Aquatic Toxicology: Concepts, Practice, New Directions

Peter G. Wells

CONTENTS

1 INTRODUCTION

Aquatic toxicology is 'the study of the effects of anthropogenic chemicals and activities, and natural chemicals, materials and activities on aquatic organisms, at various levels of biological organization, from sub-cellular through whole organisms, and to populations, communities and ecosystems' (adapted from Rand, 1995). This chapter introduces the reader to aquatic toxicology as an established subdiscipline of toxicology and environmental science.

1.1 Water Pollution and Its Effects

Aquatic ecosystems and their myriad biota and habitats are subjected to many abuses from the ever expanding human population (6.3 billion persons, circa 2008). The abuses include exposure to toxic substances in harmful amounts, physical disturbance and destruction of habitats. Since the industrial revolution, more than 200 years ago, many substances have poured into waterways causing lethal and sublethal effects to fish and other aquatic organisms, such as invertebrates and water birds, and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

generally disturbing and destroying their habitats. There is also removal of species at rates threatening their populations, for example overfishing, and the introduction of nonindigenous organisms. Massive effects, such as fish kills and water discolouration, occurred in the 1800s at locations such as eastern North America (e.g. New York and Boston Harbours) and the UK (e.g. the River Thames). Gross impacts of pollution have occurred well into the twentieth and twenty-first centuries in many countries worldwide. Owing to such impacts, notably on valuable resource species and often human health, such pollution generated concern for water quality and the condition of rivers, lakes, estuaries, coastal seas and the open ocean. This led to the preparation of chemical and biological methods for studying pollution-stressed organisms and ecosystems, and many technical engineering developments for preventing or reducing industrial discharges. Aquatic toxicology is now an established science.

1.2 History of Aquatic Toxicology: A Perspective

Water pollution has been studied and monitored over the past century. It began to attract serious regulatory attention after World War II, primarily with a focus on controlling oil spills from ships and treating the discharges of major toxic municipal and industrial effluents. In North America, the history and approaches are described by Warren (1971), Cairns and Dickson (1973), Hunn (1989) and Rand *et al*. (1995); in the UK by Lloyd (1992) and most recently by Thompson *et al*. (2005), amongst others; in Europe, by Blanck *et al*. (1978), Albaiges (1989) and Persoone *et al*. (2000); and in Australasia by R. Wu *et al*. in a series in the *Marine Pollution Bulletin* (Wu *et al*., 1999). Serious work was initiated on standardized biological test methods in the 1950s, culminating in the first general aquatic bioassay guide in *Standard Methods*, in 1961 (APHA, 1961; 1995). By the 1970s, aquatic toxicology had emerged as a new and organized subdiscipline of toxicology, with many contributors from Europe and North America. John Sprague's trilogy of papers on the measurement of pollutant toxicity to fish (Sprague, 1969; 1970; 1971) especially placed aquatic toxicology on a solid foundation in the new environmental era.

From the 1970s to the present (circa 2008), many practitioners worldwide have worked to advance the discipline and apply its methods to resolve water pollution problems. The literature is now very extensive, with between 50 000–100 000 papers and hundreds of specialized monographs and textbooks. Exposure and toxicity testing methods are now standardized, many sublethal techniques across all levels of biological organization are available (primarily as research tools), linkages to field observations and biomonitoring have been and are being established, and many special topics (see below), some of them very challenging, are being addressed. New professional meetings and societies have played a large and important role in these advances and in producing important syntheses, notably SETAC (The Society for Environmental Toxicology and Chemistry) since 1979, now in North America, Europe, Australasia, and South America, and the Canadian Annual Aquatic Toxicity Workshop series since 1974. Measurement of aquatic toxicity (acute and chronic) has been incorporated into key environmental legislation in a number of countries and is recognized by key regulatory and standards bodies (e.g. International Maritime Organization, Organization for Economic Cooperation and Development (OECD), International Standards Organization, American Society for Testing and Materials) as a key descriptor to measure, for the protection of aquatic ecosystems. Aquatic toxicity criteria are also incorporated into hazard assessment and ecological risk assessment (ERA) frameworks (Chapman and Long, 1983; Wells and Cote, 1988; EPA (Environmental Protection Agency), 1992; Wells *et al*., 1999; Suter, 2007).

Aquatic toxicology and the broader ecotoxicology, though still young fields, have made major strides towards establishing a theoretical, basic and applied foundation throughout the past 40 years (e.g. see Newman and Clements, 2008; Walker *et al*., 2006). Aquatic toxicology now is global in scope, from research to application. It is increasingly important for resolving major environmental problems, such as those in eastern European countries, with heavy industry emissions into the air and water; in the former Soviet Union (USSR) countries, with oil pipelines, various industries and nuclear wastes; in the rapidly developing, highly populated nations such as Brazil, India and China (Liu and Diamond, 2008); and in the numerous coastal states (pollution from land-based activities, oil inputs from shipping and ship-based activities, harbour and estuarine pollution, see *www.unep.org*).

1.3 Objectives and Scope of Aquatic Toxicology

Aquatic toxicology is concerned with the adverse effects of chemical substances and physical agents, alone and in combination, on aquatic organisms and their ecosystems. It started as an outgrowth of toxicology (see **Basic Elements of Toxicology**), then developed its own methods, approaches and applications. Its objectives are: (i) to understand how chemical and physical agents cause stress(es) on all phyla of aquatic organisms; this includes identifying modes of toxic action and measuring indirect effects of chemicals in and on ecosystems; (ii) to understand the implications of the effects at one level to those at other levels of biological organization; (iii) to understand the similarities and differences in response

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092

between different organisms in different ecosystems and geographic locations (of major importance, compared with classical toxicology); (iv) to calculate threshold concentrations for safe and unsafe biological effects, as part of the above and (v) to ensure that techniques are available for the practical roles of chemical screening, chemical and effluent regulation, and aquatic biomonitoring.

Hence the scope of the field is huge, encompassing many aquatic disciplines, environmental chemistry, basic toxicology, microbiology, ecology, statistics and law (see key references in Rand, 1995, Chapter 1). The field draws heavily upon classical toxicology, and modern biological and chemical science for its information and techniques, but it has many unique scientific features and wide management responsibilities. To practitioners, its interdisciplinarity and rate of advancement present many challenges.

1.4 Interconnections between Human and Aquatic Ecosystem Health

Making linkages between human health, and aquatic ecosystem health (AEH) and ecological integrity, as measured in aquatic toxicology, is increasingly common (Di Giulio and Monosson, 1996; Rapport *et al*., 1998; Di Giulio and Benson, 2002; Sindermann, 2006) and of undisputed importance in many locations. Contaminated and polluted waterways and coastal ecosystems can be disastrous both to people and to natural biota. One principle of aquatic toxicology is that the protection of AEH, in both surface and groundwater, lends protection to human health by ensuring good-quality drinking water, safe food and control of water-borne vectors of illness or disease. Chemicals accumulated in living aquatic species and habitats may prove toxic to people, for example, methylmercury in fish, such as at Minamata, Japan, in the 1950s; mercury in fish downstream from pulp mills in northwestern Ontario, Canada; arsenic in groundwater in Bangladesh; chlorinated solvents in drinking water; and natural toxins from microalgae in nutrient-rich waters. Other chemicals or mixtures, for example, petroleum hydrocarbons from oils, chlorinated phenols from wood, may impart off-flavours affecting taste and hence the marketability of fisheries products. Waters suffering from overnutrification and eutrophication (Schindler and Vallentyne, 2008) may harbour more algal toxin outbreaks, contaminating shellfish, such as mussels, clams and oysters, killing fish and birds, and threatening human consumers through direct ingestion or inhalation of toxic aerosols. Waters exposed to sewage and other municipal discharges may contain diseased fish and invertebrates, but also may prove threatening to swimmers, sailors and other users (GESAMP, 1990a), causing eye, skin, lung and orifice infections.

During the 1990s, phytoplankton in ship ballast water were implicated as vectors for bacteria that caused cholera in Peru and Brazil. More recently, there is concern about the security of water reservoirs from chemical agents and infectious pathogens, and the health effects of various persistent organics in seafood. Though not always shown as unambiguous cause–effect relationships, the links between water quality and human health are well recognized. In this context, aquatic toxicology contributes substantially to the cleanup, protection and security of water and its living resources.

1.5 The Practice of Aquatic Toxicology

Aquatic toxicology includes basic research with many different types of organisms (bacteria, algae and protozoa, to invertebrates, fish, amphibians and reptiles). Methods are constantly being improved to develop new understanding of how chemicals interact with aquatic species, from contact and uptake, to metabolism, excretion and recovery. For example, 43 of 58 phyla in total, including fossil phyla, are marine, according to Wilson and Peter (1988). There are 19 major groupings of freshwater organisms (World Conservation Monitoring Center (WCMC), 1998). To date, relatively few extant aquatic phyla and species have been tested in experiments for their sensitivity and responses to chemical contaminant exposures.

In addition to basic research on acute and chronic effects of chemicals, there are several practical areas of aquatic toxicology. These include chemical/substance screening and classification; regulatory testing and monitoring of industrial emissions; environmental-effects monitoring (often called biomonitoring) and water quality guidelines (WQGs) and objectives for different water uses. Aquatic toxicity criteria are used in chemical screening and hazard-evaluation systems, where chemicals or formulations are evaluated for their level of acute lethal and chronic sublethal toxicity prior to suitable classification for handling, transport and use. For example, using data provided by industry, and relevant literature, the United Nations GESAMP Working Group on the Evaluation of Harmful Substances Carried by Ships (International Maritime Organization, London, UK) uses two aquatic criteria—acute and chronic—in its hazard evaluation procedure (GESAMP, 2004); acute toxicity ratings are based on data from three types of standard tests (fish, cladoceran and microalgae) requested of industry, and the chronic rating is based on data from the standard reproductive cladoceran test, together with reliable published data on chronic sublethal effects and thresholds (Wells *et al*., 1999; GESAMP, 2004). The OECD is coordinating the harmonization of approaches and methods of aquatic toxicology used in classifying chemicals for transport, a timely example of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the seriousness with which aquatic toxicity data are now given in scientific, industrial, transportation and legal fora.

In many countries, aquatic toxicity tests or bioassays, and appropriate end points, for example median lethal concentrations (LC_{50}s), are also incorporated into guidelines and regulations for the testing of final effluents at source (Thompson *et al*., 2005). For example, Canada initiated this approach in the early 1970s and has used it extensively to control highly toxic industrial effluents. The OECD countries evaluated and adopted the approach after an international conference in 1984 (Environment Canada, 1984; OECD, 1987). This was a landmark event, as it emphasized the importance of pollution control at source using biological tests, rather than control only after demonstrating the presence of toxic chemicals and harm in receiving waters, analogous to prevention vs. treatment in medicine. Aquatic toxicity tests and data, combined with exposure chemistry, are now used to evaluate and control the quality of industrial discharges in many countries, and the number is growing all the time (Thompson *et al*., 2005).

Aquatic toxicity measurements, largely sublethal and biochemical, also are used in biological monitoring under natural conditions. This field is also known as biomonitoring or biological-effects monitoring. Applications are effluent regulation (Mount, 1980; Servos, 1995), research looking for unexpected sublethal effects, such as using mussels and other organisms in field bags (Salazar, 1989; Salazar and Salazar, 1993), and chemical exposure and risk assessment (Chase *et al*., 2001; Suter, 2007). This is the growing field of biological indicators or bioindicators. Biological effects can be measured from field-collected organisms, from caged organisms or from *in vitro* and *in vivo* testing of environmental extracts (Hylland *et al*., 2006). Finally, aquatic toxicity data are used to establish WQGs for various uses of water and water bodies, from industrial and agricultural to conservation.

1.6 Aquatic Toxicology and the Law

Since the 1970s, a number of Western and Australasian countries have had aquatic toxicity criteria and pass–fail levels built into their regulations under their national water-pollution legislation (Thompson *et al*., 2005). For example, the USA has bioassay criteria under its NPDES (National Pollutant Discharge Elimination System) permit programme, requiring routine biomonitoring of industrial discharges (see *http://www.epa.gov/waterscience/guide/effects.html*, accessed 3 June 2008). Canada has used its Fisheries Act in this regard since 1971, with at least six industrial-sector regulations and guidelines; the rainbow trout (*Oncorhynchus mykiss,* formerly *Salmo gairdneri* Richardson) acute toxicity test has been the mainstay of the legally valid and recognized tests in Canada. Canadian courts generally recognize that a material shown in an acute aquatic toxicity test to be toxic to fish (i.e. lethal to trout) indicates a degree of harm or potential harm to aquatic systems and, by legal definition, the material is deemed to be a deleterious substance. Canada now has over 15 toxicity tests, called biological tests, developed by an expert technical group and recognized by federal and provincial regulatory authorities. It is, however, proving to be a long process to have the courts accept data other than from established fish (salmonid) and crustacean (cladoceran) tests in criminal trials, except under unusual circumstances, such as large spills of chemicals or oils. As well, litigation against polluting industries is less frequent than in the 1970s.

In Europe, the UK uses fish (salmonid) and decapod crustacean (brown shrimp, *Crangon* spp.) tests for effluent testing, sediment testing, legal purposes and the evaluation of particular substances, such as oil spill dispersants (Thompson *et al*., 2005). The PARCOM (Paris–Oslo Commission) employs several toxicity tests for controlling the disposal of harbour sediments, industrial chemicals and substances from the offshore oil sector (drilling muds, cuttings and production water). Internationally, there is an increased acceptance of toxicity test data in national legal regimes, but except for ocean dumping (disposal) under the London Convention and chemical screening under the MARPOL 73/78 Convention, there are few formal guidance frameworks for the international application of aquatic toxicity tests.

1.7 This Chapter

This chapter presents a broad overview of some of the principles, practice and new developments in aquatic toxicology. Extensive detailed treatments are found in Rand and Petrocelli (1985), Abel (1989; 1996), Munawar *et al*. (1989a), Sprague (1990), Landis and Yu (1995; 1999), Newman (1995), Rand (1995, in revision 2008), Rand *et al*. (1995), Wells *et al*. (1998), Mothersill and Austin (2003), Blaise and Ferard (2005a; 2005b), Den Besten and Munawar (2005), Mommsen and Moon (2005), Ostrander (2005), Thompson *et al*. (2005), Hylland *et al*. (2006), Sindermann (2006), Vethaak *et al*. (2006), Farris and Van Hassel (2007) and Di Giulio and Hinton (2008).

Ecotoxicology, generally defined as 'the application of toxicology to the natural environment' (Park, 2007) or the study of the effects of chemicals on natural organisms and ecosystems (M. Depledge, personal communication), encompasses aquatic toxicology and also has a growing literature. Notable recent texts include Forbes and Forbes (1994), Hoffman *et al*. (1995), Newman and Jagoe (1996), Walker *et al*. (1996; 2001), Newman (1998), Schuurmann and Markert (1998), Shaw and Chadwick (1998), Hoffman *et al*. (2003), Landis and Yu (2004),

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

Helma (2005), Yu (2005), Ekins (2007) and Newman and Clements (2008), useful for both advanced students and professionals alike. New syntheses and specialized texts are being written frequently by the field's leaders, illustrating ecotoxicology's breadth, vitality, innovation and importance.

2 CONCEPTS AND PRINCIPLES

2.1 Definitions

Some key terms are essential for understanding the concepts of aquatic toxicology. The sources are GESAMP (2004), Pesch and Wells (2004) and Park (2007), with some minor changes.

Acute (aquatic) toxicity: Adverse effects that occur rapidly as a result of short-term exposure to a chemical or physical agent. In fish and other aquatic organisms, effects that occur within a few hours, days or weeks are considered acute. Generally, acute effects are severe, mortality being the most common one measured in aquatic organisms. A chemical is considered acutely toxic if by its direct action it kills 50% or more of the exposed population of test organisms in a relatively short period of time, such as 24–96 hours to 14 days.

Bioaccumulation: General term describing a process by which chemicals are taken up by aquatic organisms directly from water as well as through exposure by other routes, such as consumption of food and sediment containing the chemical(s). It results in the presence of the chemical(s) in the organism's tissue(s).

Bioconcentration: A process by which there is a net accumulation of a chemical directly from water into aquatic organisms, resulting from simultaneous uptake (e.g. by respiratory or epithelial tissue) and elimination.

Bioconcentration factor (BCF): A term describing the degree to which a chemical can be concentrated in the tissues of an organism in the aquatic environment as a result of exposure to water-borne chemical. At steady state during the uptake phase of a bioconcentration test, the BCF is a value which is equal to the concentration of a chemical in one or more tissues of the exposed aquatic organisms, divided by the average exposure water concentration of the chemical in the test.

Biomagnification: Result of the processes of bioconcentration and bioaccumulation by which tissue concentrations of bioaccumulated chemicals increase as the chemical passes up through two or more trophic levels. The term implies an efficient transfer of chemical from food to consumer, so that residue concentrations increase systematically from one trophic level to the next.

Chronic toxicity: Effects resulting from repeated or continuous exposure to a material for the lifespan of the species, or the greater part thereof.

Contaminants: Potentially harmful substances or agents in the natural environment that are present at concentrations above background natural levels, and below levels known to cause adverse effects.

Median effective concentration (EC_{50}): The concentration of a material which produces a 50% response in a defined end point in a population of organisms. The EC_{50} should be cited for a specific exposure period.

Inhibition concentration (IC): A point estimate of a chemical concentration that would cause a given percentage reduction (e.g. IC_{50}) in a nonlethal biological measurement of the test organisms, such as reproduction or growth. The IC_{50} should be cited for the specific exposure period, and for continuous rather than quantal (all-or-none) data.

Median lethal concentration (LC_{50}): The concentration in a solution which causes 50% mortality of the test species (usually for an acute exposure). It is calculated from the incidence of mortalities at various concentrations to which different groups of the test species are exposed. Since mortality will depend on the time of exposure, the LC_{50} should be cited for the specific exposure period. Previously referred to as the median tolerance limit (TL_m).

Log P_{ow}: See octanol–water partition coefficient.

Mechanism of toxicity: The way in which a chemical alters basic biological functions and structures in order to exert its toxic effect(s).

Microcosm: A small model of an ecosystem that incorporates some, but not all, of the parts and interactions of the natural system of interest.

Mesocosm: A system of large tanks, inside or outside a laboratory, or field enclosures in ponds, lakes or coastal waters, set up for the purposes of studying the fate and effects of chemicals, physical agents, natural variables or their combinations, under more natural conditions than achieved in smaller testing units.

Monitoring: Measuring the levels of substances in environmental media and living organisms and/or their effects, over time and space.

No observed effect concentration (NOEC): The highest concentration of a chemical or material in a toxicity test that has no statistically significant adverse effect on the exposed population of test organisms compared with the controls. When derived from a lifecycle or partial lifecycle test, it is numerically the same as the lower limit of the maximum acceptable toxicant concentration (MATC). Also called a no observed adverse-effect level (NOAEL) or no observed effect level (NOEL).

Octanol–water partition coefficient (K_{ow}): The ratio of a chemical's solubility in *n*-octanol and water at steady state; also expressed as P. The logarithm of P or K_{ow} (i.e. $\log P$ or K_{ow}) is used as an indication of a chemical's propensity for bioconcentration and bioaccumulation by aquatic organisms.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Pollutant(s): Chemical or physical agents that cause adverse or harmful effects to organisms (plants and animals); to be distinguished from contaminants.
Subchronic (aquatic) toxicity: Adverse effects on aquatic organisms that occur largely from continuous long-term exposure to a chemical or other potentially toxic material or agent, alone or in combination, but where the exposure time covers only a portion of the life cycle (lifespan) of the aquatic species tested or exposed naturally. The effects may be the result of a single exposure (e.g. to a strong acid), but more often they are the consequence of repeated or continuous long-term exposures. Subchronic toxic effects may be lethal or sublethal.
Sublethal concentration: Concentrations of substances or agents above background levels that can cause sublethal (i.e. nonlethal) effects on organisms or their populations, such as delayed growth and development, impaired behaviour or abnormal embryonic development. Some sublethal effects can eventually be lethal.
Threshold level/concentration: A concentration above which some effect or response will be produced and below which it will not.
Toxic: Capable of causing adverse effects which are detrimental to the survival or normal functioning of the individual organism.
Toxic substances or chemicals: Chemicals (single or as mixtures) that are poisonous, carcinogenic or otherwise directly harmful to plants and animals at low levels.
Toxicity identification evaluation (TIE): A set of procedures, formalized by the US Environmental Protection Agency (EPA), to identify the specific chemicals or physicochemical variables responsible for the toxicity of effluents or other complex mixtures. The approach can be used to study sediment-borne chemicals.
Water-quality objectives: Numerical concentration limit or narrative statement that has been negotiated to support and protect the designated uses of water at a specified site. An objective is more specific and location-dependent than a guideline.

Also see glossaries in Klaassen (2001), Lee (2005), Yu (2005) and Rand (2009).

2.2 Approaches to Assessing Chemicals in Water Bodies

Aquatic toxicologists use a range of approaches in the assessment of the toxicity of chemicals, industrial formulations, other mixtures of chemicals and sediments. Approaches include laboratory experiments, microcosms and mesocosms, natural field situations, accidental spills and experimental field-exposure experiments (Wells, 1984b; 1989; Rand, 1995). The choice of approach and toxicity end point depend upon the questions being asked, hypotheses being formulated, and available time and resources for the assessment (Sprague and Fogels, 1977, among others). Fate-and-effects modelling supplements all of these approaches and facilitates predictions of types, magnitudes and duration of toxic effects (D. French, personal communication).

By far the most widely used aquatic toxicity tests are laboratory techniques, largely conducted with populations of single species, cultured or collected from the wild. The responses of one or more species exposed alone to chemical treatments are measured and compared, in contrast to true multispecies assays where the responses of, and the interactions between, different species are studied in the same exposure system. Single-species tests include all of the current standardized regulatory and monitoring toxicity tests used commonly in North America, Europe and Australasia (Rand, 1995; Wells *et al*., 1999; 1998; Landis and Yu, 1999; 2004; Thompson *et al*., 2005). Such tests are also used extensively in aquatic research, including species from a few other phyla or groups, for example, specific corals, polychaete worms, molluscs, crustaceans, echinoderms and teleosts. Such laboratory tests with a few key or representative species are also the backbone of research into the responses of organisms at the suborganism level, for example biochemical, cellular, tissue and organ, and the organism level (from behaviour and physiology, to reproduction, growth and development). The standard tests adopted by agencies are the simplest and most cost-effective tests to conduct, and their use has produced most of the current data and information bases on effects and threshold levels of chemicals on aquatic organisms. For example, the information bases for salmonid fish and cladocerans are huge. Ecological realism has been sacrificed for a host of practical attributes of each test method, such as control over exposure composition and time, condition and sensitivity of the test organisms and the ease of measuring and recording responses. Microscale approaches, with automation, have evolved for these reasons, and others (see below), for powerful experimental and applied toxicity testing (Wells *et al*., 1998; Persoone *et al*., 2000; Blaise and Ferard, 2005a; 2005b).

Microcosms (small volumes, in small tanks or enclosures) and mesocosms (larger volumes, in large tanks or field enclosures) permit more realistic exposure concentrations and fates, the exposure of multiple species at different trophic levels and consequently more accurate estimates of toxicity under natural conditions (see Reeve *et al*., 1977, for marine examples). Both approaches have, for example, been used extensively in the study of petroleum hydrocarbons, oil-spill control agents, metals, and herbicides and pesticides, addressing the fate of constituents and mixtures in the sediment, water and air compartments, and the effects of chronic exposures and responses of pelagic and benthic aquatic communities. They are valuable but expensive, logistically complex, research techniques. Despite hazard evaluations

and ERAs being more realistic with these systems, their wide appeal to regulators has yet to be realized, beyond their use for assessing a few high-production pesticides, oils and constituents, and oil-spill control agents.

Studies under natural conditions have the most realistic exposure concentrations and compositions, but these are often poorly known and difficult to control and replicate, making detection and predictions of effects and clear establishment of exposure (i.e. causal) effect relationships a challenge. A recent example is the large North Sea experiment on pelagic ecosystems (Hylland *et al*., 2006); a suite of techniques showed deleterious effects of water quality near the coastline. Ultimately, such information, that is, effects of the chemicals or emissions in the receiving water bodies, is a valuable test of risk predictions and efficacy of regulatory strategies (emissions control, cleanup, recycling, replacement and conservation). Such field-oriented approaches are supplemented with valuable observations and measurements at accidental spill sites, for example, oil spills in marine waters, nuclear waste releases from sunken reactors and at experimental exposure sites, for example, oils and pesticides. However, the latter, with a few exceptions (Stokstad, 2008), have largely lost their appeal to practitioners in favour of less damaging and less expensive approaches.

2.3 Linking External Exposure, Bioavailability and Estimates of Toxicity

Whereas toxicologists dose organisms such as insects, birds and mammals directly (via oral intake, skin coatings, skin penetration or vapour inhalation), aquatic organisms receive their exposures through contact with the water column, sediment particles, ingested food (including particles) or combinations thereof. Hence, a challenge of aquatic toxicology has been to establish and control accurate chemical exposures during toxicity tests and experiments, to relate estimates of external exposure to bioavailable chemical fractions and concentrations (the so-called body residues), and to link these to indicators of toxic potency or effects. This linked sequence is necessary to establish realistic and accurate dose–response relationships and toxicity thresholds for organisms living in water (McCarty and Mackay, 1993; Beek, 2000).

Following the experiences of classical toxicology, aquatic biologists also adopted similar experimental designs and statistical treatments of exposure–response data (e.g. probit analysis, Litchfield, 1949; Litchfield and Wilcoxon, 1949; Finney, 1952; Newman, 1995). However, in so doing, they equated external water-borne and particle-borne exposures to internal doses acting at the site(s) of toxic action, assuming equivalency. This approach has at least two major limitations which have contributed to much of the variability in reported aquatic toxicity estimates for chemicals, derived using different species and water conditions. First, for many chemicals, especially those which are hydrophobic (i.e. high log P_{ow}s), external exposure (composition and concentrations) and uptake are subjected to many physicochemical and biological influences. Secondly, what is ultimately taken up by each organism more closely resembles the substance(s) causing the toxicity, providing it moves to the site(s) of toxic action rapidly and unaltered. However, this 'residue' may be subject to change through metabolism and may not resemble the substance(s) ultimately causing the effects. This situation has been long recognized, but was addressed clearly by McCarty and Mackay (1993), following studies by Abernethy *et al*. (1986; 1988). They implored toxicologists to link external exposures to body burdens and concentrations at sites of toxic action. This need is greatest for chemicals such as persistent, high-molecular-weight, organic pesticides, for example DDT (dichlorodiphenyltrichloroethane) and its residues, with low aqueous solubility, known partitioning behaviour and specific modes of toxic action.

The LC_{50}s, EC_{50}s and IC_{50}s reported in the literature are estimated based upon external concentrations causing the effects; many of these are not equivalent to LD_{50} (median lethal dose) estimates, thus complicating interpretations of precise effect concentrations and differential species sensitivities. Aquatic toxicologists generally compare the results of different sorts of tests or field exposures with different species, rather than the responses of the different species with normalized internal contaminant concentrations, a crucial distinction not yet given sufficient attention in comparative aquatic and eco-toxicology. Thus, measures of both exposure and effects provide challenges to the aquatic toxicologist.

2.4 Other Basic Concepts and Principles

Several other concepts unique to aquatic toxicology and water-pollution studies must be introduced to appreciate the complexity and uncertainties surrounding experimental estimates of toxicities of chemical substances to the many thousands of aquatic organisms living in a wide range of waters and habitats, in polar to tropical latitudes. Further detailed and fruitful discussion can be found in Forbes and Forbes (1994), Posthuma *et al*. (2002); and Newman (1995; 1998; 2001). With relatively few species and test methods in use, chosen for their high sensitivity and ease of use, aquatic toxicology attempts to estimate safe concentrations for thousands of species and hundreds of aquatic ecosystems, a daunting if not slightly overconfident task.

2.4.1 Fitting the Test to the Task

Different tasks and questions demand different toxicity tests (Sprague and Fogels, 1977). The aim is to be cost-efficient, investigate the problem and answer the question(s) with minimal, not maximum data. For example, under the MARPOL 73/78 Convention, it was generally agreed that screening industrial chemicals and complex formulations (often with incomplete compositional data) for their aquatic toxicity required acute tests with three to seven species, and a chronic or subchronic test with one species (Wells *et al*., 1999; GESAMP, 2004), as inadequate as this may seem. In contrast, definitive data on a chemical produced, transported and applied in large volumes would be derived from a much wider range of assays, especially mesocosm and *in situ*. The screening approach is in general use in most developed countries, for example industrial effluents are controlled at source with minimal tests (in Canada, solely with the rainbow trout, *Oncorhynchus mykiss* and *Daphnia magna* Cladoceran tests).

In comparison, widely used pesticides are subjected to many research and regulatory investigations (e.g. fenitrothion in eastern Canada), and certain effluents (e.g. pulp and paper) are monitored at source and in the receiving waters with a large battery of environmental effects/toxicity tests, especially using molecular biomarkers. Other examples abound from the fields of process stream, effluent, chemical and sediment testing, for example, oil spill dispersants are generally exhaustively tested and investigated (National Research Council, 1989a; 2005); contaminated sediments are investigated with a combination of bacterial, crustacean and echinoid tests (S. Carr and M. Nipper, personal communication; Bermuda Institute of Ocean Sciences, unpublished data).

2.4.2 Choice of Species for Toxicity Tests

As stated earlier, aquatic toxicology examines the effects of chemicals and chemical mixtures on only a fraction of known aquatic organisms. The responses of many phylogenetic groups are barely understood or are unknown; for example, for coastal marine waters, the zooplanktonic organisms copepods, euphausiids (krill) and chaetognaths (arrow worms) are rarely considered (Wells, 1984b). 'Representative' organisms of only a few phyla suffice as models for other habitats, such as coastal wetlands and coral reefs. Protecting aquatic ecosystems at this time, circa early 2008, is achieved largely by using a few well-known, model bioassay organisms, deriving threshold concentrations for specific substances, setting limits for discharges and calculating objectives and standards for water and sediment quality. For screening and permitting purposes, the OECD recommends considering acute toxicity data from three groups—teleost fish (usually salmonids), crustaceans (cladocerans or shrimp) and algae (microalgae, freshwater or salt)—see *http://www.oecd.org*. For definitive marine testing, conducting additional tests with annelids (i.e. polychaetes), molluscs, echinoderms (usually echinoids) and macroalgae is also recommended. However, many aquatic phylogenetic groups and most species are omitted from regulatory consideration, opening wide the question of the adequacy of protection to most aquatic biodiversity offered by such testing. In such circumstances, field observations and measurements of specific damage are a valuable guide to further focussed toxicity testing and the selection of relevant responses or toxicity end points.

Until recently, the 'most-sensitive' species approach was axiomatic in the field and was not questioned. Over the course of several decades, it resulted in the selection of a few dozen, relatively sensitive, toxicity test organisms and the development and adoption of standard methodologies (Environment Canada, 1990a; 1990b; 1990c; 1990d; 1990e; ASTM, 1993b; 1993c; 1993d; 1993e; Thompson *et al*., 2005). However, this approach has been criticized (Cairns, 1984; Cairns and Pratt, 1985; 1989), and still is, in favour of toxicity testing with as wide an assemblage as is likely to be exposed or otherwise assaulted, within an ERA framework (EPA (Environmental Protection Agency), 1992; 1996; Suter, 1993; 2007). In practice, however, the combined approaches (limited toxicity testing, ERA and TIE) have been and are useful for protecting aquatic ecosystems. For example, much pollution control has occurred in Canada simply by using one bioassay, the rainbow trout (*Onchorhynchus mykiss*) lethal bioassay (Pessah and Cornwall, 1980; Environment Canada, 1990a). At this time, most of the assembled acute toxicity databases present data from only a few species of fish, crustaceans, molluscs, aquatic insects and microalgae; some of the available databases also routinely receive standardized data (e.g. fathead minnow; grass shrimp; fairy shrimp).

2.4.3 Minimum Time to Toxic Effect and the Toxicity Curve

Regardless of the external exposure concentration, the ultimate dose of chemical or the mode of toxic action, there is always a minimum time to death of the exposed organisms, individually and as a population. This is shown by comparing acute toxicity curves for different substances (Sprague, 1969; Newman, 1995; Rand *et al*., 1995; Abel, 1996). This information is valuable because it offers insight into the mode of toxic action of different substances, for example, water-soluble neurotoxins such as domoic acid are fast acting and cause irreversible neurological damage (Wright, 1995), compared with water-immiscible nonionic surfactants that act more slowly as nonselective toxicants and disrupt membrane integrity and function, causing reversible nervous-system impairment (Wells, 1984a; National Research Council,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1989a). Providing that the exposures are controlled and characterized, the toxicity curves examined together allow comparisons of the toxicity of different chemicals, the sensitivity of different species (or toxicity tests) and the minimum times to toxic effects at different concentrations.

There is also considerable merit in plotting multiple concentration exposure–toxicity data as graphs of cumulative mortality vs. time, generating median effective times (ET_{50}s) and median lethal times (LT_{50}s). This is a less popular, but very informative time–response approach (Sprague, 1969; Newman and Dixon, 1996), and it requires fewer treatment concentrations to produce useful data.

2.4.4 Contributions to Measuring Environmental Quality

The conduct of aquatic toxicity tests on chemical substances and environmental samples provides vital data in the context of the broader environmental protection frameworks (for example for the marine environment, see UNEP, United Nations Environment Programme, 1985; Wells and Cote, 1988; GESAMP, 1991a; 1994; Gray *et al*., 1991) and ERA (Landis and Yu, 2004; Suter, 2007). The various frameworks guide acquisition and integration of appropriate data essential for descriptions of the condition of whole aquatic ecosystems under scrutiny; condition may also be referred to as environmental quality, ecosystem health or ecological integrity (see Wells and Rolston, 1991; Rapport *et al*., 1998; Wells, 2003; 2005, among others). Many of these data are from biological (environmental) effects-monitoring programmes, which use toxicity tests *in situ* or environmental samples in nearby laboratories. For example, with sediments, toxicity tests are applied with chemical characterization and benthic community analyses in the triad approach (Chapman and Long, 1983; Chapman *et al*., 1987a; 1987b), together with TIE analyses and preliminary estimates of risk, using ERA and a simple risk quotient method.

At present, in aquatic toxicology and, more broadly, ecotoxicology, both structural and functional measures of ecological health are measured (Munawar *et al*., 1989a; 1989b; Cairns *et al*., 1995; Di Giulio and Hinton, 2008), reflecting the current contributions of molecular biology, genetics and ecology to the methods of sublethal toxicity detection. Aquatic toxicology, through its emphasis on methods development over several decades, has contributed greatly to environmental monitoring programmes, particularly measuring status, trends and effects of chemical contamination (McIntyre and Pearce, 1980; White, 1984; Goldberg, 1986; Chase *et al*., 2001; Hylland *et al*., 2006; Sindermann, 2006) and guiding the selection of indicators of environmental quality (Bortone, 2005).

2.4.5 Predictive Toxicology

Linking simple and practical measures of toxicity of various classes of chemicals to anticipated effects of those chemicals and substances under natural conditions is a major goal of aquatic toxicology. Much effort has been in the field of QSARs (quantitative-structure–activity relationships) over the past three decades (Kaiser, 1984; Lipnick, 1995; Nendza, 1998; Ekins, 2007). The field is now called predictive toxicology (Helma, 2005). QSARs enable estimates of toxicity of chemicals in homologous series to be made from knowledge of the toxicity of a few chemicals in relation to their structures and physicochemical properties. The science is now quite well developed. It is used extensively by the regulatory community for assessing, ranking and classifying new industrial, food and cosmetic chemicals, and chemicals in transport. For example, QSARs are used in the hazard-evaluation procedure for harmful substances carried by ships (GESAMP, 1990c; 1988; Wells *et al*., 1999; GESAMP, 2004), and similar procedures through the OECD, where actual data are very limited, but the need for hazard ratings for chemicals in transit, by truck, rail and ship, is immediate.

Recently, both predictive toxicology (Helma, 2005) and computational toxicology (Ekins, 2007) have emerged from the QSAR research and applications, and utilize data from all branches of toxicology, as well as chemistry, statistics, computer science, medicine, biology and others. Predictive toxicology is the development 'of procedures or algorithms that are capable of predicting toxic effects from chemical and biological information' (Helma, 2005). Predictive models integrate information on chemical structures and properties, biological systems and toxic effects, with the use of export systems and statistics, and the aim to 'predict the toxic effects of untested compounds'. Computational toxicology, the science of applying computer methods to toxicity assessment, including environmental, has developed rapidly (Ekins, 2007). It has applications in the toxicity and risk assessment of chemical mixtures, computational risk assessment, QSARs, toxicoinformatics and regulations on the environmental side of toxicology. The impacts of these fields on aquatic toxicology and its mandate are just being felt.

3 PRACTICE OF AQUATIC TOXICOLOGY

3.1 Acute Toxicity: Measurement and Analysis

The measurement and expression of acutely toxic effects of chemicals is the backbone of aquatic toxicology. In

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

this context, acute toxicity methods have been reviewed in detail by many practitioners and groups (Sprague, 1969; 1973; 1990; Buikema *et al*., 1982; Rand and Petrocelli, 1985; Cairns and Mount, 1990; Adams, 1995; Rand, 1995, 2009; Rand *et al*., 1995; Abel, 1996; Environment Canada, 1999; 2005; Newman and Clements, 2008, among others). Some of the topics important to the measurement of acute (short-term) lethal and sublethal effects of water-borne chemical contaminants are briefly introduced here. Measuring acute toxicity is particularly important to the ranking of chemicals and the quality control of industrial and municipal effluents.

