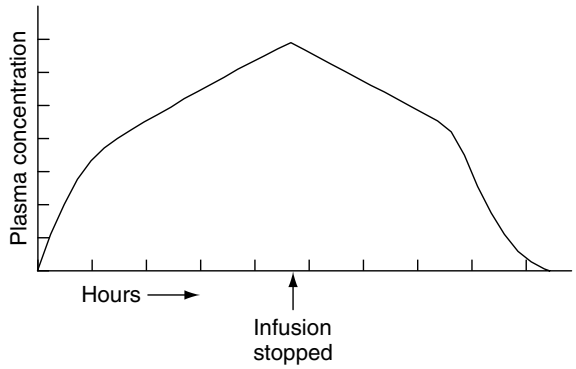

Figure 13 Theoretical depiction of the plasma concentration change during the period when a xenobiotic is administered at a zero-order rate. The xenobiotic shows a progressive transition from exponential rates of elimination to a zero-order rate of elimination until the infusion is stopped. The decrease in plasma concentration reverses in similar phases when the administration is stopped. This schematic presentation would apply particularly to a one-compartment pharmacokinetic model. (See text for explanation.)

Likewise, in view of the extensive repertoire of biotransformation capacities in human and animal species, it is unlikely that exposure to toxicants would be at 'doses' that reach such levels. Therefore, for the purpose of this chapter, we will concentrate on the kinetics of xenobiotics and their metabolites that demonstrate half-times of elimination.

6.3 Application of the Plateau Principle

The plateau principle (**Figure 12**) has wide applications for relationships between the effective 'dose' of a xenobiotic and the C_{SS}, and between the clearance of the drug and the C_{SS}. For a given xenobiotic or metabolite, the C_{SS} will vary in direct proportion to the dose or to the total body clearance (Cl) of the substance. This follows from the formula:

$$C_{ss} = \frac{\text{Dose}}{\text{Cl}} \tag{4}$$

If the xenobiotic demonstrates a one-compartment pharmacokinetic behaviour, the C_{ss} will also vary in proportion to the $t_{1/2}$ of elimination, assuming that changes in $t_{1/2}$ take place in the absence of any change in V_d. The discussion that will follow will return to the relationship between C_{ss} and dose in relation to proposals for the determination of the systemic exposure ('dose') of a xenobiotic, when this cannot be otherwise readily determined. This could include, for example, inhalation, or dermal or oral exposure.

7 ELIMINATION

The time course of elimination of xenobiotics that demonstrate one-compartment and two-compartment pharmacokinetic systems are discussed in further detail elsewhere in these volumes (see **Toxicokinetics**). One may also consult earlier publications for elaboration on these principles (Gibaldi and Perrier, 1975; Wagner, 1975; Ritschel, 1976; Renwick, 1982; Inchiosa, 2006). A summary of the kinetic principles for one- and two-compartment open models will be included here only to provide continuity of the discussion.

7.1 One-Compartment Open Model

The designation of a system as being an 'open' model is based on the knowledge or presumption that there is input and output (excretion) of the xenobiotic. That is, it is not functioning as a closed, or contained, system. The one-compartment designation implies that, initially, the xenobiotic distributes and equilibrates rapidly into the final 'V_d' to which the substance has access. Also, the kinetics of elimination appear to indicate that the equilibrium concentration ratios among various compartments (both anatomic and pharmacokinetic compartments) re-equilibrate rapidly as xenobiotic is eliminated from the body. The one-compartment open model is depicted schematically in **Figure 14**. The elimination rate constant is designated as k_{el}; it may also be simply termed k in the one-compartment model.

7.1.1 *Determination of Apparent V_d*

Because of the relative simplicity of the one-compartment system, the V_d of the xenobiotic can usually be determined graphically from the plasma concentration vs time data following intravenous administration of the substance. (see **Toxicokinetics** for a graphical presentation of such a system.) Then, extrapolation of the terminal portion of the first-order disappearance curve to the ordinate yields the concentration that would have been present at time '0' (the time of the intravenous administration) if there had been instantaneous distribution and equilibration. This value can then be used in the following equation to calculate the apparent V_d:

$$V_d = \frac{\text{Dose}}{\text{Plasma conc. at time '0'}} \tag{5}$$

Figure 14 Diagram of a one-compartment open model.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat006
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

A more precise method of determining V_d involves measurement of the entire area under the plasma concentration-time course (AUC) following intravenous injection of a known amount of a xenobiotic. The formula is as follows:

$$V_d = \frac{\text{Dose}}{\text{AUC (0 time to infinity)} \times k} \quad (6)$$

7.1.2 Half-time of Elimination ($t_{1/2}$)

The $t_{1/2}$ of elimination in the one-compartment system can frequently be estimated by inspection of the plasma concentration vs time data. It can also be determined by linear regression analysis of the first-order elimination phase ($\log_n$ plasma concentration vs time; regression coefficient $= k$; $t_{1/2}$ of elimination $= 0.693/k$).

Once the drug has equilibrated in its V_d, the plasma concentration at a time (t) after administration can be calculated as follows:

$$\text{Plasma concentration at time '}t\text{'} = \frac{\text{Dose}}{V_d} \times e^{-kt} \quad (7)$$

7.1.3 Total Body Clearance (Cl)

Total body clearance represents the sum total of all organ and tissue elimination mechanisms. It actually represents the capacity for elimination. This is obvious in the units of clearance, which are in volume (ml, l) per unit of time. It measures the percentage of the total body V_d (expressed in a volume unit) that is cleared of a solute per unit of time. A simple form of the first-order function for a one-compartment system is expressed as follows:

$$Cl = V_d k_{el} \quad (8)$$

A more precise approach, again, requires measurement of the AUC; then:

$$\text{Cl} = \frac{\text{Dose}}{\text{AUC (0 time to infinity)}} \quad (9)$$

7.1.4 Application of Pharmacokinetic Parameters for Estimation of 'Dose'

In a previous publication, approaches were suggested for the determination of a systemic dose (exposure) under conditions where this could not be easily quantified (Inchiosa, 2006). Examples of this would include inhalation, or dermal or oral exposure to a xenobiotic in an occupational or environmental setting. In the case of inhalation exposure, for example, attempts have been made to semiquantify exposure through use of the Ct product, that is, the product of the concentration in the atmosphere for a defined period of exposure. It is obvious that the Ct product provides no information about the *amount* of a possibly noxious agent that has been absorbed systemically.

Inhalation exposure, which represents an example of zero-order rate of administration, together with a first-order rate of elimination for the xenobiotic, results in accumulation of xenobiotic in the body that follows the plateau principle discussed above (**Figure 12**). However, essentially all modes of occupational or environmental exposure, inhalation, dermal, oral and so on, constitute zero-order rates of 'dosing' if one considers the chronic (average) amount per day, for example. A steady-state concentration will be reached in five to seven elimination half-times for the xenobiotic, or a metabolite, of interest. Several options may then be available to determine the systemic 'dose' (Inchiosa, 2006).

7.1.4.1 Option 1

In the case of animal experimentation with xenobiotics, where a constant intravenous dosing regimen can be used to develop the plasma C_{ss}, the systemic dose by another route (e.g. inhalation) can be calculated as follows:

$$\frac{\text{Dose (by inhalation)}}{\text{Dose (i.v. infusion)}} = \frac{C_{ss}\text{(from inhalation)}}{C_{ss}\text{(i.v. infusion)}} \quad (10)$$

The calculation produces a dose (amount per unit of time) by inhalation with the same units as that in the intravenous infusion regimen. It should be noted that the periods of intravenous infusion and exposure by another route do not have to be the same; the only requirement is that there has been sufficient time to reach steady-state conditions.

7.1.4.2 Option 2

In relation to animal experimentation, if the $t_{1/2}$ of elimination of the xenobiotic is very long, or is unknown, it may be impractical to carry out exposures for the time required to reach a plasma C_{ss}. In these cases the AUC of the plasma concentration-time curves can be compared from both intravenous infusion and inhalation (or other) exposures over the same time period. The dose in this comparison would be:

$$\frac{\text{Dose (by inhalation)}}{\text{Dose (i.v. infusion)}} = \frac{\text{AUC (from inhalation)}}{\text{AUC (i.v. infusion)}} \quad (11)$$

7.1.4.3 Option 3

In the case of environmental or occupational exposure to xenobiotics, perhaps the most convenient approach for determination of the systemic 'dose' applies knowledge of the clearance parameter to the plasma concentration data. A requirement in this approach is that the period of exposure to the xenobiotic has been long enough to have produced a plasma C_{ss} (five to seven half-times of elimination). For the one-compartment model, clearance may be calculated from Equations 8 or 9. Then, with a sampling of the plasma at an

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat006
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

expected time of steady state, the 'dose' from an environmental or occupational exposure can be calculated as follows:

$$\text{Dose per unit of time} = C_{ss} \times \text{Cl} \qquad (12)$$

It is possible that the Cl value may already be known for the xenobiotic of interest, in a species of interest. If the clearance value is not known, and it concerns a farm animal or experimental animal species, it can be determined by measuring the plasma AUC following an intravenous bolus injection, and applying Equation 9. If the Cl value is needed for human considerations, it may be possible to determine the plasma AUC in man with the use of a low, nontoxic dose of the xenobiotic, relying on the assumption, or knowledge, that it follows dose-independent pharmacokinetics. If toxicity remains a concern, perhaps a still lower dose of the substance can be used that contains a stable (nonradioactive) isotope that can be quantified.

This same approach can be used to quantify exposure to a metabolite that is formed from a xenobiotic of interest. Again, it is only necessary to know the clearance value for the metabolite, from prior studies, or as determined for the parent xenobiotic, as discussed immediately above. A plasma concentration of the metabolite, taken at a time when the entire system is at steady state, including a steady-state concentration of the metabolite, will yield the rate of exposure (dose, in $\mu g\,h^{-1}$, etc.) of the subject to the metabolite, when incorporated in Equation 12.

7.2 Two-Compartment Open Model

7.2.1 Calculation and Application of Pharmacokinetic Parameters in the Two-Compartment Model

The two-compartment open model is presented diagrammatically in **Figure 15**. Some of the basic pharmacokinetic principles must be modified when a xenobiotic does not demonstrate rapid equilibration in its ultimate V_d when first administered, and shows perhaps an even greater delay in re-equilibration as the concentration of the substance is lowered in the body as a result of excretion. In this model, it is usually possible to fit the plasma concentration vs time data following an intravenous administration into a distribution phase and an elimination phase, a two-compartment model.

The plasma concentrations following a bolus intravenous administration of a xenobiotic can be determined at any time following the administration, with the formula:

$$\text{Plasma conc. at time '}t\text{'} = Ae^{-\alpha t} + Be^{-\beta t} \qquad (13)$$

In the generalized application of this equation, A and B are constants for a unit intravenous bolus injection (1 mg, 1 μg, etc.) of the xenobiotic. They represent the extrapolated intercepts on the ordinate of the plasma concentration vs time curve for the two exponential terms in the equation, α and β, respectively. The α term is largely viewed as a first-order distribution rate constant, and β represents the first-order elimination rate constant. The elimination half-time of the xenobiotic from the two-compartment system is: $t_{1/2} = 0.693/\beta$. The α and β constants can be derived from the data representing their first-order rates of change by linear regression analysis, as described above for determining the half-time of elimination in the one-compartment model. It should be noted that the α and β constants are hybrid rate constants that are dependent upon the interaction of all of the compartmental constants.

The intercompartmental distribution constants, k_{12} and k_{21}, and the elimination rate constant from the central compartment, k_{10}, (**Figure 15**) can be calculated as follows:

$$k_{21} = \frac{\alpha B + \beta A}{A + B} \qquad (14)$$

$$k_{10} = \frac{\alpha\beta}{k_{21}} \qquad (15)$$

$$k_{12} = \alpha + \beta - k_{21} - k_{10} \qquad (16)$$

(Wagner (1975) presents the derivation of these formulas.)

Using the AUC of the plasma concentration vs time data following an intravenous bolus injection, the

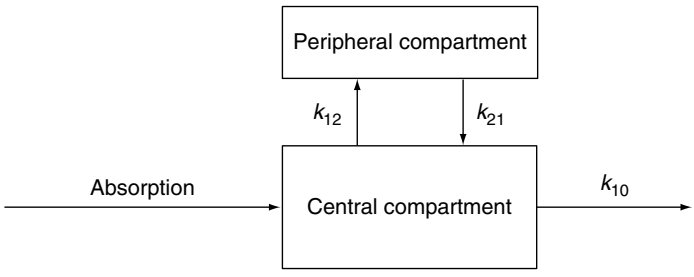

Figure 15 Diagram of a two-compartment open model.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

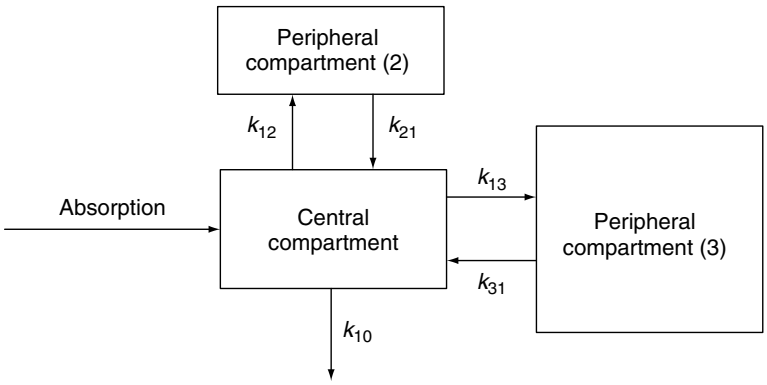

Figure 16 Diagram of a three-compartment open model.

apparent V_d in the two-compartment model is calculated with the formula:

$$V_d = \frac{\text{Dose}}{\text{AUC (0 time to infinity)} \times \beta} \quad (17)$$

Total body clearance is calculated with Equation 9.

7.2.2 Estimation of 'Dose' in the Two-Compartment Model

The same options discussed for the one-compartment model above may be applied for determination of the rate of exposure per unit of time for a xenobiotic or xenobiotic metabolite. As noted before, knowledge of the value for Cl of the xenobiotic (or a metabolite) greatly facilitates the ability to quantify the exposure that has taken place in a subject. If the clearance value is not known, it may be possible to determine it experimentally according to Equation 9. The 'dose' of the exposure can then be calculated with Equation 12. The only requirement is that steady-state conditions are prevailing at the time that the plasma is sampled for the concentration of the xenobiotic or metabolite.

7.3 Three-Compartment Open Model

7.3.1 Calculation and Application of Pharmacokinetic Parameters in the Three-Compartment Model

The complexity of calculations in the three-compartment model increases substantially over the simpler models. This model commonly provides the best fit of the plasma elimination time course for many therapeutic and nontherapeutic xenobiotics. In this model, the distribution and elimination kinetics are found to have the smallest least square deviations when the data are fit with three first-order rates (α, β, γ). The model is presented schematically in **Figure 16**. The formula for calculation of plasma concentration at any time after an intravenous bolus administration of a xenobiotic is as follows:

$$\text{Plasma conc. at time '}t\text{'} = \text{Ae}^{-\alpha t} + \text{Be}^{-\beta t} + \text{Ce}^{-\gamma t} \quad (18)$$

A, B and C are the intercepts on the ordinate for the extrapolated first order rate constants (α, β, γ), which are frequently presented as plasma concentrations (or fractional units; Shafer and Varvel, 1991) resulting from the intravenous bolus injection of a unit of xenobiotic (1 mg, 1μg, etc.).

A schematic depiction of the plasma concentration vs time course for the three-compartment system is presented in **Figure 17**. The calculation of the pharmacokinetic parameters, compartmental volumes and constants for this model requires software for nonlinear regression analysis that is supported by a Fortran compiler. NONMEM[a] is one product that has been used extensively for the determination of the pharmacokinetic parameters of many xenobiotics. STANPUMP[b] is a useful software module that can be used to simulate or predict changes in plasma concentration of a

xenobiotic as a function of any combination of bolus doses or periods of continuous infusion. This software contains preloaded pharmacokinetic constants for a number of intravenous anaesthetic agents. We have used this software extensively in our own studies on the pharmacokinetics of the opioid analgesic, fentanyl (Shibutani *et al.*, 2004; 2005). In addition, if one has knowledge of the pharmacokinetic parameters of a multicompartmental xenobiotic other than those that are preloaded, one can insert those constants in a separate routine in STANPUMP, and calculate plasma concentrations as a function of dose and time.

The volumes of distribution and pharmacokinetic constants of multicompartmental models can vary widely. Compartmental volumes and intercompartmental diffusion constants of several intravenous anaesthetic agents are presented schematically in **Figure 18**. The drawings are made to scale for the various compartmental volumes (data from Hughes *et al.*, 1992; reproduced from Inchiosa, 2006).

7.3.2 Estimation of 'Dose' in the Three-Compartment Model

The same options discussed above for the one- and two-compartment models may be used for determination of the rate of exposure per unit of time for a xenobiotic or xenobiotic metabolite. Again, knowledge of the clearance value of the xenobiotic or a metabolite, and assurance that steady-state conditions are prevailing at the time of sampling of the plasma, permit quantification of the exposure. The 'dose' of the exposure can then be calculated according to Equation 12.

7.3.3 Context-Sensitive Half-time

The studies of Hughes *et al.* (1992), represented a milestone in a new appreciation of the contribution of compartmental volumes and intercompartmental diffusion constants on the 'recovery' of subjects from intravenous anaesthetic agents; however, their observations are applicable to the rates at which the plasma is progressively cleared of xenobiotic, and how this may vary

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat006
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

greatly from the rate at which the body is cleared of drug or toxin. The rate at which the body is cleared is the common half-time of elimination; Hughes *et al.* introduced the concept of the 'context-sensitive half-time' for a measure of the rate at which the plasma is cleared of xenobiotic. The 'context' in this concept is the period of time over which the xenobiotic has been administered, before administration is stopped and one observes the change in plasma concentration. It would be difficult to overestimate the importance of this concept to appreciation of the pharmacokinetic behaviour of multicompartmental systems. Four years after the publication of this concept, an editorial in another leading anaesthesiology journal concerned with its implications was titled, '(Almost) everything you learned about pharmacokinetics was (somewhat) wrong!' (Fisher, 1996).

As noted above, the context-sensitive half-time of interest to the authors was the time required for the plasma concentration to be reduced by 50% from a level that was being maintained by a constant infusion. Their studies demonstrated that the time required for this 50% reduction could be greatly increased in relation to the preceding duration of drug administration. In the clinical anaesthesia setting, a decrease in concentration by 50% of a drug may be adequate to permit the patient to largely recover from its effects. For example, a patient may no longer demonstrate apnoea if there is a 50% reduction in the plasma concentration of an opioid analgesic agent. Also, a 50% reduction in plasma concentration of a nondepolarizing neuromuscular antagonist may equate with a return of muscle strength and spontaneous respiration. The plasma concentration data is of prime relevance in both of these examples, because the plasma interfaces closely with the receptors of importance for analgesic action in the central nervous system for the opioid (depicted as the effect site in **Figure 18**), or nicotinic receptors at the neuromuscular junction, in relation to the muscle relaxant. However, even when the site of action of a drug or toxin is more remote from the plasma, plasma concentrations are a guide to progressive accumulation or clearing of xenobiotic, since they would be expected to exist in equilibrium with deeper depots, as discussed earlier in this chapter. It should be noted that the central compartment, V_1, is not the volume of plasma, per se, but is considered to include the plasma. Also, intravenous administration is viewed as being directed to the central compartment. The context-sensitive half-time, then, is the hybrid result of the clearance rate of xenobiotic from $V_1(k_{10} \times V_1)$ and the rate of replenishment of V_1 by $k_{21} \times V_2$ and $k_{31} \times V_3$.

Some of the data from Hughes *et al.* (1992), for the relationship between duration of infusion and the context-sensitive half-times of several anaesthetic agents are presented schematically in **Figure 19**. A comparison of the magnitude of the 'context-effect' (i.e. duration of drug administration) on the 50% clearing time following termination of drug administration for fentanyl and sufentanil, demonstrates some of the implications

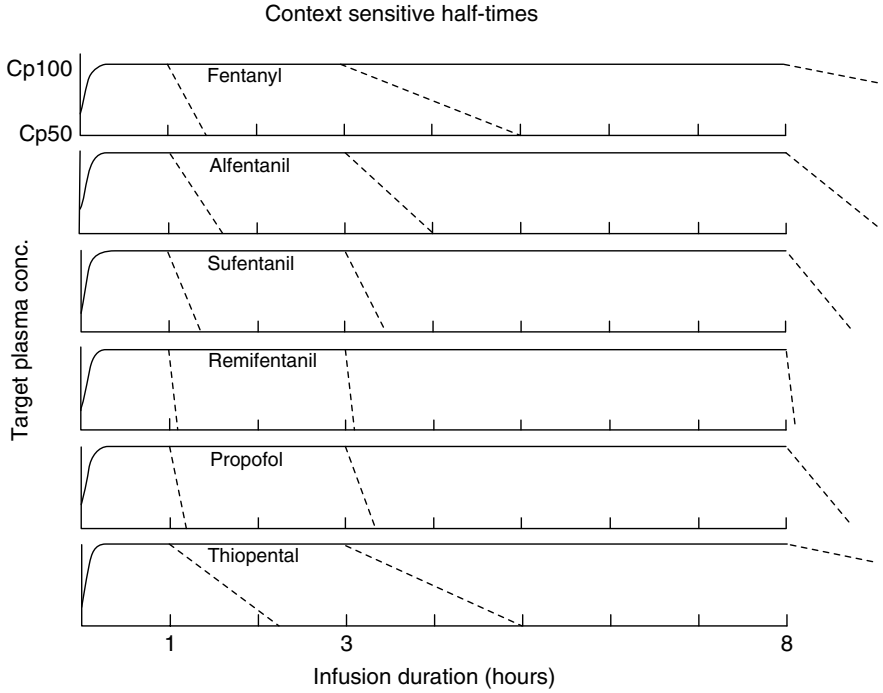

Figure 19 Schematic representation of the context-sensitive half-times of several drugs, following the termination of infusion after 1, 3, and 8 hours. See text for explanation. Data from Hughes *et al.*, 1992; Westmoreland *et al.*, 1993. (Reproduced with permission from Inchiosa, 2006. © Taylor and Francis Group.)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat006

of this concept. As the duration of infusion increases, sufentanil maintains a more rapid clearing of the central compartment than fentanyl. After eight hours of infusion, the patient would show signs of more rapid recovery from the central nervous system effects of sufentanil, than would be seen for fentanyl. The interesting paradox, however, is that the more rapid pharmacodynamic recovery from sufentanil is because the return of the drug from the peripheral compartments is more delayed than with fentanyl, so the central compartment clears more rapidly. There is actually a greater total fraction of the original body burden of sufentanil remaining in the body when the patient recovers, than the fraction that would be remaining for fentanyl at the same time; at that time the patient may still be showing marked sedation and apnoea from fentanyl.

Formulations provided by Hughes *et al.* (1992) allow application of this concept to a variety of therapeutic and non-therapeutic conditions of exposure. It should be noted that the results of Hughes *et al.* that are presented schematically in **Figure 19** are based on a typical therapeutic setting where a bolus of drug is given to establish an immediate therapeutic level, and this is followed by a graded infusion to maintain a constant plasma concentration. This sequence is commonly referred to as the BET regimen, for bolus, elimination and transfer in multicompartmental systems (Glass *et al.*, 1994). The procedure for this regimen, as presented by Hughes *et al.*, consists of a bolus of size $V_1 C\mathrm{p}_\mathrm{d}$ immediately followed by a graded maintenance infusion, Equation 19 (Hughes *et al.* formula has been expanded, for ease of application, to the following form):

$$\text{Maintenance infusion} = V_1 C\mathrm{p}_\mathrm{d}\left(k_{10} + k_{12}\mathrm{e}^{-k_{21}t} + k_{13}\mathrm{e}^{-k_{31}t}\right) \tag{19}$$

In the term $V_1 C\mathrm{p}_\mathrm{d}$ represents the volume of the central compartment, and $C\mathrm{p}_\mathrm{d}$ is the target concentration for the central compartment; since the plasma is considered to be part of the central compartment, it also represents the plasma concentration.

In the setting where this infusion regimen is being applied, Hughes *et al.* (1992) have presented the formulation for calculating the plasma concentration of the infused drug at any combination of duration of infusion and time after the infusion has been terminated. They posed, as a typical question, calculation of the plasma concentration that would exist 10 minutes after termination of a bolus and infusion regimen that had maintained a constant target concentration for a period of one hour. Their equation is presented below in an expanded form, to solve this question; t would be 10 minutes and T would be 60 minutes in this example. (In the formulas, we have preserved the authors use of A_1, A_2 and A_3 for the extrapolated intercepts of the three exponentials of the three compartment model, Equation 18, in lieu of A, B and C, respectively; they also used λ_1, λ_2 and λ_3, in place of α, β and γ, respectively.)

$$\begin{aligned} c(t) = V_1 C\mathrm{p}_\mathrm{d}\Bigg\{ & \mathrm{A}_1\mathrm{e}^{-\lambda_1 t}\Bigg[\mathrm{e}^{-\lambda_1 T} + \frac{k_{10}}{\lambda_1}\left(1-\mathrm{e}^{-\lambda_1 T}\right) \\ & + \frac{k_{12}}{k_{21}-\lambda_1}\left(\mathrm{e}^{-\lambda_1 T} - \mathrm{e}^{-k_{21}T}\right) \\ & + \frac{k_{13}}{k_{31}-\lambda_1}\left(\mathrm{e}^{-\lambda_1 T} - \mathrm{e}^{-k_{31}T}\right)\Bigg] \\ & + \mathrm{A}_2\mathrm{e}^{-\lambda_2 t}\Bigg[\mathrm{e}^{-\lambda_2 T} + \frac{k_{10}}{\lambda_2}\left(1-\mathrm{e}^{-\lambda_2 T}\right) \\ & + \frac{k_{12}}{k_{21}-\lambda_2}\left(\mathrm{e}^{-\lambda_2 T} - \mathrm{e}^{-k_{21}T}\right) \\ & + \frac{k_{13}}{k_{31}-\lambda_2}\left(\mathrm{e}^{-\lambda_2 T} - \mathrm{e}^{-k_{31}T}\right)\Bigg] \\ & + A_3\mathrm{e}^{-\lambda_3 t}\Bigg[\mathrm{e}^{-\lambda_3 T} + \frac{k_{10}}{\lambda_3}\left(1-\mathrm{e}^{-\lambda_3 T}\right) \\ & + \frac{k_{12}}{k_{21}-\lambda_3}\left(\mathrm{e}^{-\lambda_3 T} - \mathrm{e}^{-k_{21}T}\right) \\ & + \frac{k_{13}}{k_{31}-\lambda_3}\left(\mathrm{e}^{-\lambda_3 T} - \mathrm{e}^{-k_{31}T}\right)\Bigg]\Bigg\} \end{aligned} \tag{20}$$

The question may be reversed to ask how long it would take for the plasma concentration to be reduced to some percentage of the constant level that had been maintained for one hour, but has now been terminated. This can be calculated using a numerical solver such as the 'Solver' feature of Microsoft Excel[c] or the 'FindRoot' command of Mathematica.[d] These programs utilize an iterative algorithm to search for the desired result, that is, the time required for a specific percentage change from the plasma concentration at the time that the infusion (exposure) was terminated.

One of the most useful applications of the context-sensitive concept may relate to questions of dissipation of plasma concentrations and body burdens of toxicants following environmental and occupational exposures. It is reasonable to assume that such exposures may have taken place for periods of time that would have produced steady-state conditions for the xenobiotic and its metabolite(s). Hughes *et al.* (1992) provided the formulation for predicting the plasma concentration that would exist for a toxicant at some specific time after the individual had been removed from exposure; the assumption is that steady-state conditions existed at the termination of exposure. Their condensed equation has been expanded, as follows:

$$c(t) = V_1 k_{10} C\mathrm{p}_\mathrm{d}\left\{\frac{\mathrm{A}_1}{\lambda_1}\mathrm{e}^{-\lambda_1 t} + \frac{\mathrm{A}_2}{\lambda_2}\mathrm{e}^{-\lambda_2 t} + \frac{\mathrm{A}_3}{\lambda_3}\mathrm{e}^{-\lambda_3 t}\right\} \tag{21}$$

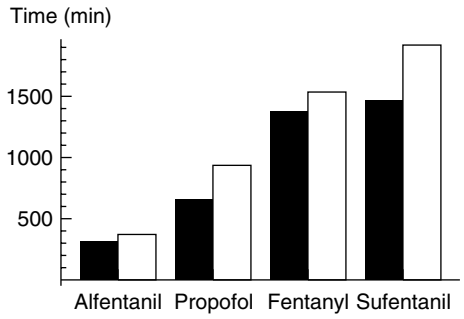

Figure 20 Times required for the decrease in plasma concentration and total body burden from steady-state conditions for four intravenous anaesthetic agents. The black bars indicate the times required for plasma concentrations to decrease by 90% from steady-state concentrations. The white bars indicate the times required for the body burden to decrease by 90% (approximately 3.3 half-times of elimination).

The question may also be posed as to the time it would take for the plasma concentration to be reduced by some specific percentage of the steady state concentration. Again, the 'Solver' feature of Microsoft Excel or the 'FindRoot' command in Mathematica can be used to solve this question. **Figure 20** presents the results for the time required for plasma concentrations to decrease by 90% from steady-state concentrations, for several of the anaesthetic agents for which Hughes *et al.* provided pharmacokinetic data. For comparison, the times that would be required for the body burden of the substance to decrease by 90% (approximately 3.3 half-times of elimination) are also presented.

8 SUMMARY

The objectives for this chapter included a presentation of the physicochemical characteristics of therapeutic and nontherapeutic xenobiotics that have a major influence in determining the rate of onset of pharmacodynamic or toxicodynamic effects. That objective was also expanded to include the role of factors that affect the extent of distribution and accumulation of xenobiotic and xenobiotic metabolites in the animal or human body. The kinetics of excretion of xenobiotics and metabolites were reviewed first for relatively simple one-compartment kinetics, followed by the principles that apply to multicompartmental systems. In all cases, procedures were proposed that would allow quantification of the systemic 'dose' of a xenobiotic, when individuals had been exposed in an environmental or occupational setting that provided no quantitative information on the actual exposure. Finally, kinetic models were proposed that would permit determination of the amount of time that it would take for the plasma to be cleared of the xenobiotic, or a metabolite, and how this might differ from the time for the total body burden to be reduced of the same substances.

Toxicokinetics

Ashley Roberts and Andrew G. Renwick

CONTENTS

1 INTRODUCTION

The generation of *in vivo* toxic effects, distal to the site of administration, may be divided into two distinct aspects: delivery to the target site for toxicity, and cellular events mediated by the chemical at the target organ or cell(s). Thus, the production of toxicity can be subdivided into **toxicokinetics** (the movement of the toxic chemical from the site of administration into the general circulation and subsequently around the body) and **toxicodynamics** (the actions of the chemical within the target organ) (**Figure 1**).

In recent years there has been an increasing emphasis on the development of *in vitro* tests for specific organ toxicity, in order to reduce the numbers of animals given toxic doses of chemicals. However, the interpretation of the results of *in vitro* tests increases the requirement for definition of the *in vivo* concentrations of the chemical that could be present in the target organ, the time course of exposure and the potential for accumulation during repeated dosing. Such information can only be obtained from appropriate *in vivo* toxicokinetic studies on the fate of the chemical within the body.

Toxicokinetics are also of importance in extrapolating both *in vitro* and *in vivo* animal data to humans. The techniques used in toxicokinetics, such as the collection of timed blood and urine samples, can also be investigated in human volunteers, providing that it is ethical to administer the chemical to humans. The basic processes involved in absorption, distribution and elimination, and their mathematical descriptions given in this chapter, are common to all chemicals which are foreign to the body, irrespective of their biological activity; for example toxins, medicines, pesticides, food additives and so on. The mathematical descriptions were developed in order to describe the fate of medicines in humans, and are usually described as *pharmacokinetics*. The use of a separate term, *toxicokinetics*, is of some value because of the implications of analysing data related to high-dose animal studies, but it should be appreciated that many of the best sources of background information

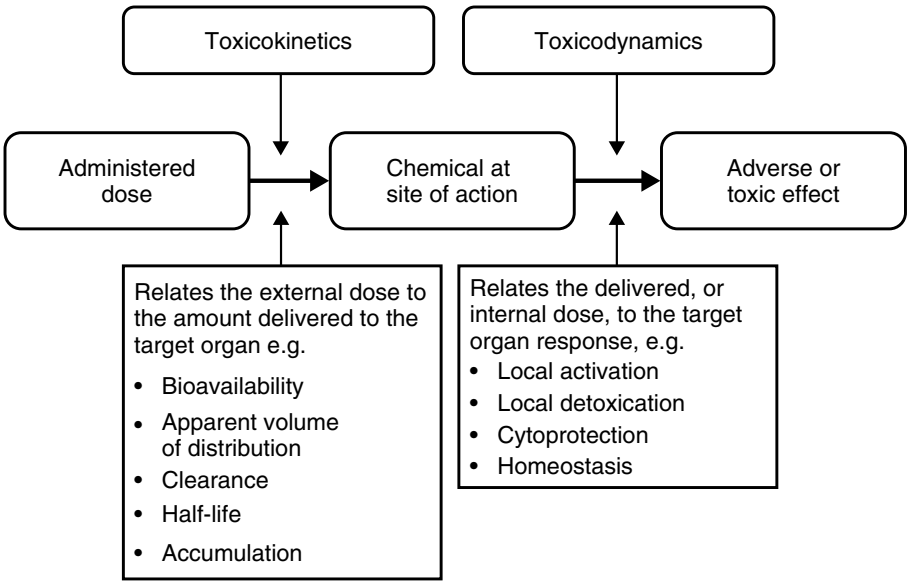

Figure 1 The relationship between toxicokinetics, toxicodynamics and toxic effects.

on 'toxicokinetics' are to be found in the 'pharmacokinetics' literature.

2 ABSORPTION, DISTRIBUTION, METABOLISM AND EXCRETION (ADME) STUDIES

The delivery of the chemical to the site of toxicity (**Figure 2**) depends on the processes of *absorption* from the site of administration into the general circulation and *distribution* via the blood to the site of action and all body tissues. Following absorption, the duration of exposure depends on the rate of *elimination* from the body, which may be by either *metabolism* or *excretion*. Absorption, distribution, metabolism and excretion (ADME) studies form an essential first step in the evaluation of the fate of the chemical in the body (Glocklin, 1982; Barton *et al*., 2006). Usually ADME studies involve following the fate of a radiolabelled dose of the chemical by measuring the total radioactivity in the excreta, and also the tissue distribution of total radioactivity by autoradiography at various times after dosing. Such studies clearly provide important information on the fate of the chemical in the body, but they provide only a part of the total investigation of the toxicokinetics of the compound. A radiolabelled compound is used to provide information on the total balance of all compound-related products whether or not they have been identified and characterized. Thus the strength of radiolabelled ADME studies is the use of *nonspecific detection methods,* which allow the detection of all compound-related products. ADME studies also provide essential data on the extent of absorption and the routes of elimination. However, this strength is also a weakness because it provides limited data on exposure of the body to the parent chemical itself or to specific identified metabolites. Identification of metabolites of the radiolabelled compound in excreta (and the circulation) using chromatographic techniques allows definition of the pathways of metabolism; such information is essential for interspecies comparisons, for the establishment of specific analytical procedures and for indications of possible metabolic bioactivation.

Investigation of the kinetics of the parent molecule itself requires the use of a *chemical-specific detection method*, which not only separates the chemical from the normal (endogenous) constituents of the sample being analysed, but also from any metabolites of the chemical that are formed *in vivo*. In cases where the toxicity of a chemical is due to a specific metabolite, then toxicokinetic studies will need to define the extent of absorption of the parent chemical, its delivery to the site(s) of metabolism, the extent of formation of the metabolite and its delivery to the target organ (**Figure 2**). Additional information essential to the interpretation of toxicity studies includes the influence of dose on the fate of the chemical, and the extent of accumulation of the parent compound and/or active metabolites on repeated administration of the compound.

Toxicokinetics represent an important part of the safety evaluation of chemicals, but because the subject is perceived as being mathematically based it tends to be regarded as difficult and rather unapproachable by biologists. This chapter will relate the underlying physiological and biochemical processes to the basic pharmacokinetic parameters and constants. This is followed by a consideration of the types of experimental data that are needed in order to determine the various parameters. The chapter will conclude with a consideration of specific

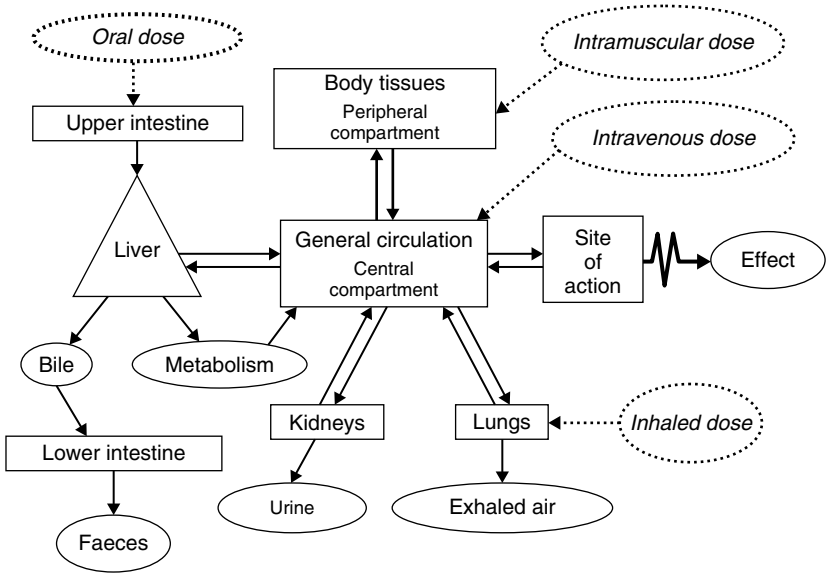

Figure 2 Delivery of chemicals to their site of action. This scheme assumes that the site of toxicity is not locally at the site of administration. Compounds absorbed from the gastrointestinal tract are transported via the hepatic portal vein to the liver before they enter the general circulation. Highly lipid-soluble compounds may be absorbed via the lacteal system.

aspects related to the interpretation of high-dose, chronic animal studies.

3 PHARMACOKINETIC PROCESSES, PARAMETERS AND CONSTANTS

Each of the basic processes involved in pharmacokinetics, that is, absorption, distribution and elimination, may be described by parameters which define the *extent* to which the process occurs and the *rate* at which it occurs. These parameters are usually calculated from the concentrations of the chemical and/or its metabolites in biological fluids, such as whole blood, plasma or urine, measured at known times after the administration of known doses.

3.1 Absorption

Absorption is the process of transfer of the chemical from the site of administration into the general circulation. Absorption from the gastrointestinal tract is studied most frequently because this is the route of exposure of experimental animals via gavage dosing or by incorporation of the chemical into the diet. Oral administration is also the most common route by which humans are exposed to chemicals either as drugs or as intentional, incidental or accidental components of the diet. The process of absorption occurs whenever the compound is given by a route other than direct intravascular injection; for example across the skin, from the airways, from subcutaneous sites and also from the peritoneal cavity.

3.1.1 Rate of Absorption

The rate of absorption depends on both the nature of the chemical and the site of administration. There are five main processes by which chemicals can transfer across cell membranes (**Figure 3**).

1. **Passive diffusion through the cell membrane:** Lipid-soluble chemicals can readily dissolve in membranes and therefore diffuse across cell walls. In contrast, ionized molecules do not readily enter the lipid membrane in the ionized form, and therefore only the unionized form freely diffuses across membranes. For strong acids and bases at physiological pH, the unionized form on each side of the membrane is in equilibrium with the ionized form; the concentrations of the ionized form may be orders of magnitude higher than the concentration of the unionized, lipid-soluble form. Thus the transfer of highly ionized chemicals across cell membranes is slow. For very strong acids and bases, and also quarternary amines (which have a fixed positive charge), the absorption rate across the intestinal wall may be slower than the rate of transfer along the bowel by peristalsis; under such circumstances a major fraction of the dose may be lost in the faeces without ever being absorbed or available to produce systemic toxicity.
2. **Diffusion through open ion channel:** Water-soluble compounds may be able to pass down

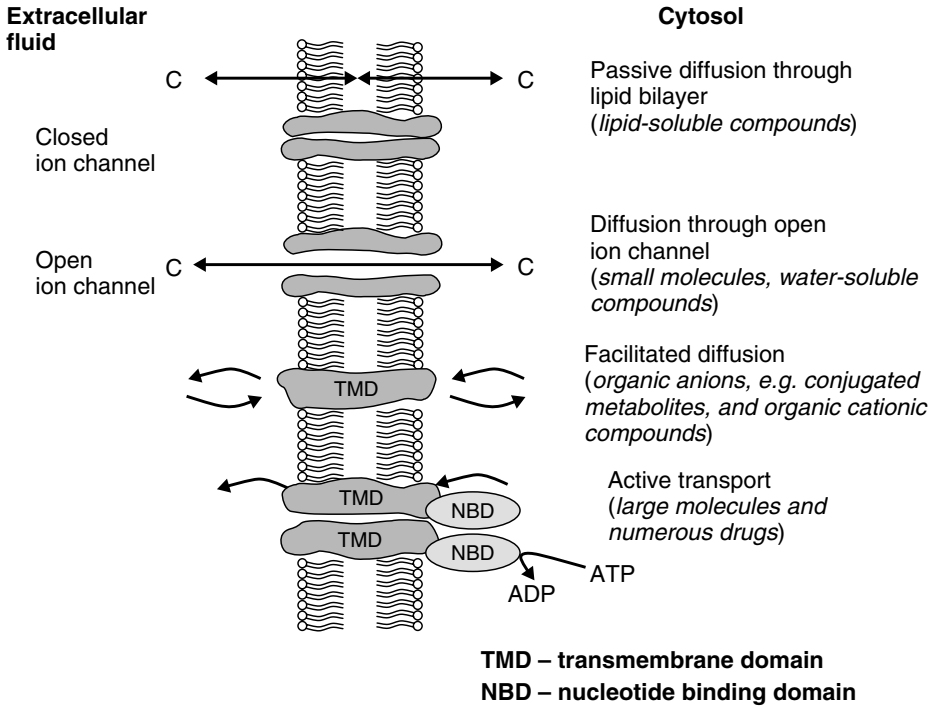

Figure 3 Processes involved in the transfer of chemicals across cell membranes. Passive diffusion is the major pathway for low-molecular-weight lipid-soluble compounds. C = chemical.

ion channels without having to enter the lipid environment of the membrane. Because ion channels are involved in the transfer of specific cations, such as sodium and potassium, this is only applicable to very small water-soluble compounds and inorganic ions.

3. **Facilitated diffusion:** This involves a membrane-bound protein, known as a solute carrier (SLC) transporter (**Table 1**) that shows substrate specificity. The process does not utilize energy, and chemicals are transported only down their concentration gradients.
4. **Active transport:** This process utilizes energy and can transport chemicals into or out of cells against a concentration gradient. It is performed by a family of nonspecific carriers termed the ATP-binding cassette (ABC) superfamily of membrane transporters (**Table 1**).
5. **Pinocytosis:** In this process the cell membrane forms a pocket containing extracellular fluid, containing the chemical, which then fuses into a sphere that is internalized. This is of negligible quantitative importance, except in the case of macromolecules which cannot otherwise cross membranes intact.

Absorption from the gut is often complex because chemicals are absorbed less effectively from the stomach, with its smaller surface area and lower pH, than from the duodenum and jejunum. In consequence there can be a delay before any appreciable absorption occurs, while the compound is in the stomach lumen. However, once the dose has left the stomach, it reaches the large surface area of well-perfused intestine, which can allow very rapid absorption.

The rate of absorption also depends on the site of administration; for example, absorption across the skin is usually extremely slow, because it involves transfer across the stratum corneum—the main permeability barrier of the body. In contrast, absorption from the airways tends to be rapid, because it involves transfer across a thin membrane which has a large surface area and a good blood supply.

In some cases absorption is so rapid that the absorption rate constant cannot be calculated, and the plasma concentration–time curve resembles an intravenous dose (**Figure 4**). A low, almost flat, profile is obtained when absorption is very slow; for example across the skin (**Figure 4**). In many cases the plasma concentration–time profiles after oral dosage are more complex than shown in this figure and often involve a lag phase prior to significant absorption.

3.1.2 Extent of Absorption

There are a number of reasons why all of the dose of a chemical introduced into the gut lumen may not be able to pass into the general circulation as the parent compound (**Table 2**).

The parameter which describes the extent of absorption is the bioavailability (F), which is defined as: *the*

Table 1 Transporters involved in cellular absorption and efflux of exogenous and endogenous compounds

Transporter	Typical substrates	Sites in the body
ABC superfamily	ATP-binding cassette superfamily of transport proteins; utilize ATP for active transport	
MDR1 or P-glycoprotein (ABCB1)	Hydrophobic and cationic (basic) molecules	Apical surface of membranes of epithelial cells of intestine, liver, kidney, blood—brain barrier, testis, placenta and lung
MRP1 (ABCC1)	Numerous drugs and glucuronide and glutathione conjugates	Basolateral surface of membranes of most cell types with high levels in lung, testes and kidney and in blood—tissue barriers
MRP2 (ABCC2)	Numerous drugs and glucuronide and glutathione conjugates	Apical surface of membranes; mainly in liver, intestine and kidney tubules
BRCP (ABCG2) Breast cancer resistance protein	Various drugs and flavonoids	Apical surface of breast ducts and lobules, small intestine, colon epithelium, liver, placenta, brain barrier and lungs
SLC superfamily	Solute carrier (SLC) superfamily of transporters. Comprises organic anion transporters (OATs) and organic cation transporters (OCTs)	
OAT1 (SLC22A6)	Numerous acids and conjugated metabolites	Kidney (basolateral), brain, placenta, smooth muscle
OAT2 (SLC22A7)	Various anions and dicarboxylic acids	Kidney (basolateral), liver
OAT3 (SLC22A8)	Similar to OAT1	Kidney (basolateral), liver, brain, smooth muscle
OAT4 (SLC22A11)	Steroid sulfate conjugates	Kidney (apical), placenta
OCT1 (SLC22A1)	Various basic molecules	Mainly in the liver, but also in kidney, small intestine, heart, skeletal muscle and placenta
OCT2 (SLC22A2)	Various basic molecules	Mainly in the kidney, but is also in placenta, adrenal gland, neurons and choroid plexus
OCT3 (SLC22A3)	Various basic molecules	Liver, kidney, intestine, skeletal and smooth muscle, heart, lung, spleen, neurons, placenta and the choroid plexus

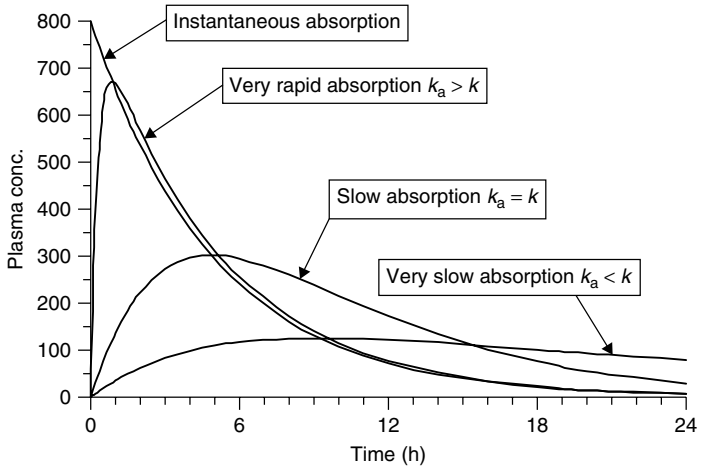

Figure 4 Plasma concentration–time curves of compounds showing different rates of absorption from the site of administration (but the same rate of elimination). k_a = absorption rate constant; k = elimination rate constant (see text).

fraction of the dose which is transferred from the site of administration into the general circulation as the parent compound.

Bioavailability is without doubt the most misused/abused toxicokinetic term; it is often used nonmathematically as a generic term for 'delivery to the site of action', which actually involves both absorption and tissue distribution, or as 'the concentration at the target for toxicity' which involves absorption, distribution and elimination.

Each of the processes in **Table 2** can cause a decrease in the amount of parent chemical able to reach the

Table 2 Reasons for incomplete absorption from the site of administration

Reason	Example
Incomplete dissolution	The compound given in the diet or as a suspension is not completely dissolved during transit through the intestinal tract.
Incomplete passage across absorptive epithelium	The compound is too polar to be absorbed completely before it is voided in the faeces (oral), or the unabsorbed dose is removed (transdermal). The rate of loss in exhaled air exceeds the rates of dissolution and absorption (inhaled gases).
Metabolism at the site of administration	The compound is metabolized or decomposes due to the pH or enzymes present in the gut lumen (oral or rectal), or inactivation by lung enzymes (inhalation).
Metabolism between site of administration and the general circulation	The compound is metabolized by the gut lumen, gut wall, or liver prior to entering the general circulation (oral dosage).

general circulation. Incomplete absorption ($F < 1.0$) may be due to:

1. an inability of the chemical to cross the lipid barrier of the epithelial membrane or transfer back from the enterocyte into the gut lumen by an efflux transporter (**Table 1**; **Figure 3**), so that the parent compound is unabsorbed, and eliminated in the faeces (indicated by ADME data), or
2. metabolism in the gut lumen, gut wall or liver prior to reaching the general circulation. This is referred to as *first-pass metabolism* since it usually occurs on the first passage through the liver during the absorption process. First-pass metabolism can result in an apparent discrepancy between radiolabelled studies and toxicokinetic data. The former may demonstrate that all of a radiolabelled dose is absorbed and eliminated in urine, but the bioavailability of the parent compound measured by a chemical-specific method may be considerably less than 1.0 (see later for method of measurement). The discrepancy arises from the nonspecific nature of radiochemical measurements which measure parent compound plus metabolites.

3.2 Distribution

Distribution is the process of reversible transfer of the chemical from the general circulation into the body tissues. The process may be characterized by both rate and extent; the corresponding parameters are the *distribution rate constant*(s) (α, k_{12} and k_{21}) and the *apparent volume of distribution* (V) (see later). Measurement of these parameters requires knowledge of the amount of compound that enters the general circulation, and therefore distribution parameters can be defined only when the chemical has been given by direct intravascular injection. Thus intravenous dosage is essential for a full description of the toxicokinetics of any compound, including food additives, for which there would never be parenteral dosage and for which parenteral toxicity studies are not necessary or useful.

3.2.1 Rate of Distribution

Because distribution is usually rapid, the distribution rate constants are measured following the administration of a single rapid (bolus) intravenous dose (**Figure 5**). The rate of distribution into tissues may be slow for two possible reasons. Firstly, distribution will be slow if the chemical has a high affinity for, and accumulates in, a tissue or organ which is only slowly perfused, for example fat or muscle. For such a compound the rate at which the tissues and blood can reach equilibrium will be limited by the blood flow to the tissues. Secondly, for highly polar chemicals the rate of entry into the intracellular fluid of all tissues may be limited by its rate of transfer across the cell membrane.

3.2.2 Extent of Distribution

The tissues into which a chemical (and/or its metabolites) distributes can be identified by autoradiography, but this technique cannot determine the overall extent to which a chemical has left the blood or plasma and entered the tissues. In addition, autoradiography cannot differentiate between parent compound and metabolites, and cannot be used to provide data in humans.

The extent of distribution of a chemical from the blood into tissues depends on a number of variables:

1. **Water solubility:** Water-soluble compounds, for example ethanol and caffeine, show limited uptake into adipose tissue or the central nervous system and are distributed to total body water.
2. **Plasma protein binding:** Chemicals which bind reversibly to plasma proteins with a high affinity show reduced tissue distribution and are retained to a greater extent in the circulation. An equilibrium is established between the concentration unbound in plasma and that (unbound) in tissues (**Figure 6**).
3. **Tissue protein binding:** Chemicals with a high affinity for reversible binding to tissue proteins will

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

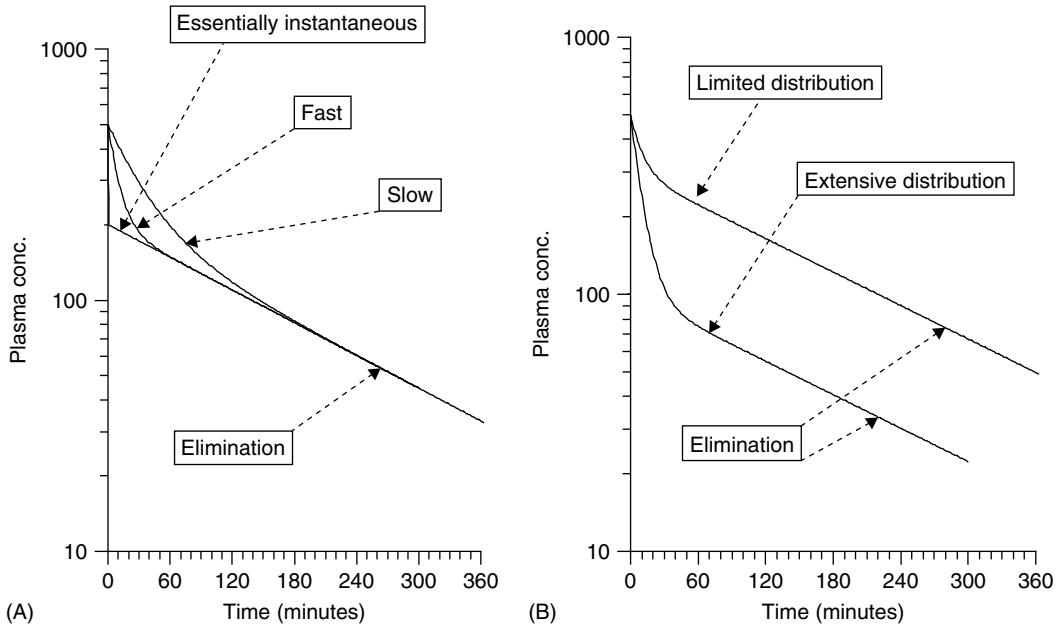

Figure 5 Plasma concentration–time curves following intravenous bolus doses of chemicals, showing different rates of distribution from the blood into peripheral tissues (A) and different extents with the same rates (B).

show more extensive distribution. The blood: tissue equilibrium relates to the unbound chemical in each compartment (**Figure 6**), and therefore the overall extent of distribution depends on the relative binding in tissues and blood.

4. **Lipid solubility:** Lipid soluble compounds are concentrated in adipose tissue, organs that have a high lipid content (such as the central nervous system), and the cytoplasmic membranes and endoplasmic reticulum of all cells in the body.
5. **Efflux transporters:** The transporters listed in **Table 1** show different tissue distributions and these, especially P-glycoprotein, can affect the tissue : plasma concentration ratio for compounds that are substrates.

Information on the concentration of a compound in a specific tissue can be determined only by analysis of that tissue. Cyclohexylamine, a metabolite of the intense sweetener cyclamate, rapidly enters the testes (Roberts and Renwick, 1989), which are the target for toxicity (Bopp *et al*., 1986). The concentrations in the testes are about four times higher than those in plasma. In contrast the hydroxylated metabolites (3- and 4-aminocyclohexanols), which are more polar detoxication products (Roberts *et al*., 1989), enter the testes less readily and there is not a high testes : plasma ratio even after chronic administration. These data illustrate that minor changes in molecular structure, such as the increase in polarity resulting from the hydroxylation of cyclohexylamine, can alter considerably the uptake into tissues, especially organs such as the brain and testes which have an efficient permeability barrier (blood–organ barrier) and facilitated uptake processes or active efflux transporters.

3.3 Elimination

There are two principal mechanisms of elimination of foreign compounds from the body.

Metabolism eliminates the chemical from the body by converting it into a metabolite, which is a different chemical species. The resulting metabolite may itself undergo further metabolism or it may be removed from the body by an excretory process. However, from a toxicokinetic perspective, the parent compound has been eliminated as soon as it has been changed into the initial metabolite. Thus, in the analysis of the kinetics of the parent compound it is essential that the analytical method separates the compound from all of its metabolites. The metabolism of foreign compounds has been the subject of numerous reviews and is discussed in detail in **Biotransformation of Xenobiotics**, **Toxicokinetics of Xenobiotic and Metabolite Distribution and Excretion**, **A Metabolomic Perspective of Small Molecule Toxicity**. The cytochrome P450 isoenzymes in the endoplasmic reticulum are important in the metabolism and elimination of lipid-soluble foreign compounds. Sometimes the initial metabolic step results in the generation of a toxic metabolite which is released into the circulation (see **A Metabolomic Perspective of Small Molecule Toxicity**), in which case measurements of the concentrations of parent compound provide information on the amount of substrate available for

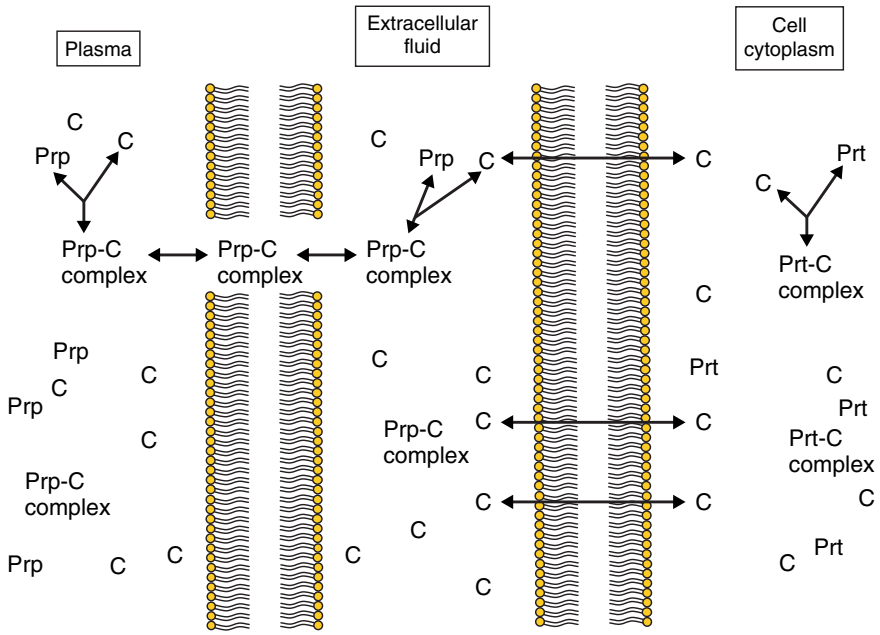

Figure 6 Plasma and tissue protein uptake and reversible protein binding of chemicals. The chemical (C) may bind as the ionized or unionized form to the plasma proteins (Prp) and tissue proteins (Prt). The total tissue : plasma ratio depends on the relative affinity of plasma and tissue protein binding.

activation, but may not be the best estimate of body exposure to the toxic moiety. Under such circumstances toxicokinetics should concentrate on measurement of the toxic moiety itself in plasma and tissues, especially the target organ. When toxicity arises from the formation of an unstable reactive metabolite, exposure to the toxicant may be assessed by a biomarker, such as measuring the products formed from the unstable metabolite either in plasma, tissues or urine. For example, the extent of formation of toxic metabolites that react with glutathione (GSH) can be assessed by measurement of the urinary or biliary excretion of the thio conjugates, that is, the GSH, cysteine or mercapturic acid metabolites. Any bioactivation processes, or covalent binding to proteins or cellular macromolecules *within the target organ*, are part of the toxicodynamics, because it is not part of the movement of the chemical around the body (kinetics).

Excretion can occur via the body's waste products, for example urine, faeces and expired air; the route of importance is determined largely by the physicochemical properties of the compound (**Table 3**) and whether the compound is a substrate for an efflux transporter in the kidney, intestine or liver (**Table 1**). When considering the toxicokinetics of a chemical, confusion can arise when trying to relate studies with radiolabelled compounds to toxicokinetic data. For example, although all of the radioactivity may be eliminated in the urine, it is possible that this is all as metabolites and not as parent compound. Under such circumstances the renal clearance (see later) of the chemical itself will be negligible, and the kidneys will not be of importance in the elimination of the chemical *per se*.

The elimination of a chemical can be divided into the rate and extent of elimination.

3.3.1 Rate of Elimination

The rate of elimination is limited by two biological processes.

1. The ability of the organs of elimination to extract the chemical from the circulation and to remove it from the body by metabolism or excretion.
2. The fraction of the body burden that is in the circulation and is available for elimination. If the compound has entered the body tissues to a major extent, so that at any time only a very small fraction of the total body burden remains in the blood and is available for elimination, then the rate at which it is transferred from the tissues back into the circulation may become the rate-limiting step in elimination of the chemical.

3.3.2 Extent of Elimination

The extent of elimination is of less importance than the rate. Following a single dose the extent of elimination will eventually be 100% of the dose. This is even true for chemicals which bind covalently to tissue macromolecules, because formation of an adduct represents elimination of the parent compound. During chronic

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 3 Routes of elimination of foreign compounds

Route	Type of chemical
Expired air	Volatile compounds, for example, gaseous anaesthetics, solvents, aerosol propellants.
Saliva	Many low-molecular-weight compounds, but reabsorption occurs on passage down the gut.
Bile	Large-molecular-weight compounds, usually conjugated metabolites rather than the parent compound. Wide species differences exist in the molecular weight threshold for significant biliary excretion. Reabsorption and/or bacterial metabolism may occur in the lower bowel.
Faeces	An important route for the elimination of compounds not absorbed from the gut, and for compounds excreted in the bile. Some chemicals can pass from the circulation into the gut lumen by diffusion or active transport and thereby undergo elimination in the faeces.
Urine	The major route of elimination for low-molecular-weight, polar compounds. Lipid-soluble compounds are filtered at the glomerulus, but reabsorbed on passage down the renal tubule, and such compounds are eliminated by metabolism and their metabolites removed in the urine and/or bile.
Milk	Both water-soluble and lipid-soluble compounds are present in milk. This route is usually of limited significance with respect to elimination from the mother but may be of critical importance with respect to exposure of the neonate.
Hair	Quantitatively unimportant, but the slow and directional growth of hair can allow an 'exposure history' to be determined based on the position of the chemical along the hair.

intake the body burden increases until the extent of elimination per day equals the daily intake of the chemical (see later).

4 DERIVATION OF PHARMACOKINETIC CONSTANTS

Most pharmacokinetic parameters are based on the measurement of the chemical in plasma samples collected at various times after dosing. In some cases the concentrations in whole blood or urine are used.

4.1 Basic Concepts

Before it is possible to describe the measurement of specific pharmacokinetic parameters it is necessary to define certain basic concepts.

4.1.1 Order of Reaction

At low doses, most processes involved in toxicokinetics can be described as *first-order reactions* with respect to substrate. That is, the rate of reaction is proportional to the amount of substrate present. Examples include passive diffusion, facilitated or active transport, metabolism, protein binding and excretion, in which an increase in concentration will increase the amount of chemical which crosses a membrane, undergoes metabolism, and so on. The equation for such reactions is:

$$\frac{dC}{dt} = kC \qquad (1)$$

where dC/dt is the rate of change in concentration, k is the rate constant and C is the concentration.

The term k is the rate constant for the process being described by the change dC/dt and may be absorption, distribution or elimination; the greater the value of k, the greater the rate of the process. The units of k are time^{-1}, and k can be regarded as the natural log of the proportion of the chemical that is changed within one unit of time. For example, if $k = 0.693\,h^{-1}$ then the concentration will change by a factor of 2 (the natural antilog of 0.693—see below) each hour.

Processes which involve an interaction of the chemical with a cellular protein, such as enzyme-catalysed metabolism or active transport, may be saturated at very high concentrations of the chemical. Under these conditions the rate of change in concentration is not proportional to the concentration of substrate available but is a constant amount per unit time. This is known as a *zero-order reaction*, which can be described by the equation:

$$\frac{dC}{dt} = k \qquad (2)$$

The rate constant (k) of a zero-order reaction can be described in terms of mass (or concentration) per unit time (e.g. $\mu g\ min^{-1}$), and this value is a constant at all concentrations.

A straight line is obtained when the data for a zero-order decrease are plotted on a linear axis (**Figure 7A**). In contrast, for a first-order decrease the rate of change is proportional to the concentration; the rate of change is high at high concentrations (i.e. a steep slope) and the slope decreases with decrease in concentration. Thus first-order reactions result in exponential decreases, and can be described by exponential equations.

$$C_t = C_0 e^{-kt} \qquad (3)$$

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

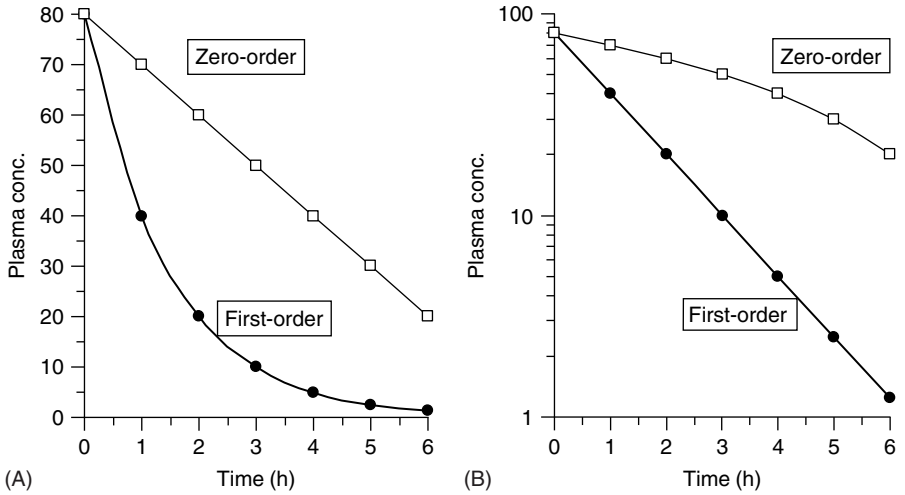

Figure 7 Graphical representations of first-order and zero-order decreases in concentrations, plotted on (A) linear and (B) logarithmic axes.

where C_t is the concentration at time t, C_0 is the initial concentration, and t is the time after dosage; or, taking natural logs,

$$\ln C_t = \ln C_0 - kt \tag{4}$$

Plotting the natural logarithm of the concentration ($\ln C_t$) against time (t) will give a straight line with an intercept of $\ln C_0$ and a slope of $-k$ (**Figure 7B**). If $\log_{10}$ is used then the intercept is $\log_{10} C_0$ and the slope is $-k/2.303$. A zero-order decrease becomes nonlinear when plotted on a logarithmic axis.

4.1.2 Half-Lives

For first-order reactions the rate constant has units of time^{-1} (e.g. min^{-1}) which is difficult to visualize. Therefore the rate of a first-order reaction is normally described by a parameter which is a reciprocal of k, and which therefore has units of time. A property of exponential decreases is that the time taken for any concentration on the curve to decrease by a factor of 2 (i.e. to halve) is a constant, and independent of concentration. This parameter is the half-life of the decrease and is related to k by the equation

$$t_{1/2} = \frac{0.693}{k} \tag{5}$$

This can be seen graphically for the first-order reaction in **Figure 7**, where the concentrations decrease by a factor of 2 between successive hourly intervals, that is, 80, 40, 20, 10, 5, 2.5, 1.25 so that the half-life in this case is 1 hour. The half-life is usually calculated from the slope of the decrease, which can be calculated by a least-squares regression analysis of the ln concentration–time curve data.

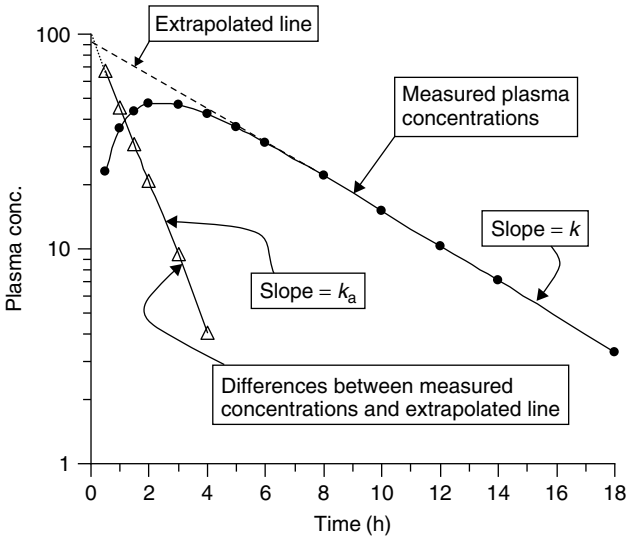

Figure 8 Plasma concentration–time curve following oral administration of a compound showing simple first-order absorption. The absorption rate constant (k_a) is calculated from the difference between the measured values and the extrapolated values (residuals).

4.2 Absorption

4.2.1 Rate of Absorption

Measurement of the rate of absorption requires information on the plasma (or blood) concentrations of the compound at frequent time intervals following a single dose administered to the site of absorption. The resulting data can be analysed in a number of ways. In the simple example shown in **Figure 8**, the absorption occurs rapidly as a first-order process, and the total concentration–time curve is dependent on two exponential terms—one for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

absorption (k_a) and one for elimination (k), that is

$$C_t = \frac{F \times \text{dose} \times k_a(e^{-kt} - e^{-k_a t})}{V \times (k_a - k)} \quad (6)$$

where

F = bioavailability (see later) and
V = apparent volume of distribution (see later).

For rapidly absorbed compounds k_a exceeds k, and therefore the term $e^{-k_a t}$ approaches zero at late time points, and the concentration–time curve is determined by a single exponential term that describes elimination (e^{-kt}). This is shown in **Figure 8** by the extrapolated line of the terminal data. If the whole dose had entered the circulation at time zero, then the concentration–time curve would have resembled this extrapolation line. The *difference* between the actual data obtained and the extrapolated line is due to the absorption of the chemical into the circulation. The differences (or *residuals*) between the actual data and the extrapolation line are then plotted (**Figure 8**) in order to derive the absorption rate constant.

The absorption and elimination of chemicals rarely show this simple pattern and more complex equations may be necessary. For example, if there is a lag time (t_{lag}) between dosing and measurable concentrations, then the time t in the equation given above has to be replaced by ($t - t_{lag}$). In addition if there is a clear distribution phase (see later) then a more complex equation involving three exponential terms may be required; in some cases the absorption rate can only be determined by comparison of oral and intravenous data. Readers are referred to Chapter 4 of Gibaldi and Perrier (1982) for further information. Characterization of the rate of absorption requires the collection of a number of plasma or blood samples (at least three or four) during the absorption phase.

In some cases the rate of absorption does not resemble either a first- or zero-order input and no model can be fitted to the data. Under such circumstances the best estimate of the rate of absorption is the mean absorption time (MAT). This is calculated from plasma concentration–time curve data after *both* oral and intravenous dosing using statistical moments analysis (see Gibaldi and Perrier, 1982; Renwick, 2008).

$$\text{MAT} = \text{MRT}_{\text{oral}} - \text{MRT}_{\text{iv}} \quad (7)$$

where

MRT = mean residence time.

The MRT is the ratio of the area under the first moment of the concentration–time curve (AUMC) divided by the area under the concentration–time curve (AUC).

$$\text{MRT} = \frac{\text{AUMC}}{\text{AUC}} \quad (8)$$

The AUMC is derived by the trapezoidal rule applied to a graph of (concentration × time) ($C \times t$), for each sample, plotted against time (t) for that sample, and therefore does not require fitting of any specific models to the data. Both the AUC and the AUMC data calculated between time zero and the last sample by the trapezoidal rule must be extrapolated to infinity for the above equation to be valid. Extrapolation of the AUC is by addition of C_{last}/β to the AUC measured by the trapezoidal rule. AUMC from the last concentration–time point to infinity is achieved by the addition of

$$\frac{t_{last} \times C_{last}}{\beta} + \frac{C_{last}}{\beta^2} \quad (9)$$

where β is the terminal slope—see later.

In the brief description above it is assumed that the compound is absorbed rapidly but eliminated slowly, for example, a lipid-soluble compound requiring metabolism. For highly polar molecules, absorption from the gut may be slow while elimination from the blood, via the kidneys, may be rapid. However, the concentration–time curve still resembles that shown in **Figure 8**. The reason for this is that the exponential function that defines the later time points is always the lower rate constant, whether it is k or k_a. Therefore, for slowly absorbed compounds the value of ($k_a - k$) will be negative when $k > k_a$, and at late time points e^{-kt} will approach zero and the concentration will be determined by ($-e^{-k_a t}$). Thus for slowly absorbed/rapidly eliminated compounds the terminal slope is determined by k_a and the more rapid increase by k—a situation described as *flip-flop kinetics*. This type of profile is the usual pattern shown by transdermal absorption.

Both the rate and extent of absorption from the gastrointestinal tract can be influenced by a number of variables such as the nature and volume of the vehicle, the dose of compound (especially in relation to its solubility) and the presence of food in the gut lumen. Toxicokinetic studies should be performed under conditions which reflect the dosing regimen used in animal toxicity studies, for example, gavage in corn oil or administration in the diet.

4.2.2 Extent of Absorption

The fraction of the dose absorbed as the parent compound (or bioavailability, F) can be determined only by comparison to conditions in which it is known that all of the dose enters the general circulation *as the parent compound*, that is, by reference to an intravenous dose given as a bolus or as a slow infusion. Because of the different shapes of the concentration–time curves following oral and intravenous doses (**Figure 9**), comparisons of the concentrations at single time points are meaningless.

The bioavailability can be calculated from the area under the plasma concentration–time curve (AUC)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007

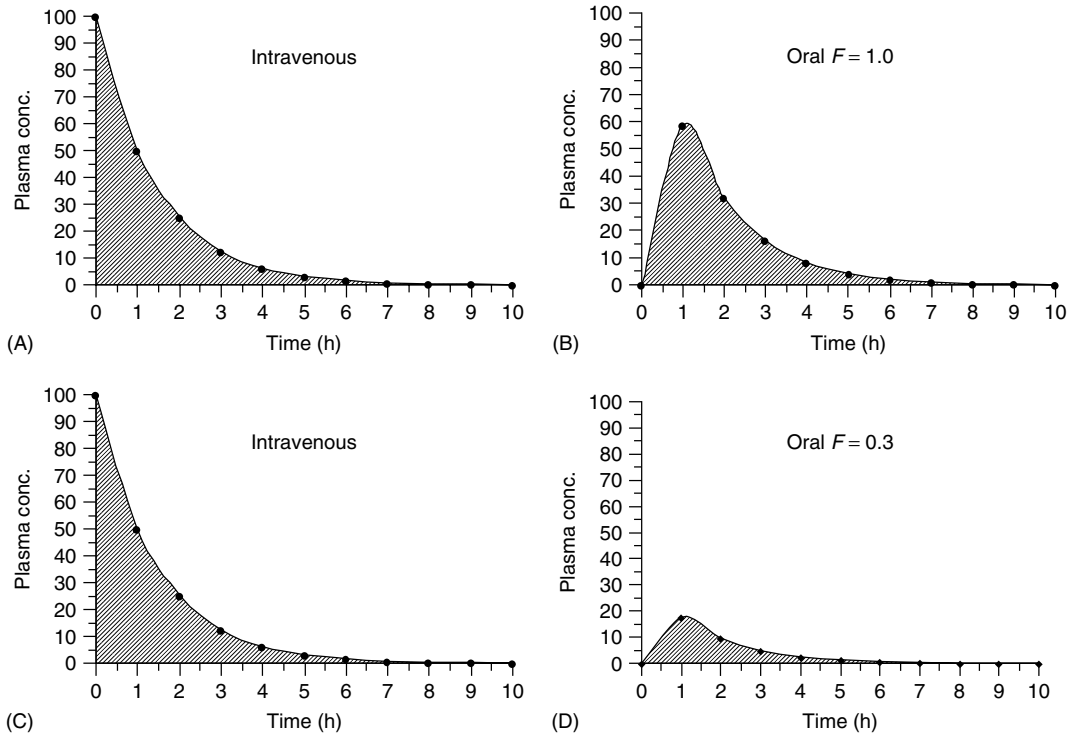

Figure 9 Comparison of areas under the plasma concentration–time curves for a compound showing complete absorption (F = 1.0; (A), (B)) and a compound showing incomplete absorption (F = 0.3; (C), (D)). The reason for the incomplete bioavailability, for example, first-pass metabolism or poor absorption from the gut lumen, cannot be determined without additional information.

between administration and infinity following both routes of administration (**Figure 9**). If the doses are identical:

$$F = \frac{\mathrm{AUC_{oral}}}{\mathrm{AUC_{iv}}} \tag{10}$$

The AUC values must be extrapolated to infinity (see above) for this equation to be valid, and therefore it is important that the concentration–time curves are followed for sufficient time to allow accurate measurement of the terminal elimination rate constant.

This is illustrated in **Figure 9**. In many cases acute toxicity may prevent the administration of a high intravenous dose, while a high oral dose may be essential to obtain measurable plasma concentrations. Under such circumstances different doses may be given by oral and intravenous routes and F is calculated as:

$$F = \frac{\mathrm{AUC_{oral}} \times \mathrm{dose_{iv}}}{\mathrm{AUC_{iv}} \times \mathrm{dose_{oral}}} \tag{11}$$

The basis for this calculation is that plasma clearance (CL—see later) is the same after each of the two separate doses (oral and intravenous). In clinical studies this is ensured by studying the same subjects on two separate occasions. For animal toxicity studies it may be necessary to study different animals for each route, in which case the age and sex of the animals should be comparable.

The use of AUC data assumes that there is no saturation of elimination and that the intravenous dose, with its possibly higher peak plasma concentrations, does not produce cardiovascular, renal or metabolic effects which could alter the plasma clearance of the compound.

The bioavailability (F) can also be calculated from urinary data. The percentage of the dose which is excreted in the urine *as the parent compound* is dependent on the amount of parent compound presented to the kidneys via the circulation, that is, the percentage of the dose excreted in the urine to time t is proportional to the plasma AUC to time t. Thus bioavailability (F) can be calculated as:

$$F = \frac{\%\text{ oral dose in urine as the parent compound}}{\%\text{ intravenous dose in urine as the parent compound}} \tag{12}$$

where the percentage dose is measured until no more parent drug is excreted (i.e. t = infinity).

The extent of absorption for different formulations or vehicles given by the same route can be compared in the absence of information from an intravenous study using the above equations. However the AUC ratio of one to the other is simply a comparison of the internal dose via each mode of administration and is not a measure of the true absolute amount of chemical that reaches the general

circulation. Such comparative ratios are sometimes called the *relative bioavailability*. To provide a clear separation of such data from the true bioavailability (F as defined above), F is often termed the *absolute bioavailability*.

4.3 Distribution

4.3.1 Rate of Distribution

The rate at which a compound moves out of the blood into body tissues is usually rapid and can only be measured when the dose enters the circulation at a rate considerably greater than the rate of distribution. In effect, this means that the rate of distribution is usually measured following an intravenous bolus dose. The plasma concentration–time curve following a bolus dose depends on the rate and extent of distribution as well as the rate of elimination (**Figure 5**).

In the simplest case (**Figure 5**; bottom line on A), essentially complete distribution will occur between dosing and the collection of the first blood sample, so that distribution will appear to be instantaneous. Thus the concentration–time curve can be described by a single exponential term (k) that is dependent on elimination processes (e.g. metabolism and excretion), and the compound achieves instantaneous distribution within a single compartment (**Figure 10**). The rate constant for a one-compartment model is usually given as k (as used above), rather than k_{10}.

However, normally a distinct distribution phase can be detected (**Figure 5**; top 2 lines on A), during which the chemical is undergoing two processes at the same time: distribution and elimination. The tissues and blood reach equilibrium when the distribution phase is complete, and the concentration–time curve becomes a simple monoexponential decrease determined by the elimination rate constant (k). For such compounds the body can be regarded as comprising two compartments with the chemical achieving instantaneous equilibrium in Compartment 1 (the central compartment), but taking a finite time for equilibration between Compartment 1 and Compartment 2 (the peripheral compartment) (**Figure 10**). Thus two exponential terms are necessary—a rapid distribution rate (α) and the slower elimination rate (β). A more correct nomenclature for such multiple exponential rate constants is λ_1, λ_2, and so on, and λ_z, where these represent the rate constants for the fastest, next fastest and slowest rate, respectively. This nomenclature is receiving increasingly wide usage. The overall elimination rate (β or λ_z) or terminal half-life ($0.693/\beta$) is *not* equivalent to k_{10}; it is a composite term involving k_{10}, k_{21} and k_{12}.

The concentration in the peripheral compartment is zero initially, and then rises during the distribution phase until equilibrium is reached, following which the concentrations decrease in parallel with those in the general

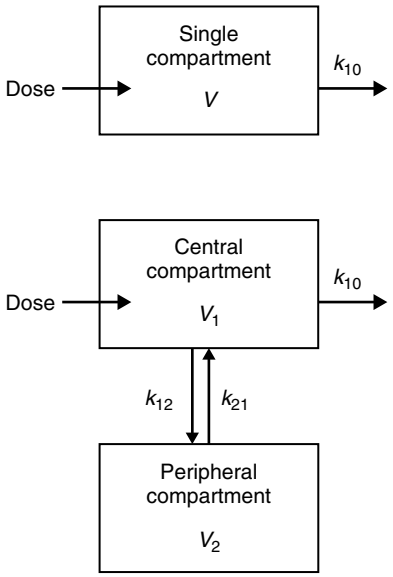

Figure 10 Simple one-compartment and two-compartment models of distribution and elimination. More complex models involving three or more compartments with elimination from both central and peripheral compartments are sometimes necessary to provide a mathematical description of the plasma concentration–time curves. (The relationships between α, β, k_{10}, k_{12} and k_{21} are given in the text; for a one-compartment system $k_{10} = k$).

circulation (**Figure 11**). The absolute concentration in the tissue will depend on the relative affinity of the blood and tissue for the compound (**Figure 6**). Tissues with different relative affinities may be part of the same peripheral compartment because this is a mathematical concept, and the only parameter that is shared is the rate of equilibrium between blood and tissue (**Figure 11**). Thus calculation of a mean concentration for the peripheral compartment is rarely of value. However, concentrations in the peripheral compartment can be predicted from a single postequilibrium measurement and knowledge of the terminal rate constant (β) in plasma.

The rate constants, α and β, and the intercepts, A and B, can be calculated by the method of residuals (**Figure 12**). The 'micro'-rate constants k_{10}, k_{12} and k_{21} can be calculated as:

$$k_{21} = \frac{A\beta + B\alpha}{A + B} \tag{13}$$

$$k_{10} = \frac{\alpha\beta}{k_{21}} \tag{14}$$

$$k_{12} = \alpha + \beta - k_{21} - k_{10} \tag{15}$$

It should be appreciated that such manipulations of derived data exaggerate any errors in the measurements. Accurate parameter estimates require that at least three to four blood samples are collected during each separate phase (e.g. α and β) and that the terminal phase is

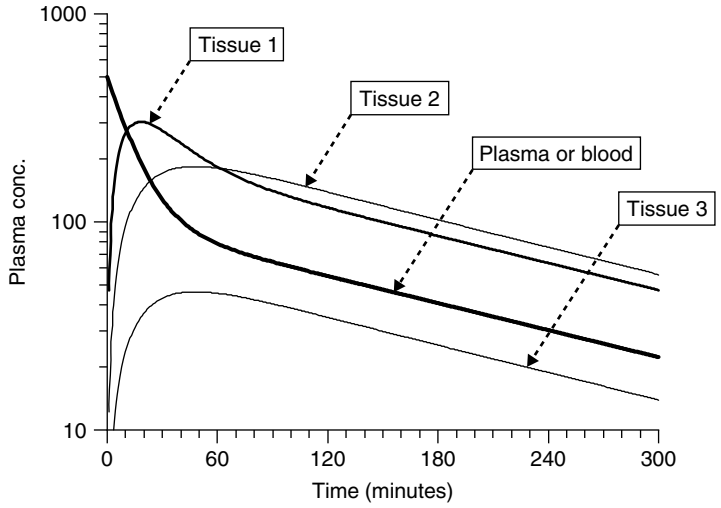

Figure 11 The concentration–time curve for a chemical in plasma (or blood) and in tissues that equilibrate rapidly (Tissue 1) or more slowly (Tissues 2 and 3) with plasma or blood. Tissue 2 shows a higher affinity than Tissue 3 but shares the same distribution rate constants; an alternative explanation for the difference is that Tissue 3 may have a highly active efflux pump on the cell membrane.

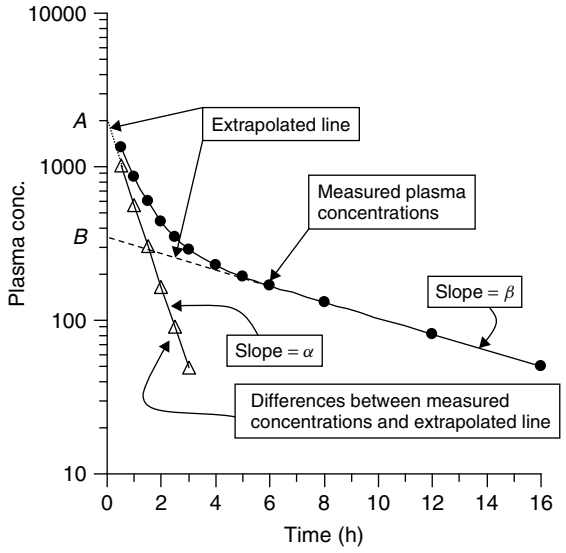

Figure 12 The use of the method of residuals to calculate distribution parameters. The terminal phase is given by $Be^{-\beta t}$ and the differences between the plasma concentrations and this line (the residuals) give the distribution phase $Ae^{-\alpha t}$.

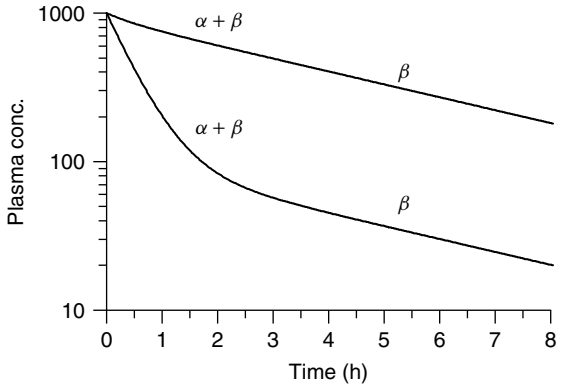

Figure 13 Plasma concentration–time curves for two compounds given as single bolus doses that have the same rate constants (α and β), but with different proportions of the dose undergoing distribution; that is, different apparent volumes of distribution. (Note—normally a higher apparent volume of distribution would result in slower elimination; see text).

followed for as long as possible and for at least two half-lives. Some compounds may require three or more exponential terms (and compartments) to provide an adequate model.

4.3.2 Extent of Distribution

The shape of the concentration–time curve following a single bolus intravenous dose is dependent on both the rate of distribution and the extent to which the dose is retained in the central compartment or distributed to the tissues (**Figure 5**). This is illustrated in **Figure 13**. In the upper line ($C_t = 100e^{-2t} + 1000e^{-0.2t}$), only one-tenth of the material is associated with distribution to the peripheral tissues ($\alpha + \beta$), and the concentration–time curve almost resembles a monoexponential decrease of slope β; the distribution phase could have been missed if the first sample had been taken at one hour, or if the assay method had a coefficient of variation greater than about 5%. In the lower line ($C_t = 1000e^{-2t} + 100e^{-0.2t}$), most of the dose undergoes distribution to the peripheral tissues (Compartment 2) and two phases are apparent,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

with distribution clearly continuing until about three hours after the dose.

The extent of distribution is characterized by the *apparent volume of distribution* (V), which can be calculated by a number of different methods. V is the parameter which relates the concentration in plasma (C) to the total body burden (Ab) with which it is in equilibrium; that is,

$$V = \frac{Ab}{C} \tag{16}$$

Thus for a one-compartment system which shows instantaneous equilibrium:

$$V = \frac{\text{dose}}{C_0} \tag{17}$$

where C_0 is the concentration at $t = 0$.

The apparent volume of distribution is the parameter which relates the total amount of chemical in the body to the plasma concentration. It can be regarded as a dilution factor and represents the volume of plasma into which the chemical appears to have dissolved.

For a two-compartment system (see **Figures 10** and **12**) the situation is more complex. dose/$(A + B)$ gives the volume of the central compartment only, because the constant A is derived prior to distribution and the attainment of equilibrium. The volume of distribution can be calculated as dose/B, but this estimate does not take into account the volume of, or amount of chemical, in the central compartment. The apparent volume of distribution usually calculated for two-compartment systems is V_β:

$$V_\beta = \frac{\text{dose}}{\text{AUC} \times \beta} \tag{18}$$

where AUC is the area under the plasma concentration–time curve between zero and infinity.

It must be emphasized that the volume of distribution is not a real volume, but is the volume of plasma (or blood if the concentration is measured in whole blood) in which the body load/burden *appears* to have dissolved. If the concentration in plasma after equilibration with all the tissues is extremely low then the apparent volume of distribution (Ab/C or dose/C_0) will be extremely high. For example, highly lipid-soluble compounds may have an apparent volume of distribution of 50 litres per kg body weight—a physiological impossibility. Thus all that the apparent volume of distribution really represents is the dilution factor between plasma concentration and body burden. It provides an indication of the extent to which the compound has left plasma and entered the tissues, but it cannot provide information on uptake into specific tissues.

If a chemical enters a tissue but is eliminated without re-entering the general circulation as the chemical itself, this is an elimination or clearance process and *does not contribute to the distribution parameters*.

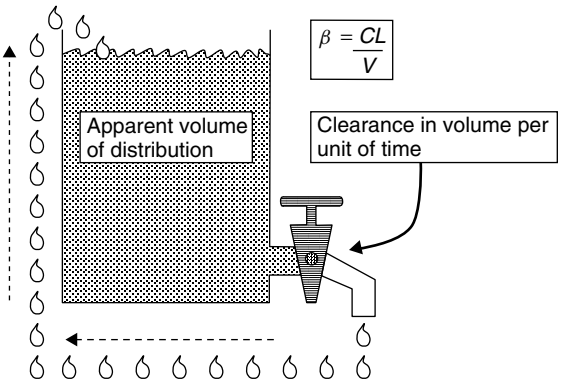

Figure 14 The relationship between apparent volume of distribution (V), clearance (CL) and overall elimination. The elimination rate constant is proportional to CL/V.

4.4 Elimination

4.4.1 Rate of Elimination

The overall rate of elimination and its associated rate constant (k or β or λ_z) depend on two independent variables. The apparent volume of distribution (V—see above) and the clearance (CL). This is illustrated in **Figure 14** by analogy to the emptying of a container of water. The rate at which the level falls in the container will be proportional to the removal (flow) through the tap (analogous to the clearance) but inversely proportional to the volume of the container (analogous to the apparent volume of distribution); that is

$$\text{rate} \propto \frac{CL}{V} \tag{19}$$

4.4.2 Clearance

A clearance process is one in which the chemical is removed permanently from the circulation, that is, by metabolism or excretion. Clearance is defined as: *the volume of blood (or plasma) cleared of chemical per unit time*. Thus, on passage through an organ of elimination the blood can be cleared of the compound, either totally or partially. The extent of uptake and removal is indicated by the decrease in concentration in the blood leaving the organ via the vein (C_v) compared with that entering via the artery (C_a). (The decrease must be due to removal, not simply distribution, which is reversible, and therefore such measurements are usually made at steady state—see later). The removal by the organ is usually expressed as

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the *extraction ratio* (*ER*).

$$ER = \frac{(C_a - C_v)}{C_a} \tag{20}$$

If all of the chemical is removed then $C_v = 0$ and $ER = 1.0$, whereas if only 10% of the arterial concentration is removed $C_v = 0.9$ and $ER = 0.1$. If *ER* approaches 1.0 then all of the blood that flows through the organ of elimination will be cleared of the chemical, and the clearance (*CL*) will equal the blood (or plasma) flow through the organ (Q). If the extraction ratio is 0.1 then only one-tenth of the organ blood flow will be cleared of the chemical, which results in the relationship:

$$CL = Q \times ER \tag{21}$$

The physiological significance of this is that the most important toxicokinetic parameter (*CL*) can be related to the blood flow to the organ of elimination (Q) and the capacity of the organs to extract the chemical (*ER*) and to remove it from the body (e.g. by metabolism). These processes are the basis for developing physiologically based pharmacokinetic (PBPK) models (see **Physiologically Based Pharmacokinetic Modelling**).

If a compound has a very high extraction ratio, then changes in organ blood flow will not significantly affect the extraction efficiency of the organ, and consequently clearance will be dependent on, and directly proportional to, the organ blood flow. If the extraction ratio is low then uptake or extraction by the organ is dependent on the time available for uptake, that is, the slower the organ blood flow (Q), the greater will be the extraction ratio (*ER*). Thus, a change in Q results in an opposite change in *ER* so that *CL* remains relatively constant and independent of organ blood flow.

There are mathematical models which characterize the relationship between *CL*, Q and *ER* (see Wilkinson, 1976). In the context of the present chapter, the importance of this relationship is that if the doses of the chemical given to animals are sufficient to alter organ perfusion, then this could influence the clearance of the chemical if it has a high extraction ratio.

The clearance (*CL*) of a chemical is perhaps the single most important pharmacokinetic parameter because it relates to the ability of the organs of elimination to remove the chemical from the body. It is defined as:

$$CL = \frac{\text{rate of elimination of the chemical}}{\text{plasma concentration}}$$

$$\text{e.g.} \quad \frac{\mu\text{g min}^{-1}}{\mu\text{g ml}^{-1}} \quad \text{or} \quad \text{ml min}^{-1} \tag{22}$$

For first-order reactions the rate of elimination at any point in the plasma concentration–time curve (see **Figure 7**) is directly proportional to the plasma concentration because *CL* is constant. The units of *CL* are volume × time^{-1} (e.g. ml min^{-1}), and clearance represents the volume of plasma (or blood if concentrations are measured in whole blood) cleared of compound per unit time. The plasma clearance, *CL,* represents the sum of all individual clearance processes such as metabolism (CL_M), renal excretion (CL_R), biliary excretion (CL_B), and so on.

$$CL = CL_M + CL_R + CL_B + \ldots \tag{23}$$

Plasma clearance is usually calculated from the dose that enters the systemic circulation and the area under the plasma concentration–time curve (AUC):

$$CL = \frac{\text{dose}}{\text{AUC}} \tag{24}$$

For this equation to be valid both the dose and AUC need to be defined properly.

4.4.2.1 Dose

Because *CL* relates to the capacity of the body to eliminate the chemical, the dose has to be fully available to the organs of elimination. Thus *CL* is calculated from the data following an *intravenous dose*, which can be given either as a bolus or as a slow infusion. If the dose is given orally then the true dose available to the organs of elimination is ($F \times$ dose administered) where F is the bioavailability, that is

$$CL = \frac{\text{dose}_{iv}}{\text{AUC}_{iv}} = \frac{\text{dose}_{oral} \times F}{\text{AUC}_{oral}} \tag{25}$$

Rearrangement of the above equation shows how the bioavailability can be calculated from AUC data, and also explains why this calculation assumes that *CL* is a constant for the two different routes:

$$F = \frac{\text{AUC}_{oral} \times \text{dose}_{iv}}{\text{dose}_{oral} \times \text{AUC}_{iv}} \tag{26}$$

It is common in papers to see a parameter termed 'oral clearance', which is $\text{dose}_{oral}/\text{AUC}_{oral}$: in reality this parameter is *CL/F*, and is of limited value because it depends on two variables, either of which could be influenced by physiological changes.

4.4.2.2 AUC

The AUC can be calculated by the trapezoidal rule between time zero and the last measured concentration, but needs to be extrapolated to infinity (see above) if the calculation of *CL* is to be valid. Consequently, it is essential for the samples to be collected until a loglinear decrease is defined clearly. The AUC can also be derived by fitting a suitable model to the data and calculating the AUC from the derived parameters; for example, $\text{AUC} = C_0/k$ or $\text{AUC} = A/\alpha + B/\beta$.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.4.3 Relationship of Clearance to Half-Life

The relationship between clearance, the terminal slope and the apparent volume of distribution can be derived from the simple definition of clearance. *CL* is the rate of elimination from the body divided by the plasma concentration; the rate of elimination from the body at any time (t) is the elimination rate constant (k) times the body burden ($V \times C_t$) and therefore:

$$CL = \frac{k \times V \times C_t}{C_t} = kV \tag{27}$$

or

$$k = \frac{CL}{V} \quad \text{and} \quad t_{1/2} = \frac{0.693V}{CL} \tag{28}$$

For a two-compartment system:

$$\beta = \frac{CL}{V_\beta} \quad \text{and} \quad t_{1/2} = \frac{0.693V_\beta}{CL} \tag{29}$$

This equation shows that the terminal elimination rate constant (k or β) is a composite parameter which is dependent on *two independent, physiological variables*; that is, *CL*, which reflects the rate of extraction and removal from blood, and $1/V$, which reflects the amount of chemical remaining in the blood and available for clearance. This inter-relationship between *CL*, *V* and $t_{1/2}$ assumes that first-order kinetics apply, that is, that the chemical does not show dose-dependent kinetics.

Renal clearance (CL_R) is the only specific clearance term that can be measured easily. CL_R may be defined as:

$$CL_R = \frac{\text{rate of elimination in urine (as the parent compound)}}{\text{concentration in plasma}} \tag{30}$$

The rate of elimination in urine can be calculated by measuring the concentration of the chemical (C_u) in the volume of urine (V_u) produced in a known time interval (Δt). If the concentration in plasma at the midpoint of the urine collection (C_{mid}) is known, then CL_R can be calculated as:

$$CL_R = \frac{C_u \times V_u}{\Delta t} \times \frac{1}{C_{mid}} \tag{31}$$

This equation can be rearranged because ($C_u \times V_u$) equals the total amount excreted (A_{ex}) over the time interval Δt, and the product ($\delta t \times C_{mid}$) is the AUC of the plasma concentration–time curve for the time interval Δt. Therefore CL_R may be calculated also from plasma AUC data and the amount excreted unchanged (A_{ex}) over the same time interval.

$$CL_R = \frac{A_{ex0-t}}{AUC_{0-t}} \tag{32}$$

CL_R is a constant for first-order reactions, and therefore the rate of excretion at any time will be proportional to the plasma concentration. Therefore the decrease in excretion rate with time will mirror the decrease in plasma concentration. Thus a graph of the natural log of the excretion rate vs. time will give a rate constant and half-life the same as those derived from plasma; therefore the terminal half-life can be calculated from serial timed urine collections without taking blood samples. Alternatively, the half-life can be calculated from the amount remaining to be excreted using the sigma-minus method (see under trans-species comparisons, below). (It is not possible to derive total plasma clearance (*CL*), renal clearance (CL_R) or the apparent volume of distribution (V) without taking blood samples.)

Metabolic clearance (CL_M) cannot be measured readily, but metabolism and renal excretion are the two principal routes of total clearance (*CL*) in many cases, and it can be assumed that:

$$CL = CL_M + CL_R \tag{33}$$

$$CL_M = CL - CL_R \tag{34}$$

$$CL_M = \frac{\text{dose}}{\text{AUC}} - \frac{\text{amount excretion unchanged}}{\text{AUC}} \tag{35}$$

$$CL_M = \frac{(\text{dose} - \text{amount excreted unchanged})}{\text{AUC}} \tag{36}$$

5 THE INTERPRETATION OF CHRONIC HIGH-DOSE ANIMAL FEEDING STUDIES

In many cases regulatory decisions use data from chronic high-dose animal feeding studies to predict possible risk for humans. However, chronic high-dose treatments can lead to changes in clearance and accumulation that would not be anticipated from single-dose studies.

5.1 Chronic Intake

During chronic intake the concentration of the chemical rises in the plasma and tissues as illustrated in **Figure 15**. Both of the hypothetical compounds shown in **Figure 15** exhibit rapid absorption and one-compartment kinetics with similar apparent volumes of distribution; therefore, the 12-fold difference in the elimination rate constant arises from a 12-fold difference in clearance. The compound in **Figure 15** with a half-life of 3 hours shows negligible concentrations remaining at 24 hours when the next dose is given. In contrast, at 24 hours the concentration of the compound with a half-life of 36 hours is about 60% of the peak value, so that there is marked accumulation with successive doses. Eventually a steady

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

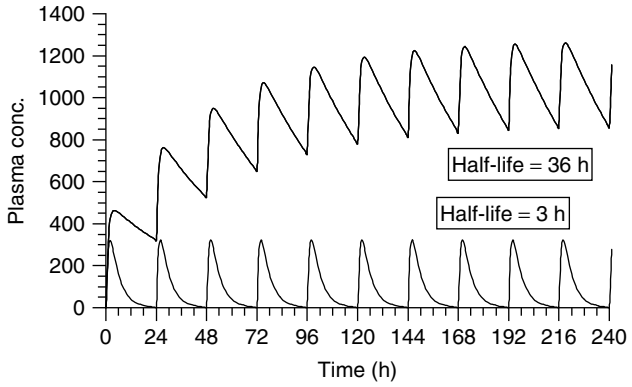

Figure 15 The accumulation of chemicals during chronic intake. In the two examples shown the compounds are given as single oral doses every 24 hours. Both compounds exhibit rapid absorption and one-compartment characteristics with monoexponential decreases (i.e. $C_t = C_0 e^{-kt}$).

state will be reached in which the rate of elimination per 24 hours equals the rate of administration, that is

$$\text{rate of input} = \text{rate of elimination} \tag{37}$$

$$\frac{D \times F}{T} = CL \times C_{ss} \quad \text{or} \quad C_{ss} = \frac{D \times F}{T \times CL} \tag{38}$$

where

D = dose administered
F = bioavailability
T = dose interval
CL = clearance, and
C_{ss} = average plasma concentration at steady state.

These determinants of C_{ss} can be deduced intuitively because C_{ss} is directly proportional to dose given and the fraction absorbed, and inversely proportional to the interval between successive doses or the ability of the organism to eliminate the chemical. It is important to note that the apparent volume of distribution (V) is not included in the equation for the average plasma concentration at steady state because at steady state the tissues and plasma are in equilibrium (see the discussion of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) later).

This equation is based on the definition of clearance (CL = rate of elimination/C) applied to the steady-state condition when the rate of elimination exactly equals the rate of administration. Thus steady-state data can be used to calculate the value of CL for intravenous data or CL/F for oral data, that is

$$CL = \frac{D \times F}{T \times C_{ss}} \tag{39}$$

$T \times C_{ss}$ is the AUC for a dose interval at steady state ($0-T$), so that this equation can also be written as:

$$CL = \frac{D \times F}{\text{AUC}_{0-T}} \tag{40}$$

This can be compared with the measurement of CL after a single dose using the AUC from time zero to infinity, where

$$CL = \frac{D \times F}{\text{AUC}_{0-\infty}} \tag{41}$$

These relationships allow the AUC_{0-T} at steady state, and the average steady-state concentration (C_{ss}) to be calculated from the $\text{AUC}_{0-\infty}$ for a single dose:

$$\text{AUC}_{0-T}(\text{steady state}) = \text{AUC}_{0-\infty}(\text{single dose}) \tag{42}$$

$$C_{ss} = \frac{\text{AUC}_{0-\infty}}{T}(\text{single dose}) \tag{43}$$

The relationship between $\text{AUC}_{0-\infty}$ (single dose) and AUC_{0-T} (steady state) is illustrated in **Figure 16**. *The AUC for a dose interval at steady state is the best estimate of chronic exposure to the chemical* and can be determined without fitting any specific model to the data. If AUC_{0-T} (steady state) is measured and does not equal $\text{AUC}_{0-\infty}$ (single dose), then the most likely explanation is a change in clearance on repeated dosage (see later).