Various approaches for assessing acute toxicity have been used—laboratory tests, microcosms and mesocosms (see below), *in situ* field experiments and observations at polluted field sites. Exposure (an integration of composition, concentration and time) is probably the most important variable in an aquatic toxicity test, and indeed in the aquatic environment. Exposure regimes in the laboratory can be static, static with replacement, continuous flow or intermittently flow-through, each with advantages and disadvantages to the water quality and realism of the chemical's fate (Buikema *et al*., 1982; Wells *et al*., 1984). If the organism is not exposed to toxic concentrations for a sufficiently long time, or if the chemical is in a form unlikely to enter the organism or cause sufficient external damage to sensitive tissues, for example, gills, then toxicity is unlikely to occur. External exposure in the aquatic environment differs radically from internal dosing used in mammalian toxicology. Early work relied on only nominal, external exposure concentrations of chemical(s) (i.e. those unmeasured in the test chambers), rather than on measured concentrations; hence, end points such as LC_{50}s were greatly underestimated for hydrophobic substances, that is, chemicals appeared less toxic than they were. This was especially true for complex industrial formulations and mixtures, and petroleum products, and is an ongoing problem for accurate hazard-assessment essential for regulation and safety (GESAMP, 2004).

A lot of effort has gone into developing continuous-flow devices, chemical analytical methods and the use of carrier solvents (Hutchinson *et al*., 2005) to overcome these challenges. Likewise, appropriate selection of test organisms is crucial; rationale exist and agreement has now been reached for different aquatic environments, from freshwater to marine, by many agencies and organizations, and many toxicity methods have been standardized (see recent ASTM and APHA manuals—ASTM, 1993a; 2007; APHA, 1995). As wide a range of different organisms across different phyla and life stages should be tested in single species toxicity tests as possible, and decisions made regarding hazard and risk ratings, using the lowest EC_{50}s or LC_{50}s or NOECs. A detailed literature exists for considering the various dose–response relationships and analyses of data (Sprague, 1969; Newman, 1995; Rand *et al*., 1995; Environment Canada, 2005), as well as for accounting for the many factors, physicochemical and biological, that influence exposures and expressions of toxicity (Newman, 1998; Landis and Yu, 2004).

3.2 Chronic Toxicity: Measurement and Analysis

Chronic or longer-term sublethal effects on humans from low-level exposure to trace industrial chemicals have been a concern to the medical profession for decades. The potential for such effects is very much under public scrutiny in North America and Europe. Many thousands of synthetic chemicals are introduced into our environment (air, water, soil, food) with little knowledge of their effects on reproduction, growth and development. The concern is that the exposure of humans, especially during development in the uterus, to chemicals that could act as endocrine disrupters, for example, oestrogen-mimicking compounds, such as diethylstilbestrol (DES), DDT and PCBs (polychlorinated biphenyls), may influence reproductive processes and success later in life (Rall and McLachlan, 1980). This issue has surfaced in recent years, particularly due to trace levels of persistent organic pollutants (POPs) in food, water and the workplace (Colburn *et al*., 1996; Rudel *et al*., 2003; Fitzgerald, 2007).

Likewise, many aquatic organisms and their populations, communities and habitats have been and are exposed in many locations over the longer term to low-level concentrations of persistent, bioaccumulative and potentially toxic industrial chemicals (Rand, 1995; Lotze *et al*., 2006). Concerns about chronic sublethal toxicity of chemicals to aquatic biota date back many years, for example, see reviews in Sprague (1971; 1976), Cole (1979), Waldichuk (1979; 1985), Sheehan *et al*. (1984), Rand and Petrocelli (1985), Howells *et al*. (1990), and recently Landis and Yu (2004) and Newman and Clements (2008). There is a large primary literature on sublethal effects of chemicals and mixtures on aquatic organisms, and many reviews on specific topics (e.g. endocrine disrupters—Rolland *et al*., 1997; large oil spills—Wells *et al*., 1995; Rice *et al*., 1996; metals—Langston and Bebianno, 1998), mostly addressing chronic or long(er)-term sublethal effects. In the ecotoxicology and marine-science fields, there have been 30 years of conferences, notably SETAC and PRIMA (Pollutant Responses in Marine Animals), where new research is presented on sublethal effects on many biological processes—hormonal function, immune function, physiology, behaviour, growth, development, reproduction and so on. Hundreds of responses and the concentrations causing them have been described, though many studies are unfortunately

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

not designed to estimate chronic sublethal threshold concentrations.

Recently, concerns about chronic toxicity have been expressed in the context of known and suspected effects of endocrine-disrupting compounds (EDCs) on aquatic organisms, wildlife and human health (Colborn *et al*., 1996; Cadbury, 1998; Kendall *et al*., 1998; Bechmann, 1999; Hutchinson, 2002; 2006; 2007; Hutchinson *et al*., 2006), as well as in the context of the ubiquitous halogenated hydrocarbons, such as certain pesticides (e.g. mirex, toxaphenes, malathion), DDT, PCBs, dioxins and furans, and some metals (e.g. cadmium, Vetillard and Bailhache, 2005).

Chemicals (so-called industrial, priority or toxic substances) affect organisms and aquatic ecosystems at various biological levels of organization (from molecules and cells to whole organisms, to communities and ecosystems) and on a wide range of life processes, at levels often well below those killing the organism in short, constant exposures. The major types of responses are biochemical, physiological, behavioural, growth, developmental and reproductive (GESAMP, 1990b; Newman and Jagoe, 1996; Newman and Clements, 2008). Reproductive and developmental effects are most important to population survival, that is, recruitment (Newman, 2001). The important chronic experiments are those that relate the time course of chemical exposures to the generation time and lifecycle of the organism, for example 28-day flagfish experiments. Investigations over several decades have concentrated on the major types of aquatic contaminants for such effects, striving to describe NOECs and MATCs on the basis of such chronic sublethal data. The key to interpreting sublethal effects is that studies must allow some measure of lowest threshold concentrations for effects, but as stated above, such estimates are often unfortunately missing in many studies.

While sublethal effects are relatively easy to detect and measure for many substances and organisms in the laboratory (e.g. following the development of crustacean larvae or echinoid embryos for several days), finding field evidence of such effects and demonstrating the causative agent(s) proves to be difficult. However, there are examples, such as with Mirex in the Great Lakes and deformities in juvenile birds (Gilbertson *et al*., 1998); imposex in marine snails exposed to organotins (Beek, 2000; Oberdörster and McClellan-Green, 2002); reproductive failures in seabirds exposed to DDT and other insecticides (Rattner *et al*., 1984; Fry, 1995); mixed function oxygenases (MFOs) and pathologies in fish near pulp mills (Servos, 1995); various effects of POPs on Arctic species (Cone, 2005) and elevated occurrences of diseases in bottom-dwelling fish and marine mammals near urban areas (Vethaak and Rheinallt, 1992; Bernet *et al*., 1999; also see Howells *et al*., 1990; Rand, 1995; Cadbury, 1998). That such effects are occurring in organisms exposed continuously to very low levels of many chemicals over long periods of time is probably more common than currently demonstrated. However, the evidence is hard to find for some aquatic environments, such as marine (Howells *et al*., 1990; Hylland *et al*., 2006). Hence, describing the causative agents, their concentrations and the aetiologies of sublethal effects and pathologies under field conditions, and finding evidence or not of recovery remains an important challenge of aquatic toxicology.

3.3 Special Topics in Aquatic Toxicology

In recent years, ecotoxicology and aquatic toxicology have expanded quantitatively and qualitatively (note the many ASTM and SETAC publications). The standard approaches for evaluating the effects of contaminants and for measuring their presence in specific habitats and ecosystems have become more sophisticated. Several research areas have evolved substantially with new developments since the 1970s, as shown in Sections 3.3 and 3.4.

3.3.1 Techniques

3.3.1.1 Modelling

A popular approach to overcoming the difficulties associated with retrospective chemical monitoring and analysis is to forecast the behaviour and fate of chemicals with models of their environmental distribution and fate. Over the past three decades, investigators have advanced the idea that the behaviour of chemicals can be predicted on the basis of comparisons between laboratory-measured properties of the chemicals and the environmental behaviour and chemical properties of compounds for which more abundant environmental data are available. For example, Baughman and Lassiter (1978) introduced the concept of the use of hypothetical 'evaluative models', based on properties of stylized environments and contaminants; these models provided quantitative approaches to exposure estimation. Mackay (1979; 2001) followed this up with the full development of fugacity modelling. The simple exposure models used today are constructed of individual submodels of the input, transport and removal processes controlling the fate of a chemical, incorporated into a model of the environment in which the chemical ultimately will be distributed. The hypothetical model environment or environmental system is constructed by conceptualizing several environmental compartments which are considered to have distinct and uniform characteristics, such as for pH, organic matter content, salinity and temperature. The discharge, loading or emission rates of a chemical are then described by discrete models. Finally, mathematical

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

relationships are developed to describe the intercompartmental transfer and removal processes that influence the dynamics of the chemical; see Mackay (2001) for a full description of the fugacity approach.

Models are being developed at three levels of increasing complexity: conceptual, comparative distribution models of a qualitative nature; quantitative, situation-specific models of a generic nature; and quantitative, site-specific models, with various applications in mind (Wrona *et al*., 2000; Koelmans *et al*., 2001; Warren and Mackay, 2005). All of them are receiving increasing attention by regulators and agencies concerned with toxic chemical management and pollution control in fresh and salt waters.

3.3.1.2 Quantitative Structure–Activity Relationships (QSARs)

Current overviews of QSARs (also called SARs or structure–activity relationships) and aquatic toxicology is found in Rand (1995), Walker (2003) and Devillers (2007), covering principles, models and uses in regulation and chemical design.

Assessing large toxicity data sets for specific chemicals provides insight into chemical structures or properties that lead to toxicity. For example, low-molecular-weight (lmw) aromatic hydrocarbons from spilled oils are biologically available and acutely toxic, the toxicity influenced by molecular weight, the presence of alkyl side chains and the species exposed; crustaceans are more sensitive than either bony fish or molluscs to lmw, readily dissolved aromatic hydrocarbons (National Research Council, 1985; 1989a; GESAMP, 1993). These relationships were developed and verified using experimental approaches and considerable knowledge of the organism's biology and physiology.

The QSAR approach proposed by Hansch (1977), in which both the physical properties and chemical structures of molecules are used to predict their biological activity, has proved highly applicable in aquatic toxicology (Kaiser, 1984; Rand, 1995). A number of experimental studies have demonstrated a high degree of toxicological predictability for aquatic organisms, with substantial agreement between expected and experimentally observed toxicity levels, within relatively homogeneous classes of organics. In some cases, the hydrophobic characteristics, expressed as the *n*-octanol/water partition coefficient (log K_{ow}), correlates highly with the activity of the molecules. Bioconcentration and bioaccumulation in some organisms can be adequately described by QSARs (Mackay, 1982), using partition coefficients such as log P (log K_{ow}), either calculated or experimentally derived. Electronic characteristics (pK_a) of the molecules have also proved useful in explaining the toxicity of several amines. A combination of hydrophobic and electronic characteristics has been shown to correlate well with the toxicities of phenols, chlorophenols and chloro-and alkylanilines. However, in many cases, log K_{ow} alone was sufficient to provide good predictive capability. The inclusion of molecular connectivity is also useful in the QSAR approach for predicting the toxicity of several other compounds.

At present, QSARs have been developed for several classes of chemicals, and allow good estimates of toxicity and mode of toxic action (Hodges *et al*., 2006; Sanderson and Thomsen, 2007). QSARs have been applied to a limited number of chemicals, necessitating expert judgement for determining the boundaries of toxicological predictability from the approach. QSARs can be applied within homologous groups of chemicals, for example, hydrocarbons, detergents and pharmaceuticals, and do offer a basis for some predictability, certainly with respect to selecting priority substances if experimental data are unavailable. QSARs have been successfully applied to the study of toxic effects of chemical mixtures and understanding some mechanisms which regulate the toxic interactions among chemicals.

To conclude, the QSAR approach is used extensively in the development of new environmentally safe products (e.g. detergents, Tsoler *et al*., 1999), in chemical ranking, classification and regulation (Walker, 2003; GESAMP, 2004) and as a component in fate modelling programmes (Mackay, 2001).

3.3.1.3 Assessing Toxicity of Chemical Mixtures

The measurement of toxic effects of chemical mixtures (Lloyd, 1987; National Research Council, 1988) remains a major topic (circa 2008) because thousands of the industrial chemicals being produced and shipped worldwide are mixtures, and most industrial and municipal emissions into air, soil, sediments and water are mixtures, not single compounds. There have been many recent studies on mixtures (e.g. Broderius, 1991; Calabrese and Baldwin, 1993, Appendix 3; Yang, 1998; Backhaus *et al*., 2000; Deneer, 2000; Parkerton *et al*., 2000; Mothersill and Austin, 2003; Lydy *et al*., 2004; Brain *et al*., 2004) and an excellent review (Lipscomb *et al*., 2007). In specific fields, such as oil pollution response, much effort has gone into determining the primary sources of toxicity in oil dispersions and mixtures of oils and dispersants (National Research Council, 1988). In some cases, for example pulp and paper effluents (Servos, 1995), and sewage, the sources of acute toxicity to fish can remain elusive due to the enormous chemical complexity of the effluents.

A number of key questions remain—can we assume that most industrial chemicals (largely organic), of similar modes of toxic action, interact additively on organisms, rather than synergistically? Is it true that 'the assessment of chemical stressors is relatively straightforward after 30 years of study', as noted by Dorward-King *et al*., in Baird and Burton (2001)? What are the best monitoring approaches to deploy near mixture outfalls? Much

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

more consideration should be made of the testing, assessment and monitoring of chemical mixtures, particularly at low levels. A larger question also remains—how do we distinguish between natural and anthropogenic (chemical) factors influencing organisms and ecosystems? This distinction may be clear for some stressors, for example, DDT and thin egg shells, organophosphate pesticides and insects, organotins and molluscs, where chemicals with specific modes of toxic action were purposely synthesized, but may be very difficult to establish for other chemicals and environmental factors, for example, sediment dynamics and burdens in coastal waters. This field is called 'multiple stressors' and incorporates the concerns for assessing chemical mixtures.

3.3.1.4 Assessing Toxicity of Sediments

Many chemical contaminants become particle bound in the water column and enter bottom sediments in the aquatic environment. From there, they may reside for long periods, for example DDT, PCBs, be taken up by demersal fish, for example winter flounders, and benthic and epibenthic invertebrates, for example scallops, or flux back into the overlaying water column as shown in dynamic estuaries, for example Halifax harbour, NS. Contaminated sediments pose large problems for coastal waters in need of constant dredging; their management is controlled by the London Convention and various national legislation. The science of evaluating sediment-bound contaminants is described in Dickson *et al*. (1987), National Research Council (1989b), Baudo *et al*. (1990), Burton (1992), Ingersoll *et al*. (1997), Stolzenbach and Adams (1998) and Wenning (2005), among others. After many conferences and discussion, there is general agreement about the choice and application of the suites of bioassay tests to use, for both freshwater and marine environments. Freshwater assays include bacteria (Microtox®), annelids (oligochaetes), crustacean (amphipods) and chironomids, while marine assays include bacteria (Microtox®), annelids (polychaetes), molluscs (oyster larvae), crustaceans (amphipods, shrimp) and echinoids (sea urchins and sand dollars, young life stages).

Sediment toxicity tests are continually being re-evaluated. There has also been recent effort to evaluate the toxicity of sediment pore waters (Nipper and Carr, 2003), within the context of the TIE approach. There is much research in this field, both on basic and applied questions, with a wide range of species (Ginn and Pastorok, 1992; Power and Chapman, 1992; Meador *et al*., 1997a; 1997b; Leppänen and Kukkonen, 2000; Hartl *et al*., 2001; Leppänen and Oikari, 2001; Meador and Rice, 2001; Oikari *et al*., 2002; Burgess *et al*., 2003; Hyötyläinen and Oikari, 2004; Moore *et al*., 2005). Much of the work is conducted on sediments contaminated by oil spills, polluted harbours and pulp-mill discharges. The uptake of sediment-borne contaminants, influence on bioavailability of influencing factors, relationships between sediment contamination and toxicity and the standardization and quality control of methods have received considerable attention (Power and Chapman, 1992; Lamberson *et al*., 1992; Wenning, 2005).

3.3.1.5 Biochemical Effects and Biomarkers

An intensive effort has been underway since the 1980s to produce practical, sensitive, reproducible, low-cost and interpretable biomarker tests to detect biological effects of chemicals under natural conditions before they cause significant harm, and to monitor the presence and effects of substances in areas subjected to waste disposal (Mehrle and Mayer, 1980; McCarthy and Shugart, 1990; Gray, 1992; Rand, 1995; 2009; Butterworth *et al*., 1995; 2001; Wells *et al*., 1998; Stephensen *et al*., 2000; Denslow *et al*., 2007; Kong *et al*., 2007). Such tests can be applied at all stages of the management of chemicals and wastes that enter aquatic ecosystems. Examples of such biochemical effects procedures are MFO systems, metallothionein-complex formation (Amiard *et al*., 2005), lysosomal-membrane stability, blood-chemical assays, cytogenetic tests (including DNA-adduct analyses) and steroid-hormone assays, the latter of great recent interest due to concerns about effects of pharmaceuticals in municipal and industrial wastewaters (Sherry *et al*., 1999).

The measurement of MFOs is one example. In higher macroinvertebrates, fish and seabirds, the enzyme systems involved in detoxification are sensitive to the presence of low levels of chemicals such as PCBs, polyaromatic hydrocarbons (PAHs) and components of industrial effluents (Coakley *et al*., 2001; Reynard *et al*., 2008; R. F. Addison, personal communication). Measuring such enhanced enzyme activity demonstrates that exposure has occurred. The detection of cytogenetic patterns and responses in marine fish (eggs and larvae) and mammals again indicates that exposure has occurred and has the potential for causing fundamental toxic effects in exposed organisms. Another recent example is the measurement of DNA adducts in whale brains in contaminated estuaries (Mathieu *et al*., 1997; 1998). Biochemical and cytogenetic/cytological techniques have considerable potential for application in marine waste management. Studies are still needed to identify in detail the dose–response relationships under field conditions. The current applicability of some of these techniques is described by Giam and Ray (1987), Malins and Varanasi (1988), McCarthy and Shugart (1990), Peakall (1992) and Shugart and Theodorakis (1998).

Recent reviews and books on biochemical ecotoxicology and biomarkers proliferate. This is a growth area in aquatic toxicology due to methods flowing from molecular biology and genetics (McCarthy and Shugart, 1990; Huggett *et al*., 1992; Peakall, 1992; Walker and Livingstone, 1992; Depledge and Fossi, 1994; Fossi, 1994; Di Giulio *et al*., 1995; Ostrander, 1996; Walker

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092

et al., 1996; Shugart and Theodorakis, 1998; Denslow *et al*., 2007). Significant strides have been made in understanding the various modes of toxic action of diverse contaminant types—from genotoxicity (PAHs), endocrine disruption (organochlorines) and neurotoxicity (organophosphorus, carbamate and pyrethroid pesticides) to mitochondrial poisons (nitrophenols) and ATP inhibitors (dichlorodiphenyl ethylene (DDE)) (Walker *et al*., 1996), much of the evidence coming from fish and avian studies. In some cases, whole new subdisciplines of biochemical ecotoxicology have developed in recent years, such as with ecotoxicogenomics, the study of gene and protein expression in organisms exposed to chemicals (Snape *et al*., 2004), and toxicologic pathology (Gillett *et al*., 2002).

Biomarkers can be considered broadly as 'biological response(s) to a chemical or chemicals that give a measure of exposure and sometimes, also, of toxic effect' (Depledge and Fossi, 1994). Biochemical biomarkers have now been investigated extensively, with the dual roles of determining whether exposure of biota has occurred and whether or not biological damage, that is, adverse biological effects, especially cumulative, due to the exposure, has taken place under natural conditions (Depledge and Fossi, 1994; Peakall, 1994; Depledge *et al*., 1995; Karouna-Renier and Zehr, 1999; Bard, 2000; Snyder, 2000; Pretti and Cognetti-Varriale, 2001; McClain *et al*., 2002; Brown *et al*., 2003; Ferrat *et al*., 2003; Amiard *et al*., 2005; Pellacani *et al*., 2005; Valavanidis *et al*., 2005; Rose *et al*., 2006).

Biomarkers with promise for aquatic environments include metallothionein induction (metals) (Amiard *et al*., 2005), acetylcholinesterase inhibition (certain organophosphorus and carbamate pesticides) (Pretti and Cognetti-Varriale, 2001), induction of MFOs (organochlorines, PAHs) (Snyder, 2000; Reynard *et al*., 2008; Payne, J., personal communication), DNA-adduct formation (PAHs), *in vitro* genotoxic assays (Pellacani *et al*., 2005), molecular responses to oxidative stress (Brouwer *et al*., 2005; Valavanidis *et al*., 2005; Kong *et al*., 2007) and formation of stress or heat-shock proteins (metals, organochlorines, thermal stress) (Depledge and Fossi, 1994; Peakall and Walker, 1994; Branton *et al*., 1999; Karouna-Renier and Zehr, 1999). Some biomolecules, such as P-glycoproteins, provide organisms with resistance to chemical contaminants at the cellular level (Bard, 2000). Metallothioneins in invertebrates exposed to metals, despite their variability, are recommended for monitoring (Amiard *et al*., 2005). Generally, suites of biomarkers rather than one particular one, at different levels of organization, and the use of sentinel species are recommended for monitoring (Depledge *et al*., 1995; McClain *et al*., 2002; Brown *et al*., 2003; Ferrat *et al*., 2003; Pellacani *et al*., 2005; Rose *et al*., 2006).

3.3.1.6 Microscale Testing in Aquatic Toxicology

Microscale toxicity testing, for the hazard assessment of effluents, chemicals and sediments, has become an important approach over the past three decades (Persoone and Wells, 1987; Blaise *et al*., 1988; 2000; Long *et al*., 1990; Blaise, 1991; Wells *et al*., 1998; 2001; Persoone *et al*., 2000; Blaise and Ferard, 2005a; 2005b; Wells, 1999). It is also called microbiotesting, a term coined by C. Blaise, small-scale toxicity testing, or rapid-screening toxicity tests (Toussaint *et al*., 1995; Shedd *et al*., 1999). 'Small' (micron to cm) and sensitive organisms, often as embryonic or young life stages, are tested in reliable, rapid and cost-effective assays, using fundamental end points of genomic and biochemical change, physiology, growth and development, and reproduction.

Various workshops in Canada have discussed microscale methods with bacteria (Microtox®, Mutatox®); giant kelps; polychaetes; rotifers; oysters, clams and abalones; amphipods, mysids and crabs; sea urchins and smelt (Chapman *et al*., 1991; Wells, 1991; Blaise *et al*., 1996). Automated marine procedures exist, Microtox® being the best known procedure, used in >50 countries. Some assays can be conducted both in the laboratory and in the field, and some are commercially available in Toxkits (e.g. rotifers, *Artemia* shrimp, *Daphnia*) (Persoone *et al*., 2000). Microscale methods are an important source of alternative assays, hence reducing the requirement for expensively cultured or field collected macroscopic species. Regulatory agencies have now adopted such tests, in Canada, the USA and other countries, with emphasis on bacterial, microalgae, invertebrates and fish (see Thompson *et al*., 2005 for an excellent overview and Nipper and Carr, 2003, for current methods).

3.3.1.7 Microcosms and Mesocosms

The evaluation of chemicals and chemical mixtures in artificial experimental ecosystems, from simple microcosm chambers, to larger and more complex mesocosms, is a valuable technique for analysing existing problems and studying and assessing the hazards and risks of new substances. Such experimental approaches can be incorporated into tiered or sequential hazard assessment schemes for detailed evaluation of chemicals in common transport and use. The experimental and application roles were summarized by Cairns (1986) and Graney *et al*. (1995), amongst others. Through the application of microcosms and mesocosms, exposure assessment and toxicity assessment can be conducted with relatively realistic simulations of field conditions, especially incorporating multiple trophic levels, hence facilitating the measure of ecological processes. Despite the costs and logistical complexities, such testing systems are still very much in use for assaying chemicals that are in large-scale use (Caquet *et al*., 2000; Hopkins *et al*., 2004; Oikari,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2006; Sundt *et al*., 2006; Mohr *et al*., 2007; Roussel *et al*., 2007; Sanderson *et al*., 2007).

Microcosms are a testing ground for the predictions of simple fate models, and the determination of toxic effects at simulated environmental concentrations. More complex mesocosms such as CEPEX (Controlled Ecosystem Pollution Experiment) and MERL (Marine Environmental Research Laboratory) (Grice and Reeves, 1982), very active in the 1980s, provided empirical evidence of the expected exposures and ecotoxicity under realistic conditions and at various levels of biological organization and complexity. Such work continues at the University of Guelph with mesocosms called limnocorrals, deployed in Ontario lakes to evaluate pesticide fate and effects (Solomon *et al*., 1980; 1985; 1986; Wilson *et al*., 2004; Brain *et al*., 2005; Jooste *et al*., 2005), and at the Bedford Institute in Halifax, with studies of dispersed hydrocarbons in large-wave tanks (K. Lee, personal communication). The greater cost and complexity of the microcosm and mesocosm approaches are often offset by the greater reliability, albeit greater variability, of the predictions. They are and should be used for evaluating chemicals and materials of long-term aquatic significance (e.g. pesticides, fossil fuels, effluents, dredging spoils, solid wastes, etc.) where the right choice of strategies for prevention, control, monitoring and emergency response has major economic and ecological implications.

The advantages of the above approaches are mainly the ability to conduct a priori as opposed to just a posteriori evaluations of chemical toxicity, thereby reducing uncertainties in the identification of missing data and information, improving the exploitation of existing data, and increasing the cost-effectiveness of acquiring field and laboratory exposure and toxicity data. Even more important from a scientific perspective, a far better understanding is obtained of the processes controlling the transport and interactions of chemicals in the aquatic environment.

3.3.2 Integration and Interpretation

Many areas of aquatic toxicology and its closely related fields have undergone significant advancements since the 1980s, in research approaches and applications. Some of these are briefly described below, as well as in Section 4.

3.3.2.1 Hazard Evaluation and Ecological Risk Assessment

Aquatic toxicology has contributed methods and interpretation to the hazard evaluation of chemicals and to the field of ERA. This is illustrated by the earlier classic work on chemicals and effluents (Cairns *et al*., 1978; Bergman *et al*., 1986) and more recently by work of GESAMP (Joint Group of Experts on the Scientific Aspects of Marine Environmental Protection) on the hazard evaluation of chemicals and mixtures carried by ships, where they are evaluated for hazard based largely on their intrinsic properties (GESAMP, 1990c; 1997b; 2004; Wells *et al*., 1999). ERA has been further developed and utilized in Europe and North America, as shown by the US Environmental Protection Agency ERA framework and its many applications (EPA, 1992; 1996; Ingersoll *et al*., 1997; Newman and Strojan, 1998; Ferenc and Foran, 2000; Benjamin and Belluck, 2001; Paustenbach, 2002; Landis and Yu, 2004; Suter, 2007).

The hazard evaluation of chemicals carried by ships is conducted by assigning ratings based on seven criteria, two of which are from aquatic toxicology—bioaccumulation and aquatic toxicity (acute and chronic) (GESAMP, 1988; 2004; Wells *et al*., 1999). The criteria, the experimental methods to produce the required data, and the 'cut-off' values within each rating system have all evolved as the science of aquatic toxicology has developed over the past few decades. Bioaccumulation is assessed using the logarithm of the *n*-octanol/water partition coefficient (log P_{ow}, also often referred to as log K_{ow}), and the BCF measured using fish or molluscs as target organisms (Wells *et al*., 1999). Considerable effort went into the design of the rating scheme for bioaccumulation and the selection of the break-point of log P_{ow} 4−<5 and BCF 500−<4000 as an indication of a high potential for a substance to bioaccumulate. For toxicity, acute toxicity ratings are based on data from three sorts of standard tests—the 96 hour LC_{50} fish test, the 48–96 hour LC_{50}/EC_{50} crustacean test and the 72 or 96 hour EC_{50} microalgal growth inhibition test (see Thompson *et al*., 2005, for details of available test methods, and the different species used by various jurisdictions and sectors). LC_{50}s or EC_{50}s below 0.1–1 mg l^{-1} are considered highly, very highly or extremely toxic. For the first time in this evaluation scheme, chronic toxicity is considered formally, using NOECs from suitable tests such as the 28 day prolonged fish test, the 21 day *Daphnia* reproduction test or the early life-stage fish test, with the cut-off for high chronic toxicity being an NOEC of 0.01–0.1 mg l^{-1}.

While not without its limitations, the hazard-evaluation scheme enables identification of most substances that have high bioaccumulation and toxicity characteristics, highlighting these for the industry, shippers and regulators. Hence, hazard evaluation is precautionary and aquatic toxicology procedures are used to identify and avoid potential problems before they occur.

ERA is at the other end of the chemical-assessment spectrum. The objective is to evaluate the ecological consequences of chemical exposures in natural ecosystems, hence the probability and level of exposure is key to whether toxicity of the chemical(s) occurs. The aquatic toxicity methods involved are more complex, more expensive, field-oriented and longer-term, and they are focussed on populations and communities of organisms, rather than the organism level. One or more aquatic

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

toxicity approaches, involving microcosms, mesocosms, *in situ* experimental sites and/or observations of natural systems, are deployed (Wells, 1984b; Rand *et al*., 1995; Stokstad, 2008), within the ERA framework of problem formulation, analysis (characterization of exposure, characterization of ecological effects) and risk characterization (EPA (Environmental Protection Agency), 1992; 1996; 2003). For full assessments, for example of a high volume, widely used organophosphorus pesticide such as fenetrothion, a selection of aquatic toxicity techniques might include acute tests on the active ingredient and the formulation, biochemical assays on tissue samples from exposed fish and invertebrates, residue-in-tissue monitoring using bivalve molluscs (clams, oysters or mussels) and benthic surveys for community impact analysis. Risk assessments provide the opportunity to consider all of the reliable methods in the arsenal of aquatic toxicology (Rand *et al*., 1995; Rand, 2009; EPA (Environmental Protection Agency), 2003) and use those most likely to give accurate estimates of toxicity and risk of effects under field conditions.

3.3.2.2 *Comparative Ecotoxicology or the Responses of Different Species*

There has been considerable effort to understand the relative sensitivity or responses of different species of aquatic organisms to contaminants of different types (Blanck *et al*., 1978; Kenega, 1978; Doherty, 1983; Sloof *et al*., 1983; Thurston *et al*., 1985; Blum and Speece, 1990; Posthuma *et al*., 2002). This field of research and application, traditionally called comparative ecotoxicology, now formally involves species sensitivity distributions (SSDs). The field is important from the point of view of selecting appropriate test organisms for chemical screening and ranking, and for the more difficult task of making field predictions of effects under many different conditions. Some progress has been made with selected chemical classes and compounds. For example, it is known that crustaceans, especially decapods, are more sensitive, that is, respond at lower concentrations, to petroleum hydrocarbons than fish, and that generally, across chemicals, young life stages are more sensitive than older life stages. Microtox® bacteria and sea-urchin embryos have proved to be the most sensitive assays for assessing the toxicity of sediments. The collective studies of the past 30 or so years have led regulatory agencies in many countries to select certain species for testing their chemicals and effluents/emissions with confidence. For example, Environment Canada uses fish and crustacean tests for monitoring effluents and amphipod and echinoid tests for screening sediments (see earlier sections); the OECD and the UN International Maritime Organization (IMO) recommend the joint use of fish, crustacean and algal assays; the US EPA recommends the use of fathead minnows, mummichogs, cladocerans, mysids, grass shrimp and microalgae. The selection of the phyla and particular species has been driven by our growing knowledge of interspecies sensitivity to chemicals, as well as by practical constraints of testing.

However, as introduced above, the collective knowledge of the comparative sensitivity of aquatic species has been confounded by the methods of exposure, so that in many, probably most cases, what is known is the different sensitivity of the tests employing certain species, not necessarily the differences or similarities between the species themselves. That is, different tests employ unique volumes of test solutions, temperatures, containers, lighting, duration times, and so on, all of which influence the fate of the tested substance and the contact with and uptake by the test species. Differences in exposure and partitioning, two of the 'three Ps' of aquatic toxicology (McCarty and Mackay, 1993), have compromised the actual comparison of species responses to contaminants. This problem is little appreciated in aquatic toxicology (Abernethy *et al*., 1986), somewhat surprising considering its relevance to ranking chemicals as to their toxicity, and protecting complex, multispecies, aquatic ecosystems.

The literature on comparative aquatic toxicology is large (witness the Google results for 'comparative aquatic toxicity', with >11 000 web sites, 05/08), with many recent studies across many phyla, species, life stages and chemicals and their mixtures, the effort largely focussed on understanding the sensitivities of different species, in different tests, and deriving threshold concentrations and estimates of safe environmental levels. The field needs further analysis and synthesis; infinite numbers of such studies are possible, at great cost, with little new fundamental knowledge generated unless the principles behind the different sensitivities are elucidated.

To this end, in recent years, the field of SSD-based risk assessment has developed (Posthuma *et al*., 2002), incorporating for the most part what is understood about species-specific differences in toxicant responses and thresholds, and applying the data to estimates of risk (Versteeg *et al*., 1998; Forbes *et al*., 2000; Newman *et al*., 2000; Forbes and Calow, 2002; Wheeler *et al*., 2002a; Van Straalen, 2002; Carsten von der Ohe and Liess, 2003; Duboudin *et al*., 2003; Hose and Van den Brink, 2004; Maltby *et al*., 2004). Studies are also conducted to understand the differences in sensitivity of fresh-vs. salt-water organisms (Hutchinson *et al*., 1998; Leung *et al*., 2001; Wheeler *et al*., 2002b), of polar organisms relative to temperate and tropical organisms (Perkins *et al*., 2005), of tropical vs. temperate organisms (Kwok *et al*., 2007), of various planktonic crustaceans exposed to organic pollutants (Sanchez-Bayo, 2005) and of organisms exposed under laboratory and field exposures (Seick *et al*., 2002). This field, as it attempts to uncover the basis of differential responses of organisms to persistent water pollutants, remains one of aquatic toxicology's greatest challenges.

3.3.2.3 *Choosing Indicators of Aquatic Ecosystem Health*

Aquatic toxicology plays a key role in choosing indicators, the species and the measures, of AEH for state-of-environment (SOE) reporting, by providing the methods for short- and longer-term monitoring of water bodies. Due to the diversity of habitats and the biodiversity of aquatic ecosystems, there are a number of challenges to this role: choosing indicators that are sensitive and practical, for freshwater, estuaries and marine ecosystems; determining how they can be combined as indexes of AEH for a water body and assisting the sorting and prioritization of the key monitoring programmes and the selection of the most useful indicators.

Much has been written on the topic of aquatic indicators (e.g. see Schindler, 1996; Sindermann, 1996; Griffith, 1998; Burger and Gochfeld, 2001; Adams, 2002; Jorgensen *et al*., 2005; Wells, 2003; 2005; Bortone, 2005; Allsopp *et al*., 2007). Toxicology plays a big role in their selection—from biomarkers to disease aetiologies. Given the rate of global environmental change (loss and degradation), including climate change, the contributions of aquatic toxicology to choosing useful indicators for monitoring water, sediment and tissue quality takes on a new urgency.

4 NEW DIRECTIONS AND CHALLENGES IN AQUATIC TOXICOLOGY

4.1 Accommodating the Complexity of Issues and Ecosystems

The issues and science of aquatic toxicology are complex and interdisciplinary in nature, hence challenging for the practitioner, while offering satisfaction when solutions are found. The responsibilities are also huge. A cornerstone principle is that AEH is linked to human health in many ways! Examples abound: from the 'ocean and human health' programmes in US and Bermuda, such as Dewailly's studies on trace contaminants in Arctic peoples and linkage back to food-chain accumulations in fish and mammals (Cone, 2005); from Shaw's research on persistent chemicals and their effects in seals (Shaw *et al*., 2005); and the recent study by Kelly *et al*. on 'food-web specific biomagnifications of POPs' (Kelly *et al*., 2007). Aquatic toxicology as a discipline is highly dependent upon the sciences of limnology and oceanography, making it very different to pure toxicology itself. To quote Hartman (2007) on forestry and fresh water in British Columbia—'. . . it is unlikely anyone can accurately project the impacts of this sequence of events (the beetle infestation of BC's forests) starting with the extensive clear cutting indicted, followed by the beetle infestation and logging salvage impacts, and followed yet further with potential massive wildfire. The nature and scale of primary effects on lake and river limnology, hydrology, sediment loading, lake and stream temperature regimes and water chemistry and temperature, can only be guessed at'. Hence, the aquatic toxicologist needs a tool kit of basic toxicology, augmented by ecology and the many subdisciplines of ecotoxicology. This is illustrated further by the examples below.

4.1.1 *Influence of Climate Change*

Climate change may influence many aspects of pollutant exposure and biological effects, as changing temperatures and other variables affect migration, breeding, date of first appearance and distributional patterns (range) (Worldwatch Institute, 2007, p. 94). The Millennium Ecosystem Assessment (MEA) report of 2005 predicted that 'the impacts of climate change on biodiversity across all ecosystems will increase very rapidly' (Worldwatch Institute, 2007, p. 94–95). The most recent IPCC (Intergovernmental Panel on Climate Change) predictions are for higher air temperatures, more droughts, more storms, sea-level rise, melting of sea ice and glaciers, and so on, all of which are predicted to occur in the twenty-first century at a fast pace and to influence aquatic ecosystems profoundly. How organisms adapt, and whether aquatic ecosystems have the required resilience to adapt are critical questions (see Poff *et al*., 2002; Walker and Salt, 2006). This is where aquatic toxicology returns to its roots in environmental and comparative physiology, and ecology, and where fundamental aquatic toxicology research must be multidisciplinary and forward thinking. Chemical stressors will be interacting on biological systems and habitats in changing ecological regimes, suggesting that aquatic toxicology should be considering novel, multifactorial scenarios for chemical exposures (see Poff *et al*., 2002).

4.1.2 *Water Pollution and Invasive Species*

One of the most pervasive and serious threats to aquatic habitats and ecosystems are invasive species. Aquatic toxicologists should be more involved with *invasive species* programmes, asking questions about chemical effects in both chemically polluted and invaded (biologically changed) environments, as well as investigating further chemically based controls. Polluted or otherwise disturbed environments appear to be more susceptible to invasive species, for example, San Francisco Bay, European waters, Black Sea (GESAMP, 1997a; Sindermann, 1996; Leppakoski *et al*., 2002). What the interplay is between the presence and success of an invasive species and the level of chemical stress in an ecosystem is worthy of investigation. Many questions require answers: Can chemicals play any new roles in controlling invasives (already applied with fire ants, zebra mussels, sea

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

lampreys and ballast-water organisms)? What are the implications of a continued chemical approach (often difficult and expensive, but successful) to further invasives control? Basically, do aquatic toxicologists have a new role to play with this issue?

4.2 Making Use of New Tools in Aquatic Toxicology and Ecotoxicology

DeCoen *et al*. (2005) stated the need for new tools succinctly: 'More quantitative relationships between the various levels of biological organization need to be established in the global implementation of the various ecotoxicological tools and methods. One of the main areas of uncertainty in aquatic toxicology at present is the extrapolation of toxicity data obtained from lab testing to effects in real-life ecosystems'. Ecotoxicology has six future needs—improved biomarkers, transgenic systems, novel markers at the proteome level, organism level effects—mechanisms of reproductive toxicology, realistic effect assessments by predicting effects of mixtures and ecological complexity in toxicity testing—interactions between pollutant stress and food availability. A major challenge is to optimize the knowledge related to the increased volume of toxicological data to construct molecular and genetic pathways explaining the mechanism(s) of toxic effects; increase our understanding of the consequences of lifecycle exposures to chemicals and chemical mixtures; increase genomic information for the species widely used in ecotoxicology; 'in toxicogenomics, a major application of gene expression profiling is to understand the genetic variability and susceptibility to toxic stress within ecosystems' (DeCoen *et al*., 2005).

4.2.1 Model Organisms in Aquatic Toxicology

As in traditional toxicology, model organisms are the backbone of the research, monitoring and regulatory activity, but many questions remain regarding their use: how many model organisms are enough, for the purposes of screening chemicals, and researching and monitoring their fate and effects in aquatic ecosystems? What are our primary models for understanding the effects of chemicals on aquatic organisms? What should they be? Is the concept of the model organism even valid in aquatic toxicology, given the enormous global aquatic biodiversity that requires protection based on the predictions of effects on very few organism types? Can current genomics help ecotoxicologists narrow down the list, given the many genes that organisms have in common (see Benson and Di Giulio, 2006)? There probably is not and should not be an upper limit on the number and type of 'model organisms' for aquatic research purposes, especially in basic research. But for screening chemicals for use and transport, for regulating final emissions, for monitoring and for teaching/training, there are good, mostly practical, arguments for limiting the numbers and types of model organisms to work with in such applications.

For research and regulatory applications, teleost fish have been worked with more than any other group (Cossins and Crawford, 2005; Mommsen and Moon, 2005; Vosyliene, 2007; Di Giulio and Hinton, 2008); many species are now incorporated into toxicity tests, both acute and chronic, in many countries. Standard methodologies have been and are developed under the auspices of EPA (USA), Environment Canada, ASTM, APHA, the OECD and ISO, in particular. Environment Canada has more than 10 model organisms in its regulatory ecotoxicology programmes (Inter-Governmental Ecotoxicological Technical Group (IGETG), 2004). Certain fish species are considered models—rainbow trout and other salmonids (Wells and Moyse, 1981; Environment Canada, 1990a; 1990b); zebrafish (Carvan *et al*., 2000; 2005; Bopp *et al*., 2006); American flagfish (*Jordanella floridae*); fathead minnows (*Pimephales promolus*) (Ankley and Villeneuve, 2006); killifish/mummichogs (Shedd *et al*., 1999; Weis, J., personal communication); sticklebacks (Hahlbeck *et al*., 2004a; 2004b; Ostlund-Nilsson *et al*., 2007) and Japanese medaka (Patyna *et al*., 1999; Farwell *et al*., 2006; Koyama *et al*., 2008), amongst others.

For freshwater invertebrates, for example, cladocerans (Mount and Norberg, 1984; Environment Canada, 1990c; 1990d; 1992; Anderson-Carnahan *et al*., 1995; Sarma and Nandini, 2006), rotifers (Janssen *et al*., 1994; Preston *et al*., 2000; Preston and Snell, 2001; Snell and Joaquim-Justo, 2007; McNair and Belem de Araujo, 2008), crayfish (ASTM (American Society for Testing and Materials), 1994) and bivalve molluscs (Farris and Van Hassel, 2007) have been used. Aquatic insects, such as mayflies and caddis flies, have also been utilized (see Wells *et al*., 1998; G. Persoone, personal communication).

Microalgal species are also used (Bengtson Nash *et al*., 2005), as are protozoa (Sauvant *et al*., 1999) and amphibians (e.g. frogs, toads) (ASTM (American Society for Testing and Materials), 1994). In soil ecotoxicology, nematodes and earthworms are used.

For marine invertebrates, an excellent overview was given by Persoone *et al*. (1984). Polychaetes (Pocklington and Wells, 1992), molluscs (ASTM, 2008), crustaceans (copepods, barnacles, decapods) (Persoone *et al*., 1984; Key *et al*., 2006; Raisuddin *et al*., 2007) and echinoderms (Bay *et al*., 1993; Nipper *et al*., 1993; Kobayashi, 1995) have been studied extensively. Small-scale techniques, acute and chronic, have become well used, especially for assaying contaminated sediments (Carr *et al*., 2001). In an international course in marine hazard assessment

and ecotoxicology, *Artemia* larvae, urchin embryos and larvae, and bacteria (Microtox®) have been used for many years for assaying and evaluating the risks of contaminated inshore sediments of Bermuda (Bermuda Institute of Ocean Sciences, unpublished data).

Having the tool kit of a few reliable core tests, acute and chronic, with model species is the objective of many countries, agencies and industries. The one primary question left unanswered is: how does one define 'enough' for model organisms, given the huge biodiversity of aquatic ecosystems (e.g. 43 phyla in the oceans alone)? What can we learn from the human health and toxicology sector, dependent on only a few surrogates (e.g. rats, mice, rabbits, monkeys) for experiments and screening of chemicals? The linkage to questions of interspecies sensitivity to chemicals is also obvious. Much remains to be done before the suite of core tests, with model aquatic species, is firmly and confidently established.

4.2.2 Evaluation of Micropollutants

For many years, concerns have been expressed about the possible longer-term health and ecological effects of exposures to chemicals present in very low amounts in natural waters (Howells *et al*., 1990). Such exposures are now referred to as micropollutants—trace elements, heavy metals, POPs such as pesticides, PAHs, polychlorinated dibenzodioxins (PCDDs), polychlorinated dibenzofurans (PCDFs) and pharmaceuticals, often present in measurable, but very low concentrations in groundwater and surface waters, particularly drinking water (Hester and Harrison, 1996; Schwarzenbach *et al*., 2006; De Verlief *et al*., 2007). Recently, concern has heightened about perchlorate found in surface and groundwater across the mid-western US states. This has implications for both ecosystem and human health, largely due to the uncertainties of the chronic effects of such trace chemicals, alone and in mixtures. The challenge of micro-pollutants was described by Schwarzenbach *et al*. (2006). They stated that 'recent research has shown that even mixtures of compounds with different modes of toxic action may cause non-negligible effects… There now are systematic investigations of mixture effects of noninteracting compounds, and countries such as Switzerland are developing water-quality criteria that include additive effects for mixtures of pesticides in surface waters'. The challenge in aquatic toxicology is to continue to conduct realistic experiments and monitoring, seeking evidence of bioaccumulation and sublethal toxicity of such trace chemicals on aquatic biota, with a special emphasis on various suspected EDCs.

4.3 Effects of Chemicals on Behaviour Such as Chemoreception

Many chemicals are pervasive and persistent in water and sediments at very low concentrations, sometimes for decadal periods, for example DDT and its residues, PCBs, PAHs. Consequently, they are of concern regarding their possible sublethal effects on basic biological processes, including the many elements of behaviour. In recent years, behavioural ecotoxicology has become an active and challenging field (Olla *et al*., 1980; Hadjinicolaou and LaRoche, 1988; Dell'Omo, 2002; Clotfelter *et al*., 2004; Kane *et al*., 2005; Gerhardt, 2007), with considerable work being conducted on the effects of pollutants (e.g. cadmium) on complex fish behaviours and their underlying physiological mechanisms (Sloman *et al*., 2003; Scott and Sloman, 2004). ASTM has issued a standard guide to the selection and application of behavioural methods for fish, amphibians and macroinvertebrates (ASTM, 2007).

Of all the behaviours, interference with chemoreception is of paramount concern. Chemoreception in fish and invertebrates plays a crucial role in food finding, reproduction, avoiding predation, schooling, finding suitable habitats, settling and metamorphosis of larvae and postlarvae (Bronmark and Hansson, 2000; Blaxter and Hallers-Tjabbes, 1992; Hebel *et al*., 1997). Some chemicals are known to interfere with chemoreception (e.g. Atema's studies with lobsters and PAHs, Atema and Stein, 1972; 1974) and many other behaviours, such as the burrowing behaviour of invertebrates in sediments (Wells and Sprague, 1976; Dell'Omo, 2002; Clotfelter *et al*., 2004). Given that organisms live in a complex chemical world, and are highly dependent upon chemical cues, subtle effects of foreign chemicals on their behaviour and chemical receptors, at very low concentrations, are not unexpected, are little understood and deserve greater attention.

Key questions that could be examined include: What are the influences of such persistent chemicals, for example the major POPs and trace pharmaceuticals in sewage effluents, on chemoreception and chemically modulated behaviour of organisms living in the water column and sediments? At what concentrations do such effects occur? What are the risks of such effects occurring in aquatic environments? Do we have sufficient techniques to permit detection of such effects, across the phyla?

4.4 Recovery and Resilience Ecotoxicology

There is a need to investigate further the potential for recovery from chemical contaminant exposures and for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat092
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the resilience of chemically contaminated species and geographic areas. Hence, there is a developing field of aquatic toxicology called recovery and resilience ecotoxicology. Recovery has been defined as 'the process leading to partial or complete restoration of a cell, tissue, organ or organism following its damage from exposure to a harmful substance or agent' (National Library of Medicine, USA, web site, *http://www.nlm.nih.gov/*). Resilience is 'the amount of change a system can undergo (its capacity to absorb disturbance) and remain within the same regime—essentially retaining the same function, structure and feedbacks (Walker and Salt, 2006). Recovery is more organism based, resilience refers to the whole ecosystems ability to bounce back from stress. Some key questions currently are: do we conduct enough recovery and resilience aquatic toxicology? What are some good examples of the value of such research and knowledge?

Early (unpublished) work in our Bedford Institute laboratory was with sea urchins, *Strongylocentrotus droebachiensis*, that survived exposures to low concentrations of oil-spill dispersants in sea water, but later succumbed in recovery tanks (clean sea water alone)—they did not recover from exposure to the very low levels of surfactants, which in short experiments were recorded as harmless (Wells, 1982). This showed that short-term, nonlethal chemical exposures could indeed be lethal. There is a recent literature in this field (Depledge, 1998; Sánchez *et al*., 1999; Sancho *et al*., 2003; Zhao and Newman, 2006). Every effort should be made to include recovery (potential) as a dependent variable in experiments and standard assays.

4.5 Other Topics in Aquatic Toxicology

Many other topics could have been considered, briefly or in depth, in this overview of aquatic toxicology, had space permitted. They would have included:

1. Effects of chemicals on particular organisms or habitats, for example, fish, amphibians and reptiles, polar and tropical environments
2. Special topics, such as endocrine disruption, community ecotoxicology, genetics and ecotoxicology, demography and ecotoxicology, and computational toxicology
3. Biological effects monitoring (see Section 1.5 for a brief mention)
4. Coastal and marine ecotoxicology
5. Effects of multiple stressors, and complexity in aquatic ecosystems
6. The role of interfaces in aquatic toxicology
7. Bioinformatics and aquatic toxicity databases
8. Standard testing, and quality assurance/control of data
9. The role of aquatic toxicology in chemical safety assessment.

The reader is encouraged to read Rand (1995; 2009) and the other publications listed in the References and Further Reading Sections for information and guidance on these topics.

4.6 Further Directions and Challenges in Aquatic Toxicology

Aquatic toxicology is a very dynamic field at present (circa 2008), given the influence of molecular biology on its techniques, the genuine convergence of ecology with toxicology and the myriad of threats to aquatic biodiversity globally. Moore (2002) succinctly summarized some of the challenges—understanding toxic mechanisms, developing simulation models of toxic effects, making linkages across levels of biological organization and exercising precaution in the face of new industrial advances.

The field is becoming both data rich and concept rich, the latter being so important given the diversity of aquatic species and habitats under chemical exposure, and the shear impossibility of obtaining data specific to every species and habitat. Practitioners cross many disciplines in order to address the fate and effects of new chemicals on aquatic ecosystems. There is much formal contact at meetings and in new studies and their publications. The interdisciplinary nature of the field is essential (Moore, 2002); it now not only bridges the science disciplines, but also human and ecosystem health, as humans are affected by unhealthy environments, especially degraded water and food quality. Aquatic toxicology is now a mature subdiscipline of toxicology, gaining much from this affiliation in its concepts, practice and new developments, and serving the needs of both humans and the aquatic environment.

5 SUMMARY

Many threats to aquatic environments and their living resources remain, with very large economic, ecosystem and human-health consequences. Such threats are being addressed vigorously by aquatic scientists, regulatory agencies, industry and their representatives and international agencies. Methods in aquatic toxicology are being continually advanced, especially benefitting from linkages to classical toxicology, molecular biology, benthic biology and nanotechnology. Current techniques are also applied more frequently in environmental effects monitoring. Aquatic toxicology continues to be a field of much vitality, innovation and change in the new millennium,

with new techniques, new understanding and the imperative of the vital importance of protecting the quality of aquatic ecosystems.

ACKNOWLEDGEMENTS

The list of terms was compiled originally by the Evaluation of Hazardous Substances Working Group of GESAMP, International Maritime Organization, United Nations, London. This chapter is dedicated to the careers and memories of Jack Anderson, USA; Davide Calamari, Italy; John Gray, Norway; Dick Lloyd, UK; David Peakall, Canada and UK; John Portmann, UK and Umit Unluata, France and Turkey. A special mention is due to Bryan Ballantyne, toxicologist extraordinaire, who will be greatly missed by all who had the privilege to work with him.

Environmental Endocrine Toxicology

Poul Bjerregaard

CONTENTS

1 INTRODUCTION

The incidence of a number of adverse effects originating in the male reproductive organs increased during the last decades of the twentieth century. In humans, this was most clearly reflected in the increased prevalence of testicular cancer, but some investigations also showed a decrease in sperm-cell numbers in humans and increased frequencies of cryptorchidism and hypospadias. In nature, sexual differentiation was affected in fish downstream of discharges from sewage treatment plants and paper mills, and alligators exposed to chemicals

after a spill showed altered sexual development. Likewise, sexual development was affected in gulls contaminated with chlorinated pesticides and in snails contaminated with tributyltin (TBT) from antifouling paints.

During the 1990s it became clear that a fairly large number of chemicals with widespread use in the industrialized world had the potential to mimic the effects of natural oestrogens in living organisms.

Based on some of these observations, Sharpe and Skakkebaek (1993) formulated the 'oestrogen hypothesis', according to which the mechanism underlying at least part of the phenomena described was the exposure of male foetuses at early stages of development to unusual amounts of the female sex hormones (oestrogens) or chemicals with oestrogenic effects.

More recently, concerns over the potential impact of chemicals with antiandrogenic effects on male development have arisen. In humans, the four phenomena mentioned above are now considered four different manifestations of the same underlying disorder—'testicular dysgenesis syndrome (TDS)'.

Disruption of endocrine systems other than the sex-hormone system has also been identified.

Table 1 Prevalence of testicular cancer (incidence per 10^5), hypospadias (%), cryptorchidism (%) and sperm cell numbers (cells ml^{-1}) in three Nordic countries

	Finland	Sweden	Denmark
Testicular cancer[a]			
1943	—	—	2.8
1960	1.0	2.6	4.6
1987	2.3	4.6	8.6
Hypospadias[b]	0.27	—	1.03
Cryptorchidism[c]			
At birth	2.4	—	9.0
At three months	1.0	—	1.9
Sperm number[d]	54	—	41

[a]Adami *et al*. (1994).

[d]Jorgensen *et al*. (2002).

2 TESTICULAR DYSGENESIS SYNDROME

2.1 Testicular Cancer

The frequency of testicular cancer has been increasing in most Western countries (Adami *et al*., 1994) and, in Denmark, which started systematic recording of cancer frequencies earlier than any other country, the prevalence of testicular cancer increased almost linearly from 1943 to the turn of the century (**Table 1**). Whereas Denmark, together with Norway, has the highest frequency of testicular cancer in the world, the incidence of testicular cancer is lower in Finland, although the frequency there has also increased since recording began (**Table 1**). Testicular cancer is most often diagnosed in men in their twenties and thirties, but the potential for testicular cancer is founded during early pregnancy (Skakkebaek, 1978). The division of early germinal cells is arrested and carcinoma *in situ* (CIS) cells are formed, which later in life initiate the development of testicular cancer. The precise mechanism—and the potential role of hormones or endocrine disrupters—underlying the formation of the CIS-cells is unknown.

The prevalence of testicular cancer varies between ethnic groups (Purdue *et al*., 2005) and it has been considered that genetic changes might explain the increase in the frequency of testicular cancer. However, the increase in the frequency has been so rapid that genetic changes have been rejected as a potential explanation. On the other hand, it has been strongly indicated by comprehensive Swedish investigations (Hemminki and Li, 2002) among persons migrating between the Nordic countries, that some kind of environmental impact (lifestyle factors, chemicals, etc.) seems to be a determining factor for the prevalence of testicular cancer. The Swedish frequency of testicular cancer is higher than the Finnish and lower than the Danish (**Table 1**). If Finnish or Danish couples move to Sweden, the frequency of testicular cancer in their offspring (born in Sweden) will increase (for the Finns) or decrease (for the Danes), respectively, approaching the frequency normally seen in Sweden (Hemminki and Li, 2002).

2.2 Sperm Numbers

Various investigations have shown that sperm numbers—at least in some geographical regions—have been or are decreasing. A meta-analysis of all previously published data (Carlsen *et al*., 1992) carried out in the early 1990s indicated a decrease of approximately 2% per year, and a similar trend was also seen in some (Auger *et al*., 1995)—but was not supported in other—subsequent investigations (reviewed by Safe, 2004).

Sperm numbers in humans show large individual variability (0 to approximately 500 million cells ml^{-1}). Men's fertility seems independent of sperm numbers for values higher than 35–40 million cells ml^{-1}, whereas fertility decreases linearly with sperm numbers below that threshold (Bonde *et al*., 1998). Approximately 40% of young Danish (Jorgensen *et al*., 2002) and Norwegian (Jorgensen *et al*., 2006) men have sperm numbers

DOI: 10.1002/9780470744307.gat093
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

below 40 million cells ml^{-1} and this is also the case in 45% of young German men (Paasch *et al*., 2008). Sperm numbers are higher among young Finnish than Danish men (**Table 1**).

The ability of an adult man to produce sperm cells is associated with adequate masculinization of the male genital tract—including the proper development of Sertoli cells in the testes—during foetal development (Sharpe and Skakkebaek, 1993).

2.3 Cryptorchidism

Cryptorchidism is the failure of one or both testes to descend into the scrotum during pregnancy. The descent of the foetal testes from their initial position in the abdominal region is regulated by hormones and in experimental animals interference with the hormonal system may lead to undescended testes (Welsh *et al*., 2008). Some investigations have shown increased frequencies of cryptorchidism among humans, but comparison with earlier data is somewhat hampered by the previous lack of clear diagnostic criteria for this phenomenon (Toppari *et al*., 2001). Recent investigations have shown that the prevalence of cryptorchidism is approximately three times higher in Denmark than in Finland (**Table 1**).

2.4 Hypospadias

Hypospadias is an abnormality in the male genital system in which the urethra opens at a site other than the tip of the penis. This phenomenon may be induced in experimental animals by exposure to chemicals disturbing sexual development (Rider *et al*., 2008). Some investigations have shown increasing prevalence in humans but, as with cryptorchidism, comparison with earlier data are made difficult due to the previous lack of clear diagnostic criteria for this phenomenon (Toppari *et al*., 2001). However, more recent investigations show that the prevalence of hypospadias is three times higher in Denmark than in Finland (**Table 1**).

2.5 Links Between the Four Phenomena

The disturbances in human sexual development (increased frequency of testicular cancer, decreased sperm count, cryptorchidism, hypospadias) were earlier regarded as separate phenomena, but recent research shows that they should rather be seen as four separate manifestations of the same basic disturbance in sexual development, and they are now looked upon as a coherent syndrome—'TDS' (Skakkebaek *et al*., 2001).

Men who develop testicular cancer have lower fertility before the outbreak of the disease than men who do not develop testicular cancer (Moller and Skakkebaek, 1999) and boys born with hypospadias and/or cryptorchidism have an increased risk of developing testicular cancer (Toppari *et al*., 2001).

Recent investigations have shown that the frequencies of cryptorchidism as well as hypospadias among newborn boys are approximately three times higher in Denmark than in Finland, the latter also having a lower frequency of testicular cancer and higher sperm counts than Denmark (**Table 1**).

2.6 Do Endocrine-Disrupting Chemicals Play a Role in Testicular Dysgenesis Syndrome?

2.6.1 Phthalates

Exposure to certain phthalates causes reproductive disorders in rats similar to TDS symptoms (Foster, 2006), the so-called 'phthalate syndrome'. Exposure of rats to phthalates over a narrow time window during foetal development suppresses the production of foetal testosterone (a necessity for masculinization of the male genital tract) resulting in reduced Sertoli cell numbers, hypospadias, cryptorchidism and reduced anogenital distance (Howdeshell *et al*., 2008b; Scott *et al*., 2008; Welsh *et al*., 2008).

Although human exposure to phthalates has generally been assumed to be very much lower than the doses necessary to induce the 'phthalate syndrome' in rats, phthalate monoester metabolites can be demonstrated in human amniotic fluid in some women (Silva *et al*., 2004) at concentrations less than an order of magnitude lower than the concentrations found in amniotic fluid in rats (Calafat *et al*., 2006) exposed to phthalate at doses eliciting effects.

Swan *et al*. (2005) investigated pregnancy outcomes in mothers exposed to phthalates and found reduced anogenital distance in the sons of women with the highest phthalate exposures during pregnancy. Main *et al*. (2006a) found a negative association between the level of monobutyl phthalate in the breast milk of mothers and the testosterone level in their three-month-old male offspring, and a positive correlation between the monobutyl phthalate concentration and the concentration of sex-hormone-binding globulin.

Thus, it seems as if the risk cannot be neglected that exposure to phthalates or mixtures of phthalates may be one—probably among several—factor that may contribute to the development of TDS in humans (Sharpe, 2008).

2.6.2 Pesticides

Many greenhouse workers have a higher exposure to pesticides than the general population and in a recent Danish investigation, female greenhouse workers were found to have an increased risk of delivering boys with cryptorchidism and reduced penis sizes relative to the general population (Andersen *et al*., 2008). The precise exposure regime for the female greenhouse workers could not be established, but known endocrine disrupters such as vinclozolin, fenarimol and prochloraz were among the 124 active pesticide ingredients registered as used in the greenhouses (Andersen *et al*., 2008).

2.6.3 PCBs, HCB and Chlordanes

A Swedish investigation of the concentration of chlorinated hydrocarbons in the blood of mothers whose sons developed testicular cancer (against control mothers whose sons did not develop testicular cancer) showed increased odds ratios for total polychlorinated biphenyls (PCBs), hexachlorobenzene (HCB) and chlordanes (Hardell *et al*., 2003). The concentrations of a number of individual PCB congeners were higher in the blood of the mothers of the cases; this was also true when grouped into oestrogenic and enzyme-inducing PCBs (Hardell *et al*., 2004); the PCB concentrations of the young men showed no differences.

2.6.4 Oestrogenic Chemicals

2.6.4.1 Synthetic Oestrogens

The example of diethylstilbestrol (DES) illustrates that human exposure to chemicals may affect male sexual development. During the period 1940–1970 a large number of women were treated with DES to counteract pregnancy complications. As opposed to natural oestrogen, DES is not bound to the sex-hormone-binding proteins in the blood, so the concentration of the chemical available for uptake into the cells is relatively high. Sons of these women showed an increased frequency of hypospadias, cryptorchidism and testicular cancer and low sperm count (reviewed by Sharpe and Skakkebaek, 1993).

However, in experimental animals, DES and also ethinyloestradiol (EE2) have far stronger oestrogenic effects (Howdeshell *et al*., 2008a) than any of the industrial chemicals humans are exposed to in everyday life. With the present knowledge about the potency of the different chemicals with oestrogenic effects, it is difficult to point out individual chemicals to which the general population is exposed at sufficiently high doses to cause changes in the sexual development of male foetuses (Sharpe and Skakkebaek, 2003).

2.6.4.2 The Oestrogen Exposure of the Foetus and the Lifestyle of the Mother

Various changes in lifestyle may have changed the natural oestrogen exposure of foetuses during the last half of the twentieth century, via changes in the general regulation of the blood oestrogen content of women (reviewed by Sharpe and Skakkebaek, 1993): (i) Fatty tissues metabolize oestrogen differently from other types of tissue, such that obesity leads to increased concentrations of oestrogen in the blood. (ii) A high content of fibre in food binds oestrogen excreted into the gastrointestinal tract such that enterohepatic recirculation (re-uptake of excreted oestrogen from the intestine) is reduced. (iii) A high content of phyto-oestrogens (e.g. from soya products) in food seems to increase the production of sex-hormone-binding proteins; this will lead to a decrease in the presence of free oestrogen in the blood. (iv) Mothers who smoke during pregnancy give birth to boys with lower sperm counts than nonsmoking mothers. Smoking mothers generally give birth to children with lower birth weights than nonsmoking mothers, and low birth weight by itself is associated with low sperm counts. (v) During a woman's first pregnancy, the regulation of sex-hormone-binding globulins in the blood is different from regulation during subsequent pregnancies, and this results in a higher exposure of the foetus to oestrogen. First-born boys have a higher risk of developing testicular cancer than boys born later in a group of siblings. Since women in the Western world have generally given birth to fewer children over the recent generations, this might potentially lead to an increase in the frequency of testicular cancer (but it would not explain the difference in prevalence between e.g. Denmark and Finland).

Furthermore, both underweight and overweight young men have lower sperm counts than men with a normal weight.

2.6.5 Could Mixtures Play a Role?

Common procedures for risk assessment of chemicals consider chemicals in single-compound exposure, generally ignoring the fact that both humans and organisms in the environment may simultaneously be exposed to a multitude of different chemicals; at best, it is assumed that the application or safety factors used when deriving, for example, acceptable daily intake (ADI)-values from no-effect levels identified in laboratory studies account for the potential effects of mixed exposure.

For endocrine-disrupting chemicals, a fair amount of knowledge about effects of mixtures has been gathered during recent decades. The general conclusion has been that chemicals with similar modes of action act additively and that mixture effects in such cases can be fairly accurately predicted by concentration or dose-addition models. This has been shown for oestrogenic chemicals in *in vitro* systems (Payne *et al*., 2000; Rajapakse

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat093
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

et al., 2001) and *in vivo* in fish (Brian *et al*., 2007; Thorpe *et al*., 2003; 2001) and for antiandrogens (Hass *et al*., 2007), phthalates (Howdeshell *et al*., 2008b) and mixtures of different classes of antiandrogens (Rider *et al*., 2008) in rats.

The effect of mixtures with dissimilarly acting chemicals may be more complicated to predict: thus, a combination of four antiandrogens with different mechanisms of action (vinclozolin (an androgen receptor antagonist), DEHP (bis(2-ethylhexyl)phthalate, a testosterone synthesis inhibitor), finasteride (an inhibitor of steroid Type II 5-reductase) and prochloraz (multiple mechanisms)) administered to pregnant rats at doses that individually caused no or little effect caused 100% hypospadias in the male offspring (Christiansen *et al*., 2008).

Humans are known to be exposed to several endocrine-disrupting chemicals simultaneously (Main *et al*., 2006b; Silva *et al*., 2004) and the potential effect of these mixtures needs to be better understood.

3 ENDOCRINE DISRUPTION IN THE ENVIRONMENT

3.1 Feminization of Male Fish Downstream from Wastewater Discharges

The initial observations of feminization of male fish in areas affected by wastewater discharges were made in England, where early stages of eggs (ovo-testes) were found in the testes in a diclinous fish, the roach *Rutilis rutilis* (Jobling *et al*., 1998). This condition was called intersex and the degree of intersex was graded into different stages, in which stage 0 is unaffected males and stage 7 is fully feminized males (Jobling *et al*., 1998). A larger investigation was initiated in which males upstream and downstream from discharges from major sewage-treatment plants were examined. The sewage-treatment plants were chosen such that there was some kind of a physical separation of the populations upstream and downstream from the wastewater discharge. No areas were found without a certain fraction of feminized male fish and downstream from some sewage-treatment plants no unaffected males were found at all. The degree of intersex in the investigated roach populations increased with increasing contamination of the rivers with ordinary household wastewater.

The oestrogenic effect of the discharged wastewater at a number of English plants was demonstrated by the induction of vitellogenin in male trout caged in or downstream from the wastewater discharges (Harries *et al*., 1996).

Feminization of male fish in areas affected by wastewater discharges has now been found in many countries in Europe, North America, Asia and Australia, and the phenomenon has been demonstrated in approximately a dozen investigated fish species.

These effects may also extend to estuarine and coastal areas (Matthiessen *et al*., 2002).

3.1.1 The Causes of the Feminization

The oestrogenicity of the wastewater is caused particularly by the natural oestrogens 17β-oestradiol (E2) and oestrone (E1) and the synthetic oestrogen, 17α-ethynylestradiol (EE2), which is used in contraceptive pills. The three chemicals are excreted mainly from women—but for the natural oestrogens, a little also from men—in the households contributing the waste water to the sewage-treatment plants.

The oestrogens are excreted from humans mainly in the form of conjugates (especially as glucuronides and sulfates) that do not have any hormonal effects. Microbial processes in the raw sewage hydrolyse the excreted conjugates and thereby re-establish the hormonal activity (Stuer-Lauridsen *et al*., 2005). Most modern sewage-treatment plants remove the majority of the oestrogens from the wastewater, but the efficiency depends of the type of plant, and the water and sludge residence times; plants with nitrification (Stuer-Lauridsen *et al*., 2005) and high retention times are most efficient.

However, even the relatively low remaining amount of oestrogen in the purified wastewater may have the potential—at least locally—to feminize male fish in areas affected by wastewater discharges. In controlled short-term experiments in the laboratory, E2 feminizes male fish (determined by induction of vitellogenin synthesis) at concentrations between 15 and 50 $\mathrm{ng\,l^{-1}}$ (Bjerregaard *et al*., 2008); oestrone is slightly less potent (50–100 $\mathrm{ng\,l^{-1}}$), while EE2 feminizes male fish (for most of the species investigated) at concentrations between 1 and 5 $\mathrm{ng\,l^{-1}}$. Concentrations of natural and synthetic oestrogens exceeding these values have been found in many wastewater discharges (Desbrow *et al*., 1998).

E2 and E1 are degraded relatively quickly in river water ($t_{1/2} < 1$ day), but with a half life for EE2 of one to two weeks (Jurgens *et al*., 2002) this chemical has the potential to exert feminizing effects fairly far downstream the wastewater discharge.

In some cases the endocrine disruption in the freshwater environment is attributed to the discharge of oestrogenic industrial chemicals. The Aire River is situated in an area in northern England with a large woollen industry in which alkylphenolpolyethoxylates are used in large amounts to degrease raw wool. In the River Aire, concentrations of nonylphenol have been measured in the water that are almost 10 times higher than needed to

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

induce vitellogenin synthesis in short-term experiments in rainbow trout (Harries *et al*., 1996).

3.1.2 The Effect of the Feminization in Populations

There is only a limited knowledge about the impact of male feminization on populations. Male roach with intersex produce lower amounts of semen than normal males (Jobling *et al*., 2002); it is, however, not known what fraction of the males must be affected (and to what degree) before it has negative consequences for the population. The timing of the readiness to spawn in the intersex males was changed relative to the females, and this lack of synchronization of spawning might be envisaged to affect the reproduction as much (or maybe even more) than the lower semen amounts of the intersex males (Jobling *et al*., 2002).

In multigeneration studies with zebra fish in the laboratory it has been found that bisphenol A and EE2 begin to reduce the reproductive success at almost the concentrations that will also induce vitellogenin production in males in short-term experiments (Segner *et al*., 2003). It is not known if the same is true for other fish species and in nature. In a Canadian field experiment, EE2 was added to a lake and maintained at approximately $5\,ng\,l^{-1}$ for a number of years. The lake's population of fathead minnow collapsed after five years (Kidd *et al*., 2007).

3.2 Masculinization of Female Fish Downstream from Paper Mills

A number of investigations in different parts of the world have documented that process water from paper production may affect the sexual development in fish. Masculinization of female fish, lower concentrations of sex hormones in the blood, reduced size of sexual organs, altered sex ratios in, for example eelpout, and several other phenomena related to normal sexual development have been observed (Larsson *et al*., 2000; Munkittrick *et al*., 1998; Tremblay and Van Der Kraak, 1999).

The exact relationships between cause and effect for these impacts have not been elucidated, but chlorinated dioxins (produced during chlorine bleaching processes) and plant sterols (present in wood) have been suspected.

3.3 The Alligators in Lake Apopka

A spill of various chlorinated chemicals in Lake Apopka, Florida, in 1980 caused a major decrease in the reproduction in the lake's population of alligators *Alligator mississippiensis* (Guillette *et al*., 1999; 1995; 1994; 1996). The male alligators developed abnormally small external sexual organs (Guillette *et al*., 1996) and the levels of sex hormones were abnormal (Guillette *et al*., 1999).

3.4 DDT-Contaminated Birds

Skewed sex ratios, feminization of male birds and reproductive problems were seen in dichlorodiphenyltrichloroethane (DDT)-contaminated populations of gulls in California and injection of relevant doses of DDT produced these effects in laboratory experiments (Fry and Toone, 1981).

3.5 Imposex and Intersex in Snails

3.5.1 Imposex

Snails belonging to the families *Buccinidae* (i.e. the dog whelk *Nucella lapillus*) and *Nassidae* are normally gonochoristic (each individual is either male or female throughout life). In the late 1960s female dog whelks were found around the Marine Biological Laboratory in Plymouth, UK, that had developed obvious male sexual characters, that is, penis and vas deferens (Blaber, 1970). An analogous phenomenon was found in the American snail species *Nassa obsoletus* (Smith, 1971; 1980; 1981), and exposure to TBT was identified as the cause of the imposed male sexual characters. In these families of snails the formation of imposed male sexual characters in females is termed *imposex* (Smith, 1971). Imposex has now been recorded in approximately 200 species of snails worldwide.

The development of imposex in females is divided into seven stages (Gibbs *et al*., 1987): Stage 0: normal female; Stage 1: formation of vas deferens initiated; Stage 2: penis development initiated; Stage 3: vas deferens 50% developed; Stage 4: vas deferens fully formed; Stage 5: vas deferens/prostate tissue beginning to block the vaginal opening; Stage 6: the capsule gland contains aborted egg capsules.

While the development of imposed male sexual characters does not seem to affect the ability to reproduce in *Nassa obsoletus* (Smith, 1980; 1981), the female dogwhelks may end up sterile in severe cases because prostate-like tissue around the vas deferens blocks the vaginal opening of the female. It is assumed that sterile females may die because they abort the eggs (that cannot be liberated via the blocked vaginal opening) into the body cavity (Gibbs *et al*., 1987).

Dog whelks are very sensitive to TBT and in adult females concentrations as low as $5\,ng\ TBT\ l^{-1}$ may

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat093
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

induce growth of penis. Young and not yet sexually mature females of dog whelks are even more sensitive than the adult individuals and exposure to less than 1 ng TBT l^{-1} in nature seems to induce growth of penis and vas deferens tissue in females (Gibbs *et al*., 1987).

Imposex occurs, not only in coastal areas, but also in open marine areas with major shipping routes (Ten Hallers-Tjabbes *et al*., 1994; 2003), for example, in the Danish Belt Area and Kattegat no normal females of the whelk *Neptúnea ántiqua* were found in a recent survey (Strand and Jacobsen, 2002).

3.5.2 Intersex

In periwinkles (e.g. *Littorina littorea*) and mud snails (*Hydrobia* sp.) the masculinizing effects of TBT are exerted in a slightly different manner than in the whelks and in these species the condition is termed *intersex* (Bauer *et al*., 1995). Intersex in the periwinkles is divided into four stages. A penis is developed in the female only in Stage 4 (which is very rarely observed). The periwinkles are far less sensitive to TBT than the whelks.

3.5.3 Effects in Populations

Many of the English populations of dogwhelks declined in numbers during the 1970s and 1980s and it is assumed that population sizes start to be affected when between 20 and 40% of the females have become sterile (Gibbs *et al*., 1991; Langston *et al*., 1990; Spence *et al*., 1990).

3.6 The Effect of PCBs in Seals and Humans

The populations of Baltic seals (grey (*Halichoerus grypus*) and ringed (*Phoca hispida*)) and Wadden Sea harbour seals (*Phoca vitulina*) showed marked decreases during the 1960s and 1970s, and, especially in the Baltic seals, a number of pathological lesions were seen (Olsson *et al*., 1992).

Several lines of evidence indicated that contamination with PCBs was responsible for these effects (Kihlstrom *et al*., 1992; Reijnders, 1986). Hydroxy metabolites of certain PCB isomers have a high affinity for binding to the thyroxin-transporting protein transthyretin in the blood and in an experiment where harbour seals were fed fish from the Atlantic (low PCBs) and Wadden Sea (high PCBs) both reproductive output and thyroxin levels were reduced in the seals fed the Wadden Sea fish (Brouwer *et al*., 1989). Although the thyroxin levels were definitely affected in the seals, PCBs possess multiple of modes of action and the altered thyroxin levels may not be the only cause of the reproductive problems.

In human populations with a high intake of PCBs from contaminated fish, effects on foetal brain development have been demonstrated (Jacobson *et al*., 1990); correct levels of thyroxin are important in the final development of brain function.

4 METHODS FOR DEMONSTRATION OF ENDOCRINE EFFECTS OF CHEMICALS

The recognition that synthetic chemicals have the potential to affect endocrine regulation, that is, by interacting with hormone receptors, has necessitated the development of test systems that can reveal this type of effect.