The increase to steady state for a compound which shows a simple monoexponential decline after an intravenous bolus dose is an inversion of the elimination phase, that is, the percentage of steady state achieved after administration for 1, 2, 3, 4 and 5 half-lives is 50, 75, 87.5, 93.75, 96.875% of the steady-state concentration (C_{ss}) or body burden ($C_{ss} \times V$). Thus it takes approximately four to five times the elimination (terminal) half-life to approach steady state. **Figure 17** shows that the rate of accumulation is directly proportional to the elimination half-life and also that the plasma concentration and therefore body burden is directly proportional to the daily dose.

The octachloro analogue of TCDD (OCDD, octachlorodibenzo-*p*-dioxin) is 100–1000 times less potent than TCDD (Couture *et al.*, 1988), but its elimination half-life in rats of three to five months is about four times higher than that of TCDD, so that even greater accumulation is possible (Birnbaum and Couture, 1988). For compounds with such long half-lives, steady state will not have been reached at the end of a 13 week study (**Figure 17**). In addition, if there

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

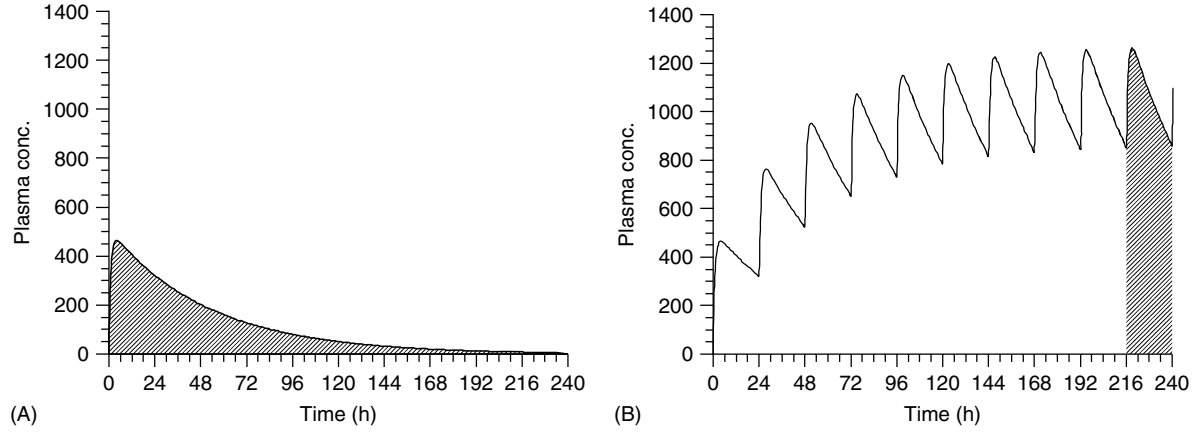

Figure 16 The relationship between $AUC_{0-\infty}$ for a single dose (A) and AUC_{0-T} for a dose interval at steady state (B). The AUC values are the same unless bioavailability or clearance of the chemical changes with repeated dosage.

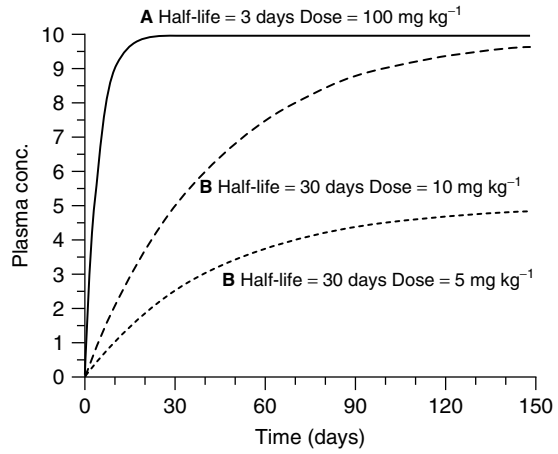

Figure 17 The effect of elimination half-life and dosage on the accumulation of a chemical during repeated dosage. (For clarity each compound is shown as being given by a continuous intravenous infusion.) The compounds have similar apparent volumes of distribution but the clearance of A is 10 times greater than that of B, so that its half-life is 10 times lower. Thus, daily intakes of 100 mg kg^{-1} of A and 10 mg kg^{-1} of B will give similar average steady-state concentrations, while a dose of 5 mg kg^{-1} of B will give an average steady-state concentration one-half of that at a dose of 10 mg kg^{-1} day^{-1}.

Table 4 The use of single-dose data to predict the time for development of steady state

The plasma concentration–time curve data are for a single dose of saccharin given orally to a human volunteer (data from Sweatman *et al*., 1981).
C—concentration in plasma, AUC_{0-t}—area under concentration–time curve to the time of the plasma sample, and % ss—percentage of steady state $AUC_{0-t}/AUC_{0-\infty} \times 100$.

is a minimum body burden or plasma concentration necessary for toxicity this may have been reached only a short while before sacrifice. Clearly the interpretation of data from 'short-term' studies should take into account the half-life of the compound, since a 90 day study may be a steady-state study for some compounds but not for others.

For a compound which shows a more complex plasma concentration–time curve (**Table 4**), for example, oral administration of a slowly absorbed compound like saccharin, the percentage of steady state at any time (t) can be calculated from single-dose data as ($AUC_{0-t}/AUC_{0-\infty} \times 100$). Thus the time to steady state can be assessed without the fitting of any model (**Figure 18**).

'Steady state' will be reached within the first 24 hours of regular dosing for compounds which have a half-life of 6 hours or less. However, there will be large diurnal variations in concentration as illustrated in **Figure 15**,

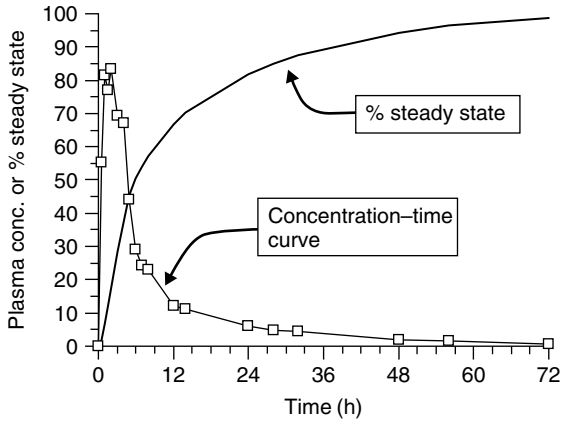

Figure 18 The relationship between single-dose kinetics and the development of steady state during chronic administration. The percentage of steady state at any time is: the AUC to that time, divided by the AUC to infinity times 100 (data from **Table 4**—except that the plasma concentrations have been multiplied by 5 to fit on the same axis as the % steady state).

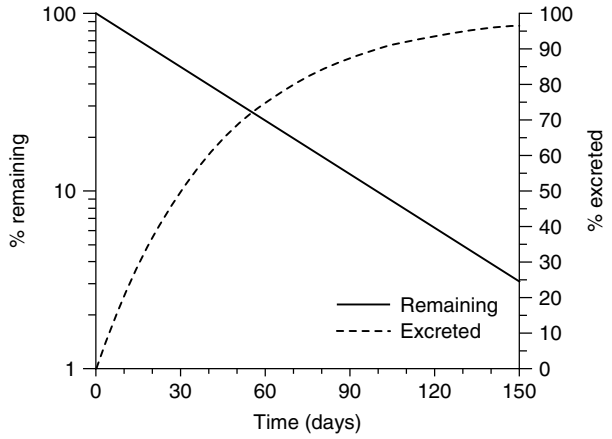

Figure 19 The calculation of the elimination rate constant from the cumulative elimination of the compound (see **Table 5** for data). This analysis assumes that either the parent compound is excreted unchanged or that the formation of metabolites is the rate-limiting step.

where the half-life of one of the compounds is only three hours. Compounds which have long half-lives will accumulate during chronic intake but show less interdose fluctuation.

The slow elimination of compounds such as TCDD allows the half-life to be calculated from the total amount of radioactivity recovered in urine and faeces each day using an adaptation of the *sigma minus method* (Gibaldi and Perrier, 1982). This method is based on measurements of the excretion of the parent compound until no more can be detected in the urine (and/or faeces). For each collection time interval the amount remaining to be excreted is calculated as: the amount excreted as parent compound to infinity minus the amount excreted up to that time; a plot of the natural log of the amount remaining to be excreted against the time at the end of the collection interval will have a slope of $-\beta$ (or $-\lambda_z$), with an intercept of the natural log of the total amount excreted unchanged. This method is applicable even in cases where excretion of the parent compound is not the major route of elimination, because the amount of parent compound excreted at any time is proportional to the plasma concentration (C) and therefore the body burden (V times C) of parent compound at that time. In the case of TCDD, the 'body burden' of TCDD remaining after each day was calculated as: dose administered minus total ^{14}C recovered in excreta to that time (**Table 5**). A plot of the natural log of the body burden vs. time was used to calculate the elimination half-life (**Figure 19**). This approach is particularly useful for calculating the elimination kinetics of compounds that are eliminated very slowly, and also has the advantage of being noninvasive. It should be appreciated that in studies on slowly eliminated lipid-soluble compounds, the radioactivity detected in the excreta may be present partly as metabolites. Under such circumstances the sigma-minus method using excretion of total ^{14}C is only valid if the body burden is as parent compound, and the metabolites, once formed, are eliminated rapidly; that is, the rate-limiting step is the initial metabolism of the parent compound.

5.2 Dose-Dependent Kinetics

A nonlinear relationship between dose and area under the plasma concentration–time curve is indicative of *dose-dependent* or *nonlinear* kinetics; in other words the compound does not obey first-order kinetics at high doses. Nonlinear kinetics can arise whenever an interaction between the chemical and a body constituent is saturated by the presence of excess chemical (**Table 6**).

Nonlinear kinetics can be detected by studying a range of single doses, but frequently nonlinearity is detected during chronic administration when the accumulation of the compound causes saturation. If saturation of elimination occurs during chronic administration, then the clearance will be reduced and the area under curve (AUC) for a dose interval will be increased. Evidence of saturation of elimination is that the AUC for a dose interval at steady state exceeds the AUC to infinity of a single dose.

Sometimes chronic administration results in the induction of the enzymes which are responsible for foreign-compound elimination. When this happens, the clearance will be increased during chronic administration, and therefore the AUC for a dose interval will be reduced, compared with the AUC to infinity of a single dose.

Table 5 Calculation of elimination rate constant by the sigma-minus method

	% dose excreted (as parent compound plus metabolites)				
Time (d)	Urine	Faeces	Total	Cumulative total	Amount remaining
0	0.0	0.0	0.0	0.0	100.0
2	1.8	2.7	4.5	4.5	95.5
4	1.7	2.6	4.3	8.8	91.2
6	1.6	2.5	4.1	12.9	87.1
8	1.6	2.4	4.0	16.9	83.1
10	1.5	2.2	3.7	20.6	79.4
15	3.5	5.2	8.7	29.3	70.7
20	3.1	4.6	7.7	37.0	63.0
25	2.8	4.1	6.9	43.9	56.1
30	2.4	3.7	6.1	50.0	50.0
40	4.1	6.2	10.3	60.3	39.7
50	3.3	4.9	8.2	68.5	31.5
60	2.6	3.9	6.5	75.0	25.0
70	2.0	3.1	5.1	80.1	19.8
80	1.6	2.5	4.1	84.2	15.8
100	2.4	3.5	5.9	90.1	9.9
120	1.4	2.2	3.6	93.7	6.3
150	1.3	1.9	3.2	96.9	3.1

The data are for the excretion of a compound which is eliminated slowly by both urine and faeces with approximately 60% of the dose excreted in faeces and 40% in urine. The method assumes that the elimination of metabolites is formation rate limited and that there is no accumulation of metabolites.
Time—time at the end of the sequential collection intervals (e.g. 2 = 0–2; 30 = 25–30 and 150 = 120–150).

Table 6 Possible sources of dose-dependent or nonlinear kinetics

Site	Mechanism	Consequences at high dose
Absorption	Dissolution	Elimination of undissolved chemical in faeces; decrease in *F*.
	Active uptake	Saturation of transport; delayed uptake, decrease in *F*.
	First-pass metabolism	Increase in *F*.
	Efflux transporter	Increase in *F*.
Distribution	Plasma protein binding	Increased availability to tissues; increase in *V*; increase in $t_{1/2}$.
	Tissue protein binding	Increased retention in plasma; decrease in *V*; decrease in $t_{1/2}$.
Metabolism	Saturation by substrate or cofactor depletion or product inhibition	Increase in AUC; decrease in clearance; increase in terminal half-life possible (e.g. cofactor depletion); increased renal excretion of parent compound; increased metabolism by alternative unsaturated pathways.
Excretion	Saturation of renal tubular secretion	Increase in AUC; decrease in renal clearance; terminal half-life often increased; increased metabolism.
Cardiac output	Decreased organ perfusion due to cardiovascular toxicity	Slower distribution; increase in AUC and decrease in clearance for compounds showing high renal or hepatic (metabolic) clearance, that is, high extraction ratio.

It should be appreciated that age-related changes in physiological processes, such as hepatic and renal blood flow, will occur during lifetime feeding studies. Dietary intake in g per kg body weight changes during the lifetime of an animal, and this will also affect the plasma concentrations and body burdens of chemicals given in the diet. Therefore it is possible that steady-state concentrations during a chronic bioassay may be age dependent. The basic equation for average steady-state concentration (C_{ss}) still applies; that is

$$C_{ss} = \frac{\text{dose} \times F}{CL \times T} \tag{44}$$

Metabolic and physiological processes, such as renal blood flow, are immature in neonatal animals and humans (Blumer, 1990; Dorne *et al.*, 2004; 2005) and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

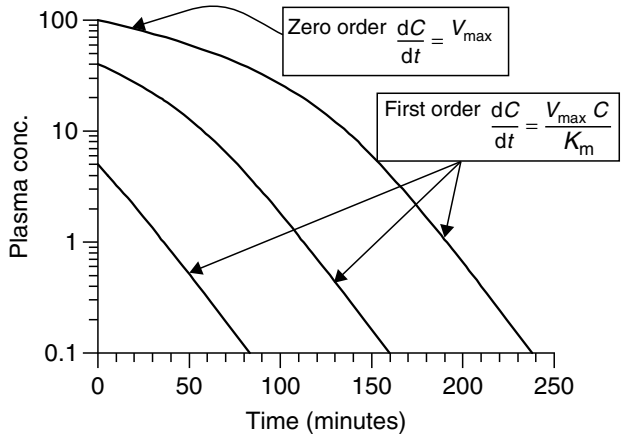

Figure 20 Plasma concentration–time curve for a compound showing saturation kinetics, given at doses sufficient to give initial plasma concentrations of 5, 40 and 100 units. The compound is eliminated by a single saturable pathway, which has K_m = 20 units and V_{max} = 1 unit per minute.

clearances may be lower than in mature individuals. The neonatal phase of a two-generation protocol may result in excessively high plasma concentrations of compounds fed in the diet due to the lower clearance, and also because of enhanced intake due to the higher food consumption in neonates (per g body weight). In ageing animals, C_{ss} may increase due to an age-related decrease in clearance, but in dietary studies to some extent this will be compensated for by a decrease in food consumption.

If saturation of elimination is detected on giving increasing single doses, this is usually seen as delayed elimination at high plasma concentrations, but with the normal rate of elimination once the concentration decreases and first-order kinetics apply (**Figure 20**). Under such circumstances the compound is said to obey Michaelis–Menten kinetics, that is:

$$\frac{-dC}{dt} = \frac{V_{max} \times C}{(K_m + C)}$$

$$\text{where} \quad \frac{dC}{dt} = \text{rate of change of concentration} \tag{45}$$

V_{max} = maximum rate of the enzyme (or transport), K_m = Michaelis constant of the enzyme (affinity constant), and C = concentration available to the enzyme.

At low concentrations $K_m \gg C, \therefore (K_m + C)$ approximates to K_m

$$\frac{-dC}{dt} = \frac{V_{max} \times C}{K_m} = \text{constant} \times C$$
$$= \text{first-order reaction} \tag{46}$$

At high concentrations $C \gg K_m, \therefore (K_m + C)$ approximates to C

$$\frac{-dC}{dt} = \frac{V_{max} \times C}{C} = V_{max} = \text{zero-order reaction} \tag{47}$$

(see **Figure 7**).

The true elimination half-life is measured when concentrations are very low, and therefore is not dose dependent (see **Figure 20**). However, the measured half-life may indicate the possibility of saturation of elimination if the concentration–time curve is not followed for long enough; for example, if measurements had been made for only 50 minutes after each dose in **Figure 20**.

The best indication of dose-dependent elimination is calculation of the clearance as the ratio of dose/AUC to infinity. This is illustrated in **Figure 20**. The initial plasma concentration (C_0) is dependent only on the dose and the apparent volume of distribution (V) (C_0 = dose/V). If linear kinetics had applied to all three doses then there would have been parallel decreases from time zero. It is clear that the slower initial elimination of the higher doses shifts these curves to the right and therefore results in higher AUCs, despite the similar terminal slopes.

A compound which shows nonlinear toxicokinetics similar to those depicted in **Figure 20** is the solvent 1,4-dioxane (Dietz *et al.*, 1982), for which an increase in intravenous dose in rats from 3 mg kg^{-1} to 1000 mg kg^{-1} (333-fold) caused a 4439-fold increase in AUC. The disproportionate increase in AUC of dioxane at high doses was associated with a decrease in the urinary excretion of the metabolite β-hydroxyethoxyacetic acid and an increase in the elimination of the solvent *per se* in the expired air.

Dose-dependent kinetics can arise from the saturation of a number of protein–chemical interactions (**Table 6**). Therefore nonlinear relationships can produce a range of different changes to the plasma concentration–time profile. A number of different approaches can be taken to demonstrate dose-dependent kinetics, for example

1. Divide the plasma concentration for each time point by the dose and plot the resulting dose-adjusted data. For purely linear and first-order processes the adjusted data will be superimposable. A consistent dose-dependent deviation indicates that nonlinearity is present but does not indicate the reason.
2. Fit a common model to the data for each dose and evaluate systematic changes in parameter estimates.
3. Measure metabolite formation either in plasma or urine. A dose-dependent change in the ratio of the AUC for the parent compound to the AUC of the metabolite (or % dose in urine) would indicate saturation of metabolism.
4. Measure tissue to plasma ratios for a range of doses to detect saturation of protein binding in either plasma or tissue.

6 THE USE OF TOXICOKINETICS IN RISK ASSESSMENT

6.1 Trans-Species Comparisons

The use of animal data to predict potential risks to humans, or to establish safe exposure levels, is based on the assumption that both the toxicodynamics and the toxicokinetics in animals are relevant to humans. There are wide differences between different animal species and between animals and humans in physiological processes, such as organ perfusion rates and in biochemical processes such as the enzymes of foreign-compound metabolism. In consequence, all extrapolations from animals to man must take into account differences in toxicokinetics.

There are two principal methods by which interspecies extrapolations may be made—*allometry* and *PBPK models*. The basis of both methods is that there are underlying similarities between mammalian species in the various processes involved in toxicokinetics. For example, the intestine contains similar digestive enzymes and provides a large surface area for absorption via microvilli, the compositions of blood and body tissues are similar across species with respect to fat and protein content so that tissue distribution should be similar, and the perfusion of the organs of elimination and the basic metabolic and excretory processes within these organs are similar. Thus, reasonable estimates of human pharmacokinetic parameters should be derived from animal data after allowing for differences in body weight, cardiac output, and so on (Poggesi, 2004). It should be emphasized that there are bound to be examples where major species differences exist, for example, in specific pathways of metabolism, which mean that chemical-specific toxicokinetic data are essential (see risk assessment below).

6.1.1 Allometry

Allometry is a mathematical extrapolation based on the body weight of an animal (Calder, 1981). Thus the value of any parameter (P) is related to the average body weight (W) of the species by an equation with two unknown variables:

$$P = aW^x \tag{48}$$

If the parameter estimate P is known in two or more species, then its value in a third species can be deduced from a simple regression equation of log P against log W. Interspecies comparisons of caffeine pharmacokinetics (Bonati *et al*., 1985) showed that the apparent volume of distribution was linearly related to body weight (i.e. $V = 0.79\ W^{1.00}$), whereas the plasma clearance (CL) showed a loglinear relationship (i.e. $CL = 6.26W^{0.739}$); the power term for clearance was similar to that for liver weight (L) (i.e. $L = 0.037W^{0.845}$).

Boxenbaum (1984) provided useful background information on the origins of allometry in pharmacokinetic scaling and extended this method by the use of Dedrick plots in which plasma concentration–time curves in different species can be made superimposable if the concentration is corrected for dose (e.g. $\mu g\ ml^{-1}$ per mg kg^{-1}) and the time is corrected for body weight (e.g. min $kg^{-0.25}$). The idea behind this latter correction is conversion to 'physiological time' which in effect relates body weight to the lifespan of the animal.

Bachmann (1989) applied allometry to the pharmacokinetics for a number of drugs in laboratory animals and humans; for each drug there was a linear relationship between the log of the apparent volumes of distribution and the log of body weights, with correlation coefficients >0.95. The log of the clearance was not as closely related to the log of the body weight unless multiplied by the maximum lifespan potential (MLP) for each species.

6.1.2 Physiologically Based Pharmacokinetic (PBPK) or Physiologically Based Toxicokinetic (PBTK) Modelling

An alternative and more scientifically sound approach is the use of physiologically based pharmacokinetic (PBPK) or toxicokinetic (PBTK) modelling (Gerlowski and Jain, 1983; Chiu *et al*., 2007; Clewell and Clewell, 2008). The basis of the method is that each major organ system, plus any specialized sites such as targets for toxicity, is taken as representing a physiological compartment. Each separate compartment has its own blood flow, tissue volume, uptake process, affinity for the compound (i.e. partition coefficient) and elimination process as appropriate (**Figure 21**). The kinetics of the compound are described by a series of flow-related equations, which can be solved following the incorporation of known physiological values (blood flows and tissue volume/mass) and experimental estimates (partition coefficients and protein binding). The main application of the technique is that species differences can be predicted based on known differences in physiological parameters. In cases where an important physiological value is not known for a species, the missing information can be derived by allometry (see above) from species in which the values are known. Additional advantages of this technique are that it allows an assessment of the impact of altered physiology, such as ageing (Ginsberg *et al*., 2004) and renal function, on the toxicokinetics and target organ exposure, and that data from human studies, such as enzyme activities, including information on human variability (Price *et al*., 2003) can be incorporated directly into the model.

A distinct advantage of PBTK modelling is its ability to incorporate both *in vitro* enzyme activity data and *in*

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

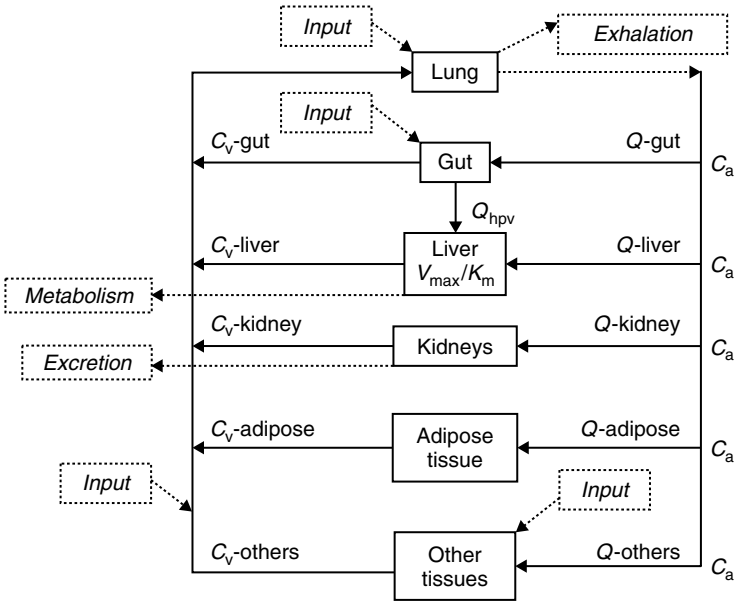

Figure 21 A physiologically based pharmacokinetic model. The rate of delivery to an organ such as muscle is given by the blood flow (Q) times the arterial concentration (C_a). The rate of removal from the organ is blood flow (Q) times the venous concentration (C_v). Input functions and output functions can be first-order or Michaelis–Menten reactions. More complex models have been used, incorporating specific targets, such as bone marrow, or additional routes such as transdermal, in which case the skin becomes a discrete compartment. hpv—hepatic portal vein.

vivo organ blood flows to produce a composite model, which can avoid misleading conclusions. For example, the rate of bioactivation of furan was similar and very high in both mice and humans; but these high rates of metabolism would not be apparent *in vivo*, because they greatly exceeded the rate of liver perfusion (Kedderis and Held, 1996). In consequence the species difference in bioactivation in the PBPK model was determined largely by liver blood flow and not the difference in enzyme activity.

Both physiologically based models and allometry can be of value to regulatory safety assessments (Scheuplein *et al*., 1990; Thompson *et al*., 2008). For example, PBTK models have been applied to the regulatory risk assessment of trichloroethene (Bogen, 1988), tetrachloroethene (Clewell *et al*., 2005) and 1,1,1-trichloroethane (Bogen and Hall, 1989), while both allometry (Beliles and Totman, 1989) and physiological models (Travis *et al*., 1990) have been used to extrapolate data on benzene from rodents to humans. Physiologically based models are far more flexible than allometry, and more complex situations, such as exposure during lactation (Fisher *et al*., 1990), can be taken into account. A more comprehensive risk assessment has been made for acrylamide that incorporated exposure and physiologically based toxicokinetic–toxicodynamic modelling (Doerge *et al*., 2008).

6.2 Approaches to Risk Assessment

Assessments of the risks for humans of exposure to chemicals are usually based on hazards identified in animal experiments, and the associated dose–response curves for the effect. There are various approaches adopted by regulatory bodies for establishing 'acceptable', 'tolerable' or 'virtually safe' exposures for humans.

6.2.1 Low-Dose Risk Extrapolation

This approach is usually restricted to effects for which there may not be a biological threshold in the dose–response relationship, such as genotoxic carcinogenicity. For other effects it is generally considered that there is no significant adverse biological response until homeostatic mechanisms have been exceeded, so that low exposure does not provoke any effect.

The method is based on extrapolation from the incidence in the experimental dose–response range in animals down to a predefined negligible risk (10^{-5} or 10^{-6}), which is also known as the virtually safe dose. This process essentially defines a negligible risk in animals, unless interspecies differences are taken into account. The approach can be improved by the incorporation of toxicokinetic data, usually in the form of PBPK modelling (Krishnan and Johanson, 2005), to correct the external dose in the experimental animals to a target-organ dose, and then to estimate the target-organ dose in humans in relation to exposure. However, such

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

toxicokinetic refinements have not altered the vast uncertainties inherent in extrapolating over at least four orders of magnitude away from the dose–response data. The outcomes of such extrapolations are determined largely by the model selected rather than the biological data or its toxicokinetic refinement.

6.2.2 Margin of Exposure (MOE)

This approach compares the doses in animals associated with toxicity, and those in humans, and is usually applied to occupational and environmental exposures. It is the ratio of a reference point or point of departure on the animal dose–response relationship, such as the benchmark dose lower limit (BMDL10) (European Food Safety Authority, 2005) with the estimated human exposure. The adequacy of the margin of exposure (MOE) is then assessed based on the nature of the exposed human groups, the duration of exposure and the nature of the hazard.

The MOE does not provide an estimate of the risk; the only conclusion possible is that the greater the MOE, the lower the risk (Barlow *et al*., 2006); but it is useful for comparisons of the risks associated with human exposures to different chemicals—providing that the reference point and exposure estimates are based on the same methods. Again PBTK modelling can be used to refine the interspecies comparison by the calculation of internal or target-organ doses in animals and exposed humans, but this would prevent comparisons of the derived MOE with the MOEs for compounds for which a PBTK model had not been used.

The MOE can also be compared with the safety factor of 100, which is used traditionally for noncancer end points (see below), although any difference between the reference point and the traditional no-observed-adverse-effect level (NOAEL) (see below) would have to be taken into account.

6.2.3 Safety Assurance Procedures

This approach is generally adopted for nongenotoxic compounds which have undergone toxicity testing before approval and prior to human exposures (so that an MOE cannot be calculated). For some chemicals, such as medicines, the approval can be based on a risk–benefit analysis because of the clear benefit to the 'consumer'. However, for other chemicals such as food additives and pesticides, there are no direct health benefits to the consumer to offset against any possible health risk. Therefore, the establishment of a 'safe dose' in animals, and interspecies extrapolation to give a 'safe dose' in humans is of critical importance. (It should be recognized that there is no such thing as absolute safety, and it is impossible to prove the absence of any phenomenon—including toxicity. Hence there are established guidelines for the conduct of toxicity studies which are designed to ensure that the absence of any adverse affects does not arise from inadequacies in the study.)

The 'safe dose' in animals is the NOAEL (expressed as mg kg^{-1} body weight per day), and this is converted to the 'safe dose' for humans by dividing by a large safety (uncertainty) factor. The 'safe dose' for humans is usually described as the acceptable daily intake (ADI), reference dose (RfD), tolerable daily intake (TDI) or provisional tolerable weekly intake (PTWI). This is the approach adopted by bodies such as the WHO/FAO (World Health Organization and Food and Agriculture Organization) Joint Expert Committee on Food Additives (JECFA; see WHO, 1987), the EFSA (European Food Safety Authority) and the US EPA (US Environmental Protection Agency).

Normally a 100-fold factor is used when the NOAEL is based on animal data, and a 10-fold factor is used when the NOAEL is derived from a study in humans (WHO, 1987). In reality the so-called safety factor is an uncertainty factor which has to allow for possible differences between test species and humans and for possible human variability (**Figure 22**). Each 10-fold factor (interspecies and interindividual) has to allow for toxicokinetic and toxicodynamic differences (Renwick, 1991). In recent refinements to this approach, the 100-fold factor is considered as a four-way box (**Figure 23**), with each 10-fold factor subdivided to allow for toxicokinetic and toxicodynamic aspects

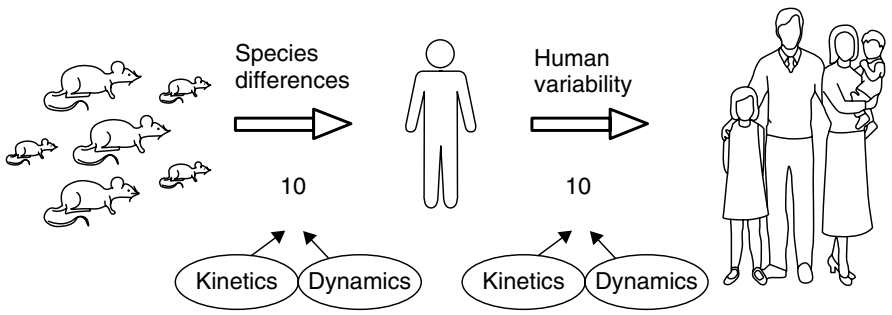

Figure 22 The use of a 100-fold safety or uncertainty factor to convert the no-observed-adverse-effect level (NOAEL) in animals into an acceptable daily intake (ADI) for humans (from Renwick, 1998).

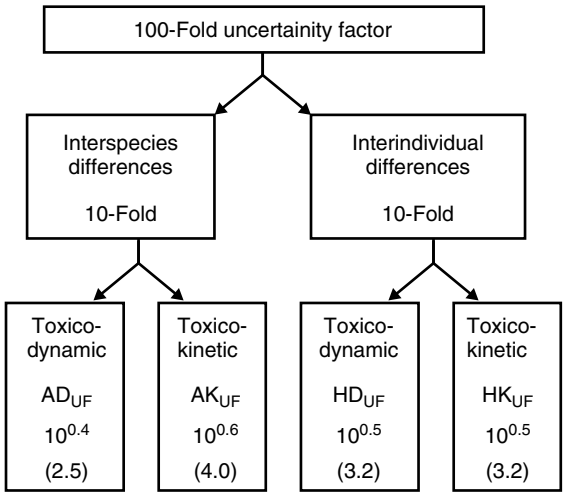

Figure 23 The subdivision of the 100-fold uncertainty factor for the introduction of chemical-specific adjustment factors (based on WHO, 1994; 2005).

(Renwick, 1993) which when multiplied together give the original factors of 10×10. The rationale for this proposal was to allow relevant data on a chemical to replace part of the 'uncertainty', and thereby provide a more scientific basis for the determination of the 'safe' human dose. The values proposed were evaluated at a WHO task group, which considered the approach valuable but revised slightly the proposed default values (WHO, 1994), which reflected the similar variation in toxicokinetics and toxicodynamics in humans (based on pharmacological data (Renwick and Lazarus, 1998)).

The issues critical to the replacement of a default value in **Figure 23** by a chemical-specific adjustment factor (CSAF) are presented in WHO (2005). These include:

1. **Separation of toxicokinetic and toxicodynamic aspects:** Human *in vivo* studies are usually limited to the determination of circulating concentrations of the chemical or its metabolites, and therefore toxicokinetics stops at the delivery of chemical to the target sites; any process occurring within the target organ should be regarded as part of toxicodynamics (including local metabolic bioactivation).
2. **Identification of toxic moiety:** It is important that the activity of the parent compound and metabolites is known. Toxicokinetic data used to calculate a CSAF should relate to the delivery of the toxic moiety (which may be a metabolite) to the target organ in relation to the external dose of the parent compound.
3. **Selection of the appropriate toxicokinetic parameters:** In most cases this would be the AUC of the toxic moiety, but peak concentration may be more appropriate, especially for acute effects.
4. **Selection of appropriate doses:** Although toxicokinetic processes are essentially first-order at low doses, it is possible that saturation may occur at the high doses used in animal studies. The correct comparison is between the toxicokinetics of the chemical in the test species at the NOAEL and in humans at the ADI/TDI that would be calculated in the absence of the toxicokinetic data.
5. **Dose metric:** The 100-fold factor and therefore the defaults shown in **Figure 23** are applied to the external dose expressed in mg kg^{-1} body weight. If the dose is calculated on the basis of the body surface area, then this will be a form of allometry (see above). In humans, body weight and surface area are related by the formula

$$SA = W^{0.425} \times H^{0.725} \times 71.84 \qquad (49)$$

where

SA = surface area
W = weight, and
H = height.

Interspecies comparisons often use simple equations in which the surface area is related to body weight$^{0.66}$ or body weight$^{0.75}$. The use of surface area rather than body weight therefore appears to allow for species differences. The difference between body weight and surface area is equivalent to a factor of about eight for mice, four for rats and two for dogs; that is, using toxicity data from rats, the 'safe dose' for humans based on surface area would be four-fold lower than that expressed on the basis of body weight.

The adequacy of the default 3.2-fold factor for human variations in toxicokinetics has been analysed for most of the major pathways of foreign-compound elimination (Dorne *et al.*, 2005). In general, the default value in **Figure 23** covers over 99% of the human population, but would not allow for situations where the compound was eliminated by a single metabolic pathway that showed a genetic polymorphism. In addition, a significant proportion of certain age groups such as neonates and the elderly would show greater variation than allowed for by the human variability factor; but such age-related differences would not need to be covered by the human variability factor if they had been studied as part of the animal database.

6.3 Examples of the Importance of Toxicokinetic Data in Risk Assessment

The various issues discussed above are illustrated by data on cyclamate and its metabolite cyclohexylamine (cyclohexanamine), chlorinated dibenzo-*p*-dioxins, and the intense sweeteners stevioside and rebaudioside A.

6.3.1 Cyclamate and Cyclohexylamine

Cyclohexylamine is a metabolite of the intense sweetener cyclamate (Renwick, 1986), which produces testicular atrophy when administered to rats but not mice at doses of 200 mg kg^{-1} per day or more in a 90 day study (see Bopp *et al*., 1986). The terminal half-life in rats is 4.6 hours following a single oral dose of 200 mg kg^{-1} (Roberts and Renwick, 1989), and therefore negligible accumulation would be expected during chronic administration via the diet, although large diurnal variations in plasma concentration would be expected. The concentration–time profile over 24 hours during chronic dietary administration was found to contain only a single broad peak each 24 hours, which arose from the nocturnal feeding habits of the rat. Very wide diurnal fluctuations would have occurred if the compound had been administered by a single daily gavage dose, illustrating that the mode of administration can have important influence on the concentration–time curve. The concentrations of cyclohexylamine in the testes increased rapidly following a single oral dose, and the testes represent part of the rapidly equilibrating central compartment. Therefore the diurnal fluctuations detected in plasma would occur also in the target organ for toxicity.

The area under the concentration–time curve is the best estimate of exposure of the whole body, (if based on plasma concentrations) or the target organ (if based on tissue concentrations). For cyclohexylamine, the AUC values for both plasma and testes were about two to three times higher in rats than in mice given the same dose in mg kg^{-1} body weight. This species difference in toxicokinetics will contribute to the marked difference in sensitivity between rats and mice fed the same dietary concentration of cyclohexylamine (Roberts *et al*., 1989). The species difference was supported by data on the relationship between the concentration in testes at steady state and the daily intake in the test animals (**Figure 24**). For example, the concentration in the rat testes at the minimally effective intake of 200 mg kg^{-1} day^{-1} was approximately 30 µg g^{-1}, while at the clearly toxic daily intake of 400 mg kg^{-1} per day (Roberts *et al*., 1989), the concentration in the testes was approximately 100 µg g^{-1}. In contrast, an intake of 400 mg kg^{-1} day^{-1}, which is nontoxic in mice (Roberts *et al*., 1989), produced concentrations of only about 25 µg g^{-1} in the mouse testes. The concentration–intake data in the rat indicated

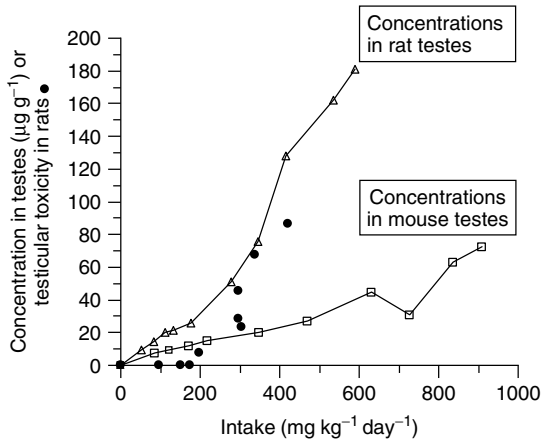

Figure 24 Concentrations of cyclohexylamine in the testes of rats and mice measured at 6 a.m. (from Roberts and Renwick, 1989) in relation to the daily intake, and the corresponding dose–response for testicular atrophy in the rat. (Data from Roberts *et al*., 1989 and Bopp *et al*., 1986.)

nonlinearity at intakes greater than about 200 mg kg^{-1} day^{-1}. This nonlinearity was also detected in plasma and probably contributed to the steep dose–response relationship for testicular atrophy in the rat (**Figure 24**).

Data from studies in humans have shown very wide person-to-person variability in the extent of metabolism of cyclamate to cyclohexylamine during regular cyclamate intake. The majority of the population (about 80%) does not form any detectable cyclohexylamine, while 2–3% of the general population can metabolize 20% or more of a daily dose (Buss *et al*., 1992). The metabolism is performed by the intestinal microflora in the lower bowel, and the metabolic process requires a period of repeated exposure to induce the metabolic activity. Therefore the rate of appearance of cyclohexylamine is slow and there are almost no fluctuations over an eight hour dose interval at steady state (Buss *et al*., 1992). In addition to the extremely wide interindividual variation, there is day-to-day intra-individual variation in subjects who have developed a high metabolic capacity (**Figure 25**) (Renwick *et al*., 2004).

The ADI for cyclamate is based on the NOAEL of 100 mg kg^{-1} body weight for testicular toxicity in rats given cyclohexylamine in a 90-day study. Clearly the default uncertainty factor for human variability (3.2 in **Figure 23**) would be totally inadequate for this example. The risk assessment by the EU SCF (Scientific Committee on Food; SCF, 2000a) used a CSAF for human variability based on the highest percentage metabolism found in the study of Renwick *et al*. (2004). The Committee took the worst-case value of 85% conversion of cyclamate to cyclohexylamine and applied a CSAF of 1.0 for human variability in toxicokinetics and a total composite uncertainty factor of 32.

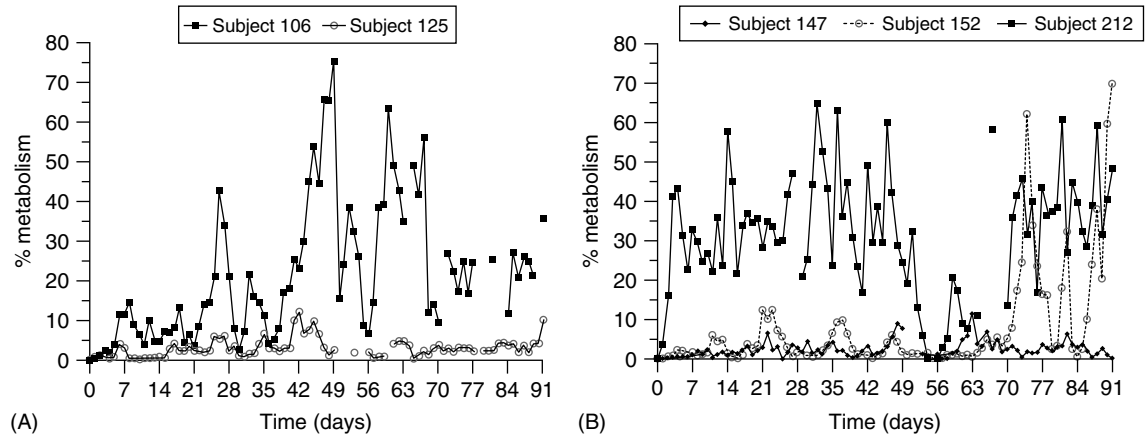

Figure 25 The daily excretion of cyclohexylamine in individuals selected from a screening study for their high metabolizing ability during the administration of 3 g cyclamate daily. (Subject 212 had a short period without cyclamate intake on days 53–55.) The data illustrate the delay prior to extensive conversion of cyclamate to cyclohexylamine and the wide day-to-day fluctuations despite repeated daily intake. (Data from Renwick *et al*., 2004.)

However, this analysis did not take into account two important variables:

1. The highest extent of metabolism on a single day in humans was applied to a NOAEL derived from a 90-day study in rats; the worst-case average extent of cyclohexylamine excretion was about two-fold lower at 40%.
2. Human variability in renal excretion, which would be the major determinant of internal dose, was not allowed for, but variation in renal tubular secretion in humans is low (Dorne *et al*., 2004) compared with other pathways (Dorne *et al*., 2005).

In reality these two deficiencies would cancel each other out.

6.3.2 Chlorinated Dibenzo-p-dioxins

Chlorinated dibenzo-*p*-dioxins, such as TCDD, are among the most toxic chemicals known, and produce acnegenic, carcinogenic, foetotoxic, immunosuppressive and teratogenic effects (JECFA, 2002). There are wide interspecies differences in acute toxicity of TCDD, with the guinea pig about 10–20 times more sensitive than the rat (Kociba *et al*., 1976) or mouse (McConnell *et al*., 1978; Beatty *et al*., 1978), while the hamster appears to be the least sensitive species (Olson *et al*., 1980a). The elimination half-life in guinea pigs (30 ± 6 days; Gasiewicz and Neal, 1979) is similar to that in rats (Rose *et al*., 1976), and only about twice that in hamsters (15 ± 3 days; Olson *et al*., 1980b). Thus the species differences in acute toxicity are not related to the ability to eliminate the compound. Major species differences in elimination half-life would not be expected because TCDD is eliminated essentially unchanged, mostly in the faeces.

There are problems with extrapolation of the data for TCDD in rodents to possible human intakes. The half-life of TCDD in humans based on the elimination by occupationally exposed individuals is about seven years, which is almost 100 times that in rats. Using a value of 7 years it would take about 30–35 years of exposure for humans to reach steady state during constant intake. The four-fold default uncertainty factor for interspecies differences in toxicokinetics (**Figure 23**) would be totally inadequate, and a different approach based on body burdens was adopted in recent evaluations by the EU SCF (SCF, 2000b; SCF, 2001), the JECFA (JECFA, 2002) and the US EPA (see NRC, 2006). The adverse effects that were the focus of the EU SCF and JECFA (2002) evaluations were developmental effects in male rats seen following *in utero* exposure to a single dose given on day 15 of gestation, or a loading dose and weekly injections (Mably *et al*., 1992; Gray *et al*., 1997a; 1997b; Faqi *et al*., 1998; Ohsako *et al*., 2001). The dose–response data in rats could be related to target organ concentrations by special toxicokinetic studies (Hurst *et al*., 2000a; 2000b), so that the safety evaluation was based on internal dose. The evaluations by JECFA (2002) and SCF (2001) allowed for the distribution phase of the bolus doses (Ohsako *et al*., 2001) and weekly subcutaneous injections (Faqi *et al*., 1998) given to rats in order to calculate the foetal tissue exposures on day 16 of gestation and the corresponding maternal body burden. The maternal body burdens in rats were then converted to human equivalent body burdens based on the species difference in half-lives.

$$\text{Body burden at steady state} = \frac{\text{daily dose} \times \text{bioavailability } (F) \times t_{1/2}}{0.693} \quad (50)$$

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat007
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The daily intake that would result in the human equivalent body burden was then calculated and used to derive a tolerable weekly intake (SCF, 2001) or a provisional tolerable monthly intake (JECFA, 2002). The usual 100-fold uncertainty factor was reduced to 3.2, because human variability in toxicokinetics was the only area of uncertainty (see **Figure 23**) not replaced by a CSAF. Both interspecies and human variability factors for toxicodynamics were reduced to 1 because at a tissue level the most sensitive human individual would be no more sensitive than the rat strains used in the studies; the interspecies kinetic factor was also 1 because the use of body burden had taken species differences into account.

However, the use of body burden would not allow for species differences in the extent of distribution (NRC, 2006). Ideally the interspecies extrapolation should have been based on the concentration in the plasma (or better still the tissues), but this would have required data on the plasma clearance of TCDD in humans because

$$C_{ss}(\text{steady-state plasma concentration}) = (\text{daily dose} \times F)/CL \quad (51)$$

The use of half-life instead of clearance required an implicit assumption that the difference in half-life between animal species and humans was solely due to differences in clearance; that is, there are no significant differences in the apparent volume of distribution.

$$t_{1/2} = \frac{0.693 V_\beta}{CL} \quad \text{or} \quad CL = \frac{0.693 V_\beta}{t_{1/2}} \quad \text{so that}$$

$$C_{SS} = \frac{\text{daily dose} \times F \times t_{1/2}}{0.693 V_\beta} \quad (52)$$

Because the body load or burden equals the plasma concentration times the apparent volume of distribution ($C \times V_\beta$), this equation can be rewritten to give the relationship between body burden and half-life:

$$C_{SS} \times V_\beta = \frac{\text{daily dose} \times F \times t_{1/2}}{0.693} \quad \text{or}$$

$$\textit{Body burden at steady state} = \frac{\text{daily dose} \times F \times t_{1/2}}{0.693} \quad (53)$$

Similar tissue concentrations in both species would occur if the apparent volume of distribution and the pattern of distribution of the body burden were the same in rats and humans. However, the extent of hepatic sequestration is higher in rats than humans; more importantly the proportion of the body mass present as fat (10% of body weight in rats and about 25% in humans—NRC, 2006) would result in two to three-fold lower concentrations in humans than in rats *for the same total body burden*. Therefore, the recent evaluations by the SCF (2001) and JECFA (2002) have overestimated the tissue exposure in humans at the body burdens that would arise from the established tolerable weekly or monthly intakes.

The SCF (2001) discussed the use of an uncertainty factor of 3.2 for human kinetic variability, but failed to recognize that major influences on half-life were body weight and body fat; as discussed above for the species differences, *a longer half-life* would arise from a higher proportion of body fat and therefore greater sequestration of the body burden in adipose tissue and therefore *lower than predicted concentrations in other nonadipose tissues*.

The interpretation of the human epidemiological data on occupational exposures to TCDD is complex, in relation to comparisons between occupational and environmental exposures. The body burdens arising from occupational exposures have usually been derived by back-extrapolation through time, based on a concentration measured some years after a period of high exposure (NRC, 2006). Occupational exposure usually occurred at some time during the working life, which established a body burden; this body burden would then increase, be maintained, or decrease depending on whether it was below, equal to or greater than the steady-state body burden associated with the subsequent environmental exposure.

This detailed analysis of the case of TCDD illustrates the critical role that toxicokinetics can play in the design and interpretation of toxicity studies, especially when the compound has a very long half-life. In addition it should be appreciated that if as a result of the animal toxicity data it were decided that the exposure of humans should be reduced immediately, it would take about seven years before the existing body burdens decreased by 50%, and about 30–40 years before they become negligible, even if input were to cease immediately and completely. In reality the persistence of TCDD in the environment (DiDomenico and Zapponi, 1986), indicates that this would be rate limiting in any attempted reduction of human body burdens.

6.3.3 Stevioside and Rebaudioside A

The leaves of the plant *Stevia rebaudiana* (Bertoni) have traditionally been used to sweeten food and beverages in South America (Soejarto *et al*., 1982; Gardana *et al*., 2003). The sweet constituents include stevioside and rebaudioside A, which are glycosides of the diterpene steviol (Carakostas *et al*., 2008). The glycosides are hydrolysed to the steviol *in vivo* in rats, pigs and humans (Nakayama *et al*., 1986; Cardoso *et al*., 1996; Geuns *et al*., 2003; 2007), and by rat caecal bacteria and human intestinal microflora *in vitro* (Wingard *et al*., 1980; Gardana *et al*., 2003; Koyama *et al*., 2003). Hydrolysis by the intestinal flora is the essential first step in the metabolism of both stevioside and rebaudioside A (Renwick and Tarka, 2008) (**Figure 26**).

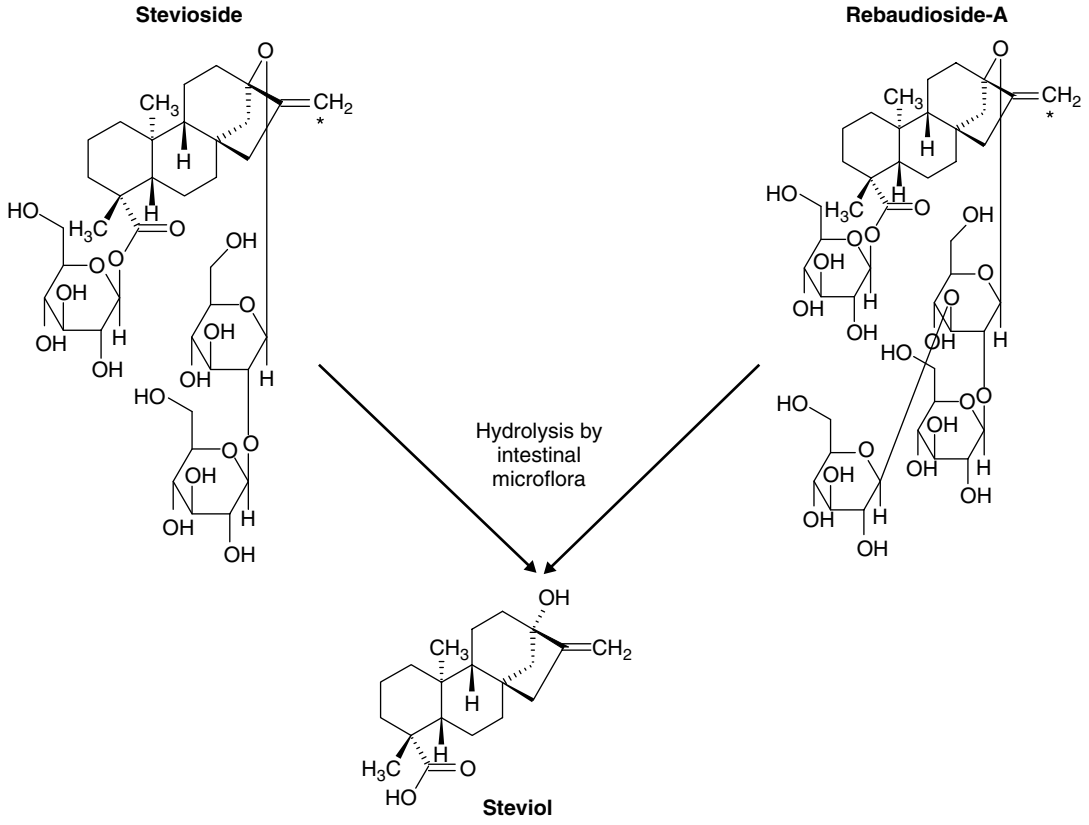

Figure 26 The metabolism of steviol glycosides.

The majority of an oral dose of the radiolabelled steviol given to rats was eliminated in the faeces and bile, mostly as steviol glucuronide, with only a low percentage of the dose eliminated in the urine (Roberts and Renwick, 2008). The authors concluded that the main route of elimination of steviol in rats is as steviol glucuronide in bile, which is hydrolysed by the gut flora to steviol and excreted in the faeces. The glycosides are extensively hydrolysed by the gut flora to steviol, although incomplete hydrolysis results in a small amount of the radiolabel in faeces as the parent glycoside (Roberts and Renwick, 2008). The major constituent in plasma after equimolar doses of steviol, stevioside or rebaudioside A was the aglycone steviol, with lower levels of steviol glucuronide and very low levels of other metabolites.

The kinetics of an oral dose of unlabelled stevioside or rebaudioside A in humans (Wheeler *et al*., 2008) were similar to those in rats except for two important differences:

1. The major route of elimination was as steviol glucuronide in the urine rather than the bile; this difference arises from the different molecular weight thresholds for significant biliary excretion of anions in rats (325) and humans (above 500), since the molecular weight of steviol glucuronide is just under 500.
2. Steviol was detected in a single plasma sample of only one subject after either stevioside or rebaudioside A. In all subjects the major circulating compound was steviol glucuronide.

Steviol glycosides are of low toxicity (Curry and Roberts, 2008). The 63rd meeting of the JECFA (JECFA, 2005) established a temporary ADI of 0–2 mg kg^{-1} body weight for steviol glycosides (expressed as steviol) based on the NOAEL of 970 mg stevioside per kg body weight per day (or 383 mg kg^{-1} body weight, expressed as steviol) in a two-year study in rats, and a safety factor of 200. The larger than normal safety factor was because of unresolved questions at that time. These questions were addressed in the recent risk assessment (JECFA, 2008) and a safety factor of 100 was applied to the NOAEL to give an ADI of 0–4 mg per kg body weight for steviol glycosides (expressed as steviol). However, the use of the standard 100-fold uncertainty factor does not take into account the species differences outlined above.

Any effects of steviol glycosides would arise from their metabolism to steviol. Almost complete intestinal hydrolysis occurs in both rats and humans. Steviol *per se* is the major circulating compound in rats given oral doses of the glycosides; the peak plasma concentrations as steviol were about 150 ng ml^{-1} after oral doses of 4.2 mg kg^{-1} of stevioside or 5 mg kg^{-1} of

rebaudioside A. The same doses of the glycosides were essentially completely hydrolysed in humans, but the absorbed steviol appeared to undergo complete first-pass conjugation with glucuronic acid; the plasma levels of steviol were below the limit of detection (100 ng ml^{-1}) in all but two samples. Although it would be difficult to derive a quantitative CSAF for interspecies differences in toxicokinetics (**Figure 23**), because the AUC for plasma steviol could not be measured in humans, it is clear from the available data that the default factor of 3.2 is excessive and a value of 1 would seem more than adequate.

7 ADDITIONAL SOURCES OF INFORMATION

It has not been possible to cover the vast subject of toxicokinetics adequately within the confines of a single chapter. There are a number of text books and review articles to which readers are referred for further information, for the interpretation of more complex situations and for sampling techniques.

7.1 General Texts

Benet (1976)—rather specialized but good background reading with respect to possible problems in geriatric animals.

Gibaldi and Perrier (1982)—a definitive text.

Benet *et al*. (1984)—based on a symposium, and therefore lacks the structure of Gibaldi and Perrier or Rowland and Tucker but contains some useful information.

Rowland and Tucker (1986)—a more advanced text with useful chapters on interspecies scaling, dose-dependent and time-dependent kinetics and response modelling.

Gabrielsson and Weiner (1997)—an excellent text book—clearly explained with large numbers of helpful diagrams.

Lipscomb and Ohanian (2007)—a useful book with many valuable chapters.

Renwick (2008)—similar to the present chapter but with an expanded section on dose-dependent kinetics, metabolite kinetics and worked examples.

7.2 Review Articles

Gehring and Young (1978)—contains interesting examples from the work of the pioneers in the application of pharmacokinetics to problems of animal toxicology.

Wilkinson (1984)—a clearly written article which deals with first pass metabolism, dose-dependent kinetics and introduces physiological approaches.

O'Flaherty (1985)—a consideration of dose-dependent metabolism.

Wilkinson (1987)—a comprehensive review of the application of clearance concepts to the elimination of foreign components; not toxicology orientated, but an excellent source of references ($n = 525$).

Scheuplein *et al*. (1990)—an interesting article on the value of toxicokinetic data to regulatory agencies such as the FDA.

Andersen (2003)—a historical review of the role of PBPK (PBTK) modelling in risk assessment.

Dixit *et al*. (2003)—a useful overview of recent developments.

Clewell *et al*. (2008)—a recent review on the introduction of quantitative chemical-specific data into risk assessment.

Physiologically Based Pharmacokinetic Modelling

Hon-Wing Leung

CONTENTS

1 INTRODUCTION

Pharmacokinetic models are used to make a rational prediction of the disposition of a chemical throughout the body. Pharmacokinetic modelling has evolved over the past several decades. An early approach assumes that data on the internal environment of a chemical, for example, tissue concentrations, cannot be obtained without employing invasive techniques. These pharmacokinetic models are developed to predict concentrations of chemicals in readily accessible media, such as blood and excreta. The plasma or blood concentration is assumed to mimic the profile in the entire body. Evidently this kind of approach cannot provide information on the concentration-time course of a chemical at the target tissue, which is not necessarily reflected by the blood concentration.

In recent years biologically based models which apply first principles, such as material balance, and incorporate physiological parameters are being developed, initially to describe the kinetics of therapeutic drugs (Himmelstein and Lutz, 1979), then environmental chemicals (Leung, 1991). These models include the exact physiology and anatomy of the animal species being described, as well as parameters such as blood flow, ventilation rates, metabolic constants, rates of absorption and excretion, tissue solubilities and binding to macromolecules (D'Souza and Boxenbaum, 1988). These models are commonly known as physiologically based pharmacokinetic (PBPK) models. **Table 1** presents a listing of PBPK models that have been developed for environmental chemicals.

1.1 Classical Versus Physiological Pharmacokinetics

In simple pharmacokinetic modelling the whole body is treated as a single compartment. More sophisticated models are created by the addition of peripheral compartments (see **Toxicokinetics**). In a multicompartment model the concentration-time course in the central compartment is typically curvilinear with a terminal linear portion. By the method of residuals or feathering, this kinetic behaviour is mathematically resolved into

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

decaying exponential terms to account for the curvature of the data. The number of exponential terms corresponds to the number of compartments in the model, each representing an exchange between a peripheral tissue or organ with the central compartment. Obviously compartmentalization by such a rigid curve-stripping process is a rather abstract mathematical construct and lacks physiological relevance.

In recent years physiological modelling has emerged as a pre-eminent approach to pharmacokinetic modelling. However, it must be emphasized that classical and physiological pharmacokinetics are not fundamentally incompatible; in fact, they share a common connection. The difference between them lies in the kinds of parameters on which the models are developed, and consequently they differ in their applications. In classical pharmacokinetic modelling, no attempt is made to assign physiological correlates to model parameters. A compartment is simply considered as a kinetically homogeneous volume with transfer constants in and out of the compartment. In PBPK modelling, compartments are treated as individual organs or tissues arranged in a precise anatomical configuration connected by the cardiovascular system. The transfer of chemicals between compartments is governed by actual blood flow rates and tissue solubilities (partition coefficients).

Because of a lack of biological constraints with conventional pharmacokinetic modelling, empirical data can be fitted by freely varying the model parameters. The best estimates of parameter values can then be statistically compared across experimental conditions, treatments or chemicals to establish whether apparent differences are significant. In contrast, any major discrepancies between the physiological model prediction and experimental data in PBPK modelling will necessitate the reformulation of the model to account for the observed behaviour. Since classical models are constructed without conformity to anatomical reality, they cannot account for physiological or biochemical alterations such as body and organ weight changes (tissue growth or atrophy) or enzyme induction and inhibition. While both classical and physiological models are capable of predicting tissue doses, albeit to somewhat different extents, classical models do not lend themselves to interspecies extrapolation of such dose-effect data (Monro, 1994).

2 THEORY AND PRINCIPLES OF PHYSIOLOGICAL MODELLING

The transfer of a chemical out of a single compartment follows Fick's law of simple diffusion, which states that the flux of a chemical is proportional to its concentration gradient. The differential rate equation describing this first-order process can be written as follows:

$$\frac{\mathrm{d}C}{\mathrm{d}t} = K \cdot \frac{\delta C}{V} \tag{1}$$

where C is the concentration of chemical in the compartment; K is the transfer constant; V is the volume of the compartment and δC is the concentration gradient.

If the transfer is perfusion- or flow-limited, then the transfer constant is the rate of blood flow (Q) to the compartment. It follows, therefore:

$$\frac{\mathrm{d}C}{\mathrm{d}t} = \frac{Q(C_\mathrm{a} - C_\mathrm{v})}{V} \tag{2}$$

where C_a is the concentration of the chemical in the arterial blood entering the compartment and C_v is the concentration of the chemical in the venous blood leaving the compartment.

Since chemicals do not equilibrate freely in body fluids, but depending on their physicochemical properties, may be sequestered in tissue lipids, the concentration determined experimentally from a tissue sample is a composite of both the free and the sequestered form. As the transfer of a chemical in a tissue compartment is assumed to be flow-limited, the chemical concentration in the venous blood exiting from a tissue is equal to the concentration in the tissue fluid, that is, the so-called free form. The partitioning of the chemical between the body fluid and tissue lipids is governed by tissue solubility or partition coefficient P, as follows:

$$P = \frac{C}{C_\mathrm{v}} \tag{3}$$

Substituting this into Equation 2, one obtains:

$$\frac{\mathrm{d}C}{\mathrm{d}t} = \frac{Q\left(C_\mathrm{a} - \dfrac{C}{P}\right)}{V} \tag{4}$$

Equation 4 represents the fundamental relationship on which all PBPK models are constructed. The expression for all nonmetabolizing, noneliminating and nonbinding tissue compartments will have this same mathematical form. The expressions for blood and other eliminating tissues such as liver, kidney and lung are more complex, but are based on the same principles of flow, mass conservation and partitioning.

3 DEVELOPMENT OF PHYSIOLOGICAL PHARMACOKINETIC MODELS

The development of a PBPK model is a highly integrative process. **Figure 1** depicts the flow processes in the development of a PBPK model. The first step involves

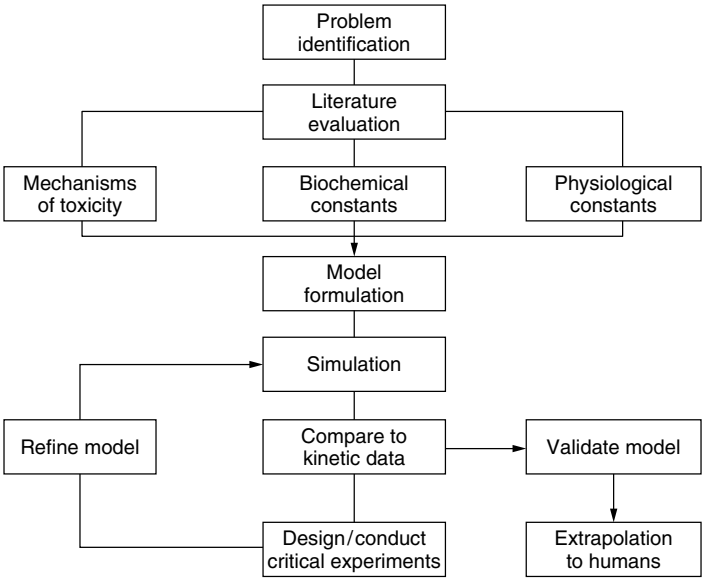

Figure 1 Flow diagram of the development of a physiologically based pharmacokinetic model. Problem identification: the finding of a particular toxicity, in a particular organ, in a particular species. Literature evaluation: the integration of available information about the mechanism of toxicity, the pathways of chemical metabolism, the nature of the toxic chemical species, the tissue-binding characteristics and the physiological parameters of the target species. From these data a model is developed to estimate the appropriate measure of tissue exposure for a wide variety of exposure conditions.

defining the nature of the problem and reviewing the literature to assess the impact of mechanism on the choice of tissue dosimetrics. The actual model formulation is divided into four interwoven steps, as follows:

3.1 Selection of Appropriate Tissue Compartments

The most natural approach to the choice of tissue compartments in PBPK modelling is to model a whole body by describing every organ and tissue. However, such detailed models, aside from the prohibitive labour and expenses to develop them, are not required in most circumstances. The selection should be governed by the degree of detail necessary to provide a satisfactory depiction of the events. A knowledge of the chemical's mode of action and its physicochemical properties will help make such a judgement. For instance, if a substance is known to accumulate in, bind to, be metabolized by or be toxic to specific organs or tissues, these should form the integral compartments of the model that are described in detail. If a chemical is highly lipophilic, then the adipose tissues should be described as a separate compartment. Other 'nontarget' organs and tissues may be lumped together with respect to similar kinds or properties, for example, richly perfused tissues representing kidneys and other visceral organs, slowly perfused tissues representing skin and muscle. The tissues or organs in the same body group are considered to have common kinetic behaviour and can be described by a single concentration profile. Naturally, if the grouping is carried out to the extreme, it degenerates to the classical one-compartment model, where the entire body is assumed to have uniform concentration. This phenomenon is most likely only if a chemical is relatively slow-acting, is hydrophilic and has no complex biochemical mode of action, such as active transport or macromolecular binding.

3.2 Formulation of the Mathematical Relationship

After the model structure has been decided, differential rate equations are written to describe the transport, metabolism, binding and clearance for each compartment. The derivation of the basic form of the equation for nonmetabolizing, noneliminating tissues has previously been described (Equation 4).

For blood, the efferent blood from each tissue compartment is assumed to combine simultaneously to yield a mixed venous blood concentration (C_b) returning to the lungs at a flow rate equal to the cardiac output (Q_b), as follows:

$$\frac{dC_b}{dt} = \sum \left(\frac{Q_i \cdot C_{vi}}{Q_b} \right) \quad (5)$$

where i = name of tissue compartment.

For metabolizing tissues such as the liver, depending on the number and type of metabolic pathways, the basic differential equation is modified by the inclusion of terms describing a first-order metabolic process (K_f)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat008
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

or a saturable Michaelis–Menten type enzyme kinetics (K_m and V_{max}) or both:

$$V \cdot \left(\frac{dC}{dt}\right) = Q\left(C_a - \frac{C}{P}\right) - K_f\left(\frac{C}{P}\right) - \frac{\left(V_{max} \cdot \frac{C}{P}\right)}{\left(K_m + \frac{C}{P}\right)} \quad (6)$$

For tissues which exhibit specific binding, in addition to the amount partitioned by solubility, the total tissue concentration will also include the portion in bound form, as follows:

$$\frac{V \cdot \left(\frac{dC}{dt}\right)}{Q} = C_a - \left\{\frac{(C \cdot V)}{(V \cdot P) + \left[\frac{B}{(K_b + C_v)}\right]}\right\} \quad (7)$$

where B = binding capacity and K_b = equilibrium dissociation constant.

Thus, the formulation of the mathematical equations is rather simple. The key consideration is to maintain mass balance within each tissue compartment as well as the entire model by carefully accounting for the inputs and outputs of the chemical.

3.3 Determining Model Parameter Values

The next step in the development of a PBPK model involves obtaining or determining the necessary model parameter values. Three classes of parameters are required: (i) anatomic and physiological variables such as organ and tissue volumes, and blood flow rates; (ii) thermodynamic parameters such as tissue solubility (partition coefficients) and binding constants and (iii) biochemical parameters such as absorption, excretion and metabolic constants.

Values for organ/tissue volumes, blood flows and ventilation rates can be readily obtained from the literature (Arms and Travis, 1988). Values not available may be scaled allometrically (Rowland, 1985). Analysis of organ weights and other physiological parameters have led to numerous equations of the type

$$X = \alpha W^{\beta} \quad (8)$$

where X = the parameter of interest; W = body weight; and α and β are numerical constants.

In general, organ size is directly proportional to body weight, and $\beta \approx 1$. For body surface area, flow rates, metabolic and clearance rates, they tend to vary to a fractional power of the body weight, and $\beta \approx 2/3 - 3/4$. Like all procedures concocted to substitute for missing information, they only provide a best guess in the absence of data. When specific information becomes available, it should be used to adjust or to supplant the procedure (Kirman *et al.*, 2003a).

Tissue:air partition coefficients for volatile chemicals can be determined by head space analysis with the vial equilibration technique, using tissue preparations or homogenates (Fiserova-Bergerova and Diaz, 1986; Gargas *et al.*, 1989; Mattie *et al.*, 1994). As a rough approximation a simple correlation approach based on other physicochemical properties such as water solubility and vapour pressure (Paterson and Mackay, 1989) or *n*-octanol:water partition coefficient (DeJongh *et al.*, 1997) may be used. Tissue:blood partition coefficients are calculated from the tissue:air partition coefficients by dividing by the corresponding blood:air partition coefficient:

$$P_i = \frac{P_{Ai}}{P_{Ab}} \quad (9)$$

where P_{Ai} = tissue:air partition coefficient and P_{Ab} = blood:air partition coefficient.

The metabolic constants V_{max} and K_m can also be estimated using a similar vial equilibration technique with tissue homogenates *in vitro* (Sato and Nakajima, 1979) or with an *in vivo* technique by measuring gas uptake (Gargas *et al.*, 1986; Filser, 1992) or the exhalation rates of animals in an exposure chamber (Gargas and Andersen, 1989). In the gas uptake study a closed recirculated exposure system is used to generate a series of uptake curves at a range of initial concentrations. The shapes of these curves are a function of P_i, V_{max} and K_m. Tissue partition coefficients are experimentally determined by the vial equilibration technique and incorporated into a PBPK model, which is then used to simulate the uptake process. An optimal fit of the family of uptake curves is then obtained by adjusting the biochemical constants for metabolism of the chemical. For materials of low vapour pressure that exhibit increasing blood and tissue solubilities, animals are first exposed by inhalation to a constant concentration of the chemical and then placed in an exhaled breath chamber supplied with fresh air flow. The chemical concentration in the exhaled breath chamber is serially analysed. The metabolic constants are estimated with the PBPK model by optimizing the fit of the elimination curves.

For nonvolatile chemicals, tissue:blood partition coefficients may be estimated by using a vial equilibration (Murphy *et al.*, 1995), an equilibrium dialysis (Lin *et al.*, 1982) or a filtration/extraction technique (Jepson *et al.*, 1994) *in vitro*, by single-pass perfusion of isolated organs in situ (Sultatos *et al.*, 1990), by bolus intravenous injection (Lam *et al.*, 1982) or by whole-body constant intravenous infusion *in vivo* (Chen and Gross, 1979). Metabolic constants for nonvolatiles are determined with traditional enzyme assays by measuring the rate of disappearance of the substrate or the formation of product in tissue homogenates *in vitro* or in exposed animals.

In general, *in vivo* metabolic constants are quite difficult to determine empirically, and for ethical reasons it is nearly impossible to determine them for humans. In situations where only *in vivo* metabolic constants are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat008
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

available for the laboratory animal, V_{max} for humans may be scaled allometrically according to the fractional power rule. Alternatively, when *in vitro* data are available, the human *in vivo* V_{max} may be estimated using a parallelogram approach (Reitz *et al.*, 1989; Kedderis and Lipscomb, 2001). The Michaelis constant K_m generally is considered to be invariant among animal species.

Absorption rate constants are estimated from the rising portion of the blood concentration-time curve, and bioavailability is determined from the area under the blood curve following intravenous and other routes of administration.

3.4 Model Calibration, Validation and Reformulation

Once the PBPK model is configured and the requisite model parameters are collected, the model is subject to calibration and validation against kinetic, metabolic and toxicity information. This is accomplished by comparing the model predictions with experimental results. These exercises can suggest additional experiments to collect crucial data for verifying or improving model performance. When the model fails to accurately simulate known kinetic and toxicity behaviour, despite modification of the model parameters consistent with physiological limits, it suggests that there may be additional mode(s) of action unaccounted for by the present model formulation. In such an instance, the model structure will need to be reformulated to justify the discrepancies. Obviously there are multiple ways to restructure a PBPK model if the objective is simply to improve the goodness of fit to the experimental results. However, model reformulation should be guided by plausible biological mechanisms, which can be verified experimentally. A model is considered to be validated when it is successful in simulating the empirical results. The more extensive the database a PBPK model is validated against, the more robust it becomes. A well-validated model can be used to make predictions of responses for a variety of exposure conditions, including ones which are difficult to perform experimentally. It also provides a means of predicting human kinetic behaviour when the biochemical constants and tissue-binding characteristics of the chemical have been determined in human tissues.

4 APPLICATIONS OF PBPK MODELLING IN TOXICOLOGY

4.1 Improving the Scientific Basis for Health Risk Assessment

The most common application of PBPK modelling in toxicology is dosimetric scaling in human health risk assessment (Leung and Paustenbach, 1995; Andersen, 2003). Because of ethical reasons, most toxicological data traditionally are derived from experiments with laboratory animals. High exposure levels are also frequently employed to maximize the likelihood of observing effects. In order to assess the human health risk from exposure to a chemical from the animal toxicity data, it will be necessary to make extrapolations of the toxic response from: (i) the test species to human; (ii) high to low exposure levels and (iii) the test route to another route of exposure.

Historically, exposure is expressed as the dose administered in proportion to body weight. This dosimetric method assumes that the response of the biological system is directly proportional to the initial concentration of the test material, which in turn correlates with the body volume. Interspecies dose adjustment is scaled according to an animal's body mass. A variation based on a similar concept of initial whole-body concentration is to scale according to body surface area (Freireich *et al.*, 1966). Despite its popularity, this form of dosimetric scaling is only marginally accurate for intraspecies extrapolation, and is rarely acceptable for interspecies extrapolation. The apparent unreliability of this approach is due to its failure to consider pharmacokinetic differences between species. The premise for this form of scaling assumes that the intensity of the toxic response correlates with the external exposure concentration or the amount of chemical administered. However, toxicity is not caused simply by the amount of chemical administered, but by the concentration of the chemical reaching the target tissues. Owing to the modifying effects of absorption, distribution, metabolism and excretion processes, target tissue dose is not always directly related to the amount of chemical administered. Another area where pharmacokinetics is important is the extrapolation of biological response from high dose to low dose. At low exposure levels typically associated with environmental conditions, pharmacokinetic processes generally proceed at rates directly proportional to the chemical concentration. However, at the high doses used in toxicity studies, many pharmacokinetic processes, especially metabolism, have a finite capacity and may become saturated. One other important application of PBPK modelling in toxicological risk assessment is extrapolation from one route of exposure to another (Chiu and White, 2006). Inter-route extrapolation is necessary because the bulk of toxicity testing has been conducted with the oral route, whereas environmental and occupational exposures typically occur by inhalation or skin contact. The general aspects of route-to-route extrapolation using PBPK modelling has been described (Gillette, 1987). Specific examples include the dermal to inhalation extrapolation of organic chemical vapours (McDougal *et al.*, 1986), inhalation to oral extrapolation of trichloroethylene (Fisher, 1990) and methylene chloride (Angelo and Pritchard, 1987), and oral to dermal extrapolation of ethyl acrylate (Frederick, 1992).

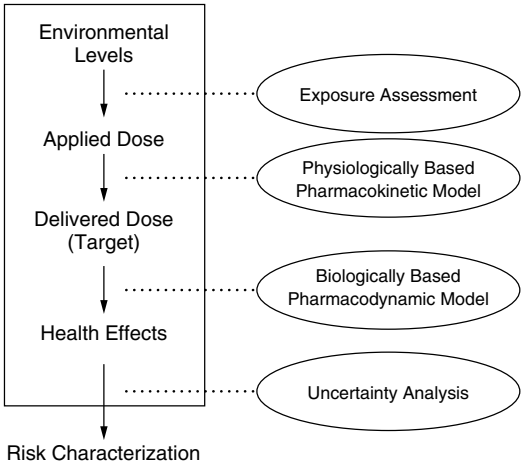

Figure 2 The roles of physiologically based pharmacokinetic and biologically based pharmacodynamic modelling in a refined health risk assessment paradigm.

PBPK modelling provides a means of estimating the tissue doses of chemicals and their metabolites over a wide range of exposure conditions in different animal species. It can provide a biologically based means of extrapolating from the animal results to predict effects in human populations. These techniques have been applied to the human cancer risk assessment of methylene chloride (Andersen *et al.*, 1987a), ethylene dichloride (D'Souza *et al.* 1987), perchloroethylene (Chen and Blancato, 1987), trichloroethylene (Bogen, 1988), 1,4-dioxane (Leung and Paustenbach, 1990), chloroform (Reitz *et al.*, 1990), ethyl acrylate (Frederick *et al.*, 1992) and vinyl chloride (Reitz *et al.*, 1996).

In a refined risk assessment paradigm **(Figure 2)**, a risk assessor conducts an evaluation of the environmental levels and the extent of exposure (frequency and duration) that provides an estimate of the administered dose (see **Risk Assessment of Chemicals**). From the administered dose, a PBPK model is then used to estimate the delivered dose. In the next step, a biologically based pharmacodynamic model is used to provide the connection between the biological effective dose and the toxic response, ultimately yielding a risk estimate. And finally an uncertainty analysis of the model parameters completes the health assessment by providing the confidence limits around the risk estimates.

4.2 Refining Experimental Designs in Toxicity Testing

Metabolism plays a salient role in regulating the toxicity of a multitude of chemicals. Almost all metabolic and many excretory processes utilize specific enzymes or binding proteins that have limited capacity and may become saturated at high substrate concentrations. When these processes are saturated, internal dose parameters, such as area under the tissue curve or the amount of metabolite formed during inhalation exposure, are not linearly related to the externally administered dose or inspired concentration. PBPK analysis of the dose-dependent processes provides an understanding of the relationship between external and internal dosimetrics under various exposure conditions. Recognition of these complex kinetic behaviours is essential to the proper design of toxicological experiments. It is particularly relevant for proper dose selection in contemporary cancer bioassays, which emphasize the use of a maximum tolerated dose. The development of a comprehensive pharmacokinetic description to examine the influence of saturable processes on the delivery of a chemical to target tissues will aid in the correct selection of dosing regimen and test species. While some *in vivo* animal experiments will always be necessary to test the accuracy of the predicted behaviour by the PBPK model, this limited work requires fewer animals than conventional experiments for assessing pharmacokinetic behaviour. Thus, a PBPK guided study design for chronic toxicity testing will enhance the information content of the experiment, while reducing the number of laboratory animals used. By the same token, it has been advocated that PBPK models can be a useful tool to facilitate the selection of drug discovery candidates in pharmaceutical development (Theil *et al.*, 2003).

4.3 Analysing Metabolic Interactions in Chemical Mixtures

In addition to uses for improving toxicity study design, PBPK models have been used to examine chemical interactions (Krishnan *et al.*, 2002; Isaacs *et al.*, 2004). An earliest example of this is the work of Andersen (1987) with a dichloroethylene and trichloroethylene mixture. In this approach a PBPK model is first constructed for the two chemicals individually, then linked via a mass-balanced differential rate equation for the liver compartment that has been generalized to account for the various modes of metabolic interaction. The PBPK models are then tested by optimizing the fit to a series of uptake data in a closed-chamber inhalation exposure to the chemical mixture. These kinetic analyses, coupled with *in vitro* interaction data, can help to delineate the correct mechanistic possibility. The advantage of this PBPK approach is that analysis of the gas uptake data instead of the hepatic metabolism data greatly simplifies the evaluation of the kinetic interactions. Furthermore, a validated metabolic interaction model can be used to readily predict the outcomes of exposures to chemical mixtures of various proportions. This would have been almost impossible if it were to be tested *in vivo*, considering the large number of permutations. Other examples of analyses of metabolic interaction utilizing PBPK modelling include the binary mixtures of

hexane with methyl-*n*-butyl ketone or 2,5-hexanedione (Mumtaz *et al.*, 1993), trichloroethylene/ethanol (Sato *et al.*, 1991b), benzene/toluene (Purcell *et al.*, 1990), toluene/*m*-xylene (Tardif *et al.*, 1993), carbon tetrachloride/kepone (El-Masri *et al.*, 1996), and carbon tetrachloride/methanol (Evans and Simmons, 1996), and the ternary mixtures of alkyl benzenes (Tardif *et al.*, 1997), vinyl chloride/trichloroethylene/1,2-dichloroethylene (Barton *et al.*, 1995), and trichloroethylene in combination with tetrachloroethylene and 1,1,1-trichloroethane (Dobrev *et al.*, 2001).

4.4 Evaluating Dosimetry During Early Life Stage Development

Recent initiatives with regards to children's health have raised the question of whether differences in pharmacokinetic processes in children may result in a different internal dose compared with adults following a given chemical exposure. Consequently there is a keen interest in the use of PBPK models to predict the dosimetry in the developing embryo, foetus, or neonate. PBPK models are well suited for this purpose because they can more readily accommodate the rapidly changing growth dynamics, changes in the state of differentiation of developing tissues, and unusual routes of exposure (e.g. maternal-mediated placental transfer and lactation). Fisher *et al.* (1989) developed the first PBPK model of pregnancy for an environmental chemical, trichloroethylene. Subsequently, models of increasing complexity have been constructed for a number of putative developmental toxicants, notably those for the glycol ethers (Clarke *et al.*, 1993; Gargas *et al.*, 2000), methyl mercury (Gray, 1995), methanol (Ward *et al.*, 1997), perchlorate (Clewell *et al.*, 2003a; 2003b), bisphenol A (Kawamoto *et al.*, 2007), acrylamide (Walker *et al.*, 2007), polychlorinated biphenyls (PCBs) (Lee *et al.*, 2007), and phthalates (Clewell *et al.*, 2008). Some of these models have focussed on a very short duration of gestation, around the critical window for teratogenesis. Under these conditions, the timescale for pharmacokinetic simulations can be shorter than the timescale for growth, which can then be conveniently ignored. Ideally, however, PBPK models of pregnancy should be validated across a wider range of conditions to permit a more reliable extrapolation to other lengths of gestation and exposure conditions. Some of these models also attempted to extrapolate internal dose in animals to human. For practical reasons, the internal dose extrapolations were limited to maternal blood or milk levels of the chemical or its metabolite. Since it is quite difficult, if not impossible, to collect controlled exposure data for environmental chemicals in pregnant women or newborn children for model validation, the reliability of extrapolations for human in utero or lactational exposures should be carefully assessed.

4.5 Establishing and Adjusting Occupational Exposure Limits

PBPK modelling has also been applied to evaluate the hazards of chemicals in the occupational setting (Sweeney *et al.*, 2001). Occupational exposures to industrial chemicals traditionally have been evaluated by monitoring the airborne concentration of the chemicals in the workplace. However, air monitoring does not represent the absorbed dose, since it ignores modifying processes such as bioavailability and metabolism. In addition, routes of exposure other than inhalation may contribute to the total body burden. In order to determine accurately the actual received dose, biological monitoring techniques can be used (Droz *et al.*, 1999). Reference standards known as biological exposure indices (BEIs) defining the acceptable levels of chemical substances in biological media have been established. PBPK models are well suited for setting BEIs, because they can readily be used to estimate chemical concentrations in a variety of body fluids or tissues corresponding to the airborne exposure concentrations. This is achieved by exercising the PBPK models at an exposure scenario corresponding to an eight hour inhalation at the airborne exposure limit (Leung and Paustenbach, 1988; Leung, 1992). Most occupational exposure limits (OELs) are established for the average or standard worker. PBPK models, however, can accommodate individual physiological variations such as body weight, body fat content, metabolic rate and so on. Theoretically, with the aid of PBPK modelling, one can develop custom exposure limits specifically tailored to a particular worker (Loizou, 2001).

While biomonitoring is a useful tool to provide evidence of exposure, it provides little information about the nature of the exposure. It is also difficult to assess health risks based on biomonitoring data, since most health-based guidelines are expressed as external exposure concentrations in air or water. As discussed earlier, PBPK models have been used successfully to establish BEIs based on external exposure in a process referred to as forward dosimetry. The inverse of the process, called reverse dosimetry, utilizes PBPK modelling to estimate external exposures based on the measured internal dose (Tan *et al.*, 2007). This reverse dosimetry method converts human biomonitoring data to the corresponding external exposure, which can then be compared with health-based guidelines (Liao *et al.*, 2007).

PBPK modelling has also been applied to setting OELs for work shifts of longer duration than the standard eight hours per day, five days per week work schedule (Andersen *et al.*, 1987b). The rationale for adjusting OELs for unusual work shifts is to ensure that workers are not placed at greater risk than those working a standard shift. Therefore, central to the development of a PBPK model for adjusting OELs for non-conventional

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

work shifts is the quantification of the degree of risk associated with the standard work shift such that the calculated OEL for the longer schedule poses no more than an equivalent risk. The selection of an appropriate risk index depends on a chemical's mechanism of toxicity. For most systemic toxicants, the risk index is the integrated tissue dose, that is, the concentration and time cross-product. An important advantage of PBPK models is their ability to track the areas under the tissue or metabolism curves. Assuming that the area under the blood curve is the proper risk index associated with styrene exposure, Andersen *et al.* (1987b) determined that a 12 hour exposure to 64 ppm was equivalent to an eight hour exposure to 100 ppm. In another example, blood carboxyhaemoglobin level was identified as the appropriate risk index for methylene chloride exposure. The OEL for nonstandard work shifts is determined by maintaining the end-of-shift blood carboxyhaemoglobin concentration at a level no greater than those observed after exposure to the eight hour time-weighted average OEL.

4.6 Assessing the Performance of Personal Protective Equipment

Traditionally, the performance of personal protective equipment such as a respirator is evaluated by measuring simultaneously the chemical concentration inside and outside the respirator. There are several problems with this approach: (i) it is rather cumbersome for the worker to carry around two air sampling trains; (ii) air sampling over the work shift only gives a snapshot of the concentration, but does not provide a concentration-time profile; (iii) since the exposure concentration rather than the absorbed dose is measured, it will underestimate the overall protection (e.g. skin absorption) offered by the protective equipment. PBPK modelling may provide a means to overcome some of these problems. The approach (Crank and Vinegar, 1992) involves measuring the post-expired breath at the end of the work shift, and using a PBPK model to estimate retrospectively the exposure concentration (i.e. the concentration leaking through the protective equipment). The PBPK model is exercised to identify combinations of exposure duration and concentration that will result in an accurate simulation of the expired breath data. Comparison of the model-predicted exposure concentration and the ambient exposure concentration will yield the protection factor of the protective equipment.

5 UNCERTAINTIES AND LIMITATIONS IN PBPK MODELLING

Since modelling is based on experimental data that have inherent errors, any model will have a certain degree of uncertainty associated with it. There are two important areas of uncertainties in the development of PBPK models. The first concerns the selection of the proper model, and the second deals with the model parameters estimated (Sato *et al.*, 1991a). When a PBPK model is used to make predictions, it should reflect these uncertainties in terms of confidence limits in the values predicted by the model, and the confidence regions around the estimated parameters.

As shown in **Figure 1**, the first step in PBPK modelling is defining the problem to be solved. The next step is to postulate several plausible physiological mechanisms to describe the data set. The third step is to use the data to discriminate between candidate models. The selection of the best model and the estimation of model parameters can be guided by statistical analysis, often with the aid of computer programs. Since small changes in input data or in the goodness of fit to a set of experimental data may significantly affect the predicted output, and, in turn, the risk estimate when the PBPK model is used to support quantitative risk assessment, the uncertainties associated with PBPK model parameters should be carefully analysed. The systematic testing of the effects of the model parameters on the model predictions in PBPK modelling is called sensitivity/variability analysis. It is typically quite difficult to obtain uncertainty estimates based on a deterministic statistical method for a highly parameterized complex model such as a PBPK model. Instead, a Bayesian approach called Markov chain Monte Carlo analysis based on a stochastic selection scheme can be used to generate a distribution of model outputs including measurements of their uncertainties (Thomas *et al.*, 1996; Hack, 2006). An example of this uncertainty evaluation in input parameters is shown in a PBPK model for carbon tetrachloride (Evans *et al.*, 1994). Finally, a PBPK model is developed to provide insight into specific questions, and should never be used for extrapolation beyond its intended purpose. Furthermore, its use for prediction should come only after a thorough validation process.

6 BEST PRACTICES FOR PBPK MODELLING

PBPK modelling has grown considerably since the very first model for an environmental chemical (dieldrin) was developed (Lindstrom *et al.*, 1974). Of the 105 chemicals shown in **Table 1**, about half of them have two or more published PBPK models. The proliferation of models, and the increasing use of these models for human health risk assessment, has called for a need to develop more systematic methods for evaluating and comparing different models, particularly for exploring the relative importance of uncertainties in model structure, dosimetrics and model parameters along with different sources of variability. In order to provide some guidance for the

[a]These chemicals have more than one model. The reference identifies the model appearing the earliest in the published literature.

modelling community, there has been the suggestion to establish some internationally recognized good modelling practices (Loizou *et al.*, 2008). These practices can facilitate sharing of models and model evaluations and consistent applications in risk assessments. Best practices allow the efficient evaluation of models through standardization, documentation and transparency. The seven-step process of model assessment for the quality of its purpose, structure, mathematical representation, computer implementation, parameter analysis, validation/calibration and documentation, as described by Clark *et al.* (2004) provides a useful framework. While establishing good modelling practice is a logical beginning, it is presently not regarded to be prudent to set any rigid acceptance criteria for a PBPK model to be used for risk assessment or regulatory purposes. This is because each chemical will need a specific model and it depends on the amount of available data to calibrate and validate the model. In addition, strict regulatory criteria have the tendency to freeze the science in time. Until PBPK modelling has reached the point of relative maturity, it is best to be flexible to take into account the emerging science in this rapidly developing field.

Evaluation of Toxicological Interactions for the Dose-Response Assessment of Chemical Mixtures

Kannan Krishnan, Sastry Isukapalli and Jonathan Boyd

CONTENTS

1 INTRODUCTION

Dose-response assessment for individual chemicals and chemical mixtures involves the characterization of the relationship between administered dose (or more appropriately target tissue dose) and tissue response, in order to facilitate the determination of safe exposure levels for humans (NRC, 1983; Health Canada, 1994; WHO, 1999; U.S. EPA, 2000). As the mixture dose-response data are often generated in laboratory studies, the extrapolation of responses observed at high doses to low exposure doses, as well as extrapolation of toxicologically equivalent doses from test animals to humans is necessary (Calabrese, 1991; Krishnan and Brodeur, 1991; Krishnan and Brodeur, 1994). Additionally, route-to-route extrapolation, duration extrapolation and evaluation of intraspecies variability in kinetics, dynamics and interactions may be required.

The science of dose-response modelling has evolved significantly over the years for individual chemicals. Models facilitating the conduct of interspecies, intraspecies, route-to-route and high dose to low dose extrapolations in the context of human health risk assessment for individual chemicals have been developed (Gehring *et al.*, 1978; Clewell and Andersen, 1985; 1987; Jarabek, 1995; Chiu *et al.*, 2007). The dose-response assessment for chemical mixtures is essentially similar to that of individual chemicals when the data are obtained for the 'whole' mixture of relevance to human exposure situation [U.S. EPA, 1986; 2000; Agency for toxic substances and disease registry division of toxicology (ATSDR), 2004; Lotz *et al.*, 2008; Meyer-Baron *et al.*, 2008]. During a component-based dose-response assessment, however, focus should be on how the slope or threshold of the components changes. Thus, if the slope of the dose-response curve or threshold of one chemical does not change in the presence of other chemicals, then there is no interaction between the first chemical and the others (Gennings *et al.*, 2005). Conversely, if the rate of change in the response with respect to the dose of the first chemical changes in the presence of other chemicals, then an interaction has occurred (Gennings *et al.*, 2005).

When interactions among chemicals occur, the consideration of mechanisms would be necessary for the conduct of scientifically sound dose-response assessment for mixtures (Haddad *et al.*, 1998; 2001; Krishnan *et al.*, 2002). Thus, when toxicity data for individual chemicals are used to predict or assess the health risk associated with mixtures of chemicals, it becomes relevant to assess how the tissue dose or the tissue response of individual chemicals is altered during combined exposures (**Figure 1**). Toxicokinetic interactions are those that lead to a change in target tissue dose per unit exposure concentration during mixed exposures compared to individual chemical exposures (Krishnan *et al.*, 1994). Interactions

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

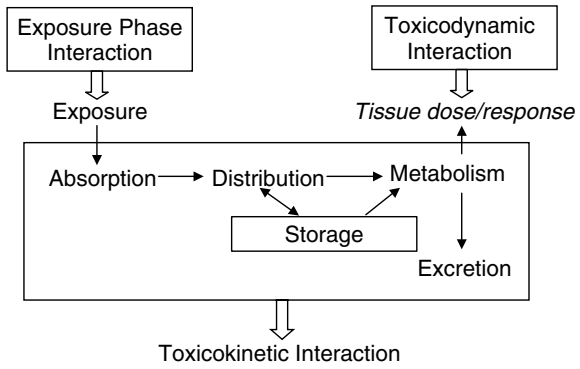

Figure 1 Potential sites or phases where interactions among chemicals occur during combined exposures.

at the toxicokinetic level imply a modulation of absorption, distribution, metabolism and/or excretion of one chemical by another **(Figure 1)**. On the other hand, toxicodynamic interactions are said to result when the tissue response per unit tissue dose differs between mixed exposures and single chemical exposures (Krishnan *et al.*, 1994). Interactions at the toxicodynamic level might involve a competition between two chemicals for binding to a receptor or an alteration by one chemical of the susceptibility, repair and compensatory effects induced by another chemical. **Table 1** lists examples of toxicological interactions observed in humans following combined exposure to environmental pollutants.

Even though there are numerous reports of the occurrence of interactions between chemicals (Calabrese, 1991; Krishnan and Brodeur, 1991; 1994), analysis of such data to determine their relevance to occupational or environmental health risk assessment of mixtures remains to be accomplished in most cases (Vyskocil *et al.*, 2007). In this regard, it is critical that the mechanisms of toxicokinetic and toxicodynamic interactions be evaluated and integrated within quantitative models to facilitate scientifically sound dose-response assessments for chemical mixtures. Such an approach will not only reduce uncertainty relating to mixture risk assessment, but also identify key data gaps that need to be addressed by focussed research programs.

The evaluation and modelling of toxicological data on interactions have been conducted either using statistical approaches (Berenbaum, 1989; Bailer and Bailer, 1999; Hamm *et al.*, 2005; Gennings *et al.*, 2005) or mechanistic approaches (e.g. Mumtaz and Durkin, 1992; Tardif *et al.*, 1993; 1995; 1997; Pelekis and Krishnan, 1997; Haddad *et al.*, 1999; 2000a; 2000b; 2001; Jonker *et al.*, 2005; Yang and Dennison, 2007). Whereas the characterization of the nature and extent of interaction is feasible with the statistical models, their use is somewhat limited with regard to extrapolations (route, species, dose, mixture complexity, etc.) required for the conduct of dose-response assessment of mixtures. However, they are critically useful in facilitating the determination of departure from additivity, as discussed in detail in **Toxicology of Chemical Mixtures**. The present chapter focusses specifically on the current approaches for evaluating toxicological interactions for the dose-response assessment of chemical mixtures. The approaches described in this chapter are: (i) interaction matrix method, (ii) interaction weighting ratio (IWR) method and (iii) physiological modelling.

Table 1 Examples of toxicological interactions among environmental pollutants reported to occur in humans (Krishnan and Brodeur, 1994)

Pollutant type	Supra-additive	Infra-additive(*)
Gases and particulates	• Particulates and sulphur dioxide • Ozone and sulphur dioxide	• Ammonia and sulphur dioxide • Carbon dust and sulphur dioxide • Selenium and mercury • Iron and mercury • Iron and cadmium • Zinc and cadmium • Zinc and lead • Lead and iron
Pesticides	• Malathion and isomalathion	—
Solvents	• Methanol and dichloromethane	• Trichloroethylene and 1,1,1-trichloroethane
	• Methyl ethyl ketone and methyl n-butyl ketone/*n*-hexane	• Trichloroethylene and tetrachloroethylene
	• Isopropanol and carbon tetrachloride	• Ethyl benzene and xylene • Toluene and xylene • Xylene and methyl ethyl ketone • Xylene and isobutanol

(*) Includes reports of metabolic inhibition.

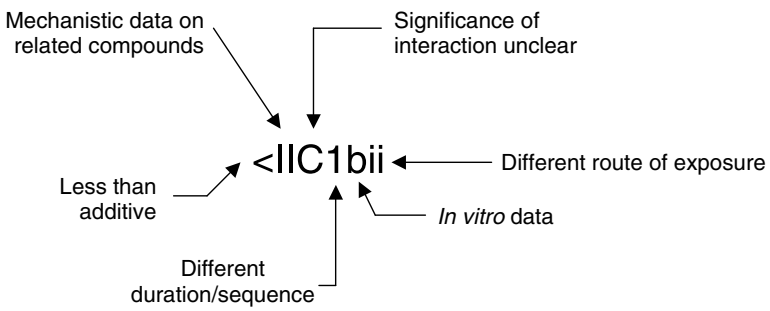

Figure 2 Example of a binary WOE classification scheme (Mumtaz and Durkin, 1992). < = infraadditive toxicity, II = inferred based on mechanistic data on related compounds, C = significance of interaction unclear, 1 = exposure duration/sequence different from that of relevance to risk assessment, b = *in vitro* data and ii = route of exposure different from that of relevance to risk assessment.

2 INTERACTION MATRIX METHOD

This approach, applied to systemically acting mixtures, involves collection and organization of the data on binary chemical interactions, which are then expressed in terms of an alphanumeric code representing the overall weight-of-evidence of the possible occurrence (Mumtaz and Durkin, 1992). This approach focusses to group the quality of interaction data into two biological categories (mechanistic understanding and toxicological significance), and three modifying categories (duration/sequence of exposure, *in vivo* and *in vitro* data, and route of exposure). The two biological categories form the basis of the assessment, while the modifying categories are used to alter the rating of the assessment to reflect the extent of relevant available data. This procedure generates an alphanumeric rating of the weight-of-evidence of binary chemical interactions (BINWOE) in mixtures (**Figure 2**), and presents them in a matrix form for any given mixture. **Table 2** presents the matrix of BINWOE scores for interactions in a mixture of 1,1,1-trichloroethane, 1,1-dichloroethane, trichloroethylene and tetrachloroethylene (Pohl *et al.*, 2003; 2004). This summary table indicates that most of the joint action of these mixture components would result in additivity, except for trichloroethylene + tetrachloroethylene, for which infraadditivity is implied based on available data. The alphanumeric expressions shown in **Table 2** can, in turn, be collapsed to yield a single number, referred to as the interaction factor for use in mixture dose-response assessment (Mumtaz and Durkin, 1992; Mumtaz *et al.*, 1994; Hertzberg and MacDonell, 2002). The interaction factor for each chemical pair within a mixture (e.g. components i and j) is calculated using the following algorithm:

$$\mathrm{IF}_{i,j} = \mathrm{HQ}_i \mathrm{BINWOE}_{i,j} \cdot (\mathrm{HQ}_i \cdot \mathrm{HQ}_j)^{0.5} \qquad (1)$$

Table 2 Matrix of BINWOE determination for simultaneous exposure to chemicals of concern

Effect of \ on toxicity of	1,1,1-Trichloroethane	1,1-Dichloroethane	Trichloroethylene	Tetrachloroethylene
1,1,1-Trichloroethane	—	Nervous system = IIC Liver and kidney = IIC	Nervous system = IIC Liver and kidney = IIB	Nervous system = IIC Liver and kidney = IIB
1,1-Dichloroethane	Nervous system = IIC Liver and kidney = IIC	—	Nervous system = IIC Liver and kidney = IIC	Nervous system = IIC Liver and kidney = IIC
Trichloroethylene	Nervous system = IIC Liver and kidney = IIB	Nervous system = IIC Liver and kidney = IIC	—	Nervous system = IIC Liver and kidney = IIB
Tetrachloroethylene	Nervous system = IIC Liver and kidney = IIB	Nervous system = IIC Liver and kidney = IIC	Nervous system = IIC Liver and kidney < IIB	—

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat009
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

where $IF_{i,j}$ refers to the interaction factor for the effect of i on the toxicity of j, HQ is the hazard coefficient of each mixture component (e.g. $HQ_i = 0.25$ means that component i is present at 25% of its guideline value), and BINWOE is the interaction term, a quantification of concern of interaction for the chemical pair i, j. The BINWOE scores range from 0 to 1.

The basis of the interaction matrix approach is that the level of concern associated with a mixture increases with increasing incidences of supra-additive interactions, and the opposite is likely to be the case with the occurrence of infra-additive interactions among mixture components. The BINWOE interaction matrix essentially provides a complete picture of the current state of knowledge of binary chemical interactions in chemical mixtures **(Table 2)**. Further, using this approach, the available data on interactions can be used to adjust the conventional hazard index (HI) for noncarcinogenic end points for a mixture as follows (Mumtaz and Durkin, 1992; Hertzberg and MacDonell, 2002):

$$HI_A = HI.UF_i^{WOE_N} \tag{2}$$

where HI_A is the hazard index calculated by adjusting for the potential occurrence of interactions among mixture components, HI is the conventional hazard index for a mixture calculated based on additivity assumption, UF_i corresponds to the uncertainty factor accounting for the potential occurrence of interactions among mixture components, and WOE (weight of evidence) is the ratio of the sum of the IF_i calculated as per Equation 1 to the maximal possible WOE score for a given mixture (Mumtaz and Durkin, 1992). The US Environmental Protection Agency has further modified this approach to facilitate the computation of interaction magnitude based on consideration of exposure levels of component chemicals, and the interaction effect on each chemical rather than on the whole mixture (Hertzberg and MacDonell, 2002).

The BINWOE approach, unlike an arbitrarily determined synergistic safety factor, provides a scientifically sound basis for determining the interaction factor for use in the dose-response assessment of mixtures. Further, it reflects the current state of knowledge on toxicological interactions (supra- and infra-additive) among components of a mixture for modifying the HI for systemic toxicity. For evaluating the interactions among mixture components with regard to their impact on cancer outcome, an IWR is useful.

3 INTERACTION WEIGHTING RATIO METHOD

The IWR method integrates available information on interactions among the carcinogenic components of a mixture to facilitate the calculation of an exponent index. The exponent index is a scale of the cancer risk associated with the mixture, based on the assumption of independent joint action. The product of IWR and exponent index is then used to classify the carcinogenic mixture according to its level of concern as low, marginal, moderate, high-moderate or high (Woo *et al.*, 1994):

The IWR is calculated as follows:

$$IWR = \frac{1 + \left(p \cdot H_{syn}\right) + \left(q \cdot H_{pro}\right)}{1 + \left(r \cdot H_{ant}\right) + \left(s \cdot H_{inh}\right)} \tag{3}$$

where H terms represent the hazard-modification scores for interactions (synergism (syn), promotion (pro), antagonism (ant) and inhibition (inh)). The terms p, q, r and s refer to weighting factors that reflect the relative importance of each form of interaction. The number 1 in both the numerator and denominator of this equation (representing additivity) keeps the lower limit of the IWR above zero, thus preventing division by zero when the terms in the denominator (H_{ant} and H_{inh}) are equal to zero. The calculation of H requires systematic identification of all possible binary pairs (interactions) within a given mixture and the use of weighting factors as detailed in Woo *et al.* (1994).