Both *in vitro* and *in vivo* test systems for the investigation of endocrine-disrupting effects exist and, since conclusions reached after use of the two types of systems are not necessarily identical, it is necessary to stress that there does not exist one and only one well-defined and commonly accepted method to demonstrate if a specific chemical has a specific endocrine-disrupting effect or not.

4.1 *In Vitro* Methods

4.1.1 Receptor Affinity

The ability of chemicals to bind to hormone receptors can be investigated in receptor-binding assays. The principle in such an assay is relatively simple: an organ with a suitably high concentration of the relevant receptor (e.g. the oestrogen receptor) is homogenized. Radioactively labelled oestrogen is added to the homogenate, the labelled oestrogen binds to the receptor, and equilibrium between free and bound labelled oestrogen is attained. If nonlabelled oestrogen is subsequently added to the homogenate, the nonradioactive oestrogen will compete with the labelled oestrogen to bind to the receptor and a new equilibrium between free and bound labelled oestrogen will be attained. In a similar way, the ability of various chemicals to outcompete the labelled oestrogen in binding to the receptor can be investigated.

In this way, the affinity of chemicals for hormone receptors may be determined for the receptors one might have an interest in (e.g. androgen or thyroxin). The method does not, however, reveal if a chemical with a high affinity for a given receptor functions as an agonist (mimics effect of the hormone) or an antagonist (inhibits the effect of the hormone by binding to and blocking the receptor) in the system.

4.1.2 Cell Cultures

The growth of some types of breast-cancer cells is stimulated by oestrogen, and this means that the oestrogenic effect of chemicals can be investigated by evaluating

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat093
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

their impact on the growth of such cell cultures. Several different cell lines have been developed for this purpose, but one of the most often utilized cell lines is the MCF-7 cell line (Soto *et al*., 1995).

The ability of chemicals to bind to and activate steroid receptors may be investigated in yeast cells into which the gene for the human oestrogen or androgen receptor has been inserted, together with a reporter gene. In the YES-assay (yeast estrogen inducible expression system) the *lac-Z* gene, coding for β-galactosidase, has been used as a reporter gene (Routledge and Sumpter, 1996). In the yeast cells used in the YAS assays, the androgen receptor has been genetically engineered into the yeast cells instead of the oestrogen receptor.

4.2 *In Vivo* Methods

4.2.1 The Uterotrophic Assay

In physiology, an oestrogen was originally defined as a compound that could cause growth of the uterus. It is therefore possible to investigate the potential oestrogenic effect of a chemical by dosing female mammals which do not themselves produce oestrogen (sexually immature animals or animals which have had their ovaries removed) with the chemical and register changes in the weight of the uterus after three days (Kanno *et al*., 2003a; 2003b).

4.2.2 The Hershberger Assay

The Hershberger assay is an androgen analogue to the uterotrophic essay. In this assay, the effect of chemicals on the weight of different organs (e.g. the prostate) associated with the sexual organs in castrated or juvenile male rats not themselves producing androgens, is determined (Owens *et al*., 2007; 2006).

4.2.3 Tests in Fish

4.2.3.1 Sexual Development

Sexual differentiation in fish is very sensitive to exposure to external sex hormones and in commonly used test species such as the zebrafish (*Danio rerio*), fathead minnow (*Pimephales promelas*) and Japanese medaka (*Oryzias latipes*), the phenotypic sex of the fish can be altered by exposure to oestrogens (feminization) and androgens (masculinization) (Holbech *et al*., 2006). Exposure to chemicals with oestrogenic, antioestrogenic, androgenic, antiandrogenic and aromatase-inhibiting effects will thus affect the sex ratio of the developing fish larvae, and this provides a sensitive system for revealing endocrine-disrupting effects which relate to the normal function of the sexual hormones.

4.2.3.2 Vitellogenin Induction

When female fish produce yolk proteins (vitellogenin) for incorporation into the eggs during preparation for reproduction, this takes place under hormonal control. Gonadotropins released from the pituitary induce the ovary to produce oestrogen, which is released into the blood. The liver responds to the oestrogen by inducing the synthesis of vitellogenin, which is released into the blood, taken up by the ovary and incorporated into the oocytes (Sumpter and Jobling, 1995).

Male and juvenile fish normally synthesize vitellogenin in very small amounts, but the synthesis can be induced by exposure to oestrogens or oestrogenic chemicals in food or water or by injection. Therefore, the concentration of vitellogenin in the blood of male or juvenile fish may be used as an excellent biomarker for oestrogenic effect, both in laboratory experiments and investigations in the field (Bjerregaard *et al*., 2008).

4.2.4 Tests for Reproductive Toxicity/Multigeneration Tests

For mammalian, avian and amphibian tests used in the risk assessment of chemicals, attempts are being made to improve and expand the scope of reproductive toxicity and multigeneration tests in order to reveal the potential endocrine-disrupting effects of chemicals. This may involve investigation of the male offspring of female rats (exposed to chemicals during pregnancy) for feminizing or demasculinizing effects. If the male rats are born with nipples or a smaller distance between the anal opening and the external genitalia (the anogenital distance) than normal, this is a sign that feminization or a demasculinization of the foetus has taken place. Thyroxin-disrupting effects of chemicals may be investigated in amphibians during metamorphosis.

4.3 *In Vivo* vs. *In Vitro* Methods

In vitro methods are generally more sensitive and less resource intensive than tests on live animals. Tests *in vivo*, however, have the advantage that the response of the intact, entire organism to the chemical is investigated.

For the inherent, endocrine-disrupting effect of a chemical to be exerted in an intact organism, the chemical must initially be taken up through the surface or via the gastrointestinal tract, be transported with the blood and thereafter reach the organ or the organs where the endocrine-disrupting effect is exerted.

In the blood, the chemicals may to a larger or smaller extent be bound to specific proteins that normally bind and transport sex hormones. If the chemicals are not bound to these proteins (e.g. in *in vitro* test systems) the amount that is available for uptake into the cells will be

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat093
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

increased and thereby the potential endocrine-disrupting effect will also be increased.

Higher organisms possess relatively efficient enzyme systems that metabolize or degrade xenobiotic chemicals. There are examples where a chemical never exerts its otherwise inherent endocrine-disrupting effect, because the organism exposed to the chemical degrades or metabolizes it before it reaches the organ where the effect might have been exerted.

Some chemicals do not possess endocrine-disrupting effects in their original form, but their metabolites do.

5 ENDOCRINE-DISRUPTING CHEMICALS

5.1 Definition

There are several definitions as to what one should understand by the term 'endocrine-disrupting chemical', but one of the most often cited definitions was made by the committee—the Endocrine Disrupter Screening and Testing Advisory Committee (EDSTAC)—that advices the US Congress on test methods in this area, and it is as follows: An exogenous substance that changes endocrine function and causes adverse effects at the level of the organism, its progeny, and/or (sub)populations of organisms.

5.2 General Modes of Action

The function of endocrine systems may be disturbed at several levels, since chemicals may affect:

1. Synthesis of hormones
2. Binding to transport proteins in the blood
3. Interaction with hormone receptors in the cells
4. Metabolism or degradation of hormones.

The interaction of chemicals with hormone receptors may lead to a mimicking of the function of the natural hormone (agonism) or an inhibition of this (antagonism); the latter may take place if the chemical binds to the receptor such that the binding of the natural hormone is blocked.

5.3 Natural Oestrogens

Endogenous hormones do not have endocrine-disrupting properties in the organism where they are produced if the hormones are functioning normally. However, natural oestrogens excreted from humans may pass sewage-treatment plants and natural oestrogens have been shown to leach from agricultural areas treated with liquid manure (Kjaer *et al*., 2007) and from livestock farms (Matthiessen *et al*., 2006). Thus, natural oestrogens may be found, for example, in freshwater and coastal environments, where they may exert endocrine-disrupting effects as previously described.

5.4 Synthetic Oestrogens and Androgens

A number of synthetic oestrogens have been developed in the pharmaceutical industry and the most relevant ones in this connection are DES and 17α-EE2, the latter being used in contraceptive pills. Both DES and EE2 have shown stronger oestrogenic effect in some test systems than the two most abundant natural oestrogens 17β-oestradiol and oestrone. Like the natural oestrogens, EE2 may cause feminization in the aquatic environment upon excretion from women after use in contraconception.

Trenbolone is a very potent synthetic androgen which is used as a growth promoter in, for example, US cattle. Trenbolone has been detected in the aquatic environment in the vicinity of cattle feedlots in USA (Durhan *et al*., 2006) and it has a strong masculinizing effect in fish (Ankley *et al*., 2003).

5.5 Phyto- and Myco-Oestrogens

Certain plants and fungi produce chemicals which have endocrine disrupting—for example, oestrogenic—effects. Some of these chemicals are found in relatively high concentrations in, for example, clover and soya.

Some of these chemicals have shown oestrogenic effects in *in vitro* as well as *in vivo* test systems. In some *in vitro* test systems the most potent of these chemicals show an oestrogenic potency approaching that of 17β-oestradiol.

5.6 Alkylphenols

Alkylphenolpolyethoxylates and alkylphenols are used in a wide variety of daily products such as detergents, cosmetics, paints and as plastic additives. The global production is approximately 300 000 tonnes per year; approximately 80% are nonylphenolpolyethoxylates and octylphenolpolyethoxylates constitute the majority of the remaining 20%.

A large fraction the alkylphenolpolyethoxylates used ends in up wastewater. Nonylphenol is degraded relatively slowly in the environment. The degradation products of alkylphenolpolyethoxylates have been shown

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat093
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to be oestrogenic in *in vitro* test systems (Routledge and Sumpter, 1996; Soto *et al*., 1991) and technical nonylphenol, 4-*t*-octylphenol, 4-*t*-pentylphenol, nonylphenol carboxylic acid and nonylphenoldiethoxylate have proved to be oestrogenic in *in vivo* experiments. Alkylphenols with branched alkyl chains are generally far more oestrogenic than alkylphenols with unbranched alkyl groups; this is true in both *in vitro* (Routledge and Sumpter, 1996) and *in vivo* (Pedersen *et al*., 1999) test systems. 4-*t*-Octylphenol is the most oestrogenic of the alkylphenols and the potency is approximately 2000–10 000 times lower than that of 17β-oestradiol (Routledge and Sumpter, 1996).

In short-term experiments with adult male fish, the threshold for induction of vitellogenin by the most potent alkylphenols is in the range 5–20 $\mu g\,l^{-1}$ (Jobling *et al*., 1996). In the uterotrophic assay it takes a dose of approximately 100 $mg\,kg^{-1}\,day^{-1}$ of the most potent of the alkylphenols to elicit an oestrogenic response (Laws *et al*., 2000); vitellogenin synthesis is induced in rainbow trout with a dose of 30 $mg\,kg^{-1}$ in the food every second day (Pedersen *et al*., 2003).

Alkylphenols affect the sexual development in fish that have been exposed to the chemicals in the laboratory during the period where sexual differentiation takes place. Exposure of medaka, *Oryzias latipes*, to 100 μg nonylphenol l^{-1} from hatching until the age of three months caused a feminization of the male fish, which developed a female sex organ next to the testicles (Gray and Metcalfe, 1997). In similar experiments with carps it has, likewise, been possible to feminize genetic males by exposing them to 4-*t*-pentylphenol (Gimeno *et al*., 1996).

In certain instances nonylphenol concentrations have been measured in the aquatic environment that are higher than the concentrations needed to feminize male fish in laboratory experiments. In some rivers in England (Sheahan *et al*., 2002), the oestrogenic effect of the river water is attributed to the presence of nonylphenol concentrations as high as 180 $\mu g\,l^{-1}$.

5.7 Bisphenol A

The world production of bisphenol A ranges between 0.5 and 1 million tonnes per year. More than 99% of the production is used to manufacture polycarbonate, epoxy and fire retardants.

The oestrogenic effect of bisphenol A has been demonstrated in *in vitro* as well as *in vivo* (Dodds and Lawson, 1936) test systems.

Bisphenol A exerts approximately the same potency as 4-*t*-octylphenol in *in vitro* test systems, while the chemical appears less potent than the most active alkylphenols in *in vivo* test systems. When rainbow trout are exposed to bisphenol A in the water it takes a concentration of approximately 100 $\mu g\,l^{-1}$ before the oestrogenic response can be detected and in the uterotrophic assay it takes a dose of approximately 100 $mg\,kg^{-1}\,day^{-1}$ to provoke an oestrogenic response; when rainbow trout are fed 30 $mg\,kg^{-1}$ every second day, vitellogenin synthesis is induced.

5.7.1 Discussion of the Low Dose Effects of Bisphenol A

Whereas there is no disagreement that bisphenol A is oestrogenic, a controversy exists concerning the exposure levels required to affect sexual development in mammals (Richter *et al*., 2007) and reproduction in the freshwater snail, *Marisa cornuarietis* (Forbes *et al*., 2008; Oehlmann *et al*., 2006).

Although the details of this controversy are too comprehensive to describe in this chapter, the discussion is important because the relevance of looking for potential effects of bisphenol A in humans increases dramatically if effective doses in experimental animals decrease from the $mg\,kg^{-1}\,day^{-1}$ range to the $\mu g\,kg^{-1}\,day^{-1}$ range.

5.8 Parabens

Parabens have been used as preservatives in cosmetics and food for 75 years (Elder, 1984). The daily intake in the middle of the 1980s in an American overview was estimated to be 1–16 $mg\,kg^{-1}$ in infants and 4–6 $mg\,kg^{-1}$ in the general population (Elder, 1984).

Methyl-, ethyl-, propyl- and butylparaben all exhibit oestrogenic activity in *in vitro* test systems such that the oestrogenic effect increases with the number of carbon atoms in the alkyl chain (Routledge *et al*., 1998). Butylparaben shows oestrogenic effect in the uterotrophic assay in rats when injected subcutaneously, but not when given in the food (Routledge *et al*., 1998). Methylparaben had no effect in the uterotrophic assay and this is also true for propylparaben tested at 100 $mg\,kg^{-1}$ (Hossaini *et al*., 2000).

Propyl- and butylparaben administered orally to juvenile rats at doses close to the ADI value (10 $mg\,kg^{-1}$ per day for butylparaben) were reported to reduce semen production as well testosterone concentrations (Oishi, 2001; 2002b) and similar effects were seen for butylparaben in mice (Oishi, 2002a). None of the results on methyl and butylparaben could be confirmed in rats by Hoberman *et al*. (2008). Kang *et al*. (2002) reported that the offspring of butylparaben-exposed pregnant rats showed decreased sperm numbers and sperm motility, but a similar experiment (Taxvig *et al*., 2008) did not show clear endocrine-disrupting effects *in vivo*, although the *in vitro* results might suggest that butylparaben may inhibit steroid synthesis by inhibiting the rate-limiting transport of cholesterol across the mitochondrial membrane.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat093
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Injected ethyl-, propyl- and butylparaben have oestrogenic effects in rainbow trout (Pedersen *et al*., 2000) and both propyl- (Bjerregaard *et al*., 2003) and butylparaben (Alslev *et al*., 2005) show oestrogenic effects after exposure via food and water; also in brown trout *Salmo trutta*, exposure to butylparaben elicits an oestrogenic response (Bjerregaard *et al*., 2008) with an EC_{50} (half maximal effective concentration) value for vitellogenin induction of $68\,\mu g\,l^{-1}$.

The parabens are assumed to be degraded relatively quickly in the skin and the gastrointestinal tract in mammals (Elder, 1984), so it has been considered unlikely that the chemicals should exert their inherent oestrogenic effect by ordinary use in food and cosmetics. In a recent experiment in which the maximally allowed amount of butylparaben was applied to the skin of volunteers, approximately 0.8% of the dose was absorbed into the blood and peak concentrations of $135\,\mu g\,l^{-1}$ were seen three hours after the administration (Janjua *et al*., 2008).

5.9 Chemical UV Filters

Compounds which absorb light in the ultraviolet region may be used as so-called chemical UV filters. These chemicals are used in sun screens and in a number of products for which an increased resistance to the effects of light is wanted, for example certain types of plastic materials.

Some UV filters have endocrine-disrupting effects (reviewed by Schlumpf *et al*., 2008). Of the UV filters tested, 3-benzylidene camphor has the strongest oestrogenic effect (Holbech *et al*., 2002).

5.10 Chlorinated Insecticides

A number of chlorinated insecticides have been suspected of exerting oestrogenic effects. Most of these insecticides were used in the Western world from around the 1950s until the use of most was prohibited during the 1960s and 1970s because of their adverse environmental effects. Some of these chemicals are, however, so persistent that this previous dispersal in nature still gives rise to exposure of humans and animals today. The continued use of some of the chemicals in developing countries likewise leads to global dispersal.

In *in vitro* test systems, *o*, *p*-DDT, an impurity in the commercial product, *p*,*p*-DDT, *o*, *p*-DDE (dichlorodiphenyl dichloroethylene), *o*, *p*-DDD (dichlorodiphenyl dichloroethane), *p*,*p*-DDD, methoxychlor, dieldrin, endosulfan, toxafene and chlordecone have shown oestrogenic effects (reviewed by Tyler *et al*., 1998).

In different types of *in vivo* test systems, *o*, *p*-DDT, *o*, *p*-DDE, methoxychlor, dieldrin, toxafene, chlordecone and γ-hexachlorcyclohexane (lindane) have shown oestrogenic effects.

Some of the examples of endocrine-disturbing effects that have been observed in nature (e.g. feminization of birds, demasculinization of alligators) are attributed to the effect of chlorinated insecticides or metabolites thereof—although without total elucidation of the mechanisms underlying the effects.

5.11 Phthalates

Phthalates are used as additives in plastics and for many other purposes and are some of the pollutants that appear in the highest concentrations in the surroundings. Of the approximately 35 phthalates that are produced commercially, nine have shown—albeit weak—oestrogenic activity in *in vitro* test systems (Harris *et al*., 1997), but the major concern is their antiandrogenic effect (Foster, 2006; Foster *et al*., 2001).

The effect doses for the antiandrogenic effects of some of the phthalates have gradually decreased over recent years and it has now been shown that the male offspring of rats treated with approximately $130\,mg\,kg^{-1}\,d^{-1}$ of the most potent phthalates during pregnancy have their sexual development affected (Howdeshell *et al*., 2008b).

Monoester metabolites of some phthalates have been demonstrated in the blood, breast milk and amniotic fluid of humans at concentrations that are not insignificant and symptoms of demasculinization (reduced anogenital distance) in newborn boys have been associated with the concentrations of phthalates in the blood of their mothers during pregnancy (Swan *et al*., 2005).

5.12 Nitrate and Nitrite

In the organism, nitrate and nitrite may be reduced to nitric oxide (NO), which acts as a signalling compound. One of the effects of NO is that it reduces the synthesis of steroids.

In rats that were exposed to nitrate and nitrite in their drinking water (at concentrations in the same range as the drinking-water limit in many countries), the testosterone concentrations in the blood decreased to approximately half of the concentration of the control group during four weeks (Panesar and Chan, 2000). In Japanese medaka, *Oryzias latipes,* the breeding success decreases when the fish are exposed to concentrations above approximately $130\,mg$ nitrate l^{-1} (Shimura *et al*., 2002).

5.13 Polychlorinated Biphenyls (PCBs)

PCBs were produced mainly during the period from World War II until around 1975 and in a total amount of approximately 1.2 million tonnes. The chemicals were used for many purposes (in transformers, capacitors, as plasticizers, in hydraulic systems, etc.) and because of their persistence, only a minor fraction of the produced amount has been degraded.

Commercial PCB products theoretically consist of 209 different specific, chemical compounds. The individual PCB isomers have different toxicological properties and among the PCB isomers and their metabolites, oestrogenic, antioestrogenic, androgenic and antiandrogenic effects have been shown.

Hydroxylated metabolites of specific PCB isomers bind to the oestrogen receptor and treatment of tortoise eggs with 2′,4′,6′-trichloro-4-biphenylol causes complete feminization of the developing foetuses (Bergeron *et al*., 1994). Other types of hydroxy metabolites interfere with binding and transport of thyroxin in the blood (Lans *et al*., 1993).

5.14 Chlorinated Dioxins

In everyday language the term 'dioxins' covers two different groups of chlorinated chemicals with 210 specific compounds. The dioxins have never been produced for any industrial purpose, but they are formed as by-products in different processes (a number of chemical syntheses, incineration, chlorine bleaching). Certain of the dioxins have a remarkably high toxicity.

The dioxins may at very low doses (as low as $0.1\,\mu g\,kg^{-1}\ day^{-1}$) harm the reproduction in experimental animals. Male offspring of female rats treated during pregnancy show effects consistent with the oestrogen hypothesis (lower sperm counts, reduced fertility, etc.).

5.15 Tributyltin (TBT)

5.15.1 TBT as an Antifouling Agent

The use of organic tin compounds as antifouling ingredients in ship paint was initiated in the 1960s (Fent, 1996). The TBT is formulated in the ship's paint in a way such that a gradual liberation to the water phase takes place. In seawater, TBT is relatively quickly degraded by bacteria and algae to mono- and dibutyltin (Lee *et al*., 1989). The half-life for TBT in seawater is in the range of days to weeks, while the half-life in sediments may be up to six months or longer (Seligman *et al*., 1986). Molluscs, such as snails and mussels take up TBT from the water and, since they have a low capacity to metabolize TBT, they may concentrate the compound to concentration factors as high as 50 000–100 000; TBT is lost from dog whelks *Nucella lapillus* with a half-life of 50–100 days (Bryan *et al*., 1987).

Higher organisms metabolize TBT by hydroxylating and subsequently eliminating the butyl groups one by one, such that the TBT is metabolized to dibutyltin and further to monobutyltin and inorganic tin that are all less toxic than TBT (Lee, 1991).

5.15.2 The Mechanism of Action for TBT

Several mechanisms of action—that do not mutually exclude each other—have been suggested for TBT's interference with sexual development in gastropods.

It has been proposed that the mechanism of action for TBT is related to the aromatase-inhibiting effect of the chemical (Bettin *et al*., 1996). There are also indications that exposure to TBT (albeit at fairly high exposure concentrations) reduces the excretion of testosterone by inhibiting sulfate conjugation of testosterone (Ronis and Mason, 1996). Regulation of free testosterone levels may in certain invertebrates be associated with the formation of testosterone–fatty-acid esters (Gooding and LeBlanc, 2001) and TBT affects the equilibrium between free and bound testosterone (Janer *et al*., 2005; Santos *et al*., 2005). TBT accumulates in gastropods to especially high concentrations in the nervous system (Bryan *et al*., 1993) and it has been proposed that TBT exerts its effect via interaction with the formation of neuropeptides involved in regulation of steroid synthesis (Oberdörster and Clellan-Green, 2000; 2002; Oberdörster *et al*., 1998; 2005).

5.16 Presently Used Pesticides

A fairly large number of presently used pesticides show endocrine activity in *in vitro* (Andersen *et al*., 2002) and/or *in vivo* test systems and space restraints only allow the description of the most important ones.

5.16.1 Fungicides

The fungicides vinclozolin and procymidone or their metabolites show antiandrogenic effects (Gray *et al*., 1999; Nellemann *et al*., 2003) in rats and fenarimol shows antiandrogenic (Vinggaard *et al*., 2005), as well as oestrogenic effects (Andersen *et al*., 2006). The imidazol fungicide prochloraz shows endocrine-disrupting activity by several mechanisms. In male rat foetuses, testosterone production is reduced (leading to a demasculinization) (Laier *et al*., 2006), whereas the sex ratio in prochloraz-exposed zebra fish larvae is shifted towards males (Kinnberg *et al*., 2007), probably because of the aromatase-inhibiting effect of the chemical.

5.16.2 Herbicides

Atrazine, which is widely used, especially in the USA has been reported to be an aromatase promoter that may demasculinize the clawed frog, *Xenopus laevis* (Hayes *et al*., 2002), with exposure to low concentrations, and feminize male American leopard frogs, *Rana pipiens* (Hayes *et al*., 2003). No such effects could, however, be demonstrated by Du Preez *et al*. (2008) in *X. laevis* exposed to atrazine.

The phenyl urea herbicide, linuron, shows antiandrogenic effects in rats (Gray *et al*., 1999).

5.16.3 Insecticides

A number of commonly used pyrethroids such as permethrin, fenvalerate, cypermethrin and deltamethrin show inherent oestrogenic activity *in vitro* (Andersen *et al*., 2002), and some of the pyrethroids show antiandrogenic effect *in vitro* (Tyler *et al*., 2000). Some of the pyrethroids have shown oestrogenic effects in some *in vivo* assays in rats (Kim *et al*., 2005) carried out, but not in others (Kunimatsu *et al*., 2002; Yamada *et al*., 2003).

Assessing Impacts of Environmental Contaminants on Wildlife

Joseph P. Sullivan and Elwood F. Hill

CONTENTS

1 INTRODUCTION

Assessing the impact of contaminants on wildlife is complex because factors that influence exposure and toxicity might vary substantially among and within habitat types. Even the prescribed application of a pesticide might evoke different degrees of risk, depending on the product formulation, how, when and where it is used, and the behaviour and sensitivity of species that frequent the treated zone and its drift perimeter. Thus, evaluation of even an obvious source of exposure might be difficult unless accompanied by immediate mortality. Then, when considering the confounding influences of pesticidal interactions, uncertainty associated with mixtures of chemicals from industrial and domestic sources, and presence of natural toxics and toxins, a spectrum of studies is needed to assess impacts of contamination on wildlife.

Historically, wildlife toxicology has focussed primarily on those species, mostly birds and a few mammals, of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

aesthetic or economic interest to man. Birds have been favoured as the principal model for toxicological research because they are abundant, highly visible, have diverse behaviours and habitat associations, and many species can be studied both in the laboratory and in their natural habitats (Heinz *et al*., 1979). More recently, wildlife toxicology has expanded to include reptiles, amphibians and terrestrial invertebrates.

Wildlife toxicology has been described as the integration of three principal strategies for understanding xenobiotic effects on wildlife (Hoffman *et al*., 1990). The first strategy is chemical screening, where a variety of toxicological tests is performed in the laboratory with what are thought to be representative species. The purpose of screening is to predict likely effects in natural populations by identifying those chemicals toxic to wildlife. End points of these tests may include lethality, reproductive impairment, behavioural aberrations, developmental changes or changes in physiological indicators of health crucial to reproduction and survival.

The second strategy is the controlled field or mesocosm study. The purpose is to confine the test subjects in a simulated natural environment and expose them to real-world scenarios. The design and end points of such studies may be widely variable depending on the chemical, its uses, potential routes of exposure and the wildlife species of concern. This type of study, as well as full-scale field trials in which the subjects are free-ranging, have been occasionally required by the United States Environmental Protection Agency (US EPA) for pesticide registration, but have lost favour because of cost and limitation on extrapolation to other sites (Tiebout and Brugger, 1995; Matz *et al*., 1998; Hoffman *et al*., 2002).

The third strategy is field ecology. Natural populations are studied *in situ* in environments believed to be polluted. These studies focus on species diversity and population dynamics in critical habitats as related to residue burdens in the species of interest and various components of the ecosystem. Ecological studies are extremely complex, costly and often too specific for extensive use in risk assessment.

The above strategies provide a comprehensive evaluation of chemical risk to wildlife, but each strategy has a functional role and rarely would all three be used in a cohesive series of studies. For example, if an area is known to be contaminated, detailed residue and ecological studies (strategy 3) may be initiated to determine whether a problem exists. Carefully designed laboratory experiments would then be conducted to validate putative cause–effect relationships between the contaminant and the susceptible species or a close surrogate. Laboratory studies may borrow from standardized tests (Strategy 1) or be specially designed to address specific field observations.

In contrast to existing contamination, chemicals are constantly under review for release into the environment as pesticides or other anthropogenic by-products. Chemical screening (Strategy 1) is then initiated for protection of wildlife resources. In the USA, the US EPA provides this regulatory function. Specific tests of birds, mammals and beneficial insects and other invertebrates are required under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) and the Toxic Substance Control Act (TSCA). Most industrialized countries have similar regulations. Accepted protocols and model species have been reviewed, updated and new tests added in national and international conferences on wildlife toxicology by the US EPA, the Society of Environmental Toxicology and Chemistry (SETAC), the American Society for Testing and Materials (ASTM) and the Organisation for Economic Cooperation and Development (OECD). A framework for avian effects assessment was developed by an expert panel at a SETAC workshop (Hart *et al*., 2001).

Standardized screening tests are especially useful for regulatory purposes because they are easily interpreted and cost effective. However, other than the single-dose LD_{50} test, none of the existing protocols provide an equal basis of comparison for all chemicals and uses. In contrast to biomedical studies, where a variety of mammalian models are used to represent different physiological systems, wildlife studies may test the actual species of interest or a close surrogate. In practice, test species are usually limited to quail and ducks that can be easily reared in captivity and subjected to a wide variety of studies from single-dose through multiple-generation exposures. Impacts on wild mammals are often extrapolated from standard mammalian laboratory tests, but no standard amphibians, reptiles or passerine bird species are routinely tested.

This chapter provides an overview of wildlife toxicology and risk assessment as a component of the broader disciplines of ecotoxicology and environmental toxicology. The focus is on anthropogenic chemicals and avian wildlife with comparison with laboratory animals and other vertebrates where appropriate. Test methods and factors affecting interpretation, predictive toxicology and ecological toxicology are discussed.

2 ENVIRONMENTAL AND ECOLOGICAL TOXICOLOGY

Environmental toxicology has been comprehensively defined as the study of the effects of toxic substances occurring in both natural and man-made environments, leading to an objective assessment of risks resulting from the presence of such substances (Duffus, 1980). *The focus of this risk assessment is protection of human health.*

Ecological toxicology, or ecotoxicology, as first defined, is essentially synonymous with environmental toxicology except that *the focus is on natural systems*

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and wild animals (Truhaut, 1975). More recently, ecotoxicology has been described as the science of predicting effects of potentially toxic agents on natural ecosystems and nontarget species, but exclusive of industrial and agricultural toxicology. This distinction is losing favour because human society and its artefacts are part of natural systems, not apart from them (Hoffman *et al*., 2002).

Wildlife toxicology, as used herein, follows this more inclusive philosophy because most sources of noninfectious wildlife poisoning are of anthropogenic origin. Although crops under cultivation and point-source industries are not usually prime wildlife habitats, they may be attractive for hydration and foraging. Also, surrounding ecosystems and wildlife populations are subject to effects from chemical movement.

3 WILDLIFE SUSCEPTIBILITY TO CHEMICAL CONTAMINATION

Wildlife may be affected directly by contact with a toxic chemical or indirectly through chemical-induced changes in the invertebrate food base (insecticides, etc.) or habitat quality (e.g. industrial emissions, herbicides). Effects of chemical exposure range from acute incidents of lethal poisoning to subtle physiological dysfunctions, behavioural aberrations and reproductive impairment. Reduction of forage may induce metabolic stress that could increase sensitivity to chemical exposure, reduce reproductive success or force emigration (Grue *et al*., 1983).

Wildlife species differ remarkably in their physiology and sensitivity to xenobiotics, but their *feeding habits seem to be the overriding determinant of susceptibility to chemical hazard.* For example, the organophosphorus insecticide diazinon is extremely toxic to some birds (LD_{50}, $<10\,mg\,(kg\ body\ weight)^{-1}$) and not so toxic to mammals (LD_{50}, $>100\,mg\,(kg\ body\ weight)^{-1}$) or amphibians ($LD_{50}$, $>1000\,mg\,(kg\ body\ weight)^{-1}$) (Gaines, 1969; Hudson *et al*., 1984). When diazinon was applied, according to its label, on turf grasses, occasional incidents of mortality were reported for insectivorous birds and small mammals. Such sporadic lethality has also been observed for birds exposed to other anticholinesterase insecticides. However, when diazinon was applied to turf that was attractive to waterfowl, such as the Canada goose (*Branta canadensis*) and American widgeon (*Anas americana*), large-scale episodes of mortality were regularly documented. This unique risk to grazing waterfowl resulted in the US EPA issuing a cancellation notice for the use of diazinon products on golf courses and sod (turf) farms (US EPA, 1986). The wildlife toxicology of anticholinesterase insecticides has been reviewed extensively (Smith, 1987; Greig-Smith *et al*., 1992; Hill, 1992; 1995; 2002; Fairbrother, 1996; Eisler, 2000).

In contrast to the comparatively labile and acutely toxic poisons such as diazinon and other organophosphorus and carbamate insecticides, many chlorinated hydrocarbons such as dichlorodiphenyltrichloroethane (DDT) are stable in the natural environment and are not as acutely toxic to wildlife (Gaines, 1960; 1969; Hudson *et al*., 1984). They do, however, biomagnify in wildlife food chains and accumulate in fat stores of vertebrates. A substantial body burden of chlorinated hydrocarbon residues and metabolites may be tolerated without overt evidence of toxicity, but such residues have been shown experimentally to affect avian reproduction (Heath *et al*., 1969; Wiemeyer and Porter, 1970). The main effect was interference with calcium metabolism in the shell gland, resulting in eggshell thinning and reduced hatchability (Lundholm, 1987). Although many experiments over the past 30 years have confirmed that a variety of chlorinated hydrocarbons may thin eggshells to some degree, dichlorodiphenylethylene (DDE), a stabile metabolite of DDT, is the most potent eggshell thinning substance.

Eggshell thinning in a natural population was first detected in peregrine falcon (*Falco peregrinus*) eggs in Great Britain during the mid-1960s, and was associated with depressed reproduction and population declines in the region (Ratcliffe, 1967). Many North American species also proved to be susceptible to effects of DDE on reproduction and experienced widespread population declines (Blus, 1995; 2002). The most affected species foraged almost exclusively on fish and included the brown pelican (*Pelecanus occidentalis*), double-crested cormorant (*Phalacrocorax auritus*), osprey (*Pandion haliaetus*) and bald eagle (*Haliaeetus leucocephalus*). In contrast, other fish-eating species such as the great blue heron (*Ardea herodias*) were comparatively tolerant of chlorinated hydrocarbons.

Cancellation, in many countries, of the more persistent chlorinated hydrocarbons such as DDT, aldrin, endrin, dieldrin and heptachlor has resulted in reduction of their residues in natural systems through time and recovery of sensitive avian species (Blus, 1995; 2002). A few chlorinated hydrocarbons, such as methoxychlor and dicofol, were not included in the cancellation orders and are considered to be of low risk in the environment.

The emphasis on reproductive toxicity in birds is not meant to diminish the acute risk of some chlorinated hydrocarbons. Although only a few chlorinated hydrocarbons are extremely toxic (LD_{50}, $<10\,mg\,(kg\ body\ weight)^{-1}$) to birds and mammals, most are readily accumulated in the lipid stores of vertebrates and under conditions of energy stress (e.g. food deprivation, migration) may be translocated in lethal concentrations (LCs) to the brain. The wildlife toxicology of chlorinated hydrocarbons has been comprehensively reviewed (Blus, 1995; 1996; Keith, 1996; Eisler, 2000; Walker, 2001).

Sensitivity of wildlife to toxic chemicals is a product of biochemical, metabolic and excretory processes. The efficiency of these processes is influenced at the organismic level by the rate, route and duration of exposure. Foremost among the physiological processes that regulate toxicity is the enzymatic mono-oxygenase system of the vertebrate liver, whose function is to increase the rate of production of water-soluble metabolites and conjugates that can be rapidly excreted. This is primarily a detoxicating system, but it can also produce metabolites that are more toxic than the parent substance. An example of mono-oxygenase toxication is the oxidative desulfuration step for maximum anticholinesterase potency of thiophosphorus insecticides such as parathion and diazinon. Mono-oxygenase metabolism of xenobiotics differs widely among species within and between taxons and generally decreases among vertebrates in the following order: mammals > birds > fish (Walker, 1978; 1980; Moriarty and Walker, 1987). Small vertebrates usually have a higher rate of mono-oxygenase metabolism than larger species, and the rate is higher in herbivores and omnivores than in carnivores (Ronis and Walker, 1989).

Other determinants of xenobiotic toxicity that vary among wildlife species include gender, age, reproductive status, genetic lineage, nutritional status and both endogenous and exogenous stressors. Except for age, the influences of these factors on wildlife responses to toxic exposure have not been thoroughly evaluated.

4 INTERSPECIES VARIABILITY

One of the challenges for assessing impacts of contaminants, particularly for site-specific assessments, is the difficulty of extrapolating among species. Often many of the species of interest on a site or of concern lack toxicity data for the contaminants of potential concern. This is particularly true for reptile species. Extrapolation among species and toxicity end points has remained one of the key areas of uncertainty in ecological risk assessment (Raimondo *et al*., 2007). A common solution when the comparative sensitivity of different species is unknown, or to protect the unknown most sensitive species, is to multiply the lowest known toxicity end point by some safety or uncertainty factor, such as a factor of 0.1 or 0.01. This approach has been criticized for introducing an unquantifiable amount of uncertainty into an assessment (Luttik *et al*., 2005). The practice of using uncertainty factors is limited by lack of consensus among scientists, regulators and practitioners about magnitudes, types and conceptual underpinnings of the uncertainty methodology (Duke and Taggart, 2000).

An important factor involved in extrapolating from one species to another is body size. Mineau *et al*. (1996) determined that a scaling factor of up to 1.55, based on body weight, was appropriate for birds when extrapolating from one species to another for a group of pesticides, mostly cholinesterase-inhibiting insecticides. Sample and Arenal (1999) found that body weight accounted for most of the variability in toxicity results among species, with scaling factors of 1.2 and 0.94 appropriate for birds and mammals, respectively, across many chemical groups.

Taxonomic relationships can be used to predict responses among Classes of vertebrate wildlife (e.g. fish, birds and mammals), but within a Class, sensitivities do not necessarily follow taxonomic line (e.g. within or across Families and Genera). Basua *et al*. (2005) investigated mercury inhibition on muscarine acetylcholine-receptor binding in the brains of five mammalian species: humans, two rodents and two mustelids. Species sensitivities, irrespective of mercury type and brain region, can be ranked from most to least sensitive: river otter (*Lutra canadensis*) > rat (*Rattus* sp.) > mink (*Mustela vison*) > mouse (*Mus* sp.) > humans.

In contrast to the taxonomic and body-weight scaling factors that have been shown to work to extrapolate acute toxicity data among species, these factors do not work well for chronic or reproductive toxicity responses (Luttik *et al*., 2005). These authors indicate the best models for extrapolation among species for chronic toxicity are those previously proposed by Luttik and Aldenberg (1995, 1997) and Luttik *et al*. (2005). The procedures proposed that safety factors of the one-sided 95% confidence limit of the hazardous dose for 5% of the species (HD_5) based on the pooled natural log (ln) standard deviations be used when only one, two and three LD_{50}s are available for a particular chemical. Otherwise, they propose to use the more conservative method (95% confidence limit) for the extrapolation, because the pooled ln standard deviation that is used is not a worst case value. Hence the probability to overpredict $\ln(HD_5)$ should be small (5%) (Luttik and Aldenberg, 1997).

Variations in diet impact how species are exposed to contaminants. Among birds, the types and numbers of seeds eaten can vary considerably (Prosser and Hart, 2005). In a study that treated seeds with the avicide 3-chloro-*p*-toluidine hydrochloride (CPTH), the model developed predicted a higher percentage of mortality for mourning doves (*Zenaida macroura*) than red-winged blackbirds (*Agelaius phoeniceus*), despite red-winged blackbirds being slightly more sensitive to CPTH. The reason more doves were predicted to be killed was because doves ate more of the treated rice than did the blackbirds (Johnston *et al*., 2005). Diet is also a driving factor in determining the normal activity levels of detoxifying enzymes. Those species that routinely eat vegetation containing natural defensive compounds tend to have greater enzyme activities than predatory species such as piscivores and most raptors (Vangilder and Drawer, 1983).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094

Many insecticides inhibit cholinesterase as their mode of action against insects. This same mode of action results in the toxic impacts to wildlife species. Different species have shown varying sensitivities to cholinesterase-specific anticholinesterases. For example, fish were found to show the least sensitivity of brain cholinesterase to monocrotophos. The differences in sensitivities of brain cholinesterase to monocrotophos were thought to be the underlying cause of the differences in toxicity among rats, pigeons and fish (Qadri *et al*., 1994).

The inherent ability of different species to detoxify contaminants is related to their P450 or mono-oxygenase enzymes, among others. The specific isozymes present can enhance or diminish the ability of a species to respond to contaminants (Andersson *et al*., 2000). A species diet is involved with the suite of enzymes present capable of detoxifying or metabolizing contaminants. Fossi *et al*. (1995) looked at seven species of birds and found that the more omnivorous the diet, the greater the induction potential of their mixed function oxidases. They concluded that birds with more omnivorous diets could better survive in highly polluted environments. In situations where metabolism of a contaminant, particularly pesticides, leads to greater toxicity, such species could be at greater risk by enhancing a chemical's toxic potency through its metabolites. Such generalizations will not hold for all species for all chemicals. Hill (1971) found that blue jays (*Cyanocitta cristata*) were more sensitive to DDT than less omnivorous species.

Interspecies correlation estimation (ICE) models are log-linear least-square regression models that describe the relationship between the acute toxicity (LD_{50}; mg (kg body weight)$^{-1}$) of a range of chemicals tested in two species (Raimondo *et al*., 2007). Interspecies extrapolation models use surrogate species, often standard test organisms, to estimate toxicity of a chemical to wildlife species for which no toxicity data exists. In North America, tests are usually conducted on mallard (*Anas platyrhynchos*) and northern bobwhite (*Colinus virginianus*), whereas European countries often use Japanese quail (*Coturnix japonica*) as their standard test species. These standard test species were frequently found to be adequate surrogate species for other wildlife species. Results of these analyses provide user guidance for use and application of ICE models in wildlife risk assessment (Raimondo *et al*., 2007). A web-based ICE tool is available from the US EPA at *http://www.epa.gov/ceampubl/fchain/webice/index.htm*. Since there is an overall lack of toxicity data for reptile and amphibian species, the terrestrial ICE models are generally restricted to birds and mammals.

Shore *et al*. (2005) provide a comprehensive review of how to incorporate species-specific breeding-season information to improve the assessment of long-term exposure to pesticides. The authors focus on how to use the data routinely collected as part of the pesticide registration process to refine a deterministic risk assessment. Rather than using standardized hypothetical species, available ecological data for indicator species are incorporated into the assessment along with existing registration data to refine the deterministic assessment. This deterministic approach produces more realistic assessments of long-term risk for birds and mammals.

5 ACUTE TOXICOLOGY

The mainstay of wildlife toxicology for more than 50 years has been experimentation with relevant species in captivity. The advantage was in testing the actual species of interest or a closely related surrogate and tailoring the experiment to evaluate a specific problem. Therefore, the wildlife toxicologist tends to rely less on standardized protocols than does the biomedical toxicologist. However, wildlife toxicology has evolved several standardized protocols for chemical screening that are used in North America, Europe and elsewhere for regulation of pesticides and other toxic substances (US EPA, 1982; OECD, 1996). These protocols include avian and mammalian single-dose acute oral toxicity tests, a five-day avian dietary toxicity test and a single-generation avian reproduction test. These and similar studies have been reviewed and refined by ASTM and OECD panels. Consensus recommendations on the choices and suitability of these tests were developed by a panel of international experts (Hart *et al*., 2001).

This section is a review of acute chemical screening methods in which wildlife species are routinely used for predictive toxicology, and factors of interpretation that may influence risk assessment. The purpose of these basic tests is to protect natural populations from chemical risk of anthropogenic origin. Depending on the expected fate and toxic action of the chemical, some combination of these tests may be the only wildlife studies considered in a regulatory risk assessment. The principal end points of the basic screening tests are lethality or reproductive impairment, with ancillary observations of behaviour and gross pathology. Histological and biochemical indicators of toxicity are not usually included in chemical screening studies, but are essential for evaluation of wildlife effects from environmental pollution and incidents of mortality.

Acute toxicity tests are designed to determine exposures that cause death or other definitive end points under a prescribed protocol. Treatment levels are based on the animal's response to the test substance rather than the substance's practical environmental residues. A steep slope has the obvious risk of proportionally little chemical required to increase effect. In contrast, a shallow slope would seem inherently safer because it takes proportionally more chemical to increase effect. Generally, this is true, but it is these substances that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

may produce toxicity at very low levels, for example, below one-tenth of the LD_{50} or LC_{50}. Carbofuran is an example of a pesticide that yields a shallow slope in both acute (Hill and Camardese, 1984) and subacute (Hill and Camardese, 1986) tests with birds and has been responsible for many unexpected incidents of wildlife mortality (US EPA, 1989; Mineau, 1993).

Acute toxicity tests provide the basis for many kinds of comparisons once statistically reliable dose–response curves have been determined for a substance with several taxonomically diverse species. For example, the relative toxicity of the substance may be compared with additional species or substances by carefully designed tests of only a few animals (Link *et al*., 1996) or by use of approximate methods for determination of the median effective dose or concentration (Gad and Chengelis, 1988). When only the general order of toxicity is desired, an approximate test of lethality should be considered (Schafer *et al*., 1973; 1983; Hudson *et al*., 1984; Schafer and Bowles, 1985; Gad and Chengelis, 1988). Such abbreviated or approximate tests are cost-effective and, of more importance, designed to reduce the number of animals that need to be tested for a statistically reliable comparison.

Approximate statistical methods were used to test about 75 species of wild birds and mammals and over 1000 chemicals between the mid-1950s and early 1980s at the US Fish and Wildlife Service's Denver Wildlife Research Center (Schafer, 1972; Hudson *et al*., 1984; Schafer and Bowles, 1985). The special value of these studies is that they were all conducted by the same techniques at one laboratory. The disadvantage is that the approximate test does not provide an estimate of the dose–response curve and therefore has limited value in risk assessment. These tests were of mostly wild-captured nonbreeding adults and remain the only toxicity statistic available for many chemicals with wildlife species.

5.1 Avian Single-Dose Acute Oral Toxicity Test

Two basic protocols have been derived for wildlife from standard bioassay techniques for preliminary evaluation of the acute or short-term lethal toxicity of pesticides and other environmentally active substances. The first is the single-dose acute oral toxicity test. This test is fundamental in evaluation of virtually all substances of suspected biological activity. The primary objective is to estimate the dose–response curve and its midpoint, the median lethal dosage or LD_{50} and its error with 95% confidence limits. The test, essentially the same as for laboratory animals, is based on administration of graded dosage of chemical in relation to body mass (i.e. $mg\,kg^{-1}$). It may be adapted to virtually any terrestrial wildlife species that can be managed in captivity. Once the statistical parameters and their associated errors have been properly determined, this test provides a means of quantifying chemical potency and comparing substances of different mechanisms and sites of action (Klaassen, 1986). The acute test also provides essential information on the course and appearance of toxicity from graded exposures that is needed for comparative diagnosis of poisoning and risk assessment (Hill and Camardese, 1984; Hudson *et al*., 1984). Too often, however, comparisons and interpretation of acute tests are focussed on the LD_{50}, exclusive of its statistical reliability and without reference to the slope of the dose–response curve or other supplemental observations that provide important clues about potential risk. The LD_{50} is a convenient index of toxicity, but its indiscriminate use can be misleading (Chan and Hayes, 1989; Hill, 1994).

The acute toxicity test of wildlife can be conducted on virtually any species that can be managed in captivity. The general procedure is to dose about 10 randomly selected overnight-fasted subjects at each of five geometrically arranged dosage levels spanning the expected 10–90% mortality levels. The standard protocol uses individually caged first-year adults of both sexes that have not yet gone through a breeding cycle. A detailed protocol for acute toxicity testing of wildlife for regulatory purposes in the USA is available (Bascietto, 1985a).

Many factors may influence the reliability of an acute test of lethality even under the rigid guidelines that have evolved for testing laboratory animals. Factors may include, but are not limited to, species, strain, age, weight, gender, husbandry practises, environmental conditions, diet, nutritional status and the volume and vehicle of test substance delivery (Gad and Chengelis, 1988). With these possibilities and that many wildlife studies use wild-captured animals of unknown heritage, specific nutritional needs or previous xenobiotic exposure, results of wildlife studies must be used cautiously even though a given experiment was conducted expertly. It is also important that these tests of lethality are neither designed nor intended to imply unequivocal recovery of survivors. The amount of time it takes to recover from the initial toxicity may render an individual more vulnerable to exposure and predation.

5.2 Avian Five-Day Dietary Toxicity Test

The second test is similar to the single-dose acute oral test, except graded concentrations of chemical are presented *ad libitum* in the feed for five days. This five-day 'subacute' test is intended to augment the acute oral test by measuring response to repeated exposures from normal feeding and accumulative effects. Careful observation for changes in behaviour and rate of feeding and for onset and course of toxic signs is especially important. Most often the rate of feeding is inversely

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

correlated with the graded concentration of toxic chemical provided the test subjects cannot fast for five days. This short-term feeding trial was optimized with young precocial birds, but it serves equally well for testing small mammals and other birds that can be maintained in captivity in good health (Hill, 1971; McCann *et al*., 1981; Grue, 1982; Ringer *et al*., 1991). In general, the best results are obtained for birds and mammals that weigh less than 100 g. Although birds weighing 100–200 g have been tested under this protocol, their response to graded concentrations of toxicant tended to be erratic, which resulted in artificially shallow dose–response curves and widely variable LC_{50}s (Hill *et al*., 1975; 1977; Hill, 1981; Hill and Camardese, 1981). This source of error and its implications have been evaluated elsewhere (Hill, 1971; Hill and Camardese, 1981; Grue, 1982).

The five-day test generates a dose–response curve; the mid-point of the dose–response curve is quantified as the median LC_{50}, its error with 95% confidence limits similar to the single-dose test above (Heath and Stickel, 1965). The LC_{50} may be expressed as mg a.i. (active ingredient) $(kg\ feed)^{-1}$ or as parts per million (ppm). It also provides descriptive information on response to potentially toxic food. The basic design uses the same number of animals, treatment levels and control groups as the full-scale acute test. In risk assessments, the daily consumption $(mg\ kg^{-1}\ day^{-1})$ can be used for an estimate of exposure leading to unacceptable risk. A detailed protocol for the dietary LC_{50} test of wildlife for regulatory purposes in the USA is available (Bascietto, 1985b).

5.3 Single-Dose Avian Embryotoxicity Tests

Single-dose acute tests are also conducted routinely on the avian embryo. In these tests, the embryo is exposed by topical treatment of test substance to the eggshell, injection into the air space or complete immersion of the intact egg for a prescribed duration (Hoffman and Albers, 1983). The avian egg is a relevant model for indication of environmental pollution because it has proved susceptible in nature to embryotoxicity and teratogenicity from air pollution, pesticide spray application, aquatic translocation and even from contaminated breast feathers of the adult (Hoffman, 1990; 1994). Mallard and northern bobwhite eggs are the preferred laboratory models for routine bioassays, but eggs from many species have been brought into the laboratory from the field and tested to validate putative causes of embryotoxicity.

The basic embryotoxicity test uses two approaches, although many variations of this bioassay have been reported (Hoffman, 1990; 1994). The first is to dose about 25 eggs at each of three to five levels for the purpose of generating a dose–response curve, its error and an LD_{50} or LC_{50} with 95% confidence limits. The second approach is more applied, where doses bracket actual field concentrations, thereby providing a realistic assessment of ecological risk.

The focal point of the first test is lethality, but includes stage-effect evaluation at different times of incubation, with the lethal effect including a seven-day chick survival period. Teratogenic effects are also monitored in a random subsample of eggs at various times of incubation, and often reveal effects at exposure levels well below the calculated median lethal levels. The second method is conducted the same as the first, except the objective is not to determine the median lethal dose, but to focus on teratogenic, biochemical and histological variables that are consistent with ecological observations. Another method is to use an applied bioassay, where eggs under natural incubation in the field are dosed and observed for hatchability and survival. Seminal reports on techniques and findings of embryotoxic and teratogenic studies of wildlife have been published (Hoffman, 1990; 1994; 1995; 2002; Hoffman and Albers, 1983).

5.4 Additional Acute Tests

Acute tests have also been conducted on amphibians and reptiles, but neither standardized procedures nor the preferred model species have been finalized for regulatory purposes in the USA. However, flow-through and static tank tests of bullfrog (*Rana catesbeiana*) tadpoles and oral dosing of adult bullfrogs and green anole lizards (*Anolis carolinensis*) have proved to be satisfactory techniques for comparative toxicology (Hall and Swineford, 1980; Hall and Clark, 1982; Hudson *et al*., 1984). Detailed reviews of amphibian and reptile testing procedures are available (Sparling *et al*., 2000; Linder *et al*., 2003).

The acute bioassay has been adapted to studies of inhalation and dermal toxicity to birds. Examples include a comparison of inhalation and oral toxicity of pesticides in northern bobwhite (Driver *et al*., 1991) and dermal tests where pesticides were applied to the feet of mallard (Hudson *et al*., 1979) and the breasts of passerine species (Schafer *et al*., 1973).

6 SUBLETHAL TOXICOLOGY

6.1 Special Studies

During the past 30+ years, the emphasis of wildlife toxicology has shifted from correlation of xenobiotic residues with lethality, to the development and validation of biochemical tests indicative of exposure and toxicity, behavioural toxicology, and simulated and actual field

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

trials. Studies address known or theoretical questions of environmental risk and vary in complexity from routine to uniquely designed experiments for implementation in the laboratory or in nature. The studies may involve a single dose or months of continuous feeding, a spot survey or several years of field sampling. Species may include a specific strain of laboratory rodent, farm-reared ducks or quail, a wild-captured and carefully conditioned surrogate species, the actual species of interest or a natural population. The design of these studies is boundless as they usually focus on special issues of putative ecological risk; a few examples are presented.

6.1.1 Biomarkers

Biomarkers have been defined as a 'biological response to a chemical or chemicals that gives a measure of exposure and sometimes, also, of toxic effect' (Walker *et al*., 2001). A biomarker response indicates the presence of a xenobiotic, its availability and that it has reached the affected tissue or organ in sufficient amounts for a period of time long enough to elicit change. The relative value of such a response to indicate harm ranges from a simple homoeostatic response to a dose-dependent progression of responses indicating a toxic process has been initiated (Melancon, 2003). An in-depth review on biomarkers as pollution indicators in wildlife was presented by Peakall (1992).

Biomarkers of exposure may provide little information on effect, but some are fairly specific to certain classes of contaminants and are efficient substitutes for more costly and time-consuming residue analysis. Most of the techniques are based on nondestructive sampling of blood, urine or faeces and are especially useful in field monitoring. Some of the more commonly used biomarkers that have both specificity and a degree of diagnostic value have been summarized and discussed by Melancon (2003) and Walker *et al*. (2001). They include inhibition of δ-aminolaevulinic acid dehydratase (lead), inhibition of cholinesterase (organophosphorus and carbamate insecticides), anticoagulant clotting proteins (rodenticides) and induction of mono-oxygenases (chlorinated and polyaromatic hydrocarbons). Avian eggshell thinning is also classed as a biomarker that is rather specific to a few chlorinated hydrocarbon insecticides, primarily DDT and its metabolites DDE and DDD (1,1-dichloro-2,2-bis(4-chlorophenyl)ethane). Another biomarker with a high degree of specificity to a few organophosphorus compounds such as leptophos and EPN (ethyl 4-nitrophenyl phenylphosphonothioate) is neurotoxic esterase, an indicator of organophosphorus ester-induced delayed neurotoxicity. Unless a particular contaminant is suspected for which there is a highly specific biomarker, it is suggested that a suite of biomarkers be used for general monitoring of pollution (Melancon, 2003).

6.1.2 Behaviour

Many pesticides and other environmental contaminants are neurotoxic and assumed capable of affecting behaviour at clearly sublethal levels of exposure. Thus, several fairly sensitive laboratory tests and a variety of field tests have been devised for wildlife to detect chemicals that may affect natural or operant behaviour. Whereas behavioural tests seem desirable, there are two fundamental difficulties in the use of such tests in wildlife toxicology: (i) the best studied and most easily performed and quantified behaviours have the least environmental relevance and (ii) the most relevant behaviours are the most strongly conserved against change (Walker *et al*., 1996). For example, operant behaviour where animals are conditioned to respond to a cue is remote from environmental reality, but it is presumed that decreased learning ability is unfavourable. Avoidance behaviour is more directly related to survival, but difficult to quantify, as is the ability to capture prey. Nonetheless, subacute exposure of birds and mammals to pesticides and other contaminants has been shown to affect an array of behaviours such as activity level, alertness, aggression, foraging and drinking, learning and memory, navigation and reproduction (Heinz *et al*., 1979; Peakall, 1985; Grue *et al*., 1991; Bennett, 1994).

Most of the behavioural studies with wildlife are conducted under highly or quasicontrolled conditions and test response to critical survival stimuli, learning and memory competency, prey-capturing skills, and chemical discrimination and aversion. Although most of these studies were well planned and have important theoretical implications for survivability, laboratory studies are highly restrictive and their projection to natural populations is speculative (Bennett, 1994).

Response to maternal calls and fleeing from danger are vital to the survival of young animals. These variables were tested in mallard ducklings whose parents had been treated with environmental concentrations of chlorinated hydrocarbon or mercurial pesticides (Heinz, 1976; 1979). In the first test, the response of newly hatched ducklings to the maternal call was measured by the time a chick took to approach a recorded call. The other test measured the same chick's avoidance of a frightening stimulus. These tests are sensitive, but limited in their use because they were designed for precocial birds. With modification of the parental treatment regime and age of pups, the same system has been used to test avoidance of the frightening stimulus in young rodents.

Tests of learning ability based on operant conditioning appear to be a sensitive indicator of xenobiotic effect in wildlife (Heinz *et al*., 1979). These tests require few specimens, but training and testing may require months (Kreitzer, 1980). The basic test is to feed hatchlings with low dietary concentrations of chemical for several months and then train the birds by hunger motivation to peck a lighted key in the conditioning chamber for a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

food reward. After learning which lighted pattern yields a reward, the pattern is changed and the ability to adjust is measured. After the chemical has been removed, the test may be repeated to test persistence of effect. The test has been performed on northern bobwhites with realistic dietary concentrations of chlorinated hydrocarbons and organophosphorus pesticides. The domestic pigeon (*Columba livia*) has proven to be a sensitive model for operant conditioning and testing for vapour toxicity (Armstrong *et al*., 1963; Leander *et al*., 1977). Application of operant conditioning to the study of behavioural effects of pesticides has been reviewed for laboratory rats and pigeons (McMillan, 1982).

Aside from the highly controlled and extremely labour-intensive laboratory tests, comparatively few studies are expressly conducted on the effects of xenobiotics on wildlife behaviour. Instead, many reports of behavioural observations were ancillary to studies of direct toxicity. For example, in a study of secondary poisoning of Siberian ferrets (*Mustela eversmanni*) fed intact laboratory rats that had been acutely dosed with zinc phosphide, it was noted during conditioning that some of the ferrets regularly ate the entrails of the rats, whereas others did not. Once zinc phosphide-treated rats were offered, ferrets eating the poisoned rat entrails immediately showed some distress and vomited. Thereafter the ferrets avoided eating the entrails although they consumed the balance of the carcass including major organs without hesitation (Hill and Carpenter, 1982).

Avoidance behaviour is a practical protection against xenobiotic poisoning of wildlife, but it is neither well understood nor often documented in nature. This important behaviour is being carefully evaluated by the US Department of Agriculture and the chemical industry, both to protect wildlife from poisoning by agrochemical application and to protect crops from wildlife depredation (Mason, 1997). The example of the ferrets selectively avoiding the entrails of the zinc phosphide-dosed rats was unique, but potential protection against acute poisoning by emesis was previously documented for kit fox (*Vulpes macrotis*) fed zinc phosphide-dosed kangaroo rats (*Dipodomys* sp.) (Schitoskey, 1975). In this example, unabsorbed zinc phosphide is present in the stomach of the prey animal in sufficient amount to stimulate emesis and emit a strong characteristic odour. With other substances such as granular (GR) anticholinesterase insecticides, neither the physiological protective reaction of emesis nor the obvious odour are as strong, and death of predators eating poisoned prey is common (US EPA, 1991).

Xenobiotic effects on reproductive behaviour have been conducted with limited relevance to natural populations. Ringed turtle-doves (*Streptopelia risoria*) provide a satisfactory model for behavioural studies because it can be easily paired, bred and managed in small battery cage units. At least 55 distinctly different behaviours have been characterized for this species under the general topics of development (infantile and juvenile), reproductive (sexual and nonsexual), aggression, escape and a variety of miscellaneous activities (Lehrman, 1955; Miller and Miller, 1958).

Outdoor pen studies have been used to study mallard hen and brood behaviours. In one study, five-day-old ducklings were gavaged with a single low dose of methyl parathion and released with their mother and untreated siblings in pond enclosures. Many behaviours were studied, including time spent in water, time spent preening and loafing, and parental attentiveness (Fairbrother *et al*., 1988). In other studies, mallard hens were dosed with methyl parathion and their nesting, brooding and attentiveness were studied (Brewer *et al*., 1988; Bennett *et al*., 1991).

Studies have also been conducted with free-ranging birds where adults were dosed with low concentrations of chemical and their nest attentiveness evaluated (White *et al*., 1983). A different breeding behaviour was tested in free-ranging sharp-tailed grouse (*Tympanuchus phasianellus*). A single dose of malathion reduced their defence of breeding territories on leks and sometimes caused bizarre behaviour (McEwen and Brown, 1966). Field studies have also shown that species such as northern bobwhite and European starlings (*Sturnus vulgaris*) are more subject to predation after organophosphorus exposure and release (Buerger *et al*., 1991). Carbamate insecticides may also affect hen–brood interactions, as demonstrated by a pen study of operational carbofuran treatment to vegetation that was associated with aberrant approach–response behaviour in mallard ducklings (Martin *et al*., 1991). Behavioural studies of organophosphorus and carbamate insecticides are especially useful because they are applied widely during the critical reproduction cycles of wildlife and have a well-defined biochemical marker, brain and blood cholinesterase, which can be used in conjunction with behavioural changes.

Behaviours other than reproduction are also studied. For example, migratory white-throated sparrows (*Zonotrichia albicollis*) were captured and exposed to dietary acephate for 14 days to determine effects on migratory orientation (Vyas *et al*., 1995). Birds were also exposed to polarized sheets to determine the mechanism by which orientation was effected. Adult sparrows did not establish a preferred orientation, but juveniles displayed a seasonally correct southward migratory orientation.

6.1.3 Avian Nestlings

Altricial nesting birds are sensitive models for ecological risk assessment. Nestlings, like neonatal mammals, are often the most sensitive life-stage to accumulation and toxicity of many chemical substances. However, whereas mammals may move their neonates, altricial

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

birds cannot. Thus, once laying commences, the eggs and nestlings might remain subject to local contamination for 5–10 weeks. During this period it is possible to evaluate natural or experimental exposure. Individual eggs, nestlings or the entire nest can be treated, and their fate monitored through observation and selective sampling. For example, specimens may be bled, biopsied or euthanized; transovarian contamination of the egg can be compared with dietary ingestion and the nestlings' oesophagus can be constricted for retrieval of food items. Some species such as American kestrels (*Falco sparverius*) and European starlings can also be attracted to nest boxes, thereby ensuring the desired distribution of nests and sample size. Similar field studies have been conducted with waterfowl, but since the precocial hatchlings do not remain at the nest site, the home area must be contained, which often restricts normal movement of the hen and brood.

Altricial nestlings can also be tested in the laboratory with species that will breed in captivity. Unfortunately, the aviculture has not been sufficiently worked out for most species and few such toxicological studies have been published. Success has been achieved with American kestrels and European starlings. The value of these species as sensitive models for toxicity testing was validated by comparison with similar studies with precocial game birds. In these experiments, hatchlings were given graded doses of chemical daily by intubation for the first 10 days posthatching. Both kestrels and starlings were consistently more sensitive to lead and a variety of herbicides and polychlorinated biphenyls than were mallards, northern bobwhites and ring-necked pheasants (*Phasianus colchicus*) (Hoffman, 1995). End points included survival, body organ and skeletal growth, and blood and organ biochemistry. The use of free-ranging and captive altricial species in contaminant toxicology has been reviewed (Hoffman, 1994; 1995).

6.1.4 Caged Field Trials

Exposure of wildlife in field enclosures to 'operational application' of pesticide was initially considered a practical approach to ecological risk assessment of agrochemical and disease-vector control products. Enclosures varied from small portable wire cages to large structures up to 30 m or more on a side. Usually one to five small passerine- to quail-sized birds were tested in the small cages for acute response. The cages were placed in the spray zone immediately prior to chemical application and removed within a few hours post-treatment. Groups of 5–20 pen-acclimatized game birds or ducks were often tested in the large pens, with observations continued for widely variable periods post-treatment. The focus of these tests was also on acute response from direct chemical application, and theoretically included effects of eating natural foods contaminated by the treatment. Such tests were also referred to as simulated field trials. The design of these studies was widely variable, but the concept was appealing and led to the US EPAs development of a standard 'pen-in-field' protocol for testing chemicals under FIFRA (US EPA, 1982). Although theoretically useful, nearly all of these tests had major flaws and the US EPA rescinded the requirement of the pen-in-field test for pesticide registration.

Although most simulated field trials have major deficiencies, there are situations where ecological risk is detectable. The best example is probably for chemicals intended for use as a foliar or systemic application to vegetation that is preferred forage for herbivorous wildlife. In this situation, comparatively small enclosures would provide ample forage for a waterfowl or small mammal species. Such a test probably would have indicated the earlier described risk to Canada geese and American widgeon from turf grass treatment with diazinon and alfalfa treatment with carbofuran. Simulated field trials would also be useful in testing the potential risk of GR formulations of pesticide. The key is to evaluate carefully how and where a chemical will be used in relation to its likely availability to wildlife before conducting such a specialized field trial.

6.2 Chronic and Reproductive Toxicity

Chronicity trials are favoured by wildlife toxicologists because they allow the study of simulated field exposure under controlled conditions with a relevant model. Most often birds are used rather than mammalian wildlife because several mammalian models are routinely tested for human health effects. Thus, there is no compelling evidence to suggest a need for additional routine chronicity testing of wild rodents and rabbits, but it has been recommended that such tests and also a carnivore such as the mink be included on a specific chemical basis (Ringer, 1988; Ringer *et al*., 1991).

6.2.1 Chronic Reproduction Test

Most avian chronicity trials are designed with reproduction as the principal end point, that is, number of young that survive to fledging or, for precocial species, the number that survive to about two weeks of age (Heinz *et al*., 1979). These tests, first designed to evaluate the reproductive effects of persistent chlorinated hydrocarbon pesticides and heavy metals, have been standardized and may be required by the regulatory agencies to support the registration of pesticides intended for use in a natural system.

The avian reproduction test provides an evaluation of a chronic dietary exposure to the chemical with the goal of determining the highest dietary concentration that produces no observed adverse effect on reproduction and the lowest concentration that produces an observed effect

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Bennett and Ganio, 1991). The results are compared with concentrations expected in the environment. Normally, this test of avian reproduction is the only standardized test of chronic dietary exposure of wildlife and the only method used for detecting long-term effects of chemicals that are either persistent in the environment or that are applied repeatedly to the environment.

The basic protocol was designed to test farm-reared mallards and northern bobwhites, but is easily adapted to other species that can be properly managed and bred in captivity and will lay an indeterminate number of eggs over an extended period. The protocol was tailored for environmentally persistent chemicals. In contrast, test concentrations for regulatory purposes are based upon residues expected under the proposed use, and multiple levels are tested to determine effect and no-effect concentrations. Test concentrations of chemicals already present in nature are based on environmental residues. Treatment commences at least 10 weeks in advance of breeding and continues to eight weeks after about 50% of the females are in lay. Eggs are collected daily and set at weekly intervals for artificial incubation. Reproductive end points include number of eggs laid, percentage fertility, embryonic development, hatchability and chick survival. An alternative approach, of perhaps more relevance, is to allow paired birds to incubate their own eggs and rear the young, because many behavioural responses must be correct for this process to succeed (Heinz *et al*., 1979). The basic protocol and alternative procedures have been thoroughly reviewed and critiqued for regulatory purposes (Bennett and Ganio, 1991).

6.2.2 Modified Reproduction Tests

As mentioned, the chronic avian reproduction test was designed for the study of ecologically persistent and accumulative pesticides and heavy metals. Environmentally plausible dietary exposure was begun well in advance of reproduction to allow for some accumulation of residue in critical organs and systems, and continued through the reproductive cycle. This approach does not work well with more labile substances such as organophosphorus and carbamate insecticides. These chemicals do not tend to accumulate in nature, and continuous low-level exposure, if not lethal, may be accommodated physiologically without serious effect on reproduction (Grue *et al*., 1991; Hill, 1995). However, intermittent chemical exposure from repeated applications of anticholinesterase insecticides may occur throughout the reproductive cycle and may lead to different effects than for continuously exposed animals. It is also possible that the response to anticholinesterase chemicals may not be the same if the initial exposure occurs at different stages in the reproductive cycle (e.g. courtship, onset of lay, incubation, foraging for altricial young). Hence specially designed research is often necessary to evaluate properly different classes of chemicals and uses.

6.3 Terrestrial Field Studies

Field studies of contaminant effects on wildlife may include resolution of a local incident of poisoning or a designed evaluation of a chemical treatment or industrial effluent. Procedures may involve detailed examination of individual specimens for evidence of gross, enzymatic and histological pathology or complex studies of local population and ecosystem perturbation.

Field studies are necessarily complex and one model will not fit all because each environmental situation is special in some way and poses unique problems for risk assessment. However, such studies should be pursued because the final proof of true xenobiotic risk to wildlife, other than direct evidence of mortality, is demonstrated only through a comprehensive field evaluation. Even then, the results may be applicable only to the specific habitat type and species studied.

7 COMPARATIVE TOXICOLOGY

7.1 Birds and Mammals

Metabolic responses to xenobiotics are similar for birds and mammals, with any differences more quantitative than qualitative (Pan and Fouts, 1978). This conclusion was based on the evaluation of more than 300 studies of 114 chemicals and 35 species of birds. The few qualitative differences are in conjugation reactions with glucuronic acid, sulfate, glutathione ornithine, glycine, taurine, ornithine and acetate. None of the reactions are believed to be related to differential sensitivity of birds and mammals to acute toxicity of anthropogenic chemicals (Pan and Fouts, 1978; Walker, 1983).

Several quantitative enzymatic differences between birds and mammals are important to differential response to acute toxic exposure. Birds generally have lower levels of hepatic monooxygenase (HMO) and A-esterase activity than do mammals, which make birds more susceptible to many environmental contaminants (Walker, 1978; 1980; Brealey *et al*., 1980). For example, carbamate insecticides are deactivated mainly by HMOs (Kuhr and Dorough, 1976) and a variety of avian species are consistently more sensitive to acute carbamate exposure than is the laboratory rat (Smith, 1987). Organophosphorus insecticides are also deactivated by HMOs, but many are first activated to a more potent oxygen analogue by the same HMO pathway (Eto, 1974). Most active organophosphorus analogues are substrates for A-esterase hydrolysis and are rapidly

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

detoxified in the liver and blood (Brealey *et al*., 1980). In a study of 14 species of birds, three laboratory mammals, domestic sheep and humans, plasma A-esterase activity was at least 13 times higher in all of the mammals than in any of the avian species (Brealey *et al*., 1980).

As a rule, birds are more sensitive to acutely toxic chemicals than are mammals, in part due to differences in HMO activity, but such generalization is not accurate for all chemicals and species. Generally, *the laboratory rat is not a good model for the prediction of acute toxicity to birds,* even for chemicals that elicit their toxicity in the same way. When chemicals of different mechanisms of toxicity and biological stability are compared, equal or larger differences between birds and rats are common (cf. Gaines, 1960; Gaines, 1969; Hudson *et al*., 1984). In contrast, *laboratory rats and mice are conservative predictors of acute toxicity to wild rodents.* In a study of the acute oral toxicity of a spectrum of pesticides to four species of voles (*Microtus orchrogastar*, *M. canicaudus*, *M. pennsylvanicus* and *M. montanus*) and laboratory rats and mice, it was determined that laboratory rodents are generally more sensitive to pesticides than the most sensitive vole, *M. canicaudus* (Cholakis *et al*., 1981). Laboratory mice were also found to be more sensitive than deer mice (*Peromyscus maniculatus*) to many pesticides and drugs, but the relationship was not consistent (Schafer and Bowles, 1985).

7.2 Factors Affecting Interpretation of Acute and Dietary Tests

7.2.1 Growth and Maturation

Acute oral LD_{50}s and five-day dietary LC_{50}s change significantly during growth and development of precocial birds. In the acute test, change is believed to be primarily influenced by developing metabolic processes that affect toxication and detoxication of xenobiotics, and an immature immune system (Hudson *et al*., 1972). The subacute test is influenced by these same processes and highly individualistic responses to dietary presentation of xenobiotic (Hill and Camardese, 1981; 1986).

Changes in avian sensitivity to acute oral dosing may follow different patterns depending on the toxic mechanism of the chemicals. For example, mallard LD_{50}s for organophosphorus compounds that require HMO activation for maximum potency (latent cholinesterase inhibitors) tend to decrease between hatch and seven days, and then increase with maturation, whereas the opposite pattern occurs for direct-acting organophosphorus and carbamate anticholinesterases. Response to central nervous system-stimulating chlorinated hydrocarbons followed the same pattern as latent cholinesterase inhibitors. In contrast, LC_{50}s typically increase with age during early growth of precocial species. The increase is probably due to larger (older) chicks eating less in proportion to body mass and being better able to reduce their food consumption (toxic exposure) during the five-day feeding trial (Hill and Camardese, 1981).

7.2.2 Physiology and Gender

Tolerance of xenobiotic exposure may be affected by many factors, such as age, sex, reproductive status, genetic lineage, nutritional status, and endogenous and exogenous stressors. Each of these variables may affect LD_{50} and LC_{50} determinations, but their importance is not well documented for wildlife. Historically, in most acute avian studies, nonbreeding subadult game birds or adult passerines of both sexes were tested. This was intended to reduce gender effects and thereby conserve the number of wild birds needed for testing general acute sensitivity to pesticides. The legitimacy of pooling sexes of reproductively quiescent birds has been validated for acute toxicity testing (Tucker and Haegele, 1971; Tucker and Leitzke, 1979). Beyond general comparisons, this narrow focus is not adequate for risk assessment, because pesticides are intensively applied during breeding seasons and knowledge of sex differences in sensitivity is essential. The importance of this variable was shown by an acute test of the organophosphorus insecticide fenthion, in which ovulating northern bobwhite were 2.3 times ($p < 0.05$) more sensitive than males (Wiemeyer and Sparling, 1991). This relationship was supported by studies with Sherman strain rats, in which females were the most sensitive sex to about 30% of the anticholinesterase insecticides tested; males were most sensitive to about 10% of the compounds (Gaines, 1960; 1969). When sex differences were detected, females were much more sensitive than males (e.g. 1.5 to fivefold); when males were most sensitive the difference was usually less than 50%. Disproportional female sensitivity is particularly important because females are more important than males for population recruitment.

7.2.3 Captivity

Adequate methods are not available to evaluate the suitability of large numbers of wild-captured animals for routine toxicity testing. Simple survival and weight maintenance for a few weeks in captivity may not reflect subtleties such as nutritional imbalance or stress response to confinement, isolation or crowding. Whether captive specimens, either wild or farm hatched and reared, truly represent their free-living counterparts is not easily determined. Limited data were provided by a series of five-day subacute feeding trials with wild blue jays, house sparrows (*Passer domesticus*), northern cardinals (*Cardinalis cardinalis*) and wild and farm-reared northern bobwhites (Hill, 1971). All wild birds were at their captive weight, in excellent plumage and believed to be

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

adequately conditioned. Blue jay was always the most sensitive species and farm bobwhite was always the most tolerant. Blue jays are adaptable generalized feeders that are generally considered to be tolerant of contaminated habitats (Bernard and Wallace, 1967). However, based on LC_{50}s, blue jays were about 1.5–50 times more sensitive than the other species to DDT and several organophosphorus insecticides. Wild bobwhites had less subcutaneous and visceral fat than did farm bobwhites, weighed about 25% less and were more sensitive to all of the chemicals tested. The wild bobwhites had been in captivity for several months, appeared healthy and were from the same local population from which the farm colony had been founded about 10 generations earlier.