The basis of this approach is that the level of concern associated with a mixture increases with increasing incidences of supra-additive interactions, and the opposite is likely to be the case with the occurrence of infra-additive interactions. Since the IWR is calculated as a ratio of the 'hazard-amplifying interactions' to the 'hazard-reducing interactions' in a mixture, this approach provides a balanced way of considering interaction data in cancer risk assessments for chemical mixtures. Accordingly, as the weighted information indicating synergism or promotion increases relative to antagonism or inhibition, the IWR and the overall assessment of hazard increase. Conversely, as the weighted information reflective of synergism or promotion decreases relative to the information indicating antagonism or inhibition, the overall assessment of the cancer hazard of the mixture decreases (Woo *et al.*, 1994).

The IWR method, similar to the BINWOE method for systemic toxicants, is essentially data based and therefore the quantitative inferences for low-level human exposures are limited. When the magnitude and impact of pharmacokinetic and pharmacodynamic (PD) interactions on the dose-response relationship of mixture components are to be evaluated for various doses, scenarios, complexities, routes and species, mechanism-based modelling approaches are relevant. In this regard, physiologically based models are useful.

4 PHYSIOLOGICALLY BASED MODELLING

Physiologically based modelling refers to the process of reconstructing mathematically the key physiological

characteristics of an organism, and describing the quantitative inter-relationships among the critical determinants of pharmacokinetics, pharmacodynamics and toxic interactions (Krishnan *et al.*, 1994; Krishnan and Andersen, 2007). This method is unique in permitting the simulation of the potential modulation of tissue dose and response due to pharmacokinetic and PD interactions within multicomponent mixtures (Andersen *et al.*, 1994; Simmons, 1996; Haddad *et al.*, 1998; 2001; Krishnan *et al.*, 2002; Yang and Dennison, 2007). Whereas physiologically based pharmacokinetic (PBPK) models are available for a number of chemicals and chemical mixtures (Simmons, 1996; Reddy *et al.*, 2005; Krishnan and Andersen, 2007; Lipscomb and Ohanian, 2007), such models for simulating the PD process in mixtures are very limited (Timchalk and Poet, 2008). The feasibility of using PBPK models to describe, predict and extrapolate the occurrence and magnitude of interactions as a function of dose levels, exposure scenarios, species, route and mixture complexities arises from the mechanistic nature and biological basis of these models.

PBPK models of mixtures correspond to a set of individual chemical models interconnected via the mechanism of interaction (Krishnan and Brodeur, 1994a) (**Figure 3**). In these models, the organism is represented as a network of tissue compartments (e.g. liver, fat, slowly perfused tissues and rapidly perfused tissues) interconnected by systemic circulation, and the rate of change in chemical concentration in the various model compartments is determined by solving mass balance differential equations (Krishnan *et al.*, 1994). To solve the model equations, the numerical values of physiological (e.g. cardiac output, breathing rates, tissue volumes, tissue blood flow rates), physicochemical (e.g. blood:air and tissue:blood partition coefficients) and biochemical (e.g. metabolic velocity for metabolism, Michaelis affinity constant, inhibition constant) parameters should be known. If one or more mechanistic determinants of chemical uptake, metabolism and disposition is altered during co-exposure (**Table 3**), then a pharmacokinetic interaction results. **Table 4** summarizes the PBPK models for mixtures of environmental contaminants available in the literature. These models facilitate the simulation of the consequence of pharmacokinetic interactions, which is often a change (increase or decrease) in the tissue dose of interacting chemicals. PBPK models, by accounting for interaction mechanisms, permit the prediction of the change in tissue dose of mixture components as a function of dose, route, scenario and mixture complexity as discussed below.

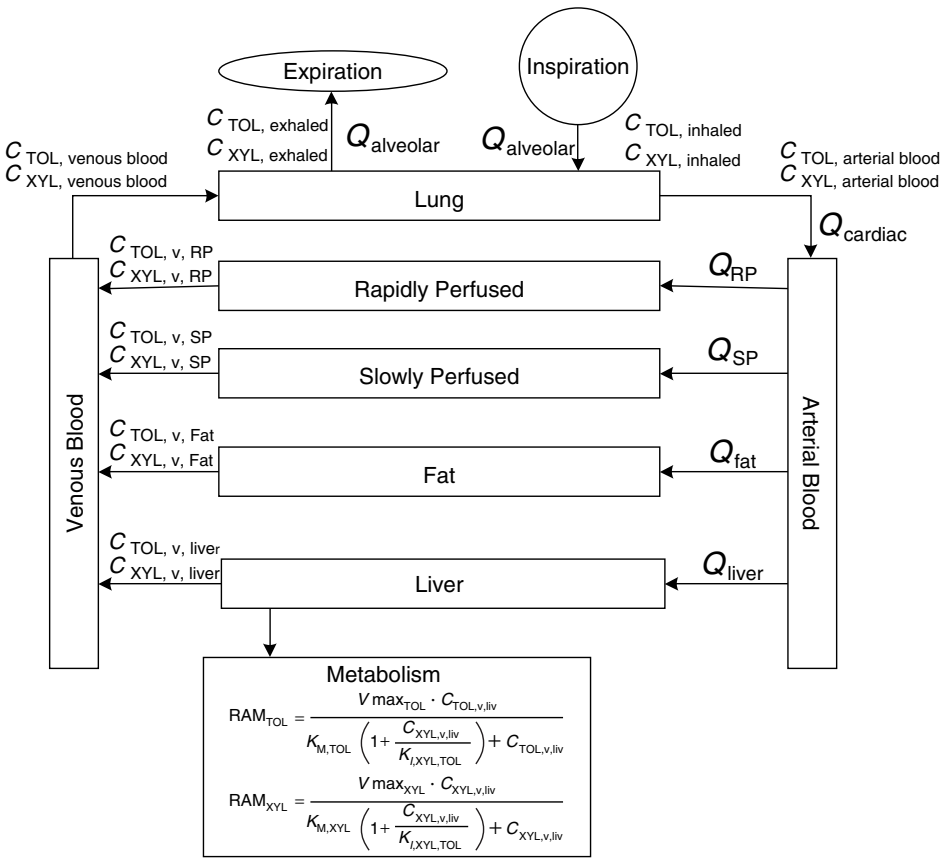

Figure 3 Schematic of a binary mixture PBPK model for inhalation exposures of toluene (TOL) and xylene (XYL) with competitive inhibition between them.

Table 3 Examples of interaction among environmental pollutants at the absorption, distribution, metabolism and excretion levels

Mechanism/level of interaction	Example of interactions	Reference(s)
Pulmonary absorption	Hydrogen cyanide can enhance the uptake of certain air-borne contaminants by increasing the pulmonary ventilation rate	Dreisbach (1977)
Dermal absorption	Enhanced dermal absorption of pesticides and metals in the presence of organic solvents (e.g. triazines in the presence of trichloroethylene, *N,N*-diethyl *-m*-toluamide in the presence of ethanol, arsenic and nickel in organic solvent mixtures)	Marjukka Suhonen *et al.* (1999), Ross and Shah (2000), Turkall *et al.* (2003), Baynes *et al.* (2005)
Oral absorption/ transportation	Low essential element status, by increasing the expression of DMT1 (divalent metal transporter 1) increases the absorption of toxic metals (Cd, Co, Cu, Fe, Mn, Pb and Zn)	Gunshin *et al.* (1997), Picard *et al.* (2000), Rolfs and Hediger (2001), Roth *et al.* (2003), Bressler *et al.* (2004), Bressler *et al.* (2007), Yokel *et al.* (2006), Madden (2003), Kwong *et al.* (2004), Cory-Slechta (2005)
Tissue distribution	Various dithiocarbamates by forming lipophilic complexes with inorganic lead, lead to greater accumulation in the lipid-rich brain compartments	Tandon *et al.* (1990), Weiss *et al.* (1990)
Tissue distribution	Competition or induction of metallothionein (a low molecular weight protein containing -SH groups) leads to toxicological interactions among metals as well as between metals and nutrients	Telisman (1995), Brzóska and Moniuszko-Jakoniuk (2001), Telisman (1995), Bobillier-Chaumont *et al.* (2006)
Metabolism	Inhibition of specific isoforms of cytochrome P450 by metals have also been reported: CYP1A1 by mercury, CYP2E and CYP3A by cadmium, and CYP1A1 by arsenic.	Ke *et al.* (2002), Alexidis *et al.* (1994), Albores *et al.* (1995)
Metabolism	Lead, by diminishing haem synthesis and changing the rate of haem degradation, leads to change in P450 levels and activities	Moore (2004), Kadiiska and Stoytchev (1980)
Metabolism	Chronic ethanol treatment enhances hepatic CYP2E1 activity, but after an acute administration, it acts as an inhibitor	Phillips *et al.* (1977), Garro *et al.* (1981), Pelkonen and Sotaniemi (1982), Peng *et al.* (1982), Miller and Yang (1984), Swann *et al.* (1984)

Table 3 (*continued*)

Mechanism/level of interaction	Example of interactions	Reference(s)
Excretion	Arsenic and selenium, during combined exposures, increase the biliary excretion of each other following the formation of the seleno bis-(*S*-glutathionyl) arsinium ion, which is subsequently excreted in bile	Zeng *et al.* (2005)
Excretion	The hepatic injury caused by dioxin leads to an impairment of biliary excretion and concomitant change in copper in tissues	Elsenhans *et al.* (1991)

4.1 High Dose to Low Dose Extrapolation

High dose to low dose extrapolations of pharmacokinetic interactions are critical to the better characterization of the dose-response relationships for chemical mixtures. A scientifically sound approach for high dose to low dose extrapolation requires that the nonlinear kinetic behaviour of the interacting chemicals be taken into account along with the dose-dependent impact of the interaction mechanism (e.g. enzyme induction, competitive inhibition). In this regard, the PBPK models have been demonstrated to facilitate the conduct of high dose to low dose extrapolations of the consequence of pharmacokinetic interactions. **Figures 4** and **5** illustrate the dose-dependent change in internal dose metrics of toluene (TOL) (blood concentration and amount metabolized) in rats with PBPK models (or equivalent steady-state algorithms) (Isukapalli *et al.*, 2008). Accordingly, the impact of increasing concentration of *m*-xylene (*m*-XYL) on the internal dose of inhaled TOL varies as a function of both their exposure concentrations. These differences in internal dose are adequately simulated with the PBPK models and such algorithms because they not only take into account the nonlinearity due to saturable metabolism, but also the additional impact of metabolic inhibition occurring during mixed exposures. This simulation approach has successfully been used for the determination of the interaction threshold, that is, the exposure concentration of mixture components at which their internal dose does not deviate significantly compared to individual chemical exposures (Tardif *et al.*, 1995; El-Masri *et al.*, 1996a). Several studies have investigated the interaction threshold as a function of mechanism and exposure concentrations of interacting chemicals (Tardif *et al.*, 1993; 1995; 1997; El-Masri *et al.*, 1996a; 1996b; Simmons, 1996; Haddad *et al.*, 2001; Dobrev *et al.*, 2002). More recently, Yang and Dennison (2007), based on PBPK modelling of gasoline and six of its components, concluded that the interaction thresholds during mixed exposures would appear to stay within the bounds of the thresholds of its respective component chemicals.

4.2 Route to Route Extrapolation

The temporal change in the effective concentration of an inhibitor at the site of interaction and the tissue dose of the toxic moiety of mixture components might vary depending upon the route of exposure (e.g. intravenous, oral, inhalation, dermal). For systemic toxicants in mixtures, the resulting toxicity is likely to depend upon the route of exposure since it is the key determinant of the bioavailability, rate of absorption and extent of first pass clearance (IGHRC, 2005). These route-dependent factors, influencing the magnitude and profile of the effective concentration of a chemical at the interaction site, may lead to differences in the magnitude of the interaction during mixed exposures. Krishnan and Pelekis (1995), as well as Nong and Krishnan (2005) demonstrated the route-to-route extrapolation (oral to inhalation) of the occurrence of metabolic interactions for human exposure to a mixture of TOL and dichloromethane (DCM) as well as mixtures of TOL, *m*-XYL and ethylbenzene (EBZ). These limited studies have shown that the PBPK models, by facilitating the consideration of route-specific phenomena, permit the simulation of the internal dose for combinations of systemically acting chemicals for each exposure route (or for aggregate exposures), to facilitate the extrapolation of the threshold of interactions from one exposure route to another.

4.3 Interspecies Extrapolation

When the dose-response information for individual chemicals and mixtures is initially obtained in laboratory animals, the determination of the toxicologically equivalent dose in humans becomes necessary. The PBPK models have been shown to be powerful in the conduct of interspecies extrapolations of single chemicals (Reddy *et al.*, 2005; Krishnan and Andersen, 2007). The determination of toxicologically equivalent doses of chemicals in mixtures not only requires adjustment for species differences in physiology, metabolism and volume of

distribution, but also necessitates the consideration of the possible interspecies differences in the extent of interactions. There are only a few examples demonstrating the validity of the use of rodent mixture PBPK models for predicting the pharmacokinetics of chemicals in humans during mixed exposures. The rat-to-human extrapolation of pharmacokinetic interactions using the PBPK modelling approach has been demonstrated for a binary mixture (TOL and *m*-XYL) and a ternary mixture (TOL-XYL-EBZ) (Tardif *et al.*, 1995; 1997). In these studies, the physiological parameters (i.e. alveolar ventilation rate, cardiac output, tissue volumes, tissue blood flow rates) of the rat PBPK models were replaced with those of humans, the maximal velocity for metabolism was scaled on the basis of body surface, whereas the affinity constants and inhibition constants representing interactive effects were considered to be species-invariant, based on the observation that the same isozyme (CYP2E1) is involved in the metabolism of these substances in both the test species and humans.

4.4 Mixture Complexity

The toxicity and dose-response relationships of mixture components may not only be influenced by the outcome

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat009
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of interactions at the binary level, but also by interactions at higher levels (e.g. ternary, quaternary). Historically, there has been a lack of predictive tools essential for simulating higher-order interactions within complex mixtures. In this regard, considerable body of work by Krishnan and colleagues (Tardif *et al.*, 1995; 1997; Haddad *et al.*, 1999; 2000a; 2000b; 2001; Krishnan *et al.*, 2002) has demonstrated the unique usefulness of PBPK models in conducting extrapolations of interactions from binary to more complex mixtures. The approach involves identifying and linking the relevant individual chemical PBPK models via interaction terms [e.g. metabolic inhibition **(Table 5)**]. PBPK models for mixtures of any level of complexity can then be created as long as the quantitative information on the mechanism for each interacting chemical pair is available or can be hypothesized. According to this methodology then, for modelling the kinetics of the components of complex mixtures, plausible binary interactions need only be characterized. In a mixture of three chemicals, for example, there are three two-way interactions. The first step here is to develop PBPK models for each component of the mixture. Then the single chemical models are interconnected at the binary level by modifying the appropriate equations (e.g. metabolism terms). If we consider competitive metabolic inhibition as the mechanism of interaction, then the equation for calculating the rate of the amount metabolized (RAM) of each component should be modified appropriately **(Table 5)**. If we consider interactions at the binary level alone, then how is it possible to simulate the consequence of a higher-order interaction (e.g. involving three chemicals)? This is where the unique usefulness of PBPK modelling becomes evident. Let us consider a mixture of three chemicals (c1, c2, c3), competing for metabolism by a P450 isoenzyme. The initial step is to model the binary chemical interaction between c1 and c2. Then, following the addition of another chemical, c3, the binary combinations c3–c1 and c3–c2 should be characterized. Subsequently, the PBPK model not only simulates the binary interactions involving c3, but also the modulatory effect of c3 on the interaction between c1 and c2 (**Figure 6**). Because, once the inhibitory effect of c3 on c2 is accounted for, this automatically impacts the inhibitory effect of c2 on c1 (i.e. $1 + C_{c2}/Km_{c2}$) (**Figure 6**). Since the exposure to chemical c3 increases C_{c2}, this then translates into a modification of the magnitude of the interactive effect of c2 on c1. Similarly, c3 may also affect the concentration of c1, which would then result in a change in the magnitude of the interactive effect of c1 on c2. Based on this analogy, it is possible to predict the influence of the addition of another chemical c4, c5, and so on. As a new chemical becomes an integral part of the network of the components of the mixture, any modulation of a binary interaction involving that new chemical has repercussions on all the others. The novel thing about this PBPK modelling approach is that it only requires data on binary interaction mechanisms for predicting the magnitude and consequence of multiple interactions within complex mixtures. This approach was initially validated for predicting the kinetics of components of a ternary mixture of alkyl benzenes (Tardif *et al.*, 1997). Further validation of the conceptual and mechanistic basis of this approach has been performed using other experimental data on interactions collected during mixed chemical exposures (Haddad *et al.*, 1999; 2000a; 2000b; Dobrev *et al.*, 2001; 2002; Dennison *et al.*, 2005).

5 PBPK MODELS AND DOSE-RESPONSE ASSESSMENT OF CHEMICAL MIXTURES

The tissue dose simulated using the interaction-based PBPK models can in turn be used to conduct dose-response analysis for mixtures. In this regard, the PBPK models are useful in simulating the change in the tissue dose of a toxic moiety (often referred to as the 'dose

Table 5 Description of metabolic interactions (inhibition) among chemicals during mixed exposures used in PBPK models

Type of inhibition	Rate of metabolism of chemical 1	Rate of metabolism of chemical 2
No interaction	$\frac{V_{max_1} \cdot C_{1,v,liv}}{Km_1 + C_{1,v,liv}}$	$\frac{V_{max_2} \cdot C_{2,v,liv}}{Km_2 + C_{2,v,liv}}$
Competitive inhibition	$\frac{V_{max_1} \cdot C_{1,v,liv}}{Km_1 \left(1 + \frac{C_{2,v,liv}}{K_{I,2-1}}\right) + C_{1,v,liv}}$	$\frac{V_{max_2} \cdot C_{2,v,liv}}{Km_2 \left(1 + \frac{C_{1,v,liv}}{K_{I,1-2}}\right) + C_{2,v,liv}}$
Noncompetitive inhibition	$\frac{V_{max_1} \cdot C_{1,v,liv}}{(Km_1 + C_{1,v,liv}) \cdot \left(1 + \frac{C_{2,v,liv}}{K_{I,2-1}}\right)}$	$\frac{V_{max_2} \cdot C_{2,v,liv}}{(Km_2 + C_{2,v,liv}) \cdot \left(1 + \frac{C_{1,v,liv}}{K_{I,1-2}}\right)}$
Uncompetitive inhibition	$\frac{V_{max_1} \cdot C_{1,v,liv}}{Km_1 + C_{1,v,liv} \cdot \left(1 + \frac{C_{2,v,liv}}{K_{I,2-1}}\right)}$	$\frac{V_{max_1} \cdot C_{1,v,liv}}{Km_2 + C_{1,v,liv} \cdot \left(1 + \frac{C_{2,v,liv}}{K_{I,1-2}}\right)}$

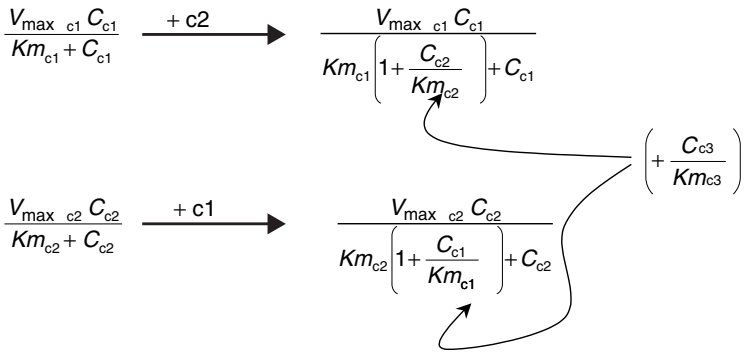

Figure 6 Predictability of the effect of chemical c3 on the interacting binary pair of c1 and c2. These chemicals are substrates of the same enzyme and are assumed to compete for metabolism. V_{max} refers to the maximal velocity for biotransformation; Km refers to the Michaelis-Menten affinity constant; C terms are concentrations of unchanged chemicals in the venous blood leaving the liver. The equations on the left-hand side of the thick arrows represent metabolism of chemicals c1 and c2 when they are present alone, and on the right-hand side represent the modification of the rate of their metabolism in the presence of an inhibitor (chemical c2 or c1). With the addition of chemical c3 to the binary mixture of chemicals c1 and c2, all one has to do is to include the binary-level interaction constants representing metabolic inhibition between chemical c3 and chemical c1, and chemical c3 and chemical c2 in the PBPK model. In this specific example, for the sake of simplicity, the inhibition constants are set equal to the Km of the inhibitor.

metric') following mixed chemical exposures. A change in the level of the tissue dose in certain cases leads to a corresponding change in toxicity. For example, as shown in the dose response curve in **Figure 7A**, an increase in tissue dose of a chemical during mixed exposures leads to an increase in the toxicity. Here, the tissue dose per unit exposure concentration is altered and the resulting increase in tissue dose is significant enough to enhance the toxicity of the chemical during mixed exposures. On the other hand, if the change in tissue dose occurs only to a smaller extent and within the threshold region of the chemical(s), then a change in tissue dose does not translate to a change in toxicity (**Figure 7B**).

Based on the tissue dose vs response relationship shown in **Figure 7A**, for genotoxic carcinogens, the probability of excess cancer in a population [P(d)] exposed to a mixture can be calculated as:

$$P(d) = q^*_{\text{tissue}} d_{\text{tissue}} \tag{4}$$

where q^*_{tissue} = the tissue dose-based cancer slope factor for each of the mixture components (1,2, . . . ,n), and d_{tissue} refers to the tissue dose of each mixture component simulated using an interaction-based PBPK model.

The application of the above approach to the dose-response assessment of chemical mixtures is illustrated in **Table 6**. In this case, using the mixture PBPK model that takes into account the interactions among the components, the change in tissue dose of the toxic moiety of DCM [i.e. the glutathione (GSH) conjugate] was simulated for various mixed exposure scenarios. The tissue dose, as well as the cancer risk attributed to DCM during mixed exposure (in comparison with single chemical exposures) increase as the interactions cause a decrease in the flux of this chemical through the CYP450 pathway (due to competitive inhibition of metabolism) combined with a proportional increase in the flux through the GSH pathway. The latter metabolic pathway is thought to be responsible for the carcinogenicity of DCM (Andersen *et al.*, 1991).

For systemic toxicants affecting the same target organ, the tissue dose-based dose-response analysis is conducted as follows:

$$\text{HI} = \sum_{i=1}^{n} \frac{C_{\text{tissue,exp},i}}{C_{\text{tissue,ref},i}} \tag{5}$$

where $C_{\text{tissue,exp},i}$ refers to the tissue concentration of the

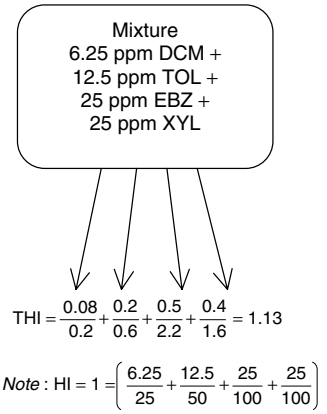

Figure 8 Comparison of the tissue dose-based hazard index (THI) with the conventional hazard index (HI) for a chemical mixture. The data for THI were obtained using the simulations of an interaction-PBPK model for mixtures. (Based on Haddad *et al.*, 2001.)

dose surrogate of component i predicted using a PBPK model that accounts for multiple interactions occurring in the mixture, and $C_{\text{tissue,ref},i}$ is the tissue concentration of the dose surrogate of component i corresponding to its maximum allowable concentration.

The PBPK-based mixture dose-response assessment for systemic effects [e.g. central nervous system (CNS) effects] is illustrated in **Figure 8**. As seen in this figure, for the mixture of DCM, benzene (BEN), TOL, EBZ and *m*-XYL, the tissue dose-based hazard index (THI) is greater than the HI, which does not take into account the metabolic interaction and its impact on the tissue dose of the components.

6 CONCLUDING REMARKS

The dose-response assessment for chemical mixtures and their components can be improved by developing integrated pharmacokinetic/PD models, even though such models are only beginning to be developed. Recently, Timchalk and Poet (2008) developed a PBPK/PD model for the mixture of chlorpyriphos and diazinon, by taking into account the mechanisms of toxicokinetics, toxicodynamics (cholinesterase inhibition), as well as the metabolic interaction between these chemicals. The PBPK/PD model was then able to simulate the cholinesterase inhibition as a function of the dose of the mixture components, thus facilitating the construction of a dose-response relationship for this mixture. Mechanistic models of receptor interactions at various levels—binding, receptor activation, as well as signal transduction—have been developed and applied for the analysis of combined drug responses (Jonker *et al.*, 2005), but not for the dose-response assessment of mixtures of environmental contaminants as yet. With the on-going research in the areas of omics, molecular toxicology and computational toxicology, it will increasingly become feasible to construct/simulate dose-response relationships for chemical mixtures as a function of the pharmacokinetic and PD interactions, as well as the concentrations of the mixture components in the human microenvironment.

Toxicology of Chemical Mixtures

Kannan Krishnan and Jonathan Boyd

CONTENTS

1 INTRODUCTION

Multichemical exposure is the rule rather than the exception in both the general and occupational environments. Even though toxicity testing protocols and health risk assessment methods applicable to single chemicals are fairly well developed, it is not the case for chemical mixtures. The fundamental additional considerations in mixture toxicology relate to the concept of additivity and the possible occurrence of interactions. The toxicity of chemicals in mixtures might be altered due to interactions occurring in the exposure, toxicokinetic and/or toxicodynamic phases (see **Evaluation of Toxicological Interactions for the Dose-Response Assessment of Chemical Mixtures**). The exposure-phase interactions may be dealt with by quantifying the parent chemicals and the reaction products in a mixture (Krishnan and Brodeur, 1991).

Toxicity assessment may be more complicated if interactions occur among the components of the mixture at the toxicokinetic or toxicodynamic level (Calabrese, 1991; Krishnan and Brodeur, 1991). Even though data on the occurrence of toxicokinetic and toxicodynamic interactions are scanty, some evidence of their occurrence in humans is available (Krishnan and Brodeur, 1994). For example, joint toxicity of sulfur dioxide and ammoniacal compounds is thought to have been encountered during the London fog disaster of 1952 (Waldbott, 1973); the increased joint toxicity of sulfur dioxide and ozone was a likely causative factor of the high mortality of Japanese children observed in the early 1970 s (Bates and Hazucha, 1974); isomalathion contributed to enhance the cholinergic effects observed in 1976 in Pakistani spraymen handling malathion (Baker *et al*., 1978); and the attenuation of the toxic effects of mercury in a Japanese population was attributed to the simultaneous exposure to elevated levels of selenium (Suzuki *et al*., 1980). Other examples of interactions among essential and nonessential elements characterized in humans include: zinc and lead, as well as iron and mercury, cadmium or lead (reviewed in Krishnan and Brodeur, 1991; Calabrese, 1991). In most cases, however, there is a lack of toxicity data (i.e. the target organ as well as the dose–response information) for the mixture of concern or there is insufficient information on the components and interactions among them.

The purpose of this chapter is to describe the concepts and methods for evaluating the toxicity of chemical mixtures. This chapter is organized in terms of the assessment of whole mixtures, similar mixtures or mixture components.

2 TOXICITY ASSESSMENT OF CHEMICAL MIXTURES

The toxicity of chemical mixtures is evaluated using integrative, dissective or synthetic strategies (Mauderly, 1993; Eide, 1996). The integrative studies focus on evaluating the mixture as a whole, whereas the synthetic approach evaluates the toxicity and interactions among components. The integrative and synthetic approaches are also referred to as 'top-down' and 'bottom-up', respectively, in mixture toxicology. The dissective

approach, on the other hand, involves the reconstruction of the toxicity of the whole mixture on the basis of toxicological evaluation of selected submixtures. In this regard, various fractionation approaches are useful for regrouping mixture constituents for further characterization of their biological activity (Mauderly, 1993; Eide, 1996).

Frequently, the purpose of mixture toxicity studies is to address one or more of the following questions:

- What are the critical effects and toxicity benchmarks (no-observed-adverse-effect level (NOAEL), lowest-observed-adverse-effect level (LOAEL)) associated with a given chemical mixture?
- How does the toxicity of one mixture (e.g. cancer slope factor) compare with another similar mixture?
- How does the whole mixture toxicity compare with the toxicity of individual chemicals or submixtures?

These concerns can be addressed using whole mixture studies, comparative potency studies and component or fraction-based studies, as discussed in the following sections.

3 TOXICITY ASSESSMENT OF WHOLE MIXTURES

The toxicity evaluations of whole mixtures focus on identifying the target organ(s) and characterizing the dose–response relationship in the target or test species. Here, the mixture is considered as a single entity; thus preparations are made taking into account the absolute and relative concentrations of the various components, their miscibility and volatility, among other factors (Yang and Rauckman, 1987). The challenges, study design and approaches for identifying critical effects and toxicity benchmarks (NOAEL, LOAEL) using whole mixtures are essentially the same as for any single chemical. Since the 'whole mixture approach' allows qualitative and quantitative evaluations of the toxicity of the mixture in consideration, there is no need to guess or judge the pertinence of data on interaction between components. The major advantage is that the dose–response data generated using the whole mixture are directly relevant for risk assessment purposes even if the composition of the mixture is not known completely, as long as it is the same for the mixture of concern and the mixture used in toxicity tests (US EPA (Environmental Protection Agency), 1997). For instance, an assessment of the toxicity of commercial hexane, which contains 52% *n*-hexane and 48% of other materials (3-methylpentane, methylcyclopentane, 2-methylpentane, cyclohexane, 2,3-dimethylbutane, 2,2-dimethylpentane, 2,4-dimethylpentane, 2,2-dimethylbutane, 2,2,2-trimethylbutane and 2-methylhexane) was conducted by Daughtrey *et al.* (1999). For this purpose, groups of animals (50 per sex) were exposed to 0, 900, 3000 and 9000 ppm of the mixture, to identify the chronic effects. Clearly, in this case the assessment of the whole mixture (commercial hexane) provided the most direct information on the toxicity of this mixture and it did not require assumptions regarding interactions among components. Another example of such data collection relates to observations made in a cohort of workers exposed to various risk factors simultaneously (e.g. Rabinowitz *et al.*, 2008). The extent to which these data can be extrapolated to other situations (i.e. high dose to low dose, interspecies and interindividual) is not known. This source of uncertainty is of concern because the extent and magnitude of interactions might vary between the doses of mixtures evaluated experimentally and the dose levels of relevance to the end user (e.g. occupational exposures vs. environmental exposures).

Even though the whole mixture approach is applicable for uncharacterized or partially characterized mixtures whose composition is stable and does not vary with time and space, the dose–response data required even for a single whole mixture can be time and resource consuming. The number of end points to be investigated in such studies can be unrealistically large (e.g. haematotoxicity, hepatotoxicity, developmental toxicity) and would be difficult to narrow down without some relevant knowledge of mixture components.

Cancer slope factors for whole mixtures may also be determined using this approach. When such data are available for mixtures of interest, they can be of use only if the identity of mixture components, their proportions and concentrations do not change with time and space. This limitation is highlighted with the cancer slope factors for polychlorinated biphenyl (PCB) mixtures. The cancer slope factors for three PCB mixtures were reported to range from 0.07 to 2.0 mg/kg(day)$^{-1}$ (Warren *et al.*, 2004). Therefore, it would appear that the cancer slope factor for Aroclor-1268 could not be assumed to be the same as that of another PCB mixture, namely Aroclor-1254 (Warren *et al.*, 2004). In such cases, an analysis of the similarity of mixtures should be undertaken.

4 TOXICITY ASSESSMENT BASED ON SIMILAR MIXTURES

A relative potency determination or comparative assessment of responses obtained in laboratory assays may be conducted for mixtures that are considered to be similar based on chemical composition, mode of action or toxicity end point (US EPA (Environmental Protection Agency), 2000). Let's assume that A is the mixture of concern, whereas the toxicity benchmark

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat010
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

for another similar mixture B has already been characterized. The human dose–response or toxicity information for mixture A can then be evaluated by making use of the dose–response information for mixture B in a parallelogram approach, in which the human dose–responses are assumed to be related in the same way as the responses in *in vitro* or short-term assays for both mixtures (Lewtas, 1985; Schoeny and Margosches, 1989). Accordingly, the relative potency of the two mixtures in a particular assay (e.g. mouse skin tumour initiation assay) is used in conjunction with the human risk estimates for the 'similar' mixture, to solve for the unknown (i.e. the human risk estimate for the mixture in hand), as follows:

$$\frac{R_A}{P_A} = \frac{R_B}{P_B} \quad (1)$$

where R_A and R_B refer to human risk estimates for mixtures A and B, and P_A and P_B are the potencies of mixtures A and B in a particular bioassay.

Additionally,

$$RP_1 = k(RP_2) \quad (2)$$

where RP_1 and RP_2 are the relative potencies of a mixture in assays 1 and 2, and k is a constant (Lewtas, 1983).

The above approach has been applied for deriving cancer risk estimates for humans based on short-term studies with roofing tar and diesel exhaust mixtures in comparison with the coke oven emissions (Lewtas, 1983). Since this approach treats the complex mixture as a single entity, potential toxicological interactions occurring among components are accounted for. Conceptually then, the comparative potency approach assumes that for similar, but not necessarily defined, complex mixtures, a measure of comparative potency based on results of *in vitro* or short-term bioassays can be correlated in a constant manner with human data. The comparative potency approach requires that human data be available for a similar mixture and this requirement seriously limits the applicability of this methodology. The assumption that the human responses for an uncharacterized mixture and a similar, characterized mixture are related in the same manner as they would be in a rodent/*in vitro* bioassay may not be true in all instances. In this regard, the *in vitro/in vivo* comparisons of dose–response behaviour are empirical, since the tissue dose of the toxic moiety and the extent of interactions might not be identical in both systems. Additionally, the comparative evaluation procedure applied for mixtures is end-point driven (e.g. genetic toxicity), and as such it only provides a biased and not a complete appraisal of the potential spectrum of critical toxic effects associated with a given mixture. This problem can be resolved with knowledge of the composition of mixtures and the target organ toxicity of components.

5 COMPONENT-BASED ASSESSMENT OF MIXTURE TOXICITY

5.1 Evaluation of the Joint Toxicity of Similarly-Acting Mixture Components

The component-based approaches focus on evaluating the relative or absolute toxicity of mixture constituents, to eventually predict the toxicity of the whole mixture. In the case of similarly acting systemic toxicants, the reconstruction of the toxicity of mixtures is frequently based on (i) dose addition, or (ii) toxic equivalency factor (TEF) approaches. Where the components of a mixture are isomers or congeners of the same chemical, or the components act by a common mechanism, the TEF approach has been used for evaluating the mixture toxicity (US EPA (Environmental Protection Agency), 2000). Dose addition assumes that the constituents of a chemical mixture behave as if they are dilutions of each other (Guidelines for the Health Risk Assessment of Chemical Mixtures, 1986; Calabrese, 1991; Mumtaz *et al*., 1993; Seed *et al*., 1995; Teuschler and Hertzberg, 1995; Hertzberg *et al*., 1998). The basis here, then, is that the true dose–response curve of each of the mixture constituents for a common end point may be different, but the slopes of these curves would be identical if their dose levels were adjusted for potency differences (**Figure 1**). Even though the dose-addition approach is applied for assessing the toxicity of mixtures of systemic toxicants (e.g. organophosphorus pesticides) that exhibit common mechanism of action, recent observations question such a narrow definition of the application domain. In fact, the study by Rider *et al*. (2008) suggests that chemicals acting on the same tissue during a critical period induce

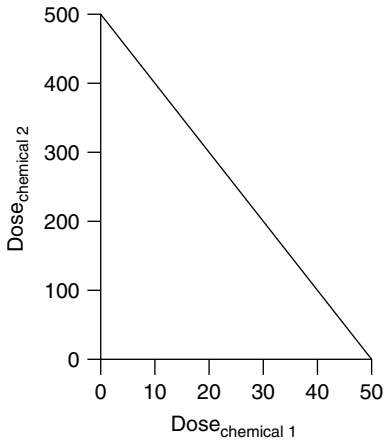

Figure 1 Illustration of the combinations of two chemicals (along the solid line) yielding the same level of response. Notice the difference in potency of the chemicals (Y axis vs. X axis; dose in arbitrary units).

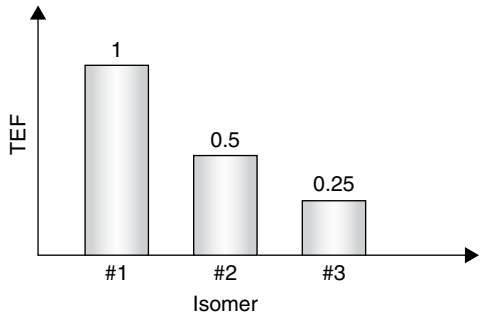

Figure 2 The toxic equivalency factor (TEF) for a reference isomer (#1) as well as for other less potent chemicals in a mixture (#2, #3).

dose additivity even though they act by different molecular mechanisms.

The dose addition approach is based on the premise that the slopes of the dose–response curves for mixture components would be identical if their dose levels are adjusted for potency differences. The potency difference correction for the dose addition approach might be improved if this was done on the basis of the target tissue dose of individual chemicals (Haddad *et al*., 2001) but this has not been done routinely.

When the components of a mixture are congeners or isomers of a chemical, the dose of (and thereby the toxicity associated with) the whole mixture has been computed on the basis of the product of isomer-specific environmental concentration and the TEF for each isomer (Safe, 1994; 1997). The TEF is the ratio of the potency of a given isomer to the 'signature or reference' isomer in a relevant toxicological assay (Barnes *et al*., 1991; Ahlborg *et al*., 1994; Petry *et al*., 1996) (**Figure 2**). The reference isomer is normally the most potent, and as such the concentrations of other isomers in the mixture are adjusted according to potency differences. This procedure then converts all isomers into the equivalents of the most potent isomer (Eadon *et al*., 1986; Barnes *et al*., 1991; Ahlborg *et al*., 1994; Petry *et al*., 1996), and sums them to get an equivalent total dose in terms of the most potent isomer, as follows:

$$TEQ = \sum_{i=1}^{n} C_i TEF_i \qquad (3)$$

where

TEQ = toxic equivalency of a mixture in terms of the most potent isomer,
TEF_i = toxic equivalency factor of isomer i with reference to the most potent isomer, and
C_i = concentration of isomer i in the mixture.

This TEQ is then used along with the dose–response data for the reference isomer to derive estimates of risk associated with the mixture (Guidelines for the Health Risk Assessment of Chemical Mixtures, 1986; US EPA (Environmental Protection Agency), 2000). A key assumption of this approach is that the toxicity induced by each of the various isomers in the mixture is qualitatively similar to that of the 'reference' isomer, even though the potency may vary. The equivalents of each isomer estimated in terms of the 'reference' isomer may be considered as being toxicologically equipotent to the 'reference' isomer. Thus, product of TEFs and exposure concentrations of all isomers/congeners in a mixture are then summed up, assuming dose additivity. TEFs for dioxins and dioxin-like PCBs have been derived (e.g. van den Berg *et al*., 1998). Accordingly, the TEF for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) is 1, whereas that for 2,3,7,8-tetrachlorodibenzofuran (TCDF) and 1,2,3,4,6,7,8-heptachlorodibenzofuran (HCDF) respectively it is 0.1 and 0.01. In other words, exposure to TCDF is similar to being exposed to a tenth of the dose of TCDD, when the exposure doses are equal; this is due to the difference in potency; that is, the chemicals are not equipotent regarding their ability to induce a particular toxic effect or perturbation of a biological process, but rather proportionally potent.

The TEF method does not take into account the possible interactions between the isomers/congeners constituting a mixture. There are a number of examples demonstrating or suggesting the occurrence of competitive interactions between structurally similar chemicals both at the toxicokinetic and toxicodynamic levels (Chen *et al*., 1991; Rao and Unger, 1995a; 1995b; Wölfle, 1997).

The TEF approach also assumes that the isomers act by a similar mechanism contributing to the induction of the same critical effect. This is not necessarily true; and as an extension of this argument it may be suggested that the most potent isomer in one bioassay may not be so with respect to another end point/assay. Therefore, the conceptual basis of this method to enable the consideration of multiple end points in deriving the TEFs should be carefully evaluated (Ahlborg *et al*., 1994). A detailed treatment of the theoretical basis of the TEF approach and limitations can be found in Neumann (1996), Putzrath (1997) and Toyoshiba *et al*. (2004).

5.2 Evaluation of the Joint Toxicity of Dissimilarly-Acting Chemicals

The component-based approach for mixtures of dissimilarly acting chemicals (i.e. independent mode of action) involves the summation of the responses due to each one of them, accounting for the level of independence (Cassee *et al*., 1998). The most conservative form of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat010
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

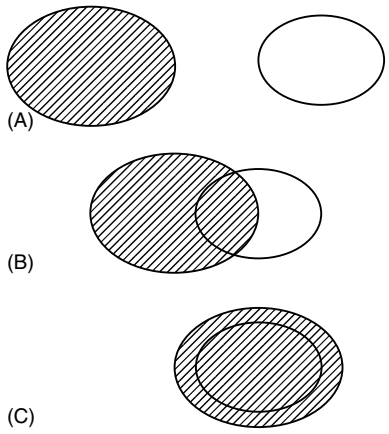

Figure 3 Illustration of the statistical concept of varying levels of independence between two events (or two chemicals in a mixture).

independent action assumes mutual exclusiveness for the events associated with chemical A and chemical B; that is, that the individuals most susceptible to chemical A will not be susceptible to chemical B and vice versa. Therefore, the response from mixed exposure to A and B will be equal to the sum of the probability of the individual events, that is, addition of the response due to A and B determined individually assuming no overlap in terms of susceptibility or occurrence of the events (**Figure 3A**). When the population susceptible to chemical A is also susceptible to chemical B, the susceptibilities are 'correlated positively'. In such cases, the proportion of individuals responding to the mixture AB will be equal to the response of the most toxic agent (**Figure 3C**) (Cassee *et al*., 1998). The intermediary scenario is one where the adverse events associated with the mixture components are not mutually exclusive (**Figure 3B**). Here, in statistical terms, one event has no effect on the occurrence or not of the other event except that both are independent. Thus, the mixture toxicity is calculated as the sum of the responses due to component 1 and component 2 minus the area of overlap (i.e. P(A) × P(B)) (**Figure 3B**).

Based on this theory of response addition and assumption of complete independence, the probability of excess cancer incidence in a given population is estimated by summing up the product of actual or projected environmental concentration (E) and the cancer slope (q*) for each of the mixture components (Guidelines for the Health Risk Assessment of Chemical Mixtures, 1986). The response addition approach so far has only been applied for the assessment of the potential health risk associated with mixtures of chemical carcinogens. Assuming additivity of responses associated with multiple chemical carcinogens is reasonable, since some (genotoxic) carcinogens are believed to act by nonthreshold mechanisms. Further, the assumption of the independence of mechanisms may be reasonable based on the premise that the greater the number of carcinogens in a mixture, the greater the probability that the mechanisms involved are dissimilar (Calabrese, 1991). However, summing the individual estimates of upper bound risks for components has been questioned because it overestimates the true upper bound. More realistic approaches that account for the possibility that all components are not likely to be present at their maximal risk level simultaneously have been described (Chen *et al*., 1991; Kodell and Chen, 1994).

As with the dose addition approach, there is a concern related to the assumption of absence of supra- and infra-additive interactions among mixture components. This assumption may not always be justified, as suggested by the available experimental data on interactions among chemical carcinogens (Rao *et al*., 1989).

Further, the response addition methodology is currently used for mixtures of substances inducing cancer in different tissues and/or via different routes of exposure. This practice involves assignment of equal 'biological' weight regardless of the site-specificity of the tumour induced by mixture components. It is well known that the 'adverse' nature of tumours is also related to the anatomical site of their location. An improved method would be to use tissue dose measures specific for each exposure route (obtained with mechanistic pharmacokinetic models) rather than exposure concentrations in the mixture risk calculation (Haddad *et al*., 2001). This methodology can also facilitate the consideration of change in tissue dose due to interactions among mixture components (see **Evaluation of Toxicological Interactions for the Dose-Response Assessment of Chemical Mixtures**).

5.3 Evaluation of Departure from Additivity

The assessment of the direction and magnitude of interactions among mixture components for various exposure conditions is a challenge. Interactions at the metabolism level have been observed in human volunteer or occupational exposure studies for the following solvent combinations: trichloroethylene and 1,1,1-trichloroethane (Pfaffli and Backman, 1972), benzene and toluene (Inoue *et al*., 1988a), ethylbenzene and *m*-xylene (Angerer and Lehnert, 1979), xylene and toluene (Tardif *et al*., 1991), trichloroethylene and tetrachloroethylene (Inoue *et al*., 1988b), as well as *m*-xylene and methyl ethyl ketone (Liira *et al*., 1988). These metabolic interactions, essentially competitive in nature, lead to reduced/delayed production and excretion of metabolites, as well as, in some cases, increased concentrations of unchanged parent chemical(s) in the blood and alveolar air. Such interactions are expected to result in supra-additive toxicity if the parent chemical is the toxic moiety. Accordingly, supra-additive toxicity during exposure

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat010
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to binary mixtures of solvents has been observed in animal studies, whenever one of the two solvents was a potent inducer of activating enzymes, or an inhibitor of detoxication enzyme system (Pass *et al*., 1985; Brady *et al*., 1989). Thus, solvents inducing hepatic CYP2E1 (cytochrome P450 2E1) upon prior administration (e.g. ethanol, isopropanol, ketones) have been shown to increase the toxicity of other solvents bioactivated by the same isoenzyme. In fact, the toxic interaction between isopropanol and carbon tetrachloride (mediated by CYP2E1) is thought to be responsible for the hepatorenal toxicity associated with two separate industrial accidents (Folland *et al*., 1976; Deng *et al*., 1987). Similarly, the outbreak of an occupational neuropathy among the textile workers in Ohio (Billmaier *et al*., 1974; Allen *et al*., 1975) and among glue sniffers in West Berlin in the 1970s (Altenkirch, 1979) were attributed to the interactive neurotoxicity involving methyl ethyl ketone and *n*-hexane/methyl *n*-butyl ketone (MnBK). However, the toxicological consequences of all metabolic interactions have not been confirmed in occupational monitoring studies (Olson *et al*., 1985; Yin *et al*., 1987).

Some of the confusion in mixture toxicology literature relates to what constitutes interaction. Generally, the term 'interaction' in mixture toxicology is used to refer to departure from additivity; however, investigators often fail to provide the definition of additivity. As discussed in the preceding section, additivity is based either on the dose or response—depending upon whether the mixture components act by similar action or dissimilar (independent) action. Comparing the toxicity of a mixture with that of its components requires an appropriate statistical model for additivity (Bliss, 1939; Finney, 1952). In the scientific literature, the generic terms such as 'infra-additive' and 'supra-additive' are increasingly being used to describe toxicological interactions. The infra-additive interactions (commonly referred to as antagonism) are said to result when the observed toxicity is less than that expected based on the addition of the dose or response of the components. Supra-additive interactions (commonly referred to as potentiation or synergism) are said to occur when the toxicity of the mixture is greater than that of its components evaluated individually (**Figure 4**).

In the case of similarly acting chemicals then, the departure from additivity can be identified as follows (Finney, 1952; Smyth *et al*., 1969):

$$\frac{1}{LD_{50_{\text{mixture}}}} = \frac{P_A}{LD_{50_{\text{component A}}}} + \frac{P_B}{LD_{50_{\text{component B}}}} \qquad (4)$$

where P_A and P_B represent the proportion of A and B in the mixture.

Here the left side of the equation represents the outcome associated with the mixture, whereas the right-hand side relates to the components taken individually. When both sides are equal (allowing for the variability and uncertainty associated with the measurements), it is considered that the mixture toxicity is additive and that interactions would not appear to contribute to change the potency of the components or the mixture as a whole. On the other hand, when the outcome for the tested mixture is greater or less than that of the sum of the contributions of individual components, then infra-additive or supra-additive interactions are said to occur.

The above concept can be understood by comparing the experimental data on the median lethal dose (LD_{50}) of mixtures and components of some organic solvents evaluated by Smyth *et al*. (1969; 1970). In the case of acetonitrile and butylether, the mixture LD_{50} is 10.43 ml kg^{-1}, whereas the LD_{50}s of the individual chemicals are 8.27 and 14.1 ml kg^{-1} for acetonitrile and butylether, respectively. Here 1/10.43 would equal the sum of 0.5/8.27 and 0.5/14.1, indicating that the 50 : 50 mixture of acetonitrile and butylether is additive. Alternately, the mixture of acetonitrile and 1,4-dioxane is supra-additive because the LD_{50} of the mixture is lower than that predicted on the basis of additivity. Thus, the LD_{50} for the mixture was 2.42 ml kg^{-1}, whereas the LD_{50}s for the individual

Table 1 Toxic interactions among environmental pollutants

End point	Supra-additivity	Infra-additivity
Hepatotoxicity	Carbon tetrachloride + trichloroethylene	Carbon disulfide + chloroform
Haematotoxicity	Carbon monoxide + nitric oxide	Lead + iron
Immunotoxicity	PCBs/dioxins	Benzene + toluene
Irritation	Sulfur dioxide + manganese dioxide	Acrolein + sulfur dioxide
Neurotoxicity	Methyl ethyl ketone + methyl *n*-butyl ketone	Toluene + *n*-hexane
Nephrotoxicity	Dimethyl aniline + methyl *iso*-butyl ketone	Cadmium + mercury
Pneumotoxicity	Sulfuric acid + nitrogen dioxide	Formaldehyde + ozone
Reproductive toxicity	Lead + cadmium	Cadmium + selenium
Teratogenicity	Lead + cadmium	Carbon monoxide + sulfur dioxide

Based on Krishnan and Brodeur (1991).

chemicals were 8.27 and 7.07 ml kg^{-1}, respectively, for acetonitrile and dioxane. Here, the experimental LD_{50} for the mixture is about one-third of the expected value based on additivity, indicating supra-additive joint toxicity of acetonitrile and dioxane in the rat (Smyth *et al*., 1970).

In the case of dissimilarly acting chemicals, the outcome (response) associated with the mixture exposure is compared with the sum of the responses due to individual components, assessed separately. When the mixture response is greater (lower) than the sum of the responses of the components, then supra-additivity (infra-additivity) has resulted. For example, if the individual responses due to components A and B are 5 units each and the mixture (A + B) response is 15 units, then this is evidence of synergism. Note that both mixture components (A, B) are toxicologically active in this case. On the contrary, if one of the components is inactive (i.e. does not induce measurable responses) and the combined response is greater than the sum of the individual responses, then such a departure from additivity is referred to as potentiation. For example, if chemical A induces 5 units of response whereas chemical B causes no measurable change in response but the combined exposure to A and B yields 20 units of response, then *potentiation* is said to have occurred. Here chemical B potentiates the toxicity of chemical A during mixed exposures. **Table 1** lists a number of interactions identified to occur among environmental pollutants.

In order to facilitate the identification of the occurrence of interactions, or verify whether the components of a mixture in fact follow additivity, a number of experimental designs are used (factorial design, ray design, central composite design and simplex design) and the results analysed using a statistical method (e.g. isobole method, response surface analysis), which essentially facilitate the definition of the boundary of additivity (Carter and Carchman 1988; Greco *et al*., 1995; Henchler *et al*., 1996; Cassee *et al*., 1998; McConkey *et al*., 2000). The full factorial design, even though representing the most comprehensive way of evaluating chemicals individually as well as in all possible combinations (Narotsky *et al*., 1995), does become cumbersome and unmanageable with increasing numbers of mixture components (**Figure 5**).

Despite the importance of the *in vivo* studies in characterizing the toxicity of mixtures and interactions, there is greater potential for *in vitro* studies to contribute to an understanding of not only the mode of action of chemical mixtures but also the occurrence of interactions (i.e. deviation from additivity) at the mechanistic level. As emphasized in the recent National Academy of Sciences (NAS) report on toxicity testing in the twenty-first century, the focus of the toxicity studies with mixtures, as with single chemicals, would need to shift from adverse effects seen at high doses to the characterization of perturbations of biological pathways (National Academy of Sciences (NAS), 2007). In this regard, *in vitro* studies have a critical role of advancing the future of dose–response evaluation of mixtures. The following section illustrates the evaluation of biological perturbations by a mixture of three chemicals using an *in vitro* system.

5.4 *In Vitro* Assessment of Mixture Toxicity: a Case Study

Rotenone, deguelin and pyridaben are natural and synthetic inhibitors of complex I of the electron transport chain (ETC), a well-studied pathway critical for maintaining cellular health. These inhibitors interfere with ubiquinone reduction and not only act upon the same enzymatic subunit within the ETC pathway, but have also been shown to interact at the same binding site (Schuler and Casida, 2001; Ino *et al*., 2003), suggesting that the mixture might follow dose addition. Beyond their central role in cellular respiration, mitochondria are key players in apoptosis, generation of reactive nitrogen and oxygen species, transduction of electrical signals, and calcium homeostasis (Skulachev, 2001; Droge, 2002; Balaban *et al*., 2005; Rizzuto and Pozzan, 2006). Thus, it is no surprise that, while complex I inhibitors are known to interrupt proton translocation at the inner mitochondrial membrane, they have also been shown

to lead to alterations in general cellular processes. For evaluation of the toxicity of mixtures of complex I inhibitors (rotenone, deguelin and pyridaben), HepG2 cells were exposed to them singly (0.001–100 μM) or as mixtures (total dose, 0.001–100 μM) for 24 hours, and cell viability was determined using the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide) assay (Boyd *et al.*, 2008). Mixtures dosing included all binary and tertiary combinations of rotenone, deguelin and pyridaben. All mixtures dosing employed a fixed-ray design (Svendsgaar and Hertzberg, 1994) based upon the calculated LD_{50} values of the individual inhibitors. Briefly, the calculated LD_{50} for each inhibitor is used to determine the relative fraction of that component within a mixture that is expected to yield an equipotent response. The mixture fraction of each individual component is then multiplied by the total dose to yield the concentration of the component at that dose. Preliminary LD_{50} values for the individual inhibitors were determined to be 67.19, 596.1 and 179.4 μM, for rotenone, deguelin and pyridaben, respectively. As an example of the dosing regime, the mixture fraction of rotenone and deguelin was calculated with each total dose (0.001–100 μM) being composed of 67.19/663.3 or 10.13% rotenone and 596.1/663.3 or 89.87% deguelin. This experimental design has been shown to be particularly well suited for side-by-side comparisons when analyzing multiple mixtures by both dose and response addition models (Payne *et al.*, 2000).

As shown in **Figure 6**, cytotoxicity, as deduced from MTT reduction, increased in a dose-dependent manner for each of the three inhibitors tested. Following 24 hour exposures, rotenone, deguelin and pyridaben reduced HepG2 viability to 14, 27 and 74%, respectively at the highest concentration examined (100 μM). At the lowest dose tested (0.0001 μM), deguelin and pyridaben both resulted in greater than 100% viability, indicating a possible hormetic response (**Figure 6**). Overall LD_{50} values for the individual inhibitors were calculated to be 20.76, 34.16 and 4610 μM for rotenone, deguelin and pyridaben, respectively. The best-fit slopes for the entire sample set were found to be -2.034 ± 0.1117 for rotenone, -1.739 ± 0.1492 for deguelin and -0.4394 ± 0.1435 for pyridaben (**Table 2**). Pairwise comparison with an F-test showed rotenone and deguelin to have similar slopes within error ($p = 0.1605$), but both were found to be significantly different from pyridaben ($p < 0.0001$).

To assess the overall predictive capability of the additivity models in these experiments, the dose–response curves were compared by F-test analysis of best-fit parameters for observed versus predictive values for mixtures (**Table 3**). The corresponding graphs of observations and their respective dose addition and response addition predictive curves are

Table 2 Slope comparison of individual dose–response curves

Comparison	Slope ± SEM	Fit
Rotenone Deguelin	−2.034 ± 0.1117 −1.739 ± 0.1492	$p = 0.1605$
Rotenone Pyridaben	−2.034 ± 0.1117 −0.4394 ± 0.1435	$p < 0.0001$
Deguelin Pyridaben	−1.739 ± 0.1492 −0.4394 ± 0.1435	$p < 0.0001$
Rotenone Deguelin Pyridaben	−2.034 ± 0.1117 −1.739 ± 0.1492 −0.4394 ± 0.1435	$p < 0.0001$

Table 3 Comparison of best-fit parameters between observed and predicted dose-response curves

Mixture components	LD_{50} mixture fraction	LD_{50} F-value (p)	
		observed vs. dose-additive predicted	observed vs. response-additive predicted
Rotenone	0.1013	1.899 (0.2308)	1.629 (0.2794)
Deguelin	0.8987		
Rotenone	0.2725	11.51 (0.0067)	1.283 (0.3625)
Pyridaben	0.7275		
Deguelin	0.7687	12.00 (0.0060)	7.797 (0.0171)
Pyridaben	0.2313		
Rotenone	0.07973	21.27 (0.0013)	127.1 (<0.0001)
Deguelin	0.7074		
Pyridaben	0.2129		

shown in **Figures 7A–D** for the mixtures tested. Examination of the observed versus predicted values from the dose addition model resulted in significant differences ($p < 0.05$) between all combinations, except rotenone and deguelin (**Table 3**). The observed versus predicted values from the response addition model resulted in a significant difference ($p < 0.05$) only for the tertiary mixture (**Table 3**). Since the individual dose–response curves of rotenone and deguelin were found to be similar within error, it was expected that both dose addition and response addition would be predictive based upon relative similarity of all parameters. Overall, the analysis of the dose–response curves resulting from challenge with binary and tertiary mixtures revealed that the appropriate model may be inhibitor-specific: rotenone and deguelin may be dose additive, whereas mixtures with pyridaben appear to fit the response addition model (Boyd *et al*., 2008).

6 CONCLUDING REMARKS

The fundamental concern with both the component-based and mixture-based toxicity assessment relates to the lack of knowledge regarding the role and importance of toxic interactions among components. There are several examples of supra-additive and infra-additive interactions among environmental pollutants (Krishnan and Brodeur, 1991; Krishnan and Brodeur, 1994). When one component interferes with the toxicokinetics or toxicodynamics of another component in the mixture, the net result is a change in the magnitude of the toxicity of the mixture, that is, deviation from the summation of the toxicity of mixture components. Despite reports of this phenomenon in several situations where humans were exposed occupationally or accidentally (Krishnan and Brodeur, 1994), there has not been any progress until recently in developing methods that permit the consideration of animal or human data on interactions in the risk assessment of mixtures. Given the enormous resources essential to characterize interactions occurring at various doses, routes and exposure scenarios, pragmatic and predictive approaches should be explored.

A pragmatic experimental approach deals with the fractionation of the complex mixture with reference to the biological activity. Alternatively, testing of the top 10 chemicals of the mixture of concern may be undertaken to guide the process of toxicity evaluation (Cassee *et al*., 1998). The relevance of such observations for

humans exposed to low doses should be evaluated with physiologically based pharmacokinetic (PBPK) models (e.g. Haddad and Krishnan, 1998; Haddad *et al.*, 1998; Haddad *et al.*, 2001; Yang and Dennison, 2007). These models can help identify the threshold of interactions for mixtures of varying complexity, composition and dose levels (see **Evaluation of Toxicological Interactions for the Dose-Response Assessment of Chemical Mixtures**).

The wealth of information on joint action of chemicals has already been used to develop a web-based tool, for evaluating the potential additivity or interactions among components of mixtures (Vyskocil *et al.*, 2007). This web tool in English and French can be found at *www.irsst.qc.ca/en/_outil_100037.html*. This tool has primarily been developed for facilitating the assessment of joint toxicity of chemicals in the occupational environment but should be useful as a starting point to identify environmental mixtures with potential concerns of supra-additivity.

Molecular and Cellular Concepts in Toxicology

Michael A. Lynes

CONTENTS

1 INTRODUCTION

Toxicant-induced changes at the molecular and cellular scale represent a microcosm of the events that occur at the tissue, organism and population levels of organization. These changes in cellular and molecular events propagate through the different levels of organization to disturb normal biological activities, and can initiate disease as a consequence. Not only does the understanding of these events enhance our ability to manage toxicant-induced diseases, but they can also be used to illuminate the normal functions of the affected biological systems. Toxic responses that occur as a consequence of exposures to environmental toxicants are largely viewed as undesirable, as are 'off-target' toxic effects of pharmaceuticals designed to modify some specific molecular target. On the other hand, there are contexts in which the toxic effect is the desired goal of the pharmaceutical, and selective toxic effects in those instances can have beneficial or therapeutic consequences. A thorough understanding of the changes that occur at the molecular and cellular levels enable both the management of biological consequences of environmental toxicant exposures, the therapeutic benefits of pharmacological toxicants and the prediction of toxic effects induced by new drugs and contaminants.

2 'THE DOSE MAKES THE POISON'

Paracelsus' (1493–1541) writings include the widely quoted, 'All things are poison and nothing is without poison, only the dose permits something not to be poisonous.' We can extend that idea by noting that toxicants are often reactive compounds that will interact with a wide array of targets in the body, and that the set of targets will be in part determined by the local concentration of the toxicant, the local concentration of relevant targets, and the delivery and processing of each of these components by the body. Often, toxicants will accumulate in specific organelles, cells, tissues and organs of the body, and thus will have their greatest effect at those locations. For example, lipid-soluble toxicants can accumulate in the liver, brain and adipose tissues.

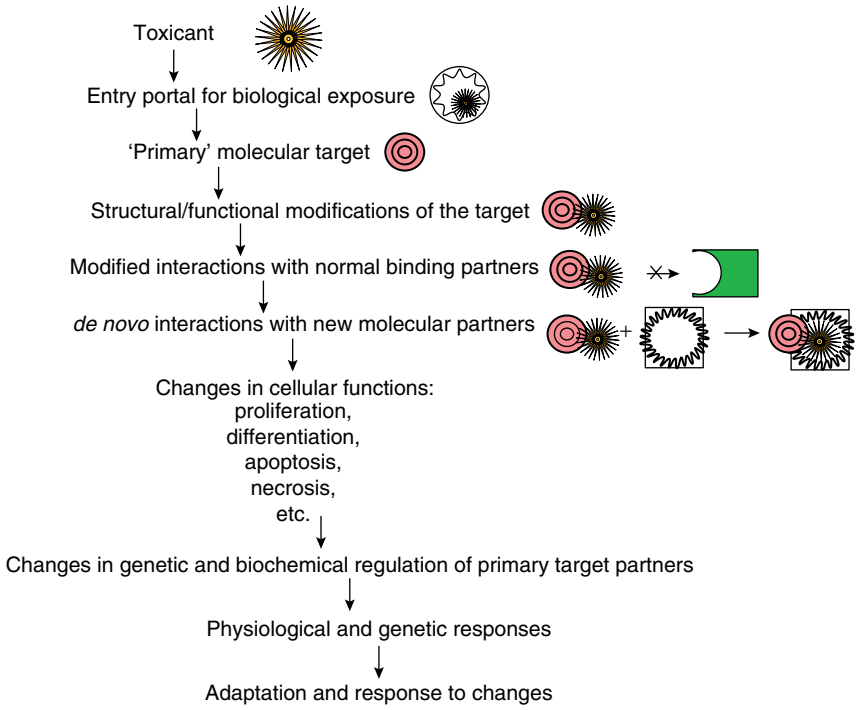

Figure 1 Initial molecular interactions with a primary biological target, and the cascade of molecular and cellular events that can ensue.

It is also true that the greatest effect may be observed where the most sensitive molecular target is at highest concentrations. Finally, it may be that the greatest cellular effects are observed in cells that are given the least time to effect repairs before autodeletion mechanisms are activated (e.g. apoptosis) to eliminate the danger posed by damaged cells. Thus, cells that have sustained toxicant-induced genetic damage and which replicate with high frequency (e.g. lymphocytes) are particularly prone to toxicant-induced death.

At the same time, the processing and bio-activation or detoxification may influence target tissues and the resulting biological effects of toxicants. For example, cadmium (Cd) initially accumulates in liver tissue (Habeebu *et al*., 1998) and can initiate the synthesis of the metal-binding protein, metallothionein (MT), while effecting hepatic cell survival and functioning (Klaassen and Liu, 1997). Subsequently, cadmium-metallothionein (Cd-MT) has been found in the circulation and appears to accumulate in the kidney. Recent reports suggest that megalin may be the membrane receptor that facilitates Cd-MT endocytosis at the apical side of kidney proximal tubule cells (Wolff *et al*., 2006; 2008). Once in the kidney, metal and metalloprotein can each have toxic effects on renal cells, though distinctions regarding the mechanisms of these effects have not yet been elucidated (Liu *et al*., 1999).

The consequences of toxicant exposure can thus be quite disseminated in the body, and overlapping timing in the occurrence of these events may make it difficult to identify a 'primary' molecular target of the toxicant (see **Figure 1**). Not only is the 'primary' molecular target altered by interactions with the toxicant, but toxicant exposure often initiates a cascade of parallel molecular events, and each of these changes may further influence the overall effect of the toxicant on cellular structure and function. Historically, the goal of many scientific investigations has been to identify the initial molecular change that initiates biological change, but recent technological advances may ultimately facilitate a systems-based approach to the understanding of these molecular changes.

3 BIOMOLECULAR SIGNATURES OF TOXICANT EXPOSURE AND THEIR DETECTION

Traditional histological and biochemical assays have long been used to identify the primary targets of toxicant exposure. These experimental approaches can yield considerable information, but are limited in the number of potential targets that can be examined in each experiment. Early large-scale investigations of the molecular changes associated with toxicant exposure often employed two-dimensional (2D) gel electrophoresis. For the most part, 2D gel electrophoresis simultaneously separates proteins in a heterogeneous mixture according to the isoelectric point and molecular weight of each

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

protein in a 2D array. The separated proteins can be nonspecifically stained, and changes to specific protein spot location and size can be compared between samples that have been simultaneously separated in parallel gels. Because the electrophoretic separation of individual protein spots is very susceptible to subtle changes in the conditions of the experimental protocol, identification of toxicant effects by traditional 2D gel electrophoresis can be difficult to exactly replicate in gels run simultaneously for comparison. Thus, this technique has been modified to label the proteins in each of a pair of samples with a different fluorescent label (differential in-gel electrophoresis, DIGE). The two samples can thus be mixed and run simultaneously on the same gel, enabling the separation of the individual proteins from each sample under identical 2D electrophoresis conditions. Each set of labelled proteins is then imaged separately, and the relative proportions of each label in the mixture at individual spots in the gel can be compared, to characterize the consequences of toxicant exposure on the entire population of separated proteins. For example, the prototype nephrotoxicant 1,2-(dichlorovinyl)-L-cysteine (DCVC) changes the expression of 23 proteins in exposed renal epithelial cells (de Graauw *et al*., 2005) as measured by DIGE. Fourteen proteins increased in concentration and nine decreased as a consequence of exposure to DCVC. The most prominent of the changes was found to involve altered Hsp27 (heat-shock protein 27) phosphorylation that appeared to be dependent on p38 kinase activity. Information about a set of proteins that is altered as a consequence of toxicant exposure can be regarded as representing a biomarker signature of such exposure. The identification of changes to a single molecular species will probably not be exclusively linked to a single toxicant because similar changes may be associated with other toxicants or disease processes. However, there may be specific patterns of molecular changes at the protein level that are able to suggest the toxicant involved, and indicate the sequence of changes that result from such exposure (Merrick and Bruno, 2004). Unique molecular signatures have been linked to the occurrence of breast cancer (Vazquez-Martin *et al*., 2007; 2008) and to other forms of cancer (Villanueva *et al*., 2006), but the identification of such signatures for specific toxicant exposures is still in its infancy (Zieziulewicz *et al*., 2003).

Assessment of the spectrum of molecular changes that result from toxicant exposure can also be done using DNA microarray technology. For the most part, DNA microarrays are filter-based or use DNA oligonucleotide targets that have been immobilized on other solid substrates as short (about 25 nucleotides) sequences arranged in a densely packed set of spots. Messenger RNA (mRNA) harvested from cells is usually converted to a complementary DNA (cDNA) coupled to a fluorescent tag, and hybridized to the immobilized oligonucleotides. A high-resolution image of the substrate is collected, and the fluorescent intensity of each individual spot on the chip is measured, as a way of determining how much of the cognate mRNA was present in the sample. Adjacent regions often are used as controls in which a single nucleotide has been substituted in the immobilized oligonucleotide in order to assess nonspecific binding. This type of analysis has been used to analyse mRNA samples harvested following toxicant exposure *in vivo* (Jeong *et al*., 2006), *in vitro* (de Longueville *et al*., 2003) and *ex vivo* (Elferink *et al*., 2008). *Ex vivo* analysis of toxicant effects has not been widely used because there are technical challenges to the maintenance of tissue explants, but this approach does offer some advantages, in that it maintains the organization and potential interactions of cells that are exposed to toxicant (Catania *et al*., 2007), without adding the complications associated with exposures in intact animals.

As with the analysis of the proteome, studies of the transcriptome may identify how the cell changes as a consequence of toxicant exposure, but characterizations of the sequence of molecular events that leads to a particular signature may be a complex challenge. This is in part due to the large number of changes that can result (both in mRNA levels and in protein concentration) following toxicant exposure. Liver samples harvested from zebrafish exposed to arsenic in the aquarium water for up to 96 hours showed an increasing number of gene functions that had been altered over the course of the experiment. By eight hours, about 500 gene functions were altered in comparison to tissues from untreated fish, and this number tripled in the ensuing 40 hours (Lam *et al*., 2006).

Recent advances in microarray technology now enable massively parallel studies of genome structure and activity using instruments such as the 454 Pyrosequencer. This instrument can use fragmented DNA coupled to beads for sequencing in picolitre volumes at rates of up to 10^9 bases per day. The system can evaluate epigenetic influences (Korshunova *et al*., 2008), and can assess the influences of cellular changes on gene expression (Sugarbaker *et al*., 2008). These types of analysis can identify structural changes to the genome that occur as a consequence of toxicant exposure, and can also identify specific changes to gene activity patterns.

The comparison of a 2D gel pattern produced with cellular extracts of control cells with a different pattern produced with separated proteins from toxicant-exposed cells can result in the identification of specific protein spots that are up- or down-regulated as a consequence of toxicant exposure. Specific identification of the protein spots from these gels often depends upon recovering the proteins from the gel, and sequencing them by matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF) or another type of mass spectrometry.

New technologies are emerging to further these microarray-based protein analyses. One of these, grating-

coupled surface-plasmon resonance imaging (GCSPRI) is based on measurements that determine changes to the refractive index at the interface between a metal (e.g. gold) sensor chip and a dielectric (e.g. water). This technology is based on the use of a diffraction grating to couple incident light energy to metal electrons (Brockman and Fernandez, 2001). Under the appropriate conditions, light can initiate a density oscillation in the electrons at the gold surface (termed a plasmon). The coupling of light to the metal electrons is sensitive to the incident angle of the illuminating light. Thus, by sweeping through a small range of incident light angles, the optimum angle for coupling can be identified. Proteins adsorbed to the surface of the sensor chip will increase the refractive index of the dielectric at the gold/dielectric interface, and will thus increase the critical angle at which maximum coupling occurs. Since the sensor chip can be simultaneously imaged and analysed for changes to the critical angle at multiple regions on the sensor chip, the assay can be used to assess multiple events of protein capture at different regions that represent different analytes measured from the same sample. Propagation of plasmons within the gold sensor chip limits the density of sensor spots on a sensor chip to approximately $10^3\,cm^{-2}$. In one configuration, individual antibodies spotted to the sensor chip at regions of interest (ROIs) have been simultaneously interrogated by GCSPRI for the capture of cognate antigens. GCSPRI has been used to assess protein levels in biological samples (Unfricht *et al*., 2005) as well as to capture cells (Jin *et al*., 2006), and can be multiplexed to make both of these measurements at once from complex biological samples. It is possible to capture and enumerate cells on the sensor chip, and to culture these cells for extended periods of time, while secreted or released analytes are detected by nearby sensor spots on the chip. In this way, microarray analysis of cellular functioning can be done in real time. Thus, the composition of a toxicant-induced biomarker signature may ultimately include individual proteins and other captured macromolecules from the biological sample, the phenotype of cells found in target tissues and the functional characterization of those cells. A second generation of the GCSPRI technology relies on coupling a fluorescent emission to plasmon generation (Reilly *et al*., 2006). Preliminary studies have shown this variation of the basic technology to be significantly more sensitive without sacrificing microarray capacity (manuscript in preparation).

4 THE INTERACTOME

As the data set that represents the biomarker signature of a cellular response to toxicant grows, it will eventually become possible to match this data with data sets that attempt to describe the molecular interactions of cellular proteins. These data sets are collected as the 'interactome' and represents data collected for a whole organism: each protein–protein or protein–DNA interaction within the network of interactions is represented by a series of directed graphs that link individual molecular components to those other components with which they interact. Many of the data sets used to create these graphic representations come from various kinds of affinity studies such as yeast two-hybrid experiments and phage display studies of molecules and molecular motifs that can bind to one another (Barrios-Rodiles *et al*., 2005). There are now a number of interactomes being developed, representing a variety of different species such as human (Brown and Jurisica, 2005), *Drosophila* (Sanchez *et al*., 1999), yeast (Shi *et al*., 2008) and *C. elegans* (Simonis *et al*., 2009).

5 SUBCELLULAR TARGETS OF TOXICANTS

5.1 The Plasma Membrane

Just as toxicants can have effects on primary and secondary molecular targets, and just as interactions between these components can influence the spectrum of affected molecular species, a variety of subcellular compartments and organelles can be altered in both structure and function as a consequence of toxicant exposure. To a certain degree, these effects depend upon the fundamental chemical characteristics of the toxicant, and on the access that they have to specific targets. **Figure 2** depicts representative cellular targets of toxic agents, ranging from those targets at the plasma membrane all the way to the genetic material of the nucleus and mitochondria. One of the initial cellular targets of toxicants can be the plasma membrane itself, where they can have their effects both at the external surface of the plasma membrane, or can have indirect effects on membrane structure by initiating apoptotic or necrotic death processes in the cell. Direct chemical effects on the membrane include changes to the lipids comprising the membrane bilayer, and proteins associated with the membrane. For example, oxidants are known to initiate lipid peroxidation, a self-sustaining cascade of events that can alter membrane integrity (Young and McEneny, 2001). **Figure 3** illustrates the consequences of lipid interactions with oxidant, and the proliferation of free radicals as a consequence of these interactions. The accumulation of these lipid peroxides can produce changes in the structure of proteins associated with the plasma membrane, the interactions of proteins/lipids in the lipid bilayer and can ultimately change the both the physical nature and the functional capacities of the membrane

itself. An illustration of physical changes in membrane integrity that can result from lipid peroxidation is shown in **Figure 4**. **Figure 4A** shows a scanning electron micrograph of normal discoid erythrocytes, while the **Figure 4B** is an image of the same erythrocytes after exposure to hydrogen peroxide. The oxidation of the lipids in the bilayer prevents the interactions between the leaflets that sustain normal erythrocyte discoid shape and in some cells this produces a change in shape called an echinocyte. In some cases, the appearance of these echinocytes is indicative of systemic oxidative damage, and can be used as an indicator of *in vivo* exposure to toxicants that elicit oxidative damage (Chukhlovin, 1996).

Direct access of the toxicant to the exterior leaflet of the plasma membrane may also result in chemical modifications of proteins found on the plasma membrane. For example, toxicants may oxidize thiols associated with surface proteins to dithiols and may inactivate these proteins as a result. This change has been suggested to render the lipid bilayer less mobile and more fragile as a result, but can also influence ion channels and other membrane functions (Padmini and Sundari, 2008; Zavodnik *et al*., 2001; Dumaswala *et al*., 2001). One of the primary defences against this oxidative stress is glutathione, which plays an important role as an antioxidant (Dumaswala *et al*., 2001; Fidelus *et al*., 1987). Other cellular antioxidant defences include other thiol-rich proteins such as MT, and the antioxidant enzymes such as catalase and superoxide dismutase. Intriguingly, there are marked differences in antioxidant capacity in different cells and that distinguishs individual species of animal. This results in differential sensitivity to oxidative stresses that influences the survival of cells under stress and can reflect the differential toxicity of some agents in certain species. For example, mouse

lymphocytes have been shown to possess lower concentrations of glutathione than human lymphocytes, making the mouse cells less resistant to dissolved oxygen in tissue culture media (Messina and Lawrence, 1992). As a consequence, to facilitate the normal function of murine lymphocytes, tissue culture media is often supplemented with β-mercaptoethanol (Chen and Hirsch, 1972) as a reducing agent.

The interactions of toxicants with the bilayer may also alter membrane and cytoskeletal dynamics in ways that influence membrane processes. Thus, the processes of phagocytosis, endocytosis and pinocytosis can all be directly disturbed by the influences of toxicants (Hodge *et al*., 2007). Oxidants can initiate actin polymerization (Hinshaw *et al*., 1991) and alter a range of cellular activities that rely on the cytoskeleton and result in cellular shape changes. Similarly, damage to the membrane can also influence protein secretion and the expression of newly synthesized membrane proteins.

Passive transport requires that the toxicant be capable of crossing the lipid bilayer and can be driven by the characteristics of the transported molecule or by membrane transporters that facilitate the transport. Active transport requires the expenditure of energy from adenosine triphosphate (ATP) hydrolysis. Membrane-permeable oxidants can cross this barrier, so agents that can generate oxidants near the plasma membrane surface can produce indirect effects without themselves crossing into the cytosol, but there is also evidence that the oxidative changes that occur at the plasma membrane itself can also change intracellular signal-transduction cascades (Urano *et al*., 1997; Waghray *et al*., 2005; Pelle *et al*., 2005). One way to experimentally separate the two phenomena (oxidation at the plasma membrane vs. the effects of oxidants within the cell) is to use membrane-impermeant oxidants such as copper phenanthroline (Duncan and Lawrence, 1989) in comparison to agents that can oxidize intracellular targets. One way in which these changes can occur is by the influences that toxicants can have on ion channels within the plasma membrane. In some cases, toxicants can traverse the membrane via ion channels (Friedman and Gesek, 1994). Noncharged molecules such as hydrogen peroxide (a nonpolar molecule that is approximately the same size as water) have recently been shown to move across plasma membranes via the aquaporin water channel (Bienert *et al*., 2007), a membrane channel that is impermeable to charged molecules. In some cases there are receptors that will be used as transition points for the movement of toxicants into the cell. For example, Cd complexed with MT has been shown to be taken up by renal proximal tubule cells after binding to megalin (Wolff *et al*., 2006). Finally, there are a range of membrane-associated uptake mechanisms (e.g. pinocytosis, endocytosis, phagocytosis) that may facilitate the uptake of toxicants in a nonspecific fashion (Kaminski *et al*., 1986).

In some instances, the act of internalizing particulate material from dying cells (which might be induced to enter a programmed death cascade by toxicant exposure) can initiate a propagating damage cascade. For example, phagocytic Kupffer cells of the liver that engulf apoptotic hepatocytes are stimulated to produce inflammatory cytokines and to induce fibrotic lesions that can perpetuate liver damage (Canbay *et al*., 2003). Internalization of quartz microparticles by alveolar macrophages has been associated with reactive oxygen species (ROS) generation, tumour necrosis factor α (TNF-α) generation and cellular toxicity, and depends upon the reorganization of the cytoskeleton to permit this internalization (Haberzettl *et al*., 2007). In instances of silica-mediated death of alveolar macrophages that follows internalization of a toxicant, ROS do not appear to be the principal

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat012
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

mechanism, but rather lysosomal damage may act to initiate apoptosis (Thibodeau *et al*., 2004).

5.2 Other Cellular Membrane Targets

As noted above, silica internalization can induce lysosomal leakage that may precede apoptotic cell death, demonstrating that not all toxicant effects on lipid bilayers operate at the external surface of the cell. The endoplasmic reticulum (ER) is a central target of many forms of toxicant-induced damage, and 'ER stress' is a term applied to any condition that disturbs the normal functioning of this important organelle in protein synthesis, protein folding and secretion. The consequences of toxicant-induced damage to this cascade of protein synthesis and folding has been called proteotoxicity (Hightower, 1991), and is accompanied by the cellular stress response in the form of synthesis of a range of molecular chaperones localized in the ER (e.g. the Grp78 and Grp94 glucose-regulated proteins (Lass *et al*., 2008; Liu *et al*., 1997)).

5.3 Toxicant-Induced Damage to Signalling Cascades

The consequences of damage to plasma membranes and the receptors expressed on the surface of the target cell can be changes to the downstream signalling mechanisms and ultimately to changed gene function and cellular activity. Similar consequences can also arise when toxicants directly or indirectly alter protein phosphorylation via influences on both kinases and phosphatases and/or second messengers in these signalling cascades. Inorganic mercury has been shown to alter CD95-dependent apoptosis-signalling cascades (Laiosa *et al*., 2007) in ways that may both illuminate this toxicant's ability to initiate autoimmune disease in humans, as well as to depress adaptive immunity (McCabe *et al*., 2007; Silbergeld *et al*., 2005). Conversely, manipulation of these targeted signalling cascades may offer therapeutic opportunities to ameliorate cellular damage by toxicants. Renal cells injured with DCVC can be protected by activation of protein kinase B (Akt) which improves mitochondrial respiratory function and stabilizes these cells (Shaik *et al*., 2008). Cd toxicity has been linked to influences on about 290 different genes in *C. elegans*, and, using interactome analysis tools, the signalling protein KEL-8 was shown to protect *C. elegans* from Cd exposure in a MAPKK (mitogen-activated protein kinase kinase)-dependent manner (Cui *et al*., 2007).

There are three different types of second messengers: the hydrophilic molecules, such as calcium ions, inositol triphosphate (IP_3) and cyclic adenosine monophosphate (cAMP) found in the cytosol; the hydrophobic molecules, such as membrane-associated diacylglycerol and the phophatidylinositols; and the small molecule gases, such as carbon monoxide (CO) and nitric oxide (NO) that can act both across membranes and within the cytosol. Calcium is a particularly sensitive indicator of cellular activation, and is quite susceptible to some forms of toxicant-mediated cellular activation or inactivation. Methylmercury, a ubiquitous environmental toxicant, is associated with elevations in free cytosolic calcium (Ca^{2+}) (Kang *et al*., 2006). Cd-induced apoptosis has also been linked to increases in free cytosolic calcium and this cell death can be attenuated by increasing the intracellular levels of the calcium-binding protein calbindin-D (Jeon *et al*., 2004).

5.4 Toxicant-induced Damage to Genetic Machinery

As receptor proteins and signalling proteins can be targets of toxicant-induced damage, so too can the enzymes and transcription factors that are responsible for regulating gene activity and for DNA and RNA synthesis. Changes to proteins that sort the chromosomes during cell division can also have toxic effects on the cell. Acrylamide has many industrial uses and is also found in some cooked foods. This neurotoxicant has been found to affect the spindle fibre proteins that are used to sort chromosomes during cell division, which could explain some of its clastogenic effects (Exon, 2006). Toxicants can also interact directly with the genetic material, forming adducts that interfere both with replication and with function of specific genes. Polycyclic aromatic hydrocarbons (PAHs) are a widespread example of an environmental toxicant that can alter the physical nature of DNA (Hu *et al*., 2008), but a broad range of agents can alkylate DNA, generate thymidine dimers, cause frameshifts in codon structure or otherwise cause chromosomal breakage and mutation. In each of these instances, the response of the cell to this genetic damage can be drawn from a range of repair mechanisms (e.g. nucleotide excision repair, photoreactivation, recombinational repair). Alternatively, the cell can sense the mutation at cell-cycle checkpoints and respond by entering the apoptotic pathway to self-deletion. A recent recognition is that early changes to the genetic structure of the individual may also have consequences to the onset of disease later in life, or the susceptibility to disease in offspring of the toxicant-exposed individual. Some of these epigenetic changes may be the result of changes to imprinted genes, or to other patterns of DNA methylation that regulate gene function (Dolinoy *et al*., 2007). The undesirable consequences of these genetic changes can include the release of the cells from normal patterns of cell

division. If the cell evades cell-cycle checkpoints, these cells may ultimately produce neoplasias that progress to cancer.

6 FUNCTIONAL CHANGES IN CELL BEHAVIOUR FOLLOWING TOXICANT EXPOSURE

A host of cellular functions fall prey to toxicant exposure. The molecular structures that are altered as a consequence of exposure may be primary changes that directly result from the exposure, they may be downstream consequences of such primary molecular changes or they may be cellular attempts to re-establish molecular or cellular homoeostasis. There are a broad range of molecular changes that together transfer information regarding changes in the extracellular environment to the cytoplasm and finally to the nucleus. These changes are often initiated by ligand interactions with receptors expressed at the plasma membrane, and precipitate a signalling cascade that includes changes in the patterns of protein tyrosine phosphorylation, phospholipid metabolism, calcium mobilization from intracellular and extracellular stores and transcription factor activation. Because these different molecular changes are tightly intertwined, it is often difficult to assess the direct effect of the toxicant when many different changes to the cascade may be altered (Pounds, 1990). However, there are many instances of change that ultimately influence cellular behaviours and result in the initiation of dramatically different outcomes including cell division, differentiation and apoptosis.

6.1 Protein Synthesis as a Consequence of Cellular Stress

The original identification of cellular protein stress responses that occur as a consequence of physical insult was done using cultures of fruit fly (*Drosophila melanogaster*) salivary gland cells (reviewed in Haak and Kregel, 2008). In these cells, polytene chromosomes are produced by multiple rounds of DNA replication without centromere replication and without cell division. As a consequence, the giant chromosomes have banding patterns that correspond to the genetic organization of the chromosome.

These bands expand, or 'puff', in a microscopically visible structure when a gene within the region becomes activated to transcribe new mRNA. When *D. melanogaster* salivary cells were cultured at an elevated temperature, many active genes were turned off, while a distinct set of new genes, the heat-shock proteins (Hsps), were activated. We now know that this set of proteins, that are turned on when cells encounter stress, are activated upon exposure to a host of different stressors, including a wide array of chemical toxins and toxicants. The initiation of synthesis is apparently induced by mechanisms within the cell that sense protein misfolding, and some of the heat-shock proteins serve as molecular machinery charged with either disassembling the misfolded proteins, or refolding them to a normal configuration. The mechanisms for the recognition of misfolded proteins are still unclear, but it appears that Bip/Grp78 recognizes the unveiling of hydrophobic regions (more often at the core of the protein in β-strands) that often accompanies misfolding (Schroder and Kaufman, 2005). An interesting hypothesis suggests that the misfolded proteins and protein aggregates are damaging to cellular processes, and that the molecular chaperones are responsible for the maintenance of normal protein configurations as a way of reducing the damage caused by toxicants that initiate these processes (Hightower, 1991).

Inhibition of the Hsps can influence a cell's progression through the cell cycle, as well as its propensity to undergo apoptosis (Okamoto *et al*., 2008). These proteins serve as a hallmark of toxicant exposure, and can also influence the functional capacities of the cell, the survival of the exposed cell and the death pathway taken by cells too damaged to recover from injury. There is a growing body of literature that shows that stress proteins of a variety of types can be released from the cell (see **Table 1** for examples of various forms of stress proteins). The original observation of the selective release of Hsps (hsp110, hsp71, hsp73) (Hightower and Guidon, 1989) has been supported with numerous subsequent observations of extracellular stress proteins (Galloway *et al*., 2008; Luo *et al*., 2008a; 2008b; Calderwood *et al*., 2007). While the actual mechanisms of release of these proteins is not well understood, there are a number of different pathways that stress-response proteins can take to exit the cell (Lynes *et al*., 2006). Since many of these stress-response proteins are synthesized on free polysomes, the mechanism of secretion must differ from the classical secretory pathway. While these alternative, nonclassical pathways are poorly defined in mammalian cells, there are software approaches to the identification of these proteins that rely on the assumption that the molecular motifs of extracellular proteins should be similar in some ways that are independent of the mechanisms of secretion or release. SecretomeP is available as online software that can be used to interrogate proteins sequences for these motifs (Bendtsen *et al*., 2004). Once released from cells, these stress-response proteins have been shown to influence cellular behaviors, as what has been termed a 'danger signal' (Matzinger, 2002). Heat-shock proteins and glucose-regulated proteins can influence immune capacity by some potentiating some responses (Galloway *et al*., 2008) and by suppressing others (Luo *et al*., 2008b).

Table 1 Toxicant-induced stress-response proteins

Stress protein	Specific examples	Example of inducing conditions	Normal cellular role
Heat-shock proteins	Hsp70, Hsp27	Heat, denaturing agents	Protein folding
Metallothionein	MT-I, MT-II	Metals, inflammatory cytokines, reactive oxygen	Redox management, essential metal reservoir
Acute phase proteins	Serum amyloid A	Inflammation	Cholesterol transport, induction of extracellular matrix digestion
Stress hormones	Glucocorticoids	Psychological and physical stress	Control of endocrine and exocrine cell development
Proinflammatory cytokines	IL-1, IL-6, TNF-α	Infection, toxicant-induced tissue damage	Cell regulation
Others	Ubiquitin	Protein damage	Protein metabolism

6.2 Metallothionein as a Central Stress-Response Protein

MT is an unusual kind of stress-response protein in a biochemical, regulatory and functional sense (Borghesi and Lynes, 1996; Lynes *et al*., 2006). The protein is very small (about 7 kDa for the most common isoforms), and is both rich in cysteine residues (about 33 mol%) and lacks histidines and aromatic amino acids (**Figure 5**). The apoprotein can be associated with Zn and Cu in nonintoxicated organisms, and can capture other divalent heavy metals such as Hg and Cd when they are present. Metal binding occurs as a consequence of hydrogen bonding and metal–thiolate bonds between the many cysteines and the metals. While MT expression can serve to protect against the damage induced by heavy metals, both by sequestering the metal and by scavenging the reactive oxygen species that can be generated by redox-active metals, there appears to be no effective mechanism for MT secretion. This may be part of the reason for the long biological half-life of metals such as Cd, which is thought to have a biological half life in humans of 20 to 30 years. Genes for MT or MT-like proteins and polypeptides are found in both prokaryotes and eukaryotes; in the mouse the genes are located on chromosome 8, and in humans they are found on chromosome 16q13. The structural genes are composed of three exons interrupted by two introns and are expressed upon exposure to a host of different inducers (see **Figure 6**). Intriguingly, MT synthesis can be induced both by toxic and nontoxic events within and surrounding the cell. Cytokines and stress hormones that influence the immune system can often produce MT biosynthesis activity, suggesting that MT may act in a variety of ways to regulate cellular biochemistry. For example, MT has been shown to suppress some

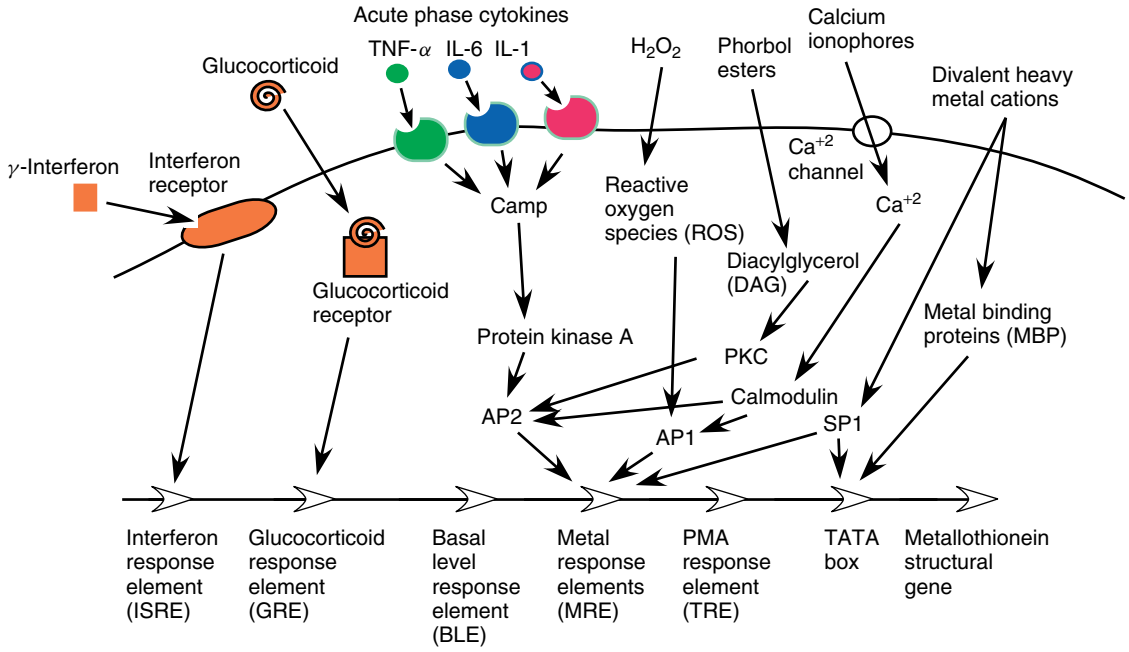

Figure 6 Metallothionein gene regulatory cascades. A variety of agents and cytokines can cross the plasma membrane or bind to receptors, activating of signalling cascades that result in transcription factor binding to the upstream regulatory regions controlling metallothionein mRNA synthesis.

immune capacities (Lynes *et al*., 2006; Youn and Lynes, 1999), while it activates lymphocyte proliferation and chemotactic responses (Lynes *et al*., 1990; Yin *et al*., 2005). MT has been shown to regulate NF-$\kappa\beta$ and Sp1, two transcription factors with important roles to play in inflammation.

Cellular interactions with stress-response proteins can take several different forms. These proteins can serve simply as delivery agents that move the associated toxicant to a new target cell or tissue. For example, MT has been shown to transport toxic heavy metals from the liver to the kidney (Klaassen and Liu, 1997). Uptake of MT at the kidney may rely on kidney-associated surface proteins; there are reports that Cd-MT can bind to megalin on kidney cells (Wolff *et al*., 2006; 2008). Other groups have reported that MT can bind other cells, suggesting that the protein may disseminate toxicants to multiple cell types (Chung *et al*., 2008; El Refaey *et al*., 1997). In addition to the simple distribution of toxicants that are associated with stress-response proteins, the production of these proteins may serve to activate cellular processes via interactions with cell surface receptors that initiate signalling cascades in the target cells. For example, some Hsps are known to bind to pattern recognition receptors (PRRs) such as Toll-like receptor (TLR)-2 and -4 (Binder *et al*., 2004). Hsp22, Hsp70 and Hsp90 all have been found in association with TLR4 (Roelofs *et al*., 2006; Triantafilou and Triantafilou, 2004), and each has been suggested to modify the immune response in the context of stress. One of the intriguing therapeutic opportunities that this raises is the possibility of using these stress proteins to intentionally manipulate the immune response in beneficial ways (Wang *et al*., 2008; Barginear *et al*., 2008; Lynes *et al*., 2006).

7 CELLULAR DEATH CASCADES

One of the consequences of cellular damage that follows toxicant exposure can be the entry into the apoptotic cascade. While this process is extensively covered in anther chapter of this work (**Cell Death and Apoptosis**), it is appropriate to briefly consider it's implications here. In this response, a series of linked enzymatic events can produce changes to the total cellular volume, resulting in shrinkage of both organelles and the entire cell body. One of the earliest events is the activation of a family of proteins known as caspases (cysteinyl aspartate-specific proteinases). Additionally, the cell will experience mitochondrial depolarization and cytochrome C release, and a redistribution of phosphatidyl serine from an asymmetric presence on the inner leaflet of the plasma membrane to an equilibrated presence on both the inner and outer leaflet. DNA fragmentation is often associated with the activation of an endonuclease that cleaves the DNA randomly between nucleosomes, producing a DNA ladder comprised of fragments in multiples of the 200 bp that encircle each nucleosome. As apoptosis progresses, there is often an endonuclease-mediated fragmentation of the DNA and a process of partitioning of the cell into smaller apoptotic bodies that appear

to arise from surface 'blebs' (Lane *et al*., 2005). One hypothesis is that these blebs are more readily processed by phagocytic cells without the release of intracellular structures that might otherwise activate inflammatory processes and inappropriate immune responses (O'Reilly and Strasser, 1999). However, apoptosis that occurs in excess of these processing mechanisms has been associated with the onset of autoimmune disease in experimental models and human disease (Schulze *et al*., 2008), suggesting that toxicants that initiate apoptosis may (in some instances) be responsible for inappropriate autoimmune activities via some similar mechanisms. There are some instances where toxicants have been shown to inhibit apoptosis mechanisms, thereby enabling the survival of cells that can be responsible for subsequent autoimmune disease. This disease could result from the survival of undesirable autoreactive cells, or it could result from the secondary necrotic cell death and initiation of inflammation by those cells that did not successfully undergo apoptosis. For example, mercury interferes with apoptosis by blockade of the assembling death-inducing signal complex (DISC) that is activated by Fas/FasL interactions (McCabe *et al*., 2005; 2003). Trichloroethylene (TCE) has recently been reported to interfere with apoptosis by activating a metalloproteinase to cleave FasL from CD4+ T cells (Blossom and Gilbert, 2006). These cells are thus potentially able to initiate some forms of T-cell-mediated autoimmune disease. A parallel mechanism may relate to toxicants that interfere with phagocytic processing of apoptotic cells, resulting in a similar autoimmune propensity (Russell and Cameron, 1986).

Another cellular death cascade is termed autophagy. This process results in the packaging of cytosol and organelles into large vesicles within a double membrane (Klionsky, 2004; Klionsky *et al*., 2008). When these autophagosomes fuse with a lysosome, the contents of the vesicle are degraded by the lysosomal enzymes. Under most circumstances, this process enables the cell to recycle cellular materials, but this process can be inappropriately initiated by the exposure to toxicants such as arsenic, hexavalent chromium (Cr[VI]) and Cd (Cheng *et al*., 2007; Di Gioacchino *et al*., 2008).

Necrosis is distinguished from these orderly processes of programmed cell death by several different characteristics. Cells that are necrotic swell as the total cell volume increases; organelles will also swell during this process. Membrane integrity is damaged, and intracellular macromolecules will be released from the cell. Unlike the orderly catabolism of the DNA that occurs during apoptosis, endonucleases fragment the DNA without regard to sequence or structure, producing a wide range of DNA fragment sizes that electrophorese as a 'smear' of DNA due to the wide range of overlapping sizes that are produced.

8 PROLIFERATION AND DIFFERENTIATION

Cells under stress can also respond by proliferation. Lymphocytes cultured in the presence of Hg, Cd and other divalent heavy-metal cations at certain concentrations, for example, will proliferate (Warner and Lawrence, 1988; 1986; Lawrence, 1981). This proliferation can result in inappropriate immune activities, as well as diminish the capacity to mount an effective immune response against antigenic challenges. Other toxicants, such as asbestos, can also initiate proliferation, in ways that implicate oxidative stress via the actions of myeloperoxidase and signal transduction cascades that involve protein kinase C (Haegens *et al*., 2005; Shukla *et al*., 2007). Neurons will make the choice to proliferate or differentiate depending on the local redox environment (Noble, 2006; Noble *et al*., 2005) which can be influenced by a range of different toxicants. In this case as well, the choice of proliferative activity by a neuronal cell can disturb normal neural circuitry and have deleterious effects on normal tissue activity.

8.1 Molecular Toxins and Toxicants as Probes and Modifiers of Biological Function

In a research context, toxicants are often useful as molecular tools with which to manipulate the biochemistry of cells. Agents that we think of as toxic in the clinical context are often employed to inhibit or modify specific aspects of cell function. For example, liposomal clodronate (dichloromethylenebisphosphonic acid) can delete macrophages after *in vivo* exposure in many tissues, including the eye (Biewenga *et al*., 1995; Slegers *et al*., 2000). This experimental deletion of this cell population enables the evaluation of macrophage contributions to a variety of disease processes. Biological mechanisms can also be studied by comparing the effects of a specific toxicant on the proteome to those induced by a different toxicant. Two types of information can come from these studies. The first is an appreciation of the similarities or distinctions in the molecular events altered by the two toxicants. In some cases, a novel toxicant mechanism may best be understood by analogy to a similar, previously studied agent. The second is a better understanding of the array of proteins that are functionally linked in normal cells, and the ways they respond to toxic insult. This approach was used to explore the effect of the toxicants 1,1-dichloroethylene (DCE) and diclofenac, which each covalently adduct hepatic proteins. In this study, bile was collected and compared after treatment with each of these agents, and was shown to differentiate the kinds of

protein changes that are unique to these different agents (Jones *et al*., 2003).

In similar fashion, toxicants have a variety of uses as therapeutic agents where the consequence of exposure is to change molecular or cellular activities within cells. The challenge is to balance the desirable toxic effects that diminish cancer cell survival or metastasis, while minimizing the unintentional toxic effects on other cell types. Cisplatin has a number of uses in cancer therapy; it is useful for the treatment of osteosarcoma, early stage non-small-cell lung cancer (NSCLC), and other malignancies, but can also effect hearing and nervous system tissues (Lewis *et al*., 2009; Sioka and Kyritsis, 2009), and can be immunotoxic as well (Kouchi *et al*., 1996).

Another new area of both experimental and therapeutic manipulation of molecular and cellular systems is also challenged by unanticipated toxic consequences. Small interfering ribonucleic acids (siRNAs) have been explored as potential immunotherapeutics for a wide range of diseases such as AIDS (Kumar *et al*., 2008) and diabetes (Marzban *et al*., 2008). These molecules belong to a class of short (20–25 nucleotides long) double-stranded RNA molecules that operate in the RNA interference pathway to block or interfere with the stability of a targeted messenger RNA. As a consequence, the role played by that mRNA is suppressed, and changes to biological activities can be elicited. While the goal is to specifically and selectively interfere with a single target's function, there have been a number of reported instances of unanticipated off-target effects of siRNAs that result from unfortunate homologies between the targeted mRNA and others (Tschuch *et al*., 2008; Colombo and Moll, 2008). Moreover, *in vivo* delivery of siRNAs can activate cellular sensors for viral nucleic acids, resulting in kinase activation and the synthesis of Type I interferon, TNF-α and other proinflammatory cytokines.

9 CONCLUSIONS

The molecular and cellular responses to toxins and toxicants underlie all other aspects of the effects of toxins, the diagnosis and management of toxicant exposure and (perhaps most importantly) the inferences we can draw about the basic biological mechanisms of the exposed organism. The study of these mechanisms has a broad range of implications for our understanding of biological systems and offers a rich opportunity for the use of this information in the therapeutic management of disease. At the same time, we have only begun to understand the influences of an exposed individual's genetic background to disease susceptibility, both as a component of the development of personalized drugs for specific patient populations and in the context of individual susceptibilities to specific toxic environments.

Cell Death and Apoptosis

Sidhartha D. Ray and George B. Corcoran

CONTENTS

1 INTRODUCTION

The study of the cellular reaction to injury is fundamental to the study of disease in all living systems. There is a basic similarity in such reactions whether the cell is that of an invertebrate, vertebrate or plant. Through this conceptual oversimplification, the science of toxicology has contributed significantly to advancing our understanding of human disease. Among the many known cellular alterations in disease, cell death, the irreversible loss of vital cellular functions and structures, is certainly the most drastic and one of the most frequently encountered and easily recognized. Cell death, a near equilibrium terminal end-stage, induced by severe physiological homeostatic perturbation, is a phenomenon inherent to all biological organisms. This endpoint can be induced by ischaemia or hypoxia, drugs or chemicals, immune reactions (complement attack), microorganisms, high temperature or radiation and a variety of naturally occurring and anthropogenic toxins. Historically, the first recognized mode of cell death was necrosis, a general term referring to the morphological stigmata of a cell that has committed to die. During this process, a cell passes through a reversible phase, often followed, with

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015

explosive rapidity, by irreversible changes resulting from adverse stimuli.