8 ACUTE ECOLOGICAL RISK

Prediction of acute chemical risk to wildlife may be confounded by many factors of anthropogenic and natural origin. A primary factor, and perhaps most easily addressed through limited additional testing, is the influence of pesticidal formulations on chemical availability and toxicity to wildlife. Some of the other factors that may affect acute chemical risk to wildlife to different degrees include the route, source and timing of exposure; possible interactions with other chemicals; infectious diseases; and weather stressors.

8.1 Pesticide Formulation

Pesticide regulations are usually based on tests of technical-grade or analytically pure substance (US EPA, 1982; 1996). Only rarely is technical-grade material actually applied in the field, and then only in very low volume, for example, a few fluid ounces per acre for insect vector control in populated areas. Instead, a chemical is normally applied as a formulated product that may differ substantially in its acute toxicity from the technical-grade material tested. As a general rule, it has been determined that GR formulations are most often less toxic than technical-grade materials, whereas, liquid formulations are usually more toxic than technical-grade products (Hill, 1986). This relationship was verified by a limited study of formulated diazinon and carbofuran toxicity to northern bobwhites from a single source and hatch (Hill, 1992). A single dose of insecticide was administered as technical grade (TG, 99% a.i. alone or in corn oil (CO) diluent), as granular (GR, 14–15% Al) or as emulsifiable concentrate (EC, 48% Al). The relative acute toxicity, based on statistically separable LD_{50}s ($p<0.05$), was EC>GR=TG>CO for diazinon and EC>CO=TG>GR for carbofuran.

8.2 Routes and Sources of Exposure

Wildlife is most often exposed to xenobiotics through the ingestion of contaminated food and water. Inhalation and dermal exposure also occur but are believed to be less common and less hazardous to wildlife than is oral ingestion (Driver *et al*., 1991). Accordingly, nearly all screening studies of xenobiotic toxicity to wildlife involve oral administration of chemicals, but such studies are usually based on a technical-grade chemical via gelatine capsule, gavage or dry mash.

The toxicity of most xenobiotics is primarily a function of hepatic metabolism, regardless of the route of entry (Natoff, 1967). Thus, many chemicals are potentially more potent if they can enter the circulatory system by routes other than the gastrointestinal tract, which shunts directly to the liver for first-pass metabolism and detoxication. Compounds that require HMO enhancement for maximum potency are exceptions. Usually, however, chemicals are not rapidly absorbed through skin and scales, important alternative routes to ingestion. Percutaneous risk is dependent on the rate (dose and time) at which the chemical penetrates the skin and varies widely among chemical formulations, sites of application and species (McCreesh, 1965; Vinson *et al*., 1965; Durham, 1967). An array of pesticides have been tested by application to the wrapped feet (i.e. tarsometatarsus, phalanges and webbing; about 2% of body surface) of adult mallards for 24 hour, and to 1 cm^2 of featherless skin area covering pectoralis muscles under the wing joint of small passerine birds (Schafer *et al*., 1973; Hudson *et al*., 1979). At the same time companion birds were dosed orally. Percutaneous and oral LD_{50}s were positively correlated in both studies (Mallard, $n=19$, $r=0.65$, $p<0.01$; passerine, $n=17$, $r=0.85$, $p<0.01$). The LD_{50}s were consistently highest for percutaneous routes, but the difference was larger when chemicals were applied to the feet of ducks than the breasts of sparrows.

Although potentially more toxic because most chemicals readily cross the mucus membrane of the lung, inhalation toxicity is considered minor compared with deposition of chemical on the skin (Durham, 1967; Driver *et al*., 1991). However, this concept has not been rigorously tested on wildlife species. For example, it is not known to what degree bats are at risk when returning to their roost during morning twilight, the time considered optimum for aerial application of pesticides.

Wildlife is exposed to anthropogenic xenobiotics in contaminated air, water, soil, seeds, foliage, invertebrates, vertebrates and formulated GR pesticide particles. All of these sources have killed large numbers of wildlife under varied environmental circumstances (Grue *et al*., 1983; Hardy and Stanley, 1984; US EPA, 1991; Racine *et al*., 1992; Blus, 1995). Noninfectious xenobiotics of natural origin such as mycotoxins have also killed large numbers of wildlife eating contaminated seeds and peanuts (Windingstad *et al*., 1989; O'Hara, 1996).

8.2.1 Air

Airborne exposure of wildlife to anthropogenic contaminants is not easily distinguished from terrestrial and aquatic sources and has received comparatively little attention. Perhaps most hazardous is short-term (minutes to a few hours) exposure to pesticidal application, but as indicated previously, inhalation toxicity is minor compared with dermal and ingestion routes (Driver *et al*., 1991). Instead, the primary concern is long-term deposition of industrial effluents over space. Usually this type of contamination is not directly toxic to most animals, but alters their dependent ecosystems, for example, acid precipitation and ozone (Laurence and Andersen, 2003). US EPA has begun to incorporate inhalation exposures into ecological risk assessments through the use of its Total Risk Integrated Methodology (TRIM) for air pollutants (Efroymson and Murphy, 2001).

One group of wildlife likely to encounter contaminated air is those that burrow in contaminated soils. To assist with the assessment of whether burrow air concentrations could exceed 'safe levels', Gallegos *et al*. (2007) used Botta's pocket gopher (*Thomomys bottae*) to develop ecological screening levels of volatile organic chemicals for burrowing small mammals. Estimates of soil pore gas can be used in place of direct measurements of burrow air concentrations. Additionally, burrowing rodents have been shown to inhale soil contaminants such as manganese and cadmium. By measuring these contaminants in the olfactory bulb of California ground squirrels (*Spermophilus beecheyi*), Bench *et al*. (2001) determined that the ground squirrels not only ingested the contaminants, but a considerable portion of their body burdens resulted from inhalation. However, for most wildlife, inhalation of metals such as cadmium is minor compared to ingestion (Burger, 2008).

8.2.2 Water

Water is a common source of xenobiotic exposure to wildlife that is poorly understood because toxicity is dependent on widely variable factors of ambient water quality, movement and the solubility and stability of chemicals. The importance and details of water quality to chemical fate, toxicity and risk are discussed elsewhere in this volume (see **Soil and Fresh Water**). With regard to pesticides, water-soluble formulations usually remain available longest in natural waters (Eto, 1974; Cardarelli, 1976; Kuhr and Dorough, 1976) and tend to be the most toxic by either acute single-dose or five-day dietary exposure of birds (Hill *et al*., 1975; Hudson *et al*., 1984; Hill, 1992). How these studies relate to water-borne exposure in nature is not clear because rates of feed and water consumption vary widely among wildlife species at different ages and seasons of the year. Smaller birds and mammals have a much higher water requirement relative to body mass than do larger species under similar ambient conditions (Robbins, 1983). Even closely related birds of similar size and feeding habits vary their rates of free water consumption from about 15 to 40% of their body mass per day at an ambient temperature of 25 °C (Bartholomew and Cade, 1963).

Few studies of pesticides in water have been reported for wildlife species, but some observations are noteworthy. Black-crowned night-herons (*Nycticorax nycticorax*) were confined for 24 hours to wading pools treated with Baytex 4 (fenthion) at rates calculated to be equal to and 10 times above registered field application rates (Smith *et al*., 1986). The high treatment had about 70 mg L^{-1} of fenthion at the surface of the water at 24 hours and resulted in no overt signs of toxicity or inhibition of brain cholinesterase activity; however, blood plasma cholinesterase was inhibited an average of 32% ($p < 0.05$). Field applications of fenthion in various formulations, at 47–100 g of active ingredient per hectare, over wetlands of variable water depths killed a variety of passerine and wading birds (Seabloom *et al*., 1973; Zinkl *et al*., 1981; DeWeese *et al*., 1983). The authors concluded that contaminated insects were an important source of fenthion in the avian mortality, but the importance of contaminated water was not dismissed. Mortality of wildlife from puddling and run-off from agriculture fields has been documented for many of the more acutely toxic pesticides currently registered for use in the USA (US EPA, 1991).

8.2.3 Mining

The presence of contaminated water is especially hazardous to wildlife in arid regions where open water is widely scattered. For example, microgold mining has resulted in hundreds of cyanide-contaminated ponds across the USA. Mines are located in variable climates from the humid southeast to the Dakotas and Alaska, but most are in the Great Basin and southwestern US deserts. Open water of mine ponds is especially attractive to wildlife in desert regions and the cyanide-treated solution and tailing ponds have killed thousands of migrating birds and large numbers of many resident vertebrate species (Clark, 1991; Clark and Hothem, 1991; Henny *et al*., 1994).

In spite of industry-wide advances in the protection of wildlife from cyanide solution ponds, mines differ widely in operational practices and their potential risk to wildlife. Much research has been done to ameliorate this risk, but owing to the high toxicity of the small solution ponds that are cycled on to the ore leaching pad, the only practical resolution is total exclusion of wildlife from the leaching field, solution ponds and their connecting ditches (Henny *et al*., 1994). The toxicity of the large tailing ponds (e.g. about 50–700 ha) may be effectively reduced by various chemical treatments. Another contributor to this risk is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

that waterfowl appear to have no aversion reaction to drinking potentially LCs of cyanide (Henny *et al*., 1994).

8.2.4 Soil and Sediments

A route of exposure that needs to be included in any risk assessment is soil or sediment ingestion. A measure of sediment ingestion by waterfowl in the Coeur d'Alene River Basin in Idaho, USA. was 18% for Canada geese and tundra swans (*Cygnus columbianus*), and 12% for ducks. The 18% value corresponded to an estimated 9% sediment ingestion rate (dry weight) (Beyer *et al*., 1998). Beyer *et al*. (1994) present the soil ingestion rates of 28 additional species of wildlife. The bioavailability of contaminants in soil varies depending on the species and the type of contaminant. For metals, normalizing their concentrations in sediment to acid volatile sulfides (AVSs) has been suggested as a universal explanation of metal availability from sediments. For organics, much attention has been given to the biota-soil/sediment-accumulation-factor (BSAF), an empirical ratio defined as the chemical concentration in tissue over the chemical concentration in soil or sediment (National Academy of Sciences, 2003).

Contaminants such as lead can be absorbed by birds from ingested sediments containing environmentally relevant concentrations, and these concentrations can be toxic (Connor *et al*., 1994; Beyer *et al*., 2000; Day *et al*., 2003). In the Coeur d'Alene River Basin, waterfowl have been poisoned for many years with lead from mine tailings and smelting activities in the area. The source of the lead was ingested lake and river sediment, not the vegetation or prey items in the diet (Beyer *et al*., 1997; 2000; Sileo *et al*., 2001).

Wild mammals will also consume large amounts of contaminated soil. Mule deer (*Odocoileus hemionus*) and white-tailed deer (*Odocoileus virginianus*) near the inactive Continental Mine in northern Idaho, USA. possessed higher concentrations of lead in their pellets than was likely from incidental ingestion of lead-contaminated soil. They appeared to be intentionally ingesting contaminated soil since clumps of sand and bits of rock were found in some pellets (Beyer *et al*., 2007).

8.2.5 Soil Inclusions

Lead poisoning of waterfowl has been documented in major waterfowl concentration sites throughout much of the world (Locke and Thomas, 1996). Prior to the ban on lead shot for waterfowl hunting, it was estimated that 2–3% of the North American waterfowl population perished from ingestion of lead pellets (Bellrose, 1959). Lead poisoning of waterfowl is believed to be almost exclusively from ingestion of pellets with little evidence of poisoning from pellets embedded in muscle or visceral tissues. In contrast, avian predators and scavengers are particularly susceptible to lead poisoning in areas of waterfowl concentrations where lead shot has been used, with the source of the poisoning usually from pellets in the alimentary canal or embedded in the prey or carcass. The toxicology and diagnosis of lead poisoning in wildlife have been extensively reviewed (Eisler, 1988; Franson, 1996; Locke and Thomas, 1996; Pain, 1996).

Like lead poisoning, white phosphorus (P_4) poisoning is mainly a problem for waterfowl that pick up small particles along with other food items in sediments. The source of the contamination was detonation of smoke-producing munitions and is largely confined to a few military training facilities, primary of which is Eagle River Flats, Alaska, USA (Racine *et al*., 1992). In the atmosphere, white phosphorus autoignites and completely oxidizes, but at low temperature in anaerobic sediments it is extremely persistent (Walsh *et al*., 1996) and acutely toxic to waterfowl (mallard oral $LD_{50} = 4\,mg\,kg^{-1}$ (Roebuck *et al*., 1998)). There is also evidence of white phosphorus poisoning predators and scavengers that feed on dead waterfowl.

In contrast to lead and white phosphorus, which are believed to be ingested primarily along with other food items, some GR pesticides may be ingested selectively. When this happens, even small numbers of exposed granules of highly toxic chemicals such as carbofuran may be lethal to many animals (US EPA, 1989; 1991). Like white phosphorus and to some degree lead pellets, secondary toxicity to predators and scavengers is from feeding on granules in the alimentary canal of the carcass rather than from residual concentrations of the substance in postabsorptive tissues and organs. Secondary poisoning from these acutely toxic chemicals is usually from exposure to the unaltered parent compound rather than from residual metabolites accumulating in postabsorptive tissues and fat as described for chlorinated hydrocarbons (Blus, 1995). Regardless of the mechanism, predatory species that normally would not ingest sediments may be poisoned through an intermediate host (e.g. bald eagle, osprey and peregrine falcon).

8.2.6 Avian Food Items

Treated seeds, like GR pesticides, are an important source of chemical exposure to wildlife when the seeds are treated with acutely toxic pesticides for soil insect control, or used as baits and repellents (Stromborg, 1977; Grue *et al*., 1983; US EPA, 1991). However, in contrast to GR materials that are most often ingested haphazardly, chemically treated seeds are readily eaten by small granivorous animals in spite of being brightly coloured for safeguarding human health. Also, the risk is not limited to seeds on the surface of the soil or small animals; large-scale mortality of greylag geese (*Anser anser*) was attributed to the uprooting and ingestion of germinating organophosphorus-treated seeds (Hamilton and Stanley, 1975). It is not known whether phytometabolism of systemic organophosphorus

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

insecticides has contributed to wildlife mortality, but increased risk to herbivores is plausible because sulfoxide and sulfone metabolites may be even more potent than the parent compound.

Pesticide residues in foliage, whether by topical or systemic soil application, may be extremely hazardous to wildlife in or adjacent to the treatment zone. Treatments to control insects in forests and orchards and on cultivated crops such as small grains, alfalfa and turf grasses have all resulted in mortality of wildlife over the years (Smith, 1987; US EPA, 1991). Foliar treatments may be especially hazardous because they may result in exposure by multiple routes when animals are in or possibly even near the spray zone at the time of treatment.

Contaminated arthropods have proved lethal to wildlife after application of insecticides of such diverse toxicity as monocrotophos, dimethoate and trichlorfon (DeWeese *et al*., 1979; Smith, 1987; Goldstein *et al*., 1996). Such poisonings are most likely from chemicals adsorbed on the cuticle of the arthropods. An adsorbed chemical is easily dissociated in the stomach of the consumer. The acute oral LD_{50}s for the above three substances for adult male laboratory rats are reported to be 18, 215 and 630 mg kg^{-1}, respectively, and for adult nonbreeding ring-necked pheasants they are 2.8, 20 and 96 mg kg^{-1}, respectively (Smith, 1987). Insectivorous bird such as the tree swallow (*Tachycineta bicolor*) have been exposed to detrimental levels of mercury (Brasso and Cristol, 2008) and organic contaminants, such as PCBs, (McCarty and Secord, 1999; Custer *et al*., 2003; Echols *et al*., 2004; Papp *et al*., 2007) present in aquatic sediments, by consuming the emerging insects that develop as larvae in the contaminated sediments.

Predatory and carrion-eating birds and mammals are also known to have died from eating vertebrates and carcasses contaminated with a wide spectrum of pesticides, including highly stable chlorinated hydrocarbons and mercurials (Eisler, 1987; Blus, 1995) and more labile anticholinesterases, such as aldicarb, carbofuran, monocrotophos, fenthion, mevinphos, phorate and famphur (US EPA, 1991; Hill, 1995). The chlorinated hydrocarbon and mercurial poisonings were mostly from accumulated carcass residues in prey, whereas the organophosphorus and carbamate poisonings were probably from eating unaltered chemicals in the alimentary canal of the prey, as described for white phosphorus and GR insecticides.

The potential for secondary poisoning of wildlife by anticholinesterases has also been demonstrated with bullfrog prey (Hall and Kolbe, 1980). Tadpoles exposed to as little as 1.0 mg of parathion per litre of water for 96 hours were force-fed to 14-day-old mallards at the rate of 5% of body mass. A single meal was lethal to the ducklings within 30 minutes. Because only parathion, and not its oxygen degradate, was found in the tadpoles and stomachs of the dead ducklings, it is likely that parathion concentrated in the protective mucus layer of the tadpoles and was almost immediately available on ingestion by the ducklings. The treated tadpoles appeared healthy when fed to the ducks. Another anticholinesterase, famphur, was implicated in a case of tertiary poisoning (Henny *et al*., 1985). Black-billed magpies (*Pica pica*) fed on hair and insects contaminated with Warbex that had been used as a back pour-on in cattle for warble control; the magpies either died or were incapacitated by the exposure and were eaten by red-tailed hawks (*Buteo jamaicensis*) which also died.

Soil-dwelling prey such as earthworms often provide a route for soil contaminants into the vertebrate food chain as they bioaccumulate many soil contaminants. Earthworms bioaccumulated fluorine from the soil of an industrial site in southern Germany, and once birds ate the contaminated earthworms, they spread the contaminant throughout the landscape via faeces (Breimer *et al*., 1989). In the urban environment of Montréal, Canada, earthworms bioaccumulated copper, lead and zinc from the soils, reaching an equilibrium with the soil concentrations after two to three weeks (Kennette *et al*., 2002). Earthworms are capable of developing mechanisms allowing them to survive in highly contaminated soils (Langdon *et al*., 2003) making contaminants available to vertebrate predators. Dietrich *et al*. (1995) attribute the deaths of buzzards (*Buteo buteo*) found dead in an agricultural field to consumption of earthworms contaminated with the insecticide carbofuran. Earthworms contaminated from the soils in which they live pass that contamination up the food chain, even to top vertebrate predators such as the peregrine falcon (Enderson and Berger, 1968).

8.3 Toxic Interactions: Chemical

Interaction among xenobiotics and between xenobiotics and natural stressors, such as climatic extremes and infectious diseases, has not been thoroughly studied for wildlife species. The few studies reported are based on subchronic exposure of birds to expected field concentrations of environmentally stable pesticides or contaminants followed by acute challenge with anticholinesterase insecticides, or studies of simultaneous exposure to combinations of common pesticides in the standard five-day feeding trial. The results of these studies are generally consistent with similar studies of laboratory animals, but there are some differences that may affect ecological risk assessment. For example, pretreatment of laboratory rodents with chlorinated hydrocarbon pesticides that increase HMO activity reduced the sensitivity to dicrotophos, parathion and EPN (Ball *et al*., 1954; Triolo and Coon, 1966; Menzer, 1970). In contrast, when DDE was fed to adult Japanese quail at 5–50 mg kg^{-1} in the feed for 12 weeks, the sensitivity to a single dose of parathion increased significantly (Ludke, 1977).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

However, when the quail were pretreated with chlordane, acute sensitivity to parathion was decreased (Ludke, 1977). This observation was also reported in similar studies of laboratory mice (Triolo and Coon, 1966).

Methylmercury decreases HMO in mammals (Lucier *et al*., 1972), blood plasma cholinesterase in birds and mammals (Dieter and Ludke, 1975; Hastings *et al*., 1975; Hill and Soares, 1984), and brain cholinesterase activity in birds (Hill and Soares, 1984). Acute carbofuran dosing was more toxic to Japanese quail pretreated with methylmercury (Dieter and Ludke, 1978). The same relationship was noted for laboratory rats dosed with carbaryl (Lucier *et al*., 1972). In contrast, parathion, which requires HMO activation to its more potent analogue, was also more toxic to Japanese quail pretreated with methylmercury (Dieter and Ludke, 1975). Because methylmercury depresses HMO activity, pretreatment with methylmercury should have increased the toxicity of direct cholinesterase inhibitors, as seen for carbamates and decreased the toxicity of organophosphorus compounds that require activation. It is suggested that blood plasma cholinesterase provides some degree of protection by binding a portion of absorbed anticholinesterase and rendering it unavailable for binding with cholinesterase in the central nervous system, the main target of acute anticholinesterase toxicity.

8.4 Toxic Interactions: Environmental

Temperature extremes and season of the year are natural stressors that can affect the toxicity of xenobiotics to wildlife, but neither variable has been thoroughly investigated in nature or the laboratory. Some findings and tentative conclusions follow. Continuous exposure to both high (37 °C) and low (4 °C) temperatures for 14 days increased the sensitivity of adult Japanese quail to the acute toxicity of parathion (Rattner *et al*., 1987). Low temperatures also caused birds to increase their rates of feeding per unit of body mass by an average of 67%. This combination of increased sensitivity and energy demand certainly increases the potential risk and probably contributes to the vulnerability of waterfowl and passerines to winter application of anticholinesterase-treated seed grains (Stanley and Bunyan, 1979; Stone *et al*., 1984). In contrast, the above-mentioned quail exposed to 37 °C ate about 55% less than those exposed to 4 °C. This implies some possible degree of protection from anticholinesterase poisoning, but in this study, the birds exposed to 37 °C were more sensitive to parathion than those exposed to 4 °C (Rattner *et al*., 1987). Heat stress was suggested as a contributor to dimethoate toxicity in an episode of sage grouse (*Centrocercus urophasianus*) poisoning in Idaho, USA (Blus *et al*., 1989). These and other examples of conflicting results from toxicity tests at extreme ambient temperatures simply reflect natural responses to conditions deviating markedly from thermoneutral for the species. Environmental factors affecting xenobiotic toxicity in wildlife have been reviewed (Rattner and Fairbrother, 1991; Rattner and Heath, 1995).

8.5 Diagnosis of Acute Exposure

Since the 1950s, acute toxicity of many chlorinated hydrocarbon, mercurial, organophosphorus and carbamate insecticides has resulted in wildlife mortality in association with agriculture throughout the world (Borg *et al*., 1969; Mendelssohn and Paz, 1977; Hamilton *et al*., 1981; US EPA, 1991; Goldstein *et al*., 1996). Acute lead poisoning from lead shot in major waterfowl concentration sites was also an international problem (Locke and Thomas, 1996). Though the causative agent was usually obvious in incidents of mass mortalities of mixed species, it was not so obvious in cases of individual deaths or small-scale mortality of single species, where infectious diseases or other exogenous stressors may have been present. Thus, specific diagnostic methods were needed to evaluate wildlife mortality properly.

Initially, the emphasis of diagnostic technology was on determination of chemical residue levels that were indicative of death from persistent chlorinated hydrocarbon and mercurial pesticides. As the 'DDT era' came to a close in the 1970s, attention shifted to the more environmentally labile, but acutely toxic anticholinesterase insecticides and to a myriad of agricultural and industrial effluents. With these substances chemical residues were not well correlated with effect and often could not be detected at all in key tissues and organs. Wildlife toxicologists, physiologists and chemists borrowed extensively from biomedical techniques for baseline work, but then had to adapt and validate methods for an array of species of widely variable physiology and sensitivity to xenobiotic exposure.

The basic techniques that have proved useful in the diagnosis of lethality or significant toxicity from a specific chemical include brain residues of chlorinated hydrocarbon pesticides (death; Blus *et al*., 1996), brain cholinesterase inhibition (death; Fairbrother, 1996) and red-blood-cell δ-aminolaevulinic acid dehydratase (lead exposure; Locke and Thomas, 1996). Diagnostic brain residues have been determined for DDT and its principal metabolites DDD and DDE, dieldrin, heptachlor, chlordane, oxychlordane, endrin, mirex and the polychlorinated biphenyl aroclor 1254 (Heinz *et al*., 1979; Blus, 1995). For each of these chemicals there is a general threshold level of residue associated with lethality that holds true across a wide range of birds and mammals (Heinz *et al*., 1979). Other tissues, such as fat, liver and kidney, may accumulate significant concentrations

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of lipophilic pesticides and other contaminants, but none has proved useful in conclusive diagnosis of lethality.

Brain cholinesterase inhibition has been used to diagnose death from anticholinesterase exposure, but the causative chemical is sometimes difficult to determine because neither organophosphorus nor carbamate residues tend to accumulate in postabsorptive tissues. However, a strong inferential diagnosis is possible by demonstrating depressed brain cholinesterase activity and detection of a known anticholinesterase in either ingesta or tissues (Hamilton *et al*., 1976; Hill and Fleming, 1982). A conservative threshold of about 50% depression in whole-brain cholinesterase activity is generally considered diagnostic of death from anticholinesterase poisoning (Ludke *et al*., 1975), although depression of 70–95% is commonly reported for birds killed in the field by organophosphorus insecticides (Hill and Fleming, 1982). In contrast, when birds are killed in the field by carbamates, whole brain cholinesterase activity may vary from near normal to depressions of only 60–70% (Hill and Fleming, 1982; Flickinger *et al*., 1986). Apparently, high levels of carbamate exposure kill by systemic neuromuscular blocking before significant penetration of the central nervous system has occurred (Westlake *et al*., 1981). Also, lower cholinesterase inhibition may reflect spontaneous postmortem reactivation of carbamylated enzyme (Hill and Fleming, 1982; Hill, 1989).

9 ENDOCRINE DISRUPTION

An environmental endocrine disruptor has been broadly defined as an exogenous agent that interferes with the production, release, transport, metabolism, binding, action or elimination of natural hormones in the body responsible for the maintenance of homoeostasis and the regulation of developmental processes (Kavlock *et al*., 1996). However, Guillette (2006) has recently suggested that the focus be expanded to include prostaglandin synthesis as a target for endocrine disruption, since these hormones are active in reproduction, immune responses and cardiovascular physiology.

In the early 1990s attention was drawn to impacts of endocrine-disrupting chemicals based to a great extent on studies from the Great Lakes region of the USA and Canada (Colborn *et al*., 1993). Exposure to endocrine-disrupting chemicals in the environment was believed to be associated with abnormal thyroid function in birds and fish; decreased fertility in birds, fish, shellfish and mammals; decreased hatching success in fish, birds and turtles; demasculinization and feminization of male fish, birds and mammals; defeminization and masculinization of female fish, gastropods and birds; and alteration of immune function in birds and mammals.

One of the most widely reported incidents where endocrine disruption was identified in wildlife was in alligators (*Alligator mississippiensis*) in Lake Apopka and Lake Okeechobee Florida, USA (Crain *et al*., 1998). They found that juvenile male alligators from contaminated lakes had lower levels of testosterone and increased levels of thyroxin. The reduction in testosterone levels was thought to be the cause of the highly publicized inhibition of penis growth in the juvenile males (Crain *et al*., 1997).

Various endocrine-disrupting contaminants such as some pesticides, phytoestrogens, pharmaceutical pollutants and heavy metals have the potential to alter sex determination, differentiation and maturation. Orlando and Guillette (2007) review the potential impacts that endocrine disruptors have on sex determination in different taxonomic groups. In teleost fishes, sex determination, differentiation and maturation can be affected and the genetic sex of the individual does not influence whether a response occurs or not. In frogs, crocodilians and turtles, environmental factors with oestrogenic activity can redirect sex determination, altering differentiation and maturation and producing apparently normal females or individuals with a mostly female phenotype. In birds and mammals, neither endogenous nor exogenous compounds with sex steroid activity affect sex determination—the formation of an ovary or testis is determined by the presence of specific genes.

These studies and many others led the US EPA to form the Endocrine Disruptor Screening and Testing Advisory Committee (EDSTAC) which published its final report in 1998. An outcome from the efforts of this committee was the development of a new series of tests for pesticides and high production volume (HPV) chemicals. The Tier 1 screening tests developed in conjunction with the OECD will include a battery of screening assays that would identify substances with the potential to interact with the oestrogen, androgen or thyroid hormone systems.

Toxicity testing required by US EPA and OECD has historically been restricted to avian tests that provide acute oral toxicity, acute dietary toxicity and reproductive toxicity. A wild mammal toxicity test protocol exists, but it is rarely performed. Once the endocrine testing has been fully implemented, the tests will be expanded to include an amphibian metamorphosis test (OECD, 2004), an amphibian two-generation test (Battelle, 2004) and an avian two-generation test (Battelle, 2005). Additional mammalian and *in vitro* tests also will have implications for impacts on wildlife.

10 PHARMACEUTICALS

Pharmacologically active compounds have been identified in wastewater treatment plant effluent (Hua *et al*., 2006) and in soils receiving treated sludge from sewage (Gielen, 2007). Pharmaceuticals are released into the environment purposefully after disposal or inadvertently

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

via excretion by consumers, primarily through sewage. Numerous bioactive metabolites from any single pharmaceutical might be excreted in combination, or the parent pharmaceutical could be abiotically transformed in sewage treatment plants or by the environment. The continual release of pharmaceuticals and metabolites gives them a 'pseudo-persistent' presence in any aquatic environment that receives sewage input from humans or domestic animals (Daughton, 2003).

It is now known that a wide range of human pharmaceuticals, including analgesics, antibiotics, steroids, many cardiovascular drugs and various drugs used to treat mental illness, are all present in water treatment effluents that enter rivers (Runnalls *et al*., 2007). Little is known about the possible ecological risks of most of pharmaceutical chemicals once they become dispersed in the environment. This lack of knowledge has resulted in a substantial amount of effort to develop data and approaches for assessing the impact of pharmaceuticals in the environment (Ankley *et al*., 2007). Sanderson *et al*. (2004a) report that ecotoxicity data were available for $<1\%$ of pharmaceuticals and their adjuvants. Elsewhere, Sanderson *et al*. (2004b) suggest the greatest impact on wildlife is the potential for a pharmaceutical class of sex hormones acting as endocrine modulators in wildlife. Since pharmaceuticals most often enter the environment via wastewater, aquatic species have received more attention regarding the impacts on wildlife than have terrestrial species. Even aquatic species lack sufficient data to decide whether pharmaceuticals pose a significant threat to the environment (Crane *et al*., 2006).

A recent example of pharmaceuticals impacting wildlife is the widespread mortality of vultures on the Indian subcontinent (Green *et al*., 2004). The Oriental white-backed vulture (*Gyps bengalensis*) was once one of the most common raptors in the Indian subcontinent. A population decline of $>95\%$, began in the 1990s. The unusual pattern of mortality was first observed in early 1997, among the vultures nesting in Keoladeo National Park in northwestern India. Birds dropped from their perches to die shortly afterwards (Risebrough, 2004). Declines, also involving *Gyps indicus* and *Gyps tenuirostris*, have continued to be reported across the subcontinent. Diclofenac was identified as the cause of the renal failure that caused the deaths of both adults and subadults (Oaks *et al*., 2004; Meteyer *et al*., 2005). Diclofenac is a nonsteroidal anti-inflammatory drug used in domestic livestock, and remains available to vultures in the carcasses from recently treated animals (Taggart *et al*., 2007).

In recent reviews (Fent *et al*., 2006; Dorne *et al*., 2007), the only conclusive effects of pharmaceuticals on wildlife were the example above of the impacts of diclofenac on vultures and the impacts that synthetic steroid hormones such as 17α-ethinylestradiol (EE2) and 17β-estradiol (E2) have on fish. Until more is known about the impact that pharmaceuticals have on wildlife, the environmental matrices in addition to water likely to contain such chemicals, and the concentrations at which these chemicals have impacts, regulating them will be difficult. However, because considerable toxicological data exists for pharmaceuticals for humans and standard laboratory test species, a first step might be to extrapolate from these species to wildlife receptors (Dorne *et al*., 2007).

Most pharmaceuticals having environmental relevance share the following properties: often, but not always, HPV combined with environmental persistence and biological activity, mainly after long-term exposure (Fent *et al*., 2006). Most environmental legislation aimed at protecting wildlife from industrial chemicals sets production volumes below which either no testing is required, or the testing is tiered, becoming progressively more rigorous as production volume increases, based on the thinking that as more of a chemical is produced, the greater the concentration likely to be present in the environment, and therefore, the greater the possibility that adverse effects on organisms will occur (Ankley *et al*., 2007). Another source for exposure of wildlife to pharmaceuticals is crops that have been genetically modified to produce pharmaceuticals (Becker and Vogt, 2005). For example since 1987, the United States Department of Agriculture's Animal and Plant Health Inspection Service's Biotechnology Regulatory Services has issued 110 pharmaceutical and industrial permits in 11 crops. Since less than 350 acres have been grown since 2002 (Smith, 2005), this is currently a minor source for exposure, but that might increase.

In early 2001, a draft guideline on ecological risk assessments for non-GMO-containing drugs was published by the European Medicines Evaluation Agency (EMEA). The first tier consists of deriving a crude predicted environmental concentration (PEC) in the aquatic compartment for the active pharmaceutical ingredient (API) or its major metabolites, based on predicted amounts used and specific removal rates in sewage treatment or surface waters. If this crude PEC is $<0.01\,\mu g\,l^{-1}$ and no environmental concerns are apparent, no further assessment is deemed necessary. Otherwise, in the second tier, a crude predicted no-effect level (PNEC) for the aquatic compartment is to be extrapolated by dividing the lowest 50% effect concentration from acute ecotoxicity tests with algae, daphnia or fish (EC_{50}, LC_{50}) by an assessment factor (usually 1000). If the ratio PEC/PNEC is <1, no further assessment is deemed necessary. Lastly, in the third tier, further considerations might be needed. This may encompass refining the environmental fate information and thereby the PEC, considering further environmental compartments and their respective PECs (up to and including field studies), but also refining the PNEC (Straub, 2002). A PEC for human pharmaceuticals of $>0.1\,\mu g\,l^{-1}$ necessitates aquatic ecotoxicity testing. However, if a drug (or one of its degradation products)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

is already known, or can be reasonably expected, to affect aquatic wildlife at concentrations $<0.01\,\mu g\,l^{-1}$, then the action limit of $0.01\,\mu g\,l^{-1}$ does not apply, and further analyses must be conducted (Ankley *et al*., 2007).

11 IMMUNOTOXICOLOGY

Factors that may influence immune responses in wildlife include age, body condition, season, developmental stage of the immune system and time required for the progression of immune responses (Grasman, 2002). In birds, the thymus and bursa of Fabricius are the sites of maturation of T and B lymphocytes, respectively. Mature T and B cells and macrophages interact in the spleen during immunological responses. Hence, the mass, cellularity and histology of these organs can provide important general information on the maturation and structure of the immune system and have been assessed in several wildlife studies (**Table 1**). While not all chemicals cause atrophy and (or) histological changes in immune organs, when such alterations occur they are usually associated with altered immunological function, making these variables useful end points in studies where lethal sampling is employed (Grasman, 2002).

Laboratory assays of immunological function are highly sensitive to contaminants. Such tests include *in vivo* skin tests for T cell function, *in vivo* antibody responses, *in vitro* lymphocyte proliferation and phagocytosis assays. Other tests include the DTH (delayed-type hypersensitivity) assay which tests for T-cell-dependent inflammation. Intradermal or subdermal injections of specific antigens to which the animal has been previously immunized stimulate T cells to release cytokinins, causing a localized inflammation. The DTH test is not very practical for use in wild birds, since it often requires multiple immunizations several weeks apart. The two most commonly used *in vivo* immune function tests in birds are the phytohaemagglutinin (PHA) skin response for T cell-mediated immunity and the sheep red blood cell (SRBC) haemagglutination assay for antibody-mediated immunity (Grasman, 2002). The PHA skin response is more practical for wild birds than the DTH test since it requires only a single injection with no prior sensitization (Rollins-Smith *et al*., 2007). PCBs (polychlorobiphenyls) and other organochlorines and lead suppressed the PHA response (Rollins-Smith *et al*., 2007).

Assessment of plasma or serum protein concentrations can provide important data on health and physiological status, including immune and inflammation responses. Relative and total amounts of albumins and α-, β- and γ-globulins are affected by infections, inflammation and physiological status. Antibody responses may increase γ-globulins. Inflammation may increase positive acute phase proteins (α-globulins such as antitrypsin, α_2-macroglobulin and haptoglobin, and β-globulins such as fibrinogen, C3, C4, ferritin and amyloid A) and decrease prealbumin, albumin and transferrin (Grasman, 2002).

While measures of immunological structure assess the status of the immune system, they do not directly test immune function (i.e. how the immune system responds to specific challenges). The PHA skin response test has been used as a measure of T-lymphocyte function in laboratory experiments and human and veterinary medicine, and is one of the most common assays in wildlife studies. Common sites of injection in birds include the wing web, wattle, dewlap and interdigitary skin. Maximal inflammation occurs 12–24 hours after injection. Usually, phosphate buffered saline (PBS), the carrier for the PHA, is injected into an alternate site (e.g. other wing web or wattle). The response to PHA is calculated as the increase in skin thickness caused by PHA minus the increase caused by PBS alone (Grasman, 2002).

Like skin tests, measurement of antibody titres following immunization with an antigen integrates a large number of immunological functions and events. The tests are minimally invasive, but do require recapture of test animals approximately one week after immunization. Enzyme-linked immunosorbant assays (ELISAs) are commonly used to assess immune function in humans, rodents and domestic animals. However, ELISAs require antibodies that specifically bind to the antibodies produced by the test subjects. Such species-specific antibody reagents are not available for most wildlife species. Alternatively, the anti-SRBC haemagglutination test has been employed successfully in many species of wild birds. Blood plasma is collected from birds approximately six days after immunization with SRBC. Serial dilutions of the plasma are incubated with SRBC in microtitre plates. If sufficient antibody activity is present, the antibodies will agglutinate the SRBC, which causes a visible spreading of the SRBC on the bottom of the wells. If sufficient activity is not present, the SRBC will not spread and will form a distinct 'button' at the bottom of the V-shaped well. The higher the antibody activity or titre, the more the plasma sample can be diluted before the agglutination stops. The agglutination activity is caused by both IgM and IgG. Preincubation of the plasma with 2-mercaptoethanol dissociates IgM, and any residual agglutinating activity is attributable to IgG, which is more prevalent in memory responses (Grasman, 2002).