Mechanisms suggested to lead to the irreversibility of necrotic changes involve the release of lysosomal enzymes, activation of membrane-active proteases/phospholipases, global impairment of ion homeostasis, damage by dangerous oxy-radicals or biological reactive intermediates (BRIs), a precipitous drop in cellular energy status, with depletion of intracellular cytoprotective agents like antioxidants, adenosine triphophate (ATP), glycogen and glutathione, malfunctioning of cytoprotective enzymes, like superoxide dismutase, catalase, peroxidase, glutathione peroxidase, poly-adenosine diphosphate (ADP)-ribose polymerase (PARP) and substantive insult to the integrity of genomic DNA beyond a critical point, culminating in failure of the plasma membrane. A comparatively recent advance in our understanding of lethal injury, however, establishes that cell death occurs via another major and distinct dynamic process termed apoptosis. Whereas necrosis is considered as unprogrammed and typically accidental or unplanned cell death resulting from adverse stimuli, apoptosis, on the other hand, is regarded as a programmed, physiological and beneficial form of cell death which can be elicited by both normal and adverse stimuli. Because the details of necrotic cell death are thoroughly discussed in other chapters of this book, this chapter will focus on drug- and chemically induced apoptotic processes and their mechanisms of action.

When apoptosis (pronounced Ap oh ′tow sis or A ′poop tow sis derived from the Greek *apo*, meaning leaf, and *ptosis*, meaning to fall off) was first described over a third of a century ago (Kerr *et al.*, 1972a), different existing terminologies were used to describe some of the seemingly unrelated changes seen in different tissues (councilman or acidophilic bodies in liver diseases (Klion and Schaffner, 1966 and see Child and Ruiz, 1968); civatte bodies in lichen planus (Montgomery, 1967); tingible bodies in lymphoid germinal centres (Nossal and Ada, 1971); basophilic or Benirschke granules characteristic of premenstrual endometrial glands (Ehrmann, 1969, etc.). The newly coined term defined and differentiated apoptosis from necrosis based solely on changes in cellular ultrastructure (Kerr, 1969; 1971; Kerr *et al.*, 1972b). The consolidation and renaming the processes of shrinkage necrosis and others noted above to apoptosis evolved exclusively on morphological grounds, when it was found to play a global role in regulating tissue morphogenesis and tissue size (see Majno and Joris, 1995). The relevance of this unique cell death process was widely underappreciated until an upsurge in interest during the 1990s focussed efforts on unraveling the mechanisms underlying this process. After two decades of intensive research and thorough examination, it is now accepted that apoptosis is a tightly regulated, energy-dependent, genetically programmed and evolutionarily conserved self-destruction process through which cells undergo organized suicide, typically for beneficial purposes.

In multicellular organisms, such beneficial functions include maintenance of optimal tissue growth and development and physiological activity involving a balance between proliferation, growth arrest and programmed cell death (PCD). Apoptotic cells, upon completion of the death mission, conclude the suicide programme by forming apoptotic bodies which are rapidly removed by the reticuloendothelial system, including macrophages and phagocytes, and to some extent neighbouring cells. Massive cell suicide by apoptosis usually does not lead to organ dysfunction, yet this can be one of the particularly cataclysmic outcomes of necrotic cell death. Another noteworthy attribute is the lack of involvement of inflammation during the progression of events. Although apoptosis and necrosis are often described as diametrically opposed modes of cell death, some ask whether they are parts of a genetic and biochemical continuum (Corcoran and Ray, 1992). Since PCD is often used synonymously with apoptosis, it is important to clarify the use of the terms programmed cell death and apoptosis. It has been appreciated for many years that not all PCD occurs by apoptosis (Clarke, 1990; Abraham *et al.*, 2007), and that apoptosis is not always programmed or scheduled to occur, as observed during development and metamorphosis (**Scheme 1**). For these reasons and for the purpose of this chapter, apoptosis and PCD are not used interchangeably. The term apoptosis is used strictly to designate cells that die with the hallmark morphology associated with this process, whereas PCD is reserved for cases in which cell death is scheduled and is not necessarily apoptotic.

Apoptosis is characterized by a series of well-defined morphological changes (see **Figures 1–4**). Initially, there is a decrease or shrinkage in cell volume (cytoplasmic condensation), the generation of a pyknotic nucleus, and condensation of chromatin along the nuclear periphery. This is followed by loss of the nuclear membrane, fragmentation of nuclear chromatin and subsequent formation of multiple fragments of condensed nuclear material, often with cytoplasm, called apoptotic bodies. These may later appear on the cell surface and be shed as vesicles, blebs and apoptotic bodies. The next stage is the phagocytosis of apoptotic bodies by phagocytes or neighbouring cells, preventing the release of cellular contents into the surrounding areas and avoiding an inflammatory response. The morphological changes associated with apoptosis contrast with those of necrosis, another primary form of cell death typically associated with pathological processes. Necrosis has been viewed as an unprogrammed and chaotic sequence characterized by cellular swelling, in which swollen intracellular structures disintegrate rather than shrinking, and by the release of cellular contents that induce an inflammatory responses in the surrounding tissue (**Figures 1–4**).

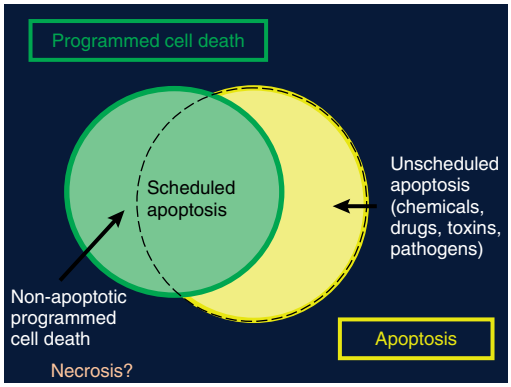

Scheme 1 Programmed cell death, apoptosis and necrosis. Apoptosis and programmed cell death (PCD) are often used interchangeably in the literature. Apoptosis involves a genetic programme that is responsible for a cell death process that is defined strictly on morphological criteria. In metazoans, there are developmental, hormonal and other programmes that schedule the triggering of cell death. Here, the term programmed cell death has been used to denote the scheduling of cell death, independent of the mode and morphology of cell death. There are many examples of cell death that are programmed, but do not involve the morphology or the genetic steps that are hallmarks of apoptosis. Similarly, there are many instances of apoptotic cell death which are unscheduled. To minimize confusion based on ambiguous terminology, it would be logical to reserve use of the term programmed to indicate that cell death is scheduled, and that programmed cell death not be equated with the genetic steps, biochemistry, morphology or occurrence of apoptosis. Thus, programmed cell death (PCD) and apoptosis should not be used interchangeably, and the former should not be used to imply the scheduling of cell death. Finally, growing evidence suggests that necrosis may be programmed in part. If this is borne out, the far left portion of the left circle that is labelled nonapoptotic programmed cell death may include a large component of cells dying by necrosis.

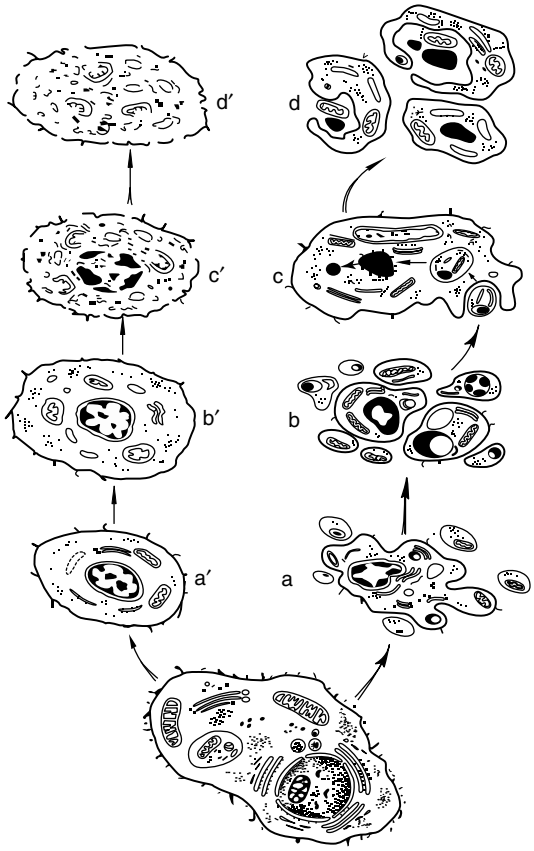

Figure 1 Morphological changes characteristic of necrosis and apoptosis. In apoptosis (right pathway, a–d), the cell condenses and shrinks (a and b) rather than swells (a′ and b′). In necrosis (left pathway, a′–d′), cell lysis follows generalized swelling and is preceded by disintegration of organelles (mitochondria, nucleus and the plasma membrane breakage (c′–d′). In contrast, cell–cell contacts which are initially retained in necrosis, are broken down early in apoptosis. This is followed with explosive rapidity by stereotypical changes that include loss of plasma membrane surface structures and compaction of the cytoplasm, coupled with the condensation of heterochromatin and its fragmentation. This phase is followed by migration of masses of condensed chromatin to the periphery of the nuclear membrane, and chromatolysis usually involving caspase-activated DNAse (Ca^{2+} and Mg^{2+}-dependent endonuclease) activation. Condensed, membrane-bound cell fragments or apoptotic bodies containing cytoplasm and intact organelles, including mitochondria, are phagocytosed by macrophages/phagocytes or other neighbouring cells (c–d). See details of phagocytosis under higher magnification in the electron micrograph in Figure 5A. Engulfed materials are internally digested to avert inflammation. Stages depicted in this figure are as defined by Searle *et al.* (1982). (Reproduced with permission from SD Ray, Long Island University.)

In recent years, two dominant dogmas regarding necrosis have come under significant challenge and this has implications for our understanding of apoptosis. First, necrosis is increasingly becoming viewed as a process that may be partially or substantially programmed (Edinger and Thompson, 2004; Bizik *et al.*, 2004; Chan *et al.*, 2003; Henriquez *et al.*, 2008). This confronts the notion that necrosis is wholly unregulated, and questions a cardinal mechanistic demarcation between necrosis and apoptosis. Second, some instances of necrosis appear to represent an aborted attempt to execute apoptosis, or perhaps more importantly, a fundamental integration of the processes underlying necrosis and apoptosis, sometimes termed aponecrosis or necroptosis (Degterev and Yuan, 2008; Formigli *et al.*, 2004; Cheng *et al.*, 2003). The latter concept may include instances of the well-recognized phenomenon of secondary necrosis that has been observed following the initiation of apoptosis. Secondary necrosis was first reported largely for *in vitro* models, but now is also well documented *in vivo* including in mammals (Silva *et al.*, 2008). Apoptotic bodies that are not phagocytosed and fully digested, and that progress to secondary necrosis,

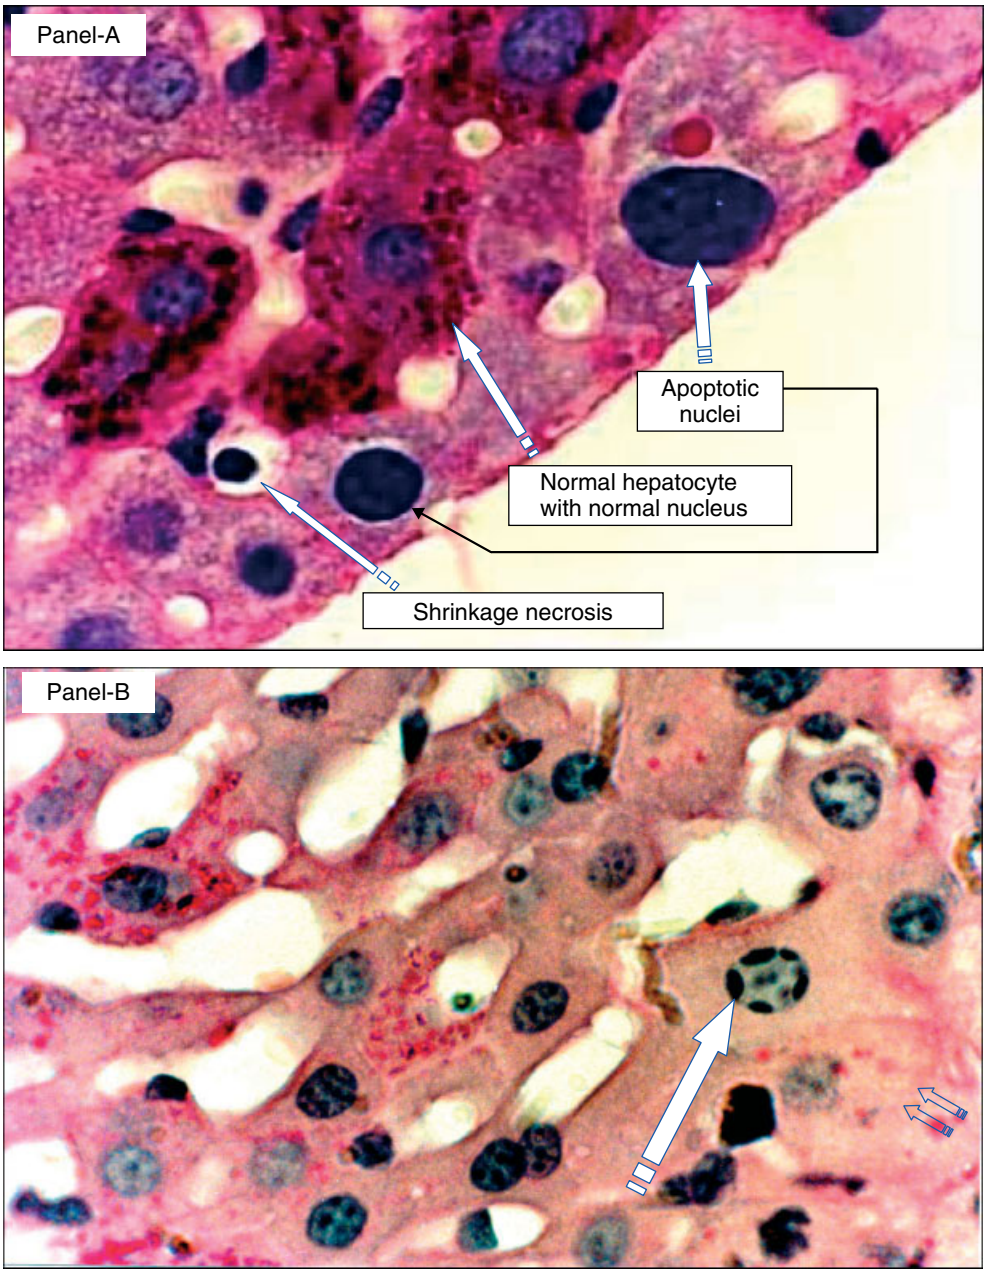

Figure 2 Paracetamol-(acetaminophen)-induced hepatocellular apoptosis and necrosis (low magnification). Light photomicrographs of paraffin-embedded mouse liver sections show early morphological changes typical of apoptosis induced by acetaminophen (500 mg/kg, ip at six hours, periodic acid-Schiff (PAS) staining, ×1000). (A) presents examples of normal hepatocytes with normal nuclei and apoptotic hepatocytes with dense apoptotic nuclei at various stages, including shrinkage necrosis. The section exhibits the beginning of apoptotic changes including condensation of chromatin, as well as abnormal enlargement of the nucleus characterized by very dense staining. Nuclear alterations are evident in the near total loss of volume regulation. Necrotic changes include nuclear and cytoplasmic damage with weak staining. A strongly PAS-positive glycogen-loaded normal hepatocyte shows normal nuclear morphology. (B) shows nuclear condensation, chromatin fragmentation and margination of the condensed chromatin to the nuclear membrane periphery, a trait typical of apoptosis. The short double arrows point to a possible necrotic cell very close to nuclear dissolution, characterized by poor nuclear staining. The long single arrow shows a hepatocyte with an apoptotic nucleus where chromatin has condensed, fragmented and migrated to the nuclear membrane. (Reproduced from Ray and Jena, 2000. © Springer.)

are the proposed basis for various serious pathologies including some autoimmune diseases (Rovere-Querini *et al.*, 2008; Zhang and Xu, 2002; Rovere *et al.*, 2000), chronic inflammation (Henson, 2005) and septicaemia (Wesche-Soldato *et al.*, 2007). Further discussion of these potentially important developments in the understanding

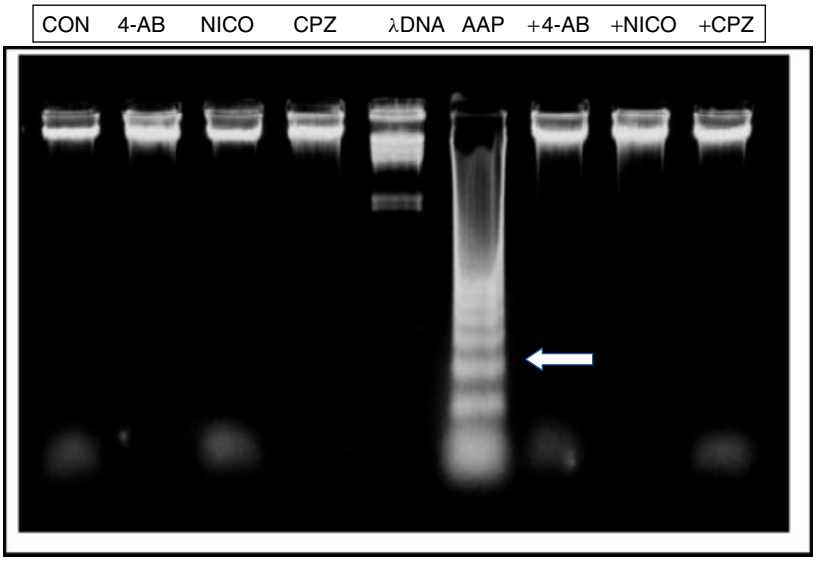

Figure 3 Paracetamol (acetaminophen)-induction of a DNA fragmentation ladder. This ethidium bromide-stained agarose gel shows DNA damage in mouse liver 24 hours after acetaminophen overdose. Mice were treated with a PARP inhibitor (4-aminobenzamide (4-AB) or nicotinamide NICO) or the Ca^{2+}-calmodulin antagonist chlorpromazine (CPZ) to assess their effects on acetaminophen-induced DNA fragmentation (15 μg per lane of DNA extracted from three animals and pooled). The loss of large genomic DNA with concomitant appearance of a classic DNA ladder typical of apoptosis was observed following acetaminophen treatment (lane 6). The two PARP inhibitors and CPZ prevented acetaminophen-induced DNA fragmentation and DNA-laddering (lanes 7–9), whereas these antagonists alone failed to alter the integrity of the genomic DNA. Legend for lanes: 1—vehicle control (CON); 2—4-AB, 3—NICO; 4—CPZ; 5—λDNA BstEII-digest; 6—acetaminophen (APP); 7—acetaminophen + 4-AB; 8—acetaminophen + NICO; 9—acetaminophen + CPZ. The appearance of a DNA ladder (lane 6) is characteristic of dissociation of the CAD-ICAD complex and subsequent activation of DFF. Severe loss of large genomic DNA is evident in the acetaminophen-exposed animals (lane 6). Note the gradual loss of fluorescent intensity close to the well, reflecting total disappearance of large molecular weight DNA. (Reproduced from Ray *et al.*, 2001. © Elsevier.)

of cell death is beyond the scope of this chapter. Interested readers are referred to other chapters in this book and to the cited publications for more information on these rapidly evolving topics.

Key characteristics of apoptosis and necrosis are described in **Table 1** and **Figures 1–4**. In apoptosis, it has been shown that cells activate an intrinsic death programme and thus actively contribute to their own demise. Apoptosis is gene-directed and influenced by extrinsic and intrinsic signals (**Table 2**). The initiating signals are fundamentally similar. For example, cells exposed to ionizing radiation may undergo apoptosis, which is highly predictable in terms of the proportion of cells affected, but they are not programmed to die unless they are exposed to radiation. Another example of apoptosis involves the ischemic death of the endometrial lining of the uterus at the end of menstrual cycle (**Table 2**). In addition, apoptosis can be affirmatively predicted in specific individual cells of the well-studied nematode, *Caenorhabditis elegans*. *Caenorhabditis elegans* matures as an adult hermaphrodite with 1090 cells, of which 131 then undergo PCD (Ellis *et al.*, 1991). Nearly all of these are apoptosis-designated cells and found at various locations. They automatically trigger suicidal death pathways at different, but precisely defined times.

This finding led to the proposed scenario in which cells receiving death signals or loss of survival signals may turn on a dormant genetic death sequence regardless of the cause. It is now clear that the regulatory mechanisms controlling apoptosis are as fundamental to life, and are fully as complex as those regulating cell proliferation. Based on the observations of the past three decades, the apoptotic response of a cell to a drug or toxin is determined at five distinct levels: (i) stimulus (e.g. drug, chemical or toxin) and its bioavailability and metabolism; (ii) cellular defense mechanisms; (iii) signal transduction pathways; (iv) status of relevant genes, particularly oncogenes and (v) intrinsic cellular susceptibility to apoptosis (**Table 2**).

2 APOPTOSIS: OCCURRENCE

Apoptosis is an operationally, morphologically and, for the most part, biochemically distinct form of cell death from necrosis (Kerr *et al.*, 1972b; Wyllie, 1987). Owing to the multitude of signals and requisite cellular metabolic events which can lead to apoptosis, a surprisingly wide range of physiological and toxicological stimuli effectively initiate this death pathway in an array

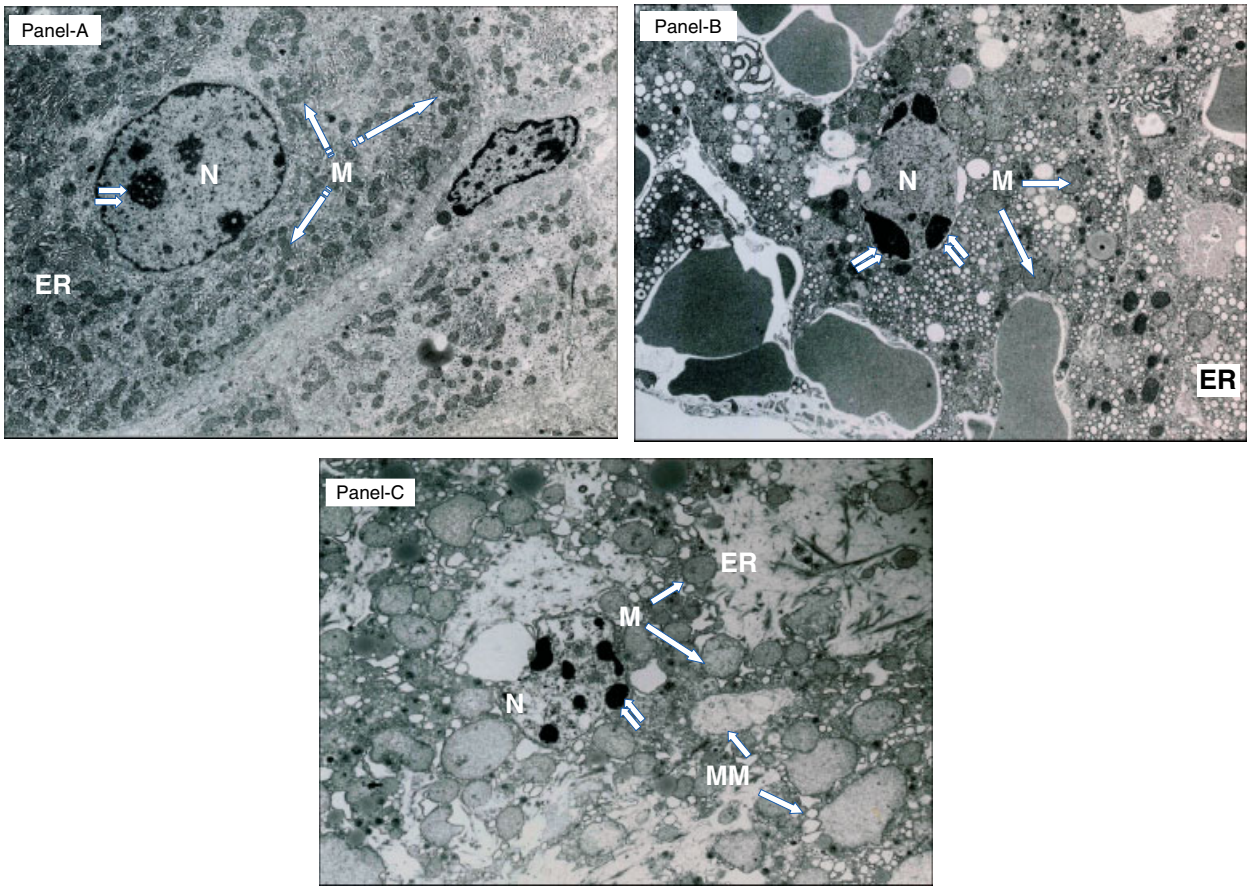

Figure 4 Paracetamol- (acetaminophen)-induced hepatocellular apoptosis and necrosis (high magnification). Electron photomicrographs of mouse liver show ultrastructural details of a normal healthy hepatocyte from a vehicle control animal (A), and an apoptotic (B) and a necrotic (C) hepatocyte from animals treated with 500 mg kg^{-1} acetaminophen i.p. at 24 hours. The nucleus of the apoptotic hepatocyte (B, ×8000) presents with characteristic morphology of apoptosis, including hypertrophic cytoplasmic changes. Note the condensation, fragmentation and margination of heterochromatin in the absence of a significant loss of mitochondrial volume. Frank degradative changes are evident in the cytoplasm and nucleus of the necrotic hepatocyte (C, ×8000). Compare volumes of cells and organelles in (A), (B) and (C). (C) shows severe mitochondrial swelling (MM) and collapse of the mitochondrial boundary, extensive nuclear damage with fragmented chromatin and collapse of the nuclear membrane, and other morphological aberrations in the cytoplasm of a necrotic cell. The double arrows signify fragmented chromatin. The single arrows identify mitochondria. Legend: ER—endoplasmic reticulum; M—mitochondria; MM—mega mitochondria; N—nucleus. Scale: 1 μm = 8 mm at ×8000. (Reproduced with permission from Ray *et al.*, 1996. © American Society of Pharmacology and Experimental Therapeutics.)

of different cell types. It is clearly evident, however, that the induction of apoptosis in any given tissue is tightly regulated, such that suicide can often only be induced by a particular tissue-specific signal. Consequently, a signal that turns on execution in one tissue may have very little or no apoptotic effect, or may even cause an opposing outcome such as proliferation, in another tissue. The wide range of cells that can undergo apoptosis *in vitro* and *in vivo*, including invertebrates, vertebrates and plants, confirms that practically each and every type of cell has a latent or active ability to execute the terms and conditions of apoptosis.

The tissue specificity of the induction of apoptosis and the molecular mechanisms by which the apoptotic process occurs have been intensively studied but remain incompletely understood. Cell death by apoptosis has been reported in plants (Basile *et al.*, 1973; von Wangenheim, 1987), nematodes (Yuan and Horvitz, 1990), insects (Lockshin and Williams, 1965), fish (Daoust *et al.*, 1984), birds (Glucksmann, 1951; Hurle *et al.*, 1977; Oppenheim, 1985), amphibians (Searle *et al.*, 1982), vertebrates (Glucksmann, 1951) and mammals (Baruch *et al.*, 1963; Compton and Cidlowski, 1992). Regression of the tadpole tail during amphibian metamorphosis serves as one of the prime examples of ontogenic apoptosis, perhaps only rivaled by the cataclysmic metamorphosis of some insects (Lockshin, 1981; Bowen and Bowen, 1990). Collapse of the tadpole's tail followed by degradation of the tail muscle is a captivating event that has been captured by classical histopathologists. Biochemists and cell and molecular biologists have

Table 1 Distinguishing features of apoptosis and necrosis

Charcteristic	Apoptosis	Necrosis
Distribution	Affects individual cells scattered throughout the tissue	Affects massive and contiguous cells
Adhesion between cells and to basement membrane	Lost early	Lost but late
Cellular morphology	a. Chromatin condensation (karyorrhexis) followed by margination as large crescents to the periphery of the nuclear membrane; fragmentation in large masses (convolution). See Figure 1B	a. Irregular clumping of chromatin, pyknosis or karyolysis, nucleolysis occasionally preceeds collapse of nuclear membrane; cells occasionally maintain their boundaries with some or no organelles. See Figure 1C
	b. Loss of cell volume (cytoplasmic compaction)	b. Very early swelling of cell, ballooning occurs frequently
Damage to organelles, for example, mitochondrion	Late (organelles mostly retain integrity), occasionally organellar swelling and bleb formation on cell surface appear very late (organelles found in blebs)	Very early swelling of organelles; cells disintegrate and lyse, appear chaotic, form blebs early (organelles are not found in blebs)
DNA breakdown pattern	Internucleosomal cleavage (Ladder-like pattern on agarose gel)	Random or irregular damage (appears as a smear on gel)
Release of lysosomal enzymes	Absent	Present
Duration of biochemical and morphological changes	Minutes to hours; propelled by macromolecular synthesis; mitochondrial permeability transition pore formation	Hours to days; lack of macromolecular synthesis; involvement of mitochondrial permeability transition pore formation unknown
Ultimate outcome	Forms apoptotic bodies, occasionally containing intact organelles	Swelling, disintegration, dissolution
Cell removal	Usually via phagocytosis by all types of resident and nonresident cells	Usually cells are not removed
Inflammation	Absent	Present
Adhesion between cells and to basement membrane	Lost very early	Lost very late
Energy requirement and signaling dependency	Strictly energy-dependent, very tightly regulated, can easily be delayed but can be inhibited only with difficulty, signaling-dependent (well-defined extrinsic & intrinsic pathways)	Energy and signaling-independent, occasionally energy-dependent, can be blocked prior to irreversible changes (e.g. plasma membrane leakage)
Genomic control	Strictly dependent	Usually independent
Scar formation	Absent (organ dysfunction reported)	Present (organ dysfunction reported)
Reversibility	Onset can be delayed but cannot be reversed after morphological changes develop	Can be blocked if detected early prior to point of no return in the absence of significant membrane damage
Overall regulation	Very tightly regulated; mostly dependent on energy status, protein synthesis, gene transcription	Independent of energy status or protein synthesis or gene transcription, may be partially regulated

also done much to unravel the mechanisms underlying this event (Weber, 1969; 1977; Kerr *et al.*, 1987).

Another classic example of apoptosis is the loss of cells from the interdigital zones during development in chickens, mice and humans (Bowen and Bowen, 1990). During embryological and foetal development of amphibians, chickens and mammals, experiments have confirmed that peripheral innervation regulates the level of cell death (Levi-Montalcini and Brooker, 1960). Later, Levi-Montalcini and Aloe (1981) demonstrated that nerve growth factor (NGF) channelled via peripheral innervation plays a significant role in controlling the number of cells in developing neuronal ganglia, and in determining the final size of ganglia. Large numbers of

Table 2 Apoptosis associated with physiological and pathological states

State or condition	Cells/organs involved
1. Normal cell turnover (in adult tissues)	Hepatocytes, adrenal cortex, intestinal crypt epithelium, spermatogonia, megakaryocytes, neutrophils
2. Embryogenesis/ metamorphosis	Epithelial cell of small intestines; deletion of interdigital webs; regression of Müllerian ducts in males and Wolffian ducts in females; palate midline epithelium fusion; most neurons; pronephros, mesonephros and metanephros regression to form nephron and tubules; human tail regression; auditory vesicle invagiation and detachment from ectoderm during the ear development; foetal penderm, intermediate epidermal cells and appendages during development and remodelling of skin
3. Thymocyte deletion	T-cell deletion during negative selection
4. Normal involutional processes	Uterine endometrium after menstrual cycle; mammary epithelium regression after lactation; hair follicles, ovarian follicular atresia, vaginal epithelial cells (stratum spinosum, stratum basalis) during late metoestrus and early dioestrus
5. Atrophic processes	Prostate changes after castration; adrenal cortex after ACTH depletion; kidney during hydronephrosis; thymus during glucocortocoid imbalance; pancreatic ductular obstruction
6. Immune-mediated cell killing	T-cells, killer cells and natural killer cells, allograft rejection, graft vs host disease, tumour necrosis factor-induced (TNF)
7. Cellular injury	Radiation, ischaemia, hyperthermia, calcium ionophores, many drugs and chemicals, toxins of plant and bacterial toxins, steroids, oxidants, carcinogens, anti-cancer agents
8. Viral diseases	Promoters: HIV (human immunodeficiency virus), human T-cell leukaemia virus, human papilloma virus, parvo virus. Inhibitors: herpes simplex virus, human cytomegalovirus, Epstein-Barr virus, vaccinia virus, cowpox virus, baculovirus, hepatitis B virus
9. Neurological diseases	Parkinson's disease, Alzheimer's disease, stroke, spinal muscular atrophy, HIV, encephalopathy, prion disease, Huntington's disease, amyotropic lateral sclerosis
10. Trophic factor withdrawal	Epidermal growth factor, insulin-like growth factor-I, estrogen, IL-2, thrombin, nerve growth factor (NGF) and transforming growth factor dysregulation (TGF-β)
11. Others	Aging, autoimmune disease, neoplasms, thermal stimuli (heat shock), drugs, chemicals

cells are deleted by apoptosis, especially in the nervous system (Oppenheim, 1985; Clarke, 1990). In mammals, the secondary palate that separates the oral and nasal cavities develops by growth, rotation and fusion of the left and right palatal shelves. The fusion of the shelves is mediated by decreased proliferation, increased adhesiveness and apoptosis of medial edge epithelial cells (Greene and Pratt, 1976; Pratt and Greene, 1976).

During vertebrate sexual differentiation and maturation, the reproductive organs show spectacular changes that involve massive apoptosis. Despite the fact that both male and female embryos begin with the same reproductive rudiments, the Wolffian duct differentiates into epididymis and vas deferens whilst the Müllerian duct regresses in the male. The opposite occurs in the female. The Müllerian duct differentiates into the uterus in mammals or oviduct and shell gland in avian species. These events are directed by hormonal scheduling programmes, and cell removal occurs by apoptosis.

All of these observations indicate that apoptosis is an equal and opposite force to mitosis (Kerr *et al.*, 1987). In certain tissues, some cells survive until the organism dies, while other cells are continually produced in self-renewing tissues. These cells undergo differentiation to perform specific functions, and later die. Noted examples of these events are the life cycles of keratinocytes and haematopoietic cells (Lord, 1979; 1986; Muel *et al.*, 1986; McCall and Cohen, 1991; von Wangenheim, 1987). Prior to their destruction by apoptosis, these cells pass through a transit compartment and a maturation compartment. Many hormone- and growth factor-sensitive tissues operate in a similar fashion and mimic the progression of events in order to maintain tissue homeostasis. Cells belonging to tissues and organs such as the liver (Benedetti *et al.*, 1988a; 1988b; Terada and Nakanuma, 1995), kidney (Glucksmann, 1951; Koseki *et al.*, 1992; Coles *et al.*, 1993), thymus (Compton and Cidlowski, 1996; Duke *et al.*, 1996), prostate (Kyprianou and Isaacs, 1988), ovary (Hopwood and Levison, 1976; Sandow *et al.*, 1979), uterus (Sandow *et al.*, 1979; Hopwood and Levison, 1976), adrenal cortex (Wyllie *et al.*, 1973), lymphoid cells (Koury and Bondurant, 1990; Williams *et al.*, 1990), brain (Mukherjee *et al.*,

1997), nervous system (Glucksmann, 1951; Oppenheim, 1991) and intestinal crypt cells (Milligan and Schwartz, 1996; see also Duke *et al.*, 1996) are vulnerable to apoptosis naturally or otherwise. The death of immature thymocytes in our body is a classic example of apoptosis (Duke *et al.*, 1996).

3 MORPHOLOGY OF APOPTOSIS

Since emerging from a relatively brief period of skeptical acknowledgement, apoptosis is now widely accepted, based in part on confirmation of its highly characteristic and remarkably stereotyped morphological changes observed under light and electron microscopy. Although the most practicable and reliable way of unequivocally distinguishing between apoptosis and necrosis is by transmission electron microscopy, high-power ($\times$1000) brightfield microscopy has generated valuable and informative results in many studies (Ray *et al.*, 1996; 2006; Ray and Jena, 2000). Pioneering pathologists and microscopists agree that nuclear morphology is the gold standard for distinguishing apoptotic from necrotic cell death.

Apoptosis is an ongoing natural process in living systems and can progress very quickly, on a scale of minutes to hours (Sanderson, 1976; Matter, 1979). Cells and apoptotic bodies are removed quite rapidly after the onset of apoptosis (Green, 2005). This has made it a cumbersome and challenging task to capture cells in various stages of this process for complete morphological analysis (Wyllie, 1987). Apoptotic cells die a clean death. The dead cells are normally engulfed and digested by phagocytes and by neighbouring cells with such speed and efficiency that their passing is histologically inconspicuous. This contrasts with necrotic cell death which is untidy and conspicuous (Savill, 1994). Under the influence of an inducing agent *in vitro* or in disease states *in vivo*, abundant apoptotic cells can be found for discrete observations. A variety of representative stimuli and inducers that can activate this process are listed in **Tables 3** and **4**. The time to onset of apoptosis after a lethal stimulus is variable, but the changes are rapid. In apoptosis, coordinated changes occur in the nucleus, in the cytoplasm, and on the cell surface. *In vivo*, apoptosis usually affects single cells or small groups of cells in an asynchronous fashion. The entire apoptotic process can be divided into four steps.

Step I. Cell shrinkage: The earliest changes observed include the loss of cell junctions and other specialized plasma membrane structures such as microvilli. Simultaneously the cytoplasm becomes hypertrophied (**Figure 4B**) and condenses, and the entire cell shrinks. Unlike necrosis, an apoptotic cell lacks swelling, but shrinks and pulls away from its neighbours without causing disturbance to tissue architecture or function.

Step II. Nuclear or chromatin condensation: This is one of the most widely observed and distinguishing features of apoptosis. At this stage, condensing fragments of chromatin coalesce into one or more large masses or several smaller masses and migrate towards the nuclear periphery and the nuclear membrane. As the process continues, the nucleus breaks down into several fragments. Under an electron microscope, these fragments appear dense and dark with the near total maintenance of volume regulation of organelles. The contraction of cytoplasmic volume is associated with loss of intracellular fluid and ions (see **Figures 2** and **4**, which depict stereotypic changes of Step II).

Step III. Formation of apoptotic bodies: The cell membrane transiently adopts a deeply convoluted outline and shows extensive surface blebbing. Subsequently, the cell breaks up into several membrane-bound smooth-surfaced apoptotic bodies that contain a variety of tightly compacted organelles and some nuclear fragments. These are designated apoptotic bodies (**Figure 5A**).

Step IV. Phagocytosis of apoptotic cells or bodies: Apoptotic bodies vary greatly in size and shape. There is no limit to the number of apoptotic bodies that are formed from a single cell, although the number can vary with the size of the cell. Apoptotic bodies are typically phagocytosed by professional phagocytes (macrophages) and to some extent by neighbouring cells serving as amateur phagocytes (glomerular mesangial cells (Savill *et al.*, 1993), renal tubular cells (Savill, 1994) and hepatocytes (Ray *et al.*, 1996)). Primary engulfing cells are typically members of the reticuloendothelial system (mononuclear phagocytes, such as macrophages and phagocytes), but also can be any other normal or abnormal cell capable of phagocytosis (Wyllie *et al.*, 1980). In fact, the largest number of *C. elegans* cell death genes identified in the seminal work of Horvitz and colleagues participate in, or are required for, efficient phagocytosis of the remnants of cells undergoing apoptosis (Ellis *et al.*, 1991; Horvitz *et al.*, 1994). Genes required for phagocytosis during apoptosis (Mangahas and Zhou, 2005) and necrosis (Chung *et al.*, 2000) differ somewhat and are now well delineated. The endocytosed apoptotic masses are rapidly degraded within lysosomes. Adjacent cells migrate or proliferate to replace the space occupied by the recently deleted apoptotic cell, unless loss of the cell is part of an ontogenic or other beneficial process. The roles of genes and signalling pathways in apoptosis are more fully discussed elsewhere in this chapter.

Although apoptotic bodies provide a potent stimulus for phagocytosis, the mechanism of recognition of apoptotic bodies by the engulfing cell is only partially understood. Apoptotic bodies are rarely found in the extracellular space without approaching or adhering

phagocytes. The recognition of an apoptotic body by the phagocytic cells appears to involve a receptor-mediated process. Three different receptor-mediated phagocytosis processes have been implicated, including macrophage lectins and carbohydrate receptors, vitronectin (thrombospondin) receptors and phosphatidylserine receptors (Savill *et al.*, 1993). Lectin-mediated binding involves an integrin-polypeptide type of molecular bridge, complemented with sugar–lectin interaction either directly or indirectly (Morris *et al.*, 1984; Duvall *et al.*, 1985; Arends and Wyllie, 1991). This notion is further supported by the observations that simple sugars (e.g. *N*-acetylglucosamine, *N*,*N*′-diacetyl-chitobiose and mannosamine) will block the recognition of apoptotic cells by macrophages (Duvall *et al.*, 1985; Savill *et al.*, 1989). The loss of sialic acid from membrane glycoproteins would expose normally masked residues such as *N*-acetylglucosamine, *N*-acetylgalactosamine and galactose, rendering these available for interaction with macrophage lectins (Dini *et al.*, 1992).

Another type of recognition of apoptotic thymocytes by macrophages involves movement of phosphatidylserine from the inner to the outer surface of the apoptotic cell. Although this phospholipid is normally located on the inner surface of the plasma membrane, its movement to the outer surface of apoptotic cells and bodies is facilitated by a decrease in the activity of aminophospholipid translocase, an enzyme which normally transports phosphatidylserine from the outside of the plasma membrane to the inside, and/or by an increase in the activity of scramblase, an enzyme that moves phospholipids in both directions (Fadok *et al.*, 1992; 1993). Yet another possibility involves exposure of the phosphatidylserine moiety on the apoptotic cell surface due to a loss of membrane symmetry. The third type of receptor, identified on the macrophage surface, is known to recognize apoptotic neutrophils by a mechanism involving vitronectin, one of the heterodimeric integrin molecules, $a_v\beta_3$, CD_{36} and thrombospondin (Savill *et al.*, 1990; 1991) receptor complexes. The Horvitz group has suggested the involvement of various genes (*ced-1*, *-2, -5, -6, -7, -8, -10*) in the corpse removal process. This type of cell removal observed during apoptosis generally benefits the organism and does not threaten neighbouring cells or structures, because toxic contents of dying cells are normally digested internally, avoiding an inflammatory outcome. Apoptotic bodies are distinct membrane-encapsulated entities that can exclude vital dyes until they are degraded. Occasionally, apop-

totic bodies bypass phagocytosis and are released into the adjacent lumen. In such instances, apoptotic bodies demonstrate progressive dilation and degradation of the engulfed contents, particularly mitochondria, in a process resulting in secondary necrosis (Searle *et al.*, 1975). There has been an expansive growth in our understanding of secondary necrosis and its role in health and disease (see Silva *et al.*, 2008).

4 BIOCHEMICAL CHANGES INVOLVED IN APOPTOSIS

Following the morphological classification of apoptosis, many isolated molecular and biochemical events were characterized, often from studies on immature thymocytes *in vitro*. Because this is a tightly regulated energy-dependent active process, cells succumbing to this phenomenon show orderly changes in a highly synchronous fashion. Some of the key elements that orchestrate this beneficial form of death are Ca^{2+} and Mg^{2+} ions, DNA and the nuclear enzyme endonuclease. Wyllie (1980) and Cohen and Duke (1984) showed convincing evidence that chromatin undergoes cleavage early during the killing of immature thymoctyes by glucocorticoids. Activation of a Ca^{2+}-sensitive endonuclease appears to be an obligatory step in the appearance of small DNA cleavage products (**Figure 5**). These investigators highlighted the role that Ca^{2+} plays in the process and proposed that faltering Ca^{2+} regulation within the cell is needed for glucocorticoids to propel cell killing in this model. In a study that examined the killing of thymocytes by the immunotoxin 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), Orrenius and coworkers concluded that this environmental chemical also promotes endonuclease-mediated DNA damage in a Ca^{2+}-dependent manner (McConkey *et al.*, 1988b).

These discoveries raise a number of important questions. How do the mechanisms of acute cell killing gleaned from these *in vitro* models relate to cell death: (i) from other forms of cell insult, (ii) in other types of cells such as the hepatocytes and neurons and (iii) under more relevant conditions such as in living animals. Although most of these questions are not yet fully answered, leading laboratories throughout the world moved forward with apoptosis research employing the DNA ladder as a biomarker to confirm drug- and chemical-induced apoptosis in a wide range of model systems. Over time, the DNA ladder became so popular as a biochemical hallmark that its use resulted in a record number of publications for a decade (**Figure 3**). In 1980, Wyllie showed that the morphological changes of apoptosis are associated with distinctive, endonuclease-dependent double-strand cleavage of nuclear DNA at the linker regions between nucleosomes. The resulting oligonucleosomal fragments are readily demonstrated using agarose gel electrophoresis (**Figure 3**). Necrosis, in contrast, is generally accompanied by random DNA degradation and histone digestion, with diffuse smearing of DNA on agarose gels.

Identification of the DNA ladder as a simple biochemical hallmark led to an explosion of investigations attempting to identify agents capable of inducing apoptosis based on their ability to produce a ladder. Several prominent exceptions to this rule were noted during this period, leading to an appropriate revision that internucleosomal DNA cleavage cannot be used as a sole criterion for diagnosing apoptosis (Collins *et al.*, 1992) in the absence of other dependable markers. The demonstration of internucleosomal chromatin degradation continues to be a valuable diagnostic aid, particularly when supplemented with morphological results and biochemical data, such as caspase activation and M30 neoantigen release (Schwartzman and Cidlowski, 1993; Wieckowska *et al.*, 2006; Hetz *et al.*, 2007). These characteristics are reproducible in both *in vivo* and *in vitro* systems comprising normal or abnormal cells. Apoptotic and necrotic cells share DNA as a common target. Most necrotic cells also show considerable DNA degradation, appearing in a smear-like pattern with haphazard, random or nonspecifically degraded fragments migrating as a continuous spectrum of sizes on agarose gels. Apoptotic cells, on the other hand, most often show a characteristic ladder-like pattern (Huang *et al.*, 1997) except when DNA cleavage ends early resulting in the formation of higher-molecular-weight fragments ranging from 50 to 700 kb (Bicknell and Cohen, 1995).

A rise in intracellular and/or intranuclear Ca^{2+} is a prerequisite for chromatin fragmentation, since the primary enzymes responsible for cleaving DNA appear to be Ca^{2+}- and Mg^{2+}-dependent. Calcium homeostasis must be under as careful regulation in the nucleus as elsewhere throughout the cell (Ray *et al.*, 1990; 1991; 1993; Ray and Corcoran, 1991). The Ca^{2+} concentration gradient present between the nucleus and the cytoplasm (Williams *et al.*, 1988) implies the existence of structures that transport Ca^{2+} across the nuclear membrane. Skeletal muscle nuclei demonstrate Ca^{2+}-stimulated ATPase activity (Kulikova *et al.*, 1982). Nuclei isolated from rat liver accumulate Ca^{2+} *in vitro* via an ATP- and calmodulin-dependent process and contain a constitutive endonuclease that responds to pathophysiological Ca^{2+} concentrations in the submicromolar range by cleaving DNA into periodic intranucleosomal fragments (Jones *et al.*, 1989).

Considerable evidence now establish that the role of Ca^{2+} is pivotal in the early stages of toxic injury leading to cell death (reviewed by Reed, 1990; Barry and Eastman, 1992; Corcoran and Ray, 1992; Trump and Berezesky, 1995; Jeong and Seol, 2008; Vanlangenakker *et al.*, 2008; Dong *et al.*, 2006). Ca^{2+} ion appears to be acting in a well-known capacity as a principal intracellular messenger to convey the consequences of initial damage from diverse sites to one or more specific

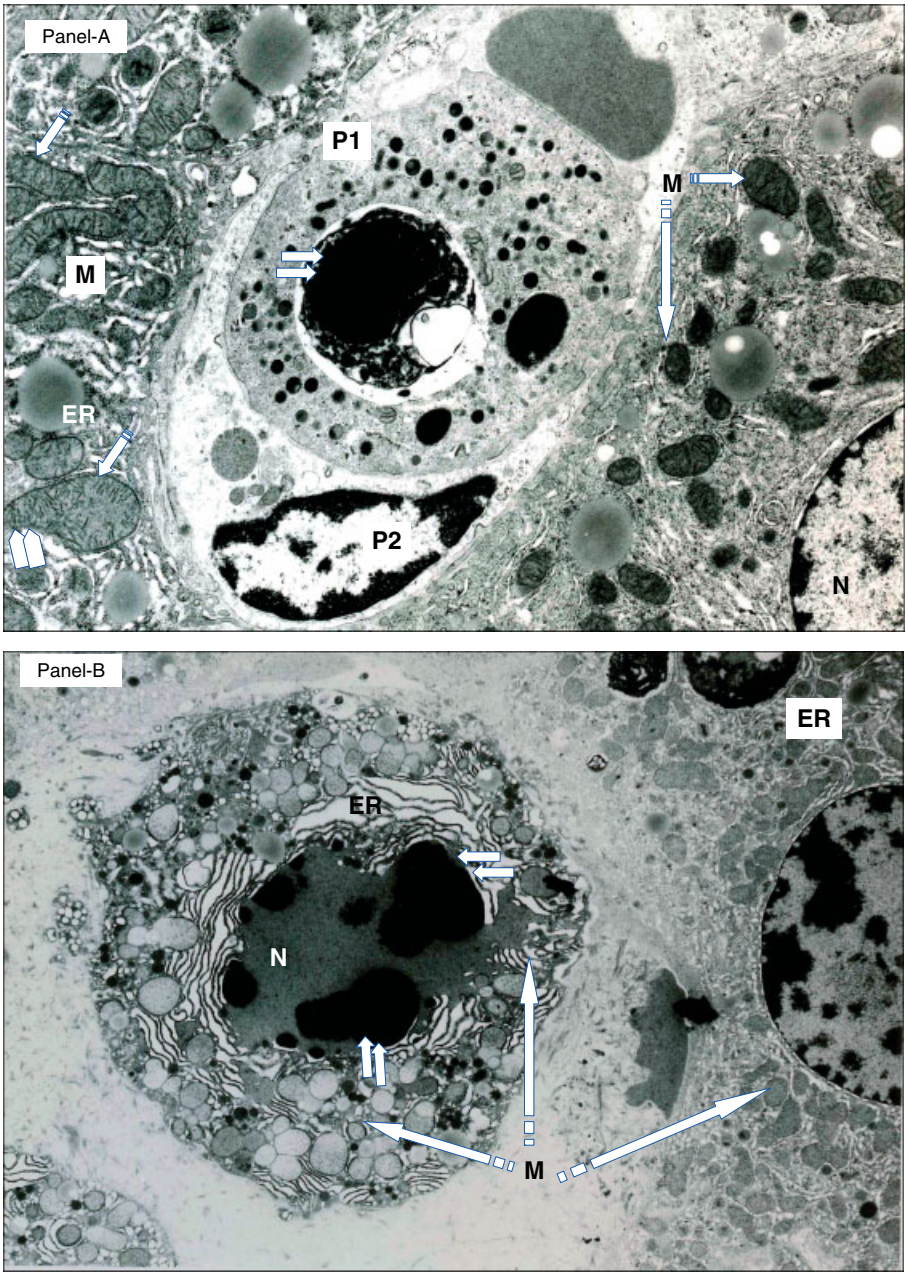

Figure 5 Dimethylnitrosamine-induced hepatocellular apoptosis and necrosis involving phagocytosis. Electron photomicrographs of mouse liver show ultrastructural details over time of apoptotic and necrotic hepatocytes from animals treated with 100 mg kg^{-1} dimethylnitrosamine i.p. In (A), a portion of a nucleus is visible at the bottom right, and the endoplasmic reticulum and numerous mitochondria appear normal. Mitochondrial inner folds are clear in several mitochondria as shown by arrows. This panel presents the phagocytosis (P1) of apoptotic bodies and remnants by a macrophage at 6 hours (×8000). Note that the macrophage-apoptotic body complex is being approached by a second cell for scavenging. Double blunt overlapping arrows (bottom left) point to disruption of the mitochondrial membrane. (B) shows both apoptotic and necrotic changes 18 hours after dimethylnitrosamine exposure (×12 000). Necrotic changes in the cytoplasm and mitochondria, and some apoptotic morphology (condensed and fragmented chromatin) are evident. In comparing the changes in volume regulation in Figure 3A and B with those in this figure, note advanced plasma membrane, mitochondrial, cytoplasmic and ER damage (distortion), including other unidentifiable morphological aberrations of the cytoplasm of a hepatocyte possibly exhibiting some features of apoptosis and others of necrosis (termed apocrosis or necraptosis) in the vicinity of a normal hepatocyte (right half of the section). Scale: 10 μm = 10 mm at ×10 000; 12 μm = 12 mm at ×12 000. Legend: M—mitochondria; N—nucleus; ER—endoplasmic reticulum; P1—phagocytosis; P2—secondary phagocytosis. secondary loci that are critical for cell viability. In addition to Wyllie's (1980) experiments involving immature thymocytes, many laboratories reported that, in apoptosis, an elevated level of Ca^{2+} after a toxic insult was the cause, while endonuclease-mediated DNA fragmentation leading to cell death was the effect (Cohen and Duke, 1984; McConkey *et al.*, 1989; 1990a; Ray *et al.*, 1990). This cause-and-effect relationship was further strengthened by results of studies exposing thymocytes to agents that elevate intracellular Ca^{2+} levels (e.g. glucocorticoids, calcium ionophores, radiation, TCDD, tributyltin, natural killer cells or cytotoxic T-lymphocytes and anti-CD_3 antibodies) or agents known to prevent intracellular Ca^{2+} accumulation [e.g. ethylene glycol tetraacetic acid (EGTA)], verapamil, chlorpromazine, nifedipine, promethazine).

Because protein synthesis is also important for mediating the influx of calcium under many circumstances, it is assumed, in the case of thymocytes, that the interaction of a glucocorticoid with its plasma membrane receptor rapidly induces the synthesis of a protein that acts as a calcium pore (McConkey *et al.*, 1996). It has been confirmed that glucocorticoid-induced thymocyte apoptosis is sensitive to treatment with actinomycin D (an inhibitor of RNA synthesis) and cycloheximide (an inhibitor of protein synthesis), whereas apoptosis induced by tributyltin is not. Further, the endonuclease inhibitor, aurintricarboxylic acid, and Zn^{2+} ion are known to inhibit fragmentation of DNA in some model systems (Benchokroun *et al.*, 1995; Zalewski and Forbes, 1995). Together, these results suggest that, although not universal, apoptosis is an active process requiring RNA and protein synthesis, especially for cell death to become irreversible. Studies demonstrating the necessity for *de novo* macromolecular synthesis for the execution of this cell death pathway make the important distinction that toxic cell death (necrosis) does not require such macromolecule synthesis.

Tributyltin-induced apoptosis provides a useful and convincing example refuting the need for new macromolecular synthesis in apoptosis. Nickel, an agent that blocks non-voltage-dependent Ca^{2+} channels, blocks tributyltin-induced apoptosis. This suggests that tributyltin interacts directly with the plasma membrane of thymocytes to open Ca^{2+} channels, facilitating Ca^{2+} entry into the cell and bypassing the need for intracellular signalling and new protein synthesis. Pathways in which new protein synthesis or new gene expression is required for apoptosis after exposure to the stimulus may be referred to as *induction* pathways. Alternatively, apoptosis can result from inhibition of protein or messenger RNA synthesis, suggesting that a cell death pathway is constitutively expressed, yet kept in abeyance by short-lived inhibitors. Pathways that induce apoptosis by inhibiting protein synthesis are termed *release* pathways, and pathways that are not influenced by inhibition of protein synthesis, such as cytotoxic T-cell mediated apoptosis, have been termed *transduction* pathways (Patel and Gores, 1995). This body of thinking stresses the global role that ion regulation plays in continued cell vitality, and emphasizes, in particular, the large number of regulatory systems that rely upon the actions of calcium ions.

The integrity of no single molecule appears to be as vital to the cell as that of DNA. Its safeguarding from any entity and its perpetuation are among the most intricate and aggressively pursued goals of homeostatic regulatory controls. In the entire apoptosis literature, three distinct patterns of DNA fragmentation have so far been reported (Huang *et al.*, 1997): (i) internucleosomal cleavage of genomic DNA (Wyllie *et al.*, 1984); (ii) 30–50 kb and larger fragment cleavage (Roy *et al.*, 1992) and (iii) single-stranded nicking (Ucker *et al.*, 1992). The classic ladder-like pattern that stems from DNA breakdown at the internucleosomal nodes generates fragments in 180–200 bp increments, bearing 3′-OH DNA termini. This type of fragmentation appears long before the onset of many of the stereotypic morphological changes and continues even after the removal of the death signal. The second type of DNA degradation appears after cleavage and involves fragmentation of a higher order loop structure of chromatin (700 and 300 kb), into about 50 kb products that anchor to the nuclear matrix in the interloop or matrix attachment regions (MARS). Release of these 50 kb fragments is thought to result from cleavage in the MARS. The larger fragments appear to be intermediates in the process of DNA fragmentation and ultimately give rise to DNA ladders. However, it is not clear whether the large fragments are produced by the activity of the enzymes responsible for forming the oligonucleosomal fragments, since concentrations of divalent cations required for their formation are different from those required by latter enzymes. It is hoped that future studies will determine whether this type of chromatin cleavage is universal, and is an irreversible commitment in all apoptotic cells, since a similar pattern of DNA fragmentation has also been found in necrotic cells (Sun *et al.*, 1994; Bicknell and Cohen, 1995; Kataoka *et al.*, 1995).

The third type of fragmentation is single-stranded breaks in core-histone-associated DNA and internucleosomal areas by the Ca^{2+}-dependent endonuclease DNase-I (Peitsch *et al.*, 1993). Addition of the enzyme to isolated nuclei, and other reconstituted systems promotes the formation of DNA strand breaks which possess the same 5′-PO_4 and 3′-OH end groups as those found in DNA fragments isolated from apoptotic cells. Two closely spaced single-stranded breaks on opposing strands of DNA will result in double-stranded DNA cleavage, providing a strong signal for the apoptotic cascade, but this does not offer a mechanism to explain overall chromatin cleavage. Parrish and Xue (2006), Widlak and Garrard (2005), Huang *et al.* (1997), and others have reviewed the characteristics of candidate

nucleases isolated from a variety of model systems. To date, DNA fragmentation factor (DFF)40/caspase-activated DNase (CAD) and EndoG (CSP-6 in *C. elegans*) have emerged as leading candidates for nuclease activity in apoptosis in mammals (see Genetic Regulation of Apoptosis). Other nucleases may also be important in various instances of apoptotic and necrotic cell death, including apoptosis-inducing factor (AIF) and its *C. elegans* homologue WAH-1, CRN1-CRN6, CYP-13, DNase-I, DNase-II, NUC1, NUC18, NUC40, NUC58, a 27 kDa nuclease and a 37 kDa nuclease. It appears that in *C. elegans*, CSP-6, WAH-1 and several CRN nucleases interact together to form a multinuclease complex called a degradasome. Endonuclease activity in cells undergoing apoptosis can be regulated directly or indirectly by protooncogenes and tumour suppressor genes, such as *c-myc*, *Ha-ras*, *bcl-2* and *p-53* (Vanderbilt *et al.*, 1982; Milligan and Schwartz, 1996; Huang *et al.*, 1997), which are discussed elsewhere in this chapter.

Transglutaminases, a family of Ca^{2+}-dependent enzymes, catalyse the formation of protein crosslinks that are biologically irreversible. No enzymes capable of hydrolysing the crosslinks formed by transglutaminases in substrate proteins have been found in vertebrates (Fesus *et al.*, 1991). These cytosolic enzymes accumulate to achieve high levels in some terminally differentiated cells and also in a number of cell types undergoing apoptosis both *in vivo* and *in vitro.* Transglutaminase is both induced and is activated during apoptosis. Although the role of transglutaminase in apoptosis is poorly understood, it is considered likely that the cross-linking of proteins stabilizes apoptotic bodies and prevents the leakage of intracellular constituents into the extracellular space, which would trigger unwanted inflammation. Intracellular activation of this enzyme can change adhesive properties (Byrd and Lichti, 1987; Nara *et al.*, 1989) and may contribute to the altered cell surface properties of the apoptotic bodies (Fesus *et al.*, 1991). Intriguingly, overexpression of the enzyme has been reported to activate apoptosis (Fesus *et al.*, 1987; Knight *et al.*, 1991).

Another group of thiol-containing and Ca^{2+}-dependent proteases, linked directly or indirectly to apoptosis, is the calpains (Martin *et al.*, 1995). Calpains, known as calcium-dependent and papain-like proteases, occur in two forms, μ-calpain and m-calpain. μ-Calpain and m-calpain have identical regulatory subunits with distinct catalytic subunits, but the Ca^{2+} requirement for activation is higher for m-Calpain. Although their distribution is ubiquitous, calpains are nonlysosomal cytosolic modulatory proteases, not digestive proteases, and are occasionally localized at the plasma membrane. Calpain substrates include cytoskeletal proteins (actin-binding proteins, e.g. fodrin/spectrin, talin and filamin and microtubule-associated proteins), membrane proteins [growth factor receptors, e.g. epidermal growth factor (receptor); adhesion molecules, e.g.integrin and cadherin; ion transporters, e.g. Ca^{2+}-ATPase; ion channels, e.g. Ca^{2+}-channel] and enzymes [kinases including protein kinase C (PKC)], calmodulin-dependent kinase; phosphatases such as calcineurin and phospholipases]. Either directly or indirectly, calpains may influence cell shape, inactivate transcription factors (*c-fos* and *c-jun*) and jeopardize signal transduction pathways by attenuating PKC activity.

Numerous Ca^{2+}-linked processes, such as activation of the interleukin-1β-converting enzyme (ICE) family of proteases, PKC, growth factor-dependent events and various signalling processes may be under the regulation of calpains (see Genetic Regulation of Apoptosis). Expression of calpains in apoptotic cells is an early event occurring long before the onset of morphological changes. The activation of calpains is thought to play a role in glucocorticoid-induced thymocyte apoptosis and FAS/APO-1-mediated apoptosis of T-cell hybridomas (Squier *et al.*, 1994). Engagement of FAS/APO-1, a tumour necrosis factor (TNF)-receptor superfamily member (CD95 in mammalian cells) with specific antibodies, or upon exposure to its natural ligand, transduces an extremely rapid, synchronous and potent apoptotic signal to a variety of cell types (McConkey *et al.*, 1996). Since calpains are Ca^{2+}-binding thiol (-SH)-containing proteins, it has been suggested that their cleavage products may be involved in promoting some of the morphological features of apoptosis. Interestingly, in *C. elegans*, the products of the cell death genes *ced-3* and *ced-4* are a sulfydryl-containing protease and a Ca^{2+}-binding protein, respectively. Other Ca^{2+}-linked processes are discussed elsewhere in this chapter.

Many different types of proteins that are either cleaved or selectively expressed during apoptosis include histone HI, topoisomerases I and II, lamins, Ul-70 kDa and the nuclear enzyme PARP (Tanaka *et al.*, 1984; Kaufmann, 1989; Ray *et al.*, 1992; McConkey *et al.*, 1995). Among these proteins, PARP has gained considerable attention. Activation of the DNA repair enzyme PARP (EC 2.4.2.30), considered another prominent biochemical event associated with apoptotic death, involves ribosylation of nuclear proteins (Marks and Fox, 1991). This process is mediated by the enzymes mono(ADP-ribosyl)transferase and poly(ADP-ribose) synthetase and involves the transfer of ADP-ribose groups from nicotinamide adenine dinucleotide (NAD) to protein acceptor sites and to existing ADP-ribose polymers. The ribosylation process facilitates DNA-excision repair and this antagonizes apoptotic processes. Massive activation of this enzyme leads to lethal depletion of NAD, and indirectly ATP. Conversely, mild activation, often seen with submaximal injury, is associated with increased repair and decreased cytotoxicity or cytolethality. Therefore, some investigators have argued that depletion of NAD and ATP induced by DNA strand breakage is a critical event in apoptotic death (Degterev and Yuan, 2008;

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015

Carson *et al.*, 1986; Wielckens and Delfs, 1986; see review by Ratnam and Low, 2007).

This ostensible antiapoptotic action of PARP is substantiated by observations that poly(ADP-ribose) synthetase inhibitors such as nicotinamide and 3-aminobenzamide may either increase or decrease the sensitivity of apoptosis-inducing agents, depending upon the concentration employed (Ray *et al.*, 1992; Yahya *et al.*, 1995). NAD, the PARP substrate, is also known to maintain cellular redox balance. Any gross shift in the physiological level of this component perturbs the tightly regulated myriad of metabolic functions coupled with cellular homeostasis, ultimately resulting in irreversible cytotoxicity. Likewise, ATP depletion leads to failure of ATP-dependent membrane pumps and results in the disturbance of the cellular ionic equilibrium, particularly Ca^{2+}, eventually causing activation of cytotoxic mechanisms involving proteases, phospholipases and endonucleases. In contrast to all these observations, H_2O_2, a potent necrogen which induces DNA strand breaks, is a powerful inducer of PARP in *in vitro* model systems. Hence both inhibition and activation of poly(ADP-ribose) synthetase may set the stage for endonucleases to proceed with their goals, either to complete or to oppose the final mission of cell, death by apoptosis (Nelipovich *et al.*, 1988; Ray *et al.*, 1992).

5 PROTEIN KINASES, SIGNALLING MECHANISMS AND APOPTOSIS

The past two decades have witnessed tremendous progress in understanding how extracellular signals are transduced across the plasma membrane and then transmitted within the cell to elicit specific physiological responses. Recently, intense interest has focussed upon the potential involvement of diverse signalling processes in the regulation of apoptosis (McConkey *et al.*, 1990b). However, many elements of the signalling system(s) involved in the induction of apoptosis remain unknown. The signal generated by a stimulus must be transmitted to effector molecules that often lie in different subcellular compartments. Transduction pathways vary according to trigger stimulus, but two major areas of focus are cytosolic calcium and protein kinases. Participation of Ca^{2+}-/phospholipid-dependent protein kinase (PKC) in intracellular signalling processes has been demonstrated in many cell types. Physiologically, the activity of PKC is regulated upon its translocation from cytosol to the membrane, and it is at the plasma membrane that the enzyme is activated by its endogenous activator diacylglycerol. The breakdown of phosphatidylinositol (PI) triphosphate by phospholipase C results in the production of diacylglycerol, a second messenger cofactor that mediates activation of the PKC. Besides the reversible activation of PKC by Ca^{2+}, phospholipids, diacylglycerol, unsaturated fatty acids and phorbol esters, this enzyme is also irreversibly activated by limited proteolysis involving the intracellular protease calpain (see discussion elsewhere in this chapter). One of the pathways of the transmembrane signalling system operates through the activation of PKC, whereas the other signal system involves receptor-mediated activation of cyclic adenosine monophosphate (cAMP)-dependent protein kinase. Information concerning a role for PKC in apoptosis mostly comes from studies with phorbol esters [12-0-tetradecanoylphorbol-13-acetate (TPA)]. These tumour promoters act by binding to the diacylglycerol-binding site on the enzyme and promoting its activation. Ca^{2+} mobilization and the calmodulin-dependent regulatory system appear to work in concert with TPA (Kizaki *et al.*, 1989) involving the pathway of interleukin-2 (IL-2) gene expression.

PKC-mediated phosphorylation of numerous protein substrates is associated with a wide range of biological effects, including stimulus secretion coupling, induction of cellular proliferation and differentiation, activation of nuclear transcription factors and cell surface receptors and tumour promotion. PKC is expressed in mammalian systems as a family of diverse serine-threonine kinases, consisting of at least nine isoforms differing in both substrate specificity and dependence upon Ca^{2+}. Mechanisms that explain the divergent actions of PKC are speculative at present. In haematopoietic cells, pharmacological agents that inhibit PKC activity, such as the isoquinolines, staurosporine and H7, inhibit the growth of both normal and leukaemic progenitors, suggesting the involvement of basal PKC activity in cell proliferation. In addition, PKC inhibitors block leukaemic cell differentiation in response to tumour-promoting phorboides. Given that cell differentiation is associated with a loss of proliferative potential, these observations indicate that PKC inhibitors may exert pleiotropic effects on haematopoietic cell behaviour. Efforts to define the role of PKC in the induction of apoptosis have been complicated by conflicting reports. Take, for example, the observations that activation of PKC by exposure to phorbol-12-myristate-13-acetate (PMA), either alone or in conjunction with Ca^{2+} ionophores, induces apoptosis in cells of lymphoid origin and that inhibition of PKC by exposure to H7 prevents glucocorticoid-induced apoptosis in murine thymocytes (McConkey *et al.*, 1995). These findings suggest that PKC activation promotes this process. On the other hand, the ability of PMA to oppose steroid-induced apoptosis in thymic lymphocytes and to prevent growth-factor-deprived haematopoietic cells from undergoing apoptotic cell death is instead consistent with an antagonistic influence (Jarvis *et al.*, 1994a; 1994b). Although most studies argue in favour of a role for PKC in apoptosis, it is important to appreciate that a specific contributory role in apoptosis is highly dependent on the context of events and cell types.

Besides PKC, other kinases have been reported to be associated with apoptosis. PI3 kinase is activated by different growth factors. Activation of PI3 kinase leads to phosphorylation of AKT (protein kinase-B). Phosphorylated AKT induces phosphorylation of Bcl-xL/Bcl-2-associated death promoter (Bad) through other kinases. Phosphorylated Bad remains inactive because it is squelched by 14-3-3 proteins, resulting in cell survival. However, dephosphorylation of Bad in the absence of phosphorylated AKT results in Bad being dissociated from 14-3-3. The dissociated Bad binds to Bcl-xL releasing Bax. This leads to apoptosis. AKT also phosphorylates procaspase-9, thereby inactivating caspase-9-mediated activation of the caspase cascade (Rohn *et al.*, 1998; Cardone *et al.*, 1998; see Section 6).

Other important biochemical determinants of apoptosis include cAMP, ceramide and the redox status of a cell. The sphingomyelin pathway, initiated by hydrolysis of the phospholipid sphingomyelin in the cell membrane to generate the second messenger ceramide, is thought to mediate apoptosis in response to TNFα, to FAS ligand (Fas-L), to photodynamic therapy, and to X-rays. Generation of ceramide, a hydrolysis product of sphingomyelin, through the sphingomyelin pathway results in the induction of apoptosis in several cell lines. At least two specific intracellular targets for ceramide have been identified: (i) a membrane ceramide-activated protein kinase and (ii) a cytoplasmic ceramide-activated protein phosphatase. Ceramide promotes the formation and release of oligonucleosomal DNA fragments, produces corresponding loss of integrity of DNA, and elicits the expression of the classical morphology of apoptosis. Interestingly, ceramide-related DNA damage consists exclusively of double-stranded breaks introduced into mature DNA, but not nascent DNA. Surprisingly, apoptosis is not initiated by diglyceride or other glycerophospholipid-derived messengers (e.g. lysophosphatidylcholine, arachidonic acid or phosphatidic acid) in U937/HL60 cells. However, a report claims that Hep-G2 cells overexpressing P4502E1 undergo apoptosis upon exposure to arachidonic acid (Chen *et al.*, 1997).

As with ceramide, cAMP promotes palatal fusion which involves apoptosis of medial edge epithelial cells (Pratt and Martin, 1975). McConkey *et al.*, (1990a) have reported that agents that elevate cAMP stimulate DNA fragmentation and produce apoptosis in thymocytes act via activation of cAMP-dependent protein kinase A. In contrast, Edwards *et al.*, (1991) have observed that analogues of cAMP inhibit apoptosis. This disparity may be due to the model system tested. Similar to cAMP and ceramide, Ca^{2+} and other agents with a role in maintaining cellular redox status including antioxidants (e.g. vitamin C, vitamin E), ADP/ATP, NAD/NADH, NADP/NADPH and GSH/GSSG ratios may influence apoptotic death by varied mechanisms. Fernandez *et al.* (1994) reported that marked GSH depletion enhances the cytotoxicity of alkylating agents (e.g. melphalan, chlorambucil), switching from the pathway of apoptosis to necrosis, whereas Cotter and coworkers (Verhaegen *et al.*, 1995) claim that antioxidants including butylated hydroxyanisole (BHA) inhibit apoptosis. Similarly, agents that deplete intracellular glutathione typically render cells more vulnerable to oxidative stress-induced apoptosis (Zhong *et al.*, 1993). The redox potential of a cell turns out to be as critical to cell survival as maintaining intracellular ion homeostasis or genomic integrity. An oxidative shift by reactive oxygen species (ROS) may modify the nature of the stimulatory signal, resulting in alteration of the direction of the response (apoptosis/necrosis/proliferation). Efficient activation of NFκB-dependent genes by TNF requires that a cell be in an oxidized state, suggesting that stimuli such as TNF and PMA may exert only a limited response if the cell is not in appropriate redox equilibrium (Israel *et al.*, 1992).

In this context, growing attention is now being devoted to mitochondrial functions during apoptosis. ROS, Ca^{2+}, the mitochondrial permeability transition (MPT) and cytochrome c (cyt-c) are presumably all important for apoptosis. The first two entities, ROS and Ca^{2+}, are directly related under a number of conditions. For example, ROS stimulate Ca^{2+} release from mitochondria, and when mitochondria cycles Ca^{2+} excessively their ROS production increases (Richter *et al.*, 1996). Mitochondria can initially protect the cell against toxic increases in Ca^{2+}. However, excess Ca^{2+} cycling can culminate in vigorous perturbation of the $\Delta\psi$ (mitochondrial membrane potential [MMP]), resulting in a variety of lethal molecular lesions. Similarly, TNFα stimulates ROS production by mitochondria, and the TNFα-induced apoptotic killing of some cell types is due to ROS-induced mitochondrial Ca^{2+} cycling since apoptosis is blocked by mitochondrial Ca^{2+} uptake inhibitors (Hennet *et al.*, 1993a; 1993b). An important observation, which provides a specific clue as to which mitochondrial parameter(s) may be important for the control of apoptosis, comes from the observation that the stabilization of $\Delta\psi$, either by overexpression of a death inhibitory gene (*bcl-2*) or by the ionophore nigericin, prevents apoptosis induced by TNFα. Many laboratories have reported that $\Delta\psi$, which is the driving force for mitochondrial ATP synthesis, decreases prior to DNA damage, and that maintenance of ATP prevents apoptosis (Shimizu *et al.*, 1996).

Ca^{2+}, oxidant chemicals and a range of other inducers (e.g. oxidative stress and alteration in cellular phosphorylation state) promote the onset of the MPT in mitochondria. The MPT reflects the opening of a highly regulated pore within the inner mitochondrial membrane. Opening of high-conductance permeability transition pores causes the onset of the transition, leading to membrane depolarization, release of ions, uncoupling of oxidative phosphorylation, permeation of sucrose and other solutes

of molecular weight less than 1500 and large amplitude mitochondrial swelling. Ca^{2+}, oxidant chemicals, Pi (inorganic phosphate) and membrane depolarization promote pore opening, whereas, Mg^{2+}, ADP, low pH and immunosuppressant ciclosporin (cyclosporine-A) favour the closed state. Oxidants, including the drug doxorubicin, are the most thoroughly studied class of inducing agents. Doxorubicin interferes with the capacity of isolated cardiac mitochondria to accumulate and retain calcium, and it does this by selectively inducing the MPT, presumably via the free-radical-mediated oxidation of critical protein thiols associated with the voltage-sensing element of the pore. Associated with this is an increased sensitivity to calcium-induced membrane depolarization and osmotic swelling. Mitochondrial osmotic swelling in response to pore formation may be responsible for the release of mitochondrial factors that are crucial in triggering the late stages of the apoptotic pathway. One such factor is cyt-c, the release of which occurs in the absence of significant changes in *Aip*, suggesting a novel mechanism for cell death commitment. cyt-c molecules from a variety of metazoan species, including the insect *Manduca sexta*, all function to induce apoptosis in *Xenopus* egg extracts. Collectively, these studies indicate that loss of mitochondrial function is a pivotal event in modulating cellular energy status and influencing cell-death processes including apoptosis (Lemasters and Nieminen, 1998; Qian *et al.*, 1999; Theruvath *et al.*, 2008).

6 GENETIC REGULATION OF APOPTOSIS

The concept of active cell death being a genetically encoded process stimulated an aggresive search for the genes involved in the regulation of cell-death. The number of ground-breaking discoveries and seminal articles published in this arena in the last decade alone exceeds the very impressive body of information accumulated in the preceding several decades. As more genetic engineering protocols and transgenic models became available, these tools produced a rapid advance of progress in this field and resulted in the discovery of many genes and vital regulatory elements across a range of model systems. In addition to the caspase-regulated pathways, **Table 5** lists of proapoptotic and antiapoptotic genes and their relationships. Active involvement of a number of these proteins has been demonstrated in either the causation or prevention of apoptotic death. Although the entire field has only grown in complexity, understanding and designing access to predictable cell death pathways may have become easier. The cornerstone for many of these findings has been the genetic blueprint of the cell death pathway described in *C. elegans*. The central components of this pathway were found to have mammalian counterparts that exhibit considerable homology and redundancy, often through multigene families. Molecular biological experiments in mammalian cells and in a wide variety of transformed cells have provided a rich and varied foundation of information and understanding.

6.1 TNFR Superfamily

The TNF family of ligands and receptors is a well characterized group of cell surface and soluble molecules capable of initiating apoptosis *in vivo* and *in vitro*. Prodeath members of this family contain a cytoplasmic death domain (DD), a protein–protein interaction motif critical for engaging downstream components of the signal transduction machinery. Following the activation of these receptors by their cognate ligands, a death-inducing signalling complex (DISC) is formed by recruitment of cytoplasmic DD-containing proteins to the receptor DD motif. Among the most carefully studied death-inducing ligand-receptor pairs is TNF/TNF receptor-associated factor type 1 (TNFR1) and CD95L (Fas)/CD95 (Apo-1). The variety of downstream effector proteins regulating and controlling apoptotic signalling cascades has resulted in links between extrinsic and intrinsic signals in order to execute a death command or a survival command. Understanding how such signals are produced and propagated is a key goal for the many laboratories studying drug and chemical-induced cell injury and cell death (**Figure 6**).

Members of the TNFR superfamily, TNFR1 (which is expressed ubiquitously), TNF receptor-associated factor type 2 (TNFR2, which is expressed primarily by the cells of the immune system) and Fas (Apo-1/CD95) primarily trigger the *extrinsic pathway* of apoptosis. TNFR1 and TNFR2, which both bind to the cytokine TNF, were the first members of the TNFR family to be identified. This superfamily includes many death receptors (DR) besides Fas and TNFR (**Figure 6**). Members of this family exhibit pleiotropic action. These receptors can trigger proliferation, survival, differentiation or death depending on the cell type, the signal type that is received by the cell, and the cellular context. Members of this superfamily play important roles in immunity mechanisms and cellular remodelling, in addition to apoptosis and cell survival. These DD proteins, TNFs and Fas-L, function as rapid inducers of cell death through the cytoplasmic tails of the receptors harbouring DDs. The amino acid sequences of these DDs may slightly vary across receptors but all share a very high degree of sequence homology. Most importantly, they provide the foundation for protein–protein interaction. The DD in a receptor tail also recruits DD-containing intracellular adaptor proteins. Upon interaction with a death ligand, the DR rapidly launch apoptosis. This scenario is well exemplified in the case of immunocompetent cells where most signals (survival and death) are

Table 5 Genes and gene products involved in regulating apoptosis

Gene or gene product	Influence on apoptosis/putative mechanism(s)	References
Bcl-2	Inhibits/delays apoptosis, binds to *Bax and Bak*	Vaux *et al.* (1992), Hockenbery *et al.* (1993a,b), Hengartner and Horvitz (1994)
Bcl-xL	Inhibits apoptosis; binds *Bax and Bak*	Boise *et al.* (1993)
A1	Inhibits apoptosis *Bcl-2* family member, early response gene, transcriptionally induced by GM-CSF	Lin *et al.* (1993)
Mcl-1	Inhibits apoptosis; *Bcl-2* family member	Kozopas *et al.* (1993), Reynolds *et al.* (1994)
Ced-9	Apoptosis inhibitor, *C. elegans* homolog of *Bcl-2*	Hengartner *et al.* (1992), Hengartner and Horvitz (1994)
BHRF-1	Bcl-2 homolog that inhibits apoptosis, Epstein Barr Virus gene	Marchini *et al.* (1991)
ASFV HMWF5-HL	African Swine Fever Virus gene homologous to *Bcl- 2*	Neilan *et al.* (1993)
Bad	Accelerates apoptosis, interacts with *Bcl-2* and *Bcl-xL; can displace Bax from Bcl-xL*	Yang *et al.* (1995)
Bak	Promotes or inhibits apoptosis; binds to *Bcl-2, Bcl-xL,* and E1B 19K; sequence homology with *Bcl-2* within BH1 and BH2 regions	Chittenden *et al.* (1995), Farrow *et al.* (1995), Karbowski *et al.* (2006)
Bax	Promotes apoptosis, binds to *Bcl-2, Bcl-xL,* E1B 19K	Oltvai *et al.* (1993)
Bcl-Xs	Promotes apoptosis, binds *Bcl-2*	Boise *et al.* (1993)
Nbk, Bik 1	Apoptosis promoter, binds to *Bcl-2,* E1B 19K, *Bcl-xL,* and BHRF1, has only BH3 domain	Boyd *et al.* (1994)
Ced-3	*C. elegans gene,* apoptosis promoter	Yuan *et al.* (1993), Kumar *et al.* (1994)
Ced4	*C. elegans gene,* apoptosis promoter homologous to caspases and Apaf-1 in mammals	Ellis and Horvitz (1986), Yuan and Horvitz (1990)
P^{35}	Baculovirus gene, apoptosis inhibitor, binds to and inhibits caspases	Bump *et al.* (1995)
CrmA	Apoptosis inhibitor, cowpox viral protein, inhibits apoptosis induced by caspases	Gagliardini *et al.* (1994), Tewari *et al.* (1995)
MORT-1/FADD	Apoptosis promoter, binds Fas; same as FADD	Boldin *et al.* (1995), Chinnaiyan *et al.* (1995)
TRADD	Apoptosis promoter, binds TNFR-1	Hsu *et al.* (1995)
Reaper	Activator of programmed cell death in Drosophila, similarity to death domain of TNFR-1	White *et al.* (1994)
P^{53}	Apoptosis promoter, tumour suppressor gene, transactivates *Bax* expression	Yonish-Rouach *et al.* (1991), Miyashita *et al.* (1994)
C-myc	Apoptosis promoter, protooncogene, transcription factor	Fanidi *et al.* (1992), Evan *et al.* (1992)
R-ras	Apoptosis promoter, binds *Bcl-2*	Fernandez-Sarabia and Bischoff (1993), Wang *et al.* (1995)

Table 5 (*continued*)

Gene or gene product	Influence on apoptosis/putative mechanisms	References
Rb	Involved during apoptosis, tumour suppressor	Freeman *et al.* (1994), de Jong *et al.* (1998)
C-fos	Upregulated during apoptosis, transcription factor, IER (immediate early response) genes	Buttyan *et al.* (1988), Janssen *et al.* (1997)
C-Jun	Upregulated during apoptosis, IER gene, AP-1 group of transcription factors	Estus *et al.* (1994), Pandey and Wang (1995), Walton *et al.* (1998)
Hsp70	Involved during apoptosis, heat shock protein	Buttyan *et al.* (1988)
Sgp-2/TRPM-2	Involved during apoptosis, transfer lipids (?), complement inhibitor (?), include *clusterin* in this family	Buttyan *et al.* (1989)
cdk-4/cdk-5	Involved during apoptosis, cyclin dependent protein kinases	Freeman *et al.* (1994)
cyclin DI/cyclin D3	Involved during apoptosis, cell cycle regulator	Freeman *et al.* (1994), de Jong *et al.* (1998)
egr-1	Apoptosis promoter, transcription factor	Liu *et al.* (1998)
Rp-2/Rp-S	Apoptosis promoters, integral membrane protein (?) and DNA binding protein (?)	Owens *et al.* (1991)
Fas/AP01/CD95	Apoptosis promoter, members of TNF receptor superfamily	Nagata and Goldstein (1995)
TNF-R1	Apoptosis promoter, cell surface receptor	Cleveland and Ihle (1995)
Dad-1	Apoptosis inhibitor	Nakashima *et al.* (1993)
Calpain	Accelerates apoptosis, induces proteolysis	Squier and Cohen (1997), Spinedi *et al.* (1998)
Granzyme B	Apoptosis promoter, serine protease, activates caspases, cytolytic to T cells	Shi *et al.* (1996a), Trapani *et al.* (1998)
Survival factors	Growth factors and cytokines such as IGF-1 and various interleukins that act to promote cell survival	Raff (1992), Harrington *et al.* (1994), O'Connor (1998)
TGF-β	Apoptosis promoter, growth factor, may influence Bcl-2 expression but not dependent upon Bax or p53	Oberhammer *et al.* (1992), Selvakumaran *et al.* (1994), Buske *et al.* (1997), Roberson *et al.* (1997)

prompted via these receptors located on the membrane surfaces. Prime examples of Fas-mediated apoptosis are: (i) cell removal under normal physiological conditions, (ii) elimination of activated mature T cells from peripheral blood at the end of an immune response, (iii) deletion of self-reacting B cells, (iv) killing of virus-infected cells by cytotoxic T lymphocytes and (v) killing of inflammatory cells at the site of immune privileged organs. Since TNFRs are associated with both inflammatory and apoptotic responses, interaction of trimeric TNF with TNFR leads to the trimerization of TNFR molecules. This leads to binding of the DD of the TNFR-associated death domain protein (TRADD) to the DD of TNFR. TNF-signalling is linked to the Fas signalling pathway through interaction of TRADD with the Fas-associated death domain protein (FADD), and binding of FADD to TRADD leads to the propagation of apoptotic death through activation of caspase-8, as in the case of the Fas and Fas-L interaction. However, interaction of TRADD with TRAF2 and receptor-interacting protein (RIP) leads to the activation of NFκB or c-Jun NH_2-terminal kinase (JNK)/activator protein (AP)-1, which in turn leads to the induction of proinflammatory and immunomodulatory genes (**Figure 11**). NFκB activation to its full capacity usually stalls apoptosis, since the second complex recruits caspase-8 inhibitor FADD-like IL-1β-converting enzyme (FLICE) inhibitory protein (FLIP). The activation of caspase-8 via proximal

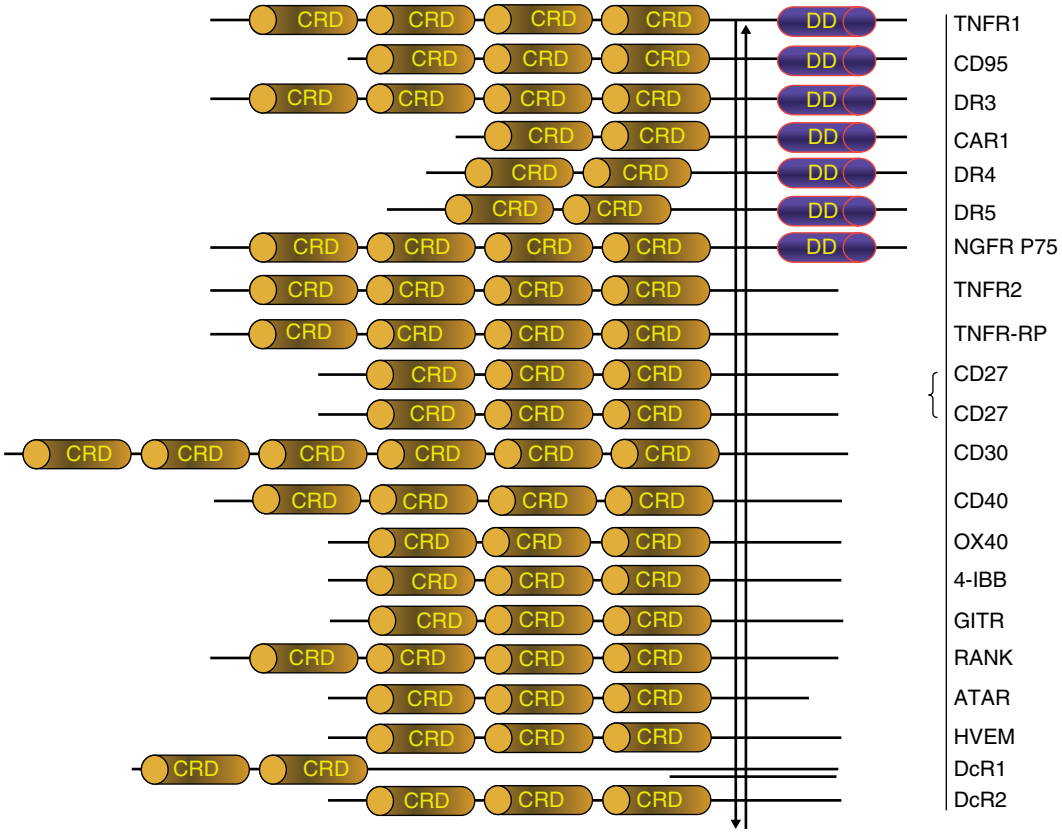

Figure 6 These TNF death receptor superfamily proteins have extracellular ligand-binding regions characterized by variable numbers of cysteine-rich (CRD) repeats. Death receptors contain death domains (DD) in the intracellular regions, which are essential for apoptosis signalling and cell death. Decoy receptors DcR1 and DcR2 compete with DR4 and DR5 for binding to TRAIL. DcR3 is a soluble receptor for FasL. The members of the TNF receptor superfamily function structurally as trimers and multimers of trimers. Single polypeptide chains are shown for simplicity. Proteins shown are mammalian and CAR1 from chicken. The TRAF family consists of six distinct proteins. Each except TRAF1 contains a ring finger domain, a zinc-finger motif, an amino-terminal TRAF domain and a carboxy-terminal TRAF domain. TRAF binds indirectly to the death domain of the receptor. TRAF2, TRAF5 and TRAF6 function as adaptor proteins that link the cell-surface receptors to downstream kinase cascades, resulting in the activation of NFκB and AP1. Neither TRAF1 nor TRAF3 activates kinase cascades. (With permission, from the Annual Review of Biochemistry, Volume 69 © 2000 by Annual Reviews.)

death signals can further activate caspase-3, cleave BH3-interacting domain death agonist (Bid) forming truncated Bid (tBid) and turn on mitochondria-centric death-promoting events. The Bid cleavage product tBid migrates to mitochondrial membrane prior to its action. Another well-known pathway involves the following: (i) caspase-8 cleaves procaspase-3 directly and activates it, (ii) the active caspase 3 cleaves DFF-45 into two heterodimeric factors DFF40 and DFF45, (iii) cleaved DFF45 dissociates from DFF40, inducing oligomerization of DFF40 that shows very high DNase activity and ultimately causes orderly internucleosomal genomic cleavage, considered a prime hallmark of apoptosis (**Figures 6** and **10**).

Another TNF family member, designated TNF-related apoptosis-inducing ligand (TRAIL), or alternatively APO-2, is also known as a rapid inducer of apoptosis in a broad range of tissues and a wide variety of transformed cell lines of diverse origin. Interest in TRAIL has risen because of its reported ability to induce apoptosis in tumour cells while bypassing normal cells. The presence of cysteine-rich domains (CRDs) characterizes the TNFR superfamily that mediates binding between ligands and these types of transmembrane domain receptors. Among these DR, the potential to induce apoptosis by TNFR1, Fas and the TRAIL receptors, DR4, DR5 and DR6 have been the centre of several investigations. To date, decoys identified for TRAIL are DcR1, DcR2 and osteoprotegerin (OPG), and a soluble Fas decoy receptor, DcR3. Interestingly, however, only DR4 and DR5 can trigger apoptosis and decoy receptors fail to elicit the activation of the downstream apoptotic signalling pathway since they lack a functional DD. This raises the issue as to how the signalling initiated by engagement of TNFR superfamily members is transduced within the cell. In response to ligand binding,

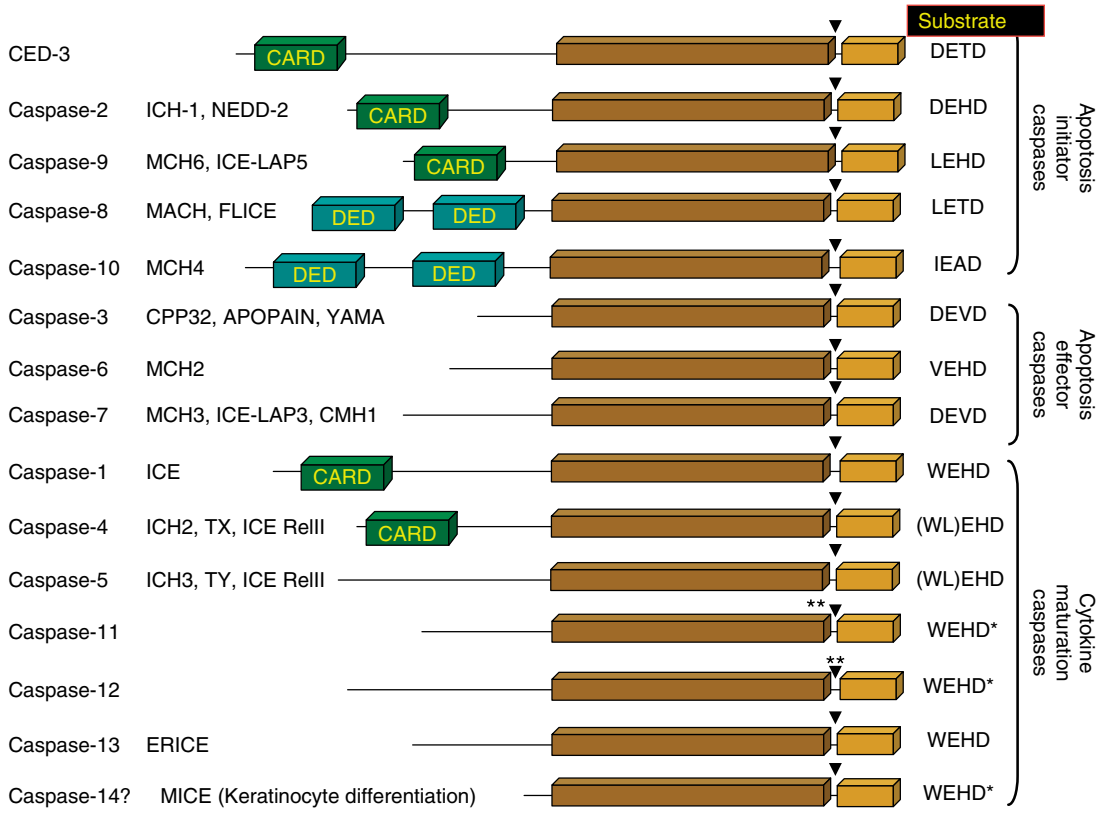

Figure 7 Classification and specificity of caspase enzymes. Caspases are cysteine aspartic acid-specific proteases because they cleave their substrates after specific tetrapeptide motifs (P4-P3-P2-P1), where P1 is an Asp residue. Members of this family are subdivided into initiators that are able to autoactivate and initiate the proteolytic processing of other caspases, and effectors that are activated by other caspase molecules and execute the final stages of apoptosis. Human caspases 1–10, mouse caspases 11–14 and *C. elegans* Ced-3 target endogenous substrates that are cleaved by effector caspases during the onset of apoptosis. All caspases have a similar structure comprised of a propeptide domain followed by a large and a small subunit. Large brown and small tan bars represent large and small subunit cleavage products, and arrow heads show cleavage sites. The propeptide can be of variable length and, in the case of initiator caspases, can be used to recruit the enzyme to activation scaffolds such as the APAF1 apoptosome. Two distinct, but structurally related propeptide motifs have been identified, the caspase recruitment domain (CARD) and the death effector domain (DED). These domains facilitate interaction with proteins that contain the same or similar motifs. Caspase activation is initiated through proteolytic processing of the caspase to generate large and small subunits that assemble into heterodimers. This rearranges the caspase active site into the active conformation. Caspases function as heterotetramers formed through dimerization of two caspase heterodimers. Initiator caspases exist as monomers in healthy cells, and effector caspases are present as preformed dimers. Not all mammalian caspases participate in apoptosis. Caspase-1, -4, -5 and -12 are activated during innate immune responses and in the regulation of inflammatory cytokine processing (such as IL1β and IL18). Caspase-12 is expressed as a truncated, catalytically inactive protein in most humans. A subset of individuals of African descent express full-length caspase-12 and appear to be more susceptible to inflammatory diseases. 400 substrates for the mammalian caspases have been identified, but the significance of many of these cleavage events remains unknown. The caspase proteases have overlapping substrate specificities that suggest partially overlapping functions. For example, despite evidence for a central role for caspase-3 in apoptosis, mice deficient in this enzyme display a defect in apoptosis only in the brain, suggesting that in most other tissues enzymes such as caspase-1 and -7 function redundantly with caspase-3. Known caspase inhibitors include Caspase-1: YVAD, DEVD, WEHD, IAP, p35, crmA; Caspase-2: WEHD, YVAD, DEVD, IETD, AEVD, IAP, p35; Caspase-3: WEHD, YVAD, IETD, DEVD, p35; Caspase-4: IETD, AEVD, YVAD, DEVD; Caspase-5: AVED, IATD; Caspase-6: VEID; Caspase-7: WEHD, YVAD, DEVD, p35; CMH-1; Caspase-8: YVAD, crmA; Caspase-9: YVAD, WEHD, AEVD; and Caspase-10: YVAD, WEHD, AEVD, DEVD. ** = aspartate cleavage site is not known;* caspase 11–14 = mouse caspases. various proteins are recruited to specific domains within the cytoplasmic tails of these receptors. It is these downstream effectors, which vary in both structure and function, that determine signalling outcomes. Some effectors are enzymes, such as kinases, phosphatases and proteases, some are adaptor proteins that serve to recruit still more signalling intermediaries and some are regulatory proteins. Understanding the nature and

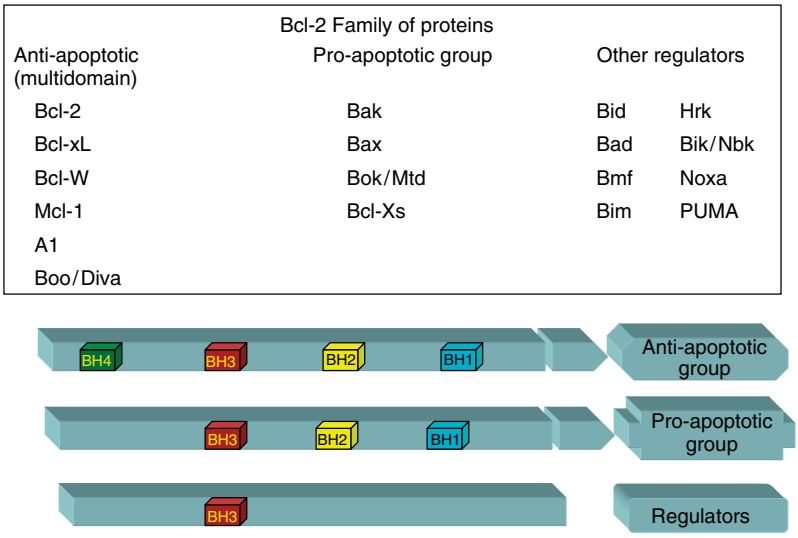

Figure 8 The Bcl-2 family of anti- and pro-apoptotic proteins. This group of proteins is comprised of three subfamilies that contain between one and four Bcl-2 homology (BH) domains. Members of the anti-apoptotic group contain all four BH domains. Most members of this subfamily also contain transmembrane domains (TM) and are therefore typically associated with membranes. The pro-apoptotic Bax-like subfamily members lack BH4 domains and promote apoptosis by forming pores in mitochondrial outer membranes. Members of the BH3-only subfamily form a structurally diverse group of proteins that only display homology within the small BH3 motif. The mammalian BH3-only protein family currently includes eight members (Bid, Bad, BmF, Bim, Hrk, Bik/Nbk, Noxa, PUMA), all of which promote apoptosis when over expressed. These proteins share little sequence homology apart from the BH3 motif, and are regulated in distinct ways. Noxa, PUMA and, to a lesser extent, Bid are transcriptionally upregulated by p53. DNA damage therefore results in the increased synthesis of these BH3-only proteins in a p53-dependent manner. Bid is activated through proteolysis by caspase-8. Bad is inactivated through growth-factor-receptor signals that result in phosphorylation of this BH3-only protein at several sites, leading to sequestration by 14-3-3 proteins. Bim is tethered to microtubules and Bmf is tethered to actin microfilaments, possibly through interactions with dynein light chain-1 and dynein light chain-2, respectively, although this remains to be conclusively demonstrated. Disruption of the cytoskeleton can liberate these proteins to promote apoptosis. Growth factors stimulate the ERK-dependent phosphorylation of Bim, and this results in proteasome-mediated degradation of this BH3-only protein. Conversely, growth factor withdrawal results in a decline in ERK signalling and elevated levels of Bim. Bcl-2 and its close relatives (Bcl-xL, MCL1, BCL2A1, Bcl-W and Bcl-B) have four Bcl-2 homology (BH) domains and all block apoptosis. Members of the anti-apoptotic group of Bcl-2 proteins inhibit apoptosis by preventing BH3-only protein-induced oligomerization of the proapoptotic Bcl-2-family members Bax and/or Bak in mitochondrial outer membranes, which would otherwise lead to the efflux of cytochrome c and other mitochondrial intermembrane space proteins. The antiapoptotic Bcl-2 proteins differentially bind to BH3-only proteins. Some BH3-only proteins, like Bid and Bim interact with essentially all anti-apoptotic Bcl-2 proteins, whereas others, like Noxa, interact only with certain Bcl-2-family members. (With permission, from the Annual Review of Biochemistry, Volume 69 © 2000 by Annual Reviews.)

functions of these downstream effectors will allow us to explain how particular cellular outcomes result from signalling through a limited number of receptors.

Experiments employing embryonic fibroblasts from caspase-deficient mice or using specific caspase inhibitors demonstrate that caspase-8 is essential for DR4-, DR5- and DR3-transduced apoptosis. However, it remains to be determined whether these receptors activate caspase-8 through FADD and/or TRADD or whether they utilize adaptors that are unknown. These receptors also have the ability to compete for the binding of death ligands to block apoptosis triggered by DR. Preassembly or self-association of DR through a distinct functional domain in the extracellular domain of the DR, termed the preligand assembly domain (PLAD), is critical for ligand binding. The activation of a conformational change or the formation of higher-order receptor complexes to acquire signal competence is achieved upon ligand binding to the preformed TNFR complex. Formation of a DISC that recruits the corresponding adaptors through the DD results from ligation of DR with ligands. Once the DISC is fully assembled and activated (death receptors and adaptors), effector molecules such as procaspase-8 bind to it and induce the activation of the downstream apoptotic signalling pathway. The aggregation of the receptors is also followed by internalization or endocytosis into an endosomal pathway. Inhibition of this internalization either chemically or by mutation may abrogate the biological response.

TNFR2, CD30, CD40, lymphotoxin receptor, the osteoprotegerin ligand (OPGL), receptor activator of

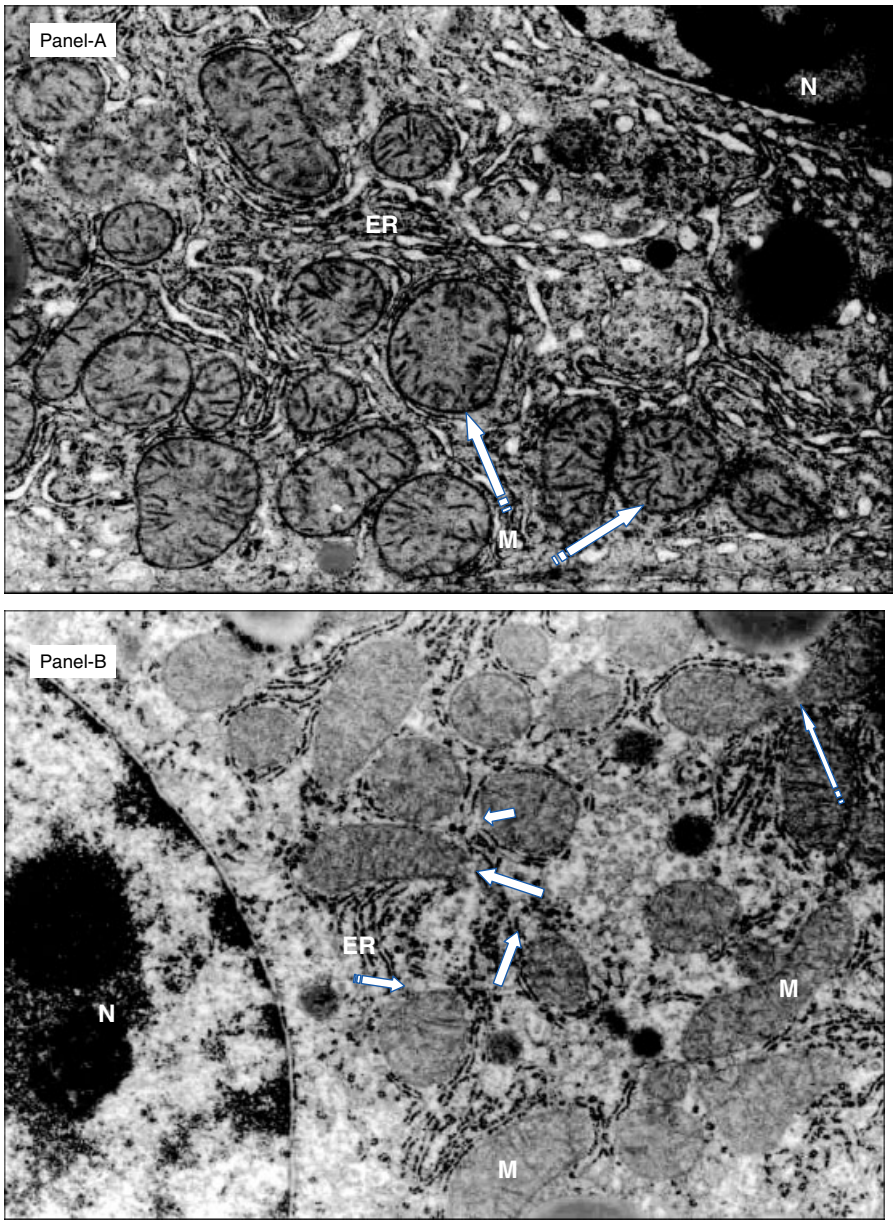

Figure 9 Dimethylnitrosamine-induced mitochondrial changes. Electron photomicrographs of mouse liver show ultrastructural details of mitochondria over time from animals treated with 100 mg kg^{-1} dimethylnitrosamine i.p. (A) shows the presence of abundant mitochondria of different shapes and sizes in a normal control animal. See intact outer peripheries of mitochondrial membranes (arrows) and prominent inner folds. (B) shows mitochondrial membrane alterations in liver after dimethylnitrosamine. This section shows the presence of abundant mitochondria of different shapes and sizes. However, the outer mitochondrial membranes are no longer intact (arrows) in several mitochondria while inner folds remain prominent. These changes in outer mitochondrial membranes accompany cytochrome c release via mitochondrial transition pores (arrows). Scale: 1 μm = 28 mm at ×28 000. Legend: M—mitochondria; N—nucleus; ER—endoplasmic reticulum. (Reproduced with permission from SD Ray, Long Island University.)

NFκB (RANK) and B-lymphocyte activating factor (BAFF) receptors constitute a second class of receptors in the TNFR superfamily. Interestingly, DDs are missing from the cytoplasmic tails of these receptors. These receptors have sequences which allow them to interact with a special set of intracellular adaptors called TNF receptor-associated factors. Cytoplasmic tails of the second class of receptors bind to only five members (TRAF1, TRAF2, TRAF3, TRAF5 and TRAF6) out of the six TRAF proteins (TRAF1–TRAF6) identified to date. Transgenic mouse models that lack expression of TNFR1 demonstrate that this receptor is involved in signalling leading to inflammation and cell survival. Ironically, however, TNFR1$^{-/-}$ mutants display impaired apoptosis. In response to a single ligand, TNF, TNFR1 mediates not only survival and inflammatory

signalling, but also apoptotic signalling, whereas, in response to TNF binding, survival and inflammation signals are primarily transduced by TNFR2. The Fas (CD95) receptor, which was originally discovered as the product of the mutated gene in MRL (Murphy Roths large)/lpr (lymphoproliferation) mice, mediates mainly signals for apoptosis in response to the binding of its ligand FasL. Fas- or FasL-deficient mice show massive lymphoadenopathy and deregulated lymphocyte homeostasis due to a lack of apoptotic death (Strasser *et al.*, 2000; Mak and Yeh, 2002; Jin and El-Diery, 2005; Elmore, 2007; Schütze *et al.*, 2008).

A relatively new TNF family member, BAFF (also called BlyS, TALL-1 or zTNF4), has recently drawn some attention due to its ability to facilitate B-cell survival. Mature B-cell hyperplasia coupled with systemic lupus erythematosus-like symptoms are associated with mice overexpressing BAFF. In contrast, a complete loss of follicular and marginal-zone B lymphocytes is observed in BAFF-deficient mice. Moreover, mice lacking BAFF exhibit deregulated T-cell-dependent and T-cell-independent antibody response. B-cell maturation antigen (BCMA), transmembrane activator and calcium modulator, cyclophilin ligand interactor (TACI) and BAFF-R are accessible to BAFF for binding. Binding to BAFF can instigate diverse signalling pathways, including the activation of caspases, the translocation of NFκB, or the activation of mitogen-activated kinases such as JNK or extracellular signal regulatory kinase (ERK). BAFF and APRIL [a proliferation-inducing ligand or TRDL 1α (TNF-related death ligand 1α)] were recently found to be trophic factors in lymphocyte malignancies and immune-related disorders. They have been identified in bronchial tissue, and a number of immune-related and immune-independent tissues (spleen, liver, lung, heart, intestine, kidney and thymus) which makes them toxicologically important.

Moment-to-moment differences in the balance between cytotoxic and cytoprotective factors and a gross imbalance between oxidants and antioxidants can dictate the severity of toxicant-induced organ injury. This general framework has been used to develop investigational models that can be studied to characterize molecular targets for future therapeutic interventions. At least in this field, several investigators have identified TNF as a critical mediator of toxicant-mediated organ injury, particularly in the liver. Hepatotoxins including tetrachloromethane (CCl_4), dimethylnitrosamine (DMN), D-galactosamine, ethanol, fumonisin B1, lipopolysaccharide, methotrexate, several peroxisome proliferators (clofibric acid, bezafibrate, ciprofibrate and nafenopin) and the plasticizer di-(2-ethylhexyl)phthalate influence liver cell death via modulation of TNFα. Similarly, TNF has also been shown to play an important role in apoptosis of both chronic and acute human neurodegenerative diseases, antineoplastic drug doxorubicin-induced cardiomyopathy, arsenic-induced immunotoxicity and oxygen-induced pulmonary toxicity. The apoptosis-enhancing effect of Fas-FasL has been reported in liver injury caused by acetaminophen (paracetamol) (Tagami *et al.*, 2003a), CCl_4 (Jameel *et al.*, 2009), ethanol (Tagami *et al.*, 2003b), bleomycin-induced dermal sclerosis (Yammamoto *et al.*, 2007), 5-fluorouracil-induced breast cancer cell death (Chhipa and Bhat, 2007), cadmium-induced podocyte apoptosis (Eichler *et al.*, 2006), valproic acid-induced prostate cancer cell death (Angelucci *et al.*, 2006) and nephrotoxicity induced by cyclosporine A, cisplatin and gentamicin (see reviews by Rezzani *et al.*, 2008; Servais *et al.*, 2008).

6.2 DISC (Death Inducing Signalling Complex)

Initiation of apoptotic death can be either receptor-mediated (e.g. Fas/CD95) or nonreceptor chemically mediated (stress-induced). Usually when Fas mediates cell death, a multiprotein complex DISC is assembled internal to the plasma membrane, which activates downstream caspases, setting the stage for the cell suicide process. The DISC was first described in the FasL-Fas apoptotic signalling pathway. Binding to Fas-L promotes receptor trimerization that in turn results in intracellular clustering of DDs followed by complex internalization via an endosomal pathway. This allows an adaptor protein called FADD to associate with the receptor through an interaction between homologous DDs on both molecules. FADD contains a death effector domain (DED) that allows binding of procaspase 8 to the CD95–FADD complex. Procaspase 8 (also known as FLICE) associates with FADD through its own DED. Caspase-8, the main initiator caspase in CD95 signalling, is expressed as two isoforms, caspase-8/a and -8/b. Both are recruited to the activated CD95 receptor. These molecules, FADD and caspase-8 are the key components of the CD95 DISC (**Figures 10** and **11**). FasL-induced clustering of Fas, FADD and caspase-8 within the DISC leads to autoproteolytic processing of caspase-8 by induced proximity and dimerization, followed by the release of the processed active proteases. Following the autoproteolytic cleavage of the enzyme, caspase-8 is released from the DISC as an active heterotetramer containing two p18 and two p10 subunits. Recently one study showed that all cleavage products of procaspase-8 actually remain bound to the DISC, including the p10 and p18 subunits of caspase-8. Studies in FADD and caspase-8 deficient mice indicated that both are required for FAS-mediated apoptosis.

Cells can be divided into two types according to the requirements of their mitochondrial pathway in FAS-induced apoptosis. In *type I* cells, processed caspase-8 is sufficient to activate directly other members of the caspase family, whose action on defined substrates leads

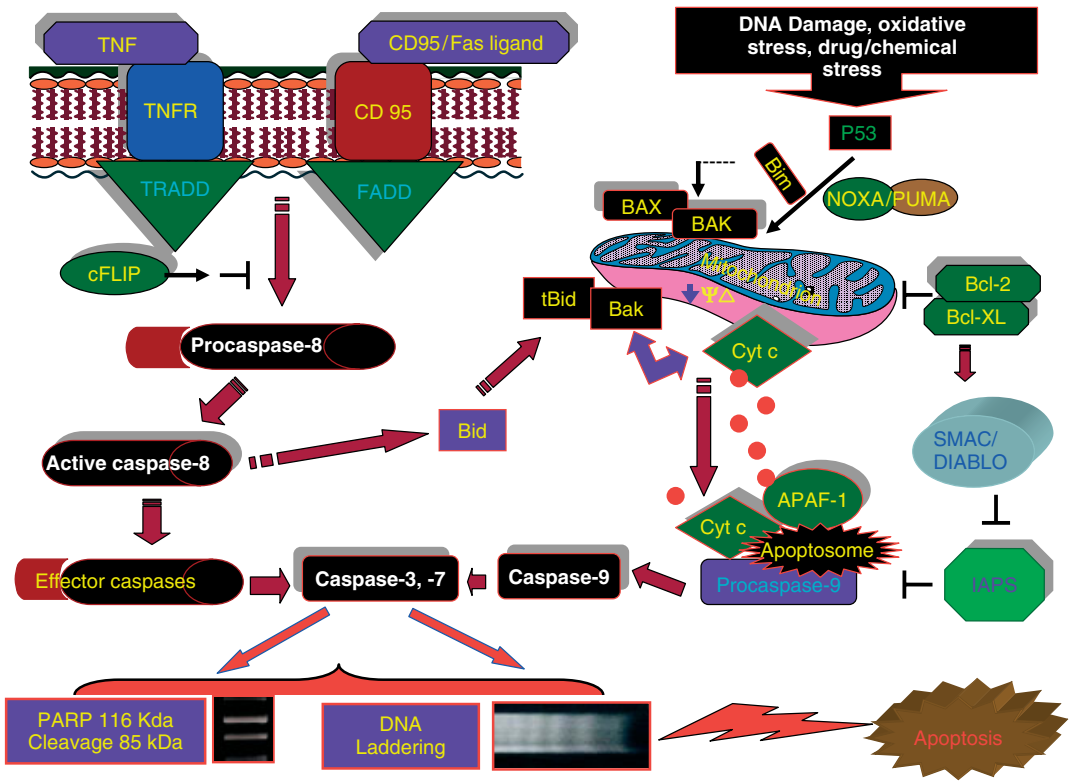

Figure 10 Pathways of apoptosis. The extracellular binding of ligands such as TNF-α or Fas-L to their respective death receptors initiates the extrinsic signalling cascades of apoptosis. Ligands bind to activate their receptors by inducing receptor trimerization. Once stimulated, the intracellular binding domains of these receptors containing death effector domain (DED) motifs initiate the assembly of the death-inducing signalling complex (DISC) and the recruitment and assembly of initiator caspase-8 and -10. Once activated DED-containing proteins TRADD and FADD have recruited procaspase-8 and -10 to the receptor complex, the latter undergo autocatalytic activation involving cleavage at specific sites. Activated caspase-8 activates caspase-3 via two mechanisms. In the first mechanism, caspases-8 cleaves Bid to tBid which translocates to mitochondria where it triggers cytochrome c release. t-Bid mediates the assembly of proapoptotic Bcl-2 family members like Bax and Bak into hetero-oligomeric complexes that form pores in the outer membrane of the mitochondria, resulting in the release of apoptosis-regulating factors such as cytochrome c. Bax and Bim can translocate to mitochondria in response to death stimuli, including survival factor withdrawal. These events are triggered following DNA damage, where p53 induces the transcription of Bax, Noxa and PUMA. Pro-caspase-9, APAF1 and cytochrome c form the apoptosome complex, which induces activation of caspase-9 and -3, and begins the cell demise process. The release of cytochrome c can be inhibited by Bcl-2 and related antiapoptotic proteins. Bcl-2 is regulated by binding to Bad, and for Bcl-2 to exert its antiapoptotic activity, the Bcl-2/Bad complex must be broken down by phosphorylation of Bad by Akt. The intrinsic (mitochondrial) and extrinsic (death-receptor) pathways converge at the level of caspase-3 activation. Its activation and activity are antagonized by IAP proteins, which themselves are antagonized by Smac/DIABLO protein released from mitochondria. In the second mechanism, activated caspase-8 directly cleaves and activates procaspase-3. Active caspase-3 cleaves DFF-45 in the heterodimer DFF40/DFF45. Cleaved DFF45 dissociates from DFF40, inducing oligomerization of DFF40 that has high DNase activity. The active DFF40 oligomer causes internucleosomal DNA fragmentation and the DNA ladder, considered hallmarks of apoptosis. This sequence is the same as proposed for CAD-ICAD cleavage, dissociation and orderly DNA fragmentation. Caspases cleave nuclear lamins, causing the nucleus to break down and lose normal structure. Fas-induced apoptosis can be effectively blocked at several stages by FLICE-inhibitory protein (FLIP), by Bcl-2, or by the cytokine response modifier A (CrmA). (Reproduced with permission from Jin and El-Diery, 2005. © Landes Bioscience.)

to the execution phase of apoptosis. In *type II* cells, efficient activation of effector caspases by Fas depends on an amplification loop that relies on caspase-8-mediated cleavage of Bid and subsequent release of mitochondrial proapoptotic factors such as second mitochondria-derived activator of caspase (SMAC)/direct inhibitors of apoptosis protein binding protein with low pI (Diablo) or cyt-c to drive the formation of the caspase-9-activating apoptosome. Active caspase-9 activates the executioner caspase-3, which in turn activates caspase-8, thereby completing a positive feedback loop. Another DED-containing protein caspase-10 has also been shown to be recruited to the DISC (**Figures 6** and **11**). Although *in vitro* studies show that caspase-10 shares similar

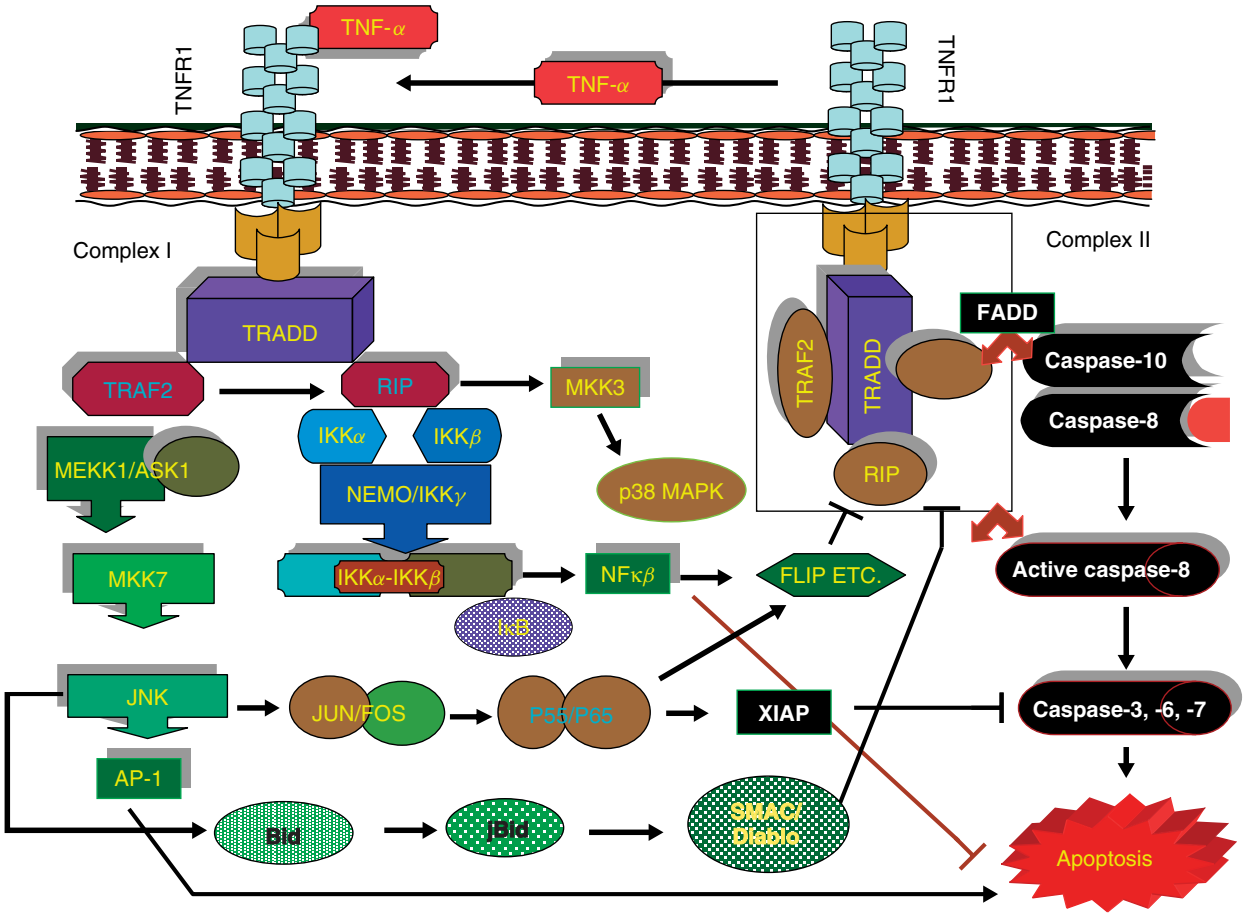

Figure 11 Cross-talk between multiple pro-survival and pro-death signaling pathways. Recent studies have demonstrated that TNFR1-induced apoptosis involves 2 sequential signaling complexes. Complex I, the initial plasma membrane-bound complex, consist of TNFR1, the adaptor TRADD, the kinase RIP1, and TRAF2 and rapidly signals activation of NFκB or JNK. In a second step, TRADD and RIP1 associate with FADD along with caspase-8, forming a cytoplasmic complex, complex II. When NFκB is activated by complex I, complex II harbors the caspase-8 inhibitor FLIP-L and the cell survives. Otherwise, cells undergo apoptosis through a complex II-mediated signaling pathway. Thus, TNFR1-mediated signal transduction includes a checkpoint, resulting in cell death (via complex II) in instances where the initial signal (via complex I and NFκB) fails to be activated. A large intracellular signaling complex forms after binding of TNF-α to its receptor and trimerization. The intracellular domain associates with the IKK complex, of which IKKα and IKKβ are essential components. NIK phosphorylates and activates these kinases, allowing them to dissociate and cause phosphorylation of IκB, the inhibitor of NFκB. The phosphorylated inhibitor can be ubiquinated, and can undergo proteolysis. Liberated NFκB translocates to the nucleus and activates gene transcription. NFκB plays an important role in TNF-α mediated expression of adhesion molecules, enzymes, cytokines and chemokines in endothelial cells. When sufficient copies of the inhibitory factor IκB are made, NFκB is sequestered in the cytoplasm using p55/p65 proteins. This process regulates inflammation. This figure depicts additional pathways such as: (i) MEKK1/ASK1, JNK, AP1 route, (ii) TRADD, RIP, IKK?/IKK?, NFκB and FLIP route, (iii) TRAF2, RIP, MKK3, p38/MAPK route, (iv) TRAF2, FADD, caspase-10, -8, and caspase-3, -6, -7 route, and (v) TRAF2, MKK7-JNK, JUN/FOS, p55/p65, XIAP, either caspase 3, -6, -7 and/or FLIP route and their impact on cell surviva/death. For example, TNFα-mediated caspase-8 cleavage and apoptosis require the sequential activation of a cascade involving JNK, Bid, and Smac/DIABLO. Typically JNK activation, which induces caspase 8-independent cleavage of Bid at a distinct site to generate the jBid, can favor apoptosis by triggering the release of Smac/DIABLO into the cytosol, inhibiting the TRAF2-IAP1 complex and consequently activating caspase-8. Translocation of jBid to mitochondria leads to preferential release of Smac/DIABLO, but not cyt-c. Released Smac/DIABLO disrupts the TRAF2-cIAP1 complex. It has been proposed that inhibition imposed by TRAF2-cIAP1 on caspase-8 activation must be relieved for the JNK pathway to induce apoptosis. Additionally, RIP (receptor-interacting protein) can also cause receptor stimulation of the inhibitor of the IKK cascade, NFκB. A third complex involves TNFR-associated factor 2 (TRAF2), which couples receptor engagement to the JNK cascade, stimulating transcription factor AP-1. Death receptor DR3, which was identified by virtue of its homology to TNFR1, assembles signaling complexes that are similar to those of TNFR1. See genetic regulation of apoptosis section for further details. (Adapted with permission from Jin and El-Deiry, Cancer Biol. Int., 2005, © Landes BioScience.)

features with caspase-8 in many aspects, findings *in vivo* demonstrated that it cannot substitute for caspase-8 in the DISC to trigger apoptosis. The reason why caspase-10 is associated with the DISC while not being essential for cell death signalling remains unclear.

6.3 Apaf-1 and the Apoptosome

Apaf-1, the central component of the apoptosome, consists of three different domains: (i) the N-terminal protein interaction domain known as the caspase activation and recruitment domain (CARD), which can bind via a homophilic interaction to the CARD of procaspase-9; (ii) a nucleotide-binding domain that shares homology with the *C. elegans* homologue CED-4 and (iii) a C-terminal regulatory domain containing multiple repeats of tryptophan and aspartate residues. The CARD is responsible for interactions with the prodomain of caspase-9. This interaction is essential to the recruitment and activation of procaspase-9. The CARD and the nucleotide-binding domains are responsible for oligomerization of Apaf-1 in the presence of cyt-c and deoxyadenosine triphosphate (dATP). WD40 repeats are thought to interact with cyt-c, as removal of this domain in Apaf-1 results in constitutive binding and activation of caspase-9. Apaf-1 exists in an inactive conformation in cells and is activated through binding to cyt-c and dATP. Structural analysis suggests that binding of nucleotides may induce significant conformational changes in Apaf-1 and that these conformational changes may drive the formation of the caspase-9-activating apoptosome.

Assembly of activated Apaf-1 into an apoptosome is complex. The structure of the apoptosome, determined by cryoelectron microscopy, reveals a wheel-shaped complex with sevenfold symmetry. The CARD and the expanded nucleotide-binding domain of Apaf-1 are located at the central hub, whereas the WD40 repeats constitute the extended spokes. Importantly, the form of this complex confirms the structural involvement of cyt-c in the formation of the apoptosome. Docking of caspase-9 to the apoptosome results in a dome-shaped structure. However, the structure of the bulk of caspase-9 remains only partly identified. The complex structure of the apoptosome is a limitation for accurate identification of domain boundaries and interfaces. Therefore, the molecular underpinnings of caspase-9 activation remain unclear. Caspase-9 plays a role in brain development and its deficiency results in embryonic lethality coupled with brain malformation. The rate of apoptosis declines in neuronal tissues derived from such mutant embryos. Caspase-$9^{-/-}$ cell types show that, like caspase-3, caspase-9 is not required in all cell types for all apoptotic events. Caspase-9 is necessary for the apoptotic death of embryonic stem cells and of thymocytes exposed to dexamethasone or γ-irradiation. However, caspase-$9^{-/-}$ thymocytes readily undergo apoptosis in response to UV irradiation or engagement of FAS (**Figures 6–11**).

6.4 *Bcl*-2: The Monarch of Cell Survival Genes

The three phases of cell death—induction, initiation and execution—characterize the progression of apoptosis. The induction phase corresponds to the initiation of the apoptotic signal, which has a specific goal. The stimuli may be composed of combinations of altered physiological signals, chemical or physical damage, or lack of survival signals. Cell death signals are predominantly transmitted via two major biochemical routes in mammalian cells: the *intrinsic* pathway and the *extrinsic* pathway (**Figures 5** and **11**; see review by Orrenius *et al.*, 2007).

The intrinsic pathway normally responds to proapoptotic signals, such as the interplay between *Bcl*-2 family members that share the BH3 domain (primarily *Bcl*-2 and *Bax*) and relies heavily on mitochondrial events. *Bcl*-2 and its family members have emerged as central regulators of the mitochondrial pathway of apoptosis (**Figure 8**). These proteins manipulate mitochondrial functions and carefully orchestrate events either to initiate the death pathway and release proapoptotic factors such as cyt-c, endonuclease-G and AIF, or to forestall the onset of the death pathway. The release of cyt-c leads to Apaf-1-mediated activation of initiator caspase-9, which in turn activates effector caspases. The *extrinsic* pathway, in contrast, is triggered by the ligation of DR belonging to the TNF-receptor superfamily. Stimulation of the Fas/TNFR receptor family by a toxicant can trigger a canonical extrinsic apoptosis pathway. Several genes and gene products participating in this process are listed in **Table 5**, **Figures 5** and **8**.

The maintenance of normal cell number in tissues (homeostasis) requires a delicate balance between the rate of cell division and the rate of cell death. When this balance favours the direction of increase in the rate of proliferation, a decrease in the rate of cell death, or both, it leads to benign or malignant tumours. Oncogenes positively influence cell proliferation and growth, whereas tumour suppressor genes (antioncogenes) act as negative regulators of growth. Since apoptosis essentially counterbalances cell proliferation, genes involved in apoptosis are essential to regulating growth. Based on this assumption, cell death research has primarily focussed upon death regulation and survival genes. Death genes maneuver the intracellular microenvironment via one-way traffic to set up execution by transducing signals, triggering other molecules and/or driving the cell cycle to a required point for exit, following the death pathway. Once apoptosis is initiated in a productive context, it

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015

proceeds via the action of gene products that are common to all types of cell death. This notion is further substantiated by the fact that once apoptosis is turned on, it typically can be delayed, but cannot be stopped.

In this arena, the first anti-apoptotic gene to be clearly identified in humans was Bcl-2 (B-cell lymphoma-leukaemia-2 gene), cloned from the breakpoint of the t(14 : 18) translocation found in the majority of follicular lymphomas. The discovery of the Bcl-2 oncogene helped to stimulate recognition of the concept that gene products that modulate the susceptibility of certain cell types to apoptosis may play an important role in the process leading to malignant transformation. This is primarily due to the survival of cells in inappropriate physiological situations. In both pathological and physiological conditions, the *Bcl*-2 gene product has emerged as a critical regulator of apoptosis. Although *Bcl*-2 is a proto-oncogene, the mechanism by which the Bcl-2 protein promotes tumour growth is very different to other oncogenes. Since *Bcl*-2 has the unique ability to rescue cells that are destined to die without affecting the rate of proliferation, it is possible that its location may be a key feature of its function. *Bcl*-2 is involved in maintaining homeostasis, including the MMP and balance of the interactions among the members of the Bcl-2 protein family [Bad, Bax, Bcl-2-interacting mediator of cell death (Bim)]. In addition, Bcl-2 has a role in the regulation of calcium homeostasis in the cell. The *intrinsic* pathway is highly sensitive to the ratio of anti- to proapoptotic factors and it serves as a rheostat that sets the threshold of susceptibility to apoptotic death. Bcl-2-deficient transgenic mice are normal at birth, but later develop to polycystic kidney disease and catastrophic postnatal immune function failure. *In vivo*, Bcl-2 prevents many forms of apoptotic death. Cumulatively, all these observations suggest an important role for Bcl-2 *in vivo*. Expression of the Bcl-2 protein has been shown to prevent apoptosis by directly enhancing cellular antioxidant capacity, possibly through directly scavenging reactive oxygen radicals, or indirectly by counteracting oxidative stress. The other potential mechanisms of action of this gene product include a role in intracellular calcium regulation, and nuclear transport and control of signal transduction pathways.

Numerous proteins with structural similarity to Bcl-2, the prototypical inhibitor of apoptosis, have been discovered in the past decade (**Figure 8**). Included in this family are Bcl-xL (long form of spliced product of *Bcl*-x), Bcl-w, A1/Bfl-1, Mcl-1, Boo/Diva, *C. elegans* Ced-9 and a number of viral homologues. These members have three or four regions with wide-ranging sequence homology (Bcl-2 homology regions BH1–BH4). Mcl-1 was cloned during a screen for genes with increased expression when a human myeloblastic leukaemia cell line was induced to differentiate by phorbol ester. It is considerably larger than Bcl-2, it is primarily membrane bound and its expression delays apoptosis induced by deregulated c-myc. Another relative of Bcl-2, A1, which was isolated from mouse bone marrow induced to proliferate with granulocyte macrophage colony-stimulating factor (GM-CSF), resembles an early response gene and is transcriptionally induced by GM-CSF. Distant relatives of the same family which favour apoptotic death are mammalian Bax, Bcl-xS (short form of spliced product of it Bcl-x), Bak and Bok/Mtd (contain 2 or 3 BH regions). A most compelling proapoptotic group of proteins, which share only a BH3 region, consists of mammalian Bad, Bik/Nbk, Bid, Hrk/DP5, Bim/Bod and Blk and *C. elegans* Egl-1.

Interestingly, proapoptotic and antiapoptotic members of the Bcl-2 protein family exhibit physical interaction, and several members of the Bcl-2 family have a conserved C-terminal transmembrane region. This region localizes proteins to the outer leaflet of the nuclear envelope, the outer mitochondrial membrane and the endoplasmic reticulum (ER). Mounting evidence suggests that the bulk of the Bcl-2 protein is on the cytosolic face of these membranes. Similar subcellular localization has been reported for Bcl-xL, A1, Mcl-1, Bax and Bak. Subcellular localization for some family members appears to be permanent, but others can change their subcellular localization. It has been reported that Bax is a cytosolic protein until the cell is directed to undergo apoptosis, when it becomes redistributed to mitochondrial membranes. It is possible that such subcellular redistribution affords a mechanism of regulating the activity of Bcl-2 family members. The limited common features of the proapoptotic members of the Bcl-2 family (all they share is a 16-amino-acid BH3 domain) may mean that each has some specific activity, such as interaction with specific upstream signalling molecules, and that their common function is to bind and antagonize the anti-apoptotic effects of their ligands. The current consensus view is that the biochemical effects of the Bcl-2 family on apoptosis are mediated through the anti-apoptotic members. Studies with transgenic mice have shown that Bcl-2-inhibitable pathways can also be blocked by Bcl-xL, Bcl-w, A1 and Mcl-1, and Bcl-2-insensitive death inducers fail to activate death by its homologues. Bcl-2/Bcl-xL expression can be regulated by cytokines, colony-stimulating factors and mitogens, whereas the activities of different proapoptotic Bcl-2 family members are regulated by distinct posttranslational modifications.

Although the precise mechanisms of how the Bcl-2 family proteins govern apoptosis remains to be fully elucidated, at least three different models of regulation have been proposed. In the first model, the proapoptotic Bax and Bak are maintained in an inactive conformation through direct interactions with one or two different antiapoptotic Bcl-2 proteins. In response to an apoptotic stimulus, BH3-only proteins bind to and neutralize the antiapoptotic Bcl-2 proteins, thereby releasing Bax and Bak. Overexpression of Bcl-2 or Bcl-xL has been reported to prevent Bax translocation and activation, and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Bak has been demonstrated to be sequestered by Bcl-xL and Mcl-1 in the mitochondria under normal conditions. In addition, certain BH3-only proteins display selective binding to specific antiapoptotic Bcl-2 family members. For instance, Bad interacts with Bcl-2 and Bcl-xL, but not with Mcl-1, whereas Noxa binds to Mcl-1, but not to Bcl-2 or Bcl-xL. Together, these observations may suggest that death-stimulus-dependent activation of more than one BH3-only protein may be required to release a proapoptotic protein to initiate apoptosis, allowing for fine regulation of apoptosis. Similarly, Bid is a proapoptotic Bcl-2 family member that is cleaved and activated by caspase-8 in response to DR signalling in a seemingly unique manner. One mechanism proposes that granzyme B enters the cytosolic compartment of the target cell by a poorly understood mechanism involving perforin, a pore-forming protein. Two early targets of granzyme B are Bid and procaspase-3, forming active caspase-3 and tBid. tBid modulates the organization of the outer mitochondrial membrane inducing formation of MPT pores and releasing the proapoptotic factors cyt-c, HtrA2/OMI (which blocks inhibitors of apoptosis) and endonuclease-G (a putative enzyme producing DNA damage) which together lead to apoptotic changes. Although the role of cyt-c was once considered limited to the electron transport chain and ATP production in mitochondria, its powerful role in apoptosis has been recognized in the last decade of the twentieth century.

A second model may involve tBid-mediated insertion and oligomerization of proapoptotic Bax into the outer mitochondrial membrane. Together, these events create a positive environment for pore formation that allows the release of cyt-c into the cytosol. Further, tBid can directly induce oligomerization of membrane-associated Bak leading to pore formation, and it has the ability to interact with cardiolipin to influence its distribution between the mitochondrial membranes or induce changes in the mitochondrial ultrastructure. cyt-c is normally bound to the inner mitochondrial membrane by cardiolipin and facilitates electron transport from Complex III to Complex IV. During apoptosis, cyt-c detaches from cardiolipin and appears as a soluble protein in the intermembrane space. Detachment of cyt-c from cardiolipin can be mediated either by direct formation of oxidized cardiolipin (CL-OOH) induced by the cyt-c-cardiolipin peroxidase, or through oxidative modification of cardiolipin by ROS originating from the respiratory chain or by phospholipase-A2-mediated formation of lysocardiolipin. Bim is another proapoptotic Bcl-2 family member that is not involved in the DR pathway, but is critical for thymocyte negative selection. Bim is also known to mediate mitochondria-regulated particulate matter-induced apoptosis in alveolar epithelial cells. Bim was isolated independently by two groups that exploited its ability to bind Bcl-2 or Mcl1 (myeloid cell leukemia-1). Apoptotic-signal-initiated induction of Bim can cause mitochondriacentric apoptosis. Alternative splicing of *Bim* yields three BH3-containing prodeath variants including BimEL and BimL. Bim-deficient lymphocytes accumulate in peripheral blood and in the spleen, and these cells are resistant to apoptotic stimuli, such as cytokine deprivation and microtubule perturbation.

Bad is a member of the BH3-only subfamily of Bcl-2 apoptosis-regulating proteins, regulated extensively by phosphorylation of serine residues and sequestration by 14-3-3 proteins. Growth factor or cytokine deprivation results in the inactivation of AKT, which induces the dephosphorylation and activation of Bad. The 14-3-3 proteins constitute a family of chaperones that are particularly abundant in the brain, like -synuclein. The 14-3-3 protein family consists of seven known mammalian isoforms. It exhibits a remarkable degree of sequence conservation, among both species and isoforms. 14-3-3 binds to many different proteins, most of which contain phosphorylated serine residues. An emerging role for 14-3-3 proteins as effectors in prosurvival signalling has captured the attention of several investigators. Binding of 14-3-3 to phosphorylated Bad (S112 and S136) appears to stabilize Bad maintenance in the cytoplasm. At least three sites on Bad can be phosphorylated *in vivo*, including S112, S136 and S155 of the murine protein. Dephosphorylated Bad is localized to the mitochondria along with Bcl-2 and Bcl-xL, where it can induce apoptosis. Mutation of any of the phosphorylation sites enhances the cell-killing ability of Bad, suggesting that Bad phosphorylation is a critical mechanism for inhibiting its activity (Hengartner, 2000; Strasser *et al.*, 2000; Zhang *et al.*, 2004–2005; Jin and El-Diery, 2005; Chen *et al.*, 2006; Youle and Strasser, 2008).

6.5 ER Stress

Because the ER is a primary site for the metabolism of drugs and toxicants, this compartment plays a major role in regulating mechanisms of cell injury and cell death. From a toxicology perspective, sizeable amounts of free radicals and biological intermediates are produced in the ER during xenobiotic biotransformation, making this site a decisive factor in the *intrinsic* pathway of apoptotic cell death. Crosstalk between ER and mitochondria catalyse numerous prodeath and antideath signals (**Figure 11**). A primary responsibility of the ER is to authenticate and allow only properly folded proteins to pass along the secretory pathway. Major forms of stress to the ER, including oxidative and reductive stress, chemical toxicity, exposure to agents regulating intracellular/extracellular Ca^{2+}-concentration, such as Ca^{2+} channel blockers and Ca^{2+} ionophores, and exposure to inhibitors of glycosylation can result in deregulated calcium homeostasis and lead to the unfolded protein response. This protein-related event is further promoted

when stress impairs the synthesis of proteins that specifically prevent further aggregation and accumulation of unfolded proteins, that induce ER-resident chaperones coupled with folding catalysts and that activate ER-associated protein degradation to remove aggregates. The continuation of such responses in the face of the ongoing stress load leads to necrosis, apoptosis, or both kinds of cell death.

Many forms of apoptosis, including those involving the ER rely on Ca^{2+}. The futile cycling of Ca^{2+} across the ER, cytosol and mitochondria during toxic redox reactions is not uncommon and creates ER stress that is unfavourable to the cell. For example, staurosporine- and ceramide-induced apoptosis employ calcium as a messenger that coordinates the amplification loop between the mitochondria and the ER. Minute amounts of released cyt-c diffuse to the adjacent ER and bind to InsP3 receptors, thereby enhancing Ca^{2+} release from the ER. Elevated levels of intracellular Ca^{2+} go on to evoke mass release of cyt-c from neighbouring mitochondria. This amplifying interplay between Ca^{2+} and cyt-c results in a dramatic activation of caspases and, in many instances, involves Bcl-2 family members including Bax or Bak. To date, only caspase-12 activation has been directly linked to Bax- or Bak-induced ER stress. The translocation of activated caspase-12 from the ER to the cytosol leads to cleavage of procaspase-9, followed by caspase-3 ultimately driving events to apoptotic death. Interestingly, caspase-12 has only been cloned from two rodent species, (mouse and rat) and several investigators continue to search for a human homologue of caspase-12. Although mice that are deficient in caspase-12 are resistant to ER stress-induced apoptosis, their cells undergo apoptosis in response to other death stimuli. Furthermore, caspase-12-deficient cortical neurons are defective in apoptosis induced by β-amyloid protein, but not by staurosporine exposure or trophic factor deprivation. Caspase-12 mediates an ER-specific apoptosis pathway and may contribute to β-amyloid neurotoxicity. Other signalling molecules, such as GADD153/CHOP, ALG-2, VCP and BAP31, may also be involved during ER stress-induced apoptosis (Rizzuto *et al.*, 2003; Liu and Baliga, 2005; Jin and El-Diery, 2005; Elmore, 2007; Schütze *et al.*, 2008).

Among various caspase-independent pathways of cell death, the granzyme A (GrA)-mediated pathway has captured considerable attention. Granzymes A, B, and 3 are members of distinct groups of serine proteases that work synergistically with perforin to induce apoptosis in target cells recognized by cytotoxic T lymphocytes and natural killer cells. Upon entry into the cell via a Ca^{2+}-dependent perforin-mediated pore, GrA triggers a caspase-independent pathway that forms single-stranded DNA nicks coupled with the appearance of apoptotic morphology. GrA-activated DNase (GAAD), which is also known as NM23-H1, is considered the prime candidate in the formation of these DNA strand-breaks. GrA triggers cell death with apoptotic features by targeting ER-associated SET complex containing the GAAD, NM23-H1, its inhibitor, the nucleosome assembly protein SET and Ape1 (apurinic endonuclease-1, also known as redox factor-1). This complex contains an inhibitor of protein phosphatase 2A (pp32), SET, HMG2, and Ape1. The SET complex presumably translocates to the nucleus in response to oxidative stress and GAAD to induce DNA strand breaks. GAAD activity is inhibited by its specific inhibitor IGAAD. In this pathway, GrA cleaves SET, HMG2, and Ape1, but not pp32, to release and activate GAAD (MacDonald *et al.*, 1999; Liu and Baliga, 2005; Li *et al.*, 2006; Elmore, 2007).

6.6 FADD, TRAF2 and RIP

It is now clear that different adaptor proteins appropriate for specific paths, upon receptor aggregation, proscribe whether TNFR1 mediates signals for apoptosis or cell survival. In fact, when TRADD binds to TNFR1, TRADD can then associate with either FADD or TRAF2 and with RIP. Therefore, recruitment of FADD to the TNFR1 complex would lead to apoptosis, whereas recruitment of TRAF2 and RIP would signal cell survival (**Figure 11**). This hypothesis was tested in genetically altered mice deficient in FADD or TRAF2 expression. FADD-deficient mice tend to die at day 11.5 of embryogenesis, indicating that FADD is essential for embryonic development. Subsequent studies in this direction revealed that FADD is expressed widely during embryogenesis, consistent with its role as being fundamental to the developmental processes. However, the precise role of FADD during embryonic development remains incompletely understood (Wang *et al.*, 1999; Strasser *et al.*, 2000; Zhang *et al.*, 2004–2005; Jin and El-Diery, 2005).

6.7 Mitogen-activated Protein 3 Kinases

During the induction of cell survival by TNFR1 engagement, a number of mitogen-activated protein 3 kinase (MAP3K) family members have been shown to associate with TRAF2 or RIP (**Figure 11**). NFκB inducing kinase (NIK) was initially proposed to be the downstream target of TRAF2 in mediating TNF-induced NFκB activation leading to survival. However, NIK-deficient mice show a specific defect in lymph node development and in lymphotoxin-β-receptor signalling, and cells lacking NIK respond normally to TNF in activating NFκB. Instead, the mitogen-activated protein extracellular signal regulated kinase kinase (MEKK-1) has been implicated in this NFκB activation pathway. In addition, MEKK-1 and apoptosis signal-regulating kinase 1 (ASK-1) are reported to mediate TRAF2-triggered JNK activation. From studies of knockout mice, however, it seems

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

that MEKK-1 is required for TNF-induced JNK activation only in embryonic stem cells and not in fibroblasts or T cells. Similarly, ASK-1 is not required for early phase TNF-induced JNK activation, and ASK-$1^{-/-}$ cells exhibit only a partial defect in sustained stress kinase activation. A new member of the MEKK family (MEKK-3) has recently been found to associate with RIP, meaning that it could play a role in downstream survival signalling (**Figure 11**). Indeed, disruption of MEKK-3 severely impairs the activation of NFκB induced by TNF, and MEKK-$3^{-/-}$ cells are highly sensitive to TNF-induced apoptosis (Jin and El-Diery, 2005; Takeda *et al.*, 2007).

6.8 NFκB and IKK

NFκB was discovered as a factor in the nucleus of B cells that binds to the enhancer of the κ light chain of immunoglobulin. Seven members have been reported in the IκB family—IκBα, IκBβ, Bcl-3, IκBε, IκBγ, and the precursor proteins p100 and p105—that bind the dimerization domain of NFκB dimers. Transcription factor NFκB is involved in cellular responses to endotoxin, inflammation and various environmental stresses. Among these, the IκB kinase (IKK) complex composed of the IKKα and IKKβ catalytic subunits and the IKKγ/NEMO (NFκB essential modulator) regulatory subunit is essential for activation of NFκB transcription factors. In the absence of environmental stress, resting NFκB is maintained in the cytoplasm through the interaction with inhibitory-κB (IκB) protein. TNFα is normally used to stimulate NFκB in various cells where NFκB is a key transcription factor whose activation promotes cell survival. The biological system in which NFκB plays the most important role is the immune system. In order to achieve NFκB activation, IκB must be removed via phosphorylation followed by ubiquitination and proteasomal degradation. Phosphorylation of IκB is mediated primarily by the IKK complex containing the proteins IKKα, IKKβ and NEMO (also known as IKKγ). IKKα and IKKβ are active kinases, while NEMO is a regulatory protein that binds tightly to both kinases. Upon optimal activation, IKK phosphorylates the IκB protein, leading to dissociation and subsequent translocation of NFκB into the nuclear compartment. Translocated NFκB binds to a κB binding site on the promoter regions and stimulates the transcription of genes responsible for expressing a variety of cytokines, chemokines, transcriptional factors and enzymes that produce secondary inflammatory mediators and adhesion molecules. The release of these cytoactive factors is cell and cellular-demand specific. In addition, NFκB activation is required for protection of cells from apoptosis, especially from that caused by members of the TNF family of death-inducing cytokines. The cytotoxic effect of TNF is only manifested when NFκB activation is blocked, either by inhibition of protein synthesis or overexpression of dominant negative mutant IκB. TNF-dependent liver failure is observed in mice deficient in either RelA (p65) or TNF-induced NFκB activation elements. The death-inducing potential of TNF is blocked or substantially limited with concomitant activation of NFκB.

Ironically, some proapoptotic DR (TRAIL-R, FAS) also have the ability to turn on the NFκB pathway. TRAF2 can recruit the IKK complex to the TNFR1 signalling complex, whereas RIP seems to stabilize the IKK complex. Mice lacking RelA (p65), a principal subunit of NFκB, die during embryogenesis due to massive hepatocellular apoptosis. In the classical NFκB signalling pathway, IKKβ is both necessary and sufficient for phosphorylation of IκB. The role of IKKα in the classical pathway is unclear, although recent studies suggest it may regulate gene expression in the nucleus by modifying the phosphorylation status of histones. The alternative pathway, however, depends only on the IKKα subunit, which functions by phosphorylating, and is activated in response to a subset of NFκB inducers including LTβ and BAFF.

Deficiency of IKKβ is embryonic lethal, with mice displaying a liver cell apoptosis phenotype similar to that of RelA knockout mice. In addition, the activation of NFκB by TNF or IL-1 is defective in IKK$\beta^{-/-}$ cells. Lethal irradiation of hosts with IKKβ-deficient foetal liver cells reveals a defect in T-lymphocyte survival. In contrast, IKKα-deficient mice do not exhibit a foetal liver defect like IKK$\beta^{-/-}$ mice. Instead, IKK$\alpha^{-/-}$ mice display abnormal limb and skeletal patterns and are defective in epidermal differentiation. Defective skin formation seems to be independent of NFκB activity and is due instead to failed secretion of a keratinocyte-differentiation-inducing factor. IKKα is not required for IKK or NFκB activation in response to inflammatory cytokines. Further studies have revealed that IKKα is required for B-cell maturation and secondary lymphoid organogenesis. NEMO (IKKβ and IKKγ/NFκB essential modulator)-deficient mice also display a phenotype of foetal liver cell apoptosis and embryolethality, consistent with an essential role for NEMO in the central pathway mediating NFκB activation. Like RelA$^{-/-}$ cells and IKK$\beta^{-/-}$ cells, NEMO$^{-/-}$ cells show an increased susceptibility to TNF-induced apoptosis. NEMO is an X-linked gene, and female NEMO$^{+/-}$ mice develop a self-limiting inflammatory skin disorder characterized by hyperkeratosis and increased apoptosis (**Figures 10** and **11**; Mak and Yeh, 2002; Hayden and Ghosh, 2004).

A typical PKC, ζPKC, has been implicated in TNF-induced NFκB activation via RIP and the adapter protein p62. ζPKC-depleted cells exhibit impaired cellular response to TNF that depends on NFκB transcriptional activity. However, ζPKC-deficient mouse embryonic fibroblasts show normal IKK activation and lower levels of TNF-dependent DNA binding to NFκB. Interestingly,

RelA (a p65 subunit of NFκB) phosphorylation is defective in ζPKC$^{-/-}$ cells, suggesting that an alternative pathway may orchestrate NFκB activation (**Figure 11**). While ζPKC$^{-/-}$ cells are hypersensitive to TNF-induced apoptosis, ζPKC$^{-/-}$ mice do not exhibit foetal liver apoptosis or embryonic lethality. In addition to ζPKC, a new family of proteins known as Pyrin proteins has been shown to associate with the IKK complex, affecting activation of NFκB. Pyrin proteins are derived from a new family of genes that accounts for several hereditary periodic fever syndromes (PFSs).

NFκB signalling is directly dependent upon the intracellular redox environment. The thiol reactive agents *N*-ethylmaleimide (NEM) and iodoacetic acid (IAA) inhibit NFκB binding to DNA, and this DNA binding can also be prevented by reducing agents, such as β-mercaptoethanol. The exact DNA binding locus of the p50 subunit includes cysteine residue Cys62, which is particularly redox sensitive. While ROS production appears to be necessary to initiate the events leading to the dissociation of the NFκB/I-κB complex and subsequent NFκB activity, excessive ROS production can oxidize Cys62 and inhibit NFκB binding to DNA. In some studies, it has been observed that translocation of constitutive NFκB into nuclei is considerably reduced, thereby interrupting the role of NFκB as an antiapoptotic factor when a reactive thiol, such as Cys179 of IKK undergoes modification by ROS, electrophiles or BRIs. For example, arsenite-mediated suppression of TNFα-induced NFκB activation is through its inhibitory action on IKK activity, and due to its covalent binding to Cys179 in the activation loop of IKK. Suppression of constitutive activation of NFκB during exposure of Hodgkin/Reed-Sternberg (HRS) cells to arsenite (iAsIII) contributes to the induction of apoptosis because constitutive NFκB activation is instrumental for cell proliferation, cell division and cell survival. This observation points to a therapeutic possibility that iAsIII-induced apoptosis in HRS cells via the inhibition of NFκB might be an effective means of treating Hodgkin's lymphoma. Likewise, substantial induction of apoptotic cell death can be achieved by inhibiting PI3K/Akt signalling by iAsIII. Some observations claim that iAsIII acts as an activator of NFκB through oxygen free radicals. This could be an early antiapoptotic response and this action of NFκB should not be ignored (Rahman and MacNee, 2000; Mak and Yeh, 2002).

TNF also has the ability to induce activation of the stress-activated protein kinase/c-Jun N-terminal kinase (SAPK/JNK) pathway (**Figure 11**). TNF-induced activation of the JNK pathway occurs through a TRADD-TRAF2 axis. TNF exposure to TRAF2 knockout mice impairs JNK activation. Analyses of MKK7- and MKK4-deficient mouse embryonic fibroblasts suggest that MKK7 is essentially involved in TNF-induced JNK-activation (**Figure 11**). JNK kinases, upon activation, translocate into the nucleus and enhance the activity of transcription factors including c-Jun and ATF2 by phosphorylating their amino-terminal activation domains. c-Jun belongs to a group of basic region-leucine zipper proteins (ZIPs) that dimerize to form transcription factors commonly designated as AP-1. The AP-1 proteins have an important role in a variety of cellular processes, including proliferation, differentiation and induction, as well as prevention of apoptosis. The AP-1 proteins very effectively interact with antioxidant response elements (ARE) (see more about ARE in Section 7.5). Unlike Fas and TRAIL signalling, TNF does not induce cell death spontaneously. Activation of NFκB by TNF mediates a strong prosurvival signalling pathway. The NFκB pathway targets several antiapoptotic factors, including c-FLICE (caspase-8) inhibitory protein (cFLIP), IEX-1L, Bfl-1/A1, X-linked inhibitors of apoptosis (XIAP), cellular inhibitors of apoptosis protein (cIAP)1, cIAP2 and Bcl-xL. Toxic effects of TNF are only manifested when NFκB activation is blocked, either by inhibition of protein synthesis or by overexpression of dominant negative mutant IkB (Nguyen *et al.*, 2003; see **Figures 10** and **11**).

Besides the above interactions, several studies now strongly attest to the fact that the prodeath potential of TNF is blunted if NFκB undergoes concomitant activation *in vivo*. Interestingly, receptors that show notable proapoptotic inclination (TRAIL and Fas) can also activate the NFκB pathway. Genetic evidence from knockout mice and mutated cell lines support the notion that all DR investigated to date require caspase-8 and the DD-containing adaptor protein FADD to induce cell death. Nevertheless, in contrast to Fas and TRAIL DR, TNFR1 is indirectly linked to FADD by TRADD, which is also responsible for bridging TNFR1 to TRAF2 and the IKK complex. These disparate TNFR1-mediated apoptotic responses have given rise to the proposal of two signalling complex cascades: (i) Complex I, the initial plasma membrane-bound complex consisting of TNFR1, the adaptor TRADD, the kinase RIP1 and TRAF2, has the ability to coordinate rapid signalling and activation of NFκB or JNK; (ii) Complex II, which assembles in the cytoplasm, involves coherent association of TRADD and RIP1 with FADD and caspase-8. In circumstances where NFκB is activated by Complex I, Complex II docks the caspase-8 inhibitor FLIP-L and the cell survives. Otherwise, the Complex II-mediated signalling pathway predominates and drives cells to undergo apoptosis. In this way, TNFR1-mediated signal transduction introduces a checkpoint, resulting in Complex II-mediated cell death in situations where the initial signal via Complex I and NFκB remains dormant or inactive for one reason or the other (**Figure 11**).

6.9 Apoptosis Execution Machinery: The Complex Interplay of Caspases

The dismantling of cellular structures during apoptosis requires extensive cooperation of proteases. An involvement of proteases in apoptosis was implicated with the discovery of Ced-3. ICE became the first homologue of the cysteine protease Ced-3 to be discovered in mammals. To date, at least 14 distinct mammalian caspases have been identified, with 11 coming from the human genome. Seven mammalian caspases, including four initiator and three effector caspases, are known to play important roles in apoptosis. All caspases are produced in cells as catalytically inactive zymogens. As a consequence of intrachain cleavage, the catalytic activity of effector caspases is enhanced by several orders of magnitude. In their zymogen forms, caspases typically undergo proteolytic cleavage at two Asp-X sites, producing an autocatalytic activation cycle. Activation of the caspase cascade is the commonest mode of initiating cell death involving the downstream effector arm (caspase-3, -6 and -7) and/or the upstream initiator arm (caspase-8 or caspase-9). Downstream partners are usually more abundant and active than members of the upstream group. These observations are overwhelmingly supported by the results of *in vitro* studies demonstrating that procaspase-3 and -7 can be activated by caspases-6, -8, -9 and -10.

Caspases are the central players in apoptosis. Two classes of caspases exist, including the **initiator** caspases, which begin the apoptotic cascade in response to extracellular signals transduced by cell surface receptors such as TNFR1, and the **effector** caspases, which serve as the executioner caspases. Functionally, however, caspases can be classified into a third group. Caspase-1, -4 and -5 and mouse caspase-11 and -12 are designated **inflammatory** caspases because they primarily function in the regulation of inflammatory processes. Caspases are directly implicated in several mechanisms that trigger inflammation, including caspase-1 during exposure to bacterial components and subsequent changes in the intracellular ionic environment, and activation of the inflammasome by ASC, Ipaf and the Nacht leucine-rich-repeat protein (NALP)s group (members of two subgroups of the NOD-LRR family). The inflammasome, which has been termed the linebacker of innate defense (Drenth and van der Meer, 2006) and bears strong similarity to the DISC and Apaf-1, has been considered vital for the onset of activation of inflammatory caspases. Caspase-2, -8, -9, and -10 belong to a functional group of long prodomain **initiator** caspases, whereas, caspase-3, -6, and -7, belong to a functional group of short prodomain **effector** enzymes. Various apoptotic signalling pathways activate initiator caspases when assisted by a series of polyprotein complexes, whereas the receptor-mediated extrinsic pathway is usually launched after ligation of receptors and followed by formation of the DISC before subsequent activation of procaspase-8. Cleavage of caspases is a common denominator of the two pathways of apoptosis operating in mammalian cells. The **intrinsic** pathway depends on mitochondrial involvement, whereas the **extrinsic** pathway is generally independent of mitochondria involvement. Mitochondria play a vital role at this crucial juncture to decide the fate of the cell. This organelle evaluates the intensity of the extrinsic signals and the intrinsic signals, but finally takes a stand to dispense what is necessary or beneficial for the organism. If the net result commands the triggering of apoptosis, cyt-c is released from mitochondria at a level sufficient to initiate the activation of **effector** caspases. If the level of apoptotic signalling is not sufficient, then survival signals are typically propagated to neutralize or delay death signals. Genetic regulation of the apoptotic pathways varies considerably across cell types and in response to toxicological reactions. The evidence now shows, perhaps not surprisingly, that not all elements are required in all cell types or in all response to apoptotic agents Shi *et al.*, (1996b).

As noted, **inflammatory** caspases (1, 4, 5, 11, 12, 13 and 14) are involved in inflammation instead of apoptosis. Initiator caspases have long prodomains and contain either a DED (caspase-8 and -10) or a CARD (caspase-2, -9), which mediates the interaction with upstream adaptor molecules. Effector or executioner caspases (3, 6, and 7) contain short prodomains and are typically processed and activated by upstream caspases and perform the downstream execution steps of apoptosis by cleaving multiple cellular substrates. Initiator and effector caspases are activated by different mechanisms. Typically, signalling pathways that lead to caspase zymogen processing can be subdivided into two major categories: DR-mediated and mitochondria-mediated pathways. Some apoptotic signals trigger oligomerization of death adaptor proteins like Apaf-1 and FADD. Death adaptor oligomers, in turn, induce the aggregation of procaspases. Based on insightful studies, it was presumed that initiator caspases are autoproteolytically activated when brought into close proximity to each other, giving rise to the concept of the induced proximity model. This model was later redefined by the proximity-induced dimerization model. The apoptosome-mediated facilitation of homodimerization of caspase-9 is derived from these concepts. Increased local concentrations of caspase-9 may be an operational consequence of this proximity-induced dimerization. Similarly, the DISC induces dimerization and subsequent autoactivation of caspase-8. The productive conformation of the active site in initiator caspases may be stabilized in these complexes. The adaptor-driven activation of caspases depends on conserved motifs within their long prodomain. Two such motifs, the CARD of caspase-9 and -2 and the DED of caspase-8 and -10 mediate their homophilic interactions with CARD- or DED-containing adaptor proteins Apaf-1 or FADD. Evidence from knockout mice indicates

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

that caspase-8 is required for all known DR-mediated apoptotic pathways whereas caspase-9 is mostly involved in mitochondria-mediated apoptotic pathways.

To date, nearly 400 substrates for the caspases have been discovered. Caspase targets can be subdivided into major categories that include (i) apoptosis mediators, (ii) apoptosis regulators, (iii) structural proteins, (iv) DNA repair proteins and (v) proteins critical to cell-cycle regulation. PARP and other DNA repair enzymes, lamin, gelsolin, PKC, and the p53 inhibitor MDM2 often become the targets of effector caspases. Some caspases, like caspase-3, are capable of inducing morphological changes typically associated with apoptosis, like plasma membrane blebbing by removing a negative regulatory domain from the kinase p21-activated protein kinase 2. Among the most well-known caspase effects observed during apoptosis is cleavage of the CAD–iCAD complex. CAD is normally held dormant because of its binding to an inhibitor, iCAD (also called DNA fragmentation factor). During apoptosis, iCAD is cleaved by caspases from the CAD–iCAD complex, leading to the release of an active endonuclease and producing characteristic internucleosomal DNA cleavage. This DNA cleavage ladder became a parameter considered to be the hallmark for apoptosis for over two decades. Internucleosomal DNA cleavage is now known to occur in forms of nonapoptotic dell death. Today, the DNA ladder remains a useful diagnostic tool in assessing cell death, but is no longer accepted as an absolute biomarker of apoptosis.

It is worth noting that within the caspase cleavage cascade, both proapoptotic and antiapoptotic protein kinases can also become targets of proteolysis. Some of the antiapoptotic kinase targets of caspases are AKT, focal adhesion kinase (FAK) and RIP. The activation of transcription factor NFκB is an important prosurvival mechanism. Apoptosis can become favoured via its signalling pathway when the p65RelA subunit of NFκB and upstream activating kinase IKKβ are inhibited through caspase-dependent cleavage. Proapoptotic kinases, such as ROCK1 kinase, PAK2 (p21-activated kinase 2 and MEKK1) are known to be cleaved and activated by caspases in various tissues. TNF-dependent ROCK1 kinase was reported to be modulated by caspase-3 and was considered necessary and sufficient for membrane blebbing during apoptosis. Likewise caspase-3-mediated cleavage of an active form of PAK2 has also been implicated during the formation of apoptotic bodies. Some form of stress during genotoxicity and Fas-induced apoptosis activates MEKK1 and apoptotic MEKK1 signalling involving JNK activation. These are some of the unique properties of caspases.

This arm of apoptosis research has not only generated considerable interest, but also produced a foundation of high quality research publications. Most mechanisms of activation of initiator caspases were explored using isolated proteins, and in the absence of involvement of adaptor protein complexes that are responsible for their intracellular activation. Adapters belong to continuously evolving classes of proteins that are major contributors to apoptosis signalling pathways. These proteins contain a variety of protein-binding modules that link protein partners together and facilitate the creation of larger signalling complexes. By linking specific proteins together, cellular signals are propagated to elicit appropriate responses back from the cell to the environment. In this arena, the induced proximity model, which stresses the importance of active site conformation and interaction within the adapter–protein complex, may best describe the initiator caspase activation mode, whereas the proximity-driven dimerization model, which emphasizes the dimerization process, may best describe how initiator caspases respond to induced proximity. The former offers a specific explanation as to how the initiator caspases are activated. Irrespective of how these caspases launch their activation scheme, their enhanced catalytic activity stems from their altered active site conformation. The particular role of adapter proteins is to bring the caspase zymogens together in a precise conformation, enabling them to undergo autocatalytic activation.

6.10 Caspase-1

Caspase-1 is the prototypical member of the **inflammatory** subclass of caspases involved in cytokine maturation. This class also includes caspases 4, 5, 11, 12, 13 and 14. Caspase-1 is synthesized as a 45 kDa proenzyme that undergoes proteolytic cleavage at Asp residues to produce the active enzyme. The active caspase-1 enzyme is a hetrotetramer comprised of two P20 and two P10 subunits, with the catalytic site being formed by amino acids from both these subunits. The active cysteine is located within the P20 subunit. Caspase-1 is considered a proapoptotic caspase containing an N-terminal CARD domain. It undergoes activation through interactions with other CARD-containing proteins such as ASC, RIP2 and NLRC4 via homotypic CARD–CARD interactions. Because of its long N-terminal prodomain, caspase-1 can be considered to belong to the initiator group of caspases, and therefore could potentially act proximally in a cascade leading to apoptosis.

A breakthrough in the identification of the mechanisms controlling activation of inflammatory caspases came from the identification and characterization of the 'inflammasomes'. Inflammasomes are large, multimeric protein complexes (700 kDa) that recruit inflammatory caspases and trigger their activation after sensing various antigenic and metabolic stresses. It has now become evident that several NLR family members fulfill important roles in the assembly of inflammasome complexes to induce caspase-1 activation. NALP1 and NALP2 are founding members of the NOD-like receptor family, and these inflammasomes are often defined by the distinguishing NLR family member that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

links recognition of specific pathogens to the proximity-induced autoactivation of caspase-1. Currently, four distinct inflammasomes have been identified: the NALP1 inflammasome (NACHT domain-, leucine-rich repeat-, and PYD-containing protein 1b), the NALP2 inflammasome (NACHT-LRR- and pyrin domain-containing protein 2), the NALP3 inflammasome (NACHT-LRR-PYD-containing protein-3) or cryopyrin, and the IPAF (ICE protease-activating factor) inflammasome. Other NOD-like receptors (NLRs), including NALP3 and NOD2, which are associated with inflammatory disorders, have also been described. The NALP1 and NALP3 inflammasomes are located in the cytoplasm and can, therefore, detect intracellular infection through recognition of microbial pathogen-associated molecular patterns. The inflammasome pathways cooperate with Toll-like receptor pathways to mediate a rapid and appropriate response to pathogens and genotoxic stress (Lamkanfi *et al.*, 2007). Future studies will unravel the exact role of this complex during drug or chemical-induced toxicity.

6.11 Caspase-2

Caspase-2 (CASP-2, ICH-1L, ICH-1L/1S, ICH1, NEDD2), a member of the ICE family, is activated during apoptosis by another ICE member, a caspase-3 (CPP32)-like protease(s). When cells are induced to undergo apoptosis, endogenous caspase-2 is first cleaved into three fragments of 32–33 and 14 kDa, which are then further processed into 18 and 12 kDa active subunits. The caspase-3-selective peptide inhibitor *N*-acetyl-Asp-Glu-Val-Asp-aldehyde (DEVD-CHO) inhibits caspase-2 activation, DNA fragmentation and mitochondrial dysfunction in a concentration-dependent manner in *in vivo* models. In addition to being localized in the cell nucleus, caspase-2 is found in the Golgi complex where it cleaves golgin-160 at a unique site insensitive to cleavage by other caspases. Because caspase-2 is located at the Golgi complex, and it cleaves a Golgi substrate early during apoptosis, it has received attention as a potentially important site for generating and transducing unique proapoptotic signals. The contributions of golgin family members are also being studied carefully for their role in Golgi structure and function, particularly in vesicular traffic. The fact that golgin-160 is a substrate for three different caspases suggests that it may be involved in apoptosis. By virtue of its physical location and its role in membrane traffic, the Golgi complex is gaining acceptance as an important new regulator for sensing and integrating information about the intracellular environment. The significance of this organelle is further highlighted by the fact that proteins involved in apoptotic signalling—TNFR1, Fas, an isoform of PKC, PI(3) kinase and ceramide—are situated at Golgi membranes. Caspase-2 is unique among the caspases in that it has features of both upstream caspases, a long prodomain, and downstream caspases, DEXD substrate specificity. The prodomain of caspase-2 has been shown to be essential for the dimerization and autoprocessing of precursor caspase-2 molecules. This caspase-2 prodomain also interacts with a homologous domain in the death adaptor protein RAIDD, implicating caspase-2 as an upstream activator of a distinct caspase pathway.

6.12 Caspase-3

Most caspase $3^{-/-}$ mice die at or before birth. The few survivors are smaller than their wild-type littermates and have severe abnormalities limited to the brain, expressed as enlarged brains, skull defects, excess accumulation of neurons and visible head masses. These masses are ectopic protrusions of supernumerary cells that accumulate in place of the pyknotic clusters usually derived from apoptosis during normal brain development. Caspase-3 is thus crucial for normal embryonic development. Caspase-3 deficiency also dramatically reduces the ability of many cell types to undergo apoptosis in different settings. For example, apoptosis of oncogenically transformed mouse embryonic fibroblasts induced by a chemotherapeutic agent is greatly compromised in the absence of caspase-3. Activation-induced cell death of peripheral T cells is also greatly reduced. However, while caspase-3 is necessary for efficient apoptosis of embryonic stem cells following UV irradiation, it is not required for apoptosis induced by γ-irradiation.

The requirement for caspase-3 in apoptosis induced by a given stimulus can be tissue specific. For example, while TNF induces the apoptosis of caspase-$3^{-/-}$ thymocytes, transformed caspase-$3^{-/-}$ mouse embryo fibroblasts (MEFs) are resistant to this stimulus. Furthermore, caspase-3 knockout mice display an apoptotic defect in response to both intrinsic and extrinsic pathway stimuli. It appears likely that caspase-3 is required for certain critical events during apoptosis, but is not required for all the events. In response to certain stimuli, caspase-$3^{-/-}$ cells fail to develop oligonucleosomal DNA degradation or chromatin condensation yet exhibit other physical signs characteristic of apoptosis. Thus, while caspase-3 is an important or required player in many instances of apoptosis, it is dispensable for apoptosis in other settings. Almost all caspases, including caspase-3, have the ability to cleave PARP, and the 85 kDa PARP cleavage product has become regarded as a hallmark of apoptosis. In addition, the 45 kDa subunit of DFF undergoes cleavage into two intermediate fragments of 30 and 11 kDa under the influence of caspase-3.

Numerous drugs and chemicals directly or indirectly impair Ca^{2+} homeostatsis to induce cytotoxic reactions. The restoration of tight regulation of intracellular Ca^{2+} concentration in various locations, such as the mitochondrion, the ER, the cytosol and the nucleus, can rescue

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

a cell from otherwise lethal consequences of lost regulation. Protracted impairment of regulation triggers an irreversible cascade to death. One means that cells use to maintain close control of internal Ca^{2+} is via channels at the cell membrane which change in response to calcium levels in the ER. These are called Ca^{2+}-release activated Ca^{2+} channels (CRAC; Orai proteins) channels. CRACs operate in conjunction with regulator proteins called stromal interacting molecules (STIMs), which act as the ER calcium sensor that activates the Ca^{2+} channels when Ca^{2+} levels drop. Interestingly, caspases do not spare this regulatory system.

Various components of the Ca^{2+} signalling machinery are cleaved by caspases, with potentially different cellular consequences. The IP3 receptor type 1 (IP3R1) has been identified as a caspase-3 substrate, and IP3R1 cleavage results in the inhibition of IP3-induced Ca^{2+} release and activity. Since Ca^{2+} release may act as a potentiating loop of apoptosis, such an effect could represent a negative feedback mechanism, reducing apoptosis. Besides IP3R1, caspase-3 can also target Ca^{2+}-permeable glutamate receptors of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) subtype and contribute to neuronal apoptosis associated with Alzheimer's disease. Inactivation of this target can abrogate excitotoxicity and Ca^{2+} overload in neurons destined for apoptosis. Another vital target that undergoes cleavage under the influence of this caspase is plasma membrane Ca^{2+}-ATPase (PMCA), the most effective channel contributing to the rapid return of $[Ca^{2+}]$ to basal levels. Isoforms of this channel (neuron-specific PMCA2 and the ubiquitous PMCA4) are substrates of caspases. While PMCA2 is cleaved in neurons in the *in vivo* setting following excitotoxic stimulation and ischaemia stress in the brain, PMCA4 is cleaved in non-neuronal cells during staurosporine-induced apoptosis. Cleavage of PMCA results in loss of function and aberrant intracellular Ca^{2+} transients. Other important targets of caspase-3 are (i) Naρ/Ca2ρ transporter (NCX) type 1 in cerebellar granule neurons undergoing apoptosis, and (ii) hepatitis B virus X protein-expressing liver cells. Taken together, these alterations of Ca^{2+} concentrations and signalling capability constitute a powerful potentiation loop, facilitating the rapid commitment of cells to caspase-3-dependent apoptotic death. Future studies may reveal cooperative roles for other organelles during Ca^{2+} signalling and caspase-dependent apoptosis.

6.13 Caspase-8/FLICE Inhibitory Protein

Caspase-8 (Mach, Mch5) is the key initiator caspase downstream of the apoptosis pathway induced by TNFR1 and other DR. The binding of TNFα to its receptor TNFR makes the receptor intracellular DD available for binding to TRADD. TRADD is an adaptor protein that in turn elicits the binding of FADD, which in turn mediates the binding of procaspase-8 to this multiprotein complex. Caspase-8 also interacts with FADD through homologous DED regions, which result in the proteolytic processing of the inactive procaspase-8 into the active caspase-8 enzyme. Usually, aggregation and close proximity result in the activation of caspase-8 such that its caspase domain is processed into two active subunits: (i) c-FLICE (caspase-8) inhibitory protein (c-FLIP: FLICE inhibitory protein), and (ii) a cellular homologue of viral FLICE (caspase-8) inhibitory protein. However, c-FLIP lacks the enzymatic activity of a caspase, and it is thought that c-FLIP recruited by FADD to the receptor complex in the place of caspase-8 hinders the progression of apoptotic signals (**Figure 11**). FLIP, acting as an important regulator of DR-mediated apoptosis, has also been identified in the DISC. So far, two forms of FLIP have been cloned, termed c-FLIPS (short) and c-FLIPL (long). c-FLIPS contains tandem DEDs and is highly homologous to the N-terminus of caspase-8. c-FLIPL contains, not only the tandem DEDs, but also a protease-like domain, homologous to caspase-8, but without enzymatic activity. The role of FLIP in DR-mediated apoptosis is still controversial, and recruitment of FLIP to the DR of DISC can disable DISC-mediated processing and release active caspase-8. Typically, FADD-deficient embryos and embryos lacking c-FLIP do not show signs of imbalanced apoptotic cell death. Therefore, the developmental defects observed in these mutant mice are probably apoptosis-independent. In contrast, cells lacking c-FLIP are highly sensitive to DR signalling and DR activation. Caspase-8 and c-FLIP thus appear to play critical, but opposite, roles in regulating DR signalling. With caspase-8 being an initiator caspase, it can proteolytically activate several other effector caspases, including caspases-3, -6 and -7. Activated effector caspases proteolytically digest a number of target proteins and set the apoptotic cell death into motion (Shi, 2005; Kuribayashi and El-Diery, 2008).

6.14 Caspase-11

Caspase-11 is present only in vertebrates and commonly known as an inflammatory caspase (also known as a group I caspase). These are encoded by three main genes in humans, caspase-1, caspase-4 and caspase-5, and three main genes in mouse, caspase-1, caspase-11 and caspase-12. In mammals, all these caspases are characterized by the presence of a CARD domain at the N-terminus. Human, chimpanzee and mouse inflammatory caspases share significant sequence homology and are organized in a single locus. Caspase-11 can physically interact with caspase-1 to promote its activation. Elevated expression of caspase-11 under pathological conditions is directly responsible for activation of caspase-1, making caspase-11 an upstream regulator of caspase-1. The expression of caspase-11 is undetectable in healthy mice

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015

and highly induced upon injection of lipopolysaccharide. These mice fail to produce mature IL-1β and are resistant to shock induced by bacterial endotoxins. Moreover, caspase-11-deficient embryonic fibroblasts are resistant to apoptosis induced by ectopic expression of caspase-1, further supporting caspase-11 as an upstream activator of caspase-1. Based on expression profiles, human functional orthologues to caspase-11 have been proposed to be caspase-5 and caspase-4. Caspase-5 together with caspase-1 are found to be components of the NALP1 inflammasome, a complex involved in the activation of caspase-1. The inflammasome is a unique intracellular complex which is assembled upon activation of inflammatory caspases and has the ability to cleave and activate IL-1 and IL-18. The role of the inflammasome is becoming increasingly studied in the field of caspase activation and caspase–caspase cooperation. It appears that different inflammatory caspases may cooperate to exhibit their maximum activity. Sequence comparisons of the caspase domain and prodomains of the inflammatory caspases suggest that both caspase-4 and caspase-5 probably arose following the duplication of a caspase-11 ancestor gene. Emerging evidence with regards to the capase-11 orthologue caspase-4 suggests that caspase-4 may play a role in ER stress-induced apoptosis, an interpretation that awaits further confirmatory evidence.

Caspase induction during apoptosis has been studied using intracellular zinc-depleted cells. The depletion of intracellular zinc is achieved with the chemical N,N,N',N'-tetrakis (2-pyridylmethyl) ethylenediamine (TPEN). Among the caspases examined, only caspase-11 was increased by TPEN. Caspase-11 activity also increased, which results in caspase-3 activation. Cycloheximide or actinomycin D blocks caspase-11 induction, reduces caspase-11 and caspase-3 activation, and attenuates TPEN-induced neuronal apoptosis. Blockade of caspase-11 by a chemical inhibitor or its genetic deletion attenuates TPEN-induced apoptosis, indicating a critical role of caspase-11 in TPEN-induced cell death. Although mitochondria-mediated caspase-9/-3 activation also contributes to TPEN-induced apoptosis, caspase-11 is likely a key inducible apoptosis-inducing protein.

6.15 ASK

ASK-1 is a MAP3K that is involved in the cellular apoptotic response resulting from oxidative stress, ER stress, calcium overload, lipopolysaccharide and receptor-mediated inflammatory signals such as TNF. ASK-1 overexpression induces mitochondrial-dependent caspase activation leading to apoptosis. ASK-1-deficient mice have revealed that ASK-1 is required for apoptosis. However, the functions of ASK-1 are not limited to the apoptotic pathway, because this protein is also involved in the control of cellular proliferation, differentiation and survival. The mitogen-activated protein kinase (MAPK) cascades are multifunctional intracellular signalling pathways that are evolutionarily conserved in all eukaryotic cells. Three main MAPK cascades include the ERKs, JNKs and p38 MAPKs pathways which have been well characterized (**Figure 11**). Each MAPK cascade consists of three classes of serine/threonine kinases, MAPK, MAPK kinase (MAP2K) and MAP2K kinase (MAP3K). MAP3K phosphorylates and thereby activates MAP2K, and activated MAP2K in turn phosphorylates and activates MAPK. A growing number of MAP3Ks has been identified, each of which activates single or multiple downstream MAPK cascades. Extensive characterization of several MAP3Ks has demonstrated that MAP3Ks are crucial to sensing extracellular and intracellular stimuli and regulating cellular responses through the activation of downstream MAPK pathways (Takeda *et al.*, 2007).

6.16 Signalosome and Apoptosis

The COP9 signalosome (known as CSN) is an evolutionary conserved large multiprotein complex that consists of eight polypeptide subunits termed CSN1-CSN8, found in all eukaryotes. In order to stabilize cellular proteomics, ubiquitination and proteasome-mediated degradation of diverse proteins are crucial for eukaryotic physiology and development. The diverse functions of the COP9 complex include regulation of several important intracellular pathways, including the ubiquitin/proteasome system, DNA repair, angiogenesis, cell cycle, developmental changes, and some aspects of immune responses. The largest class of E3 ubiquitin ligases is the cullin-RING ligases (CRLs) which are themselves positively regulated through conjugation of the ubiquitin-like peptide RUB/NEDD8 to cullins. The CSN interacts with components of the ubiquitin(Ub)-proteasome system (UPS) known as cullin-RING Ub ligases. The CSN behaves genetically as an activator of CRLs, although it neutralizes CRL activity *in vitro*. This apparent paradox was recently reconciled in different organisms, as the CSN was shown to prevent autocatalytic degradation of several CRL substrate adaptors. RUB modification is antagonized by the CSN and it dissociates covalent bonding of RUB from cullins. Although the UPS and the CSN determine the stability of regulatory molecules involved in apoptosis such as p53, Bax, Bak and Smac, the exact function of the system in apoptosis is still not known. Inhibitors of CSN-associated kinases induce accumulation of p53 and apoptosis in tumor cells, and the UPS in concert with the CSN controls the degradation of IκBα, a major regulator of the key survival factor NFκB. A recent study has demonstrated that CSN-mediated deneddylation can be regulated by active caspase 3 and that the CSN executes a specific function during the apoptotic process (Hetfeld *et al.* 2008).

Another group of investigators has shown that endogenous ASK1 constitutively forms a high molecular mass complex, which they designate as ASK1 signalosome, and ASK2 is a presumed novel component of the ASK1-signalosome in which ASK2 may modulate the capacity and sensitivity of the signalosome for various stresses and elicit appropriate cellular responses. The basal activity and stimulation-dependent activation of ASK1 are highly regulated by ASK1-signalosome. Various ASK1-interacting proteins that have been shown to regulate ASK1 activity are candidates for components of the ASK1-signalosome. Among them, thioredoxin (Trx) was the first identified ASK1-interacting protein and plays a critical role in the regulation of ASK1 activity. Trx inhibits ASK1 kinase activity by direct binding to the N-terminal region of ASK1. Members of ASK family serve as a MAP3K of the JNK and p38 MAP kinase pathways and play critical roles in response to cellular stress and the innate immune response. ROS-dependent activation of ASK1 is accomplished by the dissociation of Trx from ASK1 followed by inclusion of TRAF2 and TRAF6 in the ASK1-signalosome (Fujino *et al.*, 2007). These stresses may include diabetes, various cardiovascular diseases, oxidative stress, UV, anticancer agents and metal-induced toxicity (Noguchi *et al.*, 2005; Fujino *et al.*, 2007; Takeda *et al.*, 2007; 2008).

7 INTRINSIC APOPTOTIC PATHWAYS

7.1 Mitochondria: Sensor and Master Operator

This vital intracellular energy-producing organelle governs most intrinsic apoptotic pathways. The same characteristics that make mitochondrial uniquely important for cell health, its dependency on oxygen, its ATP synthase for ATP synthesis, its anatomy and its genetic autonomy, also make it a sensitive and powerful control point for adverse events affecting the cell. One critical characteristic of mitochondrial function is the importance of its outer membrane and the vulnerability of this membrane to toxicants and free radicals which can induce the MPT. MPT is primarily governed by Bcl-2 family members. The MPT results in pores that comprise the voltage-dependent anion channels (VDAC) in the outer membrane, the adenine nucleotide translocator (ANT) in the inner membrane, and several auxiliary Bcl-2 family apoptosis-regulating proteins. The basic unit of the MPT pore is the voltage-dependent anion channel-adenine nucleotide translocase-cyclophilin D (VDAC-ANT-CyP-D) complex located at contact sites between the mitochondrial inner and outer membranes. Pro-apoptotic signals open the ANT in the inner mitochondrial membrane and the VDAC in the outer mitochondrial membrane. Pore opening causes water and ions to invade into the matrix, leading to an equilibration and transient dissipation of the MMP. This phenomenon leads to matrix swelling and eventually to the rupture of the outer membrane, releasing proapoptotic proteins into the mitochondrial intermembrane space. In cases where toxic effects are independent of the MPT, other proteins like VDAC may promote formation of pores to advance the death process. Mild MPT perturbations slightly and reversibly compromise ATP production, whereas gross MPT perturbations set the stage and switch the death programme via release of proapoptotic molecules. Both Bcl-2/Bcl-xL and Bax/Bak interact with VDAC to modulate MPT pores. The antiapoptotic Bcl-2 and Bcl-xL close the VDAC channel, whereas the proapoptotic Bax and Bak open the VDAC channel to release cyt-c. A delicate balance between antiapoptotic members (Bcl-2 and its relatives Bcl-xL, Bcl-w, A1 and Mcl-1) and multi-BH domain pro-apoptotic members (Bax, Bak and Bok) maintain cell viability, whereas an imbalance between these two groups favouring proapoptotic members leads to cell death.

In addition, up to eight short BH3-only protein members, such as Bid, Bad and Bim also show proapoptotic activity. Prior to launching of the death programme, the damage-sensing BH3-only proteins clearly lie upstream of Bax/Bak, because they cannot kill cells that lack both Bax and Bak. Prominent investigators in the field suggest that a transcriptionally independent pathway leads to loss of MPT at the outer mitochondrial membrane, permitting efflux of pro-apoptotic proteins in a Bax/Bak-dependent manner. Although cytosolic Bax exists as a monomer in healthy cells, it undergoes conformational changes at both polar ends, migrates to the outer membrane, and oligomerizes during onset of apoptosis. Likewise, Bak a monomer, localized to mitochondrial membrane in normal cells, also undergoes conformational changes and forms larger aggregates during apoptosis. Small numbers of Bak molecules are usually found to be bound with VDAC2 in healthy cells. In the absence of inhibition by VDAC2, Bak demonstrates an enhanced allosteric conformational activation resulting in the release of pro-apoptotic factors conducive to increased apoptotic death. For example, ethanol intoxication involves oxidative stress accompanied by mitochondrial membrane permeabilization and cyt-c release. Bax translocation to mitochondria is oxidative stress-dependent, and the translocated Bax interacts with VDAC. Free radicals such as superoxide can also open the VDAC channel, resulting in the release of cyt-c and cell death. The VDAC–ANT complex is also chemotactic for other proteins, particularly kinases such as hexokinase and glycerol kinase. ANT has been identified as an important target for ROS during apoptosis induced by doxorubicin and arsenic trioxide (**Figures 5–11**).

DOI: 10.1002/9780470744307.gat015
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

A significant change in the mitochondrial outer membrane potential is known to release an important group of proteins known as cellular inhibitors of apoptosis proteins, including Smac/DIABLO, HtrA2 (Htr2/Omi: high temperature requirement protein A2) and GSPT1/eRF3. The cIAPs are emerging as key proteins in the control of cell death. cIAPs have the ability to halt the progression of apoptosis by inhibiting caspase activity. The first four amino acids of mature Smac/DIABLO, AVPI, interact tightly with the BIR3 domain of XIAP. Peptides with identical sequence homology have proven to be strong inhibitors of cIAPs and greatly sensitize cells to TNFα- and TRAIL-induced apoptosis. Omi/HtrA2 can also proteolytically cleave and inactivate cIAPs and is presumably a more efficient cIAP suppressor. Smac/DIABLO, HtrA2/Omi and GSPT1/eRF3 bind cIAPs in a competitive manner similar to caspases. For example, Smac/DIABLO and cyt-c are released simultaneously during apoptosis to neutralize the inhibitory influence of cIAPs and promote cyt-c -dependent caspase activation. Smac/DIABLO seems likely to play an important protective role in DR-mediated apoptosis. Some studies suggest that caspase-3 and caspase-7, but not caspase-1, can be ubiquitinated by cIAP2 and that caspase-7 and caspase-3 are specific targets for cIAP2-mediated ubiquitination. cIAPs can act via inhibition and/or through ubiquitination. This later interaction may be another novel way of controlling the induction of apoptosis through the negative regulation of caspases. Additional evidence suggests that cIAPs prevent apoptosis initiated by Fas signalling and etoposide, whereas in nonapoptotic cells, inhibition of unwarranted caspase activation by cIAPs can be deemed a blessing in disguise to prevent the catastrophic consequences of caspase activation. Nevertheless, most members of this evolutionarily conserved family clearly maintain an antiapoptotic function.

In addition to their release of caspase activating proteins, mitochondria are the prime sources of several other pro-apoptotic proteins that are independent of caspase activity. In recent years, much effort has been invested in identifying caspase-independent apoptotic cell death pathways during toxic reactions, degenerative diseases and tumour growth. It is now known that in addition to their critical role in the production of cellular energy, mitochondria are also the source of key proapoptotic molecules that are distinct from caspase activation. For example, AIF, once released into the cytosol, translocates to the nucleus in response to death stimuli provoked by p53, UVB, *N*-methyl-*N*-nitro-*N*-nitrosoguanidine, H_2O_2 and *N*-methyl-aspartate. Once in the nucleus, AIF specifically induces chromatin condensation at the peripheral nuclear membrane, and stimulates extensive genomic DNA fragmentation. Under some circumstances, AIF cooperates with cytosolic factors to permeabilize mitochondrial membranes and accelerate apoptosis. Classic experiments have demonstrated the inability of zVADfmk to forestall AIF-induced apoptosis, implying that its actions are caspase-independent despite cells demonstrating the classic morphologic features of apoptosis. Definitive genetic evidence establishes an essential role for AIF during early mammalian development. AIF is instrumental for the first wave of apoptotic death during embryonic development, tissue morphogenesis and cavitation. Another vital caspase-independent factor that is released by mitochondria into the cytosolic compartment is endonuclease-G. This genome-sensitive enzyme translocates to the nucleus and produces oligonucleosomal DNA fragmentation in an orderly fashion. It is believed that endonuclease-G is indispensable for DNA fragmentation, particularly during caspase-independent apoptosis. Interestingly, however, adequate expression of Bcl-2 in a timely manner effectively protects cells from both caspase-dependent and caspase-independent apoptosis. This unique property of Bcl-2 may be attributable to its ability to prevent mitochondrial membrane perturbations and release of endonuclease-G.

It is established that cells of diverse origin utilize several mitochondrial proteins to orchestrate apoptotic cell death. cyt-c, IAP and endonuclease-G are located inside the mitochondria, whereas their targets are in cytoplasm (Apaf-1 and Smac/DIABLO) or the nucleus (genomic DNA). The purpose of this spatial segregation insures that these target proteins execute their lethal actions only when needed during apoptosis, and that cells have adequate opportunity to counteract them if and when necessary. It is also worth noting that these proteins are only transiently released into the cytoplasm, yet their lethal actions require processing and endorsement by the mitochondria. For example, Apaf-1 activation will not occur unless cyt-c is in its appropriate configuration (folded into its mature haeme-bound form), and IAP antagonism may falter if the target sequence of Smac/DIABLO in mitochondria is not removed. In metabolically active healthy cells, spatial partition of these proteins is advantageous for mitochondria because: (i) cyt-c is a requisite element of the mitochondrial respiratory chain, (ii) AIF safeguards the intracellular microenvironment from oxidative stress through its pyridine nucleotide-disulfide oxidoreductase domain and (iii) HtrA2/Omi degrades denatured proteins once serving as molecular chaperones. Several lines of evidence suggest that HtrA2/Omi has a duality of function, promoting DNA fragmentation in a pro-apoptotic environment and maintaining mitochondrial functions in normal cells in a fashion analogous to cyt-c. It will be interesting to see whether future studies demonstrate other functions for Smac/DIABLO and endonuclease-G that may even be anti-apoptotic in nature.

Ca^{2+}-mediated mitochondrial regulation of apoptotic cell death has been a focus of research for decades. Ca^{2+} signals directly or indirectly activate various kinases,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

including the PKC family. At present, 12 PKC isozymes have been identified based on cofactors required for maximal activation. These isozymes include the classical isozymes α, $\beta 1$, $\beta 2$ and γ, which require calcium and diacylglycerol for activation, the novel isozymes δ, ε, η, θ and μ, which require only diacylglycerol for activation, and the atypical isozymes ζ, ι and λ, which require phosphatidylserine, but not calcium or diacylglycerol for activation. Thus, pro-apoptotic Ca^{2+} signals are well known, but with considerable variation in experimental models, results regarding protein kinases have been often contradictory. In most experimental systems, the classical isoforms, PKCα, PKC$\beta 2$ and PKCε, as well as the atypical isoforms PKCζ, PKCι and PKCλ, appear to be antiapoptotic, whereas overexpression of PKCδ and PKCθ show proapoptotic activities. In fact, under special circumstances, PKCα plays the role of a survival factor. PKCα is often inhibited during apoptosis, as seen in its dephosphorylation after treatment with ceramide. The fact that both calpains and caspases result in PKCα degradation lends credence to this view. Although the atypical PKCs ζ and λ have been proposed to antagonize apoptosis, their mode of interaction remains poorly understood.

The novel PKCδ has been suggested to participate in the mitochondria-dependent apoptotic pathway triggered by different drug and chemical stimuli. A catalytically active fragment of PKC is generated by proteolysis in cells undergoing apoptosis in response to ionizing radiation, DNA-damaging drugs, and antiFas antibody. As for the site of action of PKC, it is known to translocate during apoptosis to mitochondria, as well as to the Golgi complex (Emoto *et al.*, 1995; Konishi *et al.*, 1999), where it is activated through a tyrosine-phosphorylation step. Among the multiple subtypes of PKC, PKCδ has been implicated as a proapoptotic kinase, mostly by acting as a target of caspase-3 (Li *et al.*, 1999; Roderick and Cook, 2008).

7.2 Apoptosome and Caspase-9

Caspase-9 is considered to be an initiator caspase. The apoptosome, a multimeric complex involving Apaf-1, cyt-c and the cofactor dATP/ATP, is instrumental for its activation. It has been more than a decade since the mitochondrial respiratory chain pigment cyt-c was found to be a classic activator of caspase-3, and its receptor was affirmatively identified as Apaf-1. Later, investigators working on the oncoprotein Bcl-2 demonstrated that cyt-c leakage from mitochondria can be blocked by this anti-apoptotic gene. Multiple mechanisms of cyt-c release can occur cuncurrently within one model of cell death. This crucial event is demonstrated by the formation of a cyt-c and dATP-dependent Apaf-1/caspase-9 complex, and its ability to trigger some of the effector caspases, such as the caspase-3 and -7. Further biochemical characterizations have disclosed that a coherent assembly of dATP/ATP, cyt-c and Apaf-1 forms the apoptosome. The convergence mechanism involves interaction between the apoptosomal caspase recruitment domain of Apaf-1 with the prodomain of procaspase-9, resulting in zymogen procaspase-9 recruitment and its activation. Activated caspase-9 binding to the apoptosome increases catalytic activity severalfold through apoptosomal allosteric regulation of caspase-9 activity.

Apoptosis execution requires the closely coordinated activation of initiator caspases. p53-induced protein with death domain (PIDD) appears to be a bystander during the complex interplay of caspases. Prototypically, caspase activation is triggered upon complex-mediated clustering of inactive zymogen molecules, such as in the caspase-9-activating apoptosome complex. Likewise, caspase-2, which is involved in stress-induced apoptosis, is recruited into a large protein complex that contains PIDD. Increased amounts of PIDD expression result in spontaneous activation of caspase-2 and sensitization to apoptosis by genotoxic stimuli. PIDD has also been shown to play a critical role in DNA damage-induced NFκB activation. Upon genotoxic stress, a complex involving PIDD, RIP1 and NEMO is formed. Cells stably expressing PIDD show enhanced genotoxic stress-induced NFκB activation, through augmented sumoylation (a small ubiquitin-like modifier) and ubiquitination of NEMO. Knockdown of PIDD and RIP1 expression abrogates DNA damage-induced NEMO-modification and NFκB activation (Shi, 2005).

7.3 p53

Considerable focus has been directed to the role of another gene product in apoptosis, p53, also termed the guardian of the genome. It has earned a prominent position in the periodic table of the genes, and has been implicated in such fundamental cellular functions as growth inhibition, redox regulation, coactivation of numerous pathways, apoptosis regulation via extrinsic and intrinsic pathways, apoptosome activation, abrogation of survival signals via the AKT pathway and cancer therapy. This suppressor gene codes for a 53 kDa protein that orchestrates how organisms cope with DNA damage by either stalling cell division or inducing cell death. Transcriptional activation of the $p21^{WAF1}$ cyclin-dependent kinase inhibitor plays a key role in the induction of cell cycle arrest by p53. p53 contains three functional domains: an amino-terminal transcriptional activation domain, a central sequence-specific DNA binding domain and a carboxy-terminal oligomerization domain. The majority of p53 mutations sequenced from human tumours map to the sequence-specific DNA-binding domain and impair the ability of p53 to bind DNA. This nuclear p53 tumour suppressor gene is the most widely mutated gene

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in human cancers. p53 encodes a transcriptional activator whose targets include genes that regulate genomic stability, cellular response to DNA damage and cell cycle progression. It was appealing to think that p53-induced tumour suppression arises through the activation of cell suicide that is irreversible, rather than through imposition of an inherently reversible arrest of cell growth, as previously thought. The consensus now is that p53 can induce growth arrest or apoptosis depending on the physiological or pathophysiological circumstances or cell type, and that both activities are potentially involved in tumour suppression.

While the p53-mediated pathway is the most common mechanism of radiation-induced apoptosis, a large body of evidence suggests ceramide may be a second messenger in mediating radiation-induced apoptosis in specific systems *in vitro* and *in vivo*. Emerging data suggest that radiation acts directly on the plasma membrane of several cell types, activating acid sphingomyelinase, which generates ceramide by enzymatic hydrolysis of sphingomyelin. Ceramide then acts as a second messenger in initiating an apoptotic response via the mitochondrial system. Radiation-induced DNA damage can also initiate ceramide generation by activation of mitochondrial ceramide synthase and *de novo* synthesis of ceramide. In some cells and tissues, Bax is activated downstream of ceramide, regulating commitment to the apoptotic process via release of mitochondrial cyt-c. p53 also accumulates and directs apoptosis in response to DNA damage in skin, thymocytes and intestinal epithelium. High levels of constitutive c-myc expression or exposure to chemotherapeutic agents elicits a p53-dependent apoptotic response.

The past three decades have witnessed intense scrutiny of the activities of p53 and how at the molecular level it oversees a kind of cellular damage-control system to limit aberrant cell growth in response to DNA damage, oncogene activation, hypoxia and the loss of normal cell–cell contact. p53 implements cellular growth restriction by inducing senescence, cell cycle arrest (G_1-S and G_2-M checkpoints) or apoptosis. The molecular rationale for inducing cell cycle arrest vs apoptosis continues to be investigated and remains incompletely understood. Normally, p53 expression level, the type of stress signal, the cell type and the cellular context at the time of stress are principal factors that guide how p53 will maximize the benefit to the host. The binding of p53 to its canonical binding sequence in target genes has been proposed as a possible mode to deal with cells going through chaotic consequences. Surprisingly, however, the ability of p53 to activate target genes through a noncanonical sequence has also been reported. At the genetic level, the sequence of events is envisioned as follows. The binding affinity of p53 for the promoter of the p21WAF/CIP1 (p21: a cell-cycle-regulating gene) remains more-or-less unaffected in response to DNA damage, whereas binding to the promoter of the DNA-repair-associated gene GADD45 is reduced. UV and alkylating agents can induce two specific genes in human and hamster cells, known as growth arrest and DNA damage-inducible proteins 45 and 153 (GADD45, GADD153). This is due primarily to oxidation of Cys277 residing within human p53. Although the mechanism of Cys277 oxidation remains to be defined, it may be associated with oxyradicals that are produced in response to exposure to high-dose UV light. Under reducing conditions, the affinity of p53 for the GADD45 promoter is increased, which suggests that the reduction of Cys277 is necessary to permit binding of p53 to C-rich binding sequences, such as that of GADD45. It is interesting that selenomethionine-mediated reduction of Cys275 and Cys277 residues can signal p53 to recruit the p53-binding redox factor Ref1 and stimulate DNA-repair instruments through GADD45 induction, without affecting cell growth. Thus, the redox state of Cys277 on p53 appears to serve as a switch for activating the DNA repair machinery, and this event may have implications in cancer chemoprevention (Goodrich and Lee, 1992; Miyashita and Reed, 1995; Haupt *et al.*, 2003; Li *et al.*, 2006; Kuribayashi and El-Diery, 2008).

p53 is important but is not the lone player in this arena. Its new family members p63 and p73 have been implicated in assisting p53 in inducing apoptosis. The high level of sequence homology between p63, p73 and p53 proteins, particularly in the DNA binding domain, allows p63 and p73 to transactivate p53-responsive genes causing cell cycle arrest and apoptosis. Therefore, p63, p73 and p53 genes form a family of transcription factor. Investigations of the effect of p63 and p73 on p53 transcriptional activity with knockout MEFs has disclosed two discrete groups of target genes. For one group, p53 alone is sufficient to induce p21 and mdm2 genes, whereas the induction of apoptotic genes PERP (p53 apoptosis effector related to PMP-22), Bax and Noxa requires a co-operative effort of p63 and p73 together with p53. This would suggest an essential role for both p63 and p73 in p53-induced apoptosis. Cooperative roles for these genes have been described during normal mouse development and DNA damage with participation of Abl tyrosine kinase and p73.

Keeping all of these actions in focus, p53 has been shown to be able to activate the extrinsic apoptotic pathway through the induction of genes encoding three transmembrane proteins: Fas, DR5 and PERP. More specifically, p53 induces *Fas* mRNA expression by binding to elements found in the promoter and first intron of the *Fas* gene. This induction is tissue specific and γ-irradiation-dependent. P53 can enhance *Fas* transcription, causing overexpression of Fas at the cell surface via increased trafficking of the Fas receptor from the Golgi. The other pro-apoptotic member that is induced by p53 is DR5/KILLER, the death-domain-containing TRAIL. p53-induced DR5 in response to DNA damage can propagate cytolethality via caspase-8. P73 or p53 expression

transactivates endogenous p53 expression through direct binding of p73 or p53 protein to the *p53* promoter, thereby forming a previously unknown positive feedback loop regulating human p53 expression. Importantly, interference with p53-mediated autoregulation of *p53* transcription results in aberrant cell cycle regulation and abolishes a p53-mediated apoptotic response to DNA damage. The other target involved during genomic damage is PERP, which has a p53 response element. Significantly higher levels of PERP mRNA in apoptotic cells suggest a role for this gene, which is directly targeted by p53 (Goodrich and Lee, 1992; Miyashita and Reed, 1995; Haupt *et al.* 2003; Li *et al.*, 2006; Wang and El-Diery, 2006; Kuribayashi and El-Diery, 2008).

p53 can function as a transcription factor and activate the transcription of death genes like Bax or repress the transcription of survival genes like Bcl-2. Compared with p53-expressing wild-type controls, tissues from p53-null mice show reduced Bax expression and elevated Bcl-2 expression. Several Bcl-2 family members are p53 targets, including Bax, Noxa, PUMA and the previously discussed Bid. Bax is the first member of this group shown to be induced by p53, and p53-responsive elements have also been identified in the *Bax* gene. During activation-induced stress, Bax forms a homodimer and releases cyt-c from mitochondria, which results in caspase-9 activation. The requirement for Bax in p53-mediated apoptosis appears to be cell-type dependent, however, in humans, PUMA encodes PUMA-α and PUMA-ß, both BH3-domain-containing proteins. The onset of growth arrest or death in response to exogenous p53 expression requires a specific balance between PUMA and p21. If p21 is disrupted via gene targeting, the cells die through apoptosis. If the PUMA gene is also disrupted in such cells, apoptosis is prevented. These observations suggest that the balance between PUMA and p21 is pivotal in determining the response to p53 activation and provide a model for understanding p53 mutation in cancer. Moreover, it is well established that PUMA expression generates a prodeath environment via mitochondrial translocation and mulitmerization of Bax. Thus, Bax is an absolute requirement for PUMA-dependent apoptosis. Unlike PUMA, Noxa contains a single p53-responsive element in its promoter and is induced in response to X-ray irradiation. Noxa encodes a BH3-only protein and hence it is speculated that it assists p53-mediated apoptosis in a manner consistent with *PUMA* and *Bax*. Besides *Bax*, *PUMA* and *Noxa*, *Bid* mRNA is also known to increase considerably in a p53-dependent manner. Thus, it appears that p53 expression is mitochondria-sensitive and some intrinsic pathways are intimately linked to p53, which can tilt the balance towards proapoptotic events.