White blood cells are the effector cells of immune responses and have been assessed in many immunotoxicological studies of avian wildlife (**Table 1**). Lymphocytes are important for T-cell-mediated and antibody-mediated responses, as well as nonspecific natural killer cell cytotoxicity. Monocytes are important for phagocytic responses. Neutrophils or heterophils provide an important first line of defence against

Table 1 Measures of immunological structure in toxicological studies of free-living and captive avian wildlife species

Variable	Species (captive/wild)	Contaminant(s)	Findings/comments	Reference
Immune organ mass /cellularity/ histology	Mallard (C)	Selenium	No effect on spleen mass	Fairbrother and Fowles (1990)
	Mallard (C and W)	Lead	Decreased spleen mass in females intubated with 2 #4 Pb shot	Rocke and Samuel (1991)
	European starling (C)	DMBA	Decreased spleen mass and cellularity in adults exposed subcutaneously to 125 mg (kg body mass)$^{-1}$	Trust *et al*. (1994)
			Decreased bursa mass in nestlings exposed orally to 100 mg (kg body mass)$^{-1}$	
	Tree swallow (W)	Orchard pesticides	Body and thymus masses correlated with collection date; bursa mass associated with spraying; some histological alterations associated with spraying.	Bishop *et al*. (1998)
	Herring gull (W)	Dioxin-like organochlorines	Negative association between thymus mass and liver EROD (ethoxyresorufin *O*-deethylase) activity (index of exposure to dioxin-like chemicals); no associations between thymus mass and organochlorine concentrations measured in eggs	Grasman (2002)
	Herring gull (W)	Organochlorines	Negative associations between PCBs and thymocyte numbers and between DDE and lymphoid cells in bursa in pipping herring gull embryos	Grasman unpublished data
White blood cell numbers	Japanese quail (C)	Paraquat, ethyl methanesulfonate	Increased heterophils, decreased lymphocytes and monocytes	Clark *et al*. (1988)
	Mallard (C)	Selenium	No effect on white blood cell numbers	Fairbrother and Fowles (1990)
	Mallard (C and W)	Lead	Decreased total white blood cells, heterophils, lymphocytes and monocytes in males intubated with 2 #4 Pb shot; no effect in females	Rocke and Samuel (1991)
	American avocet (W)	Selenium, arsenic, and boron	Increased heterophil/ lymphocyte ratio in one pond following *in ovo* exposure	Fairbrother *et al*. (1994)

Table 1 (*continued*)

Variable	Species (captive/wild)	Contaminant(s)	Findings/comments	Reference
	European starling (C)	DMBA	Increased heterophil/lymphocyte ratio in adults exposed subcutaneously to $\geq$50 mg (kg body mass)$^{-1}$ or orally to 300 mg (kg body mass)$^{-1}$	Trust *et al*. (1994)
	Japanese quail (C)	Lead	Marginally significant increase in heterophil/lymphocyte ratio in corn-fed quail exposed to 100 and 400 ppm lead in drinking water; no effects seen in lead-exposed quail fed commercial feed	Grasman and Scanlon (1995)
	Herring gull (W)	PCBs, DDE	No associations with white blood cell numbers	Grasman *et al*. (1996)
	Caspian tern (W)	PCBs, DDE	Positively associated with heterophil/lymphocyte ratio in one year only	Grasman *et al*. (1996)
	Mallard (C)	PCBs	No effects on white blood cell numbers	Fowles *et al*. (1997)
	Tree swallow (W)	Orchard pesticides	Heterophil numbers negatively associated with collection date; lymphocyte numbers reduced with pesticide sprays	Bishop *et al*. (1998)
	Zebra finch (C)	Oil sands tailings water	No effect on white blood cell numbers	Smits and Williams (1999)
	Herring gull (W)	PCBs, DDE, dioxin-like chemicals	In adults, total WBC and heterophil numbers positively associated with liver EROD and negatively associated with DDE, lymphocyte numbers negatively associated with PCBs, and heterophil/lymphocyte ratio negatively associated with liver EROD; in prefledglings, heterophil-lymphocyte ratio positively associated with dioxin-equivalents	Grasman *et al*. (2000b)
	Caspian tern (W)	PCBs, DDE	Plasma PCBs and DDE negatively correlated with % monocytes and positively correlated with % basophils	Grasman and Fox (2001)
Plasma proteins	Herring gull (W)	PCBs, DDE	Positive association with B_2-globulins in prefledglings	Grasman *et al*. (2000a)
	Caspian tern (W)	PCBs	Positive association with B_1-globulins and negative association with a-globulins in prefledglings	Grasman *et al*. (2000a)

bacterial infections, while eosinophils fight parasitic infestations. Blood cell counts are minimally invasive and relatively easy to conduct. Total and differential white-blood-cell counts are commonly used as clinical indicators of immunological and infection status. Decreased numbers of specific cell types may suggest reduced functions associated with these cells, and increased numbers may suggest a response to infection. In either case, altered white blood cell counts should be followed up by tests of immune function to better characterize potential immunological effects (Grasman, 2002).

11.1 Amphibians

Amphibian metamorphosis is a complex process, during which the developing immune system is undergoing rapid development and expansion. Contaminants such as perchlorates can alter thyroid hormone activity, thus impairing the development of the immune system. Similarly, contaminants that interfere with the action of corticosteroid hormones can inhibit the naturally occurring loss of lymphocytes at metamorphosis, which could lead to the development of autoimmunity due to adult-specific lymphocytes that emerge at metamorphosis (Rollins-Smith *et al*., 2007).

Environmentally relevant concentrations of atrazine, metribuzin, aldicarb, endosulfan, lindane and dieldrin showed immunosuppression in juvenile leopard frogs (*Rana pipiens*) and African clawed frogs (*Xenopus laevis*). Spleen cell numbers were reduced and phagocytic activity was impaired. Lymphocytes from pesticide-treated leopard frogs exhibited reduced T-cell proliferation *in vitro* in response to mitogens, and the frogs developed increased parasitism when challenged with parasitic nematodes (Rollins-Smith *et al*., 2007). An impaired immune system resulting from exposure to pesticides or other contaminants also can make amphibians more susceptible to infection by trematodes. Exposure to malathion and atrazine affected the degree of infection of wood frog (*Rana sylvatica*) tadpoles by trematodes capable of inducing limb deformities. Increased malathion or atrazine caused a greater degree of parasitism and fewer circulating eosinophils (Rollins-Smith *et al*., 2007). Exposure to contaminants that alter the rate of metamorphosis could impair immune defences of amphibians in a variety of ways that are not well understood (Rollins-Smith *et al*., 2007).

Little is known regarding the impact of contaminants on immune response in amphibians in general, with even less known about the specifics in urodele amphibians (salamanders). Urodele amphibians lack some of the more evolved aspects of lymphocyte-mediated, specific immunity that are present in anurans (frogs and toads), birds and mammals (Froese *et al*., 2005).

11.2 Birds

The study of immunotoxicology in birds lags behind mammalian immunotoxicology. The structure and function of the avian immune system has often been affected by a diverse array of contaminants, including heavy metals, pesticides, petroleum hydrocarbons and organic industrial chemicals (Day *et al*., 1995; Galloway and Handy, 2003; Rollins-Smith *et al*., 2007) and possibly the explosive 2,4,6-trinitrotoluene (TNT) (Gogal *et al*., 2002).

No field studies of measured immune suppression have reported an association with an avian epizootic. It is more likely that the immune suppression in adult birds resulting from low-level chronic stress (e.g. crowding onto poor-quality habitat, food reductions or climate stress) and (or) environmental contaminants causes slow but consistent morbidity and mortality associated with multiple pathogens, rather than an acute epizootic with a single pathogen. Increased fitness costs associated with such stress may significantly alter genetic diversity and species survival over time (Fairbrother *et al*., 2004).

11.3 Terrestrial Mammals

Human and wildlife monitoring studies have identified perfluoroalkyl acids (PFAAs) and perfluorooctane sulfonate (PFOS) worldwide (Lau *et al*., 2007; Peden-Adams *et al*., 2007). There has been substantial progress in understanding additional aspects of the toxicology of these compounds, particularly related to the developmental toxicity, immunotoxicity, hepatotoxicity and the potential modes of action. Principally from studies in laboratory mice, PFAAs have led to decreased body weight, elevation of liver weight and decreases in thymus and spleen weight (both absolute and relative weights). The primary humoral response to horse red-blood cell immunization was prevented by perfluorooctanoic acid (PFOA) pretreatment while *ex vivo* spleen cell proliferation in response to both T- and B-cell activation was attenuated by the fluorochemical (Lau *et al*., 2007). Studies show that these perfluorinated compounds induce peroxisomal proliferation, induce hepatomegaly, alter steroidogenesis and decrease body weight, accompanied by a wasting syndrome; however, effects on immune function have not been addressed at length. Sulfluramid, a perfluorinated pesticide, targets T-dependent, IgM antibody production at exposure levels 10-fold less than that observed with overt toxicity (as indicated by decreases in body weight gain) (Peden-Adams *et al*., 2007).

One possible mechanism of PCB toxicity to wildlife is through immunosuppression and subsequent increase in disease rates. When white-footed mice (*Peromyscus leucopus*) were exposed to PCBs as adults via the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat094
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

diet, their offspring exhibited impacts to their immune response. The thymus was the most severely affected organ of the immune system; thymic weights did not differ between the groups, but the number of thymocytes of the treated animals was significantly lower than that of the control animals. Toxic effects, especially on the immune system, of chronic exposure to PCBs, at levels comparable to exposure found in contaminated sites in the USA, are evident in adult white-footed mice. The thymus seems to be the most persistently affected organ. However, these alterations did not translate into any evident impairment of the specific humoral immune response to the T-dependent antigen assayed (Segre *et al*., 2002).

Immune function was measured in populations of wild cotton rats (*Sigmodon hispidus*) inhabiting replicated reference and contaminated study sites at an abandoned oil refinery in Oklahoma four times from 1991 to 1992. Several measures of immunocompetence were examined including immune organ mass and cellularity, haematology, *in vivo* hypersensitivity, macrophage function, killer cell activity and lymphoproliferative responsiveness. *In vitro* proliferation of splenocytes, either spontaneous or induced with concanavalin A (Con A), was the most consistent and reliable indicator of immunotoxicity (McMurry *et al*., 1999).

11.4 Marine Mammals

Marine mammals have received attention regarding the impacts of contaminants on their immune response. Although mechanisms of action are often ill-defined in field studies, a common pattern of adverse health effects observed in contaminant-exposed individuals and populations includes developmental, immunologic and reproductive effects. Despite having been banned in North America for three decades, the highly persistent PCBs continue to present a toxic risk to wildlife and dominated the contaminant profiles in studies of British Columbia and Washington State harbour seals (*Phoca vitulina*). Gertrude Island (Puget Sound) harbour seals were particularly contaminated, having PCB concentrations that were several times higher than those sampled in the adjacent coastal waters of northern Washington State and southern and central British Columbia. The observed negative relationship between circulating thyroxin and PCB concentrations in harbour seals contributes to the notion that PCBs represent a significant health concern at the top of the food chain (Tabuchi *et al*., 2006). However, Barron *et al*. (2003) state that, based on very limited blubber data, current levels of PCBs might not pose a risk to Steller sea lions (*Eumetopias jubatus*), in comparison to immunotoxicity tissue benchmarks. They indicate that there are insufficient data to reject the hypothesis that contaminants play a role in the continued decline of Steller sea lions, and suggest that a coordinated monitoring programme be developed which can be related to key biological, ecological and laboratory toxicity data. Ross *et al*. (1995) identified immunotoxic impacts in harbour seals fed herring from the Baltic Sea, but could not determine which of the contaminants identified in the herring was responsible.

Soil and Fresh Water

Trond Peder Flaten and Eiliv Steinnes

CONTENTS

1 INTRODUCTION

In the environmental science literature, nature is commonly divided into different spheres. In this respect, the soil is termed the *pedosphere*. The pedosphere interacts with all the other spheres; the lithosphere (the Earth's crust), the hydrosphere, the atmosphere and the biosphere. In particular, soil and water systems are intimately inter-related through a complex web of interactions. Almost all soils contain water, and all water systems contain suspended (mainly soil-derived) solid particles. Most chemical reactions in nature take place at the interface between solids and water (Stumm and Morgan, 1996). Most dissolved and suspended material in water has passed through soil and ground. Therefore, in most cases it is necessary to apply an integrated approach to the discussion of toxic substances in soil and fresh water. The prime focus in the present chapter is on soil; water will be discussed mainly as an exposure route from soil to humans.

Matter moves through the different spheres in nature in biogeochemical cycles. Transport is mostly in water via the hydrological cycle, as dissolved ions and molecules, or as colloids and suspended particles, and most substances present in fresh water will have passed through the soil. Thus, the concentrations present in water will depend on which chemical reactions these substances undergo in the soil. Also, a particular element may exist in nature as many different *species*, that is, different physicochemical forms of the same element. For example, the element iodine may exist in aqueous solution as I_2, I^-, I_3^-, HIO, IO_3^-, as ion pairs or complexes, as various organic iodo compounds or adsorbed on suspended solids (Stumm and Morgan, 1996). Properties such as mobility, toxicity and

bioavailability of a particular element generally depend heavily on its speciation.

For a particular element, the most important variables governing speciation are: (i) particulate vs. dissolved state in aqueous solution, (ii) variations in oxidation state and (iii) ligand(s) to which the element may be chemically bound. Some general relationships between the fundamental chemical properties of different elements and their respective biological effects may be illustrated by comparing aluminium and mercury. These two metals are on the extreme ends of the scale from class A metals, which largely bind to oxygen-containing ligands (both in the environment and in biological systems), to class B metals, which seek sulphur- and nitrogen-containing ligands (Nieboer and Richardson, 1980). Mercury, being the archetypal class B metal, binds strongly to the ubiquitous sulfydryl groups on proteins and enzymes, whereas sulfydryl groups are totally irrelevant as targets for aluminium toxicity. Further, while variation in oxidation state is a major determinant of the biological properties of mercury (0 in metallic, gaseous mercury, +1 or +2 in inorganic salts and +2 in methylmercury), +3 is the only biologically relevant oxidation state for aluminium. For aluminium, on the other hand, many different potential ligands are available in the environment and in biological systems, and sorting out which ligands are relevant under different conditions has proved to be a very difficult task.

The speciation of an element may change several times from its source, through cycling in the environment and on its way through different compartments of the organism to the final target site. For example, acid precipitation (Section 5.6) leads to mobilization of aluminium from soils and bedrock (Driscoll and Postek, 1996). In the subsequent transport of dissolved aluminium through soil water, groundwater, rivers and lakes, aluminium may change ligands several times, depending on the chemistry in the different bodies of water. Relevant ligands in natural waters include OH^-, F^-, H_4SiO_4, HSO_4^- and a host of naturally occurring organic compounds. After uptake from the gastrointestinal tract, aluminium probably largely follows the iron pathway in being bound to transferrin in blood and extracellularly, while the slightly more acid intracellular environment favours binding to phosphate-containing ligands, such as inositol or membrane phosphate groups (Birchall and Chappell, 1988).

The chemical reactions taking place in water (including the aquatic phase of soils) are commonly categorized in the following types: acid–base reactions; oxidation–reduction reactions (equilibria depending largely on the availability of oxygen in the soil–water system); dissolution–precipitation reactions; complexation reactions and ion exchange–adsorption reactions (Stumm and Morgan, 1996). The overall balance of all such reactions determines how a particular substance distributes between the solid and aqueous phases in nature, and hence its mobility, and ultimately its availability and potential toxicity to humans and other organisms.

When toxic substances in soil and water are discussed, the focus is usually on anthropogenic pollutants, as in this chapter. However, one should not forget that the natural environment in many cases contains harmful concentrations of various compounds. For example, in a study conducted in pristine areas of Norway, where the mineral galena (lead sulfide) occurs in the bedrock, Låg and Bølviken (1974) reported lead concentrations (dry matter) of up to 10% in soil, 0.4% in moss and 0.04% in grass. They concluded that natural metal poisoning of soil and vegetation is more common than previously thought, and that it seems possible that in such areas the local herbivores may accumulate metals. In the Tantramar swamp in New Brunswick and Nova Scotia, Canada, Dykeman and de Sousa (1966) reported copper concentrations up to 7% dry weight in surface peat that was filtering naturally copper-rich spring water (up to 1 mg l^{-1} Cu) emerging into a marsh. These two examples concern metals, but the natural environment also contains many substances that until recently were believed to have exclusively anthropogenic sources. Notably, a large number of chlorinated and other halogenated organic compounds are produced naturally by plants, marine organisms, insects, bacteria, fungi and mammals, and by other natural processes such as volcanoes and forest fires. The number of known natural organohalogens has passed 2000 and is increasing rapidly (Gribble, 1996). Naturally produced halogenated compounds include chlorinated phenols, chloroform and even such compounds as dioxins (Ferrario *et al*., 2000) and chlorofluorocarbons (Frische *et al*., 2006). Plants and animals secrete such chemicals mainly as part of their chemical defence—as feeding deterrents, irritants or pesticides—and some of these compounds may find clinical use as antibiotics or antitumour agents.

We have chosen to devote more space to metals than to organic compounds. Among the metals, particular attention is given to cadmium, not because it is that more important than, for example, lead or mercury as an environmental health hazard, but because it serves well to illustrate different principles and mechanisms in soil- and water-related environmental toxicology.

The main emphasis in this chapter is on relevance to human health. There are numerous possible pathways of potentially toxic compounds from soil–water systems to humans. In some cases, humans are directly exposed, through airborne dust or through hand-to-mouth contact, which is particularly relevant for children. However, the transfer of toxic substances from soils to humans is usually indirect, through uptake in food plants, through further transfer up food chains (e.g. to fish and game) and

through leaching into water and intake through drinking water.

Because it constitutes an important pathway from soil via fresh waters to humans, drinking water is treated in some detail, both under different headings in Section 5 and in Section 6 on drinking water. We have also chosen to give considerable attention to the possible human health effects of acid precipitation (Section 5.6). Ecotoxicology, that is, the branch of toxicology that studies the toxic effects of substances on nonhuman organisms that constitute the biosphere (Hoffman *et al*., 2003), is treated in other chapters in this book.

2 GENERAL DESCRIPTION OF THE NATURE AND PROPERTIES OF SOILS

The Earth's bedrock is almost universally covered by unconsolidated material known as *regolith*, the thickness of which may vary from negligible to hundreds of meters. *Soil* is usually defined as the upper layer of the regolith influenced by processes governed by climate and by living organisms. This layer, typically around 1 m thick, is where plants grow. It is therefore the basis of all higher forms of life on land, and differs from the underlying material in several respects. It is higher in organic matter, since plant residues deposited originally on the surface have been transformed by soil animals and decomposed by micro-organisms. Being near the surface, the soil has been subject to more intense weathering than the deeper layers of the regolith. The main factors determining the properties of the soil (termed *soil-forming factors*) are climate (particularly temperature and precipitation), the living organisms, the surface topography, the time period for soil formation and the properties of the mineral material (termed the *soil parent material*) where the soil formation takes place. For a standard textbook on soil and soil properties, see Brady (1990); special attention to soil chemistry is given by Sposito (1989), and McBride (1994) gives a treatment emphasizing the environmental chemical aspects of soils.

2.1 Soil Components

Soil consists of four major components: mineral material, organic matter, water and air. Water and air occupy the pore space in between solid particles of mineral and organic material. A typical volume composition of a fertile agricultural soil may be as follows: mineral, around 50%; air, 20–30%; water, 20–30% and organic, around 5%. In undisturbed natural soils, accumulation of organic matter to a much higher fraction often occurs in the surface layer, especially in temperate regions. Because the soil organic matter has a high binding capacity for many inorganic and organic chemical compounds, such *humus* layers may accumulate toxic substances added to the soil surface. The free soil water, often named *soil solution*, is very important as the medium for plant root uptake of nutrients and other substances, for the release from and fixation to the soil solid phase, for chemical reactions in soils in general, and for vertical and horizontal transport of dissolved components. This vertical transport in the soil solution is essential for the development of soil horizons and soil profiles (see below).

2.2 Soil Horizons and Soil Profiles

Soils are subject to *weathering*. Products of this weathering, especially if they have been moved vertically, give rise to characteristic layering. A vertical section of a soil, called a *profile*, consists of more or less distinct horizontal layers termed *horizons*. The properties of these horizons greatly influence the growth of higher plants. Conversely, plant growth is a main driving force behind the development of soil horizons, owing to the properties of the organic matter formed from decaying plant residues. Soil horizons with high contents of organic matter are generally dark in colour, and the organic acids formed during decomposition greatly enhance weathering of mineral matter. The different horizons in a soil profile may have very different chemical and physical properties (e.g. different pH values), so a contaminant introduced into a soil system may be strongly enriched in one of the horizons.

The soil-profile development forms the basis of soil classification. Soils are very heterogeneous, and different systems for soil classification are used in different countries and by different organizations. A detailed discussion of soil classification is beyond the scope of this chapter (see Brady, 1990).

2.3 Soil Texture

One of the factors that is important for the soil as a growth medium for plants and for the chemical reactions in the soil is the *texture* (size distribution of soil particles). The main classes are, in the direction of finer particles: gravel, sand, silt and clay. The clay fraction (particle diameter <0.002 mm) is especially important in this respect. The clay particles have a higher surface-to-mass ratio than the coarser particles, and hence a higher capacity to bind ions and molecules. Soils with high clay contents also have a greater water-holding capacity than more sandy soils, and are hence more resistant to drought.

2.4 Mineralogical and Chemical Composition of Soils

The mineralogical composition of a newly formed soil depends on the mineral composition of the parent rocks. Young soils contain appreciable amounts of unchanged primary minerals from the parent rocks, such as various feldspars (aluminosilicates), micas (iron and aluminium silicates) and quartz (SiO_2). In the course of time the primary minerals are subject to weathering reactions, whereby they are transformed to secondary minerals (layered silicate clays) and lose most of their original content of alkali and alkaline earth elements. In very old soils, such as found in large parts of the tropical zone, the further weathering reactions have largely transformed the mineral material into oxides and hydroxides of aluminium and iron.

The elemental composition of a soil thus depends on both the character of the parent material and its weathering state. In addition, some elements may be added to the surface soil in significant amounts from the atmosphere, by natural cycling processes. In coastal areas surface soils may be enriched with elements supplied from the marine environment such as the major sea-salt cations sodium and magnesium (Låg, 1968), the halogens chlorine, bromine and iodine (Låg and Steinnes, 1976) and even the essential trace element selenium (Låg and Steinnes, 1974). This is mainly due to spray formation on the sea surface by the action of strong wind and subsequent atmospheric transfer of sea-salt aerosols to land areas. In the case of iodine (Lovelock *et al*., 1973) and selenium (Cooke and Bruland, 1987) the cycling is probably biologically driven: volatile organic compounds, for example, CH_3I and $(CH_3)_2Se$, are produced by marine organisms and released to the atmosphere, where such compounds are eventually transformed to inorganic forms by photochemical processes and transported on to land with sea-salt aerosols.

The content of a particular element in soil may vary naturally over several orders of magnitude, and may reach toxic concentrations even in cases where human influence is not involved. Thus, the concept of natural background concentrations should be used with care. All too often, the presence of high concentrations of metals or other substances in an environmental medium is interpreted as the result of anthropogenic pollution, when the explanation may be natural variations in concentrations. In **Table 1** mean concentrations in the Earth's continental crust and typical levels in soils are shown for some metals of concern in human toxicology.

Table 1 Concentration levels (mg kg^{-1}) of some metals in the Earth's continental crust (Wedepohl, 1995) and in soils (Bowen, 1979)

Metal	Mean crust	Soil	
		Median	Range
As	1.7	6	0.1–40
Cd	0.100	0.35	0.01–2
Cr	126	70	5–1500
Cu	25	30	2–250
Hg	0.040	0.06	0.01–0.5
Ni	56	50	2–750
Pb	14.8	12[a]	2–300
Zn	65	90	1–900

[a]Prior to human contamination.

2.5 Soil Organic Matter

The organic matter in soil forms an important part of the total soil system. It is formed by decomposition of plant litter and dead soil organisms, and consists of a very complex mixture of chemical compounds, from easily degradable materials such as carbohydrates and proteins to humic substances, which are secondary products very resistant to further degradation and thus form the most stable component of the soil organic matter. During the degradation, organically bound nitrogen and phosphorus are gradually transformed into inorganic forms that are reused as plant nutrients. Humic substances have a high capacity to attract cations because of the negative charges formed by dissociation of protons from acidic groups on the humus surface. These negatively charged sites may form strong, chelate-type bonds with metals such as copper, lead and mercury.

3 MATERIAL BINDING, CYCLING AND TRANSFORMATION IN SOIL

The chemical reactions and transformations that take place in soils occur in the soil solution and on the interface between the solution and soil particles. The nature and extent of these reactions depend largely on the conditions in the solution phase (pH, redox level, concentration and type of dissolved organic matter, etc.) and also on the properties of particle surfaces, which govern the distribution of ions and molecules between the solution and the solid phase. Moreover, the catalytic action of micro-organisms is essential for almost all redox reactions occurring in the soil, including the breakdown of natural and anthropogenic organic substances. Since a majority of chemical reactions occurring in soil are strongly pH dependent, the pH of the soil is a particularly important factor. The pH level is also of fundamental importance for plants and soil biota.

Chemical substances may be bound to the surface of soil particles by various mechanisms (McBride, 1994) representing a wide range of binding strengths. The types of bonds involved will largely dictate the mobility,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat096
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

bioavailability and toxicity of different substances. Ionic species in the soil solution tend to be electrostatically attached to opposite charges on the solid surface, in which case they may be easily exchanged with another ion of the same charge. In some cases stronger chemical bonds are also involved: metals such as copper, lead and mercury may be complexed by ligands on humus surfaces, in particular carboxylic acid groups. Metals bound in this way may be quite immobile in the soil, and thus hardly available for uptake into plants. The potential toxicity of the metal is therefore greatly reduced by such binding. For example, in the Tantramar copper swamp in Canada, the peaty soil, containing up to 7% copper, supports a rich growth of trees and ground-cover species typical of wet areas in the region (Dykeman and de Sousa, 1966). The reason is probably that the copper is immobilized and therefore 'detoxified' by chelation by the humic compounds in the peat. On the other hand, such strong binding may cause accumulation in the humus-rich top layers of soils to high concentrations of substances steadily supplied to the soil (see Section 5.5). Metal cations may also be complexed by humic substances dissolved in the soil solution. These low-molecular-mass compounds (fulvic acids) may thus solubilize metals from the soil solid phase. Anions such as fluoride and phosphate may be bound to mineral surfaces by so-called ligand exchange, that is, by displacement of OH^- or H_2O from coordination positions at the particle surface. Ligand exchange is favoured at low pH, whereas cation complexing is more efficient at higher pH values. This is because at low pH there are few OH^- ions in the soil solution to compete with the surface-bound anions, and at high pH there is little H^+ in the solution to compete with the metal cations. For substances that are weak bases (e.g. triazine herbicides) or weak acids, variations in binding strength as a function of pH may be difficult to predict, but binding is usually strongest at pH values in the vicinity of the pK value of the acid or base.

Organic molecules can also be sorbed to soils to a considerable degree (Nicholls, 1991). For organic ions (e.g. the cationic herbicides diquat and paraquat) the mechanisms are similar to those described above for inorganic cations and anions. However, uncharged organic molecules also show some sorption on soils, but in this case the binding mechanisms are less well characterized. In many cases, hydrogen bonds and nonspecific van der Waals bonds, which are both weak relative to ionic and covalent bonds, are probably involved. In addition, dissolution of uncharged, hydrophobic substances in water is not an energetically favourable process, because the hydrogen bonds between individual water molecules must be disrupted in the process. As a result, such substances tend to reduce contact with water and seek relatively nonpolar environments, such as soil organic matter. Hence the capacity of the soil to bind electrically neutral organic compounds increases with increasing organic matter content. In general, nonpolar substances, such as polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs), tend to be more strongly sorbed on humus than on mineral surfaces (Mackay, 2001; Ockenden *et al*., 2003).

Clay (particle diameter < 0.002 mm) is the most important size fraction for chemical reactions in soils because of its large specific surface area. The smaller the particle, the larger is its area per mass unit: The dispersed colloidal phases in natural waters may have specific surface areas as high as hundreds of $m^2\ g^{-1}$ (Stumm and Morgan, 1996). The clay fraction in soils mainly consists of three particle categories: silicate clay, oxide and humus. Clay minerals and humus generally exhibit an excess negative surface charge, which may attract cations. The surface charge of oxide minerals, on the other hand, may be predominantly positive or negative depending on pH in the soil solution. Soils thus have a high capacity to store cations, in particular if the clay content or organic matter content is high. On the other hand, sandy soils have a much smaller capacity to bind both metal cations and organic compounds.

Plant root uptake of chemical substances from the soil solution is normally restricted to ionic compounds, predominantly inorganic ions, but is not limited to ions that are essential nutrients to the plant. Some toxic metals can also be absorbed quite effectively by the plant roots and transferred into plants used for human consumption. For example, cadmium can be readily taken up from the soil by plant roots, perhaps because it is chemically similar to the essential plant nutrient zinc. Some metals may therefore be a concern as contaminants in food crops, in addition to their possible contamination of groundwater after leaching from the soil. The plant uptake of a particular element depends on its forms of occurrence (speciation) in the soil, and numerous chemical extraction procedures have been proposed to 'mimic' the fraction of one or more elements available to plant uptake (Hlavay *et al*., 2004). Extractants used are typically buffered or nonbuffered salt solutions, weak acids and solutions of strong complexing agents such as EDTA (ethylenediaminetetraacetic acid). A particularly large amount of work has been performed in relation to cadmium added to agricultural soils as an impurity in phosphate fertilizers (Singh and Steinnes, 1994). Even in this case, however, no single extraction procedure has been found that adequately predicts the plant-available fraction of cadmium in different crops and soil types. Lead and mercury, on the other hand, are in most cases rather unlikely to be taken up by plant roots and transferred to the green parts of the plant.

For elements where the uptake in plants is high relative to the amount present in the soil, a major fraction of the total amount of the element present in the soil–plant system may be continuously and rapidly circulated with uptake in plants and subsequent return to the soil surface layers when the plants die or shed their leaves, and this

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat096
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

organic material is broken down and the element released to the soil solution.

Fungi possess extensive underground networks of mycelia that act as an extremely efficient system for extracting metals from the soil (Lepp, 1992; Berthelsen *et al*., 1995a). Mushrooms therefore often contain high concentrations of one or more toxic metals, but large differences exist between different species concerning which elements they seem to prefer (Lepp, 1992). Individuals with high consumption of wild mushrooms may therefore considerably increase their intake of one or more toxic elements.

Most organic soil contaminants are not likely to be much absorbed by plant roots (Ryan *et al*., 1988), so regarding human exposure, the main concern about such organic compounds is not intake via plant foods, but possible groundwater contamination. Unlike metals, they are subject to degradation in the environment. In general, the types of processes that may reduce the concentrations of organic substances in surface soils are: (i) volatilization from the soil to air; (ii) leaching from surface soil to groundwater; (iii) biodegradation; (iv) photolysis and chemical reactions; (v) physical transport processes and (vi) apparent loss through the formation of irreversibly bound, nonextractable residues (Alcock and Jones, 1996). The most persistent organic contaminants, however, such as PCBs (Meijer *et al*., 2002), dioxins (Hassanin *et al*., 2005) and PAHs (Pichler *et al*., 1996) may stay in the soil for decades, and thus represent a potential hazard, although in the case of PAHs the evidence has been subject to discussion (Koivula *et al*., 2004).

4 MATERIAL TRANSPORT BETWEEN SOIL AND WATER

When assessing the risks that toxic compounds in soil or water pose to humans, it is essential to know how the compounds are transported between soil, water and other parts of the environment, notably the atmosphere. For example, a volatile substance with low water solubility will tend to escape from water into the atmosphere. Substances with a high positive electric charge will generally bind strongly to negatively charged colloids in soils and thus be effectively immobilized.

The chemical composition of natural water is affected by several geological, atmospherical and biological factors (Bricker and Jones, 1995). Two physical factors are particularly important in determining the chemical composition of natural water; the residence time and the pathways along which the water moves in the soil–water system. The longer the residence time, the better is the opportunity for chemical reactions between the water and the materials in contact with it. The pathways determine which materials the water comes into contact with during its passage through the system; water following shallow pathways generally has a shorter residence time and comes in contact with more weathered and consequently less reactive minerals than water following deeper pathways.

Regarding trace elements in natural water, it is very important to realize that older concentration data are often erroneously high, owing to sample contamination and inadequate analytical quality control. As a consequence of clean techniques used during sampling and analysis, the concentrations of many trace elements in natural water have been found to be orders of magnitude lower than previously thought (Stumm and Morgan, 1996, Chapter 10.2).

Of the total amount of water on Earth, only about 2.5% is fresh water. Three quarters of this fresh water is locked up in ice and one quarter is groundwater, most of which is not readily available for human use. Rivers, streams and lakes together constitute less than 0.01% of the water on the planet (Berner and Berner, 1987), but this fraction is by far the most important for mankind. Water in nature is continuously in motion through the *hydrological cycle* (Berner and Berner, 1987). The cycle is driven by energy from the sun and by gravity. Only a tiny fraction of the total amount of water on Earth circulates through the cycle each year. As water moves through the hydrological cycle, constituents may be added or removed. Examples of processes adding constituents to water are mineral dissolution in soils, pollution and uptake of gases from the atmosphere. Several of the steps in the hydrological cycle may effectively remove constituents from the water, notably during the evaporation step, during percolation in soils where micro-organisms degrade organic compounds and where constituents of the water are sorbed on particles, and when water is flushed out of the system in question. Collectively, such processes are termed *self-purification* of water. The term self-purification may also be applied to soil. Self-purification of soil is generally much slower than for water systems.

5 POLLUTION OF SOIL AND WATER SYSTEMS

5.1 Introduction

For most trace elements, human activities have a major impact on both regional and global cycles. At least for arsenic, cadmium, copper, nickel, lead, vanadium and zinc, global anthropogenic emissions to the atmosphere by far exceed natural emissions (Nriagu and Pacyna, 1988). Furthermore, for most of the trace metals, the annual anthropogenic input to water exceeds the quantities emitted to the atmosphere, and direct discharges

from human activities to soil are even higher (Nriagu and Pacyna, 1988). Thus, mankind has a major influence on the global biogeochemical cycling of many trace elements. This has resulted in considerable increases in the circulation of several toxic metals through the soil, water and air, inevitably resulting in their transfer to human food chains and increased human exposure.

The global nature of the anthropogenic influence is perhaps best seen in studies of successively dated snow and ice layers in Antarctica and Greenland, which show that, for example, lead concentrations in snowfall over Greenland increased 200-fold from pre-industrial times to the 1970s (Boutron *et al*., 1994). Of course, not only metals, but also organochlorine compounds and other anthropogenic organic contaminants, have also become widespread in the environment, sometimes on a global scale (Simonich and Hites, 1995; Gambaro *et al*., 2005).

Fortunately, however, the common view that pollution of the environment is ever on the increase is not correct in all instances. Recent decades have witnessed large efforts to reduce anthropogenic releases of many priority hazardous substances to air, water and soil. As a result, sometimes dramatic improvements of the environment have occurred, for example in some major rivers such as the Thames and the Rhine (Zehnder, 1993). In the Rhine, water concentrations of lead and cadmium have been reduced by more than 90% since the 1970s (Zehnder, 1993). In Greenland snow, the concentration of lead has decreased by a factor of 7.5 and those of cadmium and zinc by a factor of 2.5 from 1970 to 1990 (Boutron *et al*., 1991). The atmospheric deposition of lead in southern Norway, mainly by transboundary pollution from other parts of Europe, has been reduced almost 20-fold over the last 30 years (Steinnes *et al*., 2007), but most of the previously supplied lead still resides in the surface soil. For dioxins, there are clear trends in many countries and in many environmental compartments that the concentrations have been greatly reduced in recent years, resulting also in a reduced human intake of dioxin (Alcock and Jones, 1996). However, the concentrations of dioxins in soils have not declined as rapidly as in other media (Alcock and Jones, 1996), because dioxins are strongly bound and not easily degraded in soils. The bulk of the environmental burden of dioxins resides in soils (Harrad and Jones, 1992; Hassanin *et al*., 2005). Thus, although the anthropogenic release of many pollutants has been reduced in recent years, deposits of those compounds that are not easily degradable, especially in soils and sediments, will continue to affect ecosystems and humans for a considerable time.

The efforts to reduce emissions of toxic and environmentally harmful compounds are most evident in the developed countries. It is of utmost importance that economic progress in the developing world does not entail the same degree of emissions that characterized the now developed countries when they were at the same stage. Such emissions in the developing world have the potential globally to more than offset the reductions attained in the developed part of the world.

With the efforts to reduce emissions of priority hazardous substances, large point sources have become of less quantitative importance than nonpoint, diffuse sources (except in the vicinity of the point sources). Now, diffuse sources, often related to everyday use and subsequent disposal of ordinary consumer products, dominate for many pollutants delivered to the air, water and soil environment. In many cases, transport through air is very important. This transport may be effective over very long distances, in some cases even globally. The potential for environmental contamination through long-range transport may be illustrated by the concentrations of lead and cadmium in natural surface soils of southern Norway, which are 10-fold higher than the natural levels, owing to long-range atmospheric transport from other parts of Europe (Steinnes *et al*., 1989, cf. Section 5.5).

In addition to direct introduction of toxicants into the environment, human activity may mobilize naturally occurring toxic compounds, such as aluminium and arsenic. Aluminium is the most common metal in the Earth's crust, and is solubilized from soils following deposition of acid precipitation (Driscoll and Postek, 1996, cf. Section 5.6). In deep groundwater wells in Bangladesh and India, arsenic is solubilized from arsenic-containing minerals in the bedrock (Smedley and Kinniburgh, 2005, cf. Section 6.4).

Soil salinization, which is a large problem globally, also potentially increases human exposure to several elements. Soil salinization occurs largely as a result of irrigation in agriculture: as water evaporates or is taken up by plants, the salts originally present in the irrigation water may build up in the soil, and the resulting high concentrations of salts in the soil may limit crop production (Pritchard and Amthor, 2005). As the salt contents of the soil increases, certain elements may be taken up by crops and enter the food chain.