Another p53-dependent direct pathway involves the formation of the apoptosome. p53 is known to facilitate cyt-c release through the induction of target genes encoding BH3-only proteins, and it also induces *Apaf*-1 expression through a response element within the *Apaf*-1 promoter. p53 also has a direct impact on the caspase cascade in both transcription-dependent and -independent mechanisms. Caspase-6 activation has been achieved under the influence of p53. In response to DNA damage, p53 directly induces caspase-6 expression through a response element within the third intron of the gene. There are several other ways that p53 participates in the induction of apoptosis. Some apoptotic signals accentuate localization of p53 to the mitochondria preceding cyt-c release and procaspase-3 activation. p53-deficient Saos-2 cells undergo apoptosis when exposed to mitochondrial-import leader peptides. Permeabilization of the outer mitochondrial membrane by formation complexes with antiapoptotic Bcl-xL and Bcl-2 proteins is another event linked to p53 expression. Therefore, it is reasonable to speculate that the mitochondrial localization of p53 is not the only transcription-independent mechanism by which p53 promotes apoptosis (Haupt *et al.*, 2003).

p85 is another gene that appears to be sensitive to oxidative stress, although its precise role in cell death is unclear. PI3K activates AKT, a serine/threonine kinase, through phosphorylation of Ser473 by the 3′-phosphoinositide-dependent kinase PDK1. This results in phosphorylation of a range of targets by AKT, with the most prominent being Mdm2, a major inhibitor of p53. The final outcome of this event is that the Mdm2 accumulates in the nucleus, boosts Mdm2 interactions with p300, and reduces the affinity of Mdm2 for p19ARF. Consequently, AKT augments the inhibition and destabilization of p53 by Mdm2. Interestingly, stress-induced activation of p53 counteracts the inhibitory effects of this survival pathway by multiple mechanisms. The well-characterized pathways are: (i) promotion of caspase-mediated cleavage by p53, and subsequent degradation of the AKT protein itself, (ii) induction of p53-mediated expression of the PTEN tumour suppressor gene, and subsequent coding of a phosphatase that dephosphorylates PI3K, thereby impairing AKT activation and (iii) p53-induced expression of cyclin G, which recruits the phosphatase PP2AB′ to the Mdm2-p53 complex where it dephosphorylates Mdm2 at the AKT phosphorylation sites. These feedback loops determine survival vs apoptotic outcome in the interplay between p53 and the AKT survival pathway. This balance is often interrupted in cancer, either by mutations in PTEN or the amplification of Mdm2.

Lastly, the *ATM*/p53 (ataxia telangiectasia-mutated gene) signalling pathway is another route that involves p53 and tumorigenesis. The *ATM* gene encodes a protein kinase that acts as a tumour suppressor. Ionizing radiation-induced DNA damage activates ATM, stimulates DNA repair and blocks cell cycle progression. ATM-dependent phosphorylation of p53 is considered the prime interaction that makes this route relevant.

7.4 c-Myc

c-Myc is a nuclear transcription factor that functions as a master regulator of the cell cycle and thus proliferation, differentiation, neoplasia and cell death. The *c-Myc* gene is the cellular homologue of the viral oncogene *v-myc*, and is known to play a prominent role in carcinogenesis. To date, three Myc proteins have been reported in mammals, c-Myc, N-Myc and L-Myc. The *c-Myc* mRNA encodes two short-lived phosphoproteins initiated at independent CUG and AUG translational start sites. c-Myc is the prototypical member of a family of DNA binding proteins that contain carboxy-terminal basic helix-loop-helix leucine zipper (bHLH-LZ) domains. The transcriptional activity of c-Myc requires dimerization with Max, another member of the family. These heterodimers bind specifically to CACGTG sites in DNA. c-Myc harbours N-terminal transcriptional activation domains, and c-Myc–Max heterodimers preferentially activate transcription. Myc–Max heterodimers regulate the transcription of many target genes, and the *c-Myc* gene encodes a nuclear phosphoprotein of approximately 60 kDa. *c-Myc* was identified as a protooncogene and an immediate early response gene and, thus, attention initially focussed on its role in the cell cycle. Enforced activation or cells that are deprived of survival factors readily induce expression of c-Myc and undergo apoptosis. The expression of c-Myc and cofactor Max appears transiently during castration-induced and post-lactation breast regression-induced apoptotic death of prostate and mammary cells, respectively.

In apoptotic cell death, the apparent role for c-Myc was unexpected and paradoxical because of its already recognized role in cell cycle progression through G_1–S and in cell transformation. Extensive experimental evidence shows that cdc25A, a phosphatase, activates cyclin-dependent kinases (Cdks) essential for a G_1-to-S transition and its expression is induced by c-Myc. c-Myc levels are higher in growing cells than in quiescent cells, indicating that expression of c-Myc is necessary for cell proliferation. This is supported by the fact that its downregulation triggers growth arrest and differentiation. c-Myc targets may include the ornithine decarboxylase (ODC), p53 and cdc25A genes. Increased ODC activity leads to increased superoxide levels as a consequence of polyamine metabolism, suggesting that oxidative stress may be involved in c-Myc-induced apoptosis. Nonetheless, ODC inhibition attenuates, but does not prevent apoptosis in c-Myc-overexpressing myeloid cells. Several recent publications have focussed on the connection of apoptosis, induction of p53 and c-Myc. It is clear that the roles of p53 and c-Myc in apoptosis are multidimensional.

In mammalian cells, another pathway by which c-Myc and apoptosis are linked is via $p19^{ARF}$ localization to nucleus. ARF responds to proliferative signals generated by p53 activation using c-Myc because the ARF promoter responds to c-Myc. The ARF tumour suppressor protein acts at a checkpoint that protects against unscheduled cell proliferation with tumorigenic signalling. c-Myc activation is known to upregulate ARF transcription, and in turn, ARF promotes the p53 response by inhibiting Mdm2. This ARF-Mdm2-p53 axis sets a threshold for cellular proliferative signalling. Receipt of excessive proliferative signals can be pro-apoptotic due to the induction of ARF-mediated p53-dependent apoptotic signalling. Alternatively, ARF can interact and bind with c-Myc and substantially reduce the ability of Myc to activate transcription, and push the balance towards inducing hyperproliferation coupled with transformation. Thus excessive Myc expression provides a strong selection pressure for events that dismantle apoptotic signalling pathways. Because ARF is a target of Myc activation, the loss of ARF, like the loss of p53, can attenuate Myc-induced cell death. Overall, it seems like the normal role ARF is to respond to hyperproliferative signals, thereby facilitating p53 activation through a signalling mechanism that differs from those induced by DNA damage. c-Myc-induced apoptosis has also been shown to cooperate with extrinsic death-receptor signalling, such as Fas-L and Fas receptor expression. This is achieved by c-Myc-mediated down-regulation of FLIP expression. Transcriptional stimulation of c-Myc-dependent ODC activity is another way that proapoptotic and/or proliferative responses are regulated.

The role of c-Myc in cellular metabolism is an emerging field of research. Besides ARF, another factor is becoming increasingly prominent in the arena of c-Myc-regulated apoptosis. This factor, called nuclear respiratory factor 1 (NRF-1), is a member of a unique family of evolutionarily conserved transcription factors that are critical for eukaryotic development, mitochondrial respiration and biogenesis in particular. Human NRF-1 has been shown to transactivate the promoters of a number of mitochondrial genes. Well-designed studies have concluded that c-Myc is capable of up-regulating the expression of a number of NRF-1 target gene products, including cyt-c, COX5B, and COX6A, and possibly mitochondrial oxidative phosphorylation. NRF-1 is particularly important in cell growth and development, as homozygous knockouts of this gene are embryonic lethal. Functional NRF-1 sites have been found in genes encoding at least one subunit of each of the respiratory complexes III, IV and V. One of the well-studied NRF-1 target genes is cyt-c, a gene shown to play a critical role in both the electron transport chain and in apoptosis. cyt-c-null mice do not live beyond day 10 owing to respiratory insufficiency, and cells derived from these embryos are apoptosis resistant. The addition of serum restores induction of synthesis of cyt-c coupled with enhanced respiration. Ultrastructural studies with electron microscopy have revealed intramitochondrial electron-dense zones, formation of mega mitochondria, disorganized mitochondrial membranes, fragmented nuclei and

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

membrane blebbing. The distinct electron-dense mitochondrial phenotype and increase in mitochondrial size seen in NRF-1-overexpressing cells suggest extensive import of mitochondrial proteins, which may be responsible for disruption of the mitochondrial membrane. These events clearly establish a link between apoptosis and the selective activation of NRF-1 genes. Further, the ability of Bcl-2 to inhibit both NRF-1-and c-Myc-induced apoptosis is consistent with the induction of shared apoptotic signalling pathways, resulting in mitochondrial dysfunction and cell death.

Several toxicological studies have shown that a variety of stimuli including cytokines, ionizing or UV irradiation, heavy metals and oxidative stress can elevate c-Myc mRNA levels in a range of tissues *in vivo* and *in vitro*. Environmental and industrial toxins trichloroethylene and dichloroacetylene produce a genotoxic metabolite *S*-(1, 2-dichlorovinyl)-L-cysteine (DCVC) that is highly nephrotoxic. DCVC-exposed cells die either via apoptosis or necrosis as a result of multiple mechanisms, such as covalent binding of a reactive metabolite, loss of glutathione, increased levels of cellular Ca^{2+} and ROS, disruption of the actin cytoskeleton and membrane lipid peroxidation. Interestingly, DCVC induces c-Myc mRNA in a manner that is linked, at least in part, to an increase in cellular Ca^{2+} content and oxidative stress. Cells exhibiting dysregulated c-Myc expression in the absence of adequate levels of growth factors tend to undergo apoptosis, whereas in lymphocytes, antisense oligonucleotides to c-Myc block activation-induced apoptosis but not steroid-induced apoptosis. Together, these events may be interpreted the following relationships. Growth arrest, c-Myc off and growth factors absent; population expansion, c-Myc on and growth factors present; and apoptosis, c-Myc on and growth factors absent. In summary, the effects of c-Myc depend on cell type and stimulus and are not needed for all forms of apoptosis. Inappropriate expression of c-Myc may have evolved as a mechanism to prevent the development of neoplasia. This is particularly true for cells with dysregulated c-Myc expression in situations where complementary growth-factor-mediated signals are absent. The molecular mechanisms mediating these opposing functions of the c-Myc protein will require additional investigation (Morrish *et al.*, 2003; Vafa *et al.*, 2002).

7.5 ARE

Oxidative stress is now a phenomenon being investigated by many disciplines, including toxicology because of its involvement in many drug- and chemical-induced toxic reactions. Impairment of the respiratory chain can cause oxidative stress through superoxide production. Oxidative stress, once substantial, can overwhelm the cell when the available antioxidants fail to oppose the oxidative burden. Therefore, antioxidant research in toxicology has gained considerable momentum in the twenty-first century. Oxidants, antioxidants, and inflammatory and antiinflammatory agents modulate the activation of redox-sensitive AP-1 and NFκB, which were discussed earlier in this chapter. AP-1 and AP-1-like AREs have also been reported to modulate the expression of γ-glutamylcysteine synthetase (γ-GCS), the rate-limiting enzyme in *de novo* GSH biosynthesis. A catalytic heavy subunit, c-GCS-HS, and a regulatory light subunit, c-GCS-LS, constitute γ-GCS. It has also been reported that the 5′-flanking promoter region of both the human catalytic γ-GCS-HS and regulatory γ-GCS-LS genes contain putative AP-1 and AREs (Antioxidant Response Elements). These are necessary for γ-GCS expression in response to diverse toxic stimuli. Various inflammatory lung diseases exhibit elevated lung fluid glutathione levels and this increase in GSH may be due to up-regulation of GSH synthesis by AP-1 and ARE activation. The cytoprotective role of GSH during toxic reactions remains paramount, and contributes to the substantial interest in AREs (Rahman and MacNee, 2000; Shih *et al.*, 2003; Lee and Johnson, 2004).

Promoter regions of genes encoding conjugating (phase II) detoxification enzymes and of antioxidant proteins contain *cis*-acting regulatory elements or enhancer sequences known as ARE. ARE were first described in 1989 as enhancer elements, similar to a TPA-responsive element (TRE) or an AP-1 site in the rat glutathione S-transferase (GST)-P gene. Soon, similar *cis*-acting regulatory elements or enhancer sequences were found in rat GST Ya, mouse GST Ya, and human NAD(P)H: quinone oxidoreductase-1 (NQO1). Collectively, these studies provide a common ground for exploring related mechanisms of detoxification gene induction. It is now established that ARE sequences are found in many genes, and that they play an important role in downstream gene expression. Some prominent ARE-driven genes that encode rat GST A1, mouse GST A1, rat GST P1, rat NQO1, human NQO1, human glutamate-cysteine ligase (GCL), mouse ferritin-L, mouse metallothionein-1, and mouse uridine diphosphate (UDP)-glucuronosyl transferase (UGT). Interestingly, the aryl hydrocarbon (Ah) receptor mediates expression of functionalization (phase I) drug metabolizing enzymes through XRE regulatory elements. However, little was known about transacting factors or binding proteins for ARE sequences until the discovery of Nrf2 (NF-E2 related factor 2).

Nrf2, a close relative of Nrf1, is a basic leucine zipper protein (bZIP) in the Cap'n'Collar (CNC) transcription factor family characterized by the presence of a 45 amino acid homology region referred to as the CNC domain. It has been proposed that CNC family member, Maf transcription factor, can also bind to the ARE sequence based on the striking resemblance of the ARE consensus sequence to the Maf recognition element

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat015
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(MARE). The primary structures of members of the CNC-bZIP subfamily are also well conserved in the basic DNA-binding and protein dimerization domains. This family includes p45NFE2, Nrf1, Nrf2, Nrf3, Bach1 and Bach2. The Nrf2-dependent ARE-driven gene NQO1 is important because of its ability to combat oxidative stress. In the meantime, the role of the AP-1 transcription factor in ARE activation has been explored because of its similarity in binding sequence to the ARE sequence. It has been shown that PMA and *tert*-butylhydroquinone (tBHQ) increase GST Ya gene expression through AP-1, whereas AP-1-mediated-ARE activation is PKC-independent. Many proteins were suggested to be regulated by ARE, but the mechanisms underlying ARE activation did not begin to unfold until the identification of Nrf2. It was proposed that the transcription factor binding to ARE might be an AP-1- related protein because both human NQO1-ARE and rat NQO1-ARE contain AP-1 and AP-1-like elements. Tissue-specific expression of the Nrf2 transcription factor is identical to that of NQO1, and the DNA binding sequence for Nrf2 is identical to the ARE sequence. Together these findings indicate that Nrf1 and Nrf2 interact with ARE and drive cellular defense pathways on demand (Rahman and MacNee, 2000; Shih *et al.*, 2003; Lee and Johnson, 2004).

Studies using Nrf2 knockout mice show decreased expression levels of GSTs and NQO1 compared to wild-type. Neurons from $Nrf2^{-/-}$ mice are more sensitive to oxidative stress compared with those from $Nrf2^{+/+}$ mice and overexpression of Nrf2 dramatically increases resistance of neurons to oxidative cell death. Microarray analysis of oligonucleotides has revealed that Nrf2 regulates the orchestrated gene expression of detoxification enzymes, antioxidant proteins, anti-inflammatory proteins, calcium homeostasis proteins and signalling molecules. An oxidative stimulus with simultaneous up-regulation of ARE-driven genes by Nrf2 appears to be efficient in increasing cellular detoxification and antioxidant capacity, implying a role for the Nrf2-ARE pathway as a cellular antioxidant defense mechanism. Nrf2 is sequestered in the cytoplasm by Keap1, whereas ARE activation signals from protein kinase pathways and electrophiles disrupt the Nrf2–Keap1 complex leading to nuclear translocation of Nrf2 and transcriptional activation of ARE-driven genes. This relationship is supported by evidence that Nrf2 knockout mice are more vulnerable to 1-methyl-4-phenylpyridinium (MPP^+) and rotenone-induced oxidative stress. Biochemical analysis of brain tissues from post-mortem Parkinson's disease patients have disclosed elevated ARE-regulated enzymes such as haeme oxygenase-1 (HO-1) and NQO1, suggesting the possibility of common transcriptional regulation (Rahman and MacNee, 2000; Shih *et al.*, 2003).

Additional evidence comes from studies with the most commonly used analgesic in the world, acetaminophen (paracetamol). Acetaminophen overdose leads to an immediate adaptive defense response in the liver involving various mechanisms, including the nuclear translocation of redox-sensitive transcription factors such as Nrf-2, which sense chemical danger and set cell defenses into motion. Thus, with respect to acetaminophen, Nrf-2 genes of immediate significance are those involved in glutathione synthesis such as γ-GCS, GSTs, UGTs and haem oxygenase. Importantly, it has been observed that nuclear translocation occurs at nontoxic doses of acetaminophen and at time-points before overt toxicity is observed. However, with increasing doses of acetaminophen, there is a progressive decline in nuclear translocation, transcription, translation and protein activity as the rate of drug bioactivation and the adverse consequences of oxidative stress overwhelm cell defenses. There have been several reports describing the modulation of Fas- or TNF-RI-mediated apoptosis by GSH. According to these reports, acute GSH depletion induced insensitivity to DR stimulation, while during prolonged GSH depletion increased DR-mediated apoptosis occurred. Several reports conclude that Nrf2 activity influences the sensitivity of death signalling, and overexpression of Nrf2 protects cells from Fas-induced apoptosis. In addition, *N*-acetyl-L-cysteine (NAC), a precursor to GSH, protects cells from Fas-mediated killing in HeLa cells. All of these results advance our understanding of the genetic link between xenobiotic-induced oxidative stress, ARE and apoptotic death (Morito *et al.*, 2003; Xu *et al.*, 2005).

In conclusion, genetic analysis of cell death has identified key genes, proteins and interlinked pathways that regulate and execute cell death. Structurally related vertebrate genes that appear to play similar roles have been identified and characterized, indicating that the general framework of cell death mechanisms has been conserved over the course of evolution. Depending upon the circumstances, cells may either oppose or follow the instructions of a single gene or of several genes in a concerted manner to orchestrate or bypass the apoptotic pathway, whichever is sensed to be more beneficial for the organism. Since the discipline of toxicology primarily deals with unraveling mechanisms of cell injury and cell death, considerable interest in apoptosis research will continue well into the foreseeable future. Additionally, efforts are underway to manipulate or connect key regulatory points on apoptotic pathways in order to develop novel strategies to delay, reverse or prevent the contributions of this mode of cell death to major diseases such as cancer and neurodegeneration. It is clearly established that protection from apoptosis can be achieved at four different levels: (i) interception of an apoptosis-inducing stimulus, (ii) antagonism of an apoptosis-inducing trigger; (iii) interference with signal transduction cascades and (iv) blockade of catabolic enzymes participating in cell death. The race to develop pharmaceutical agents based on our understanding of apoptosis began at the end of the last century and will continue on into the twenty-first

century, with the hope of developing break-through therapeutic classes with new abilities to intervene or prevent diseases for which the current prognosis is poor.

The advantages of a self-orchestrated cell death process in the removal of unnecessary, damaged or dangerous cells are abundant. However, this strategy can and often does fail during toxic injury to cells. A fundamental flaw of apoptosis is that its emergence, development and maintenance as a system are driven by the evolution and effectiveness of self-preservation and survival genes. Apoptosis-deficient cells, as seen in many cancers, refuse to die and require new strategies to be defeated. The pathways that lead to activation of apoptosis vary among different cells despite similar stimuli, and different cells respond differently to varied stimuli. Yet the final pathway leading to cell death remains nearly the same. Emerging trends in this field show that gene and antisense agents directed at *Bcl*-2 have promise in some models and may evolve into acceptable therapies in the treatment of some human cancers. Intracellular and extracellular interference with specific protein–protein interactions by select inhibitors may offer another viable approach. Progress achieved in this direction appears rather impressive when viewed in the context of the age of this field, which spans only a couple of decads. Several approaches now show some promise in new apoptosis-based therapies.

8 DRUG- AND CHEMICAL-INDUCED APOPTOSIS

It seems at first paradoxical that cell life is dependent on cell death. Perturbations of normal life processes by toxic chemicals enable us to learn about the life processes themselves and represent an important dimension of the inherent value of the science of toxicology in achieving health and safety. Life processes are highly dynamic, involving the continuous turnover of cells, subcellular structures and biological molecules that often produce opposing effects exemplified by death and regeneration, damage and repair, injury and compensation, and degradation and resynthesis. Therefore, in order to understand the science of toxicity more precisely and within its broadest contexts, the result of exposures to drugs and chemicals might be regarded as the product of divergent biological processes. This includes homeostasis on the one hand and injury followed by compensation and/or repair on the other (see Lotti, 1995). Advances in our journey to understand lethal injury at the molecular level have built on discrete, novel observations. Successive observations have stimulated activity related to that biochemical or regulatory change and have often resulted in heightened interest in one or another implicated subcellular organelle. Over time, attention has focussed on a specific favoured organelle, including the plasma membrane, the cytoplasm, mitochondrion, the lyososome and other subcellular organelles, only to wane and give way to the next target. In considering this history of events, a most important stimulus for increased interest in the role of the nucleus in lethal injury has come from the studies of apoptosis. With the advent of the millennium, research emphasis continues to be placed upon cytoprotection and disease prevention strategies based on the knowledge gained from these mechanistic studies.

Among an ever-increasing number of agents that trigger or cause apoptosis, cancer chemotherapeutic agents, glucocorticoids and retinoids are among the most extensively characterized. Environmental contaminants such as dioxin, polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs) and tributyltin are also capable of triggering apoptosis in target tissues under environmentally relevant exposure scenarios. Natural and anthropogenic agents capable of provoking apoptosis include sanguinarine (Ahmad *et al.*, 2000; Mackraj *et al.*, 2008), the cannabinol anadamid (Pushkarev *et al.*, 2008) ochratoxin-A, gliotoxin, diphtheria toxin, thapsigargin, staurosporine and genistin (McConkey *et al.*, 1995). From the abundance of accumulating reports it appears that many drugs and chemicals capable of causing necrosis are potential apoptogens and vice versa. Likewise, most antinecrogens can be effective inhibitors of apoptosis and vice versa (Ray *et al.*, 1996; 2006).

Studies on acetaminophen offer some insights into these important but unresolved relationships. It is known that acetaminophen directly alkylates genomic DNA both *in vivo* and *in vitro,* and that this widely consumed analgesic produces genotoxic effects in a variety of test systems (Dybing *et al.*, 1984). These findings have now been extended to show that acetaminophen inhibits DNA synthesis and increases single-strand breaks and sister chromatic exchanges of V79 Chinese hamster cells (Hongslo *et al.*, 1988). Although some of these events appear relatively late and may relate more to the carcinogenic potential rather than the hepatotoxic potential of acetaminophen, they are important in that they demonstrate the ability of acetaminophen to damage DNA directly or to inhibit systems that maintain DNA integrity.

A series of publications by Ray, Corcoran and collaborators established that acetaminophen-induced cell death *in vivo* (Ray *et al.*, 1990; 1991; 1993; 1996; Ray and Corcoran, 1991) closely resembles aspects of apoptosis *in vitro* and *in vivo*, particularly as apoptosis is described for the lymphoid cell model using immature thymocytes (Wyllie, 1980; Cohen and Duke, 1984). Classic apoptotic damage including Ca^{2+} accumulation, DNA fragmentation in the form of a ladder, and decreased nuclear DNA recovery all appear prior to major hallmarks of necrosis, that is, extensive leakage of alanine aminotransferase (ALT) into plasma and quantifiable liver histopathology in mice. The timing of these events suggests that faltering Ca^{2+} regulation throughout the cell, but particularly in the nucleus, leads to the same kind of endonuclease

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

activation seen relatively early during apoptosis, and thoroughly documented during thymocyte killing *in vitro* (Wyllie, 1980; Cohen and Duke, 1984). Shen *et al.* (1991; 1992) recapitulated and further explored these acetaminophen-induced *in vivo* effects in cultured hepatocytes *in vitro.* It is now well established that hepatotoxic doses of acetaminophen *in vivo* induce death of hepatocytes by apoptosis as well as necrosis (Alison and Sarraf, 1994; Ray *et al.*, 1996; 2006; Liu *et al.*, 2003).

Numerous cells undergoing apoptosis are found in the liver long after the progression of toxicity due to acetaminophen, even 24 hours after drug exposure. Given that apoptotic cells are very rapidly removed from *in vivo* systems, the presence of a large number of this type of cell very late in the toxicosis raises two possible explanations: (i) A rapid onset of apoptosis in a large population of cells that cannot be quickly removed or (ii) A decreased efficiency of the removal process as it is overwhelmed during advancing toxicosis and declining homeostasis (Ray *et al.*, 1996). Similarly, Pritchard and Butler (1989), using the powerful carcinogen and potent hepatotoxin, immunotoxin and nephrotoxin, DMN, demonstrated its ability to induce apoptosis in the liver *in vivo.* Later, Ray *et al.* (1992) discovered some of the biochemical steps, demonstrating the involvement of Ca^{2+} dysregulation in this DMN-induced death cascade. Changes leading to cell death were consistent with histochemical and ultrastructural changes of apoptosis observed by Pritchard and Butler (1989).

The biochemical changes involved in both DMN- and acetaminophen-induced apoptosis (Ray *et al.*, 1992; 1993) were similar and primarily involved intranuclear Ca^{2+}-mediated endonuclease-dependent fragmentation of genomic DNA. This observation was further substantiated by the effects of Ca^{2+}-channel blockers verapamil and chlorpromazine, which prevent Ca^{2+} entry into the hepatocellular nucleus and protect DNA from the endonucleolytic attack, ultimately resulting in the prevention of hepatotoxicity and lethality (Ray *et al.*, 1993). In some of the *in vitro* experiments, aurintricarboxylic acid, an inhibitor of endonuclease and protein synthesis, successfully blocked DNA fragmentation and cell death (McConkey *et al.*, 1989; Shen *et al.*, 1992). Strika *et al.* (1998), using the loop diuretic furosemide, showed that it can induce apoptosis in addition to necrosis in the mouse liver and kidney. Faa *et al.* (1994) using a translational inhibitor, cycloheximide, demonstrated its potential to induce apoptosis in rat liver by electron microscopy. The ultrastructural changes observed in this study are classically apoptotic. Later, using transgenic L_{37}SV40 liver cells, the apoptosis-inducing potential of cycloheximide was shown to be due to growth factor deprivation (Bulera *et al.*, 1996).

The interaction of toxicants and apoptosis is complex and the mechanisms of interaction differ across toxicants. The apoptosis-inducing potential of a variety of carcinogens has been addressed at great length. For many years, research with PAHs has focussed on the ability of these common environmental chemicals to induce cell transformation. Many investigators share the notion that carcinogens antagonize or alter the apoptotic pathway, improving the chances that a cell with aberrant DNA or oncogenic mutations will survive. In contrast, carcinogens can also be powerful inducers of apoptosis. PAHs offer a classical example. Within the PAH chemical group, 7,12-dimethylbenzaanthracene (DMBA) is among the most cytotoxic and immunosuppressive agents that has been studied. DMBA causes apoptotic death of cells in a variety of tissues *in vivo* and in A20.1 murine B-cell lymphoma *in vitro* (Burchiel *et al.*, 1992; 1993; Yamaguchi *et al.*, 1997). Aryl hydrocarbon receptor (AhR)-mediated effects on a Ca^{2+}-endonuclease may be responsible for triggering the apoptotic events observed in these studies. The involvement of a Ca^{2+}-endonuclease has been unequivocally demonstrated in TCDD -induced thymic cell apoptosis (McConkey *et al.*, 1988a). Fuchs and Pruett (1993) have shown that morphine induces mouse thymocyte apoptosis *in vivo* but not *in vitro,* and suggest that both glucocorticoid and opiate receptors are involved in the process. The antitumour antibiotic mitomycin C, a DNA synthesis inhibitor, induces aspermatogenic cell apoptosis in mouse testes (Nakagawa *et al.*, 1997). Representative agents that induce apoptosis *in vivo* and *in vitro* are listed in **Tables 3** and **4**.

Numerous studies indicate that chemotherapeutic agents are capable of triggering apoptosis of both malignant and normal cells. Drugs as diverse as alkylating agents [*N*-(5,5-diacetoxypentyl)doxorubicin], DNA topoisomerase II inhibitors (fostriecin, etoposide, dactinomycin), DNA-intercalating compounds [adriamycin 1-β-D-arabinofuranosylcytosine; Ara-C], DNA-binding compounds (actinomycin-D), DNA crosslinking agents (cisplatin; nitrogen mustard), protein phosphatase (1A, 2A) inhibitor (okadaic acid), PKC inhibitors (Ara-C, staurosporine, H7) and microtubule-disrupting agents (vinblastine, vincristine, colchicine, nocodazole) have all been demonstrated to be potent inducers of apoptosis although by different mechanisms (**Tables 3** and **4**).

Another highly relevant and widely studied hepatotoxin, ethanol, has received heightened attention for many decades. Accumulating data indicate that apoptotic death occurs in addition to necrotic death in several hepatobiliary diseases, including ethanol-induced liver injury *in vivo* (Benedetti *et al.*, 1988a; 1988b; Goldin *et al.*, 1993; Baroni *et al.*, 1994), cholestasis, viral hepatitis, alcoholic and nonalcoholic steatohepatitis and fibrosis (Malhi and Gores, 2008), as well as in *in vitro* model systems (Chen *et al.*, 1997). Unlike acetaminophen and some higher alcohols [C_3 (propan-2-ol) to C_8 (octanol)], however, one bolus LD_{50} dose of ethanol fails to induce apoptosis in the rat liver. Higher alcohols such as butanol, pentanol, hexanol and octanol are potent inducers of

apoptosis in the normal rat liver. Ray and coworkers also found that spontaneously hypertensive rats are more sensitive to the apoptosis-inducing potential of alcohols (Manolas *et al.*, 1997). The same group found that moderate ethanol exposure ramping from 3 to 5% over three weeks followed by low-dose acetaminophen (300 or 400 mg kg^{-1}, i.p.) dramatically potentiate the acetaminophen-induced apoptotic death rate in mouse liver cells *in vivo* (Ray, 1997).

Although oxidative stress has been proposed to be a principal stimulus leading to apoptosis in this case (Kurose *et al.*, 1997), it is difficult to pinpoint a definitive mechanism for ethanol-induced apoptosis, since the dose, duration, route of exposure and models are diverse. Increased expression of Bcl-2 protein has been demonstrated in ethanol-exposed rat livers (Yacoub *et al.*, 1995). However, this increase in Bcl-2 expression was found to corretate with the presence of an excess number of inflammatory cells and may not have involved an increase in expression of the gene in the liver cells. Similar observations were reported by Dhruva and Ray (1996), Dhruva *et al.* (1996), and Ray (1998) in acetaminophen-treated mouse livers, where Bcl-2 protein was found in mouse liver. Regulation of hepatocellular apoptosis by Bcl-2-dependent and Bcl-2-independent mechanisms may exist (Oberhammer *et al.*, 1992). Future studies with ethanol are needed to elucidate its interaction at the organelle level (e.g. MPT or cyt-c release) and/or at the genetic level (e.g. Bcl-2 regulation).

Oxidative damage induced by ROS is a normal aspect of aerobic life. Damage occurs at the structural level to cellular and subcellular organelles, and at the functional level to macromolecules including enzymes, DNA, proteins and carbohydrates. Damage inflicted by ROS species including $O^{2-\cdot}$, H_2O_2, $HO\cdot$ and others has been termed oxidative stress. The role of oxidative stress in apoptosis has been extensively reviewed (Buttke and Sandstrom, 1994; Ray *et al.*, 2001; 2004; Hickey *et al.*, 2001; Surh, 2003). Many agents, whether physical (ionizing/UV radiation) or chemical (redox cyclers including antineoplastic agents) are capable of provoking oxidative stress in addition to inducing apoptosis mediated by a variety of ROS (Buttke and Sandstrom, 1994; Pallardy *et al.*, 1997; Bagchi *et al.*, 1998b). Evidence that oxidative stress can induce apoptosis comes from studies in which apoptosis induced by ROS can be inhibited by antioxidants.

One such example is TNFα. Stimulation of the TNFα receptor promotes intracellular production of ROS through increased mitochondrial superoxide anion formation. Inhibition of ROS production by *N*-acetylcysteine or the free radical scavenger thioredoxin prevents apoptotic cell death (Buttke and Sandstrom, 1994; Pallardy *et al.*, 1997). The Fas antigen, which is structurally related to the TNF receptor, also induces apoptosis when crosslinked with antiFas antibodies. Its ability to induce apoptosis in cells has been shown to be blocked by thioredoxin. Exogenous sources of ROS such as H_2O_2, and exogenous *tert*-butyl hydroperoxide induce apoptosis at doses well below the necrogenic doses. Quinone compounds that undergo redox cycling and cause superoxide radical formation, such as menadione and 2,3-dimethoxy-1,4-naphthoquinone also induce apoptosis (McConkey *et al.*, 1988b). Chronic inhibition of superoxide dismutase transcription or activity causes apoptotic death. Intracellular ROS appear to activate genes responsible for apoptosis, conceivably through an oxidative-stress-responsive nuclear transcription factor such as NFκB (Sen and Packer, 1996).

Over the past two decades, free radicals related to ROS and nitric oxide (NO) have been the subject of intense study and considerable debate. NO orchestrates a range of useful biological activities as well as deleterious pathophysiological activities. It is synthesized from molecular oxygen and the guanidino group of L-arginine by a family of closely related enzyme isoforms of nitric oxide synthase (NOS: EC 1.14.13.39). NO is a messenger molecule that participates in drug-induced hepatotoxic reactions, relaxation of smooth muscle, neurotransmission and killing of tumour cells and bacteria. Evidence suggests that biochemical and toxicological effects of NO are mediated, in part, by $ONOO^-$ (peroxynitrite: a reaction product of NO with superoxide anion, $O^{2-\cdot}$). NO and $ONOO^-$ have each been shown to induce necrosis in model systems (Ignarro, 1990; Nathan, 1992), and their apoptotic potential in murine macrophages, human epithelial cells and HL-60 cells is well established (Messmer *et al.*, 1995; Sandoval *et al.*, 1997 Sen *et al.*, 2008).

Mechanisms proposed for NO toxicity include its interaction with protein thiol groups or iron–sulphur proteins or by direct DNA damage. The genomic damage induced by radiation or by drugs such as etoposide can result in apoptosis. NO may signal different forms of cell death depending on the type and/or the steady-state concentration of the NO redox species involved. A link between p53 expression and NO synthesis dependence has been established (Messmer *et al.*, 1994), although the connection between antideath gene *bch*, NO and apoptosis remains open for investigation (Dhruva and Ray, 1996; Dhruva *et al.*, 1996). Similarly, the precise role of Kupffer cells, macrophages, neutrophils and phagocytes requires further scrutiny, because these cells play an important role during NO-induced apoptosis *in vivo.*

Many agents are genotoxic while others lack genotoxicity. Among the latter, TCDD, trichloroethylene (TCE), dichloroethylene (DCE), CCl_4, trichloromethane ($CHCl_3$), hexavalent chromium compounds, cadmium compounds, nickel compounds and tributyltins have been thoroughly investigated. Surprisingly, some of the historically known compounds like ethyl-methane sulfonate, CCl_4 and $CHCl_3$, lack the ability to induce apoptosis despite the observations that their toxicities

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

are Ca^{2+}-dependent (Long *et al.*, 1989; Ray and Fariss, 1994). In contrast, other agents including DCE, TCE, and TCDD are efficient inducers of apoptosis (Blankenship *et al.*, 1994; Costa, 1998). In addition to TCDD (McConkey *et al.*, 1988b), other mechanistically well-defined examples from this category are tributyltin oxide (bis(tri-*n*-butyltin) oxide) and tributyltin-induced apoptotic death of immature thymocytes in culture (Raffray *et al.*, 1993). Investigators have demonstrated that tributyltin oxide, a potent but relatively nonspecific agent, activates thymocyte apoptosis independent of protein synthesis and under conditions of severely compromised cellular energetics. This argues against the well-accepted notion that apoptosis is a highly regulated intracellular event which is energy dependent and requires transcriptional and translational control. Unlike the oxide form of tributyltin, tributyltin chloride is a potent and rapid inducer of apoptosis *in vitro*. *In vivo*, dibutyltin chloride seems to be much more potent in inducing thymic atrophy (Dobbelsteen *et al.*, 1997).

Accumulating evidence indicates that metals may either positively or negatively influence apoptotic processes. Some forms of metals, such as calcium, magnesium, cadmium and chromium, favour apoptosis, whereas Zn^{2+} may either favour or antagonize apoptosis (Sunderman, 1995; Wolf *et al.*, 1997). Furthermore, some metals exert an antagonistic influence on the action of other metals. Cadmium suppresses chromium-induced apoptosis (Shimada *et al.*, 1998). Metal-induced apoptosis is a leading issue for toxicology and remains at the centre of public health concerns over environmental exposures.

Although the mechanisms of many antiapoptotic agents such as cholesteryl hemisuccinate are unknown, the fact that dimethyl sulfoxide, a membrane-permeable solvent hydroxyl radical scavenger, thioredoxin, an intracellular thiol reducant, *o*-phenanthroline, a hydroxyl radical formation blocker, *N*-(2-mercaptoethyl)propane-1,3-diamine, an inhibitor of membrane peroxidation and the antioxidant vitamins C and E, as well as exogenous catalase, prevent apoptotic death in a variety of model systems (Buttke and Sandstrom, 1994) substantiate the role of ROS in apoptosis. Cholesteryl hemisuccinate prevents both of the apoptotic and necrotic forms of cell death induced by acetaminophen *in vivo* (Ray *et al.*, 1996).

Varied studies offer evidence that agents that influence PARP activity, for example, 3- and 4-aminobenzamide (**Figure 3**), NAD, nicotinamide, caffeine and theophylline, depending upon the model system and concentration used, either abrogate or escalate drug- or chemically induced cell death. However, the same agents interfere with transmembrane signalling mechanisms in different model systems, such as thymocytes (Ray *et al.*, 1992; McConkey *et al.*, 1995; Yahya *et al.*, 1995). The nitroso-containing free radical scavenger 5,5-dimethyl-1-pyrroline-N-oxide (DMPO) blocks methylprednisolone-induced apoptosis, and the Ca^{2+}-ATPase inhibitor thapsigargin, the Ca^{2+} chelator EGTA, the Zn^{2+} chelator *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)ethylenediamine, Zn^{2+} salts (Bagchi *et al.*, 1997) and the topoisomerase II inhibitor etoposide block apoptosis in a variety of model systems under diverse conditions. The commonly used antioxidant BHA (frequently added as a preservative in foods), dithiocarbamates (DTCs), diethyl dithiocarbamate (DETDTC) and dimethyl dithiocarbamate (DMDTC) serve as anti-apoptotic agents in radiation-induced leukaemic cells (Verhaegen *et al.*, 1995).

9 SUMMARY AND CONCLUSIONS

Apoptosis is a process of single-cell deletion requiring active participation of the cell in its own demise. It occurs during both physiological conditions, such as neural development, and pathological conditions such as acute myocardial infarction, ischaemia and stroke. It is morphologically distinct from necrosis and characteristically presents with cell shrinkage, dense fragmented chromatin and cellular budding with fragmentation. The process results in the formation of apoptotic bodies that are quickly phagocytosed by a variety of cells, thereby keeping the integrity of the tissue intact. In contrast to necrosis, apoptosis typically does not induce an inflammatory response. Apoptosis can result from an imbalance between the activation of effector genes which promote cell death and repressor genes which enhance cell survival. Of these, Ca^{2+} regulation and several Ca^{2+}-dependent events have been scrutinized. Much of the evidence remains indirect and some even speculative. It is also not clear once a particular cell turns on the death programme *in vivo* or *in vitro*, how the neighbouring cells react. Although in *in vivo* model systems many of the biochemical pathways for apoptosis are well characterized yet not fully understood, the TNFR superfamily, the caspases and the *bcl-2* gene products are clearly implicated in effector roles, and ceramide, ROS, MPT and cellular energy status have been implicated as mediators. Cell cycle regulatory elements have gained considerable attention, and it is established that apoptosis may require the action of several molecules that are normally involved in regulating cellular proliferation. It is also evident that the mechanisms necessary for completing apoptosis exist in every cell.

Much has occurred to propel apoptosis into the forefront of basic and clinical research. This outcome was founded upon identification of genes that control cell death and has resulted in an appreciation of the roles of apoptosis in development, health and disease. Apoptosis is often a beneficial form of cell death in development and therapeutics, but is increasingly recognized as the basis of many drug- and chemical-induced toxicities. The induction of apoptosis after a toxic assault

can also be seen as beneficial, since loss of aberrant cells by apoptosis can impose a minimal negative impact on the host. Instances have been reported where apoptosis has been observed either in the near total absence of genomic DNA digestion (Ucker *et al.*, 1992) and in the absence of a nucleus (Jacobson *et al.*, 1994). It now appears that apoptotic and necrotic processes paradoxically share many similar intracellular mechanisms, including oxidative and reductive stress, Ca^{2+} dysregulation, DNA fragmentation, MPT, cellular energy status and membrane potential fluctuations. Raffray and Cohen (1997) elegantly addresses these concepts, and offer their opinion that apoptosis and necrosis are essentially distinct modes with limited molecular and cell biology overlaps. Yet increasing evidence indicates that apoptosis and necrosis are parts of a cell death continuum (Wyllie, 1987; Corcoran and Ray, 1992; Ray and Raje, 1994; Tomei *et al.*, 1994; Ray *et al.*, 1996).

The search for commonalities that unify drug- and chemical-induced cytotoxic mechanisms has met with limited success. From an operational standpoint, the killing of some cells can be viewed as occurring via direct means, whereas the killing of others takes place via indirect means. In toxicant-induced cell injury which ultimately results in cell death, changes that are responsible for cell death are joined and effectively concealed by a host of powerful but futile stimuli from a network of control systems that attempt to return the cell to homeostasis. While the control network strives to return to homeostasis, systems that are devoted to cellular repair and regeneration also become engaged through a number of common mechanisms. It is apparent why most cell responses during lethal injury are not directly related to the ultimate cause of cell death. Only a select response or subset of responses is considered to be capable of producing permanent irreversible damage and the ultimate loss of viability.

The cell is considered the smallest autonomous unit of living systems that has the capability to receive information from its environment, to transduce it according to the genetic information encoded in DNA and finally to put out appropriately processed signals into its environment in order to realize teleonomically designed organized functions (Ji, 1997). The widespread involvement of apoptosis in diverse conditions gives rise to the notion that targeting this response will lead to the development of novel therapeutic regimens. The presence of apoptotic machinery in tumours suggests that its induction could be used as a therapy. The ability to modify sensitivity to apoptosis through the regulatory pathways has clear implications for the treatment of malignancy. Potential strategies fall into three categories: directly inducing apoptosis by cytotoxic agents, enhancing vulnerability to apoptosis to increase the efficacy of other therapies and boosting the resistance of normal cells to apoptosis (Bellamy *et al.*, 1995). Among these, direct antitumour therapy targeting apoptotic modulation may prove to be much less systemically toxic than standard chemotherapy and could also be used in an adjuvant manner, to increase the susceptibility of tumours at the time they are exposed to chemotherapy (Rudin and Thompson, 1997). The question of cause–effect in drug-induced apoptosis seems to be most crucial in order to appreciate the impact of apoptosis on chemotherapy and to position the protective action of death-inhibitory genes. The successful developments of agonists and antagonists of this process can provide important new access points of various regulatory pathways. Already, newly acquired knowledge concerning the regulation of apoptotic cell death is being applied clinically in the development of prognostic indicators to predict disease progression and for the treatment of cancer. Apoptosis-targeting strategies currently being tested in clinical trials involve the use of antisense oligonucleotides (*Bcl*-2, XIAP, ML-IAP), recombinant biologicals (TRAIL receptor, DR5, CD95-Fc, Survivin-2B, TNFα, caspases) and classical organic pharmaceuticals (caspases, IAP, p53, cyt-c, JNK). It is rather early to tell whether the overall strategy of modulating cell death signalling pathways will prove to be clinically useful, but treatment successes, should they be realized would represent important victories for the strategy of rationale drug development.

ACKNOWLEDGMENTS

Constant help received from numerous graduate and undergraduate students and colleagues throughout the world during the preparation of this manuscript is acknowledged. Special thanks are due to Dr Nelu Jena, Tufts Univ. School of Medicine, Boston, Massachussetts, for his input on the genetic regulation section of this chapter.

A Metabolomic Perspective of Small Molecule Toxicity

Andrew D. Patterson and Jeffrey R. Idle

CONTENTS

1 INTRODUCTION

Recently, the Society of Toxicology redefined toxicology for the National Library of Medicine as follows: 'Toxicology is the study of the adverse effects of chemical, physical or biological agents on living organisms and the ecosystem, including the prevention and amelioration of such adverse effects' (http://www.toxicology.org/AI/PUB/SI05/SI05_Define.asp). The key word in this catch-all definition, that separates toxicology from other disciplines such as pharmacology, therapeutics or ecology, is 'adverse'. Immediately, we notice that a value judgement is required. After all, Lucretius wrote in 50 BC 'What is food to one man is bitter poison to others' (*De Rerum Natura*, book IV, line 637) and therefore the adverse effects of chemicals have been long recognized as nonuniversal. Adrien Albert appreciated that toxicity is often species-selective (Albert, 1951) and, moreover, Charles Darwin understood that 'No-one supposes that all the individuals of the same species are cast in the same actual mould'. This has become an axiom of the field of pharmacogenetics (Idle, 1988). Thus, 'adverse' is, at worst, a subjective, and, at best, a relative, concept. This is one reason why it is desirable to have objective biological indicators of toxic effects, biomarkers that do not depend on a qualification by species, individual or phenotype, but that reflect the interaction between an exogenous chemical and an enzyme, receptor or other biological mediator of toxicity. Such biomarkers may be a sign of changes in gene expression, that is, transcriptomic biomarkers, they may indicate changes in protein expression and/or stability, that is, proteomic biomarkers, or they may reflect fluxes of small cellular metabolites, that is, metabolomic biomarkers. In this chapter we will discuss metabolomic biomarkers of small molecule toxicity and provide an introduction to methods of metabolomic analysis, discuss the short history of metabolomics in toxicology, and present a future perspective of metabolomics in toxicological science.

2 WHAT IS METABOLOMICS?

There are many descriptions of metabolomics and a few definitions to be found in the scientific literature. The situation is complicated by the existence of an apparent rival name, 'metabonomics'. This term was introduced by Jeremy Nicholson and his colleagues at Imperial College London and defined as follows: 'the quantitative measurement of the dynamic multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification' (Nicholson *et al.*, 1999). However, the term has been used almost

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat016
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

exclusively to describe nuclear magnetic resonance spectroscopy (NMR)-based studies, many of which have been carried out by the Imperial College group itself. A more detailed discussion of the two apparently rival terms has been made (Robertson, 2005). In PubMed, citations for 'metabonomics' are only a third of those for 'metabolomics'. Although interchangeable, the two terms appear to mean different things to different investigators, so it is worth clarifying here that the definition of Nicholson for metabonomics equally applies to metabolomics. The attraction of the latter is that the complete set of small molecules in a cell, tissue or organism is usually referred to as the metabolome, and therefore metabolomics would seem to follow logically, as genomics follows the genome or proteomics follows the proteome. Some have proposed the compromise term 'metabolic profiling' (Clarke and Haselden, 2008). Nevertheless, it is not the definition of metabolomics that is important, but its characteristics. A further remark must be made about some of the published studies on NMR-based metabonomics and that is that they do not, in fact, adhere to the definition of metabonomics. Specifically, metabonomics is said to be 'the quantitative measurement of...' and yet, almost invariably, no attempt at quantitation of analytes is made. There is little doubt that the considerable body of NMR-based literature has contributed significantly to the noninvasive and semiquantitative investigation of small molecule toxicity. The message here is that metabolomics should be employed to identify candidate elevated or attenuated biomarkers of chemical toxicity and then these should be evaluated quantitatively outside of the metabolomic platform.

3 LCMS-BASED METABOLOMIC METHODS

Many of the problems inherent in NMR-based metabolomics studies can be overcome through the use of liquid chromatography-mass spectrometry (LCMS). In this case, instead of each high concentration constituent of the biological matrix giving rise to multiple, sometimes overlapping, signals in a highly complex NMR spectrum, each constituent is usually resolved in time as a single peak in a chromatogram that yields an accurate mass and can be subjected to tandem mass spectrometry (MS/MS) that yields unequivocal identities of large numbers of analytes. Such peaks are readily amenable to quantitation. When combined with ultraperformance liquid chromatography (UPLC), MS instrumentation, such as quadrupole–orthogonal time-of-flight mass spectrometry (QTOFMS), can typically yield ~5000 ions in both positive and negative electrospray ionization (ESI) mode. Each of these ions will have a retention time (RT) value (on the UPLC column), a mass-to-charge ratio (m/z value) and an intensity value. Each biological sample analysed may therefore generate 30 000 data points. A typical metabolomic experiment that employs UPLC-ESI-QTOFMS methodologies can easily generate a million data points. Yet, hidden in these data may be a single elevated biomarker. Thus, the need for multivariate data analysis (MDA) methods to reduce the data set to a manageable form.

Figure 1 shows a typical metabolomics protocol in which either humans or laboratory animals are subjected to a '±' sample collection protocol. In one arm of this study blank samples, that is, devoid of experimental chemical exposure, are collected from each individual subject or animal. These might be spot urines, timed urines, blood samples or even saliva, sweat or sebum samples. In the second arm of the study the individual subjects or animals are exposed to a chemical or mixture of chemicals. This might entail administration by mouth of a drug or other xenobiotic, or could involve exposure by inhalation or in the diet. Multiple samples at different time points after either an acute or chronic exposure can be taken. The next phase of the study involves analysis of the samples. Ideally, samples should be labelled and then randomized. For LCMS-based metabolomics, sample preparation requires minimum effort. For urine, addition of acetonitrile, chilling and centrifugation is sufficient to remove any particles and also precipitate and remove proteins. Samples can then be injected into the analytical instrument.

Figure 2A shows a working Waters Q-Tof Premier™ (right) coupled to a Waters Acquity UPLC® (left). The UPLC employs small-particle-size columns, typically 1.7 μm. This permits higher chromatographic resolution, shorter chromatography times and the use of less solvent per sample analysis. A typical UPLC chromatogram will be of 10 minutes duration, with a total of 12 minutes for equilibration, run time and analysis. An equivalent high-performance liquid chromatography (HPLC) run would take of the order of 50 minutes. This improved throughput is essential for metabolomic studies, which can generate very large numbers of samples that may need to be injected both in positive ion (ESI+) and negative ion (ESI−) modes. Exiting from the UPLC column, the eluate is electrosprayed into the mass spectrometer. Many biological molecules form positive and negative ions that are inherently unstable and fragment in the front end of the instrument. Accordingly, attention must be given to voltage settings in this part of the instrument to minimize in-source fragmentation, while permitting a usable ion yield. **Figure 2B** depicts the workings of a QTOFMS instrument. Ions pass through an ion guide immediately preceding initial resolution by a quadrupole. Ions traverse the collision cell, which is used to fragment the ions in MS/MS experiments. Finally, ions enter the time-of-flight chamber, where they are resolved by mass, with a mass accuracy of typically 1–5 ppm. The instrument is capable of acquiring spectra, say from 50–850 Da, at a rate up to 20 per second. Thus, in a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat016

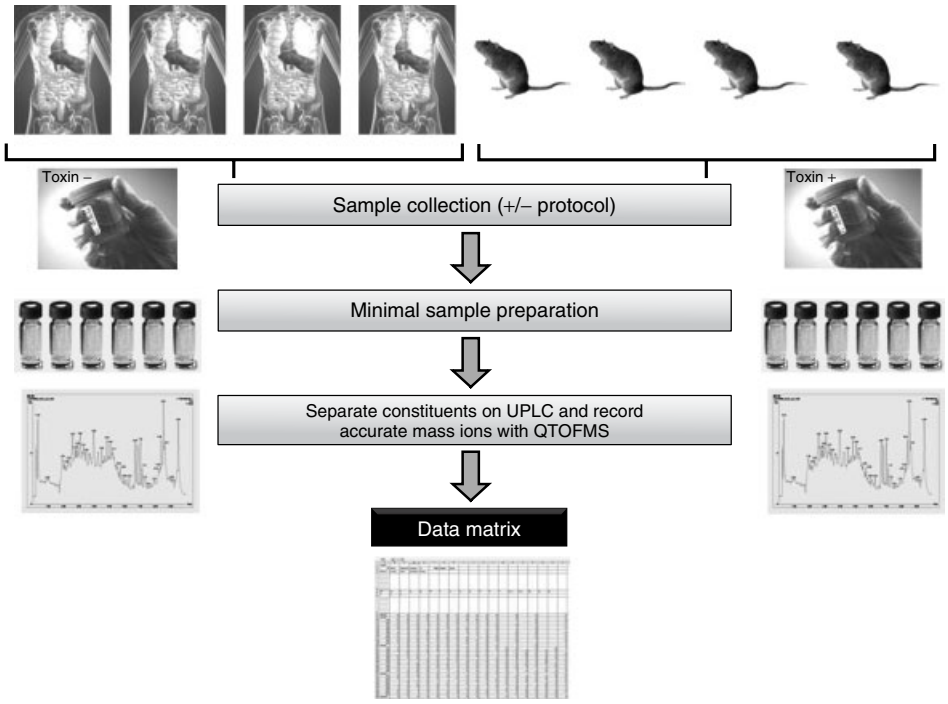

Figure 1 Metabolomics workflow. Biological samples, such as urine, serum, sweat, saliva or sebum, are collected from human subjects or laboratory animals that have been exposed (TOXIN+) or not exposed (TOXIN−) to a small molecular toxicant. Minimal sample preparation and analysis by UPLC-ESI-QTOFMS leads to production of a data matrix of retention time, m/z and ion abundance. The primary objective of a metabolomics experiment is production of this data matrix.

typical 10 minute chromatogram, over 10 000 full spectra can be collected. It is not unusual in a metabolomics experiment with only 20 samples to acquire 5000 negative and 5000 positive ions per sample, thus a total of 200 000 ions. These data are stored in a data table with values of RT, m/z and relative abundance for each ion. The total number of data for this small experiment is thus 600 000. The primary objective of a metabolomics experiment is to produce this data spreadsheet. Since a variable in the data table should correspond to the same ion in all of the samples, the first manipulation of the data is to align the peaks, that is, to ensure as best as possible that the positive ion of, say, $m/z = 116.0711$ (corresponding to proline at a mass error of 0.9 ppm) has an RT = 0.31 min for all samples. This peak alignment procedure, carried out by the instrument software MarkerLynx™, requires the judicious setting of peak width parameters so that the software does not record multiple proline peaks at slightly different RT values. Noise in the data set can also be reduced by means of data scaling, commonly using the Pareto scaling method, whereby the value of each variable is divided by the square root of its standard deviation. Once the aligned and scaled data table is in hand, the data must be analysed using chemometric methods. Therefore, metabolomics first involves analytical chemistry followed by a mathematical solution.

There has been a proposed initiative in the metabolomics field to report, for each experiment, the 'metadata' or information about the experiment as well as to standardize terminology and construct databases for disseminating information to the public (Castle *et al.*, 2006; Fiehn *et al.*, 2006; 2008; Jenkins *et al.*, 2004; Sansone *et al.*, 2007; Scholz and Fiehn, 2007). The metadata includes such details as sample preparation, chromatography and mass spectrometry (MS) conditions, as well as descriptions of data preprocessing and analysis. Based on standards set forth by these groups, the metabolomics standard initiative (MSI) was established such that independent validation of experiments could be conducted and to facilitate the exchange of data (Metabolomics Standards Initiative, 2008; Sansone *et al.*, 2007). With this in mind, each metabolomics experiment should be carefully documented and annotated in as much detail such that the experiment could be reproduced from scratch.

3.1 Quality Control

Before proceeding with the data analysis it highly recommended to inspect visually the chromatograms to ensure that the downstream statistical analyses are robust and reliable. For this purpose a set of standard operating procedures must be established and followed well before entering the data analysis stage. The following are few important suggestions:

DOI: 10.1002/9780470744307.gat016
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

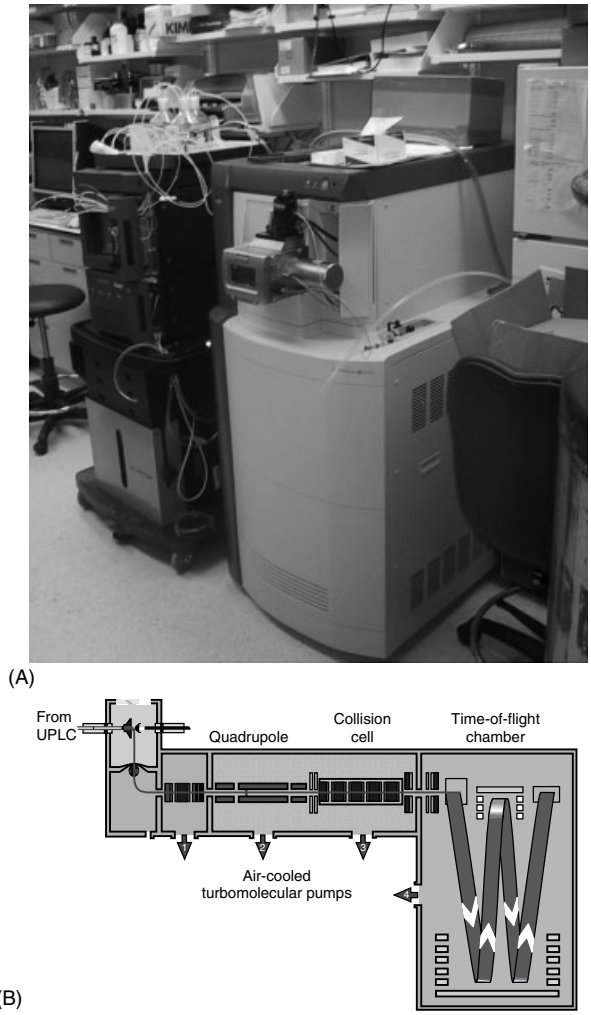

Figure 2 (A) A working UPLC-ESI-QTOFMS. Samples are injected into a Waters Acquity™ UPLC® and the eluant electrosprayed into a Waters Q-Tof Premier™ QTOFMS. (B) Production of ions by electrospray and their resolution by QTOFMS. Ions are first partially resolved by a quadrupole and pass through a collision cell which is used to fragment ions in MS/MS experiments. Ions are resolved by accurate mass and detected with a typical mass error of 1–5 ppm.

1. Inspect the internal standard peak shape and require that its RT is relatively stable across all samples. Other known compounds, such as creatinine in urine, can be monitored similarly. Deconvoluting software will find it difficult to align peak RTs if the chromatography is not consistent and may report missing values when they are indeed present. If these conditions are not met, it may be possible to use relative RT to correct for any chromatography problems.
2. Inspect the intensity of the internal standard and other known compounds. Ensure they are within historical ranges. Reduced sensitivity will hinder investigations looking for low abundance biomarkers and may indicate a need for maintenance of the instrumentation.
3. Investigate the influence of injection order. Ensure samples were properly randomized and that the variability associated with the injection order does not influence the results (Enot *et al.*, 2008).
4. If using instrumentation capable of accurate mass measurements, be sure the reported m/z values have been acquired with acceptable mass error (<10 ppm, preferably <5 ppm). In addition to checking the accurate mass of the internal standard or from a cocktail of compounds, it is wise to also check the accurate mass measurement of compounds known to be contained within a sample. Otherwise it will be exceedingly difficult to identify unknowns based on inaccurate mass measurements. For example, in metabolomic analysis of urine, it is possible to determine the accurate mass of creatinine (Formula = $C_4H_7N_3O$, MW = 113.0589) and calculate the mass error in ppm. Error in ppm can be calculated as follows, where mass_e is the experimental mass and mass_c is the calculated mass:

$$\text{Error in ppm} = \frac{\text{mass}_e - \text{mass}_c}{\text{mass}_e} \times 10^6$$

4 CHEMOMETRICS

If your experiment needs statistics, you ought to have done a better experiment.

Lord Rutherford

The analysis of such huge data sets cannot be accomplished manually. Chemometrics, the application of mathematical or statistical methods to chemical data (Lavine and Workman, 2008), provides a means of extracting useful information from data-rich experiments (Trygg *et al.*, 2007; Wiklund *et al.*, 2008). Chemometric methods of data analysis include the MDA methods of principal components analysis (PCA) and projection to latent structures (PLS). In addition, a new method of increasing popularity is the machine learning algorithm 'random forests'. This has found utility in analysis of DNA microarray data and in proteomic analysis (Barrett and Cairns, 2008; Datta, 2008; Diaz-Uriarte and Alvarez de Andres, 2006; Shi *et al.*, 2005) but shows great potential as a tool for metabolomics.

4.1 Data Matrix and Pre-Processing

In the case of hyphenated techniques such as liquid chromatography coupled with mass spectrometry (LC-MS), it is necessary to generate a data matrix that is suitable for MDA. This process includes deconvoluting and aligning the peaks across all the samples and recording

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat016
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the measured values such as peak area. Both freely available (e.g. XCMS) and commercial (e.g. MarkerLynx™, Waters Corporation) software are useful for data extraction (Smith *et al.*, 2006). Once the data matrix has been populated it is wise to normalize (e.g. divide by an internal standard or cocktail of internal standards, or sum the total ion chromatogram to some arbitrary value) to reduce the influence of sample preparation and instrument variability on the outcome and to improve the overall quality of the data for downstream statistical analysis and modelling (Enot *et al.*, 2008; Sysi-Aho *et al.*, 2007). Additionally, the normality of the data should be inspected given that many statistical methods assume an approximate Gaussian distribution (Steuer *et al.*, 2007). Normalization should be done with great care as it may introduce unwanted artefacts (Sysi-Aho *et al.*, 2007). Additionally it is recommended that the data matrix be inspected for very low or zero values, and while these may be removed using some predetermined criteria, it should be investigated if these values are truly not important. Once the data matrix has been generated and the data is determined to be of sufficient quality, then the next phase of data analysis can be undertaken. This complete data handling process is shown in **Figure 3**.

4.2 Statistical and Data Modelling Approaches

4.2.1 Principal Components Analysis (PCA)

PCA is a so-called unsupervised method of analysis, meaning that manual labels of inputs are not used. Put more simply, if the analysis is one of urine samples from chemically exposed and chemically unexposed animals, classification by exposure is not used in the PCA analysis. PCA is a common and highly popular unsupervised method for analysing metabolomics data, particularly as a 'first pass' analysis to discover important latent variables as well as potential outliers. PCA is a dimension reduction tool permitting the visualization of high-dimension data in, typically, two- or three-dimensional space. PCA works by first finding the maximum variance in the dataset (i.e. the first principal component) and then describes the remaining variance in subsequent, orthogonal components (Eriksson *et al.*, 2006). Information can be obtained by viewing the scores plot (i.e. the samples projected onto principal components) and loadings plot (i.e. the variables influencing the location of the samples in the scores plot) to understand which variables are contributing to the observed group separation

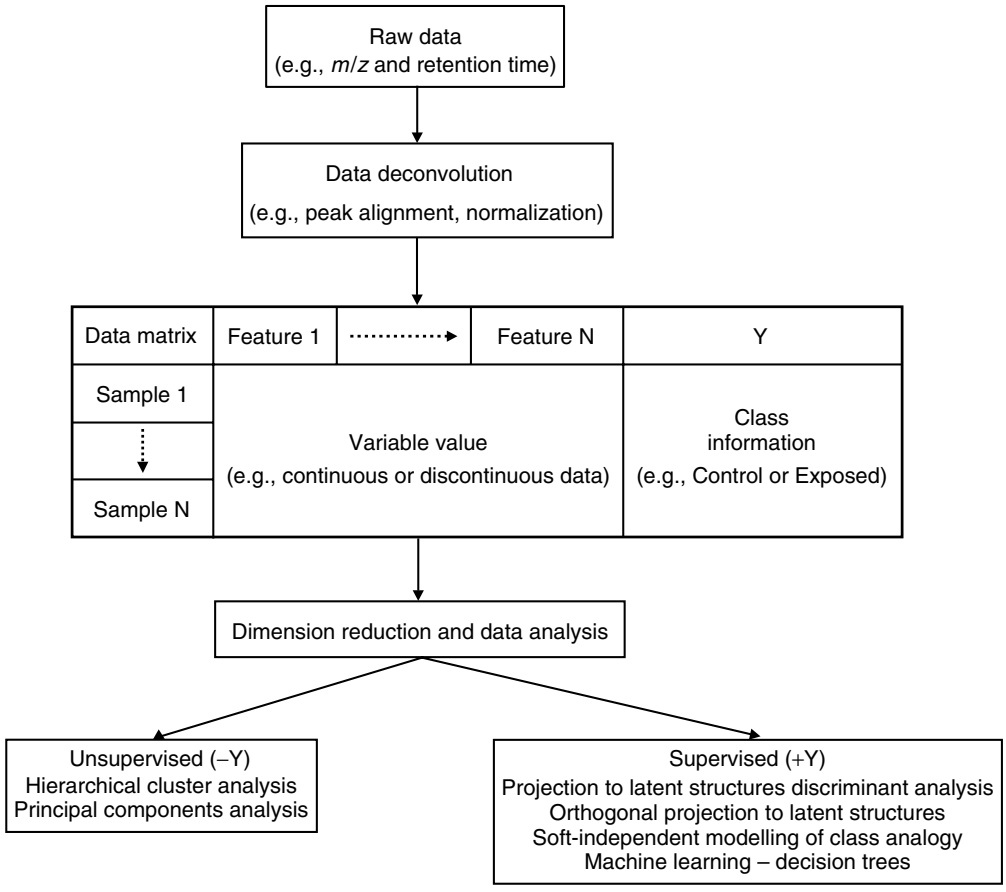

Figure 3 Mathematical and statistical manipulation of the raw data matrix to yield metabolomic solutions. Single ion chromatographic peaks are typically aligned and normalized using the instrument software MarkerLynx™.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat016
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Eriksson *et al.*, 2006). Data modelling and visualization by this method, particularly for MS, requires that the data be scaled in order to cope with the different ranges of input data. Scaling methods such as unit variance (UV), dividing each variable by its standard deviation across the samples, is useful to eliminate the influence of highly abundant variables, and hence those with greater variance, on the resulting model. Other popular scaling methods include Pareto scaling (see above) (van den Berg *et al.*, 2006). It is important to note that scaling is likely to be experiment dependent and that various scaling methods should be investigated. A more detailed description of PCA can be found elsewhere (Trygg *et al.*, 2007)

We will illustrate PCA using data from a very simple experiment whereby four male C57BL/6 mice were allowed access to a normal diet (NIH31 chow) and their urine collected for 24 hours. The mice were then switched to a synthetic diet (AIN-93G) and, after seven days, a second 24 hour urine sample was collected. The samples were analysed according to the protocols in **Figures 1** and **3**. Based upon positive ions, the PCA score scatter plot (or scores plot) for these eight mouse urine samples is shown in **Figure 4A**. It is immediately apparent that the four samples from mice on the normal chow and the four samples from mice on the synthetic chow form two distinct clusters. They have separated

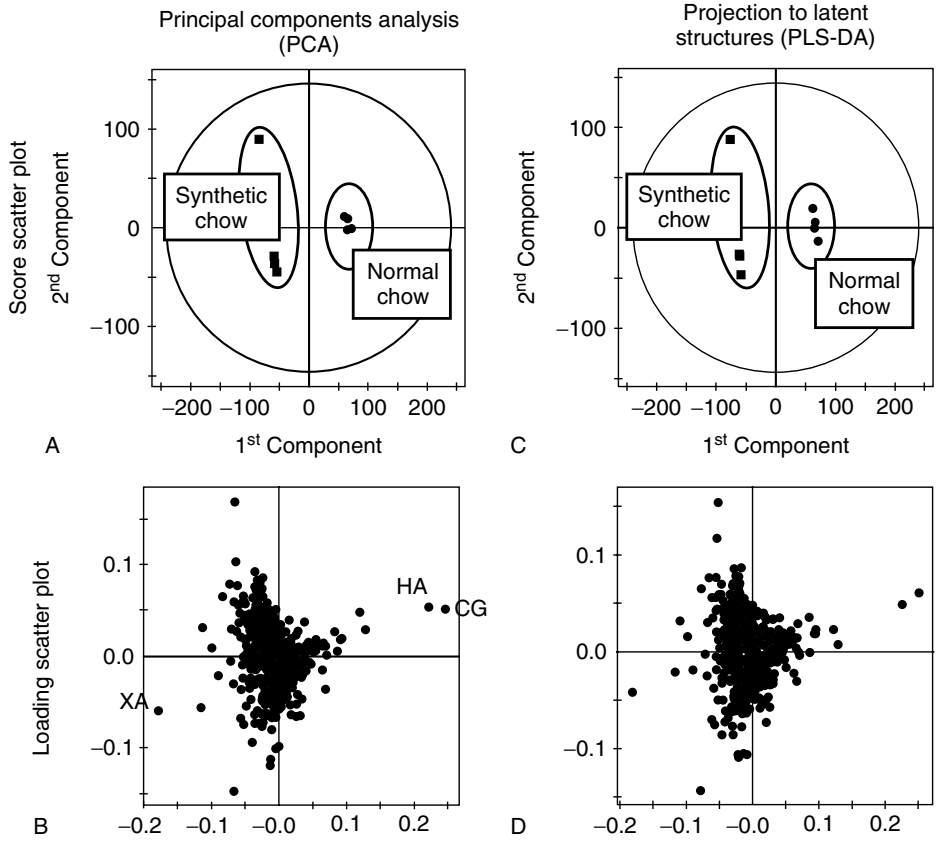

Figure 4 (A) A score scatter plot (scores plot) for a principal components analysis (PCA) of urine from mice fed on a normal chow and then switched to a synthetic chow. Note that the principal variation is encompassed in principal component 1 (*x*-axis). The mean value of the second component is approximately the same for both groups. PCA is an unsupervised analysis, meaning that class information, that is, knowledge of the diet for each sample, is not used in the analysis. (B) A loading scatter plot (loadings plot) for a principal components analysis (PCA) of urine from mice fed on a normal chow and then switched to a synthetic chow. Two principal outliers are associated with the normal chow (CG, cinnamoylglycine; HA, hippuric acid) and one with the synthetic chow (XA, xanthurenic acid). (C) A score scatter plot (scores plot) for a projection to latent structures (PLS-DA) of urine from mice fed on a normal chow and then switched to a synthetic chow. Note that the principal variation is encompassed in principal component 1 (*x*-axis). The mean value of the second component is approximately the same for both groups. PLS-DA is a supervised analysis, meaning that class information, that is, knowledge of the diet for each sample, is used in the analysis to help build a model to separate the classes. Note that this scores plot is virtually identical to the PCA scores plot in Figure 4A because the PCA separation is so good that little supervision using class information (normal vs synthetic chow) is required to give a separation. (D) A loading scatter plot (loadings plot) for a partial least squares discriminant analysis (PLS-DA) of urine from mice fed on a normal chow and then switched to a synthetic chow. Note the same outliers are present as in the PCA loadings plot in Figure 4B.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat016
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in principal component 1 (PC1) but not in principal component 2 (PC2), mean values of PC2 being similar for the two clusters. From this, we can immediately deduce that there are urinary constituents detectable by UPLC-ESI-QTOFMS that are quantitatively, or even qualitatively, different between the two sets of urines. These inbred mice of the same sex and age differed only in their diet, and this was sufficient to yield separation in the PCA scores plot. Exposure to a toxic chemical or mixture of chemicals would surely, therefore, give a similar result. The ions that gave rise to the clustering into distinct metabolomic phenotypes can be seen in the loading scatter plot (loadings plot) in **Figure 4B**. The black data cloud represents the urinary metabolome of male C57BL/6 mice. However, there are some ions that have moved out from this cloud and a shift to the right is associated with the normal chow and a shift to the left with the synthetic chow. The two right-side outliers have masses of 131.049^{+} and 105.034^{+}, corresponding to fragment carbonyl ions from cinnamoylglycine (CG) and hippuric acid (HA; benzoylglycine), respectively. The single left-side outlier has a mass of 206.044^{+}, corresponding to the protonated molecular ion $[M-H^{+}]$ of xanthurenic acid (XA). These three biomarker assignments were confirmed by cochromatography with authentic standards and by tandem MS (data not shown). According to this preliminary metabolomic analysis, switching male C57BL/6 mice from a normal to a synthetic diet causes a decrease in urinary output of CG and HA, and an increased urinary excretion of XA. At this point, it is possible to return to the original UPLC-ESI-QTOFMS chromatograms and verify this finding. **Figure 5** shows an extracted ion chromatogram for the three masses referred to above, both for urine from a mouse that had been fed the synthetic chow for nine days and urine from the same mouse that had previously been fed the normal chow for nine days. These raw data clearly substantiate the metabolomic findings that, out of ~5000 positive ions, three dietary markers emerged. Normal chow is associated with the excretion of these two glycine conjugates of aromatic acids that are derived from gut floral metabolism of the plant metabolite chlorogenic acid (CGA), an ester of caffeic acid (CfA) and quinic acid (QA) (see Section 18.5). The synthetic chow does not contain these precursors of cinnamic and benzoic acids (BAs). XA, in contrast, is not made by the colonic microbiota, but rather is a degradation product of tryptophan (Zhen *et al.*, 2007). Its urinary excretion from the normal chow can be seen from **Figure 5** to be rather meagre. However, the switch to the synthetic diet provokes an approximately 50-fold increase in its urinary excretion, which may represent an increased synthesis of XA, presumably because the synthetic diet is rich in tryptophan. Nevertheless, this simple metabolomics experiment, with PCA analysis, has revealed two diet-dependent distinct urinary metabolomic phenotypes, a 'HA/CG' and a 'XA' phenotype.

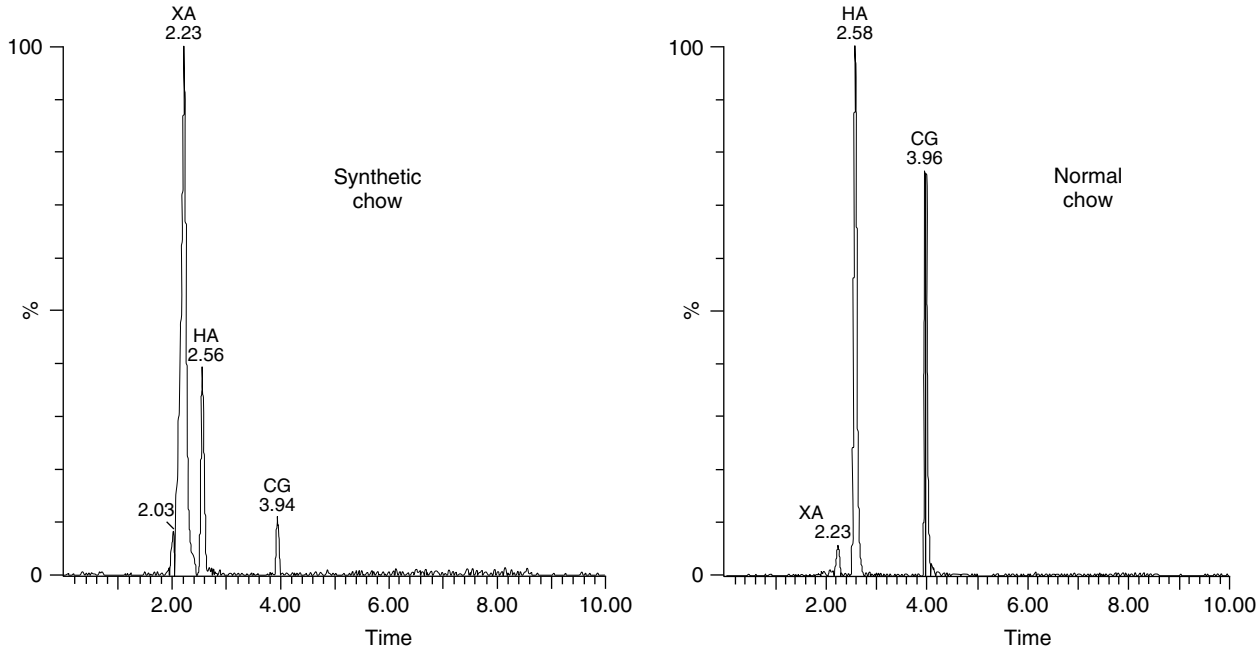

Figure 5 Extracted ion chromatograms for positive ions corresponding to xanthurenic acid (XA), hippuric acid (HA) and cinnamoylglycine (CG). These mass chromatograms confirm the findings of the loadings plots (Figure 4B and D), that XA urinary excretion is low on normal chow, but is highly elevated after switching to the synthetic chow. Additionally, relative urinary excretions of HA and CG are decreased after switching to the synthetic chow, consistent with the metabolomic findings.

4.2.2 Projection to Latent Structures (Partial Least Squares)—Discriminant Analysis

PCA is a simplistic view of the data matrix and, as might be expected, complex datasets may not be well resolved by PCA. Projection to latent structures-discriminant analysis (PLS-DA) is a supervised method where user-provided class information is employed to maximize the class separation in the model. It can be a useful approach to uncover latent variables (from the loadings) and can be used to classify new input samples. As in PCA, information can be obtained by inspecting the scores and loadings plot. However, using the scores plot may be misleading and, instead, class predictions may be a worthwhile substitute (Westerhuis *et al.*, 2008). Like PLS-DA, orthogonal PLS-DA (orthogonal projection to latent structures-discriminant analysis (OPLS-DA)) is a supervised method, but unlike PLS-DA, OPLS-DA concentrates the intended class variation into the first component and places the unwanted variation, or noncorrelated variation, into the subsequent components (Johan Trygg, 2002). However, these approaches are powerful and are likely to model noise, making the interpretation of these models difficult (Westerhuis *et al.*, 2008). It is therefore essential that the models are properly validated by permutation tests or other cross-validation methods. Ideally, the data should be split into training and test sets, but, as is common with most metabolomics studies, sample number is often small making this validation method difficult.

The utility of PLS-DA supervised analysis can be demonstrated using the same data set as was used for the PCA analysis above. **Figure 4C** shows that the PLS-DA scores plot is virtually identical to the PCA scores plot in **Figure 4A**. This is because the separation by PCA is so good that little model building by PLS-DA is required. In addition, the PLS-DA loadings plot in **Figure 4D** is virtually identical to the PCA loadings plot in **Figure 4B**, with the same three biomarkers being identified. However, there is one last data manipulation that is possible and that is production of a loadings S-plot from the PLS-DA model, shown in **Figure 6**. The S-plot has a unique feature not found in the regular loadings plots (**Figure 4B** and **D**) and that is the depiction of relative abundance of the ion on the *x*-axis and the fit to the PLS-DA model on the *y*-axis. Careful inspection of this S-plot reveals that there are a number of lower abundance ions with almost a perfect fit to the model. These ions will be tightly associated with either the normal chow (top right) or the synthetic chow (bottom left) and, once identified, they are likely to reveal the effects of switching the diet on the metabolism of the mouse. In stark contrast, the two ions marked with arrows, while appearing to be outliers and therefore of interest, are actually poorly correlated to the PLS-DA model and are therefore not worthy of further investigation.

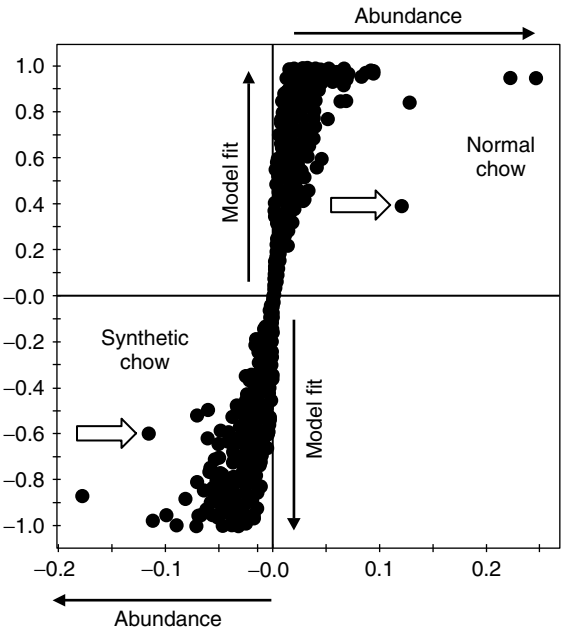

Figure 6 A loadings S-plot from a PLS-DA model of the urinary data from mice maintained on normal chow and then switched to a synthetic chow. This type of data presentation shows ion abundance (*x*-axis) vs goodness of fit to the PLS-DA model (*y*-axis). The same outliers are present as in PCA and PLS-DA loadings plots (Figure 4B and D) in the normal chow quadrant (upper right; CG and HA) and the synthetic chow quadrant (lower left; XA). Note that the arrowed markers, while clearly outliers, are poorly correlated to the PLS-DA model, that is, the difference between normal and synthetic diets.

4.2.3 Random Forests Machine Learning Algorithm

In order to expand and improve the sensitivity of discovery efforts, analytical tools that are less prone to over-fitting are positive additions to any metabolomics programme. Random forests, a machine learning algorithm, is useful in this regard and is freely available for use in the R software environment (http://cran.r-project.org). The random forests algorithm builds an ensemble of decision trees using the classification and regression tree method (Breiman, 1984). The algorithm is simple to deploy, and, unlike PLS-DA and OPLS-DA, overparameterization is relatively rare (Breiman, 2001; Enot *et al.*, 2006; 2008). Additionally, random forests easily handles high-dimensional data and can incorporate additional data points (e.g. clinical data, gene expression) into the analysis. The output is easily interpreted as it gives ranked estimates of the most important variables that can be displayed as box plots. However, the rankings of the top variables can vary slightly, so it is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat016
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

advisable to run multiple ($n = 25$) random forests iterations and keep track of those consistently top-ranked variables. Furthermore, features of the random forests, such as the proximity matrix, can be used to display graphically the similarities and dissimilarities existing in the data set (e.g. multidimensional scaling (MDS) plots).

The utility of random forests can be demonstrated with a data set of the same four male C57BL/6 mice maintained on normal chow and four male DBA mice housed and fed similarly. **Figure 7** shows the MDS plot after the eight urine samples were analysed in ESI+ mode by UPLC-ESI-QTOFMS and the data table subjected to random forests analysis. A clear segregation of the two strains of mice was obtained. The difference between these samples is due to genetic and not environmental factors. This analysis also produces a list of ions that most varied between the two groups (data not shown) and this can be employed in the normal manner for biomarker discovery (see Section 18.4.3).

4.2.4 Self-organizing Maps

The metabolome, unlike the genome, transcriptome or proteome, is poorly annotated, making final structural determination a difficult and time-consuming task. While methods such as PCA, PLS-DA, OPLS-DA and random forests are useful for data modelling and for defining the most important variables associated with each class, they are not useful for providing a global view of the metabolome. The self-organizing map (SOM) algorithm is useful in this regard because it can present the metabolomic data in a manner that is visually appealing and intuitive (Kohonen, 2001). Moreover, simple comparisons can be made among samples without the need for any metabolite identification. SOMs are not widely used in metabolomics analysis but they have been applied to metabolomic studies of *Arabidopsis*, diabetes and ionizing radiation (Hirai *et al.*, 2005; 2004; Makinen *et al.*, 2008; Patterson *et al.*, 2008).

Gene expression dynamics inspector (GEDI) is one example of a software package that can be used for analysis and visualization of patterns in metabolomic data matrices (Eichler *et al.*, 2003). This software was developed originally for the interpretation and visualization of gene expression data. Its utility as a tool in metabolomics investigation has recently been realized (Patterson *et al.*, 2008; Tyburski *et al.*, 2008). GEDI creates a two-dimensional heatmap-like mosaic of coloured tiles for each sample based on the SOM algorithm. Additionally, GEDI can compute 'average' mosaics in order to identify common patterns within each group. The complete GEDI program package can be found at http://www.childrenshospital.org/research/ingber/GEDI/gedihome.htm.

The utility of GEDI SOMs can be seen in **Figure 8**. This represents in each window a holistic view of the male C57BL/6 mouse urinary metabolome and the effect of diet on it. What is clear is that the representations illustrated by PCA and PLS-DA loadings plots (**Figure 4**), and even in the PLS-DA loadings S-plot (**Figure 6**), do not give the fullest picture of the effect of diet change on the urinary metabolome of these mice. On average, each of the 247 tiles in this 19×13 mosaic contains 20 ions. Deep red indicates high abundance and deep blue low abundance, with shades of red, orange, yellow, green and blue in between. A large

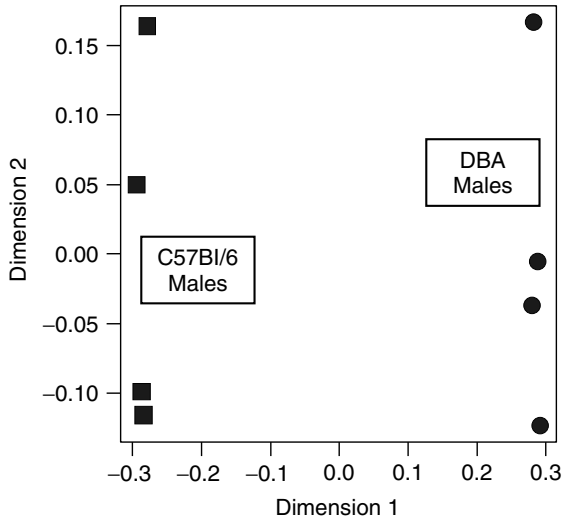

Figure 7 Multidimensional scaling (MDS) plot derived from a random forests analysis of mouse urine from four male C57BL/6 mice and four male DBA mice, all maintained on normal chow. This clear separation is due to genetic and not environmental differences.

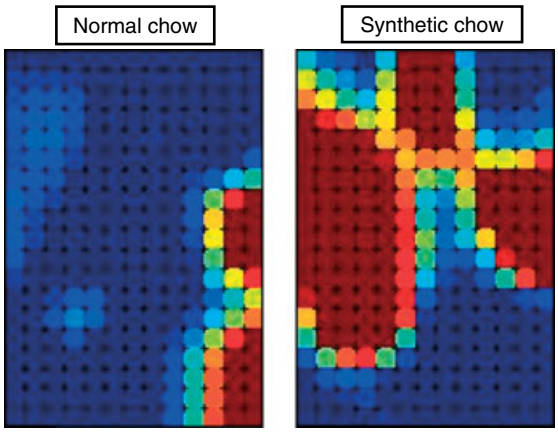

Figure 8 GEDI self-organizing maps (SOMs) giving a holistic view of the mouse urinary metabolome and how it changes in response to diet. Each tile in the mosaic contains approximately 20 ions. Colour indicates abundance of ions—deep blue for low abundance to deep red for high abundance. These heat maps have shades of red, orange, yellow, green and blue in between. Note that a significant proportion of the urinary metabolome 'heats up' after changing to the synthetic chow, indicating an increased urinary excretion of analytes.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat016
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

proportion of the urinary metabolome 'heats up' on changing from a normal to a synthetic diet, with a small area (bottom right) 'cooling down'. Returning to the PCA and PLS-DA loadings plots in **Figure 4B** and **D**, the same phenomenon is now apparent, with the lopsided shift of the urinary metabolome towards the synthetic chow side (left). Understanding which ions covary under different conditions will be useful for metabolic pathway construction.

4.3 Biomarker Solution

Anonymous ions are not biomarkers, they are the footprints of biomarkers. Each m/z value still needs to be translated into a physical chemical entity. Unlike the preceding parts of the metabolomic process, there is relatively little computational or bioinformatics assistance to be had with this process. However, there are some useful databases, but in the processing of ions into chemicals, this is where the bottleneck lies. In addition, provisional biomarkers require confirmation with authentic standards, which may or may not require chemical synthesis. Two principal factors determine the degree of difficulty of biomarker solution: (i) the m/z value and (ii) the mass error in the estimation of m/z. The larger the value of m/z and the bigger the error, the greater number of empirical formulae are possible. Discussed below are a number of tools that aid conversion of an accurate mass (m/z value) into candidate empirical formulae and then candidate biomarkers.

4.3.1 Seven Golden Rules

Even the use of instrumentation such as a Fourier-transform ion cyclotron mass spectrometer (FT-MS) or an Orbitrap mass spectrometer, that can routinely give ultrahigh mass accuracies of <1 ppm, is insufficient for calculating unique empirical formulae without resort to the use of isotope ratio data (Kind and Fiehn, 2006). To assist in this process, the Metabolomics Fiehn Laboratory at the University of California (Davis) has a description of a useful piece of downloadable software called Seven Golden Rules on its web site (http://fiehnlab.ucdavis.edu/projects/Seven_Golden_Rules). Examples of its use and a full account of its functionality have been published (Kind and Fiehn, 2007). Unlike many other tools, Seven Golden Rules employs heuristic filtering of molecular formulae, eliminating those that match the accurate mass, but that (i) contain elements other than C, H, N, O, S and P, (ii) do not obey certain chemical rules regarding orbitals and valency, (iii) have incorrect M, M + 1, M + 2 isotope patterns, (iv) have C to H ratios outside of the range 0.125–3, (v) have inappropriate ratios of C to N, O, P and S, that (vi) contain multiple high-element counts, such as $C_{26}H_{28}N_{17}O_1P_3S_8$ (which would pass the other rules) and (vii) yield improbable formula once trimethylsilyl groups have been subtracted. This last rule applies only to metabolomic studies performed by GC-MS (gas chromatography coupled with mass spectometry), where polar protons are frequently replaced by trimethylsilyl groups [$(CH_3)_3$-Si-] by chemical derivatization. These are the Seven Golden Rules. Isotope ratios are particularly important and these same authors have reported that even a mass accuracy of 0.1 ppm is insufficient to derive an empirical formula for masses >185.9760 Da when the elements C, H, O, N, S and P are included in the search (Kind and Fiehn, 2006). A surprising and important finding during the development of this software was that correct isotope ratio measurement was more important than mass accuracy (Kind and Fiehn, 2007).

4.3.2 Madison Metabolomics Consortium Database (MMCD)

Madison Metabolomics Consortium Database (MMCD), which is maintained by the National Magnetic Resonance Facility at Madison, is a resource for metabolomics research based on NMR spectroscopy and MS. The goal of the MMCD has been to support high-throughput NMR and MS approaches to the identification and quantitation of metabolites present in biological samples (Cui *et al.*, 2008). This web site (http://mmcd.nmrfam.wisc.edu) permits an accurate mass to be entered, together with a mass error value and will seek to solve the formula of protonated ($[M+H]^+$) and deprotonated ($[M-H]^-$) molecular ions, together with Na^+, K^+ or NH_4^+ adducts. Solutions are presented as hits in databases such as PubChem (http://pubchem.ncbi.nlm.nih.gov), Chemical Entities of Biological Interest (ChEBI) (http://www.ebi.ac.uk/chebi), Kyoto Encyclopedia of Genes and Genomes (KEGG) (http://www.genome.jp) and the Human Metabolome Database (HMDB; http://www.hmdb.ca). This is a very useful means of identifying endogenous molecules based upon accurate masses.

4.3.3 ChemSpider

Providing access to millions of chemical structures and integration into a multitude of other online services, ChemSpider is the richest single source of structure-based chemistry information, with almost 20 million chemical structures (http://www.chemspider.com). Using the tool 'properties search' in ChemSpider it is possible to input an accurate mass, set a mass error limit and adjust the mass by the addition or subtraction of hydrogen and electrons, to allow for protonated and deprotonated molecular ions. Unlike Seven Golden Rules and MMCD, it is currently not possible to allow for adducts with sodium and so on. However, the databases used by ChemSpider contain over 60% of all

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat016
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

chemical entities ever synthesized, so this is nevertheless an extremely valuable resource for solving protonated and deprotonated molecular ions. That notwithstanding, many biological molecules may evade solution even with ChemSpider. For example, the vitamin E component α-tocopherol is excreted in urine as the β-D-glucuronide of α-carboxyethyl hydroxychroman (α-CEHC) (Pope *et al.*, 2002), which has an empirical formula of $C_{22}H_{33}NO_{10}$ and a protonated molecular ion of $m/z = 472.2183$. Searching this mass in ChemSpider at mass tolerances of 10, 5, 1 and 0.1 ppm yielded 1134, 282, 128 and 7 hits, respectively, none of which was α-CEHC glucuronide.

4.3.4 Lipid Mass Spectrometry Prediction Program

This is a small program that can be downloaded from LIPID MAPS (http://www.lipidmaps.org). This software permits input of accurate masses with mass tolerances of $\pm$0.1, 0.2, 0.5 and 1.0 amu (Da) for the following lipid classes, glycerophospholipids, glycerolipids, cardiolipins, sphingolipids, fatty acids and cholesterol esters. In addition, a variety of modified molecular ions can be specified, for example, $[M+H]^+$, $[M+Na]^+$, $[M+K]^+$, $[M+NH_4]^+$, $[M-H]^-$ and $[M.Cl]^-$. This is a very useful tool for analysing metabolomic data from serum or plasma. Target lipid biomarkers can then usually be purchased from Avanti Polar Lipids (http://www.avantilipids.com), the supplier of authentic standards to LIPID MAPS.

4.3.5 MassTRIX

Apparently, MassTRIX, an online tool for annotating metabolites, stands for mass translator into pathways and is housed on servers at the Helmholtz Zentrum, München (http://mips.gsf.de/proj/metabolomics/index.html). It is possible to paste in a list of ions, perhaps the top 100 hits from random forests or OPLS-DA, nominate a mass error of 0.1, 0.2, 0.5, 1.0, 2.0, 3.0 (default), 4.0 or 5.0 ppm, choose a KEGG database to search, choose one of a huge number of species from which your experimental data were derived and, if necessary, restrict the search to a particular list of KEGG metabolic maps or KEGG enzymes. The job runs in the background on your browser and will usually take over one hour to complete. The output should be a list of positive hits for endogenous compounds, which can be viewed in their respective KEGG metabolic maps. This tool is useful for starting to build a systems biology view of the problem under investigation. A fuller description has been published (Suhre and Schmitt-Kopplin, 2008).

4.3.6 Common Sense, the Human Expert System

It is a regular experience that the above tools can yield biomarker solutions to exact masses that, when passed through a human expert system, are clearly nonsense. Such examples include simple esters of carboxylic acids, halogenated compounds, cyano compounds, *N*- and *O*-ethyl, isopropyl, butyl, isobutyl, and so on, compounds. Many other types of chemicals are biologically implausible. A human expert system that applies a biochemical common sense to the solutions obtained is an absolutely essential component of the biomarker solution process. Finally, when all these hoops have been passed, the final question is availability of the compound. A search of the Sigma-Aldrich catalogue (http://www.sigmaaldrich.com) is a first step, then other suppliers, as found in ChemExper (http://www.chemexper.com). Failure to find a supplier of the authentic compound naturally leads to chemical synthesis.

4.3.7 Quantitative Studies

As mentioned in Section 18.2, historical metabolomic studies have very often failed to quantitate biomarkers that are reported as being 'elevated', 'raised' or 'decreased' in certain biological circumstances. We believe that, wherever possible, it is important that metabolomics yields quantitative data as well as a qualitative solution to biological problems such as in toxicology, for example. Metabolomics is therefore useful for identifying candidate biomarkers, which then need to be confirmed by tandem MS methods against authentic standards. Then the job is done and investigators may leave the metabolomics platform and carry out standard analytical chemical determinations of concentrations of the confirmed biomarkers in the appropriate biological samples, for example, urine or tissue extracts of animals exposed to toxicants vs unexposed, or from exposed transgenic mice and control wild-type mice. Knowing the quantitative, as well as the qualitative, biochemical changes that are provoked by the toxicant at the organ level provides a more solid foundation for discerning mechanisms of toxicity. Where urine has been the biological matrix of choice, it is prudent to normalize excretions as μmol mmol^{-1} creatinine, unless the study involves a change in protein intake, alteration of renal function, or some other variable that would *per se* alter the creatinine output, in which case a mole quantity should be quantitated from a 24 hour timed urine collection.

5 PITFALLS IN METABOLOMIC STUDIES

There are many pitfalls to be aware of when conducting a metabolomics study. Even when using a single inbred strain of mouse, it is possible to introduce experimental

Table 1 Confounding variables in metabolomic studies

Confounding factor	Rationale
Diet	The influence of diet on the metabolome is well documented and has been reported in both animal (Fardet *et al.*, 2007; Fearnside *et al.*, 2008; Gu *et al.*, 2007; Phipps *et al.*, 1998) and human (Assfalg *et al.*, 2008; Gu *et al.*, 2007; Lenz *et al.*, 2004; Rezzi *et al.*, 2007; Stella *et al.*, 2006; Walsh *et al.*, 2006; Zeisel, 2007) studies. While not always possible and/or feasible with human studies, metabolomic investigations with animals should be strictly controlled for diet such that control and disease/treated animals are receiving matched diets. Purified diets, or in the case of humans, precollection diets, may be useful for eliminating or reducing metabolomic 'noise' associated with plant-based diets (Walsh *et al.*, 2007).
Gut microbiota	An often overlooked and underappreciated contributor to the host metabolome is the gut microbiota (Martin, 2007; Martin *et al.*, 2007; Robosky *et al.*, 2005; Robosky *et al.*, 2006; Turnbaugh *et al.*, 2006; Wang *et al.*, 2004). The gut flora population numbers near 10^{13} bacteria and estimates suggest that there may be anywhere from 500 to 1000 different species of bacteria present in the human gut (Backhed *et al.*, 2005). There is nearly 10 times the number of bacteria compared to all the somatic and germ cells in humans, and remarkably, the gut flora contains nearly 100 times the number of genes present in the human genome (Xu and Gordon, 2003). Particular care should be taken to ensure that animal models have similar complements of gut microbiota.
Age Gender Genetic background Environment	Metabolomic profiles are strongly influenced by diurnal variation, age, gender, genetic background and other environmental stimuli (Bollard *et al.*, 2001; Fearnside *et al.*, 2008; Goodacre, 2007; Lutz *et al.*, 2006; Plumb *et al.*, 2003; Plumb *et al.*, 2005; Rock *et al.*, 2007; Slupsky *et al.*, 2007; Williams *et al.*, 2005). Urine collection from animals in metabolic cages may induce unwanted stress associated with isolation and handling (Bollard *et al.*, 2001). These factors must be extremely well-controlled and their potential influence on the metabolomic outcome understood before conducting any metabolomic investigation.

confounders. A list of potential confounders is given in **Table 1**. A major consideration is diet and its impact on the gut microbiota. It has already been ably demonstrated in **Figures 4–6** and **8** that the composition of the diet can radically affect the urinary metabolome, for example. In major part this is due to the cooperation of the gut microbiota, which contributes significantly to the host metabolome. This process is worthy of consideration in further detail because of its potential impact on the raw data of experiments and the interpretations made from them. **Figure 9** shows the relationship between just one small aspect of plant metabolism, the catabolism of phenylalanine and both host and gut microbiota metabolism. Plants synthesize *trans*-cinnamic acid (CnA) from phenylalanine (Phe). This is converted through *p*-coumaric acid (CmA) and *p*-coumaroyl-CoA (Cm-CoA) to CGA or alternatively through CfA and caffeoyl-CoA to CGA. Dietary CGA passes through the gut where it is metabolized by colonic microbiota to CfA and QA. The QA is aromatized through cyclohexane carboxylic acid (CHCA) to BA. The CfA is metabolized by gut microbiota to CnA and phenylpropionic acid (PPA). These end-products of bacterial metabolism are absorbed and are all are reconciled in the liver as BA, conjugated with glycine and excreted in urine as HA, giving rise to the 'HA phenotype'. However, in the small intestine, CGA may be absorbed and converted in the liver and kidneys to CfA and QA, and further to ferulic acid (FA), protocatechuic acid (PcA), then to vanillic acid (VA). These catechol acids (CfA, FA, PcA and VA) are excreted in urine as sulfate and glucuronic acid conjugates and this comprises the 'chlorogenic acid metabolite phenotype' ('CGAM phenotype'). Thus, the HA phenotype is indicative of gut microbiota metabolism and the CGAM phenotype of host hepatic and renal metabolism.

When conducting metabolomics studies in humans there is much less control over the potential confounding variables listed in **Table 1**. However, for metabolomics to be a useful tool it needs to work in human populations, not just for inbred strains of laboratory animals. Targeted determination of metabolites in relation to human health and disease has been the highly successful activity of clinical chemistry departments in hospitals the world over. The practice of clinical chemistry dates back

to nineteenth-century Germany, with the evolution of simple tests for constituents of blood and urine. Today, there are of the order of 500+ discrete chemical tests that can be performed on human biological matrices for the purpose of diagnosis. However, as a research tool, small molecule biochemistry has been eclipsed for some decades by the pursuit of macromolecules, in particular DNA and proteins. This was not always the case and the contribution of small metabolite profiling to human health has been discussed elsewhere (Idle and Gonzalez, 2007). In 1971, Evan and Marjorie Horning, from Baylor College of Medicine in Houston, published an account of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

metabolic profiling of urinary organic acids and steroids, which stated, 'In essence, "metabolic profiles" are multicomponent GC analyses that define or describe metabolic patterns for a group of metabolically or analytically related metabolites" (Horning and Horning, 1971). In the same year, a second paper on urinary profiles of organic acids was published (Mamer *et al.*, 1971). Metabolic profiling, in particular, for urinary organic acids and amino acids, has been common practice in the diagnosis of inborn errors of metabolism, since these early pioneering studies. Metabolomics, on the other hand, is not biased towards one or more chemically related groups of analytes, such as organic acids. There is no reason, however, why metabolomics should not provide at least the same quality of insight as targeted metabolic profiling that has been used for decades by clinical chemistry laboratories. Obviously, interindividual differences in diet and the gut microbiota will play a major part in determining the metabolome of different human subjects, but it is anticipated that this higher level of background metabolic noise should not disguise the potent metabolic signals that derive from pathological states.

6 METABOLOMICS AND SMALL MOLECULE TOXICITY

Chemical toxicity frequently has a metabolic component. The classical chemicals in this regard are the so-called genotoxic carcinogens. Recognition that polycyclic aromatic hydrocarbon, nitrosamine and heterocyclic amine carcinogens required metabolic activation by host enzymes in order to react chemically with nucleic acids and proteins has been one of the great milestones in cancer research. Perhaps the central metabolic contribution to toxicology is detoxication, the rendering of molecules less toxic, more water soluble and readily excretable by metabolic processes commonly referred to as 'drug metabolism' (Williams, 1963). So, drug metabolism plays a major role in determining plasma, urine and target organ concentrations of chemical toxicants and their metabolites, which may or may not harbour biological activity. Metabolomics is able to offer a means to uncover metabolites of chemical toxicants in various biological matrices and also biomarkers of the biological responses of tissues to such toxicants.

6.1 Metabolomic Biomarkers of Tissue Response to Small Molecule Toxicants

6.1.1 Studies Using NMR

Virtually all the original studies were performed using NMR under the rubric of metabonomics. Studies up to 2002 have been comprehensively reviewed in the context of the 'development of high throughput toxicity screening systems for lead candidate selection' by the pharmaceutical industry (Shockcor and Holmes, 2002). A huge amount of compendia data has been catalogued. A summary of the data up until 2002 is given in **Table 2**. This clearly shows that there are no more than about 30 specific metabolomic biomarkers that were detected by NMR and that these were described as being elevated, decreased or unchanged, in relation to various toxic stimuli. The commonest findings reported in these studies were: (i) decreased levels of citric acid, creatinine, 2-oxoglutaric acid, HA and succinic acid or (ii) increased levels of creatine, taurine, acetic acid and glucose. Robertson has reported a list of 11 'usual suspects', comprising the aforementioned list plus lactic acid and trimethylamine/trimethylamine *N*-oxide (TMAO) (Robertson, 2005). It would seem that NMR-based metabolomic studies of liver and kidney toxicity (primarily) have a rather limited perspective on the metabolome. It is worth noting that the 11 'usual suspects' are among the highest abundance analytes in urine and could probably be detected by techniques much less sophisticated than high-field NMR. The purpose of using a $500 000 MS platform in metabolomic investigations is precisely to get as broad a coverage of the metabolome as possible. There have been reports, however, that contradict the foregoing reports of studies with a high yield of unusual biomarkers that are revealing of mechanisms of toxicity. A good example is the hepatotoxicity of hydrazine in the rat (Nicholls *et al.*, 2001). Analysis of urine from hydrazine-dosed rats revealed decreases in hippuric, citric, succinic, 2-oxoglutaric and fumaric acids, together with creatinine and TMAO (except for fumaric acid, all from the 'usual suspects' (Robertson, 2005)). In addition, urinary taurine, creatine, threonine, *N*-methylnicotinic acid, β-alanine, lactic acid, 2-aminoadipic acid, citrulline, $N\alpha$-acetylcitrulline and arginosuccinate (only 3/10 were 'usual suspects') were all elevated. In plasma, glycine, alanine, isoleucine, valine, lysine, arginine, tyrosine, citrulline, 3-D-hydroxybutyric acid, creatine, histidine and threonine were all elevated. Presumably, this increased flux of amino acids reflects proteolysis in the liver arising from necrosis and apoptosis. The most interesting finding in this report was the elevated levels of 2-aminoadipic acid, a lysine degradation product (http://www.genome.ad.jp/dbget-bin/show_pathway?map00310+C00956). Moreover, citrulline is a degradation product of the amino acids arginine and proline (http://www.genome.ad.jp/dbget-bin/show_pathway?map00330+C00327) and also an intermediate in the urea cycle, which produces arginine and fumaric acid by arginosuccinate lyase (EC 4.3.2.1; http://www.genome.ad.jp/dbget-bin/show_pathway?map00220+4.3.2.1). Collectively, these findings are consistent with an increased protein and nitrogen turnover due to hepatic necrosis and apoptosis. It was proposed by

Table 2 Metabolomic biomarkers in relation to organ toxicity of small molecule toxicants

NMR biomarker	Up or down	Toxicity (see footnotes)
Citric acid	↓	A, AA, ANIT, CC, CT, DCVHC, HCB, LA, MC, PAP, P, PA, SC, SF, TCTFP, TA, UN
Citric acid	↑	CP, DCVC
Creatine	↑	A, AA, CC, CT, G, H, LA, PA, TA
Creatinine	↓	DCVHC, HCB, H, MC, PAP, P, SF, TCTFP, UN
Taurine	↑	A, AA, BHT, CT, E, G, LA, PA, TA
2-Oxoglutaric acid	↑↓	A, PI
2-Oxoglutaric acid	↓	AA, ANIT, CT, DCVHC, E, G, HCB, LA, MC, PAP, PA, SC, SF, TCTFP, UN
Lactic acid	↑	AA, CP, IFO, LA, P
Phenylacetylglycine	↑	AA, AM, CQ
N-Methylnicotinamide	↑	AA
N-Acetylglycine	↑	BE, CE, PI
Acetic acid	↑	ANIT, DCVHC, G, HCB, LA, MC, PAP, PA, SF, TCTFP, TA, UN
'Bile acids'	↑	ANIT, G
Dimethylglycine	↑	AM, BE, CE, CQ
Glucose	↑	ANIT, BHT, CC, CF, CP, CPT, DCVHC, E, HCB, IFO, LA, MC, PAP, P, PA, SC, SF, TA, TCTFP, UN
Hippuric acid	↓	ANIT, CF, CP, CPT, DCVHC, G, HCB, H, IFO, LA, MC, PAP, P, SC, SF, TA, UN
Succinic acid	↑↓	BE, CE
Succinic acid	↑	DCVC
Succinic acid	↓	ANIT, CT, DCVHC, G, HCB, LA, MC, PAP, SF, TCTFP, TA, UN
Adipic acid	↑	BE, CE
Glutaric acid	↑	BE, CE
Alanine	↑	CP, PA
Trimethylamine *N*-oxide	↑↓	BE, CE, PI
Trimethylamine *N*-oxide	↑	IFO, PA, TA
Trimethylamine *N*-oxide	↓	H
Glutamine	↑	CP
Glycine	↑	CP, IFO
'Amino acids'	↑	DCVHC, HCB, MC, PAP, P, SF, TCTFP, TA, UN
'Organic acids'	↑	DCVHC, G, HCB, MC, PAP, P, SF, TCTFP, TA, UN
Betaine	↑	G
Urocanic acid	↑	G
2-Aminoadipic acid	↑	H
β-Alanine	↑	H
Fumaric acid	↓	H
Histidine	↑	IFO
N-Acetylcitrulline	↑	H
'β-Hydroxybutyric acid and other ketone bodies'	↑	IMI
'*N*-Acetyls'	↑	LA
Valine	↓	P
Formic acid	↑	PA
'Macromolecules'	↑	PA
Threonine	↑	SF
Urea	↑	UN

Abbreviations of toxicant (tissue or process): A = adriamycin (heart, kidney), AA = allyl alcohol (liver), AM = amiodarone (lung), ANIT = α-naphthylisothiocyanate (liver), BE = 2-bromoethanamine (kidney, mitochondrial dysfunction), BHT = butylated hydroxytoluene (liver), CC = cadmium chloride (testis), CT = carbon tetrachloride (liver), CF = cefoperazone (unspecified), CP = cephaloridine (unspecified), CPT = cephalothin (unspecified), CE = 2-chloroethanamine (kidney, mitochondrial dysfunction), CQ = chloroquine (liver), DCVC = *S*-(1,2-dichlorovinyl)-L-cysteine (kidney), DCVHC = *S*-(1,2-dichlorovinyl)-L-homocysteine (kidney), E = ethionine (liver), G = galactosamine (liver), HCB = hexachlorobutadiene (kidney), H = hydrazine (liver), IFO = ifosfamide (unspecified), IMI = imipenem (kidney), LA = lead acetate (liver, lung, kidney), MC = mercuric chloride (kidney), PAP = *p*-aminophenol (kidney), P = paraquat (kidney, lung), PI = propyleneimine (kidney), PA = puromycin aminonucleoside (kidney), SC = sodium chromate (kidney), SF = sodium fluoride (kidney), TCTFP = 1,1,2-trichloro-3,3,3-trifluoro-1-propene (kidney), TA = thioacetamide (liver, kidney), UN = uranyl nitrate (kidney). Adapted from published data (Shockcor and Holmes, 2002).

the authors (Nicholls *et al.*, 2001) that this elevated 2-aminoadipic acid results in a reduction of kynurenic acid in the brain and thus acts as a glial toxin, perhaps explaining the neurotoxic effects of hydrazine. These authors revisited this problem using ^{1}H magic-angle spinning (MAS) NMR on various tissues (Garrod *et al.*, 2005). They were unable to detect 2-aminoadipic acid in the hippocampus, but did find it in millimolar quantities in the kidney cortex, where it was proposed to be the result of inhibition of 2-aminoadipate aminotransferase, an enzyme that, in common with other aminotransferases, uses pyridoxal 5′-phosphate as a cofactor, which is sequestered by hydrazine. The authors also state that this sequestration is what leads to the elevation of many amino acids in plasma and urine. They note that the role of 2-aminoadipic acid in hydrazine toxicity was still elusive, but that the kidney may play a role. This report, like so many other in this field, contains no quantitation beyond an 'increase (↑) or decrease (↓)' in the biomarkers discovered. Nevertheless, these reports (Garrod *et al.*, 2005; Nicholls *et al.*, 2001) contribute an important advance in the understanding of the toxicology of hydrazine.

6.1.2 Studies Using MS

MS has a number of distinct advantages in metabolomic studies. In one structured comparison of NMR and MS methods in metabolomics (Robertson, 2005), MS is given a 'big advantage' over NMR in two areas, sensitivity and resolution of metabolites and an 'advantage' over NMR in selectivity. It would appear that MS fails on 'reproducibility (across labs)', 'potential for sample bias' and in 'quantitation'. The major criticism of LC-MS, specifically ESI methods, has always been ion suppression (Annesley, 2003). Many studies have shown that constituents in the sample matrix suppress the formation of ions unevenly across the chromatogram. In a metabolomics study, this could have the effect of suppression of ionization, and therefore detection, of certain analytes and thus reduce the scope of the data matrix generated. However, the yield of biomarkers using, for example, UPLC-ESI-QTOFMS is so high that ion-suppression effects can be tolerated, but not ignored. These are, in general, specific to a particular segment of the chromatogram. Providing that off-platform calibration and quantitation is performed to determine actual concentrations of biomarkers, for example, in $\mu mol\,mmol^{-1}$ creatinine in urine, then ion suppression becomes less of a problem. If LC-MS-based metabolomic studies adopted the same standards as typical NMR-based studies, that is, reporting merely increases and decreases of analytes, then ion suppression could have a much greater impact.

The power of UPLC-ESI-QTOFMS applied to metabolomics is ably demonstrated by a study of the activation of the nuclear receptor PPARα in mice. PPARα ligands are hepatocarcinogens in rodents (Gonzalez and Shah, 2008) and robust biomarkers for their nuclear receptor-mediated effects would be of great value. A comparison of PPARα-null and wild-type mice that were fed for 14 days a diet containing the potent PPARα ligand Wy-14,643 (0.1%) revealed three urinary metabolomic phenotypes associated with the mouse *Ppara* $+/+$ and $-/-$ genotypes (Zhen *et al.*, 2007). **Figure 10A** shows a PCA scores plot with both treated and untreated $-/-$ mice clustered into one phenotype. This firstly demonstrates the absence of any major 'off-receptor' effects, that is, in the absence of the PPARα receptor, no detectable effect on the urinary metabolome was observed. It should be noted that all potential metabolites of Wy-14,643 had first been purged from the data matrix, which is relatively straightforward since they can be identified from the chlorine isotope ratio, since Wy-14,643 contains a single chlorine atom. If this procedure had not been carried out prior to data deconvolution (**Figure 3**), the treated and untreated $-/-$ mice would have separated on the basis of urinary metabolites of Wy-14,643. **Figure 10A** also shows that the wild-type ($+/+$) mice cluster and separate, both on the basis of treatment (first component) and genotype ($+/+$ vs $-/-$; second component). The net effect of treating $+/+$ mice and $-/-$ mice is a shift in both first and second components of variance, in this case, from upper left to bottom right. The intriguing separation of the untreated $+/+$ and $-/-$ mice into two distinct urinary metabolomic phenotypes, is indicative of the presence of endogenous activators of the PPARα receptor. **Figure 10B** shows the presence of two major biomarkers for PPARα receptor activation in the mouse, labelled HDOPA and DHOPA. These correspond to 11β-hydroxy-3,20-dioxopregn-4-en-21-oic acid (**Figure 10C**) and 11β,20-dihydroxy-3-oxopregn-4-en-21-oic acid (**Figure 10D**), respectively, two corticosteroid acids formed from corticosterone. The identity of the PPARα target genes responsible for the formation of these two compounds, as well as their interconversion, is the subject of current investigation. This study (Zhen *et al.*, 2007) underscores the power of MS-based methodologies in metabolomics.

6.2 From Drug Metabolism to Drug Metabolomics

As was stated above, small molecule toxicity comprises a discernible metabolic component, involving the metabolic detoxication and also metabolic activation of chemical toxicants. Knowledge of the metabolic disposition of drugs, environmental chemicals and other xenobiotics to which humans may be exposed is essential. The field of drug metabolism has its origins in the mid-nineteenth century. Early studies invariably involved the

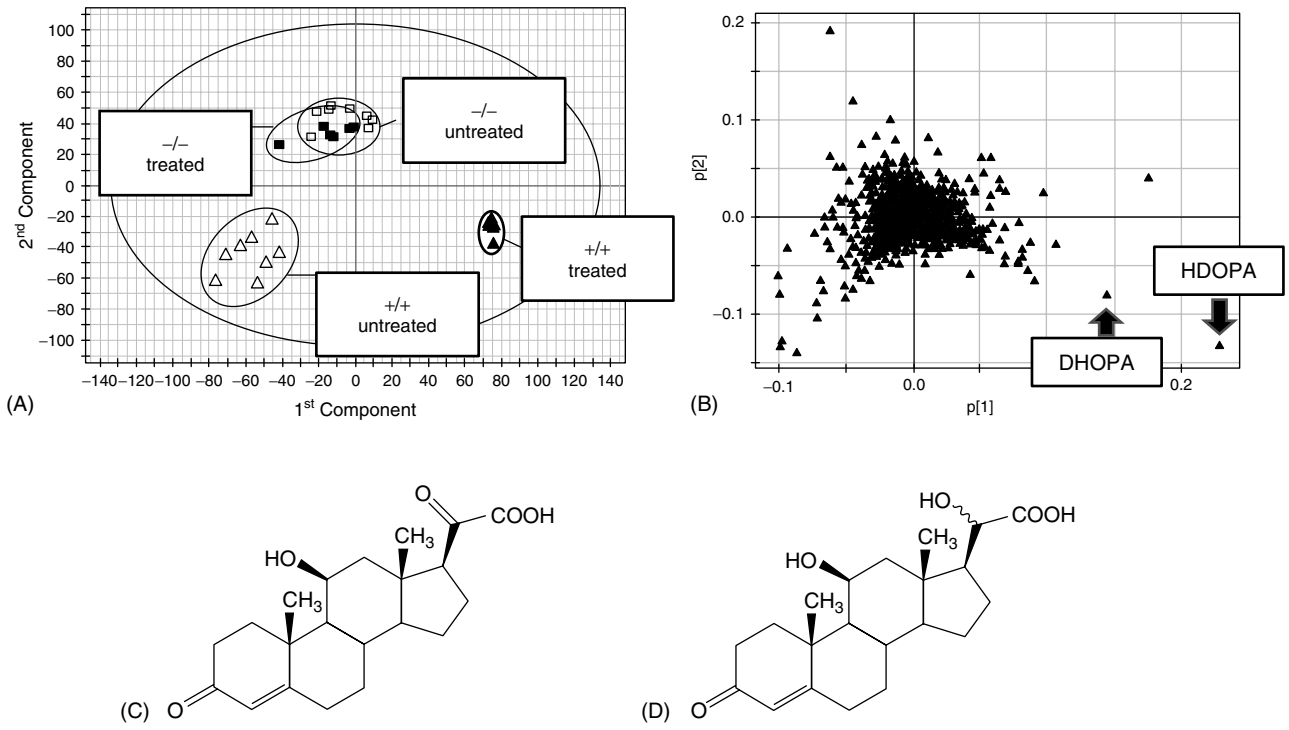

Figure 10 Discovery of urinary biomarkers for PPARα activation in the mouse by UPLC-ESI-QTOFMS based metabolomics. (Adapted from published data (Zhen *et al.*, 2007).) (A) PCA scores plot showing clustering of treated (0.1% Wy-14,643 diet for two weeks) and untreated (normal chow) *Ppara*-null $(-/-)$ mice and clear clustering and separation of treated and untreated *Ppara*-wild-type $(+/+)$ mice. (B) PCA loadings plot showing two principal ions (361.201^+ = HDOPA and 363.216^+ = DHOPA; see below) that contributed to the separation of treated $+/+$ and $-/-$ mice in the scores plot. (C) Structure of HDOPA (11β-hydroxy-3,20-dioxopregn-4-en-21-oic acid). (D) Structure of DHOPA (11β,20-dihydroxy-3-oxopregn-4-en-21-oic acid).

isolation, purification and often crystallization of metabolites from urine. Degradative chemical reactions and derivative formation were the underpinnings of the field, based almost exclusively on a knowledge of organic chemistry on the part of investigators. Little was known about the biology of drug metabolism in these early days. Technology has always spurred the quantum leaps in drug metabolism, as in other areas of life sciences. The introduction of visible and ultraviolet spectrophotometry in the 1930 s (Beinert, 1994), radiolabelled compounds (Dziewiatkowski, 1949; Dziewiatkowski and Wingo, 1949), spectrofluorimetry (Klatzkin *et al.*, 1949) and partition chromatography in the 1940s (Martin and Synge, 1941a; Martin and Synge, 1941b) catalysed the expansion of the field of drug metabolism. However, the subsequent introduction of GC, GC-MS, HPLC and LC-MS into drug metabolism has provided the underpinning to the explosion of studies in this field. Today, the phrases 'drug metabolism' and 'xenobiotic metabolism' appear in the abstracts of over 10 000 papers listed in PubMed.

A relatively short time ago, drug metabolism studies were laborious, time-consuming and often incomplete. **Figure 11** contrasts an experiment conducted in 1974 with one in 2008 that reflects a major revolution in technology. In **Figure 11A**, the fate of BA is being investigated in a particular species of African fruit bat, Franquet's epauletted bat (*Epomops franqueti*) (Collins *et al.*, 1977; Idle, 1976). A related bat, the Indian fruit bat or flying fox (*Pteropus giganteus*) had been reported to be the only species of 21 studied not to convert BA to HA (Bridges *et al.*, 1970). Subsequently, it was reported that this species conjugated BA by a novel alternative route, with glutamic acid (Idle *et al.*, 1975). **Figure 11** shows the relatively poor chromatographic resolution of thin-layer chromatography (TLC) and that the use of radiolabelled substrates and cochromatography with authentic metabolites could still leave the job unfinished. There are at least two unidentified metabolites, A and B. **Figure 11B** shows the extreme resolving power of UPLC, in this case with a longer column eluted over 20 minutes. All available acylcarnitine derivatives are resolved by this method. Moreover, accurate mass spectra at a rate of 20 per second are collected across the whole chromatogram, ensuring identity of analytes. It is the ultrahigh resolution of UPLC, combined with the accurate mass determination of QTOFMS and MDA that furnishes a unique toolbox in drug metabolism studies.

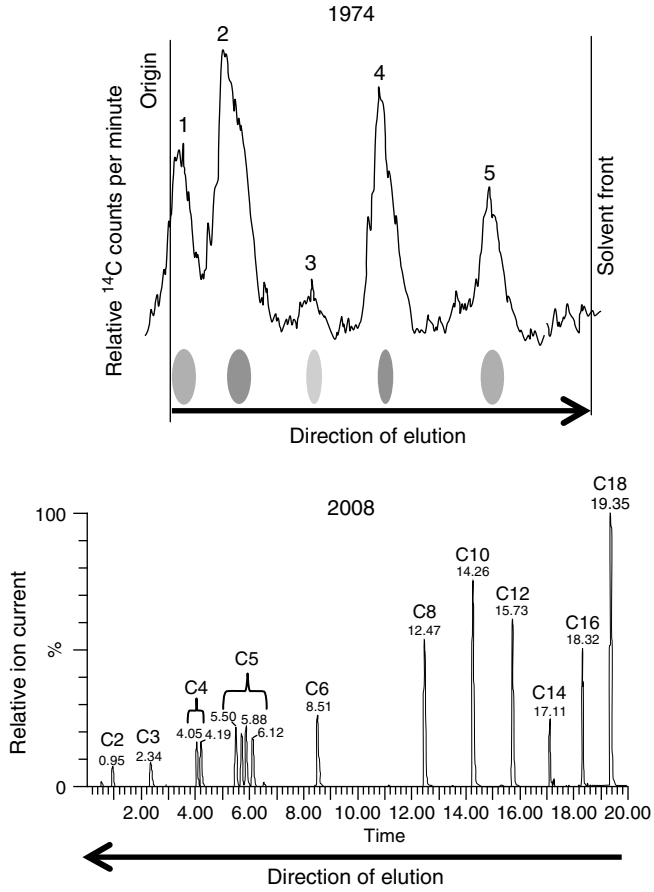

Figure 11 Advances in drug metabolism since 1974. (A) A radiochromatogram of urine from a Fraquet's epauletted fruit bat (*Epomops franqueti*) that had been administered [^{14}C]benzoic acid. This experiment was conducted in 1974 by elution of urine on silica gel thin-layer chromatography (TLC) plates with benzene: acetone: glacial acetic acid (6 : 2 : 1 v/v). 1 = unidentified metabolite A, 2 = benzoyl-β-D-glucuronide, 3 = unidentified metabolite B, 4 = benzoylglutamic acid + benzoylglycine (hippuric acid), 5 = benzoic acid. (B) Separation by UPLC and detection by ESI-QTOFMS of 15 acylcarnitines, from C2 (acetylcarnitine) up to C18 (stearoylcarnitine). This experiment was conducted in 2008.

6.2.1 A Re-examination of the Metabolism of Aminoflavone

Aminoflavone (NSC686288) is a candidate antitumour agent active against a broad range of tumour cell lines whose selectivity was believed to be due to metabolism by CYP1A1 to DNA-reactive metabolites. The sulfotransferase SULT1A1 had also been demonstrated to play role in aminoflavone cytotoxicity *in vitro*. However, the *in vivo* metabolism of aminoflavone had not been characterized. Using a metabolomic approach in the mouse, aminoflavone was shown to be biotransformed into 13 metabolites, 12 of which were novel (Chen *et al.*, 2006). **Figure 12** shows the chemical structures of aminoflavone and 13 metabolites. Only $N^{4'}$-hydroxy-aminoflavone was known prior to this study. This study demonstrated that aminoflavone undergoes hydroxylation in positions 3-, $N^{4'}$- and N^5, together with certain dihydroxylations. Conjugations include *O*-glucuronides, *N*-*O*-glucuronides, *N*-glucuronides, *O*-sulfates and *N*-*O*-sulfates. The *N*-*O*-glucuronides and sulfates probably represent chemically reactive and cytotoxic metabolites. This study demonstrates the power of the UPLC-ESI-QTOFMS metabolomics approach in understanding the toxicology of small molecules. Moreover, metabolomics in combination with genetically modified mice considerably improves our understanding of the chemical–biological interactions *in vivo* of aminoflavone. Using *Cyp1a2*-null mice and *CYP1A2*-humanized mice, the role of murine Cyp1a2 and human CYP1A2 in the metabolism of aminoflavone was greatly advanced (Chen *et al.*, 2006).

6.2.2 A Re-examination of the Metabolism of Arecoline, Arecaidine and Arecoline 1-oxide

Arecoline and arecaidine are the principal areca nut alkaloids to which some 600 million people are exposed through the habit of areca nut chewing. Despite areca alkaloids being the fourth most prevalent exposure from habitual use, after alcohol, caffeine and nicotine, little

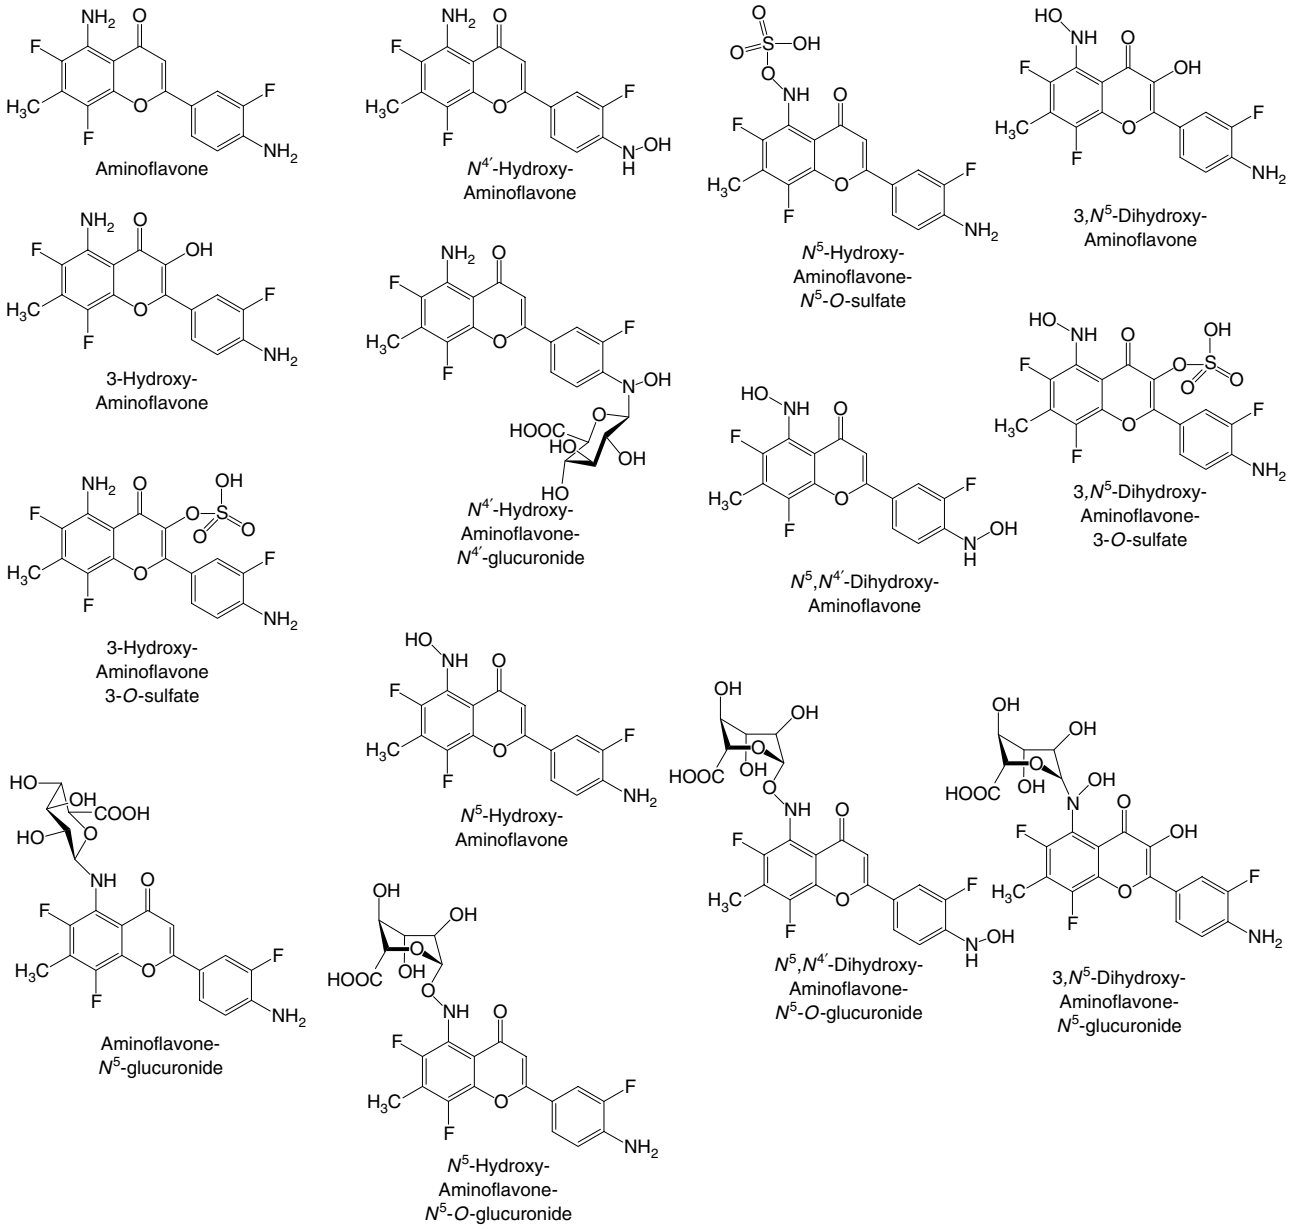

Figure 12 Aminoflavone and 13 urinary metabolites in the mouse determined by UPLC-ESI-QTOFMS metabolomics. Metabolite identities appear under each structure.

was known about their metabolism *in vivo* (Giri *et al.*, 2006). Arecoline had been previously reported to be metabolized to arecaidine by demethylation and to an *N*-oxide metabolite (Nery, 1971). In addition, an *N*-acetylcysteine conjugate of arecaidine had been reported (Boyland and Nery, 1969). A metabolomic study was undertaken after administration of arecoline and arecaidine to mice (Giri *et al.*, 2006). Additionally, the further metabolism of arecoline 1-oxide, the principal metabolite of arecoline, was investigated using a metabolomic protocol, also employing UPLC-ESI-QTOFMS (Giri *et al.*, 2007). These studies led to the expansion of known arecoline metabolites from 3 to 14. In addition to three *N*-oxides, three mercapturic acid metabolites and their mercaptan degradation products were reported (**Figure 13**). These novel metabolic insights should lead to further studies on the toxicity and potential carcinogenicity of areca alkaloids.

6.2.3 A Re-examination of the Metabolism of 2-Amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP)

2-Amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) is ubiquitous in the human diet and is a potent rodent carcinogen, relying on metabolism to exert its mutagenic and carcinogenic potential (Turesky, 2002). In common

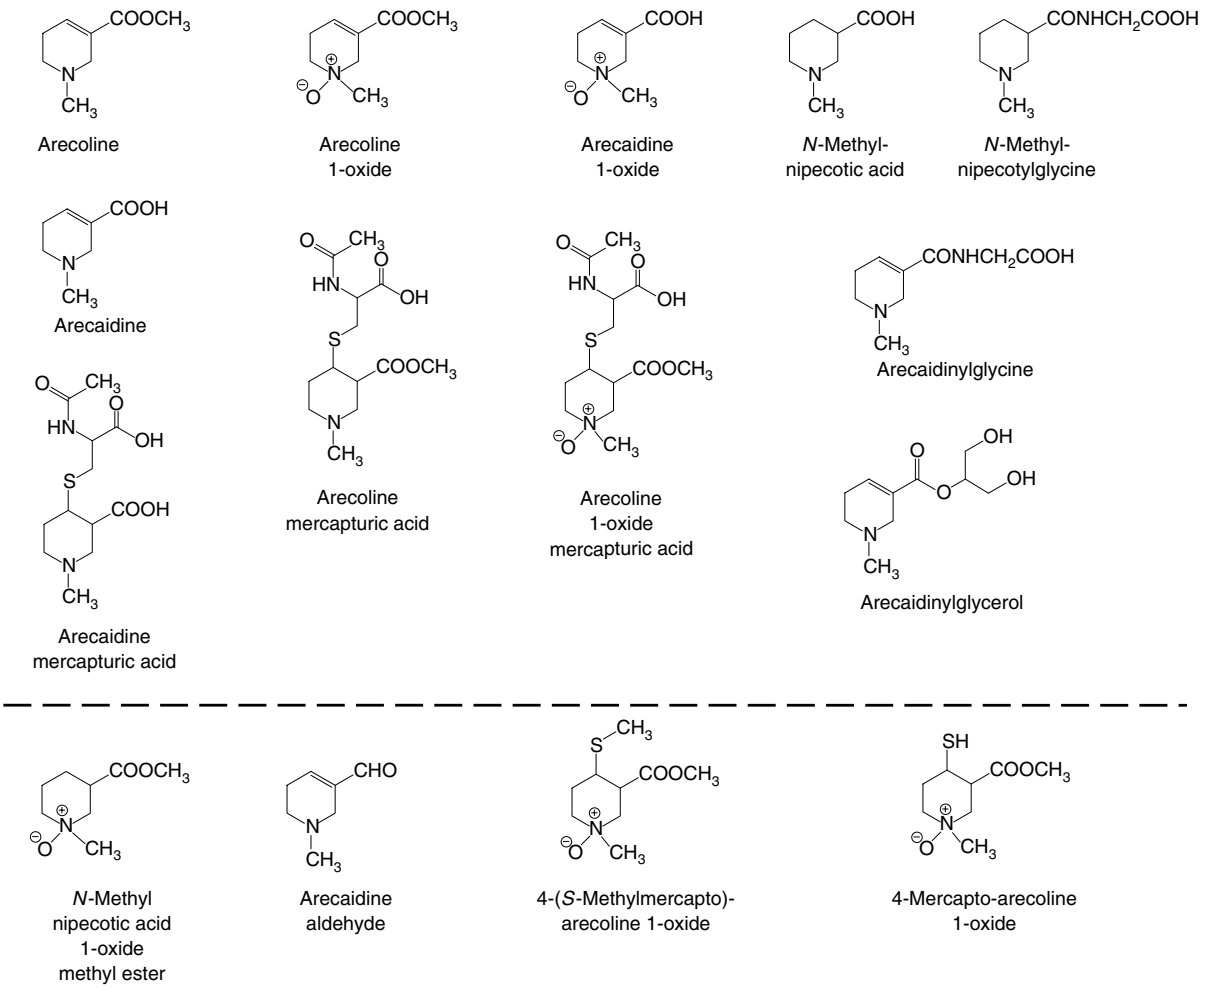

Figure 13 Arecoline and 14 urinary metabolites in the mouse determined by UPLC-ESI-QTOFMS metabolomics. Above the dotted line are metabolites determined after administration of arecoline to mice. Below the dotted line are additional metabolites determined after administration of the principal arecoline metabolite arecoline 1-oxide. Metabolite identities appear under each structure.

with other dietary heterocyclic amines, PhIP undergoes *N*-oxidation by cytochromes P450 followed by acetylation or sulfation to yield DNA-reactive metabolites (Turesky, 2002). The metabolism of PhIP in the mouse was re-examined using a metabolomic protocol after analysis of treated and untreated mouse urine by UPLC-ESI-QTOFMS (Chen *et al.*, 2007). **Figure 14** shows that this methodology identified 17 urinary metabolites of PhIP in the mouse from which the formation of two others, 4′,5-dihydroxy-PhIP and 4′,N^2-dihydroxy-PhIP, can be inferred by the presence of their conjugates in urine. Identities of metabolites were confirmed by mass fragmentography. Of the PhIP metabolites detected, eight were novel. These insights into the metabolism of PhIP, by hydroxylation and sulfate and glucuronic acid conjugation, aid our understanding of both the metabolic activation and detoxication of this important potential human carcinogen.

6.2.4 A Re-examination of the Metabolism of Melatonin

Melatonin is a pineal hormone that contributes to biological rhythmicity in a wide number of species. Oral melatonin preparations are sold without prescription in many countries. Consequently, millions of people are exposed to pharmacological doses, orders of magnitude above amounts released daily by the human pineal gland. Melatonin is claimed to possess antioxidant properties, but doubts exist regarding the extent to which these antioxidant properties are influenced by the metabolism of melatonin (Ma *et al.*, 2006). In addition, there has been a debate regarding the nature of the principal urinary metabolite of melatonin in the mouse, whether it is the 6-*O*-sulfate (Skene *et al.*, 2006) or the 6-*O*-glucuronide (Kennaway *et al.*, 2002). UPLC-ESI-QTOFMS-based metabolomics is particularly well

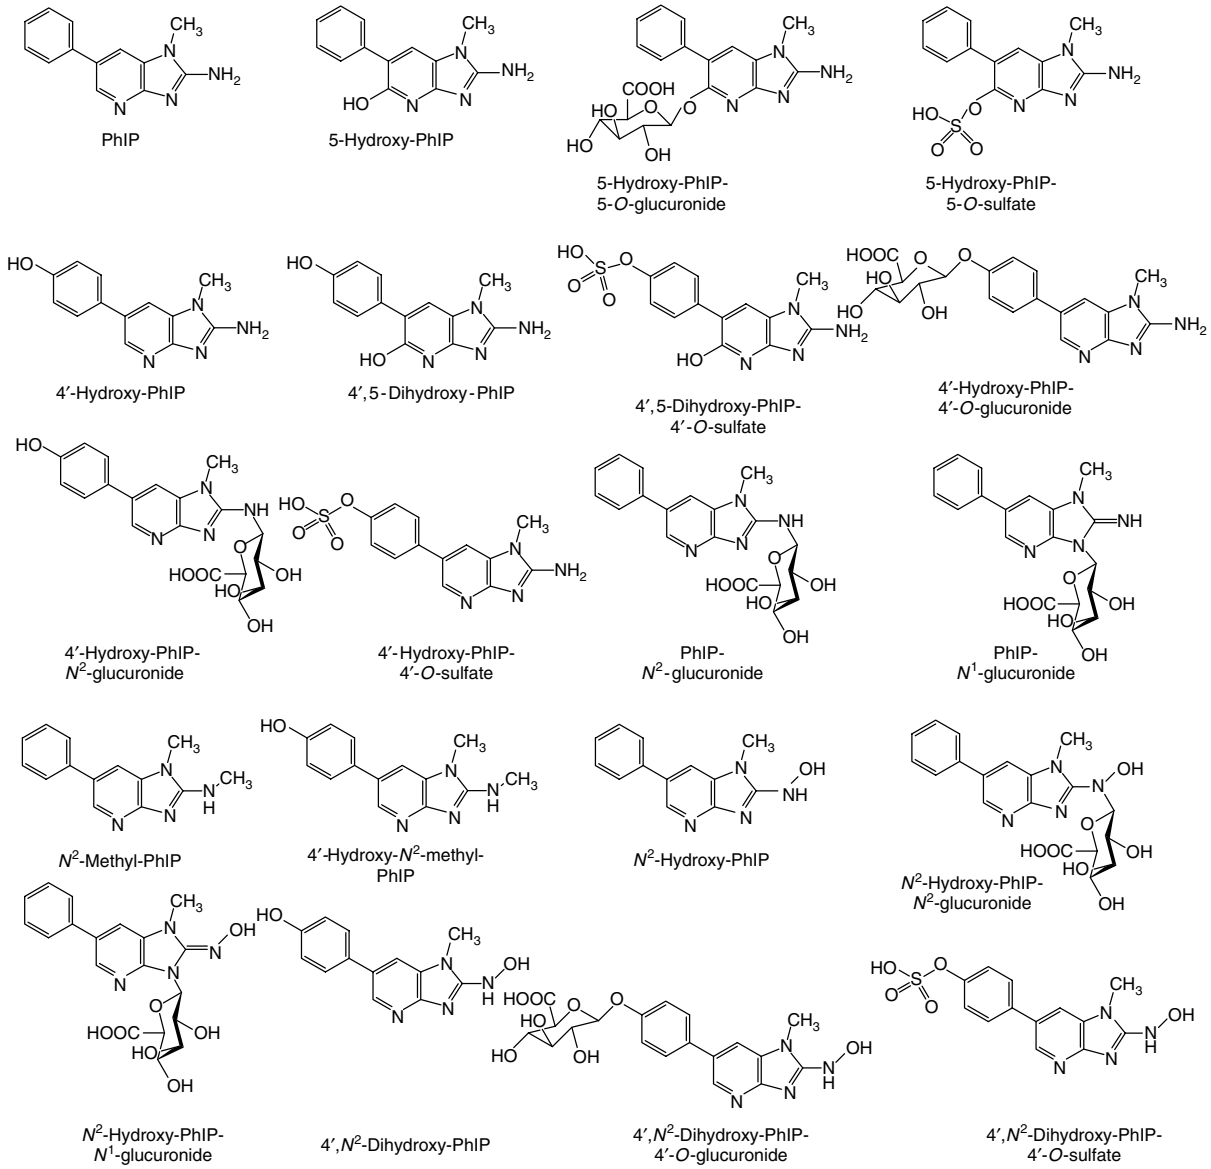

Figure 14 PhIP and 19 urinary metabolites in the mouse determined by UPLC-ESI-QTOFMS metabolomics. Metabolite identities appear under each structure. PhIP = 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine.

placed to contribute to these issues. A study has been reported in which melatonin was administered to mice and the MS data matrix analysed by OPLS to determine the presence of melatonin metabolites in mouse urine (Ma *et al.*, 2008). **Figure 15** shows the OPLS loadings S-plot from this study. Fourteen metabolites of melatonin in the mouse were characterized, seven of which were novel. This study also reported that N^1-acetyl-N^2-formyl-5-methoxykynuramine and N^1-acetyl-5-methoxykynuramine, known melatonin antioxidant products, were not detected in mouse urine. Finally, the debate over sulfation vs glucuronidation of 6-hydroxymelatonin was settled using the same strains of mice as the previous investigators (Kennaway *et al.*, 2002; Skene *et al.*, 2006). The metabolomic study, combined with ESI− and ESI+ mass fragmentography and specific enzymic deconjugation reactions established that the principal excretory product of melatonin in the mouse is 6-hydroxymelatonin 6-*O*-glucuronide, with the 6-O-sulfate virtually undetectable (Ma *et al.*, 2008).

6.2.5 A Re-examination of the Metabolism and Toxicity of Paracetamol

Paracetamol (*N*-acetyl-*p*-aminophenol; APAP; acetaminophen in the USA) is the biggest single cause of avoidable and fatal hepatotoxicity in developed countries. Its metabolism has been studied for over 50 years and provides an important case example of the essential role of metabolism in drug toxicity (Gonzalez, 2007). A metabolomics study has been reported in which three novel metabolites of APAP were uncovered in

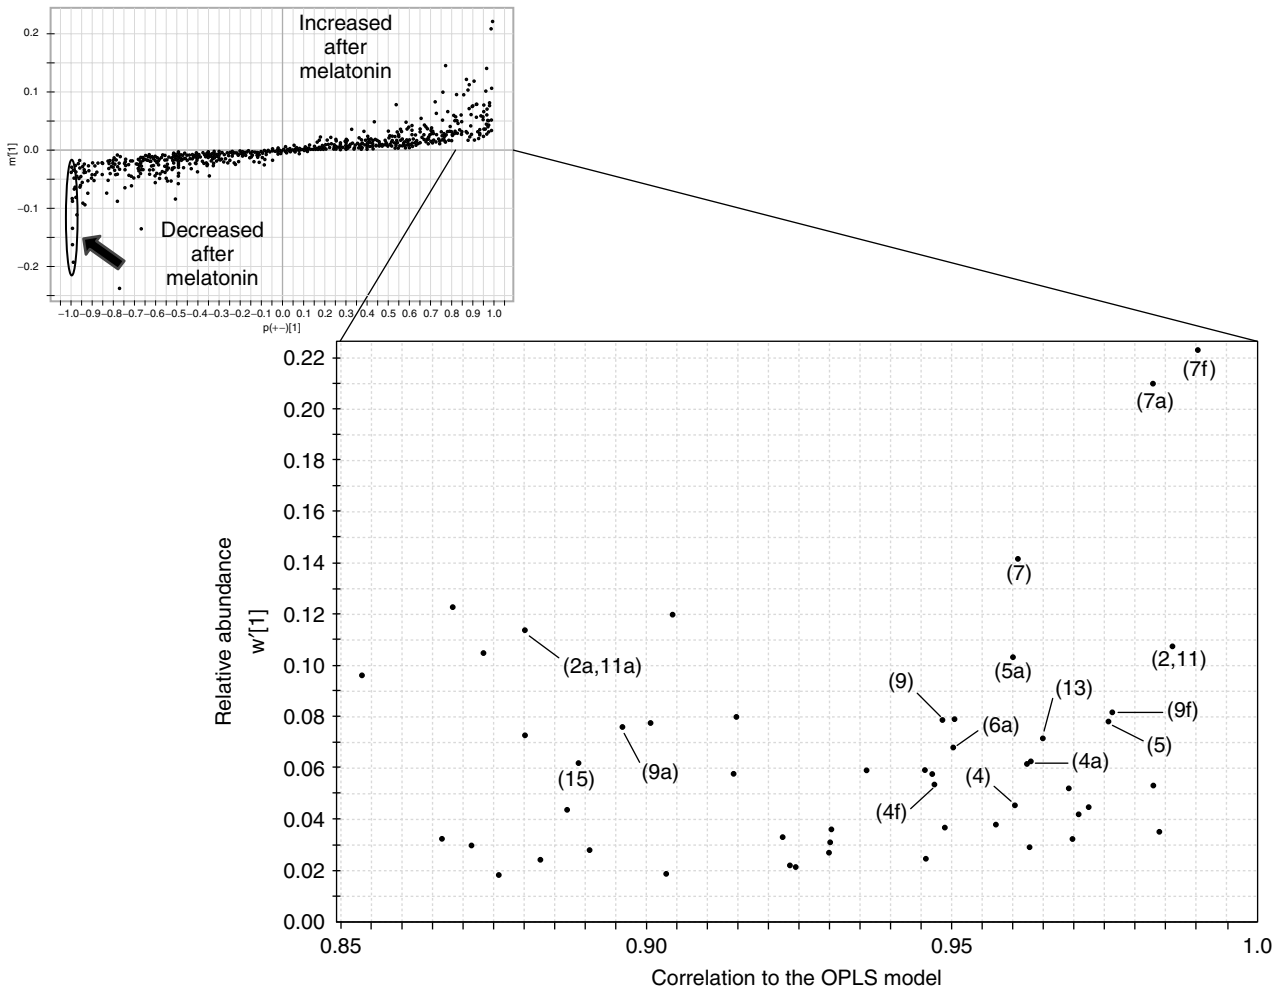

Figure 15 OPLS loadings S-plot for determination of the urinary metabolites of melatonin in the mouse. (Adapted from published data (Ma *et al.*, 2008).) The top panel shows quadrants containing ions that are increased and decreased after melatonin administration. The arrowed group of ions represents urinary constituents that were suppressed, and with perfect correlation to the OPLS model, after melatonin administration. The expanded quadrant shows melatonin metabolites that were identified from authentic standards, by specific enzymic deconjugation reactions, and by mass fragmentography. Metabolites are: 1 = unchanged melatonin (ion not shown), 2 = 6-hydroxymelatonin, 3 = *N*-acetylserotonin (ion not shown), 4 = melatonin *N*-glucuronide, 5 = 2-oxomelatonin, 6 = dihydroxymelatonin, 7 = 6-hydroxymelatonin 6 − *O*-glucuronide, 8 = 6-hydroxymelatonin 6-*O*-sulfate (ion not shown), 9 = *N*-acetylserotonin 5-*O*-glucuronide, 10 = *N*-acetylserotonin 5-*O*-sulfate (ion not shown), 11 = *cyclic*-3-hydroxymelatonin, 12 = 6-hydroxy-*cyclic*-3-hydroxymelatonin (ion not shown), 13 = *cyclic*-*N*-acetylserotonin 5-*O*-glucuronide, 14 = *cyclic*-melatonin (ion not shown), 15 = 5-hydroxyindolylacetaldehyde. Subscripts a and f refer to Na^+ adducts and in-source fragments, respectively.

the mouse (Chen *et al.*, 2008a). The study detected the usual APAP metabolites, specifically, unchanged APAP, APAP cysteine conjugate, *N*-acetylcysteine conjugate, glucuronic acid conjugate, sulfate conjugate and 3-methoxy-APAP glucuronide. However, an APAP dimer was detected (**Figure 16**) that was shown in additional experiments to derive from the action of reactive oxygen species (ROS) on APAP. Moreover, a benzothiazine derivative was deduced by mass fragmentography of an ion of $m/z = 281.0054^+$, corresponding to the empirical formula $C_{11}H_9N_2O_3S_2^+$. The incomplete structure is given in **Figure 16**. In common with model benzothiazine derivatives, this metabolite also arises from the action of ROS. Finally, it was reported that the cysteine conjugate of APAP underwent transamination to the corresponding keto acid, and that this reaction occurred almost exclusively in the kidney (Chen *et al.*, 2008a). Through the use of *Cyp2e1* +/+ and −/− mice, it was possible to conclude that CYP2E1 contributes to the toxicity of paracetamol by the generation of ROS. This study combined genetically modified mice with

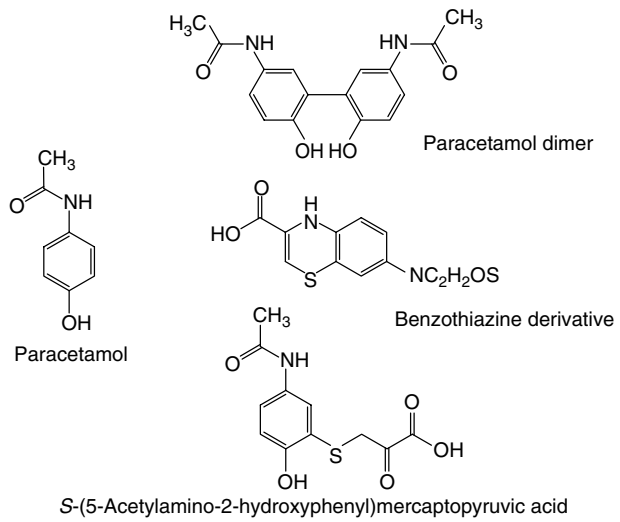

Figure 16 The structure of paracetamol and three novel metabolites in the mouse determined by UPLC-ESI-QTOFMS.

high-resolution UPLC, accurate mass ESI-QTOFMS, unsupervised PCA and mass isotopomer analysis, and demonstrated that this unique platform is able to derive novel metabolites of a highly investigated drug like paracetamol.

7 FUTURE PERSPECTIVES FOR METABOLOMICS IN TOXICOLOGY

The literature ably demonstrates that rapid screening for biomarkers of organ toxicity can be performed using either NMR- or MS- based metabolomic methodologies. In the same way that there is unlikely to be a consensus on the use of the terms metabolomics, metabonomics and metabolic profiling, there is unlikely to be agreement on the relative advantages and disadvantages of the NMR and MS platforms. This is a young science, still yet to establish its relevance and value to a host of more recognized disciplines. The pharmaceutical industry has adopted the subject very rapidly and it is becoming clearer that the potential of metabolomics as a high-throughput, relatively low-cost, technology is considerable.

While the high abundance so-called 'usual suspects' (see Section 18.6.1.1) may be sufficient for high-throughput screening protocols, they do not have sufficient information content to inform about mechanisms of toxicity. It is possible to generate NMR data beyond this dataset that is more informative, as was the case with hydrazine toxicity (Garrod *et al.*, 2005; Nicholls *et al.*, 2001). However, it is our experience and contention that the best starting point in a metabolomics study of a small toxic molecule is to deploy MS-based protocols, especially UPLC-ESI-QTOFMS, with its high resolution of metabolites and accurate mass determination of resultant ions. The potential of ion suppression must be worked around and this becomes less of a concern when preliminary biomarkers of toxicity are further investigated on a second platform, for example, triple quadrupole MS or GC-MS, not just for the purposes of qualitative confirmation, but also for quantitation. Examples of this protocol have been published (Tyburski *et al.*, 2008; Zhen *et al.*, 2007). Regarding the mechanisms of toxic responses, UPLC-ESI-QTOFMS-based metabolomics has also proved useful in delineating the inflammatory response of the mouse gut to administered sodium dextran sulfate (Chen *et al.*, 2008b) and in improving the understanding of biological responses to ionizing radiation, both *in vitro* (Patterson *et al.*, 2008) and *in vivo* (Tyburski *et al.*, 2008). Further exploration of such questions by the addition of GC-MS and GC-time-of-flight (TOF) platforms is likely to be very productive. One of the major limitations of standard rapid-throughput UPLC methods is that most of the highly polar urinary metabolites elute in under one minute. However, solid-phase extraction, followed by derivatization and GC-MS analysis produces excellent resolution of polar metabolites. GC-MS has provided the underpinning to plant metabolomics since its inception (Dixon *et al.*, 2006; Fiehn, 2002; Fiehn *et al.*, 2008; Taylor *et al.*, 2002) and, together with UPLC-ESI-QTOFMS, will surely become a major force in 'toxicometabolomics' in the future.

Finally, it must not be forgotten that a significant proportion of human and animal toxicology is dependent upon metabolism of small molecules, by the host and microbiota. Understanding detoxication and metabolic activation pathways for small molecules is essential to a fuller recognition of their potential as toxicants. It has been demonstrated ably here (see Section 18.6.2) that MS-based metabolomics produces unrivalled insights into the metabolic disposition of small chemical entities. Given the technologies available and likely to evolve in the short term, one may anticipate an exciting future as metabolomics combines with functional genomics and proteomics to deliver systems toxicology. This threshold is akin to that in molecular biology in the early 1980s, just prior to the invention of the polymerase chain reaction (PCR) and the subsequent dissemination of PCR thermocyclers throughout the scientific community. A subject with an enormous perceived potential went, almost overnight, from an esoteric and exclusive domain to a widespread and highly democratic set of simple techniques that, through automation due to commercial interests, permitted the sequencing of the human genome, and over 180 others. Functional genomics is also in the process of democratization, with the spread of technology for DNA microarrays and single nucleotide polymorphism (SNP) mapping. Metabolomics waits in the wings for its turn. It is not helpful to the average investigator if metabolomics can only be carried out in labs with high-field NMR spectrometers or time-of-flight, Fourier-transform ion cyclotron resonance, or Orbitrap

mass spectrometers that are expensive to purchase and maintain and require great expertise for the acquisition and interpretation of data. What is needed is the PCR thermocycler equivalent for metabolomics that can bring metabolomics into any laboratory. As has been stated elsewhere (Idle and Gonzalez, 2007), this will require a commitment of the best minds in academic research, as well as a willingness of industrial manufacturers to fulfil the collective vision of a world with simple, cheap and reproducible metabolomic profiling, a true electronic dog's nose.

ACKNOWLEDGMENTS

ADP wishes to acknowledge the National Institute of General Medical Sciences for a Pharmacology Research Associate Program Fellowship. JRI wishes to acknowledge United States Smokeless Tobacco Company for a grant for collaborative research. Metabolomics research in the Laboratory of Metabolism (Chief, Frank J. Gonzalez, PhD) is funded by the NCI Intramural Research Program of the National Institutes of Health (NIH) and, in part, by grant number U19 AI067773-02 from the National Institute of Allergy and Infectious Diseases (NIAID) and supplementary funding from NIAID for medical countermeasures against radiation (to J.R. Idle and F.J. Gonzalez). We wish to thank our innumerable colleagues in Bethesda, Bern and Praha who are engaged in metabolomics research and who help make our professional lives so interesting. Finally, one of us (JRI) is indebted to his long-time friend and collaborator Frank Gonzalez for taking this journey with him into metabolomics down an uncertain and sometimes rocky path.

Endocrine Disruption in Toxic Responses

Shigeyuki Kitamura, Kazumi Sugihara, Kazuo Nakamura, Yaichiro Kotake, Akihiko Kashiwagi and Nariaki Fujimoto

CONTENTS

1 INTRODUCTION

Many endocrine-disrupting agents, including industrial materials, pesticides, pharmaceuticals and phytochemicals, have been identified by the use of *in vitro* assay systems and *in vivo* studies in laboratory animals. These chemicals are widely distributed in the environment, and are able to mimic or antagonize the biological functions of natural hormones. Indeed, abnormalities thought to be due to such agents have been found in animals throughout the world. There is also thought to be a risk to humans, for example, diethylstilboestrol (DES) syndrome. Xenoestrogens can accumulate in our environment, and may play a role in the increasing incidences of breast cancer, testicular cancer and other problems of the reproductive system in humans. Risks due to endocrine-disruptors in the environment are discussed in this chapter.

2 ENDOCRINE DISRUPTING ACTIVITY *IN VITRO* AND *IN VIVO* IN ANIMALS

Many environmental xenobiotics have been shown to exert hormonal effects at the cellular and organism levels. These compounds are able to mimic the biological activity of sex hormones and thyroid hormones (TH), and are called endocrine-disrupting chemicals (EDCs). They include insecticides, such as kepone, o,p'-dichlorodiphenyltrichloroethane (o,p'-DDT), dieldrin, methoxychlor, and industrial chemicals used in the plastics and detergent industries, such as alkylphenols and bisphenol A (BPA), and polychlorinated biphenyl (PCB) congeners (Soto *et al.*, 1994; Gaido *et al.*, 1997; Andersen *et al.*, 1999). Quantitative structure–activity relationship (QSAR) work on the structural features of oestrogen receptor (ER) ligands shows that an unhindered hydroxyl group on an aryl ring and a hydrophobic group attached *para* to the hydroxyl group are essential (Anstead *et al.*, 1997; Fang *et al.*, 2000; Shi *et al.*, 2001; Hong *et al.*, 2002). Ligand binding assays and studies in a reporter/transcriptional system for the ER support the requirement for these structural features (Nishihara *et al.*, 2000; Blair *et al.*, 2000). Among these compounds, those which are lipophilic and persistent may be accumulated through the food web, posing a health threat to humans and animals. Xenoestrogens can accumulate in our environment, and may play a role in the increasing incidence of breast cancer, testicular cancer and other problems of the reproductive system in humans. Interactions of oestrogenic and antiandrogenic compounds with the respective hormone receptors have been demonstrated to account for most of the endocrine-disrupting actions, and these chemicals

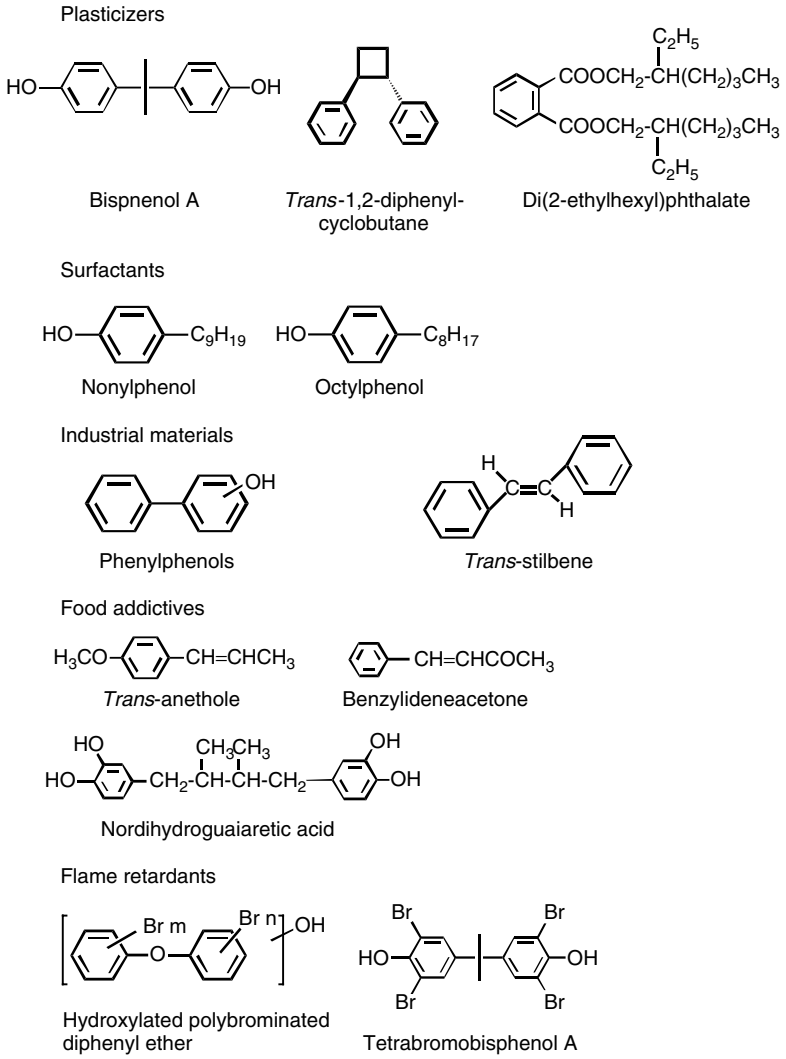

Figure 1 Endocrine-disrupting chemicals on environments.

can alter reproductive development in mammals. The effects of proestrogens, which are activated to oestrogens by metabolic systems, must also be taken into account. EDCs including proestrogens shown in this chapter are listed in **Figure 1**.

2.1 Oestrogenic, Antiandrogenic and Thyroid Hormone Disrupting Activities of Endocrine Disrupters

2.1.1 Plasticizers

BPA (2,2-bis-(4-hydroxyphenyl)propane) is an industrial raw material for manufacture of polycarbonate and epoxy resins, and contaminates the end products. It can be detected in liquid from canned vegetables and in the saliva of patients treated with dental sealants (Brotons *et al.*, 1995; Olea *et al.*, 1996; Hashimoto *et al.*, 2001). Bisphenol B (2,2-bis-(4-hydroxyphenyl)butane), bisphenol F (4,4′-dihydroxydiphenylmethane), bisphenol AD (ethylidenebisphenol), bisphenol AF (1,3-trifluoro-2, 2-bis-(4-hydroxyphenyl)propane), tetramethylbisphenol A (TMBPA), 3,3′-dimethylbisphenol A and bisphenol S (bis-(4-hydroxyphenyl)sulphone) are also used as materials for polycarbonate resin. Tetrachlorobisphenol A (TCBPA) has been found in the effluent from waste-paper recycling plants (Fukazawa *et al.*, 2001). Kuruto-Niwa *et al.* (2002) reported that oestrogenic polychlorinated BPAs were not easily biodegraded.

BPA and some related compounds exhibit oestrogenic activity towards cell lines, such as oestrogen-responsive breast cancer cell line MCF-7 cells, and endocrine-disrupting effects *in vivo* (Krishnan *et al.*, 1993; Gaido *et al.*, 1997; Ashby and Tinwell, 1998; Ashby *et al.*, 2000; Tinwell *et al.*, 2000; Kim *et al.*, 2001; Matthews *et al.*, 2001). But there were remarkable differences in activity. TCBPA showed the highest activity, followed by bisphenol B, BPA and TMBPA. Antioestrogenic activity against 17β-oestradiol (E2) was

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

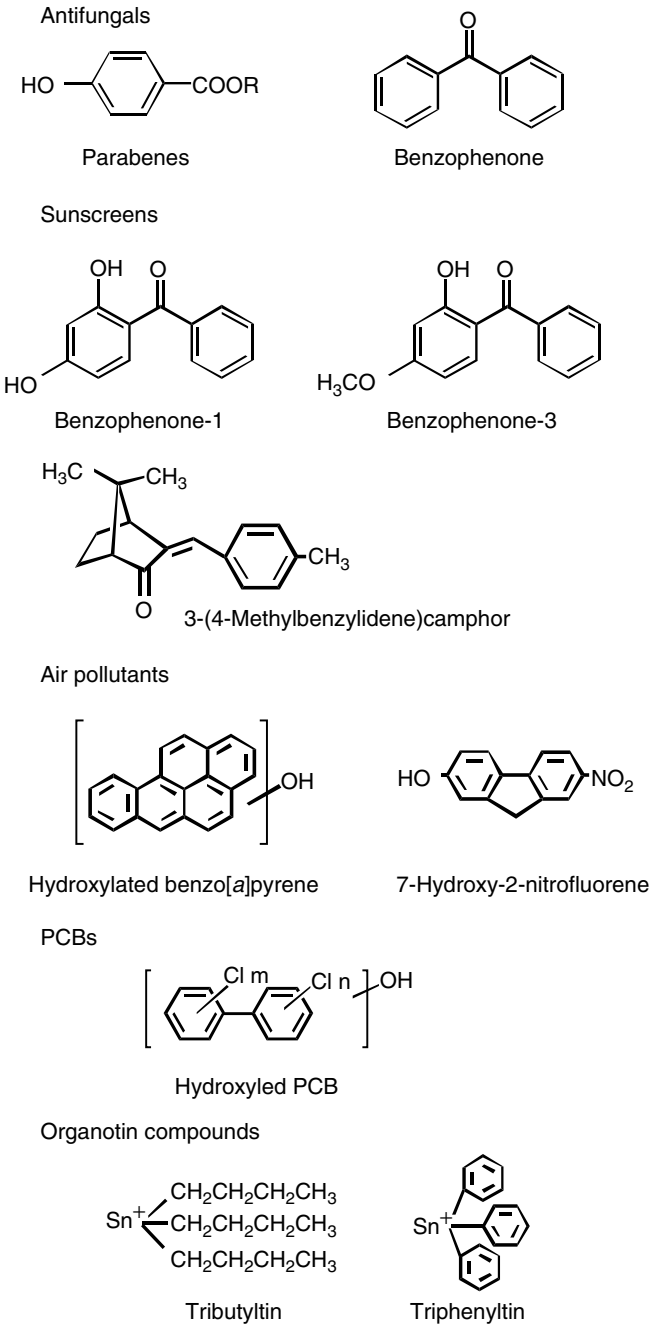

Figure 1 *continued*.

observed with TMBPA. BPA gave positive responses in *in vivo* uterotrophic assays using ovariectomized mice. In contrast, BPA and some related compounds showed significant inhibitory effects on the androgenic activity of 5α-dihydrotestosterone (DHT) in mouse fibroblast cell line NIH3T3. TMBPA showed the highest antagonistic activity, followed by bisphenol AF, bisphenol AD, bisphenol B and BPA. In contrast, TMBPA and 3,3′-dimethylbisphenol A exhibited significant thyroid hormonal activity towards rat pituitary cell line GH3, which releases growth hormone (GH) in a TH-dependent manner. These results suggest that the 4-hydroxyl group of the A-phenyl ring and the B-phenyl ring of BPA derivatives are required for these hormonal activities, and substituents at the 3,5-positions of the phenyl rings and the bridging alkyl moiety markedly influence the activities (Kitamura *et al.*, 2005a). In the metabolism of BPA, the 3-hydroxyl metabolite (catechol-type metabolite) was formed by human and rat liver microsomes and exhibited oestrogenic activity (Elsby *et al.*, 2001a). The glucuronide metabolite proved to have no oestrogenic activity (Pottenger *et al.*, 2000). BPA is further activated when it is incubated with rat S-9 mix (Yoshihara *et al.*, 2001), affording dimer-type metabolites which

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

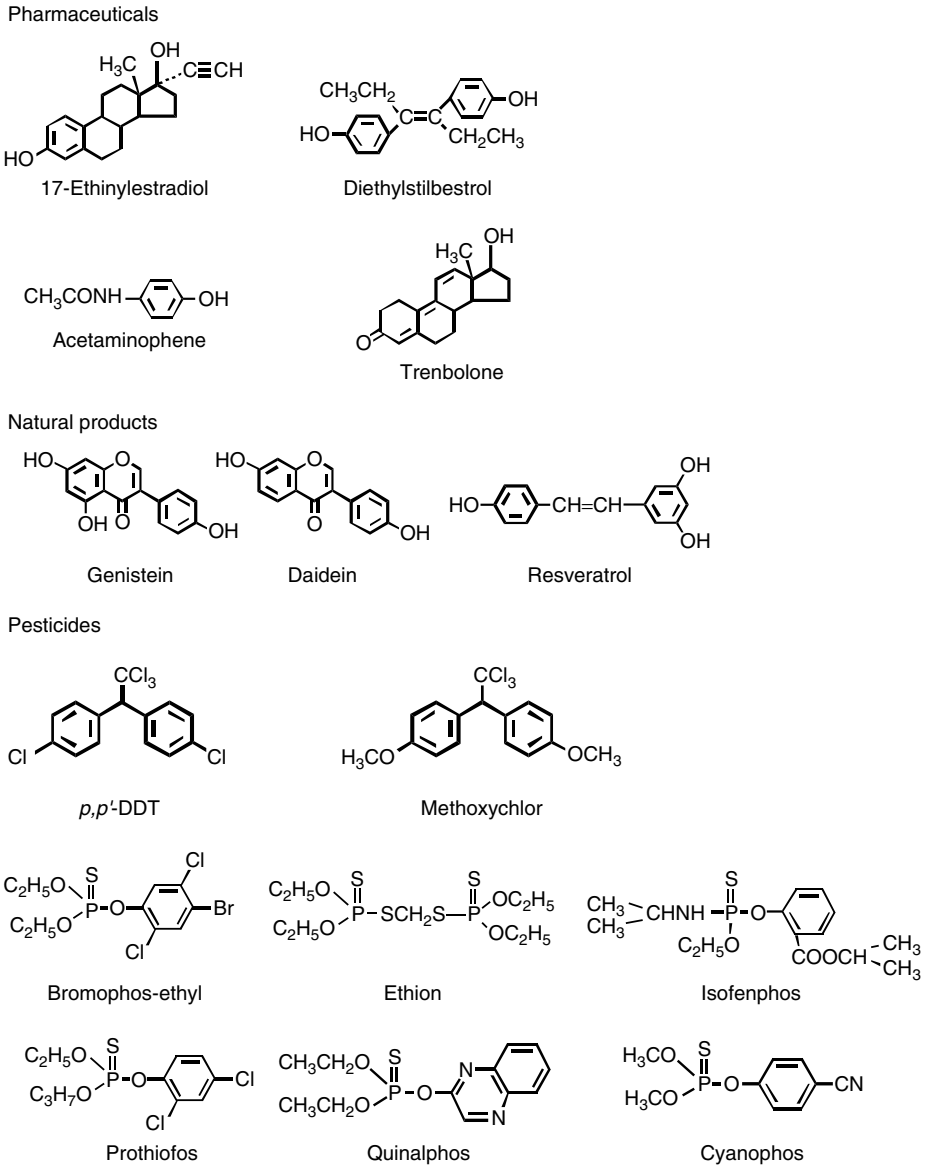

Figure 1 *continued*.

show higher activity than BPA. Such further activation of xenoestrogens must also be considered in the risk assessment of xenoestrogens.

Styrene oligomers, such as *trans*-1,2-diphenylcyclobutane, *cis*-1,2-diphenylcyclobutane, 1,3-diphenylpropane, 2,4-diphenyl-1-butene, 2,4,6-triphenyl-1-hexene and 1α-phenyl-4β-(1′-phenylethyl)tetralin are incorporated into polystyrene resin as impurities in the course of manufacture, and may have a variety of biological actions, including hormonal activity (Kawamura *et al.*, 1998). Polystyrene has been used to manufacture food containers for take-away, such as coffee cups, meat trays, salad boxes and soup bowls, as well as instant food containers, in which instant foods such as Japanese noodles, buckwheat noodles, Chinese noodles, chow mein, spaghetti and rice are cooked by adding hot water. There are reports indicating that styrene oligomers migrate from these containers into the food contents (Sakamoto *et al.*, 2000).

Ohyama *et al.* (2001) reported that some styrene dimers and trimers were oestrogenic in a cell proliferation assays with oestrogen-responsive MCF-7 cells. However, Nobuhara *et al.* (1999) reported that styrene oligomers did not induce the proliferation of MCF-7 cells. Kitamura *et al.* (2003a) also reported that these styrene oligomers were negative in the oestrogen screening assay. However, some styrene oligomers, such as *trans*-1,2-diphenylcyclobutane, *cis*-1,2-diphenylcyclobutane, 1,3-diphenylpropane and 2,4-diphenyl-1-butene, exhibited oestrogenic activity after metabolic activation with liver microsomes of phenobarbital-treated rats. *Trans*-1-(4-Hydroxyphenyl)-2-phenylcyclobutane, which was produced by liver microsomes, exhibited a significant oestrogenic activity. Recombinant human cytochrome

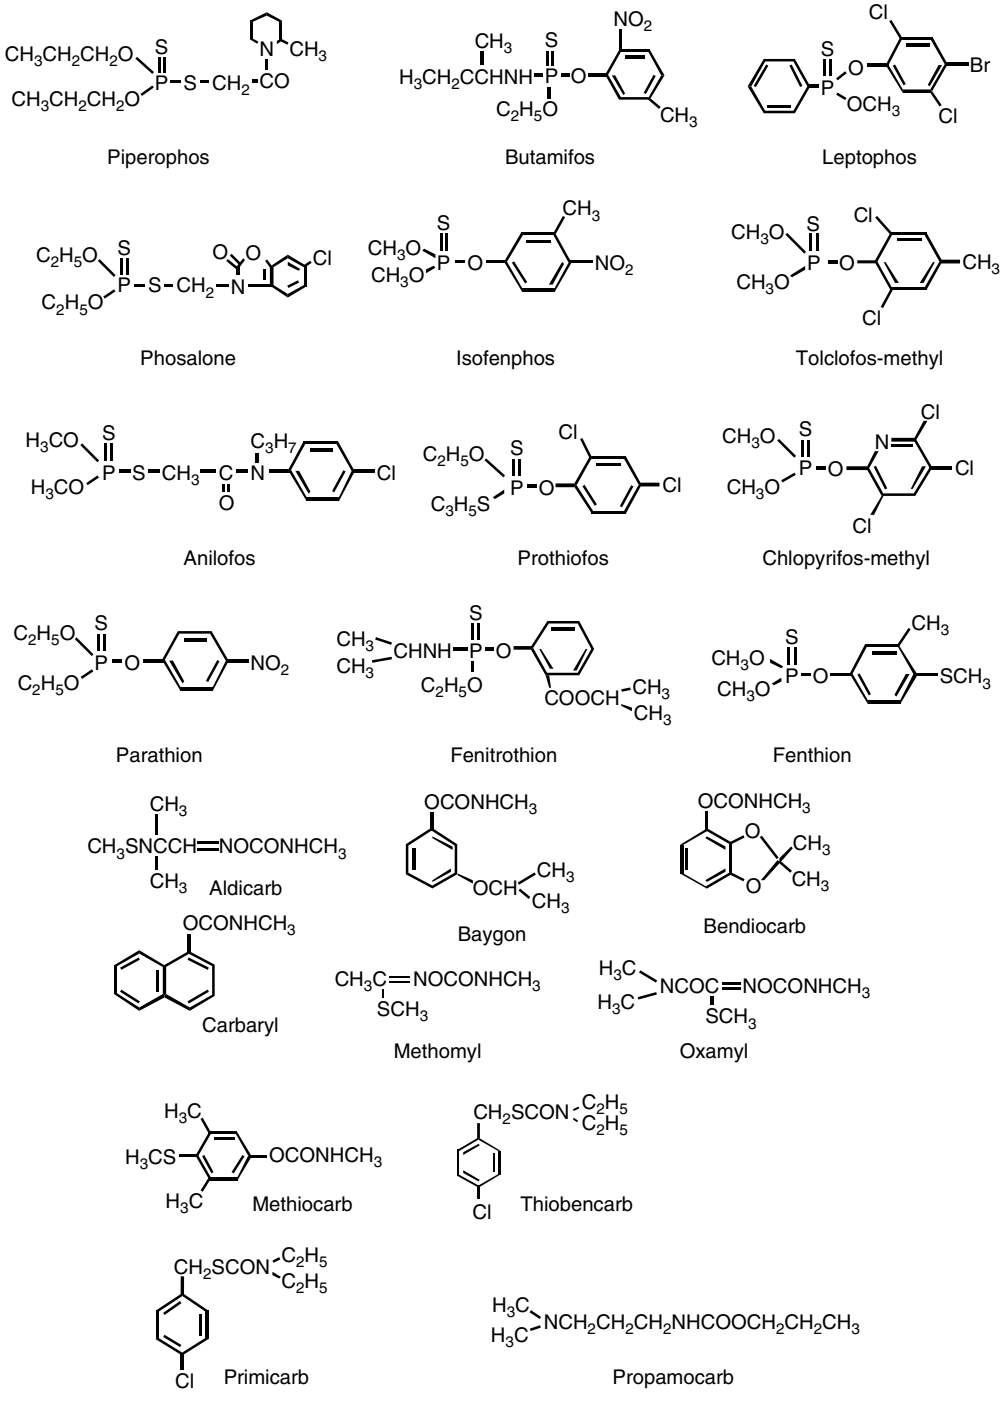

Figure 1 *continued*.

P450 (P450) 2B6 and rat P450 2B1 were responsible for the activation. In contrast, P450 1A may be mainly responsible for the activation of 2,4-diphenyl-1-butene. Thus, some styrene oligomers exhibit oestrogenic activity after metabolic activation to form the hydroxylated metabolite.

Phthalate esters are the most abundant man-made chemical contaminant in our environment. They are mainly used as plasticizers to impart flexibility to nitrocellulose, polyvinyl resins for vinyl floors, food wraps, cosmetics, medical products and toys, and are produced industrially in large quantities. They can leach out of these materials into water, soil or food (Murature *et al.*, 1987). Thousands of tons of plastics are disposed of annually in landfill sites, thus enabling phthalate esters to migrate into groundwater via the soil. The ubiquity of these compounds in the aqueous environment is well known, and their presence has been reported in river water and drinking water, as well as in fish and sediments. High levels of di(2-ethylhexyl) phthalate (DEHP)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

was detected in diet samples obtained from hospitals (Tsumura, 2002). Commonly detected species include di(*n*-butyl) phthalate (DBP), dimethyl phthalate, diethyl phthalate, DEHP, di(*n*-octyl) phthalate and butyl benzyl phthalate. The general population may be exposed to these chemicals via their diet, either from food contamination, or from food or drinks directly contaminated by plastic wraps containing phthalates. In most cases, the greatest exposure is from food. Levels of DBP in foods range from 50 to 500 mg kg^{-1} in the USA. Recently, phthalates have been attracting attention because of their disrupting action on the endocrine system. Some phthalate plasticizers are reported to show oestrogenic activity due to their affinity for ER (Jobling *et al.*, 1995; Nakai *et al.*, 1999). Disruption of androgen-regulated male reproductive development has also been reported (Mylchreest *et al.*, 1999; Hoyer, 2001). Mylchreest *et al.* (1999) reported that the reproductive toxicity of DBP is not due to affinity for androgen receptors (ARs). Phthalate is metabolized via multiple pathways, resulting in the production of deacylated derivatives and their glucuronide conjugates, and hydroxylated derivatives (Saillenfait *et al.*, 1998). The monoester metabolites are believed to be the toxic species, including reproductive toxicity (Foster *et al.*, 2000, 2001; Fukuoka *et al.*, 1995; Oishi and Hiraga, 1980). In contrast, Picard *et al.* (2001) reported that the metabolites of butyl benzyl phthalate are easily produced in MCF-7 cells used for the test, but do not show an oestrogenic effect on MCF-7 proliferation.

Jobling *et al.* (1995) reported that some phthalate esters are weak oestrogens in a yeast reporter assay. Picard *et al.* (2001) demonstrated that butyl benzyl phthalate shows oestrogenic activity in E-screen, and the phthalate is deactivated by dealkylation. Nakai *et al.* (1999) also reported that dialkyl phthalates have binding affinity for ER. We have shown that the 4-hydroxyl and 3-hydroxyl metabolites are major metabolites of dimethyl phthalate and DBP in a rat liver microsomal system. The *in vivo* oestrogenic activity of phthalate esters had previously been believed to be due to monoalkyl metabolites. It is necessary to reconsider the mechanism of reproductive toxicity of phthalate esters. It is also important to consider the activity of metabolites produced from the parent compounds in the assessment of the toxicity of chemicals. Butyl benzyl phthalate is antiandrogenic in *in vitro* yeast-based assays (Sohoni and Sumpter, 1998). Di-*n*-amyl phthalate was positive in the Hershberger test (Yamasaki *et al.*, 2004). Hydroxylated derivatives of phthalate esters were positive in the oestrogen test (Toda *et al.*, 2004).

Recently, nitrile-butadiene rubber has been used instead of polyvinyl chloride to make disposable gloves for use in the food industry. It is reported that 4,4′-butylidenebis(6-*t*-butyl-*m*-cresol) and 2,4-di-*t*-butylphenol, which were eluted from the gloves, are antiandrogenic in *in vitro* reporter gene assays (Satoh *et al.*, 2008). The activity of 4,4′-butylidenebis(6-*t*-butyl-*m*-cresol) was higher than that of *p*,*p*′-DDE (dichlorodiphenyldichloroethene) and similar to that of BPA. 4,4′-Butylidenebis(6-*t*-butyl-*m*-cresol) also showed antioestrogenic activity in the assay system.

2.1.2 Surfactants

Nonylphenol is a degradation product of nonylphenol ethoxylate, which is used as a nonionic surfactant in detergents, paints, herbicides and cosmetics. Nonylphenol is also used as a stabilizer and antioxidant in plastics. Nonylphenol is a mixture of various isomers that have alkyl side chains represented by C_6H_{19}. It is commonly found in rivers, estuaries and other aquatic environments. Nonylphenol is an endocrine-disruptor, having oestrogenic and antiandrogenic activities (White *et al.*, 1994). Watanabe *et al.* (2004) demonstrated that 4-nonylphenol binds both ER α and β. Branched 4-nonylphenol isomers exhibited especially high oestrogenic activity (Shioji *et al.*, 2006). 4-Nonylphenol also binds to and activates pregnane X-receptor (PXR), and induces P450 3A (Masuyama *et al.*, 2000). *In vivo* studies also demonstrated that nonylphenol is uterotrophic in immature rats (Lee and Lee, 1996). Nonylphenol has been shown to weakly bind androgen and progesterone receptors in mammalian *in vitro* assays and yeast-based assays (Sohoni and Sumpter, 1998; Laws *et al.*, 2000). Paris *et al.* (2002) demonstrated that 4-*tert*-octylphenol exhibits antiandrogenic activity with α and β oestrogen activities in reporter cell lines. AR was down-regulated with ER α and β in gonadal tissue of hermaphroditic fish after exposure to nonylphenol (Seo *et al.*, 2006). Nonylphenol in wastewater in India exhibited antiandrogenic activity in the Hershberger assay (Kumar *et al.*, 2008). Octylphenol, a degradation product of alkyl ethoxylates, is also oestrogenic in *in vitro* oestrogen assays (White *et al.*, 1994).

2.1.3 Industrial Materials

Phenylphenols are used as household insecticides, especially for indoor applications (Grossman, 1995; Paris *et al.*, 2002), and as intermediates in the manufacture of rubbers and resins. These hydroxylated derivatives all showed oestrogenic activity. However, 2-hydroxydiphenyl and 3-hydroxydiphenyl showed lower activities than 4-hydroxydiphenyl and 4,4′-dihydroxydiphenyl. Soto *et al.* (1997) reported that 2-hydroxydiphenyl, which is used as an antifungal, is a weak oestrogen, and the related compounds 4-hydroxydiphenyl and 3-hydroxydiphenyl are oestrogenic.

Trans-4-Hydroxystilbene and *trans*-4,4′-dihydroxystilbene both show oestrogenic activity, being about as potent as DES in oestrogen screening tests. *trans*-Stilbene was converted to the active metabolites, *trans*-4-hydroxystilbene and *trans*-4,4′-dihydroxystilbene, by rat

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

liver microsomes, and the oestrogenic activity of *trans*-stilbene might be due mainly to *trans*-4-hydroxystilbene and slightly to *trans*-4,4′-dihydroxystilbene. In contrast, *cis*-stilbene was not metabolized to the corresponding hydroxylated metabolites in a liver microsome system (Sugihara *et al.*, 2000). In an *in vivo* oestrogen test using ovariectomized (OVX) rats, *trans*-stilbene, as well as 4-hydroxylated stilbene, was positive (Sanoh *et al.*, 2006). This indicates that *trans*-stilbene exhibits oestrogenic activity after metabolic activation *in vivo*.

2.1.4 Food Additives

It is also reported that *trans*-anethole, a flavour agent, is not oestrogenic, but 4-hydroxy-1-propenylbenzene, the demethylated metabolite of *trans*-anethole, exhibits oestrogenic activity (Nakagawa and Tayama, 2003). Butylated hydroxyanisole, a food additive used as an antioxidant and food preservative in food, food packing, feed, cosmetics and pharmaceuticals, has antioestrogenic activity, but not oestrogenic or antiandrogenic activity *in vivo* in rats (Kang *et al.*, 2005).

Benzylideneacetone also has a use as a flavouring additive for cosmetics, detergents, cigarettes and foods (Opdyke, 1973). This food additive is metabolically activated to an oestrogen by a microsomal enzyme system, and the 4-hydroxy derivative, which is a major metabolite in the microsomal system, has oestrogenic activity (Kohno *et al.*, 2005).

Nordihydroguaiaretic acid (NDGA) is an antioxidant which has been used to preserve oils and food. It also has anticancer activity. NDGA is a member of the lignans, which are generally regarded as phytoestrogens. NDGA has oestrogenic activity *in vitro* with the estrogen-responsive element (ERE)-luc reporter system using NIH3T3 cells and the oestrogen-responsive cell growth assay in a pituitary cell line MtT/E-2. Uterotropic assays in rats indicated oestrogenic activity *in vivo*, but only at a dose as high as $100\,mg\,kg^{-1}$ body weight/two days for 10 days. NDGA is able to bind both ERα and ERβ. Interestingly it preferentially induced ERα-mediated ERE-luc activity, although the binding affinity of NDGA was about the same with both receptors. However, with ERβ, NDGA showed only weak agonistic action, and it antagonized the oestrogenic action when administered with E2 (Fujimoto *et al.*, 2004).

2.1.5 Flame Retardants

Brominated flame retardants are widely used throughout the world in building materials, paints, synthetic textiles and plastic products, including epoxy resin electronic circuit boards and other electronic equipment (Alaee and Wenning, 2002; Darnerud *et al.*, 2001; Darnerud, 2003; De Wit, 2002; Sjödin *et al.*, 2003). Polybrominated diphenyl ethers (PBDEs) and tetrabromobisphenol A (TBBPA) have been detected in environmental samples, such as sediments, fish and birds, and also in human breast milk and blood (Sjödin *et al.*, 2001; Thomsen *et al.*, 2002; Oberg *et al.*, 2002; Fischer *et al.*, 2006; Harrard and Porter, 2007; Inoue *et al.*, 2006; Schecter *et al.*, 2006). The halogenated compound was also found in air samples at an electronics recycling plant (Sjödin *et al.*, 2001). Thomsen *et al.* (2001) detected TBBPA and TCBPA in human plasma lipids at levels of $4–200\,pg\,g^{-1}$ plasma. Some PBDEs may influence the endocrine system in wildlife. It has become evident that exposure to PBDEs can lead to TH disturbances and neurotoxicity in experimental animals, wildlife and humans (Hallgren and Darnerud, 2002; Mariussen and Fonnum, 2003; Viberg *et al.*, 2003; Fukuda *et al.*, 2004; Hamers *et al.*, 2006; Sakai *et al.*, 2003; Zhou *et al.,* 2001a; 2002). It has been suggested that hydroxylated PBDEs may disrupt TH status, because of their structural similarity to TH. Hydroxylated PBDEs may have high binding affinities for the serum TH binding protein transthyretin (TTR) and thyroid hormone receptor (TR), thereby displacing the natural ligand. TBBPA and TCBPA exhibited significant thyroid hormonal activity towards rat pituitary cell line GH3, which releases GH in a TH-dependent manner (Kitamura *et al.*, 2002a). 1,2,5,6,9,10-Hexabromocyclododecane also exhibited TR-mediated gene expression (Yamada-Okabe *et al.*, 2005).

Affinity for TR of some hydroxylated PBDEs was comparatively examined. 4-Hydroxy-2,2′,3,4′,5-pentabromodiphenyl ether and 3-hydroxy-2,2′,4,4′-tetrabromodiphenyl ether showed binding affinity for TR. However, 2,2′,3,4,4′,5′-hexabromodiphenyl ether, decabromodiphenyl ether, 4-methoxy-2,2′,3,4′,5-pentabromodiphenyl ether, 4-hydroxy-2,2′,3,4′-tetrabromodiphenyl ether and 4′-hydroxy-2,2′,4-tribromodiphenyl ether did not show affinity for TR. In contrast, 4′-hydroxy-2,2′,4-tribromodiphenyl ether exhibited significant oestrogenic activity in an oestrogen-responsive reporter assay in MCF-7 cells. However, the adjacent bromo-substitution of 3- or 4-hydroxylated PBDEs markedly decreased the oestrogenic activity. These findings suggest that hydroxylated PBDEs act as TH-like agents, as well as oestrogens. A 4- or 3-hydroxyl group in PBDEs is essential for thyroid hormonal and oestrogenic activities, while adjacent dibromo substitution favours thyroid hormonal activity, but not oestrogenic activity.

It has been reported that some PBDEs and TBBPA have oestrogenic, antiandrogenic and antiprogesteronic activities *in vitro* (Kitamura *et al.,* 2002a; Olsen *et al.*, 2003; Stoker *et al.*, 2005; Hamers *et al.*, 2006). Ceccatelli *et al.* (2006) reported that a PBDE, PBDE 99, may cause ER disruption *in vivo* in rats. Richardson *et al.* (2008) reported that PBDE 47 disturbed TH in mice *in vivo*. Lilienthal *et al.* (2006) also reported that PBDE 99 influences sexual development and causes sexually dimorphic behaviour in rats. Antiestrogenic activity against E2 was observed with TBBPA. TBBPA and TCBPA gave positive responses in an *in vivo* uterotrophic assay using

ovariectomized mice. In contrast, BPA and some related compounds showed significant inhibitory effects on the androgenic activity of DHT in mouse fibroblast cell line NIH3T3.

Recently, organophosphorus esters such as tris-(2-chloroethyl) phosphate and tris-(2-chloropropyl) phosphate have been widely used as flame retardants, especially as fire-preventing agents in polyurethane foams. These flame retardants exhibited cytotoxicity in the presence of S9 mix, but did not show oestrogenic or antioestrogenic activity in *in vitro* assay systems (Follmann and Wober, 2006).

2.1.6 Antifungals

Parabens are in widespread use as preservatives in foods, pharmaceuticals and cosmetics. Since the human population is widely exposed to parabens, their endocrine-disrupting effects may be a serious problem for humans. The oestrogenic activities of parabens such as methylparaben, ethylparaben, propylparaben and butylparaben have been reported in *in vitro* screening systems (Byford *et al.*, 2002; Terasaka *et al.*, 2006).

Antiandrogenic activities of some parabens were examined using reporter gene assays with Chinese hamster ovary (CHO)K1 cells. Isobutylparaben, *n*-butylparaben, isopropylparaben and *n*-propylparaben exhibited antiandrogenic activity. However, relatively short side chain parabens, ethylparaben and methylparaben, had no effect (Satoh *et al.*, 2005). Prusakiewicz *et al.* (2007) also reported that parabens exerted their oestrogenic effects by elevating levels of oestrogens through inhibition of oestrogen sulfotransferasesin skin. The inhibitory activity increased with increasing paraben ester chain length, similarly to paraben sulfotransferase oestrogenicity. In contrast, some parabens were active in the yeast two-hybrid system, but their activities were eliminated by S9 treatment (Morohoshi *et al.*, 2005).

Propylparaben shows an oestrogenic effect in rainbow trout. When sexually immature, rainbow trout were kept in water containing propylparaben at 225 $\mu g\,l^{-1}$, plasma vitellogenin was markedly increased after 12 days (Bjerregaard *et al.*, 2003). *p*-Hydroxybenzophenone, which is formed from benzophenone, an antifungal agent, in rat hepatocytes, is also oestrogenic (Nakagawa and Tayama, 2001; Nakagawa and Suzuki, 2002).

2.1.7 Sunscreens

Hydroxybenzophenones, such as 2,4-dihydroxybenzophenone (benzophenone-1) and 2,2′,4,4′-tetrahydroxybenzophenone (benzophenone-2), have the ability to absorb and to dissipate ultraviolet (UV) light A (400–315 nm) (Klein, 1992). Consequently, they are used as UV stabilizers in plastic surface coatings on food packaging to prevent polymer degradation and loss of quality of the packed food owing to UV light irradiation. These compounds may be transferred from the packaging to the contents, and subsequently ingested by humans. However, they are natural components of plants such as mango and muscat grape, and are also used as flavourings. It has been reported that some derivatives have cytotoxic effects (Matsumoto *et al.*, 2003). Hydroxybenzophenones and their derivatives are also used as sunscreens for humans. These compounds are reported to be absorbed through human skin, and bioaccumulation may occur in wildlife and humans (Felix *et al.*, 1998; Hagedorn-Leweke and Lippold, 1995; Hayden *et al.*, 1997; Jiang *et al.*, 1999). In spite of some toxic effects of benzophenone, such as hepatotoxicity, hydroxylated benzophenones are safe for topical application to humans. Acute and subchronic systemic toxicity of these compounds after dermal application is considered to be rather low (Burdock *et al.*, 1991; Dutta *et al.*, 1993; Okereke *et al.*, 1995). However, some problems have arisen with photoallergic reactions in patients with suspected clinical photosensitivity (Schauder and Ippen, 1997).

Some hydroxylated benzophenones also show oestrogenic activity in the yeast two-hybrid system with ER and coactivators (Kawamura *et al.*, 2003). It was also reported that 2-hydroxy-4-methoxybenzophenone (benzophenone-3), 2,4-dihydroxybenzophenone, 2,2′,4,4′-tetrahydroxybenzophenone and 4-hydroxybenzophenone are weakly positive in the uterotrophic assay using immature rats (Schlumpf *et al.*, 2001; Nakagawa and Tayama, 2001; Koda *et al.*, 2005). Jarry *et al.* (2004) reported that 2,2′,4,4′-tetrahydroxybenzophenone is oestrogenic in the uterotrophic assay using immature rats, and also decreased l-3,3′,5-triiodothyronine (T3) and thyroxin (T4) levels in the rats. Androgenic and antiandrogenic properties of hydroxylated benzophenones are also an important problem. Yamasaki *et al.* (2003) reported that some hydroxybenzophenones do not act as antiandrogens in the Hershberger assay. Satoh *et al.* (2001) also found that benzophenone has no affinity for AR. Ma *et al.* (2003) reported that benzophenone-3 is a weak antagonist for AR. Suzuki *et al.* (2005) comparatively examined the oestrogenic and antiandrogenic activities of benzophenone and 16 of its derivatives, which are used as UV stabilizers, by means of hormone-responsive reporter assays in various cell lines. Hydroxylated benzophenones exhibited oestrogenic activity in human breast cancer cell line MCF-7, but their activities varied markedly. The highest activity was observed with 2,4,4′-trihydroxybenzophenone (2,4,4′-triOH-BP), followed by 2,3′,4,4′-tetrahydroxybenzophenone, 4,4′-dihydroxybenzophenone, 2,2′,4,4′-tetrahydroxybenzophenone, 4-hydroxybenzophenone and 2,4-dihydroxybenzophenone. Benzophenone itself showed little activity in the assay. In contrast, benzophenone and some related compounds showed significant inhibitory effects on the androgenic activity of DHT in rat fibroblast cell line

NIH3T3. The highest activity was observed with 2,4,4′-triOH-BP, followed by 2,3′,4,4′-tetrahydroxybenzophenone, 2,2′,4,4′-tetrahydroxybenzophenone, 3-hydroxybenzophenone and 2,2′-dihydroxybenzophenone. 2,4-Dihydroxybenzophenone, 2,4,4′-triOH-BP and benzophenone gave positive responses in uterotrophic assays using ovariectomized rats, and 2,4,4′-triOH-BP was positive in the Hershberger assay using castrated rats. They suggested that a 4-hydroxyl group on the phenyl ring of benzophenone derivatives is essential for high hormonal activities, and the presence of other hydroxyl groups markedly alters these activities.

4-Methylbenzylidene camphor (4-MBC) and 3-benzylidene camphor are also UV absorbers used in sunscreens. They stimulated MCF-7 cell proliferation. 4-MBC and 3-benzylidene camphor bound to ERβ (Mueller *et al.*, 2003; Schlumpf *et al.*, 2004; Klann *et al.*, 2005). In uterotrophic assays in immature rats, 3-benzylidene camphor showed high potency, being almost as active as genistein. 4-MBC and 4-hydroxybenzoic acid isobutyl ester also had a stimulating effect on uterine weight (Tinwell *et al.*, 2002; Schlumpf *et al.*, 2004; Koda *et al.*, 2005). They suggested that active metabolites with different receptor binding characteristics are formed, as the activity on immature rat uterus could not be explained in terms of binding to ERβ. 4-MBC also interferes with the thyroid axis after the developmental exposure of rats (Maerkel *et al.*, 2007). UV filters also enter aquatic ecosystems, and 4-MBC was most frequently found, followed by benzophenone-3 (Balmer *et al.*, 2005). In contrast, 4-octylphenylsalicylate and 2,2′-dihydroxy-4,4′-dimethoxybenzophenone acquired oestrogenic activity after metabolic activation by S9-mix in the yeast two-hybrid assay system (Morohoshi *et al.*, 2005).

2.1.8 Air Pollutants

Polycyclic aromatic hydrocarbons (PAHs) are environmental pollutants formed during the incomplete combustion of organic materials such as fossil fuel, wood and others, including automobile exhaust, domestic heating and industrial processes. Humans are exposed to PAHs from air, water, diet and cigarette smoke. PAHs are carcinogenic in humans and animals. Many PAHs are negative in oestrogen screening tests. However, some reports suggest that hydroxylated PAHs act as xenoestrogens. It was demonstrated that hydroxylated metabolites of benzo[*a*]pyrene exhibit oestrogenic activity. The 1-,3-,7- and 9-hydroxylated metabolites had binding affinity for ER, but the 7,8- and 9,10-dihydroxy metabolites did not (Charles *et al.*, 2000; Fertuck *et al.*, 2001; Bader, 2005). De Wiele *et al.* (2005) also reported that polycyclic aromatic hydrocarbons were transformed to oestrogenic hydroxylated metabolites by human colon microbiota. As oestrogenic compounds in cigarette smoke condensate, 2-hydroxyfluorene, 2- and 3-hydroxyphenanthrenes, and 1-hydroxypyrene were identified (Kamiya *et al.*, 2005). Some hydroxylated PAHs were also reported to be antiestrogenic in a yeast assay system (Tran *et al.*, 1996; Hirose *et al.*, 2001). 1-Hydroxypyrene was identified as an oestrogenic compound in diesel exhaust particulates (Noguchi *et al.*, 2007). 4-Nitrophenol in diesel exhaust particles is both oestrogenic and antiandrogenic (Li *et al.*, 2006). Hayakawa *et al.* (2007) compared the oestrogenic/antioestrogenic activities of 63 monohydroxylated PAHs using the yeast two-hybrid assay system, and found that hydroxylated PAHs having three to five rings show these activities. Hydroxylated PAHs having four rings, such as 3-, 4- and 10-hydroxybenzo[*a*]anthracenes, and 2-hydroxychrysene showed especially high oestrogenic activity, and hydroxylated PAHs having four rings such as 2- and 3-hydroxybenzo[*c*]phenanthrenes, 2-hydroxybenz[*a*]anthracene and 3-hydroxychrysene showed high antioestrogenic activity. Antiandrogenic activity of some PAHs was reported in a reporter gene assay system (Vinggaard *et al.*, 2000; Kizu *et al.*, 2003). Both Vinggaard and Kizu's studies demonstrated that aryl hydrocarbon receptor (AhR) was required for the antiandrogenic effect of PAHs. Lin *et al.* (2004a) also demonstrated that the AhR signalling pathway is involved in the effect of benzo[*a*]pyrene on AR expression.

Nitropolycyclic aromatic hydrocarbons, which are carcinogenic and mutagenic, enter the environment from diesel engine exhaust, urban pollution sources, cigarette smoking and so on (Wang *et al.*, 1980; Rosenkranz and Mermelstein, 1983). Nitropolycyclic aromatic hydrocarbons should also be examined to see whether nitro reduction or hydroxylation of the aromatic rings activates these compounds to xenobiotic oestrogens, as is the case for their carcinogenicity. 2-Nitrofluorene is a typical carcinogenic nitropolycyclic aromatic hydrocarbon (Möller *et al.*, 1989). 2-Nitrofluorene was detected in diesel exhaust particles as a major component, together with nitropyrenes, and was also detected as a major pollutant in the atmosphere (Campbell and Milton, 1984). It was shown that 2-nitrofluorene exhibits a significant oestrogenic activity after activation by rat liver microsomal mixed function oxidase of 3-methylcholanthrene-treated rats. In this case, 7-hydroxy-2-nitrofluorene was formed as a major metabolite and exhibited a significant oestrogenic activity (Fujimoto *et al.*, 2003).

2.1.9 Polychlorinated Biphenyls

PCBs have been widely used throughout the world as industrial chemicals for heat transfer and electrical insulation. However, they have contaminated almost every component of the global ecosystem, including wildlife and human adipose tissue, breast milk and serum, due to their lipophilic character. They have been reported

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to have a variety of toxic effects, including immunotoxicity, neurotoxicity, developmental toxicity, hepatotoxic effects, reproductive toxicity and carcinogenesis (Safe, 1994). In recent years it has become evident that exposure to PCBs can also lead to TH disturbances in wildlife and humans (Brouwer *et al.*, 1998; Porterfield and Hendry, 1998). Decreased levels of circulating plasma T4 following PCB exposure have been found in laboratory animals (Brouwer *et al.*, 1998; Barter and Klaassen, 1994). Disturbance of TH metabolism, such as glucuronidation, sulfation or deiodination, with PCBs was also reported (van Birgelen *et al.*, 1995; Brouwer *et al.*, 1998).

Some hydroxy-PCBs, which are metabolites of PCBs, are reported to show antithyroid hormonal activity in addition to oestrogenic activity (Lans *et al.*, 1994; Connor *et al.*, 1997; Korach *et al.*, 1988; Cheek *et al.*, 1999; Kitamura *et al.*, 2005b). The potency of hydroxylated PCBs to compete for binding with TR was tested, in view of their structural resemblance to the THs. Korach *et al.* (1988) reported that some hydroxy-PCBs, such as 4,4′-dihydroxy-3,3′,5,5′-tetrachlorobiphenyl, competitively bind to ER and exhibit oestrogenic activity in the mouse uterus. Other reports also show that hydroxylated PCBs are oestrogenic or antioestrogenic with respect to binding to ER (Moore *et al.*, 1997; Ramamoorthy *et al.*, 1997). Connor *et al.* (1997) demonstrated complex structure–oestrogenicity/antioestrogenicity relationships for hydroxylated PCBs. In the case of hydroxy-PCB, adjacent chloride substituents decreased the oestrogenic activity (Kitamura *et al.*, 2005c). The catechol-type metabolite of PCBs was also shown to induce oestrogenic activity (Garner *et al.*, 1999).

It has also been reported that hydroxylated PCBs can disrupt TH status by high binding affinity for the serum TH binding protein TTR (Lans *et al.*, 1993; 1994; Cheek *et al.*, 1999). Kitamura *et al.* (2005c) comparatively examined the TH-disrupting and oestrogenic activities of 14 hydroxylated PCBs by means of binding assays with TR, as well as TH-dependent growth assays and assays of production of GH in pituitary cell line GH3 cells, and also evaluated the oestrogenic activity observed in ERE-luciferase reporter assays. 4-Hydroxy-2,2′,3,4′,5,5′-hexachlorobiphenyl, 4-hydroxy-3,3′, 4′,5-tetrachlorobiphenyl and 4,4′-dihydroxy-3,3′,5,5′-tetrachlorobiphenyl, which have been detected as metabolites of PCBs in animals and humans, and six other 4-hydroxylated PCBs markedly inhibited the binding of triiodothyronine to TR. These hydroxy-PCBs also enhanced the proliferation of rat pituitary cell line GH3 cells and stimulated their production of GH. However, 4-hydroxy-2′, 4′, 6′-trichlorobiphenyl, 4-hydroxy-2,2′,5,5′-tetrachlorobiphenyl, 4-hydroxy-2,3,3′, 4′-tetrachlorobiphenyl, 2,3′,5,5′-tetrachlorobiphenyl and 2,3′, 4′,5,5′-pentachlorodiphenyl did not show affinity for TR. Only 4-hydroxy-2′, 4′, 6′-tetrachlorobiphenyl exhibited a significant oestrogenic activity in oestrogen-responsive reporter assays in MCF-7 cells. However, 3,5-dichloro substitution of 4-hydroxylated PCBs markedly decreased the oestrogenic activity. Thus, it was suggested that a 4-hydroxyl group in PCBs is essential for thyroid hormonal and oestrogenic activities, and that 3,5-dichloro substitution favours thyroid hormonal activity, but not oestrogenic activity.

The levels of these active metabolites in the body would be critical in determining whether these compounds actually show activity *in vivo*. Sandau *et al.* (2000, 2002) reported that the amount of total hydroxylated PCBs in normal human populations is of the order of $0.15-0.46\,\mathrm{ng\,g^{-1}}$ wet weight of blood, but in highly exposed populations, such as the Inuits, the concentration can reach as much as $11.6\,\mathrm{ng\,g^{-1}}$ wet weight of blood. The average values for Inuit men and women are 1.73 and $1.01\,\mathrm{ng\,g^{-1}}$ blood, respectively. The concentration of hydroxylated PCBs in humans is thus two or three orders of magnitude less than the concentration shown to cause thyroid hormonal activity in this *in vitro* study. Therefore, these effects may not occur in the real world. High levels of hydroxylated PCBs in marine mammals may be expected (Hoekstra *et al.*, 2003). These compounds may be accumulated in the animal body, especially marine mammals, through the generations and by bioconcentration in the food chain.

Serum TH levels are tightly regulated through the hypothalamus–pituitary–thyroid axis *in vivo*, but this may not be the case for these chemicals, which may act directly on the endocrine organs. In contrast, it was reported that hydroxylated PCBs disrupt the central nervous system through antagonistic action against THs (Iwasaki *et al.*, 2002; Miyazaki *et al.*, 2004). If hydroxylated PCBs are taken up into foetuses, these compounds may induce TH-disrupting effects through this action in combination with the agonistic mechanism. Darnerud *et al.* (1996) also reported that hydroxylated PCBs bind with foetal TTR, and this is accompanied with a decrease in foetal plasma thyroxin levels. It is necessary to assess the *in vivo* endocrine-disrupting action of hydroxylated PCBs, taking into account the other TH-disrupting actions of these compounds.

2.1.10 Organotin Compounds

Organotin compounds have been used as heat stabilizers in vinyl chloride polymers, industrial catalysts for polyurethane foam and silicones, and biocides for bacteria and fungi. In particular, tributyltin and triphenyltin have been widely used as biocides, agricultural fungicides, wood preservatives and disinfecting agents in circulating industrial cooling waters, as well as in antifouling paint for ships and aquaculture nets. Organotin compounds are toxic to sexual development of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

marine species at low concentrations (Beaumont and Badd, 1984). Molluscs are the most sensitive species, and shell malformations have been observed in oysters, as well as reduced growth and population decline (Alzieu, 1991; Widows and Page, 1993). Imposex, imposition of male characters in female organisms of some gastropod species, has been widely observed, and leads to reproductive failure and consequent population decline (Gibbs and Bryan, 1994; Horiguchi *et al.*, 1997). Organotin compounds are also neurotoxic and immunotoxic in mammals (Cooke *et al.*, 2004). Contamination with organotin compounds has been reported in wild animals, especially in marine organisms (Snoeij *et al.*, 1987). Organotin compounds also contaminate human food, especially shellfish, and water, mainly through contributions from industrial effluents and from leaching of polyvinyl chloride water pipes. Humans exposed accidentally or occupationally to organotin compounds develop seizures, episodes of severe pain and psychic disturbances (Fortemps *et al.*, 1978; Ross *et al.*, 1981). Kannan *et al.* (1999) reported that butyltin compounds were detected in the order of monobutyltin > dibutyltin > tributyltin in human blood, and the average level of total butyltin compounds in blood collected from subjects in Michigan was 21 ng ml^{-1}, with a maximum of 101 ng ml^{-1}, which corresponds to the lower levels in sea mammalians.

Imposex can be caused by increased androgen levels through inhibition of aromatase (CYP19) activity by tributyltin (Betin *et al.*, 1996). However, the concentration required for the inhibition is very high compared to environmental levels. Recently, it was demonstrated that organotin compounds function as retinoid X receptor (RXR) agonists, and aromatase is inhibited as a result of the high affinity of organotin compounds for RXR (Nakanishi *et al.*, 2005; Nakanishi *et al.,* 2006a). Yonezawa *et al.* (2007) also reported that tributyltin and triphenyltin inhibited osteoclast differentiation in mouse monocytic RAW264.7 cells through RXR, but monobutyltin and dibutyltin did not show such activity. In contrast, organotin compounds also are reported to inhibit the activity of steroidogenic enzymes such as 3β-hydroxysteroid dehydrogenase type II, 5β-reductase type II and 17β-hydroxysteroid dehydrogenase types I and III with aromatase in animals *in vitro* (Doering *et al.*, 2002; Lo *et al.*, 2003). However, Nakanishi *et al.* (2006b) found that tripropyltin, tributyltin and triphenyltin enhanced the activity of 17β-hydroxysteroid dehydrogenase type I in human placenta. Thus, these organotins stimulated 17β-oestradiol biosynthesis, and are expected to induce higher levels of E2 in human placenta. Haemoproteins such as P450 isozymes and neuronal nitric oxide synthase (nNOS) were also inhibited by organotin compounds, like aromatase (Kim *et al.*, 1998; Ohashi *et al.*, 2004).

2.1.11 Pesticides

2.1.11.1 Action of Pesticides In Vitro

Chlorinated insecticides, such as kepone, *o*, *p*′-DDT, dieldrin and methoxychlor, are known to have oestrogenic activity (Andersen *et al.*, 1999). *p*, *p*′-DDE, vinclozolin and ketoconazole (antifungal agents), and linuron, iprodione, chlozolinate, procymidone, chlornitrofen, fenitrothion and fenthion (insecticides) have antiandrogenic activity (Kelce *et al.*, 1995; Gray *et al.,* 1999a; Tamura *et al.* 2001; Kojima *et al.*, 2003; Kitamura *et al.*, 2003b; Wong *et al.*, 1995; Ostby *et al.*, 1999; Lambright *et al.*, 2000; McIntyre *et al.*, 2000). *p*, *p*′-DDT (1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane) is metabolized to *p*, *p*′-DDD (1,1-dichloro-2,2-bis(4-chlorophenyl)ethane) and *p*, *p*′-DDE (1,1-dichloro-2,2-bis(4-chlorophenyl)ethylene) by reductive dechlorination and dehydrochlorination, respectively, and *p*, *p*′-DDD is further oxidized to *p*, *p*′-DDA (2,2-bis(4-chlorophenyl)acetic acid) in animals and fish (Esaac and Matsumura, 1980; Kitamura *et al.*, 2002b). *p*, *p*′-DDD shows oestrogenic activity and *p*, *p*′-DDE shows antiandrogenic activity (Kelce *et al.*, 1995). The metabolites of *p*, *p*′-DDT and *o*, *p*′-DDT described above exhibit oestrogenic activity, like the early established environmental oestrogen *o*, *p*′-DDT (Forster *et al.,* 1975; Chen *et al.*, 1997; Nelson *et al.*, 1978). Nelson (1974) showed that some of these DDT metabolites have uterotropic effects *in vivo*. Gray *et al.* (1999) reported that *p*, *p*′-DDT was antiandrogenic, as well as *p*, *p*′-DDE. Methoxychlor requires demethylation by liver microsomal mixed function oxidases, including CYP 1A2 and 2C19, to elicit oestrogenic activity (Stresser and Kupfer, 1998; Elsby *et al.*, 2001b). Schlenk *et al.* (1997) also reported that methoxychlor was activated to oestrogen in fish. The widespread use of these pesticides and fungicides in the environment may alter male sexual development and reproductive processes (Kelce and Wilson, 1997).

Andersen *et al.* (2002) tested 22 pesticides for effects on proliferation of MCF-7 cells, and interference with the activation of ER and AR. They reported that chlorpyrifos, prochloraz, fenarimol, endosulfan, dieldrin, pirimicarb, propamocarb, methiocarb and tolclofos-methyl exhibited oestrogenic activity in cell proliferation assays and transactivation assays using MCF-7 cells. Kojima *et al.* (2004) examined the oestrogenic activity of 56 pesticides in *in vitro* reporter gene assays using CHO cells. They found that prothiofos, bromophos-methyl, tolclofos-methyl, quinalphos, leptophos, cyanofenphos, dichlofenthion, EPN (ethyl *p*-nitrophenyl phenylphosphonothionate), ethion and bromophos-ethyl showed affinity for ERα and ERβ. Butamifos showed the highest activity among positive compounds for ERα. No antioestrogenic activity was observed with any of pesticides tested.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Kojima *et al.* (2004) also reported that fenitrothion, anilofos, EPN, prothiofos, parathion, methyl parathion, tolclofos-methyl, piperophos, ethion, butamifos, phosalone, dichlofenthion, fenthion, cyanophos, leptophos, bromopho-ethyl, quinalphos, isofenphos and fenitrothion (MEP) oxon showed inhibitory effects on the androgenic activity of DHT in a reporter gene assay using CHO cells transfected with human AR (hAR). Fenthion, an organophosphorus pesticide, which is widely used throughout the world as a broad-spectrum insecticide for numerous crops, showed antiandrogenic activity against the androgenic activity of DHT in a reporter assay using NIH3T3 cells (Kitamura *et al.*, 2003b). Tamura *et al.* (2001) reported that fenitrothion competitively inhibited DHT-dependent human AR activation in HepG2 cells. The potency of fenitrothion was about 8- to 35-fold higher than those of *p*, *p*′-DDE and linuron, well-known environmental antiandrogens (Maness *et al.*, 1998; McIntyre *et al.*, 2001). Sohoni *et al.* (2001) observed activity of fenitrothion in recombinant yeast expressing the human AR. In this literature, fenitrothion showed the highest activity among the pesticides tested. Fang *et al.* (2003) reported that methyl parathion, parathion and triphenyl phosphate were positive in a comparative binding assay to AR.

Chlorpyrifos induced gene expression of gonadotropin-releasing hormone (GnRH) in a hypothalamic cell line, GT1-7, suggesting that it may have an impact on the hypothalamic–pituitary–gonad axis (Gore, 2002; Kojima *et al.*, 2004). It is also reported that chlorpyrifos may interfere with testosterone metabolism, potentially leading to hormonal imbalance (Usmani *et al.*, 2003). Bisson and Hontela (2002) reported that diazinon inhibited adrenocorticotropic hormone (ACTH)- and dibutyryl-cAMP-stimulated cortisol secretion in adrenocortical cells of rainbow trout. Takeuchi *et al.* (2006) examined agonistic activities of 200 pesticides for peroxisome proliferator-activated receptor α (PPARα), which regulates fatty acid metabolism. They showed that diclofop-methyl, pyrethrins and imazalil act as agonists for PPARα, and further, PPARα-inducible P450 4A was induced in mice treated with diclofos-methyl and pyrethrins.

Pyrethroid insecticides are widely used throughout the world as a wide-spectrum insecticide for numerous crops and also for indoor pest control in the public health sector and housing (Casida *et al.*, 1983; Roberts and Hutson, 1999). Pyrethroids act on the axons in the peripheral and central nervous systems of insects, causing prolonged opening of sodium channels (Aldridge, 1990; Miyamoto *et al.*, 1995). Some authors have indicated that hydrolysis products of permethrin have endocrine-disrupting potential (Stratton and Corke, 1982; Tyler *et al.*, 2000; McCarthy *et al.*, 2006). Several endocrin-disrupting actions, such as oestrogenic, antioestrogenic, antiandrogenic and antiprogestagenic activities, have been reported (Eil and Nisula, 1990; Garey and Wolff, 1998; Go *et al.*, 1999; Kim *et al.*, 2004). Chen *et al.* (2002) reported that some pyrethroid pesticides were positive in oestrogen screening assays, E-screen assays, ER competitive binding assays or pS2 expression assays. Go *et al.* (1999) reported significant oestrogenicity of sumithrin and fenvalerate in an assay using MCF-7 cells. Antioestrogenic activity of pyrethroids was also reported (Kim *et al.*, 2004). Several synthetic pyrethroids, such as sumithrin, fenvalerate and permethrin, as well as naturally occurring pyrethrins, interact with AR (Parker *et al.*, 1984; Eil and Nisula, 1990). Tyler *et al.* (2000) showed that metabolic and environmental degradation products of pyrethroids have oestrogenic, antioestrogenic and/or antiandrogenic activity.

Urea-type pesticides, propanil, linuron and diuron, which are herbicides widely used around the world, have the ability to bind to AR (Cook *et al.*, 1993; Bauer *et al.*, 1998). Indeed, linuron is structurally related to the nonsteroidal antiandrogen, flutamide, and its IC50 value for competition at the AR is approximately three and half times that of flutamide. In contrast, prochloraz, inhibited the aromatase activity of human placental microsomes and human JEG-3 choriocarcinoma cells (Mason *et al.*, 1987; Vinggaard *et al.*, 2000; Andersen *et al.*, 2002). Linuron decreased accessory sex organ weights in sexually immature and mature rats treated with linuron. In linuron-treated mature rats, serum E2 and LH levels were increased (Cook *et al.*, 1993). Imidazole-like fungicides such as imazalil and prochloraz were potent inhibitors of aromatase (Sanderson *et al.*, 2002). Atrazine, which is widely used as a selective pre-emergence herbicide, has a low affinity for ER and AR. However, atrazine influenced these hormone levels through inhibition or induction of hormonal-regulating enzymes. Atrazine and vinclozolin increase aromatase levels by binding to and inhibiting phosphodiesterase, resulting in increased transcription of the aromatase gene through elevated cyclic adenosine monophosphate (cAMP) levels (Sanderson *et al.*, 2002; Roberge *et al.*, 2004). The pesticide vinclozolin is also known to exhibit antiandrogenic activity after metabolic activation (Kelce *et al.*, 1994; Gray *et al.*, 1994). A diphenyl ether-type herbicide, chlornitrofen, exhibited oestrogenic and antiandrogenic activities in *in vitro* reporter gene assay system using CHO cells. The antiandrogenic activity was higher than that of *o*, *p*′-DDT (Kojima *et al.*, 2003). Nitrofen also caused TR-mediated gene expression (Yamada-Okabe *et al.*, 2005).

Some carbamate pesticides such as aldicarb, Baygon (propoxur), bendiocarb, carbaryl, methomyl and oxamyl weakly activated oestrogen- or progesterone-responsive reporter genes in breast MCF-7 and endometrial (Ishikawa) cancer cells (Klotz *et al.*, 1997). Kojima *et al.* (2004) examined the oestrogenic activity of 22 carbamate pesticides and reported that methiocarb is agonistic against human ER (hER)α and ERβ. Further, they found that the activity against ERβ was higher than that against ERα. In contrast, Andersen *et al.* (2002)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018

reported that methiocarb exhibits oestrogenic activity in cell proliferation assays and transactivation assays using MCF-7 human breast cancer cells. Methiocarb acted as an AR antagonist, as well as an ER agonist. It inhibited the androgenic response to R1881 at the concentration of 20 μM in transactivation assays using CHO cells (Andersen *et al.*, 2002). Kojima *et al.* (2004) reported that methiocarb and thiobencarb inhibited the androgenic activity of DHT in CHO cells transfected with hAR at 2.8×10^{-6} M and 9.4×10^{-6} M (IC20), respectively. Activation or inhibition of enzyme activities involved in steroid hormone synthesis might also alter endogenous hormone levels. Pirimicarb and propamocarb enhanced the activity of CYP 19 (aromatase), which catalyzes the conversion of C19 steroid to oestrogens (Andersen *et al.*, 2002).

2.1.11.2 Action of Pesticides In Vivo in Animals

Quinalphos, an organophosphate insecticide, exhibited oestrogen-like action in vaginal cornification and increased the uterine wet weight (uterotrophic assay; Clark *et al.*, 1980) in immature and ovariectomized mature rats at 1 mg kg day^{-1}, subcutaneous (SC), for three days, but the activity was weaker than that of aldrin (Chatterjee *et al.*, 1992). Regarding antiandrogenic activity, fenthion was positive *in vivo* in the Hershberger assay (Hershberger *et al.*, 1953) using castrated male rats (Kitamura *et al.*, 2003b). When fenthion (25–50 mg kg day^{-1}) was subcutaneously dosed together with testosterone propionate (0.5 mg kg day^{-1}) for seven days, the effect of testosterone on the weights of the prostate and seminal vesicles was significantly suppressed. Antiandrogenic activity of fenitrothion has also been reported in the Hershberger assay using castrated male rats (Tamura *et al.*, 2001). Chlorpyrifos-methyl showed antiandrogenic activity after metabolic activation in the Hershberger test using rats (Kang *et al.*, 2004). To investigate whether fenitrothion has an impact on androgen-dependent sexual differentiation, the effects *in utero* exposure were further examined in rats (Turner *et al.*, 2002). Pregnant Sprague–Dawley (SD) rats were administered fenitrothion by gavage from gestation day 12 to 21. In male offspring maternally exposed at 25 mg kg day^{-1}, a reduction in anogenital distance (AGD) was evident on postnatal day 1, although the effect was transient, and no abnormalities in male organ development were noted at postnatal day 100. Administration of fenitrothion at high dosages (55 mg kg^{-1}, three days) has been reported to reduce testicular cytochrome P450 (Clos *et al.*, 1994). A decrease in serum testosterone levels also was detected at this dosage.

The ability of parathion to interfere with the metabolism of androgens, as well as with androgen uptake, in male accessory organs in rats was described back in the 1960s (Kupfer, 1967; Schein and Thomas, 1976; Thomas and Schein, 1974). The oral administration of parathion (1.3–5.2 mg kg day^{-1}) caused significant alterations in the metabolism of testosterone in mice. An early study suggested that this compound competitively inhibits androgen binding to its receptor (Schein *et al.*, 1979). Parathion was reported to interfere with mouse spermatogenesis, and this may be related to its prenatal toxicity in mammals. An organ culture study with mouse testis revealed that parathion directly suppresses normal testicular differentiation (Rojas *et al.*, 1998). An increase of apoptosis in spermatogonia by this pesticide was also reported (Bustos-Obregon *et al.*, 2001). Quinalphos is also known to have adverse effects on the testis and male accessory glands in rats (Ray *et al.*, 1991; Ray *et al.*, 1992). When Wistar rats were given this compound at 0.25 mg kg day^{-1} (interperitoneal; ip) for 26 days, massive degeneration of germ cells in the testis, with a reduction in the sperm count, was evident (Ray *et al.*, 1992).

Malathion can disrupt thyroidal activity. In young adult rats, administration of malathion at 60 μg rat day^{-1} for 21 days resulted in decreased serum T3 and T4 and increased TSH levels (Akhtar *et al.*, 1996). A significant delay of growth was observed in tadpoles in water containing malathion at 1 mg l^{-1}, suggesting a decrease in thyroid function (Fordham *et al.*, 2001). In the freshwater catfish, *Clarias batrachus*, malathion decreased serum T3 level, but accelerated T4 synthesis in the pharyngeal thyroid. Extrathyroidal conversion of T4 to T3 was also inhibited (Sinha *et al.*, 1991b; 1992). Rawlings *et al.* (1998) reported that chlorpyrfos and dimethoate decrease serum T4 levels in ewes treated with these chemicals at 12.5 and 0.2 mg kg^{-1}, respectively, three times a week, for 43 days. The teleost fish, *Channa punctatus* (Bloch), exposed to cythion at 2–4 ppm in water developed hypertrophy and hyperplasia in the follicular epithelium and a reduction of colloid content in the thyroid (Ram *et al.*, 1989). Treatment of bullfrog tadpoles (*Rana catesbeiana*) with malathion significantly delayed developmental progression (Fordham *et al.*, 2001). Malathion inhibited T3 binding to TTR, but did not bind to the ligand-binding domain of TRβ in a study using recombinant Japanese quail TTR and TR (Ishihara *et al.*, 2003). This affinity for TTR may account for the effect of malathion on serum TH levels *in vivo*.

When a high dose of carbaryl was orally administered to male rats (100 mg kg^{-1} body weight, five days a week), marked histopathological changes in the testes were seen, with degeneration of spermatogenic cells (Pant *et al.*, 1995). These effects were associated with declines in epididymal sperm count and % sperm motility and increased abnormal sperm morphology. Adult male Wistar rats fed with laboratory chow containing 1.0, 6.3 or 203 ppm benomyl exhibited decreased ejaculate sperm counts, decreased testicular weight and a lowered male fertility index (Barnes *et al.*, 1983). In catfish, carbaryl exposure produced a reduction in the number of oocytes,

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

deformity in oocytes at different stages, and a reduction in the gonadosomatic index (Kulshrestha and Arora, 1984). When female Swiss mice were orally administered with this chemical at 1 mg kg^{-1} body weight per day, there was a significant decrease in the number of oestrous cycles and in the duration of the phases of each cycle (Baligar and Kaliwal, 2002). Rats dosed with carbofuran (1.5 mg kg^{-1}, sc) showed transient endocrine disruption, that is, the levels of progesterone, cortisol and E2 were significantly increased, while the levels of testosterone were decreased (Goad *et al.*, 2004). In fish, treatment with 0.5–1 mg l^{-1} of carbofuran inhibits oocyte maturational processes in females (Chatterjee *et al.*, 1997) and causes deleterious testicular changes, included necrosis of Leydig cells (Ram *et al.*, 2001). In contrast, an impairment of the duration of oestrous cycles in rats treated with mancozeb was observed (Mahadevaswami *et al.*, 2000).

Carbamate insecticides disrupt serum TH levels in rodents and fishes. In a study with SD rats fed with aldicarb at 10 ppb, metribuzin at 10 ppm or methomyl at 1 ppm in drinking water (6–16 weeks), the serum thyroxin levels increased significantly (Porter *et al.*, 1999). In catfish, carbaryl exposure (12 mg l^{-1}) for 96 hours suppressed serum T4, but elevated serum T3 levels, while 16 days' exposure (5 mg l^{-1}) decreased both T3 and T4 (Sinha *et al.*, 1991a). Rawlings *et al.* (1998) reported that carbofuran caused a significant increase in serum thyroxin level, and triallate increased the basal LH level compared with that of control ewes. In the teleost fish, *Channa punctatus*, treatment with carbaryl at 1.7 ppm for 30 days also caused a decline in the level of T4 and an elevation in T3 (Ghosh *et al.*, 1989). In the same species, long-term exposure (six months) to carbofuran at 4.5 ppm led to histological abnormalities of the thyroid gland, including hypertrophy, hyperplasia and degeneration of follicular epithelial cells, and a reduction in colloid content, along with retardation of thyroid function. Another study also found a greater susceptibility of the younger group to chronic toxicity of carbofuran as compared with adults in this species (Ram, 1988). Mancozeb can disrupt thyroid function, and its degradation product, ethylene thiourea, is causally related to thyroid cancer in animals (Steenland *et al.*, 1997; Chhabra *et al.*, 1992).

2.1.12 Pharmaceuticals

Some pharmaceuticals have high endocrine-disrupting activity in wildlife. Their residues in aquatic environments may present a serious problem, because these medicines have high biological activities. For example, acetaminophen (paracetamol), clofibrate, ibuprofen, cimetidine, 17α-ethinylestradiol, antibiotics and so on are detected in aquatic environments (Boxall, 2004). 17α-ethinylestradiol at aquatic environmental concentrations causes reproductive failure in zebrafish (Nash *et al.*, 2004). However, Folmar *et al.* (2000) reported that 17α-ethinylestradiol did not enhance vitellogenin (a biological marker for oestrogens in fish) levels in the blood of male sheepshead minnow at environmental concentrations of this pharmaceutical. DES, a potential oestrogen, has been used medically as a substitute for endogenous oestrogen and as hormonal therapy for prostate or breast cancer, and also to prevent threatened abortions (Metzler, 1984; Smith and Brookline, 1948). However, it may induce vaginal adenocarcinoma (Herbst *et al.*, 1971). Its oestrogenic activity is about the same as that of E2 in *in vitro* oestrogen screening tests.

Acetaminophen exhibited weak antioestrogenic activity in Ishikawa cells (Dowdy *et al.*, 2003). Trenbolone acetate, which is used to promote growth in cattle, exhibited androgenic activity *in vivo* in the Hershberger assay and *in vitro* androgen-dependent gene expression assays. The activity is exhibited by the active metabolite, 17β-trenbolone, and is as potent as that of testosterone propionate (Hotchkiss *et al.*, 2007).

Natural hormone steroids and synthetic steroids, such as 17α-ethinylestradiol and mestranol, are also a group of endocrine disruptors, which are excreted by humans and animals. Although these steroids are found in various environments, the risk arising from them is not adequately understood (Ying *et al.*, 2002). Most natural steroids may be short-lived and do not accumulate in tissues. In contrast, synthetic steroids may be more stable and may remain in the body longer than natural steroids (Tapiero *et al.*, 2002).

2.1.13 Natural Products

Phytoestrogens are plant chemicals, which have various actions, including fungicidal, plant-hormonal and plant-protective activities. Some phytoestrogens structurally resemble endogenous oestrogens. These oestrogens have higher potential to disrupt oestrogen signalling than industrial xenoestrogens, and exposure is generally repeated or prolonged. However, dietary phytoestrogens show some beneficial effects in patients with oestrogen-dependent diseases. Asian populations consume a diet that is rich in phytoestrogens, and suffer lower rates of hormone-dependent cancers compared with Western populations. Thus, are phytoestrogens friends or foes? This has been discussed for a long time (Barrett, 1996). Unlike industrial xenoestrogens, phytoestrogens are readily metabolized and rapidly excreted from the body. Phytoestrogens exert pleitotropic effects involving kinase inhibition, cell cycle regulation and antioxidative properties. These actions are are likely to contribute to the beneficial effects of phytoestrogens.

Phytoestrogens are usually termed isoflavones. They tend to bind preferentially to ERβ, and act as agonists and antagonists (Tikkanen and Adlercreutz, 2000; Ikeda *et al.*, 2002). Aglycones of soy isoflavones such as genistein, dihydrogenistein and equol bind to ER receptors.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Their binding ability to ERβ, which is comparable to that of E2, is higher than that to ERα (Morito *et al.*, 2001). Breinholt and Larsen (1998) investigated the oestrogenic activity of 23 flavonoids in assays based on the transcriptional activity of ER in yeast and proliferation of MCF7 cells, and showed that eight flavonoids, including naringenin, apigenin and kaempferol, were active. Daidzin and genistin prevent bone loss in ovariectomized rats (Ishida *et al.*, 1998). In contrast, oestrogens regulate lipid metabolism. Phytoestrogens also reduce obesity and decrease adiposity (Bhathena and Velasquez, 2002; Cederroth *et al.*, 2007).

It was demonstrated that resveratrol, which is a derivative of stilbene found in grapes and wine, is an agonist for ER (Gehm *et al.*, 1997). A comparison of the oestrogenic activities of some stilbene derivatives indicated that the 4-hydroxyl group of the A-ring plays a most important role and the vinyl linkage is necessary for high activity. Hydrophobicity of the B-ring also plays an important role, because the oestrogenic activity of hydroxystilbene is higher than that of hydroxystyrene. A *p*-hydroxy group in the A-phenyl ring, a vinyl linkage, a B-phenyl ring and a hydrophobic linkage are necessary for maximal activity of stilbene derivatives (Sanoh *et al.*, 2003).

Koda *et al.* (2007) demonstrated that all-*trans*-retinoic acid has antioestrogenic activity in an *in vivo* uterotrophic assay. They suggested that up-regulation of retinoic acid receptor and RXR mRNA expression levels was responsible for the activity.

2.2 Developmental Toxicity of Endocrine-Disrupting Chemicals

Exposure to EDCs during the development period, pre- or postnatal, can cause irreversible effects in humans and animals. In this period, nuclear receptors have different roles from those in adults, and the adverse effects of EDCs appear after development.

DES and BPA disrupt normal development of the reproductive tract (vom Saal *et al.*, 1998; Laws *et al.*, 2000; Gupta, 2000) and prolonged administration is a risk factor for carcinogenesis. Exposure to $10\,\mu g\,kg^{-1}$ body weight BPA during gestation days 14–18 altered maternal behaviours in mice (Palanza *et al.*, 2002). In another study, the UV filters 4-MBC and 3-benzylidene camphor were administered to the parent generation before mating, during pregnancy and lactation, and to the offspring until adulthood. Neonates exhibited enhanced prostate growth after 4-MBC and altered uterine gene expression after both chemicals. 4-MBC and 3-benzylidene camphor delayed male puberty and affected reproductive organ weights of adult offspring (Schlumpf *et al.*, 2008). Mice prenatally exposed to methoxychlor showed changes in reflex development and periadolescent mice showed decreased reaction times in exploring both a novel environment and a novel object (Palanza *et al.*, 1999).

Administration of antiandrogenic chemicals may alter sexual differentiation. *In utero* treatment with AR antagonist, flutamide, vinclozolin and p,p'-DDE, results in ventral prostate agenesis and testicular nondescent, and male offspring display increased incidences of epididymal and testicular lesions (Gray, 1999b).

Concern about thyroid-disrupting chemicals has increased because of the critical role that TH plays in brain development. Thyroid disrupting chemicals alter the structure or function of the thyroid gland, alter regulatory enzymes associated with TH homeostasis, or change circulating or tissue concentrations of THs. More important effects of EDCs are disruption of TH in the prenatal and postnatal stages, resulting in brain developmental dysfunction, especially in the nervous system (Crofton, 2008). Organochlorines such as dioxins, PCBs, and PBDEs could all lead to TH disruption, and affect serum total T4 concentration (Crofton *et al.*, 2005).

2.3 Disruption of Thyroid Hormone Homeostasis in Wildlife

Global climate change is receiving particular attention because it has the potential to cause habitat destruction, desertification and biodiversity loss, and also may have a serious impact on human health and society. The problem of man-made chemicals released into the environment has also been of great concern in recent years.

One example of the importance of TH to vertebrate growth and development is amphibian metamorphosis (Kollros, 1961; Kaltenbach, 1966; Dodd and Dodd, 1976). Frog THs are structurally identical to mammalian THs (Dodd and Dodd, 1976), and frog TRs are highly homologous to other vertebrate counterparts. Type II deiodinase (DI-2) converts T4 into the much more biologically active T3 through the removal of an outer ring iodine molecule, whereas type III deiodinase (DI-3) inactivates T4 and T3 by removal of an inner ring iodine molecule. The biological functions of T3 are mediated by interaction with TR, which belongs to the nuclear hormone receptor family (Zhang and Lazar, 2000). TR forms a heterodimer with a RXR, thereby acquiring binding ability to thyroid hormone response elements (TREs) located in the promoter regions of target genes, followed by binding of T3 to enhance gene transcription (Shi, 2000). Amphibian metamorphosis is triggered and controlled by THs, and thus it seems highly probable that TH synthesis, TH transport and TH metabolism are all potential target areas for the disrupting effects of environmental chemicals.

Tadpole tail resorption during anuran metamorphosis is a dramatic change resulting from apoptosis, or programmed cell death, and is controlled by TH (Shi,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2000). Addition of THs to the water or medium used in rearing premetamorphic stage tadpoles results in an enhanced metamorphic process, and such TH-induced enhancement has proven to be a useful tool for investigating the effects of environmental chemicals. The expression of key genes important for the TH signalling pathway can be easily monitored in real-time throughout development in transgenic tadpoles and frogs carrying enhanced green fluorescent protein (EGFP) transgenes relevant to the thyroid axis and to metamorphosis. TH function is regulated by a complex interplay between the hypothalamus, pituitary and thyroid glands (HPT) (Lechan and Fekete, 2006). For mammals the hypothalamic thyrotropin-releasing hormone (TRH) stimulates the biosynthesis and release of thyroid stimulating hormone (TSH) in the pituitary gland, followed by release of T4 and T3 from the thyroid gland into the circulation. For developing tadpoles the hypothalamus controls TSH release via corticotrophin-releasing factor (CRF), rather than TRH (Shirey *et al.*, 2006).

Several investigations have shown that PCBs adversely affect amphibian metamorphosis. Jelaso *et al.* (2005) reported that long-term dietary exposure to Aroclor 1254 (A1254) delayed progression through metamorphosis in developing *Xenopus (X.) laevis*. Shirey *et al.* (2006) found that exposure of *X. laevis* tadpoles to an environmentally relevant concentration (50 ppb) of A1254 resulted in delayed metamorphosis and altered gene expression of TTR and DI-2 and DI-3. This change in DI-2 expression is consistent with the findings of Morse *et al.* (1996), who reported that conversion of T4 to T3 is significantly decreased in the developing brains of rats after exposure to A1254 *in utero*. Long-term exposure (up to completion of metamorphosis) of *X. laevis* tadpoles to the technical PCB mixture Clophen A50 reduced plasma T4 levels and significantly delayed metamorphosis (Gutleb *et al.*, 2000; 2007).

Goto *et al.* (2006) reported that T3-treated *R. ruosa* tadpole tails displayed marked apoptotic features, including DNA fragmentation and ladder-like DNA profiles, as opposed to little or no fragmentation or ladder formation for T3 + BPA-treated tails. They also found that BPA suppressed spontaneous *Silurana tropicalis* metamorphosis controlled by endogenous circulating TH. These results indicate that BPA acts as a TH antagonist. BPA was also found to block spontaneous and T3-induced metamorphosis in *X. laevis* tadpoles (Iwamuro *et al.*, 2003). Iwamuro *et al.* (2006) reported that BPA acts as a T3 antagonist by suppressing TRα and TRβ gene expression in *X. laevis* tail tissue. Goto *et al.* (2006) reported that in transgenic *X. laevis* tadpoles carrying plasmid DNA containing TRE and 5′-upstream promoter regions of the TRβA1 gene linked to an EGFP gene, T3 induced strong EGFP expression in the hind limbs. This expression was suppressed by BPA, indicating that BPA may act as an antagonist to prevent the binding of T3 to TR, resulting in suppression of TR-mediated gene expression.

TBBPA also suppresses T3-enhanced tadpole tail absorption, and suppresses spontaneous and T3-induced amphibian metamorphosis, including tadpole tail apoptosis. It also inhibited strong T3-induced EGFP expression in transgenic tadpole hind limbs. These findings indicate that TBBPA acts as a T3 antagonist (Kitamura *et al.*, 2005b; Goto *et al.* 2006). Exposure to TBBPA, however, results in accelerated metamorphosis in Pacific tree frog *Pseudacris regilla* tadpoles, suggesting that this chemical substance acts as a TH agonist (Veldhoen *et al.*, 2006). The effect of TBBPA on TH action may show a substantial species-dependence.

3 TOXICOLOGICAL EFFECTS ON THE REPRODUCTIVE SYSTEM

EDCs originally called environmental oestrogens, bind to steroid hormone receptors and act as agonists (‘mimicking oestrogens’) or antagonists. They are naturally occurring chemicals or environmental contaminants, and could affect the reproductive system physiologically regulated by sex steroid hormones. A primary concern therefore is whether these chemicals alter the reproductive system and reduce the number of offspring without displaying significant acute toxicity (Hollander, 1997; Hotckiss *et al.*, 2008; Markey *et al.*, 2002; Waring and Harris, 2005).

3.1 Invertebrates

Well-documented imposex in molluscs caused by tributyltin exemplifies the reproductive effects of environmental chemicals in invertebrates (Birchenough *et al.*, 2002). Ttributyltin was widely used in antifouling paint on ships, and although its use was restricted during the 1990s, high levels of contamination are still found in some areas. Ttributyltin causes the imposition of male sex organs (penis and vas deferens) and leads to reproductive failure. Early studies demonstrated that imposex in these organisms was related to an increased level of testosterone, which may not have comparable functions to those in vertebrates (LeBlanc and McLachlan, 2000). The investigation of the effects of EDCs on invertebrates, which forms a part of ecotoxicology, is a huge challenge, considering that they comprise 95% of all terrestrial and aquatic animal species, with huge diversity (Hutchinson, 2002).

3.2 Fish, Amphibians, Reptiles and Birds

In vertebrates, oestrogens play a fundamental role in sex-differentiation, development of sex characteristics and reproduction. Environmental oestrogens could disrupt the reproductive function, although the dose ranges may be very diverse and mechanisms differ. In fishes, exposure to sewage effluent induced abnormal synthesis of vitellogenin (the precursor of egg yolk protein) in male liver. It is associated also with an increase in 'intersex' population, which reduces fertility (Jobling *et al.*, 2002; Jobling and Tyler, 2003). High levels of contaminations of nonylphenol, octylphenol and BPA, as well as synthetic pharmaceutical oestrogens, have been found in rivers (Jobling *et al.*, 2006). In frogs, a herbicide, atrazine, disrupts male gonadal development at the concentration of 0.1 ppb, well below the level of environmental contamination. This malformation is associated with the depletion of androgens and production of oestrogens, probably due to the activation of aromatase (Hayes *et al.*, 2006; Tavera-Mendoza *et al.*, 2002). The effect was well documented in Florida alligators (Gallagher *et al.*, 2001; Lind *et al.*, 2004; Semenza *et al.*, 1997). At Lake Apopka, Florida, which was polluted with ficofol, DDT and its metabolites, male alligators were feminized (smaller penises and testis) and the females had ovarian abnormalities, resulting in low hatching rates of eggs. In birds, an early study showed that injection of DDT into gull eggs led to feminization of males, with development of ovarian tissue and oviducts (Fry and Toone, 1981). In Japanese quail, DDT exposure altered the morphology of the oviduct and the shell gland, impairing egg laying, although male reproductive glands were not significantly affected (Halldin, 2005).

3.3 Mammals (Laboratory Rodents)

In mammals, the reproductive system is orchestrated by oestrogen, androgens and pituitary hormones, comprising the hypothalamic–pituitary–gonad axis. Moreover, oestrogens and androgens play a key role in foetal and neonatal development of the reproduction system. Although endocrine disruptors could affect the function of the adult reproductive system, this requires high exposure and the effects are generally reversible. One of the rare cases of EDCs affecting reproductive functions in adults has been recognized in sheep since the 1940s. Feeding clover containing phytoestrogens, quol and coumestrol causes infertility in these animals (Rossiter, 1970). Nevertheless, toxicological effects by EDCs at environmentally relevant levels could occur in the developmental stage of the reproductive system (Maffini *et al.*, 2006; Markey *et al.*, 2003). There was much argument about the existence of so-called 'low-dose effects' before the recognition of this problem (vom Saal and Hughes, 2005). In any event, we should keep in mind that, as with other toxicological studies, our present knowledge about the effects of EDCs in mammals largely comes out of investigations with laboratory rodents (**Table 1**).

3.3.1 Male Reproductive Glands

Since the development of male reproductive glands is regulated by oestrogen as well as androgens, both oestrogenic and androgenic EDCs may cause adverse effects. In addition, AhR agonists such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and PCBs also cause problems, probably through disruption of the androgenic and oestrogenic pathways.

Foetal exposure to antiandrogens may cause malformations in androgen-dependent tissues. Male SD rats treated

Table 1 Effects on reproductive glands with perinatally administered antiandrogenic and estrogenic chemicals

Representative chemicals	Male	Female	
Flutamide DDE, vinclozolin prochloraz, linuron	Cryptorchidism, hypospadias, prostate agenesis, decrease in weight of testis, SV and epididymides	—	Gray *et al.* (1999), McIntyre *et al.* (2001)
DES (high dose)	Cryptorchidism, hypospadias, decreased sperm output and decrease in prostate size	Cystic ovaries, virginal adenocarcinoma, uterus hyperplasia	Cheek and McLachlan (1998), Newbold (2004)
DES (low dose)	Increase in prostate weight, decrease in weight of epididymides	Smaller vagina, smaller endometrial lamina propria	Gupta (2000), Markey *et al.* (2005), Walker *et al.* (1990)
BPA (low doses or environmentally relevant doses)	Increase in prostate weight, decrease in epididymides, decreased ERb in POA	Smaller vagina, smaller endometrial lamina propria, increased ducts and end buds in mammary gland, altered pattern of oestrous cycle	Markey *et al.* (2001), Markey *et al.* (2003), Ramos *et al.* (2003), Rubin *et al.* (2001)

with an antiandrogen, flutamide, during gestation days 12 to 21, showed prostate agenesis and decrease in weight of the seminal vesicles, testes and epididymides, along with a reduction of AGD and retained nipples (McIntyre *et al.*, 2001). Perinatal administration of vinclozolin, a fungicide whose metabolites are androgen antagonists, reduced prostate, seminal vesicle and epididymal weights (Gray *et al.,*1999; Kelce *et al.*, 1994). Another antiandrogen, DDE, was reported to exhibit similar effects (Kelce *et al.*, 1995; 1997; You *et al.*, 1998). In the category of antiandrogenic chemicals, there are inhibitors of testosterone synthesis, such as prochloraz (fungicide) and linuron (herbicide), which have similar prenatal effects (Blystone *et al.*, 2007; Hotchkiss *et al.*, 2004; Lambright *et al.*, 2000; McIntyre *et al.*, 2000; Vinggaard *et al.*, 2005; Wilson *et al.*, 2004).

The effects of high doses of synthetic oestrogens, DES and ethinyl oestradiol, on male reproduction have been well documented (Cheek and McLachlan, 1998; Newbold, 2004). When pregnant mice were treated with DES, the incidence of cryptorchidism and hypospadias increased and sperm concentration decreased in the male offspring (McLachlan *et al.*, 1982; Yoshida *et al.*, 1999; 2000). Ethinyl oestradiol also causes disruptions, including poorly formed testis, cryptorchidism and reduced number of Sertoli cells. Similar reproductive dysfunctions have been reported in humans, that is, sons of mothers treated with DES during pregnancy, although the data are not consistent (Atanassova *et al.*, 2005; Joffe, 2003; Steinberger *et al.*, 1977; Steinberger and Chowdhury, 1977; Swan, 2000). Neonatal exposure to high doses of oestradiol permanently altered prostatic growth. Prins has shown that rats treated with oestrogen at postnatal day (PND) 3 showed a decrease in prostate size, along with reduced prostatic responsiveness to testosterone in adulthood (Prins, 1992; Prins *et al.*, 1993). Changes in expression of oestrogen and ARs were reported be involved (Prins *et al.*, 1998; Prins and Birch, 1997).

The development of the prostate gland seems to be very sensitive to oestrogenic chemicals, including BPA. vam Saal and colleagues have demonstrated that foetal treatment with BPA (2–20 $\mu g\,kg^{-1}$ body weight) affected the prostate development and adult prostate weight was increased by 30% (Welshons *et al.*, 1999). They also showed that foetal low-dose exposure to other xenoestrogens, methoxychlor and DES, had the same effect (Palanza *et al.*, 2002; vom Saal *et al.*, 1997). AR mRNA in mesenchyme cells isolated from foetal mouse prostate is up-regulated by oestradiol as well as BPA, which may account for the facilitation of androgen responses (Richter *et al.*, 2007). Neonatal low-dose exposure to oestrogen increases prostate weight, though the effect may not be permanent through adulthood (Putz *et al.*, 2001a; 2001b). Increase in size of the preputial gland and decrease in epididymis size by BPA have been reported (Cagen *et al.*, 1999a; 1999b).

Prenatal exposure to TCDD, a strong AhR agonist, also has an impact on reproductive parameters. Pregnant mice were treated with TCDD on gestation day 14 and the male offspring exhibited decreases in ventral prostate, coagulating gland and thymus weights (Ko *et al.*, 2002; Lin *et al.*, 2002; 2004b; Mably *et al.,* 1992a, 1992b; Theobald and Peterson, 1997). Decreases in pituitary gland weight and epididymal sperm numbers were also found. Disruption in oestrogenic signals may be involved, since TCDD could interfere with the oestrogen pathways (Biegel and Safe, 1990; Ohtake *et al.*, 2003).

3.3.2 Female Reproductive Glands

Since the development of female reproductive glands is regulated primarily by oestrogen, EDCs with oestrogenic activity could cause adverse effects. AhR agonists are also able to alter the oestrogen signalling. Effects of *in utero* exposure to high doses of DES on female reproductive glands have been well described, including structural malformations in oviduct, uterus and vagina. High doses of oestrogenic EDCs, such as *p-tert*-octylphenol, induce abnormal differentiation in developing rat uteri via abnormal ER expression and subsequent alteration of cell proliferating activity (Yoshida *et al.*, 2002).

Prenatal exposure to BPA induced anatomical changes in mouse ovaries, an increase in the ovarian tissue occupied by antral follicles, and a decrease in the corpora lutea. Environmentally relevant doses of BPA cause changes in the reproductive tract including decrease in weight of the vagina and endometrial lamina propria and increased proliferative activity of epithelium in the endometrial glands (Markey *et al.*, 2003; Newbold *et al.*, 2007; Schonfelder *et al.*, 2002; Suzuki *et al.*, 2002). Prenatal administration of TCDD also alters female reproductive development. *In utero* exposure to TCDD induces cleft phallus, vaginal thread formation, and reduced ovarian weight (Gray *et al.*, 1997; Gray and Ostby, 1995; Wolf *et al.*, 1999).

3.3.3 Hypothalamic–Pituitary–Gonad Axis

Toxic effects of EDCs on the reproductive system occur indirectly through the hypothalamus–pituitary axis that regulates gonadal function via pituitary hormones, such as luteinizing hormone (LH) and follicle stimulating hormone (FSH). It is well known that high dose administration of oestrogen or DES suppresses GnRH release from the hypothalamus, reducing LH/FSH secretion from the pituitary gland, which results in reduction of testosterone production in males (feminization) and halting of the oestrus cycle in females. Prenatal exposure to a low level of BPA (0.1 $\mu g\,kg^{-1}$ body weight per day) altered patterns of oestrous cyclicity and decreased levels of plasma LH in adulthood in SD rats (Rubin *et al.*, 2001). In male Long–Evans rats,

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

perinatal exposure to BPA ($2.4\,\mu g\,kg^{-1}$ body weight per day) resulted in a decrease in plasma LH level (Akingbemi *et al.*, 2004). In male Wistar rats, lower levels of administration of BPA (25 and $250\,ng\,kg^{-1}$ body weight per day) caused changes in expression of ERα in the preoptic area of the hypothalamus (Ramos *et al.*, 2003). TCDD administered perinatally also may alter the hypothalamic–pituitary–gonad axis (Theobald and Peterson, 1997).

4 EFFECTS OF ENDOCRINE DISRUPTERS ON THE CENTRAL NERVOUS SYSTEM

Another important toxicity that should be considered is neurotoxicity. Most toxic actions against neurons are irreversible and can lead to serious disorders, because neurons are not readily replaceable and neuronal circuits are vulnerable. Environmental chemicals penetrate especially easily into the brain during the foetal and neonatal periods, because the blood–brain barrier is not completely formed.

The gonads are key organs in sexual differentiation, but sexual differentiation of the brain is also important, because the hypothalamic–pituitary axis controls spermatogenesis or oogenesis via gonadotropin secretion. There are differences in the brain, as well as other organs, between males and females, and the difference in the hypothalamus is especially striking. Several lines of evidence suggest that the number of apoptotic cells in these nuclei is sex-dependent in postnatal developing rats. Sex differences in the number of apoptotic cells have been found in the central division of the medial preoptic nucleus (MPNc) and the anteroventral periventricular nucleus (AVPV) in developing rats. The sexually dimorphic nucleus of the preoptic area (SDN/POA), which involves the MPNc, is the pivotal region in sexual differentiation. In rats, the SDN/POA in male hypothalamus is two to five times larger than that in female hypothalamus (Gorski *et al.*, 1978; 1980), and this brain region regulates sexual behaviour and gonadotrophin levels (Arnold and Gorski, 1984; De Jonge *et al.*, 1987; Lephart *et al.*, 2001; Preslock and McCann, 1987).

SDN/POA is affected by perinatal exposure to hormones. When female rats were given testosterone in the perinatal period, the SDN/POA in adults became as large as in males. In contrast, when rats were castrated in the neonatal period, the SDN/POA in adults became as small as in females. Therefore, differentiation of the SDN/POA depends on systemic testosterone exposure at the early stage, as well as in the genital tract. However, this masculinization is due to oestradiol formed from testosterone by aromatase.

In contrast, the AVPV in female rats is larger than that in males. Sexual differentiation of the AVPV results from exposure of the male nervous system to oestrogen formed by aromatization of testicular testosterone secreted in the first few days after birth. Thus, it has been hypothesized that exposure to EDCs during this critical period could alter the sexually dimorphic expression of TH and the overall expression of ERα in the AVPV.

Chemicals which mimic or inhibit these hormone actions are therefore possible sexual differentiation-disrupting compounds. When female rats were treated pre- and postnatally with testosterone or DES they became anovulatory and their SDN/POA developed to be equivalent in size to that of normal males. Identical treatment of male rats resulted in deficient testicular development, but had no influence on SDN/POA volume (Döhler *et al.*, 1984). In female rats, treatment with DES either perinatally (from day 16 of gestation to PND 10) or postnatally (birth to day 10) was equally effective in increasing the volume of the SDN/POA compared to that in controls. Prenatal treatment (day 16 of gestation to birth) with DES also increased the volume of the SDN/POA, but this increase was significantly smaller than that achieved with the other treatments (Tarttelin and Gorski, 1988). In another study, neonatal rats received injections of either corn oil, DES, genistein or zearalenone on Days 1–10 of life and were castrated on Day 21. The animals were killed by decapitation on Day 49. Volumes of the SDN/POA of the exposed groups were compared. In females, 0.1 mg DES, 1000 mg genistein and 1000 mg zearalenone increased SDN volume; 100 mg genistein and 100 mg zearalenone had no effect. There was no difference in SDN size among the male groups (Faber and Hughes, 1991).

The volume of the SDN/POA in Long–Evans rats was significantly altered by a change in diet at 80 days of age, at which point one-half of the males or females fed phytoestrogen-rich diet (containing 600 mg of phytoestrogens per gram of diet) from birth were switched to phytoestrogen-free diet until 120 days of age (Lund *et al.*, 2001). Males initially fed a phytoestrogen-rich diet but subsequently changed to a phytoestrogen-free diet had significantly smaller SDN/POA volumes than males fed a phytoestrogen-rich diet for a long time. These data suggest that consumption of phytoestrogens via a soy-rich diet significantly influences SDN/POA volume during adulthood.

A subsequent report showed that males fed a phytoestrogen-free diet displayed decreased SDN/POA volumes compared to males on a phytoestrogen-rich diet (Lephart *et al.*, 2003). However, in females, the SDN/POA volumes were not affected by the diets. Females fed a phytoestrogen-rich diet displayed larger AVPV volumes than males on the same diet, or females on a phytoestrogen-free diet. Males fed the phytoestrogen-free diet had larger AVPV values than did phytoestrogen-rich diet-fed males. When the SDN/POA region was examined in lifelong phytoestrogen-free diet-fed males, more apoptotic cells were present than in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

males fed the phytoestrogen-rich diet, while in the AVPV region, the opposite results were obtained. In summary, dietary consumption of phytoestrogens can alter hormone-sensitive hypothalamic brain volumes in rodents during adulthood.

Nevertheless, many other reports have found little effect of EDCs on SDN/POA. To evaluate the impact of dietary exposure to EDCs during the sensitive period of brain sexual differentiation, maternal SD rats were fed three representative chemicals, methoxychlor (24, 240 and 1200 ppm), genistein (20, 200 and 1000 ppm) or diisononyl phthalate (DINP; 400, 4000 and 20 000 ppm), from gestational day 15 to PND 10. These three chemicals caused signs of maternal toxicity at high doses; females showed endocrine disrupting effects, such as irregular oestrous cyclicity and histopathological alterations in the reproductive tract and anterior pituitary. But, the SDN/POA volume remained unchanged in all cases (Masutomi *et al.*, 2003).

The reproductive function, as well as pathohistological change in reproductive organs, in postpuberty rats treated subcutaneously with 300 mg g^{-1} BPA or 2 mg g^{-1} oestradiol benzoate from PND 1 to 5 was examined. Oestradiol benzoate markedly reduced the volume of the SDN/POA in males. On the other hand, all male and female rats treated postnatally with BPA showed normal reproductive function and no histopathologic abnormalities of reproductive organs. BPA did not affect the volume of the SDN/POA (Nagao *et al.*, 1999).

BPA was administered to pregnant Crl:CD BR SD rats by gavage at 0, 3.2, 32 or 320 mg kg day^{-1} from gestation day 11 to PND 20. DES at 15 mg kg day^{-1} was also used, as a chemical with known oestrogenic effects. Treatment with BPA also had no detectable effect on the volume of the SDN/POA. However, DES at 15 mg kg day^{-1} increased the volume of the SDN/POA of female offspring, as well as influencing their normal oestrous cyclicity following puberty (Kwon *et al.*, 2000).

It is also reported that oestrogenic compounds affect the AVPV. Animals were given four subcutaneous injections of 50 mg E2, 250 mg genistein, or 250 mg BPA at 12 hour intervals over PND 1 and 2 and sacrificed on PND 19. E2 treatment masculinized TH immunoreactivity in the female AVPV, while exposure to genistein or BPA demasculinized TH immunoreactivity in the male AVPV. In addition, they identified a population of neurons coexpressing TH and ERα, located primarily in the medial region of the AVPV. Normally, females have nearly three times as many double-labelled cells as males, but these cell numbers were defeminized by E2, genistein or BPA treatment (Patisaul *et al.*, 2006).

Bax and Badare proapoptotic proteins, while Bcl-2 and Bcl-xL are antiapoptotic proteins. The ratio of these proteins is important for apoptosis. The expression levels of Bcl-2 family members and active caspase-3 were compared in postnatal male and female rats (Tsukahara *et al.*, 2006). In the AVPV-containing tissues of PND 1 rats, there were significant sex differences in the levels of Bcl-2 (female > male) and Bax (female < male) proteins, but not of Bcl-xL or Bad proteins. In the MPNc-containing tissues of PND 8 rats, there were significant sex differences in the protein levels of Bcl-2 (female < male), Bax (female > male) and Bad (female < male), but not Bcl-xL. Immunohistochemical analyses showed significant sex differences in the number of active caspase-3-immunoreactive cells in the AVPV on PND 1 (female < male) and in the MPNc on PND 8 (female > male) (Tsukahara *et al.*, 2006). Oestrogen up-regulated Bcl-2 expression and down-regulated Bax expression in the MPNc of postnatal rats (Tsukahara *et al.*, 2008).

The female AVPV contains a higher number of cells expressing tyrosine hydroxylase. DES (1 mg) injected daily during the first week after birth, like oestradiol or testosterone, significantly reduced later tyrosine hydroxylase expression in the AVPV of females by approximately 40–65% compared to oil-treated controls (Lansing and Lonstein, 2006).

Chemicals which modify AhR-mediated neuroendocrine functions are candidate neurotoxic endocrine disrupters. AhR is an important transcription factor which mediates transcription of various molecules, such as P450 1A, but AhR ligands also affect many other functions. Many environmental chemicals can change endocrine physiology and neuroendocrine functions, but AhR-mediated effects have been well studied. The AhR pathway also crosstalks with oestrogen (Hombach-Klonisch *et al.*, 2005; Ohtake *et al.*, 2003), androgen (Jana *et al.*, 1999; Morrow *et al.*, 2004) and thyroid (Yamada-Okabe *et al.*, 2004) hormone receptor pathways.

Sex-specific physiological changes are recognized with perinatal treatment of TCDD or other AhR ligands in animal models. These studies started about 15 years ago: Peterson *et al.* and Gray *et al.* demonstrated that perinatal exposure toTCDD of male offspring of rats resulted in less masculine sexual behaviours and an increased propensity to show female mating behaviours (Mably *et al.,* 1992; Bjerke *et al.*, 1994; Gray *et al.*, 1995). TCDD changes hormone action by binding to AhR. Therefore, the distribution of AhR and its coactivators, such as aryl hydrocarbon receptor nuclear translocator (ARNT), is important for TCDD action. AhR is expressed in the SDN/POA, in which ER is coexpressed, and which is sensitive to perinatal steroid hormone actions. AVPV also has abundant expression of AhR (Petersen *et al.*, 1989a; 1989b), and this raises the possibility that TCDD may affect sexual differentiation in these regions.

The hippocampus is a part of the limbic system and plays a part in long-term memory and spatial navigation. It has an essential role in the formation of new memories about experienced events. Some researchers prefer to consider the hippocampus as part

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat018
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of a larger medial temporal lobe memory system responsible for general declarative memory. The hippocampus mainly consists of the CA1, CA2 and CA3 regions, and the dentate gyrus is also conventionally included in it.

Synaptic plasticity is the ability of the connection between two neurons to change. There are several underlying mechanisms that cooperate to achieve synaptic plasticity, including changes in the quantity of neurotransmitter released into a synapse and changes in how effectively cells respond to those neurotransmitters. Since memories are postulated to be represented by enormously interconnected networks of synapses in the brain, synaptic plasticity is one of the important neurochemical foundations of learning and memory. Long-term potentiation (LTP) and long-term depression (LTD) are two basic processes of long-term plasticity. LTP is the long-lasting enhancement in communication between two neurons that results from stimulating them simultaneously. Since neurons communicate via chemical synapses, and because memories are believed to be stored within these synapses, LTP and its opposing process, LTD, are widely considered to be the major cellular mechanisms that underlie learning and memory. LTP and LTD are observed in glutamatergic excitatory neurons, mediated by Ca^{2+} via the *N*-methyl-D-aspartic acid (NMDA) receptor.

Oestradiol has a rapid influence on the synaptic plasticity of rat hippocampal glutamatergic neurons in slices. Many electrophysiological studies showed the effects of oestradiol on LTP and LTD in rats and mice (Foy *et al.*, 1999; Vouimba *et al.,* 2000). Moreover, the role of oestradiol in slowly modulating hippocampal plasticity has been researched, because the hippocampus is known to be a target for the actions of gonadal oestrogens reaching the brain via the circulation. For example, the density of dendritic spines in CA1 pyramidal neurons is modulated *in vivo* by oestrogen replacement in ovariectomized animals (Gould *et al.*, 1990; Woolley and McEwen, 1992) and by androgens in castrated animals (MacLusky *et al.*, 2005), leading to the increase of spines.

Since the synaptic plasticity is modulated by oestradiol, environmental endocrine disruptors might affect synaptic plasticity (Kawato, 2004). When BPA was injected to pregnant mice or Japanese monkeys, it was detected in maternal and foetal brains (Uchida *et al.*, 2002). BPA can reach the brain and disturb oestrogen functions in the brain. Though endocrine disrupters are efficiently metabolized in the liver, only low levels of drug-metabolizing enzymes were expressed in the brain (Kishimoto *et al.*, 2004; Miksys and Tyndale, 2002). Therefore, endocrine disrupters are expected to stay in the brain for a long time. These findings suggest that endocrine disrupters actually reach mammalian brains and may disrupt their functions. It has been demonstrated that 10–100 nM BPA, DES and 4-nonylphenol have effects on LTD and spinogenesis (Ogiue-Ikeda *et al.*, 2008).

5 EFFECTS OF ENDOCRINE DISRUPTERS ON THE IMMUNE SYSTEM

BPA can modulate both the endocrine and immune systems, resulting in alterations of homeostasis, reproduction, development and behaviour (Al-Hiyasat *et al.*, 2002; Tyl *et al.*, 2002; Sawai *et al.*, 2003; Funabashi *et al.*, 2004). Furthermore, halogenated derivatives of BPA and BPA-dimethacrylate, as well as BPA, are widely used as plastic products, dental sealants, and flame-retardants for building materials, paints, polystyrene resins and electronic circuit boards. Depolymerization of these products allows BPA and its derivatives to leach into foods, into infant formulas from plastic bottles, into saliva of patients treated with dental sealants, and into packed fresh foods (Brotons *et al.*, 1995; Biles *et al.*, 1999; Olea *et al.*, 1996; Vivacqua *et al.*, 2003). Alkylphenol ethoxylates are widely used as surfactants and detergents in domestic and industrial products and are commonly found in wastewater. These compounds are degraded to more resistant alkylphenols, such as 4-*n*-nonylphenol and 4-*n*-octylphenol, and have been detected in fish muscle tissue and foods. These compounds were also reported to exhibit oestrogenic activity (Andersen *et al.*, 1999).

Alizadeh *et al.* (2006) studied whether or not administration of BPA modulates T helper (Th) cell immune responses in mice challenged with ovalbumin (OVA), and found that BPA treatment of naïve animals resulted in lower titres of total IgE and higher levels of IgG2a, followed by higher levels of IFN-γ, interleukin (IL)-12 and intact IL-4 in response to OVA. In contrast, in OVA-pretreated groups, BPA did not affect production of total or OVA-specific IgE, or OVA-specific IgG2a, and resulted in lower production of IFN-γ. Furthermore, BPA resulted in impaired lymphocyte proliferation in response to concanavalin A in naïve animals, but not in tolerant animals. They concluded that BPA results in augmentation of Th1 immune responses, but has no significant effect on an established tolerance to OVA.

It has been reported that both BPA and 4-*n*-nonylphenol significantly enhance IL-4 production in keyhole limpet haemocyanin (KLH)-primed $CD4^+$ T cells in a concentration-dependent manner, and treatment with BPA or nonylphenol (NP) *in vivo* resulted in a significant increase of IL-4 production in $CD4^+$ T cells and of antigen-specific IgE levels in the sera of KLH-primed mice. The enhancing effect mapped to a region in the IL-4 promoter containing binding sites for nuclear factor (NF)-AT. Furthermore, it appeared that the transcription factor NF-AT was involved in

the enhancing effects of BPA and 4-nonylphenol on IL-4 production (Lee *et al.*, 2003). Occupational health hazards that may be associated with BPA include allergic contact dermatitis (ACD) secondary to BPA exposure. Most ACD occurs in workers handling BPA-containing products, such as plastic products, and in workers exposed to epoxy adhesive tapes, foams and dental products. The cutaneous penetration of BPA through pig skin was examined *in vitro* using a Franz cell. After 2, 5 and 10 hours of exposure, total BPA content in skin was 3, 6.9 and 11.4% of the applied dose, respectively. BPA remained essentially on the skin surface and accumulated mainly in the dermis. As the pig skin model is a reliable predictor of percutaneous penetration in humans, these findings may be reassuring for workers in contact with BPA-containing products.

EDCs may cause immune disturbance, because disruption of endocrine function seriously affects the immune system. A number of biological mediators, including tumour necrosis factor (TNF)-α and nitric oxide (NO), participate in the defence mechanisms, and they are produced by macrophages in response to microbial toxins, such as bacterial endotoxin (Hong *et al.*, 2004; Araya *et al.*, 2002; Goering *et al.*, 2000). Hong *et al.* (2004) reported that carbaryl, alachlor, nonylphenol, octylphenol, tributyltin and triphenyltin inhibited lipopolysaccharide (LPS)-induced NO production *in vitro*, whereas 2,4-dichlorophenoxyacetic acid and BPA enhanced its production. On the other hand, zineb and alachlor enhanced LPS-induced TNF-α production by mouse peritoneal macrophages *ex vivo*, while alachlor inhibited LPS/IFN-γ, (interferon-γ)-induced NO production *ex vivo*. Therefore, they considered that some EDCs exert modulatory activity on endotoxin-induced macrophage activation, either positively or negatively, suggesting that these compounds may affect the development of infectious diseases.

Yoshino *et al.* (2004) studied the effect of prenatal exposure to BPA on the immune system in mice, and demonstrated that prenatal exposure to BPA may result in the up-regulation of immune responses, especially Th1 responses, in adulthood. It is widely accepted that females have superior immune responses to males, but the mechanisms through which sex hormones may enhance T cell responses are still poorly understood. Some researchers have suggested that oestrogen may enhance humoral immune responses and may be involved in the pathogenesis of autoimmune diseases, and also that it may be able to alter cytokine production and T-cell subset distribution (Ito *et al.*, 2001; Correale *et al.*, 1998). Several reports have indicated that oestrogen significantly increased IFN-γ and IL-2 mRNA in concanavalin A-activated thymocytes, splenic lymphocytes and enriched splenic T cells, though it had no marked effect on IL-4 mRNA. Therefore, it has been suggested that oestrogens may modulate the immune system by regulating cytokines (Fox *et al.*, 1991; Karpuzoglu-Sahin *et al.*, 2001a; Calemine *et al.*, 2003). DES is a synthetic oestrogen which was given to millions of women. Karpuzoglu-Sahin *et al.* (2001a) found that the DES-induced increase in IFN-γ secretion is due to hormonal effects on T cells, but not on antigen-presenting cells (APC), suggesting that: (i) oestrogens upregulate secretion of IFN-γ, a vital immunoregulatory cytokine and (ii) inappropriate exposure of developing foetuses to DES may permanently alter the cytokine programming of lymphocytes (Karpuzoglu-Sahin *et al.*, 2001b).

Maret *et al.* (2003) analysed the effect of oestrogens on CD4 T cell activation and differentiation after immunization with exogenous antigens, and they found that administration of low doses of E2 to castrated female mice produced a striking increase of antigen-specific CD4 T cell responses, as well as selective development of IFN-γ-producing cells. Quantitative assessment of the frequency of T cells bearing a public TCR β chain CDR3 motif demonstrated that the clonal size of primary antigen-specific CD4 T cells was dramatically increased in immune lymph nodes from E2-treated mice, and ERα, but not ERβ, was necessary for the enhanced E2-driven Th1 cell responsiveness. Furthermore, ERα expression in haematopoietic cells was essential, since E2 effects on Th1 responses were only observed in mice reconstituted with bone marrow cells from ERα+/+, but not ERα-deficient mice. Therefore, they considered that oestrogen administration promotes strong antigen-specific Th1 cell responses through a mechanism that requires functional expression of ERα in haematopoietic cells. In the mouse, OVX leads to significant reductions in cancerous bone volume, while oestrogen (E2) replacement not only prevents bone loss, but also can increase bone formation. Zhou *et al.* (2001b) reported that mesenchymal stem cells (MSCs) treated *in vitro* with E2 displayed a significant increase in ERα mRNA and protein expression, as well as alkaline phosphatase (ALP) activity and proliferation rate. In contrast, E2 treatment resulted in a decrease in ERβ mRNA and protein expression, as well as apoptosis, in both OVX and sham-operated mice. Therefore, they considered that oestrogen *in vitro* directly augments proliferation and differentiation, ERα expression and osteogenic gene expression, and inhibits apoptosis and ERβ expression in MSCs obtained from OVX and sham-operated mice. Coexpression of ERα, but not ERβ, and osteogenic differentiation markers might indicate that ERα functions as an activator and ERβ functions as a repressor in osteogenic differentiation in MSCs.

It has been reported that E2 attenuates responses to endoluminal injury of the rat carotid artery, at least in part, by decreasing inflammatory mediator expression and neutrophil infiltration into the injured vessel, with a major effect on the neutrophil-specific chemokine cytokine-induced neutrophil chemoattractant (CINC)-2 β (Xing *et al.*, 2007). Miller *et al.* (2004) investigated

whether or not E2 inhibits expression of adhesion molecules, chemokines and proinflammatory cytokines in rat carotid arteries in the early hours after balloon injury, and found that expression of mRNAs for adhesion molecules (P-selectin, vascular cell adhesion molecule-1 and intercellular adhesion molecule-1), chemoattractants CINC-2beta and monocyte chemoattractant protein (MCP)-1, and proinflammatory cytokines (IL-1β and IL-6) was markedly increased in injured arteries of ovariectomized + vehicle rats at two hours and was reduced at 24 hours, thus attenuating the stimulus for leukocyte entry and negatively modulating the injury response. In contrast, E2 significantly attenuated expression of the proinflammatory mediators at two hours and E2 significantly inhibited neutrophil chemotactic activity of arterial homogenates. From these results, they concluded that E2 attenuates the early vascular injury response, at least in part, by negatively modulating proinflammatory mediator expression and the resultant chemotactic activity of injured vessels for neutrophils. Segura *et al.* (1999) investigated the effects of BPA on the viability of macrophages obtained from Wistar rats and reported that BPA did not significantly alter macrophage viability at high concentrations, but it did dose-dependently decrease the adherence index of rat peritoneal macrophages. A high concentration of BPA also caused significant inhibition of the adherence index. They therefore considered that BPA can alter macrophage adhesion. Because adhesion is the first step in the phagocytic process of macrophages and in antigen presentation, BPA could inhibit macrophage function and modulate immune and inflammatory responses in dental pulp and periapical tissues.

The effects of BPA on prolactin (PRL) secretion and the expression of a PRL-regulating factor from the posterior pituitary in the oestrogen-sensitiveFischer 344 (F344) rats were investigated, and it was reported that BPA increased PRL gene expression, PRL release and proliferation of anterior pituitary cells, albeit with 1000- to 5000-fold lower potency than oestradiol. In contrast, BPA had similar efficacy to oestradiol in inducing hyperprolactinemia in oestrogen-sensitive F344 rats, though SD rats did not respond to BPA. Posterior pituitary cells from E2- or BPA-treated F344 rats showed strongly increased PRL gene expression upon coculture with GH3 cells stably transfected with a reporter gene. Like E2, BPA induced ERE activation in transiently transfected anterior and posterior pituitary cells. These results indicated that: (i) BPA mimics E2 in inducing hyperprolactinemia in genetically predisposed rats; (ii) the *in vivo* action of E2 and BPA in F344 rats is mediated, at least in part, by increasing PRL-regulating factor activity in the posterior pituitary; (iii) BPA appears to regulate transcription through an ERE, suggesting that it binds to ERs in both the anterior and posterior pituitaries (Steinmetz *et al.*, 1997). This brings into question the safety of sealants and other resin-based dental materials, due to the reported presence in them of BPA and its dimethacrylate ester. Schafer *et al.* (1999) noted that both BPA and BPA-dimethacrylate at concentrations at or above 10^{-6} M significantly increased cell proliferation, and the effect was similar to that seen with 10^{9} M oestrogen. Furthermore, flow cytometric studies showed that these mitogenic effects occurred within 24 hours of exposure to oestrogen, BPA, or BPA-dimethacrylate. Therefore, BPA and BPA-dimethacrylate cause cell proliferation at micromolar concentrations that exceed the effective concentrations of oestrogen by 1 to 10 000-fold.

Oestrogen also plays a role in the immune system. For instance, previous studies have shown that oestrogen has stimulatory effects on humoral immune responses, but suppressive effects on cellular responses. More recent studies demonstrate that oestrogen increases the secretion of IFN-γ from splenic lymphocytes, which play a major role in regulating the function of all key immune cells. It has been reported that BPA decreases the substrate adherence capacity of antigen-presenting cells, including macrophages, *in vitro*. BPA also increases the nonspecific proliferation of spleen cells in response to the mitogen concanavalin A *in vitro.* Yoshino *et al.* (2004) investigated the effect of exposure to BPA on antigen-specific antibody production and proliferative responses of lymphoid cells in mice. They also examined whether exposure to BPA-modulated Th1 immune responses, which play a role in cellular responses, as well as Th2 immune responses, which are involved in humoral responses.

In vitro BPA exposure stimulates breast cancer cell lines to proliferate, increases progesterone receptor expression in a uterine cell line, and induces c-*fos* gene expression (Steinmetz *et al.*, 1998; Bergeron *et al.*, 1999; Schafer *et al.*, 1999). Several *in vivo* studies document reproductive effects of low-dose BPA exposure. Microgram quantities of BPA were shown to be oestrogenic in F344 rats, as judged from increased prolactin expression (Steinmetz *et al.*, 1997). Male offspring of BPA-treated pregnant mice showed increased prostate size and decreased epididymal weight (Gupta, 2000; Nagel *et al.*, 1997). A review of these studies led the Endocrine Disruptors Low-Dose Peer Review Panel to conclude with caution that exposure to very low doses of BPA can cause biological effects (Kaiser, 2000). Few reports have appeared concerning BPA and immune function. *In vitro*, BPA has been shown to inhibit lymphocyte mitogenesis (Sakazaki *et al.,* 2002), MCP-1 production (Inadera *et al.*, 2000) and macrophage adhesion (Segura *et al.*, 1999). The inhibition of INF-γ by BPA appears to be long-lasting and may be due to remodelling of the INF-γ promoter. Recruitment of the histone acetylase CREB-binding protein (CBP) to a promoter contributes to increased transcription (Valapour *et al.*, 2002). Both the nuclear factor-κB (NF-κB) and ERα pathways use CBP (Harnish *et al.*, 2000; Kushner *et al.*, 2000). NF-κB is a critical transcription factor for several cytokine

genes, including INF-γ (Sica *et al.*, 1997). BPA bound to the ER may sequester proteins, such as CBP, required for NF-κB-induced cytokine gene expression, thereby reducing cytokine production. On the other hand, a recent report indicates that BPA activates the transcription factor cAMP-responsive element binding protein (CREB) (Quesada *et al.*, 2002). Expression of the INF-γ promoter is down-regulated by CREB-ATF1 binding to both proximal and distal elements and by their competition for binding with Jun/ATF2 proteins (Penix *et al.*, 1996; Zhang *et al.*, 1998). Activation of CREB due to BPA exposure may explain the diminished production of INF-γ (Sawai *et al.*, 2003).

6 INFLUENCE OF ENDOCRINE-DISRUPTING CHEMICALS ON HUMANS

Human exposure to individual EDCs is generally considered to be low, and in addition, the compounds are much less potent than natural hormones. However, humans are expected to be exposed to mixtures of potential EDCs. Hence, potential additive or synergistic effects have to be considered to assess the human risk. Furthermore, *in vivo* potency is often different from *in vitro* potency, since the mechanisms of hormonal action of chemicals may not be adequately reflected by the *in vitro* assays.

Human exposure to BPA has increased due to an increase in the use of epoxy resins and polycarbonate plastics. The primary route of human exposure is foods, via migration from containers. As BPA has been detected in river water samples, intake of fish or seafood may be a route for human exposure (Belfroid *et al.*, 2002). The daily intake is thought to be below $1\,\mu g\,kg^{-1}$ body weight per day (Kang *et al.*, 2006). Careful study is needed to see whether these levels of BPA may have an endocrine disruptive effect on humans. Foetuses are especially susceptible, because the level of uridine 5' -diphosphate (UDP)-glucuronosyl transferase, which is a major detoxification enzyme for BPA, is extremely low (Cappiello *et al.*, 2000). Several reports indicate that BPA can pass through the placenta into infants (Miyakoda *et al.*, 2000; Takahashi and Oishi, 2000; Schonfelder *et al.*, 2002).

Pesticides such as DDT and methoxychlor are well known to act as endocrine disruptors (Guillette *et al.*, 1994). The putative endocrine-disrupting effect of pesticides in wildlife is largely a prediction based on data obtained in laboratory animals. However, investigations of incidents involving misuse of pesticides have revealed virtually no endocrine-disrupting activity of these chemicals (Flickinger *et al.*, 1984).

Permethrin causes some toxic symptoms at high oral doses (Bradbury and Coats, 1989). Accidental and occupational human exposures involving dermal contact have caused acute poisoning (Altenkirch *et al.*, 1996; Chen *et al.*, 1991; Laskowski, 2002). Developmental neurotoxicity of pyrethroids has also been suggested. Neonatal rats are more sensitive than adults to pyrethroids (Shafer *et al.*, 2005). A neurotoxic effect of pyrethroids on mammalian cells was observed (Soderlund *et al.*, 2002; Kakko *et al.*, 2004). A variety of reversible symptoms, such as headache, dizziness, nausea, irritation of skin and nose and paresthesia, following exposure have been reported (He *et al.*, 1989). Exposure to the pesticide could be cumulative as regards neurotoxicity. There is potential human exposure to pyrethroids. Attempts have been reported to detect urinary metabolites of permethrin, such as phenoxybenzoic acid, in humans, as an indicator of exposure (Angerer and Ritter, 1997; Leng *et al.*, 1997; Shan *et al.*, 2004). Phenoxybenzoic acid in the urine of pest control operators was in the range $0.5–277\,\mu g\,l^{-1}$, whereas it was undetectable in the urine of nonexposed subjects (Leng *et al.*, 1997). Asakawa *et al.* (1996) also reported that phenoxybenzoic acid was detected in the urine of agricultural workers who applied permethrin to cabbages grown in open fields in Japan. Pyrethroid exposure of the general population in Germany was suggested by the fact that its metabolites were detected in the urine of volunteers (Schettgen *et al.*, 2002). It was demonstrated that metabolites of permethrin are formed by carboxylesterase and the P450 system (Nakamura *et al.*, 2007). The activities of these enzymes could be important determinants of pyrethroid exposure in humans. Fan *et al.* (2007) suggested that atrazine-induced aromatase expression was correlated with reproductive cancers in humans.

Organophosphate and carbamate insecticides are widely used in agriculture and for pest control. Chlorpyrifos, an organophosphate insecticide, has been found in human blood in Spain (Pitarch *et al.*, 2003), in human urine in the USA (Olsson *et al.*, 2003) and in human breast milk in India (Sanghi *et al.*, 2003), together with organochlorine pesticides. There are many opportunities for human exposure. As the pesticides are thought to be readily absorbed through skin, monitoring is an essential component of exposure assessment. In a study of exposure to chlorpyrifos, diazinon, propetamphos and diazinon in volunteers, almost all of these pesticides were found to be excreted after an oral dose, but large amounts were recovered in the skin surface after a dermal dose (Cocker *et al.*, 2002; Garfitt *et al.*, 2002). Tuomainen *et al.* (2002) reported that after application of malathion in greenhouses, the level of the pesticide in urine of workers reached a maximum at 6–7 hours and then rapidly decreased. Colosio *et al.* (2002) measured the ethylenethiourea levels in urine of workers in vineyards as an indicator of mancozeb, and reported that the levels in the workers were much higher than in controls, being especially high in operators of open tractors. In contrast, infants and children may have other opportunities to be exposed to

organophosphate and carbamate insecticides. Gurunathan *et al.* (1998) reported that chlorpyrifos persistently accumulates on residential surfaces and toys accessible to children after household application. Exposure of children to organophosphate insecticides can be evaluated by measuring urinary biomarkers and their metabolites, and may be related to potential adverse health effects (Eskenazi *et al.*, 1999).

Environmental antiandrogens may affect the development of the male reproductive system (Kelce and Wilson, 1997). As androgens initiate and maintain spermatogenesis, environmental antiandrogens may contribute to the decline in sperm content that is suspected to be occurring in humans and other animals. It is reported that organohalogen compounds, such as PCBs, TCDD and DDE, may contribute to the decreased sperm counts and male reproductive capacity (Sharpe, 1995). Furthermore, inhibition of AR-mediated actions during the embryonic stage may lead to developmental alteration of male external genitalia (Foster, 1997). In humans, although a causal relationship between exposure to endocrine-disrupting pesticides and reproductive disorders has not been established, some recent reports predict an effect on humans. Sherman (1996) reported birth defects of the central nervous system in children exposed *in utero* to chlorpyrifos. Weidner *et al.* (1998) indicated increased occurrence of cryptorchidism in sons of female gardeners. Abell *et al.* (2000) also indicated reduced fecundity in female greenhouse workers. There are conflicting results concerning the association of exposure of pregnant women to pesticides with changes of foetal growth or length of gestation (Grether *et al.*, 1987; Savitz *et al.*, 1989; Fenster and Coye, 1990; Restrepo *et al.*, 1990; Thomas *et al.*, 1992; Willis *et al.*, 1993; Kristensen *et al.*, 1997; Xiang *et al.*, 2000; Perera *et al.*, 2003; Eskenazi *et al.*, 2004). Further examination is needed to clarify the influence of insecticides on humans and wildlife.

Nitric Oxide Pathways in Toxic Responses

Jeffrey D. Laskin, Diane E. Heck and Debra L. Laskin

CONTENTS

1 INTRODUCTION

Originally described as a by-product in the chemical manufacturing industry and as an urban air pollutant, the discovery that nitric oxide gas is produced biologically and functions as an important physiological mediator was quite unexpected. Prior to the 1980s, crystallographers capitalized on the free-radical nature of nitric oxide for protein analysis, using its ability to bind to iron as a method to identify precise structural features of haem-containing proteins (Chien and Dickinson, 1977). The finding that nitric oxide could bind to, and activate, guanylyl cyclase, an important class of haem-containing enzymes, provided a novel tool for investigating enzyme activation and suggested a potential mechanism underlying the actions of vasodilators that release nitric oxide (Arnold *et al*., 1977; Katsuki and Murad, 1977; Katsuki *et al*., 1977). Further work showing that nitric oxide is produced endogenously and induces relaxation of smooth muscles led to studies of other physiological actions of nitric oxide, including its ability to regulate vascular tone, neuronal activity and macrophage-mediated cytotoxicity, and the enzymes that mediate nitric oxide biosynthesis (Furchgott, 1995). It is now well established that at low concentrations, nitric oxide modulates many biological processes in cells and tissues. However, when produced in excessive amounts or at inappropriate times and/or places, nitric oxide contributes to pathophysiological responses. Whether or not this causes tissue injury and/or induces significant pathology depends on local concentrations of enzymes that generate nitric oxide, its metabolism to toxic intermediates, and its degradation and detoxification in target organs. As a highly diffusible gas that can readily cross cell membranes, nitric oxide acts both as an autocrine and paracrine mediator of toxicity (Wood and Garthwaite, 1994; Porterfield *et al*., 2001). Thus, xenobiotics can induce nitric oxide production in target cells, causing oxidative and nitrosative stress and cytotoxicity. Nitric oxide can also diffuse out of the cells into surrounding cells and tissues, amplifying tissue injury.

2 NITRIC OXIDE SYNTHASES

Nitric oxide is derived from L-arginine in a sequential two-step reaction mediated by the enzyme, nitric oxide synthase (Stuehr, 2004). This enzyme catalyzes a five-electron oxidation of L-arginine to nitric oxide and L-citrulline, NADPH (nicotinamide adenine dinucleotide phosphate) and oxygen serving as cosubstrates. Three isoforms of nitric oxide synthase have been identified. These include two relatively low-output forms of the enzyme, endothelial nitric oxide synthase (eNOS or NOS-3) and neuronal nitric oxide synthase (nNOS or NOS-1), and a high-output inducible or macrophage form of the enzyme (iNOS or NOS-2). Whereas eNOS plays an important role in regulating vascular tone, signalling and remodelling, as well as leucocyte–endothelial interactions, platelet aggregation and angiogenesis, nNOS mediates neurotransmission (Stuehr, 2004; Sessa, 2004; Chatterjee and Catravas, 2008). In contrast, iNOS is important in cytotoxicity and inflammatory tissue injury, and is expressed in large amounts in macrophages (Lowenstein and Padalko, 2004). eNOS is localized in peripheral vascular endothelial cells, as well as in brain

vasculature and in motor neurons, while nNOS is found in astrocytes, myocytes, the prostate and the adrenal medulla. An additional form of nitric oxide synthase has been identified in the inner membranes of mitochondria, which may be derived from one of the three isoforms of the enzyme (Carreras *et al*., 2007). Although the specific gene product for this enzyme is unknown, it is thought to function in the regulation of mitochondrial electron transport (Haynes *et al*., 2004; Carreras *et al*., 2007).

The different isoforms of nitric oxide synthase are homodimers. Each of the enzymes contains flavin cofactors which mediate electron transfer from NADPH in one subunit of the enzyme to haem iron in an oxygenase domain of the other subunit. The oxygenase reaction of nitric oxide synthase requires tetrahydrobiopterin; eNOS and nNOS are also calcium/calmodulin-dependent (Stuehr *et al*., 2004). Enzyme activity and nitric oxide biosynthesis is regulated by the availability of L-arginine, as well as essential cofactors, including oxygen, NADPH, flavin adenine dinucleotide, flavin mononucleotide and tetrahydrobiopterin, and for eNOS and nNOS, calcium. Enzyme activity can also be regulated by post-translational modification and protein interactions (Roman *et al*., 2002). For example, nitric oxide biosynthesis via eNOS is regulated by S-nitrosylation, fatty-acid acylation and phosphorylation, as well as interaction with hsp90 and β-actin (Sessa, 2004; 2005; Gratton *et al*., 2004; Tummala *et al*., 2008). The activity of eNOS is also controlled by the membrane scaffolding protein caveolin-1, which sequesters eNOS in caveolae and inhibits its activity (Minshall *et al*., 2003; Su *et al*., 2007). Similarly, nNOS is negatively regulated by phosphorylation (Bredt *et al*., 1992). In post-synaptic terminals, this form of nNOS is activated by calcium following glutamate-induced activation of *N*-methyl-D-aspartate (NMDA) receptors (Zhou *et al*., 2008).

Nitric oxide production is also regulated by expression of nitric oxide synthase proteins. For example, iNOS is controlled transcriptionally by the stability of the transcripts and their translation (Kleinert *et al*., 2003). Initially thought to be expressed only in macrophages and to participate in cytotoxicity, it is now known that many different cell types can be induced to express iNOS and to generate nitric oxide, an activity that may be important in chemical toxicity (see further below). A number of diverse stimuli, including endotoxin, inflammatory cytokines and growth factors, are known to regulate expression of iNOS (Heck *et al*., 1992; Pacher *et al*., 2007). The endothelial and neuronal forms of nitric oxide synthase are also regulated by changes in protein expression. For example, eNOS protein is up-regulated in endothelial cells in diabetes (Hink *et al*., 2001) and nNOS protein in spinal-cord injury (Conti *et al*., 2007).

3 NITRIC OXIDE SIGNALLING AND TOXICITY

Containing a single unpaired electron, nitric oxide is a highly reactive free radical, a property that contributes to its cell signalling and cytotoxic activity (Nathan, 2003; 2004). The most well-characterized target for nitric oxide is ferrous iron in haem (Angelo *et al*., 2008), an interaction that is key to the ability of nitric oxide to regulate guanylyl cyclase (Arnold *et al*., 1977; Katsuki and Murad, 1977; Katsuki *et al*., 1977; Nakane, 2003). By binding to haem, nitric oxide allosterically activates its catalytic site, leading to increased intracellular cGMP (cyclic guanosine monophosphate) and the activity of cGMP-dependent kinases, enzymes that control numerous physiological activities including vascular tone, neuronal activity, cell growth and differentiation (Angelo *et al*., 2008). A critical role for the nitric-oxide–cGMP pathway in pathology has been identified in cardiovascular diseases, where diminished activity can lead to increases in vessel tone and an increased risk of thrombosis (Nakane, 2003; Hare and Stamler, 2005; Marin and Sessa, 2007).

Other important targets for nitric oxide include enzymes that contain transition metals and those that generate free radicals in their catalytic cycle (Pacher *et al*., 2007). For example, nitric oxide readily binds tyrosyl radicals in ribonucleotide reductase, resulting in inhibition of enzyme activity and DNA synthesis (Kwon *et al*., 1991). Nitric oxide also reacts rapidly with the superoxide anion, forming peroxynitrite (Pacher *et al*., 2007; Szabó *et al*., 2007). In fact, there is much evidence to support the idea that cytotoxicity caused by excessive production of nitric oxide is mediated in large part by peroxynitrite. Superoxide anion is formed in cells from many sources, including mitochondrial respiration, redox cycling, NADPH oxidases and xanthine oxidase (McCord, 1998). In either direct one- or two-electron oxidation reactions, or via indirect radical-mediated reactions, peroxynitrite can react with biological molecules, including lipids, proteins and nucleic acids, processes that trigger oxidative injury and perturbations in cell signalling (Alvarez *et al*., 1999; Radi *et al*., 2000; Alvarez and Radi, 2003; Rubbo *et al*., 2008). Peroxynitrite-induced tissue injury has been linked to many diseases, including neurodegeneration, diabetes, stroke, heart disease and cancer. Additional reactive nitrogen species derived from nitric oxide that can contribute to toxicity include nitrite, nitrogen dioxide, nitronium and nitrosonium cations, nitroxyl, nitrosoperoxycarbonate anion and nitryl chloride (Nathan, 2003). Each of these intermediates possesses distinct chemical and biological reactivities that may be important in the cytotoxic actions of nitric oxide in cells and tissues.

Modification of proteins and subsequent alterations in their structure and function is an important mechanism by which reactive nitrogen species initiate biological activity and/or cause cellular damage. The best characterized modifications are nitration, glutathionylation and S-nitrosylation (Alvarez and Radi, 2003; Shelton and Mieyal, 2008; Townsend, 2007). Both nitric oxide and peroxynitrite induce protein nitrotyrosine formation; peroxynitrite is significantly more effective than nitric oxide in generating nitrotyrosine modifications and this is often used as a marker of peroxynitrite production in cells and tissues (Pacher *et al*., 2007). Nitric oxide can also form nitrogen dioxide; further reactions with nitric oxide generate N_2O_3, a strong nitrosating agent that is highly reactive with protein thiols, as well as with primary and secondary amines (Pacher *et al*., 2007). S-Nitrosylation of critical sulfhydryls groups in proteins is known to regulate the activity of such groups; examples of modified proteins include cytoskeletal proteins, membrane receptors and channels, and protein kinases and phosphatases (Foster *et al*., 2003; Hess *et al*., 2005). The enzyme-independent and reversible attachment of glutathione or other low-molecular-weight thiols to cysteine sulfdryls in proteins is referred to as glutathionylation (Shelton and Mieyal, 2008). Formed via the S-nitrosylation of glutathione and protein thiols, S-nitrosylglutathione may serve as a store and/or transporter for nitric oxide (Foster *et al*., 2003; Hess *et al*., 2005). Nitric oxide can be removed from S-nitrosylglutathione enzymatically by S-nitrosylglutathione reductase, an intracellular regulator of S-nitrosothiols (Liu *et al*., 2004; Hedberg *et al*., 2003).

Reactive nitrogen species can also react with nucleic acids and lipids leading to toxicity. Damage to DNA can cause mutations, leading to necrosis and/or apoptosis (Szabó and Ohshima, 1997; Ohshima *et al*., 2006; Sawa and Ohshima, 2006), as well as altered cell growth and differentiation, potentially resulting in the development of cancer (Sawa and Ohshima, 2006). Peroxynitrite is also known to form 8-nitroguanine adducts in RNA and DNA (Szabo *et al*., 1996; Szabó and Ohshima, 1997; Ohshima *et al*., 2006). In DNA, this can lead to G:C to T:A transversions, which are mutagenic (Yermilov *et al*., 1995). The reaction of reactive nitrogen species with lipids can either directly or indirectly generate a variety of biologically active products, including electrophilic lipids such as 4-hydroxynonenal and 15-deoxy-Δ12,14-prostaglandin J2 (Catalá, 2009; Forman *et al*., 2008; Uchida and Shibata, 2008), lipid peroxides (Kim *et al*., 2008) and receptor agonists, such as nitrolinoleic acid and lysophosphatidylcholine (Villacorta *et al*., 2007; Manini *et al*., 2008). Electrophilic lipids can directly modify proteins and DNA (Zmijewski *et al*., 2005), while nitrolinoleic acid and other nitrated unsaturated fatty acids can inhibit smooth muscle cell proliferation. Reactive nitrogen species can also regulate metabolism of sphingolipids, which are important in cell growth, differentiation and apoptosis (Perrotta *et al*., 2008).

Detoxification of reactive nitrogen species is important in limiting tissue injury and a number of pathways have been identified that are involved in this process. However, some of these products also possess cytotoxic activity. For example, the reaction of nitric oxide with oxyhaemoglobin leads to its conversion to inactive nitrate (Angelo *et al*., 2008). In contrast, the reaction of peroxynitrite with carbon dioxide generates nitrogen dioxide and carbonate radicals; both of these products are reactive and can modify critical carbohydrates, proteins and nonprotein thiols and intracellular thiols (Denicola and Radi, 2005; Pacher *et al*., 2007). Cellular antioxidants, including glutathione, uric acid and selenium compounds also react with and protect cells against reactive nitrogen species (Pacher *et al*., 2007). It should be noted that nitric oxide itself can also function as an antioxidant. By eliminating superoxide anion, an important intermediate in the generation of highly reactive hydroxyl radicals, nitric oxide can limit cellular damage induced by reactive oxygen species (Pacher *et al*., 2007; Coulter *et al*., 2008). Nitric oxide has also been reported to act as a chain-terminating agent when it reacts with thiyl radicals, forming nitrosothiols (Benhar *et al*., 2006; Gaston *et al*., 2006).

4 NITRIC OXIDE AS A MEDIATOR OF CHEMICAL TOXICITY

It is now well established that nitric oxide plays an important role in the toxicity of a variety of xenobiotics in many different tissues, including the liver, lung, skin, brain and cardiovascular system (**Table 1**). That nitric oxide contributes to toxicity is based on findings that cell damage is associated with excessive production of nitric oxide and/or by increased expression of NOS protein and activity and consequent expression of biomarkers of nitric oxide production (e.g. nitrosyl-modified proteins, lipids and DNA; the appearance of oxidation products of nitric oxide in body fluids such as blood and urine). Indirect markers of nitric oxide production, including increases in cGMP, as well as downstream effectors of the nitric-oxide–cGMP pathway are also detectable in target tissues (Arnold *et al*., 1977; Katsuki and Murad, 1977; Katsuki *et al*., 1977; Fesenko *et al*., 1985; Fiscus and Murad, 1988; Boswell-Smith *et al*., 2006). Evidence to support a role for nitric oxide in chemical toxicity is also based on the findings that selective NOS inhibitors effectively prevent tissue damage. Abrogation of chemically induced tissue injury is also observed in genetically engineered mice lacking the different isoforms of NOS. It should be pointed out, however, that in some cases, xenobiotic-induced nitric oxide production is associated with protection against tissue injury. This is thought to be

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat020
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

due to the antioxidant properties of nitric oxide. Whether or not nitric oxide plays a pathological or protective role in toxicity is dependent on the toxicant, the target tissue and the extent to which toxicity is mediated by reactive oxygen species.

Numerous studies have demonstrated that nitric oxide participates in chemically-induced hepatotoxicity (Nussler *et al*., 1995; Milbourne and Bygrave, 1995; Losser and Payen, 1996; Gardner *et al*., 1998; 2002; Jaeschke *et al*., 2002). iNOS has been identified in both resident and inflammatory liver macrophages, as well as in hepatocytes, sinusoidal endothelial cells and stellate cells (Helyar *et al*., 1994; Laskin *et al*., 1995; Gross and Wolin, 1995; Gardner *et al*., 1998). By binding to haem-containing proteins in hepatic drug-metabolizing enzymes, nitric oxide can either inhibit or activate drug metabolism. Exposure to hepatotoxicants such as paracetamol (acetaminophen), ethanol, carbon tetrachloride, and endotoxin has been reported to activate Kupffer cells, as well as inflammatory macrophages, sinusoidal endothelial cells, stellate cells and/or hepatocytes, to express iNOS and produce excessive quantities of nitric oxide (Helyar *et al*., 1994; Laskin *et al*., 1995; Laskin and Pendino, 1995; Chamulitrat and Spitzer, 1996; Rockey, 1997; Rockey and Chung, 1997; Matsumoto *et al*., 2000; Spitzer and Spitzer, 2000; Zhu and Fung, 2000; Gardner *et al*., 1998; 2002; 2003; Rockey, 2003). Although this has been correlated with nitrotyrosine staining of the liver (Hinson *et al*., 1998; Gardner *et al*., 2002; 2003), the precise role of nitric oxide and peroxynitrite in hepatotoxicity appears to be dependent on the toxicant. Thus, while some studies have suggested that reactive nitrogen species are toxic, in other models, they appear to play a protective role. For example, in animals pretreated with inhibitors of iNOS, such as aminoguanidine, or in transgenic mice with a targeted disruption of iNOS, hepatotoxicity induced by acetaminophen or endotoxin is significantly reduced (Ialenti *et al*., 1992; Wright *et al*., 1992; Losser and Payen, 1996; Gardner *et al*., 1998; 2002; Laskin *et al*., 2001c). In contrast, hepatotoxicity is augmented in iNOS knockout mice treated with carbon tetrachloride (Morio *et al*., 2001). Similar increases in carbon tetrachloride-or endotoxin/*C. parvum*-induced hepatotoxicity have been described in animals pretreated with iNOS inhibitors (Harbrecht *et al*., 1992; Muriel, 1998; Taylor *et al*., 1998; Zhu and Fung, 2000), which is thought to be due to a loss of the ability of nitric oxide to reduce levels of cytotoxic oxidants (Pacher *et al*., 2007).

In the lung, the toxicity of a number of toxicants, including ozone, silica, particulate matter and paraquat is reported to be mediated by nitric oxide (Zhu *et al*., 1998; Porter *et al*., 2006; Fakhrzadeh *et al*., 2002). Several prominent cell types in the lung, including alveolar and interstitial macrophages and bronchiolar and alveolar Type II epithelial cells have the capacity to produce nitric oxide via iNOS after exposure to proinflammatory cytokines or bacterial-derived endotoxin (Pendino *et al*., 1993; Punjabi *et al*., 1994; Shan *et al*., 2007). Nitric oxide is known to play a key role in regulating airway responsiveness and bronchiole relaxation (Bhalla, 1999; Castranova *et al*., 2002), as well as macrophage-mediated cytotoxicity and cell proliferation (Laskin *et al*., 2001a; Laskin and Laskin, 2001). These latter activities are likely to be significant in tissue damage and in the regulation of alveolar epithelial regeneration following injury (Laskin *et al*., 2001c; Laskin and Laskin, 2001). Acute exposure of rodents to ozone or silica results in increased production of nitric oxide via iNOS by alveolar macrophages and Type II cells (Zeidler *et al*., 2004; Fakhrzadeh *et al*., 2008). Lung macrophages, as well as Type II cells isolated from animals exposed to ozone and silica produce increased amounts of nitric oxide in response to inflammatory mediators, indicating that the toxicants sensitize these cells to produce cytotoxic mediators (Laskin *et al*., 1995; 2001a; 2001b). Tumour necrosis factor-α (TNFα) is a critical inflammatory mediator stimulating nitric oxide production in lung macrophages following ozone inhalation in mice; animals deficient in TNFα are protected from ozone toxicity and fail to produce nitric oxide in response to ozone (Fakhrzadeh *et al*., 2008). Both ozone-and silica-induced toxicities are ameliorated by inhibitors of nitric oxide biosynthesis, as well as in iNOS knockout mice (Fakhrzadeh *et al*., 2002; Zeidler *et al*., 2004), strongly supporting a cytotoxic role for nitric oxide in the pathogenesis of lung injury caused by these agents.

Nitric oxide-mediated toxicity in the lung and brain is also associated with exposure to paraquat (Day *et al*., 1999; Denicola and Radi, 2005; Djukic *et al*., 2007). Paraquat is known to induce toxicity via redox cycling, a process mediated by a number of different enzymes, including NADPH cytochrome P450 reductase, thioredoxin reductase and nNOS (Smith and Brian, 1991; Day *et al*., 1999; Gray *et al*., 2007). Paraquat toxicity in the lung is associated with increased nitric oxide production and inhibitors of NOS have been reported to mitigate tissue injury (Mustafa *et al*., 2002). In the brain, dopaminergic neurons are susceptible to paraquat toxicity and this may be important in the development of Parkinson's disease. Toxicity is attributed to both oxidative and nitrosative stress (Hara *et al*., 1991; Djukic *et al*., 2007). Nitric oxide has been linked to excitotoxicity, a process of neuronal cell death caused by activation of excitatory amino-acid receptors, in particular, NMDA/glutamate receptors (Knott and Bossy-Wetzel, 2008). NMDA is coupled to nitric oxide production, presumably through the activation of nNOS via receptor-mediated calcium mobilization (Dawson and Dawson, 1998). NOS inhibitors, as well as haemoglobin, are effective in blocking glutamate-mediated neurotoxicity *in vitro* (Parathath *et al*., 2007). It has been suggested that

	Doxorubicin	Vasquez-Vivar *et al*. (1997)

[a](*N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine).

paraquat initiates excitotoxicity by stimulating glutamate efflux via a nitric-oxide-dependent mechanism (Shimizu *et al*., 2003a; 2003b; Dinis-Oliveira *et al*., 2006). Nitric oxide has also been reported to mediate the toxicity of *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) in the brain. MPTP is structurally similar to paraquat and may induce nitric oxide production via oxidative stress (Yokoyama *et al*., 2008). NOS inhibitors have also been shown to inhibit MPTP toxicity in mice (Watanabe *et al*., 2008) and in astrocytes. Anti-inflammatory agents suppress MPTP-induced NOS, suggesting that they may be effective in treating Parkinson's disease (Carbone *et al*., 2009).

Nitric oxide is also known to contribute to the toxicity of doxorubicin and arsenic in the cardiovascular system. Doxorubicin is one of the more prominent clinically utilized antitumour agents (Wadler *et al*., 1986). However, toxicity, which includes chronic heart failure and degenerative cardiomyopathy, has limited its use (Ferreira *et al*., 2008). Like paraquat, doxorubicin is known to redox cycle and its toxicity is thought to be due, at least in part, to the generation of cytotoxic reactive oxygen intermediates (Doroshow, 1983; Davies and Doroshow 1986; Doroshow and Davies, 1986). Redox cycling can occur via eNOS, where electrons are diverted from nitric oxide biosynthesis (Day *et al*., 1999). Nitric oxide is crucial for cardiovascular function and inhibiting its activity may be an important mechanism of toxicity (Schulz *et al*., 2004). Doxorubicin redox cycling also leads to the production of the superoxide anion. Thus, localized production of low amounts of nitric oxide may result in the generation of cytotoxic concentrations of peroxynitrite. Indeed, production of peroxynitrite has been described in mouse models of doxorubicin-induced heart failure (Weinstein *et al*., 2000; Mihm and Bauer, 2002; Mihm *et al*., 2001; 2002). Moreover, cardiac dysfunction following doxorubicin treatment is associated with nitration of cardiac myofibrils (Weinstein *et al*., 2000). Cardiomyocyte mitochondria are also targeted by peroxynitrite generated following doxorubicin exposure (Mihm *et al*., 2002). That peroxynitrite is important in doxorubicin-induced cardiomyopathy is evident from the findings that metalloporphyrin peroxynitrite decomposition catalysts protect against the development of doxorubicin-induced cardiac dysfunction (Pacher *et al*., 2003). Recent studies have also shown that disruption of eNOS protects against cardiac injury, dysfunction and mortality induced by doxorubicin (Neilan *et al*., 2007). Interference with doxorubicin-induced cardiotoxicity by a competitive inhibitor of FasL, a mediator of apoptosis and cellular inflammatory responses, was also reported to be associated with reduced expression of iNOS, as well as nitric oxide and peroxynitrite production (Niu *et al*., 2009).

Epidemiological studies have demonstrated a strong association between arsenic exposure and cardiovascular disease (Engel and Smith, 1994; Wang *et al*., 2002). Arsenic is thought to function by activating a membrane-bound NAD(P)H oxidase in vascular endothelial cells (Smith *et al*., 2001) and vascular smooth muscle cells (Lynn *et al*., 2000), a process that generates superoxide anion. Localized reaction of superoxide anion with nitric oxide can lead to cytotoxic concentrations of peroxynitrite in the cardiovascular tissue. In a mouse model, arsenic exacerbates artherosclerotic plaque formation and increases nitrotyrosine formation within the plaque (Bunderson *et al*., 2004). In rats, arsenic increases vascular leakage, a process abrogated by NOS inhibitors (Chen and Chen, 2008). Arsenic has also been found to induce peroxynitrite formation in bovine aortic endothelial cells (Bunderson *et al*., 2002). Taken together, these data suggest an important contribution of nitric oxide in arsenic-induced cardiovascular toxicity.

It is well recognized that the clinical use of cisplatin is limited by nephrotoxicity (Hensley *et al*., 2009). Cisplatin is known to induce oxidative damage in the kidney, including lipid peroxidation and to reduce intracellular antioxidants (Weijl *et al*., 1997; Yoshida *et al*., 2000; Antunes *et al*., 2001; Mora *et al*., 2003). Nitric oxide is an important mediator of kidney function including the control of renal microcirculation and in tubule activity. Recent studies have shown that cisplatin-induced renal injury is associated with up-regulation of mitochondrial NOS and nNOS, and an accumulation of nitrites in mitochondria (Jung *et al*., 2009). Cisplatin-induced increases in iNOS have also been described (Adams *et al*., 2009). In a rat model, an inhibitor of iNOS has been shown to reduce cisplatin-induced histological damage and to cause increases in proteinuria, decreases in creatinine clearance, tubulointerstitial infiltration and staining for 3-nitrotyrosine (Chirino *et al*., 2008). These data indicate that nitric oxide is involved in cisplatin toxicity, and suggest that reducing or preventing renal oxidative/nitrosative stress may improve therapeutic outcomes with this antitumour agent.

Nitric oxide has also been reported to mediate ultraviolet light B (UVB)-induced skin toxicity (Romero-Graillet *et al*., 1997; Gonzalez Maglio *et al*., 2005). Early studies showed that nitric oxide is produced by mouse and human keratinocytes (Heck *et al*., 1992). Subsequently, Romero-Graillet *et al*. (1997) reported that UVB irradiation induces the release of nitric oxide and the generation of cGMP in cultures of human keratinocytes. Nitric oxide also mediates a delayed vasodilator response to ultraviolet light (Warren *et al*., 1993; Warren, 1994). It has been demonstrated that all isoforms of NOS are present in the skin and that substantial levels of nitric oxide are generated during the wound-healing response (Stallmeyer *et al*., 1999). Nitric oxide production during wounding has been identified as a critical regulator of vascular endothelial growth factor expression, an important angiogenic factor in the proliferative phase of skin repair (Frank *et al*., 1999). UVB light is known to induce keratinocyte apoptosis. An antiapoptotic role for nitric oxide in the skin has been proposed, since UVB-induced apoptosis of dermal and epidermal cells is enhanced in iNOS- and eNOS-knockout mice, respectively (Weller *et al*., 2003). UVB light has also been reported to inhibit γ-interferon-stimulated nitric oxide production in macrophages and keratinocytes (Sur *et al*., 2002).

5 CONCLUSIONS

Nitric oxide is well recognized as a key soluble mediator in the pathogenesis of tissue injury induced by many toxicants. Xenobiotics or their metabolites can directly injure tissue, generating reactive oxygen and nitrogen species. Excessive production of these mediators leads to oxidative stress and may result in production of additional proinflammatory and cytotoxic mediators by target cells and/or infiltrating leucocytes. Resulting nitric oxide and its oxidation products can activate many different biochemical and molecular signalling cascades that contribute to toxicity. Nitric oxide can also participate in inflammatory processes that promote tissue damage. Further studies on the pathways by which nitric oxide induces pathology will be crucial for a better understanding of the mechanisms leading to xenobiotic-induced cell damage and tissue injury, and for the development of therapeutic interventions aimed at mitigating toxicity resulting from chemical exposures.