5.2 Pesticides and Fertilizers

Pesticides have received particular attention in environmental toxicology. This is not surprising in view of the fact that pesticides are introduced into the environment deliberately to eradicate or harm certain forms of life (the word 'pesticide' means a substance that can kill any organism considered by humans to be a 'pest'). If pesticides were specifically toxic to the organisms they were intended to harm, they might not represent as much of a threat. However, most pesticides are toxic to many different types of organisms, including humans, so pesticide application to soils or crops often represents a potential threat to the health of humans or to the environment. Different pesticides have very different binding

properties and mobilities in soil–water systems. Pesticides will not be discussed further in this chapter (see **Toxicology of Pesticides**).

Fertilizers are added to soil in order to increase crop production. Whether the fertilizer is 'synthetic' (a mixture of specific chemical compounds) or 'natural' (animal manure, etc.), its application may cause contamination of soils and waters, either from the main constituents (notably phosphorus and nitrate leaching to receiving waters; health effects of nitrate in drinking water is discussed in Section 6.5), or from impurities. The most important such impurity is cadmium, which is present naturally, sometimes in high concentrations, in the sedimentary phosphate rocks which are used as raw materials for phosphate production. In addition to cadmium, arsenic, copper and zinc may be present in high enough concentrations in certain fertilizers to cause concern (Singh and Steinnes, 1994). Repeated use of high-metal fertilizers may cause accumulation of these metals in the soil, with the possibility of transfer to the human food chain. Cadmium is of particular concern in this respect, because the mean population intake is uncomfortably close to the health effect threshold (Buchet *et al*., 1990; WHO, 1992; Järup *et al*., 1998; Nordberg *et al*., 2007), because plant food is the main source of cadmium in the human diet (WHO, 1992), and because fertilizer (and sewage sludge, see below) applications in many cases have been shown to considerably increase the cadmium content of agricultural soils (Page *et al*., 1981). For example, Mulla *et al*. (1980) reported a 14-fold increase in the cadmium content of cultivated surface soil after 36 years of application of triple superphosphate.

Sewage sludge is a complex mixture of organic and inorganic compounds that are precipitated from wastewater during mechanical, biological and chemical treatment. Municipal sewage sludge is commonly used as a soil fertilizer owing to its high contents of organic matter, phosphorus and nitrogen. This use of the sludge also solves a large disposal problem. However, sewage sludge may contain a wide variety of undesired substances originating from households, from commercial buildings and from industries whose wastewater systems are connected to the municipal piping system. Repeated application of sewage sludge may cause the accumulation of such substances in the soil, uptake in food crops grown in the soil or contamination of groundwater. The most problematic chemical substances are metals, notably cadmium, but also lead, mercury, nickel, copper, zinc and chromium (Alloway and Jackson, 1991; Singh and Steinnes, 1994). There are large variations in metal concentrations in sludges between treatment plants and also between countries, probably reflecting different industrial inputs to the wastewater systems (Singh and Steinnes, 1994). In many countries, control measures have reduced the contents of cadmium and other metals in sewage sludge, and limit values have been set in the European Union (**Table 2**) and elsewhere. Thus, both phosphate fertilizers and atmospheric deposition (Section 5.5) are currently more important sources for cadmium input to agricultural soils than sewage sludge (WHO, 1992).

Various organic contaminants in sewage sludge, such as solvents, PAHs, PCBs and dioxins, may also be present in levels high enough to be of concern (Harrison *et al*., 2006). Sewage sludge may also contain pathogenic micro-organisms, which may survive in soil or water from days (bacteria) to months (viruses) to years (helminth eggs), depending on the environmental conditions (Straub *et al*., 1993). Such micro-organisms in sewage sludge thus represent a potential hazard for communicable disease transmission through contamination of groundwater.

5.3 Waste Disposal Sites

Hazardous waste disposal sites represent a large problem in the industrialized world. Soil and groundwater around such sites may become contaminated by a plethora of chemical substances, for example, metals and solvents such as di-, tri- and tetrachloroethylene and carbon tetrachloride. A related problem is leakage of petroleum components from the hundreds of thousands of underground storage tanks, notably at fuel stations. It is very difficult to ascertain the possible health effects that may result from potential human exposure to components mobilized from such waste disposal sites. Most such sites

Table 2 The European Economic Community limit values for metals when sewage sludge is used in agriculture

Metal	Cd	Cu	Hg	Ni	Pb	Zn
Soil concentrations[a]	1–3	50–140	1–1.5	30–75	50–300	150–300
Sludge concentrations[b]	20–40	1000–1750	16–25	300–400	750–1200	2500–4000
Amounts added per year[c]	0.15	12	0.1	3	15	30

[a]Limit values for concentrations of metals (mg kg^{-1} dry matter) in soils (if one or more of the metals in the soil exceeds these limit values, the use of sludge is prohibited).
[b]Limit values for concentrations of metals (mg kg^{-1} dry matter) in the sludge.
[c]Limit values for amounts of metals (kg ha^{-1} yr^{-1}) which may be added annually to agricultural land, based on a 10 year average (EEC, 2008)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat096
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

contain many different potentially toxic compounds, and producing high-quality exposure data retrospectively is usually not possible. In addition, epidemiological studies usually lack the power to definitely establish that there is no health effect, owing to the small numbers of exposed people.

The best known example of potential health problems from a waste disposal site is probably Love Canal, Niagara Falls, USA (Hoffman, 1995). Here, the Hooker Electro-Chemical Company built a residential neighbourhood on top of a site where some 22 000 tons of toxic chemical waste were buried. This waste included more than 6000 tons of the pesticide lindane, 2000 tons of chlorobenzenes and 200 tons of dioxin-contaminated trichlorophenol. Gradually, studies showed that the residential environment was heavily contaminated, and in 1978, President Jimmy Carter declared the first federal emergency for a non-natural environmental disaster in the USA. The 239 homes most seriously affected were condemned, and after nearly 10 years of very expensive clean-up efforts, the New York Department of Health issued a declaration of habitability, and a programme to redevelop the neighbourhood and move families back was started. The studies of possible health effects among the inhabitants of Love Canal were inconclusive (Hoffman, 1995).

The anaerobic waste disposal sites used so far may be replaced in the future by aerated sites, where the degradation of organic matter will go faster and leave less unhealthy products. Aeration is currently being used to stabilize existing landfills (Rich *et al*., 2008).

Technologies for cleaning contaminated soils, notably through bioremediation (Singh and Tripathi, 2007), is a rapidly developing field with some spectacular innovative efforts. Bioremediation provides technologies based on the use of living organisms, usually bacteria and fungi, to remove pollutants from soil and water, preferably *in situ*. This approach is usually more cost-effective than more traditional techniques such as incineration of soil. Bioremediation is becoming the technology of choice for the remediation of many contaminated environments, and has been shown effective for cleaning soil from a wide range of compounds including metals, petroleum hydrocarbons, PAHs, and PCBs. When using higher plants capable of hyperaccumulating metals and other substances, the term phytoremediation is often used (Audet and Charest, 2007).

5.4 Industry and Mining

A comprehensive and detailed discussion of possible impacts of mining and industrial activities on soil and water composition is beyond the scope of this chapter. Particularly, metal mining and smelting are very important sources of metal contamination of soils, both on a local and on a regional scale (Davies, 1983; Dudka and Adriano, 1997). Closed mines continue to contaminate their surroundings, mainly owing to large heaps of tailings, which are finely ground particles of ore and rock left behind as a waste product. Studies of the environmental and health impacts of historic mining sites have been conducted, especially in the UK. For example, one study shows that 100 years after the closure of two mines, large amounts of cadmium, lead, zinc and copper were still entering the surrounding soil, water and plant systems (Merrington and Alloway, 1994). Elevated concentrations of metals in plants growing on soils in the vicinity of metal smelters have been extensively documented (Davies, 1983). Thus, the potential for increased human exposure to metals through the food chain clearly exists in the vicinity of such sites.

5.4.1 Cadmium

Together with mercury and lead, cadmium has been the metal causing most concern in environmental toxicology. In contrast to mercury, where fish clearly stands out as the one main exposure source of concern, it is difficult to pinpoint even a few important sources of cadmium exposure for the general population. Cadmium came into focus as an environmental toxicant shortly after World War II, when a mysterious bone disease was found to be endemic, particularly among elderly women who had borne many children, in the basin of the Jinzu river in west-central Japan (Tsuchiya, 1978). The disease was named Itai-itai (ouch-ouch) because of the severe pain it caused in the muscles and bones of victims. After extensive epidemiological and other studies it has come to be accepted that the Itai-itai syndrome was due to long-term cadmium exposure. The cadmium was emitted into the Jinzu river from a zinc–lead–cadmium smelter upstream of rice fields, resulting in high concentrations of cadmium in rice. The characteristic skeletal changes found in the older women are not usually observed in occupational cadmium poisoning. However, Itai-itai disease was always accompanied by the classical proteinuria typical of cadmium poisoning (see below).

The Itai-itai incident is unique in that in no other nonoccupationally exposed population has the intake of cadmium been nearly as high. However, there are also indications of subtle clinical effects associated with lower-level intake in other populations after soil contamination with cadmium. The critical organ (that is, the organ where the first adverse effects occur with increasing exposure of a population) for long-term low-level cadmium toxicity is the kidney. Tubular proteinuria (increased excretion of low-molecular-mass proteins), commonly diagnosed by increased urinary β_2-microglobulin, is the earliest sign of presymptomatic cadmium-related kidney damage (WHO, 1992; Nordberg *et al*., 2007). Early renal damage seems to occur at considerably lower exposure levels than formerly

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat096
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

believed (Järup *et al*., 1998; Nordberg *et al*., 2007). In the Belgian Cadmibel study (Belgium is the main producer of cadmium in Europe, with widespread environmental contamination by the metal), there was a 10% probability (in nonsmokers) of elevated urinary excretion of β_2-microglobulin, retinol-binding protein, *N*-acetyl-β-glucosaminidase, amino acids and calcium, when cadmium excretion exceeded 2–4 $\mu g\,day^{-1}$ (Buchet *et al*., 1990). The generally accepted critical level of cadmium in the renal cortex is $200\,mg\,kg^{-1}$, corresponding to a urinary excretion of about $10\,\mu g\,day^{-1}$ (WHO, 1992). However, initial signs of proteinuria seem to be present in a small percentage of people with renal cortex levels as low as $50\,mg\,kg^{-1}$ (Järup *et al*., 1998).

Soil contamination of cadmium is common around many nonferrous metal mines and smelters, particularly those processing zinc ores. Owing to the close geochemical similarity between zinc and cadmium, zinc ores always contain appreciable amounts of cadmium, and zinc mining and smelting are important sources of cadmium emissions to the environment. In the village of Shipham in the UK, which was the site of a large zinc mine between 1650 and 1850, much of the soil is severely contaminated by cadmium from old mining slag heaps. These heaps were levelled and developed for agriculture and housing, and the cadmium concentrations are some of the highest reported, up to $750\,mg\,kg^{-1}$ in surface agricultural soil, and a median value of $91\,mg\,kg^{-1}$ in surface garden soil (Thornton, 1988). Cadmium levels in locally grown vegetables in Shipham were reported to be typically 5–20 times normal values (Sherlock *et al*., 1983). For example, the mean cadmium levels (fresh weight) were $680\,\mu g\,kg^{-1}$ in lettuce and $790\,\mu g\,kg^{-1}$ in spinach. Different dietary studies showed mean daily intakes of cadmium of 29–36 $\mu g\,day^{-1}$, of which 14–17 $\mu g\,day^{-1}$ came from locally grown vegetables. Four people had cadmium intakes above $400\,\mu g\,day^{-1}$.

The intake of cadmium in Shipham was higher than average for the UK, but not much so, suggesting that the majority of the inhabitants did not consume high amounts of the heavily contaminated locally grown vegetables. The mean urinary excretion of β_2-microglobulin, an early indicator of kidney damage (see above), was higher in Shipham residents ($77\,\mu g\,day^{-1}$) than in a control population ($55\,\mu g\,day^{-1}$), but apart from this, no adverse health effects that could be attributed to cadmium were found (Strethlow and Barltrop, 1988). Furthermore, the concentrations of cadmium in soil, house dust and crops were not significantly correlated with urinary cadmium and β_2-microglobulin.

On the other hand, a study in Belgium found a strong correlation ($r = 0.76$) between soil cadmium and cadmium in residents' urine for 703 randomly selected residents in 10 districts, six of which where close to zinc smelters (Staessen *et al*., 1994). Residents in the six polluted districts had slightly higher urinary cadmium (1.18 vs. $0.89\,\mu g\,day^{-1}$), serum creatinine (100 vs. $97\,\mu mol\,l^{-1}$) and urinary excretions of β_2-microglobulin (109 vs. $95\,\mu g\,day^{-1}$), retinol-binding protein (136 vs. $118\,\mu g\,day^{-1}$) and *N*-acetyl-β-glucosaminidase (1.78 vs 1.38 U day^{-1}). Locally grown vegetables, such as celery (2.43 vs. $0.68\,mg\,kg^{-1}$) and beans (0.42 vs. $0.15\,mg\,kg^{-1}$), also contained more cadmium in the polluted districts.

Cadmium is discussed further in Section 5.6.1.

5.5 Atmospheric Deposition

It has been evident for a long time that in the immediate vicinity of a point source, severe pollution of soil and water can result from transport of contaminants through the air and subsequent ground deposition. It is only in recent decades, however, that it has been realized that even in areas very far from large sources of pollution, considerable contamination of soil and water systems may occur after long-range atmospheric transport. Even in the polar regions, studies of drilled ice cores clearly document that the deposition of metals and other compounds has increased gradually through the centuries (Boutron *et al*., 1994). Extensive studies in Norway have demonstrated the regional diffuse contamination of soil, water and vegetation resulting from long-range atmospheric transport from source regions further south in Europe, most of which are more than 1000 km away (Steinnes, 1989; Steinnes and Henriksen, 1993; Berthelsen *et al*., 1995b; Steinnes *et al*., 1997; 2007). In little-disturbed natural soils in the southernmost part of the country, the concentrations of lead, cadmium and arsenic in the humus layer are consistently many-fold higher than in corresponding soils from central and northern Norway, and the correspondence with the geographical atmospheric deposition patterns for these elements is remarkable (Steinnes *et al*., 1997, cf. **Figure 1**). The elevated concentrations were mainly found in the humus layer, that is, the uppermost few centimetres of the soil; deeper soil layers seem little affected by the atmospheric deposition. This is probably due to strong complexing of the metals by humic substances (cf. Sections 2.5 and 3). These metals may be mobilized, for example, by acid deposition (Section 5.6), but the potential for mobilization varies greatly among different metals. It is noteworthy that in large areas in southern Norway, the concentrations in the soil humus layer of cadmium are typically 1–3 $mg\,kg^{-1}$ and of lead 100–250 $mg\,kg^{-1}$, equal to the limit values for agricultural soils treated with sewage sludge in the European Union (**Table 2**). From the 1970s, however, the long-range atmospheric transport of many metals to Norway has been distinctly reduced (Amundsen *et al*., 1992, cf. **Figure 1**), owing to pollution-reducing efforts in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

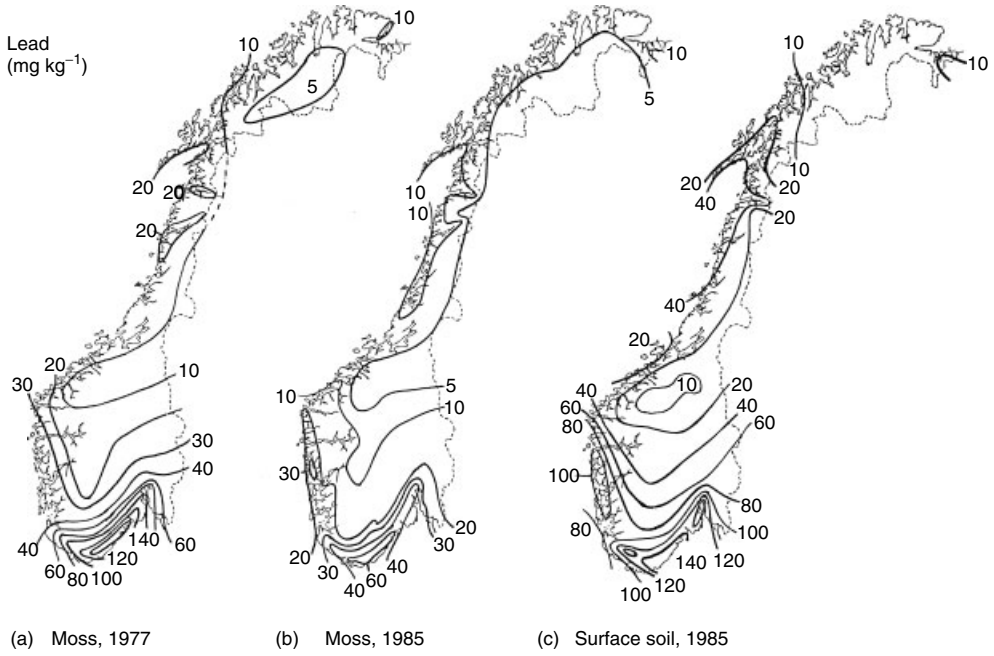

Figure 1 Concentrations of lead (mg kg^{-1} dry weight) in approximately 500 samples of terrestrial moss (*Hylocomium splendens*) sampled in 1977 (a) and in 1985 (b), and of the humus layer of natural soils in Norway (c). Because mosses lack a root system, they obtain most of their supply of chemical substances directly from atmospheric deposition. Since the carpet of living moss tissue is built up during a period of three to five years, the content of metals reflects an integrated measure of the atmospheric deposition during that period. The reduced concentrations of lead in moss from 1977 to 1985 mainly reflects reductions in the levels of lead in gasoline in Europe during this period.

most European countries. Even with fairly strong reductions in depositions, however, levels in the soil surface layers may continue to rise for elements that are very strongly complexed by humic substances.

The striking geographical patterns of metals in Norwegian surface soils (**Figure 1**) are partly reflected in local plants and further up the terrestrial food chains, indicating a potential for increased human exposure to toxic metals. For example, in a study of leaves and twigs of birch, Scots pine and cowberry, levels of cadmium were about five times higher in South Norway than in Central Norway (Steinnes, 1989). Regional studies of liver from lambs (Frøslie *et al*., 1985), moose, reindeer and red deer (Frøslie *et al*., 1984) showed similar geographical trends, most pronounced for lamb liver, where the mean value for lead was 10 times higher in the southernmost location than in the areas with lowest lead deposition (Frøslie *et al*., 1985). The levels of cadmium in kidneys of moose, reindeer and red deer also followed a similar distribution (Frøslie *et al*., 1986). For the few individuals with a high intake of organs from such game, this could represent a significant increase in the intake, especially of cadmium, but Frøslie *et al*. (1986) stated that there is no health hazard involved in the consumption of meat from wild ruminants.

When discussing the extent of soil contamination from diffuse atmospheric deposition, it is important to make a distinction between agricultural soils and natural soils. In the natural soil, the deposited metals in most cases tend to concentrate in the uppermost few centimetres of the soil (see above). In agricultural soils, on the other hand, the amount of contaminants deposited on the surface is mixed within the plough layer and therefore distributed into a larger volume of soil, so the concentrations are much lower (Singh and Steinnes, 1994). The anthropogenic contribution, however, is likely to be in a form more mobile in the soil than the natural content and hence more plant-available, in a similar way as metals added with sewage sludge or commercial fertilizers.

Persistent organic compounds, such as PAHs (Aamot *et al*., 1996), PCBs (Lead *et al*., 1997) and dioxins (Hassanin *et al*., 2005), are also supplied to soils from long-range atmospheric transport to a certain extent, in addition to contributions from local pollution sources and application of sewage sludge (Section 5.2).

5.6 Acidification and Human Health Effects

Acidification of soil and water resulting from the deposition of acid rain (or more generally acid precipitation) is a major environmental problem. The precursors of acid rain are mostly gaseous oxides of sulphur and nitrogen, introduced into the atmosphere by combustion of fossil fuels,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat096
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

smelting of metal sulfides and from natural sources. The sulphur and nitrogen oxides are oxidized in the atmosphere and react with water to form sulfuric and nitric acid. These acids are very water soluble and are deposited on the ground with precipitation. Typical pH values in precipitation over large affected regions are 4.0–4.5, but in extreme cases, pH values below 3 and even below 2 have been recorded. Much is known about effects of acidification on fish and other aquatic organisms, forests and soils (Overrein *et al*., 1980; Grennfelt *et al*., 1995), but less is known about possible human health effects (Goyer *et al*., 1985; WHO Working Group, 1986; Nordberg, 1990; Oskarsson *et al*., 1996).

Basically, two conditions have to be met for acid precipitation to cause significant problems in a particular area:

1. The rainwater has to be acidic enough. Rainwater is naturally slightly acidic because CO_2 from the atmosphere forms carbonic acid when dissolved in water; distilled water in equilibrium with the ambient atmosphere has a pH of about 5.6. In practice, rainwater pH has to be well below 5 for ecological problems to arise.
2. The buffering capacity of the soil has to be low. In most watersheds, most of the rainwater percolates through the soil before it reaches the waterways. During this percolation, more or less of the acids in the rainwater will be neutralized depending on the properties of the soil. Therefore, the ecological impact of acid precipitation in a particular area largely depends on the neutralizing capacity of its soil and bedrock. The most sensitive areas are those with shallow or no soil overlying granite or gneiss bedrock; deep, calcite-rich soils, on the other hand, have the ability to neutralize large amounts of acid, so soil and, particularly, aquatic ecosystems in such areas will be little affected.

Because it typically takes a few days for the oxides of sulphur and nitrogen to be completely oxidized in the atmosphere to sulfuric and nitric acid, serious acidification sometimes occurs in areas several hundreds and even thousands of kilometres away from the pollution sources, notably in Scandinavia as a result of transport from Continental Europe and the UK, and in Canada resulting from transport from the USA. However, in these areas, pollution-reducing efforts have resulted in reduced deposition of acids and clear tendencies for the slow recovery of acidified lakes and rivers (Wright *et al*., 2005), although the problem is far from solved. On the other hand, acidification is a large and increasing problem in China (Larssen *et al*., 2006) and other rapidly developing countries.

When assessing the possible human-health effects related to acid precipitation, it is useful to distinguish between direct effects, associated with the predepositional phase, and indirect effects, associated with the postdepositional phase (Goyer *et al*., 1985). Direct effects are those resulting from direct human exposure to acidic substances from ambient air. Such direct effects are only relevant in urban areas or close to point sources in general, and will not be discussed in this chapter (see **Air Pollution**).

The possible indirect health effects of acid precipitation are those resulting from acidification of soil and water. The major area of concern is increased mobility of toxic compounds, mainly metals (Nelson and Campbell, 1991). Since the solubility of most metals increases with decreasing pH, acid precipitation will leach soil-bound metals into the soil solution, both metals naturally present and metals deposited from the atmosphere (cf. Section 5.5). As the soil solution percolates downwards through the soil profile, the dissolved metals may precipitate when they reach a soil horizon with higher pH. With continuing supply of acid, the deeper layers of the soil may also be acidified, allowing the dissolved metals to reach the groundwater and eventually streams and lakes. Human exposure may be influenced by two main routes, namely accumulation of toxic compounds in food chains and contamination of drinking water. Increased solubility of metals in soils may lead to increased metal levels in food plants and animals, and in drinking water sources.

As a secondary effect, decreased pH in drinking water sources may lead to increased leaching of substances from corrosion in the water distribution system. Relevant substances include lead from lead pipes and solder, zinc and cadmium from galvanized pipes, faucets and solder, copper from copper pipes and asbestos from asbestos–cement pipes.

The most relevant metals for possible health effects of acid precipitation are mercury, cadmium, lead and aluminium. It is not known whether aluminium exposure constitutes a health risk to the general population. Mercury, cadmium and lead, on the other hand, are 'classical' toxic metals. All three metals tend to accumulate in the body over time, and the margins of safety between the mean population intakes and the health effect thresholds are not comfortably wide, at least not for possible susceptible subpopulations. Furthermore, exposure and body burden for these three metals, as for many other substances, follow skewed distributions in the population. This implies that a seemingly small increase in the average population intake may result in a relatively larger proportion of individuals exceeding the health effect threshold (Flaten, 1997). Therefore, every increase in population intake could have clinical relevance and should be avoided, including increases associated with acidification. Thus, although at present there is no firm evidence directly linking human health effects to soil and water acidification, the existing indications of increased

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat096
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

exposure to cadmium, methylmercury and lead by itself warrant that the problem be taken seriously.

5.6.1 Cadmium

Cadmium is also discussed in Section 5.4.1. Food and tobacco smoke are the main sources of cadmium exposure for the nonoccupationally exposed population (WHO, 1992). Cereals and vegetables are the most important dietary sources. In contrast to many other metals, for example, lead and mercury, cadmium is easily taken up by plant roots, and increases in soil cadmium generally results in increased plant uptake by the metal (Page *et al*., 1981; WHO, 1992). Therefore, it is important that the cadmium concentration in agricultural soils is kept low. Cadmium, like most other metals, shows increased mobility in soil and water with decreasing pH. In addition to soil cadmium concentration, soil pH is the most important factor influencing plant cadmium accumulation. A reduced soil pH clearly increases the uptake of cadmium in various food crops, for example, rice, wheat, carrots and potatoes (Page *et al*., 1981; Öborn *et al*., 1995). For example, the average cadmium content of carrots in the study by Öborn *et al*. (1995) was about 175 μg (kg dry weight)$^{-1}$ at pH 7 and about 480 μg kg^{-1} at pH 5. Lime applications to acid soil will cause reduced cadmium levels in crops, but high liming rates may actually increase cadmium concentrations (Öborn *et al*., 1995). This puzzling effect may be due to competition between calcium and cadmium ions on soil particles, in that calcium ions from lime replace cadmium ions on soil exchange sites, thereby mobilizing cadmium and increasing its availability to the plants (Christensen, 1984).

Regarding drinking water, significant amounts of cadmium are present in some soldering materials and in parts of certain taps (faucets), but mostly in older water systems. In addition, galvanized (zinc-covered iron) water pipes always contain some cadmium. In larger waterworks, acid source water will in most cases be treated to increase pH and reduce corrosivity, but in small waterworks and single-household systems, such treatment will generally not be used. In Norway, for example, drinking water pH values in the range 4.5–5.5 are not uncommon (Flaten, 1991). Drinking water sources mostly contain less than 0.05 μg Cd l^{-1} (Méranger *et al*., 1979; Nriagu *et al*., 1996; Lydersen *et al*., 2002). This constitutes a negligible contribution to the typical daily intake of cadmium, which in most countries is around 10–30 μg (WHO, 1992). Little systematic work has been done on leaching of cadmium and other metals from plumbing systems. In Seattle, where the drinking water was quite corrosive, the median cadmium values of water samples collected in residential buildings with galvanized water pipes were 0.63 μg l^{-1} for standing and 0.25 μg l^{-1} for running water samples, and the corresponding values for buildings with copper pipes were 0.02 and 0.01 μg l^{-1} (Sharrett *et al*., 1982). Hence, although leaching of cadmium from pipes and plumbing is most probably not an important source of cadmium exposure at the population level, in certain households acid drinking water may contribute appreciable amounts of cadmium through such leaching.

In Norway, concentrations of cadmium in liver and kidneys of wild moose, reindeer and red deer are markedly higher in areas influenced by acid precipitation than in 'background' areas (Frøslie *et al*., 1986). This would represent an increased intake for individuals consuming organs from game. However, the extent to which the increased organ concentrations are due to acidification or to the concomitant atmospheric deposition of cadmium (Section 5.5) is unknown.

5.6.2 Lead

The critical effects for chronic, low-level exposure of lead are neurological and haematological; the major risk is central nervous system toxicity (Skerfving and Bergdahl, 2007). The last decades have witnessed a gradual and severalfold reduction in the threshold level for lead in blood below which no adverse effects are anticipated, and recent studies have indicated subtle cognitive and behavioural deficits in newborns and very young infants, possibly even below 100 μg l^{-1} (Schwartz, 1994; Canfield *et al*., 2003).

There are several toxicologically relevant sources of lead, notably dust, soil, paint chips, food and drinking water. Acid precipitation may contribute to increased lead intake chiefly through drinking water. Where corrosive water is supplied through lead-containing pipes and plumbing, drinking water may be the dominant source of lead (Elwood *et al*., 1984). Thus, acidification of drinking water clearly has the potential to cause increased intake of lead, where the drinking water installations contain lead. In many older urban areas, notably in the UK, lead water pipes are still in use. More commonly, the source of lead is lead-based solder joining metal pipes; lead solders have been used since Roman times. An additional source is brass, a common compound in drinking water faucets and other installations. Brass commonly contains about 2% lead to make it malleable. Raising the pH of drinking water in Glasgow and Ayr resulted in clinically relevant rapid falls in blood lead in postpartal women (Moore *et al*., 1985), demonstrating that drinking water pH really can be important for the intake and body burden of lead.

The potential of acid rain to cause increased concentrations of lead in the sources of drinking water is less than for cadmium. This is because lead is much less mobile in terrestrial ecosystems than cadmium, owing to stronger complexation by humic substances (Bergkvist *et al*., 1989). However, we do not know enough of the mechanisms involved to exclude the possibility that acidification-induced increases in the mobility of lead in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the environment may be toxicologically relevant. The fact that a study in Norway showed the mean concentration of lead in the liver of outdoor-grazing lambs to be 10 times higher in the most acidified area than in background areas is disturbing (Frøslie *et al*., 1985). However, as mentioned in Section 5.6.1, this increased liver lead may be due to the intake of lead directly deposited from the atmosphere on plants and soil, rather than to lead mobilized by acidification.

5.6.3 Mercury

For mercury, environmental pathways, exposure routes, absorption, metabolism and toxicological properties vary widely with speciation (Berlin *et al*., 2007). Environmental transport of mercury is mainly through the atmosphere, where it exists almost exclusively in the elemental form (Hg^0), as a gas or adsorbed to the surface of small particles. This elemental mercury may then be oxidized to the more water-soluble divalent form (Hg^{2+}), dissolved in raindrops and deposited from the atmosphere. In soil and water, Hg^{2+} can be: (i) reduced to gaseous Hg^0, thereby returning mercury to the atmosphere or (ii) methylated by micro-organisms to CH_3Hg^+. The electrically neutral methylmercury species, CH_3HgCl, $(CH_3)_2Hg$ and so on are lipophilic, and can thus readily pass biological membranes and be concentrated by ecological food chains—a process known as bioamplification or biomagnification: any substance that is more soluble in the tissues of simple organisms than in the surrounding water will be a more concentrated component of the diet of the more complex species which feed on the simpler ones. Methylmercury has a very strong tendency for bioamplification. Concentrations are highest in large predatory fish such as pike; levels above $1\,mg\,kg^{-1}$ in muscle are not uncommon.

Fish and fish products are the only significant sources of human intake of methylmercury (WHO, 1990). Eating 200 g of pike containing $1\,mg\,kg^{-1}$ of methylmercury results in an intake of 200 µg, equal to the WHO recommended provisional tolerable weekly intake (WHO, 1990). In fact, northern pike is the species of fish with the highest consumption per user in the USA; the estimated number of users of northern pike is 2.5 million, with a mean consumption of $17.4\,g\,day^{-1}$ (Goyer *et al*., 1985).

The critical effects of methylmercury are neurotoxic. Extensive evidence indicates that the developing nervous system is more sensitive to methylmercury toxicity than that in adults (WHO, 1990; Berlin *et al*., 2007). Methylmercury readily crosses the placenta, so the main concern is the intake of high-methylmercury fish among women of childbearing age. The Swedish National Food Administration has since 1991 advised pregnant and lactating women, and women planning to have children in the near future, to abstain totally from eating a number of specified fresh-water fish species.

Studies in several countries show, within a given geographical area, a fairly strong negative correlation between pH values of lake water and methylmercury body burdens in fish (WHO Working Group, 1986). Although a cause-and-effect relationship has not been established, the indications that acidification increases methylmercury in fish are quite strong, and the potential increase in methylmercury intake for individuals consuming such fish is clearly toxicologically relevant.

5.6.4 Aluminium

Acidification leads to mobilization of aluminium from otherwise very poorly soluble minerals such as feldspars and kaolinite in soils and bedrock. The result is greatly increased aluminium concentrations in ground and surface water and also in drinking water (Flaten, 1991). Aluminium is the main toxicant damaging fish populations and other aquatic life in acidified areas (Driscoll and Postek, 1996). The main target organ in mature fish is the gills; death is due to disruption in iono- and osmoregulation and respiratory dysfunction.

The possible human toxicity of aluminium has been a matter of controversy for well over 100 years (Flaten *et al*., 1996; Krewski *et al*., 2007). The first human conditions generally accepted to be causally related to aluminium exposure occurred in the 1970s, shortly after the introduction of routine dialysis therapy in patients with chronic renal failure (Alfrey *et al*., 1972). These conditions are a fatal encephalopathy commonly termed dialysis dementia, fracturing osteomalacia and a microcytic hypochromic anaemia occurring despite adequate iron stores (Alfrey, 1993). The patients received aluminium into the bloodstream via high-aluminium dialysate or consumed large oral doses of aluminium-containing phosphate binders. The dialysate was prepared by diluting a concentrate with ordinary tap water. Since there is no doubt that acidification of soil and water can cause greatly increased concentrations of aluminium in fresh water, it seems highly likely that acidification has contributed to a number of cases of dialysis encephalopathy, osteomalacia and anaemia through the tap water used to prepare the dialysate. Although, of course, causal inference cannot be made for individual patients, it may be noted that the first cases of dialysis encephalopathy in Norway occurred in two hospitals situated in areas highly influenced by acid precipitation. The concentrations of aluminium at the waterworks serving the two hospitals were approximately 150 and $300\,\mu g\,l^{-1}$, respectively (Flaten, 1991). It is generally accepted that dialysate aluminium concentrations should be kept below $10\,\mu g\,l^{-1}$ to prevent aluminium accumulation and toxicity in dialysis patients. Since about 1980, hospitals have treated the water used to prepare dialysate to

remove aluminium, mostly by reverse osmosis, and osteomalacia and especially encephalopathy are now rare in the dialysis population.

In dialysis patients, tissue accumulation of aluminium to levels high enough to cause toxicity is mainly due to a combination of: (i) very high exposure, partly directly into the bloodstream and (ii) these patients' lack of kidney function, which is the main excretion route for aluminium (Krewski *et al*., 2007). Although there are also reports of similar neuro- and osteotoxicity in certain patient groups without kidney failure (Flaten *et al*., 1996), the question whether aluminium exposure of any kind represents a health problem for the general population remains open (Krewski *et al*., 2007). The most controversial issue is whether aluminium exposure is causally related to Alzheimer's disease (Exley, 2001; Miu and Benga, 2006). Several epidemiological studies from different countries (Flaten, 2001; Krewski *et al*., 2007), have indicated a relationship between drinking-water aluminium and Alzheimer's disease. However, even at high concentrations (100–300 $\mu g\,l^{-1}$), drinking water contributes only a fraction of the total aluminium intake, which is typically in the order of a few milligrams per day (Pennington and Schoen, 1995). Persons consuming antacids may ingest more than 1 g of aluminium daily, and the handful of epidemiological studies attempting to relate antacid intake to Alzheimer's disease have been negative (Flaten, 2001; Krewski *et al*., 2007).

However, aluminium is poorly absorbed in the gastrointestinal tract; the consensus is that about 0.1–0.4% of the dietary intake is absorbed (Krewski *et al*., 2007). Hence it is possible that the aluminium present in drinking water is more bioavailable than that present in food and medications, although recent evidence seems to contradict this (Stauber *et al*., 1999; Yokel *et al*., 2001). It is also conceivable that some natural water may contain small amounts of organic aluminium complexes with properties similar to those of aluminium maltolate, stable enough to pass through the stomach and accumulate in brain and bone (van Ginkel *et al*., 1993). Hence a real association between drinking-water aluminium and Alzheimer's disease cannot be dismissed (Krewski *et al*., 2007). In any case, it is indisputable that acid precipitation has resulted in increased human exposure to aluminium through drinking water.

5.6.5 Other Substances

Copper is an essential element with a daily requirement of 1.0–1.5 $mg\,day^{-1}$ (WHO, 1996). Background concentrations of copper in fresh water rarely exceed a few $\mu g\,l^{-1}$ (Méranger *et al*., 1979; Nriagu *et al*., 1996; Lydersen *et al*., 2002), but tap water often contains much higher concentrations. More than 1 $mg\,l^{-1}$ of copper is not uncommon, because in many countries, most of the domestic water pipes are made of copper. The copper concentration increases with increasing contact time between water and piping, and flushing decreases water copper content. The time necessary to flush out the high-copper water depends on the length of the copper pipes. The corrosion rate of copper pipes is highly pH-dependent; corrosivity increases rapidly with decreasing pH. Therefore, water acidification will increase copper exposure in places where the water is not treated at the waterworks to increase pH and reduce corrosivity. Since the typical daily intake of copper is in the order of 2 mg or less (WHO, 1996), drinking water may contribute substantially to copper intake in areas with corrosive water, especially if the pipes are not thoroughly flushed before use.

For the essential trace element *selenium*, in contrast to the situation for the elements discussed above, mobility in soil and water seems to *decrease* with decreasing pH, although other variables, such as the presence of oxides in soils and the redox level may complicate the relationship (Frankenberger and Benson, 1994). Hence it is possible that human intake of selenium, which may be suboptimal for many individuals, may be reduced following acidification of the environment. A study in Sweden indicated that subjects in acidic areas had slightly lower plasma selenium levels than subjects from a reference area (medians 85 vs. 90 $\mu g\,l^{-1}$) (Svensson *et al*., 1987). In addition, there seems to be an inverse relationship between the methylmercury content of fresh-water fish and selenium contents of water. In fact, adding selenium to lakes in Sweden has resulted in severalfold reductions of the mercury level in fish (Paulsson and Lundbergh, 1989). Thus, if acidification generally reduces the availability of selenium in the environment, this may result both in reduced human intake of selenium and increased intake of methylmercury.

Exposure to *asbestos* may also increase following environmental acidification. The source is asbestos–cement, which is widely used as a material in water pipes. In addition, asbestos–cement roofing tiles have been used as catchments for household drinking-water cisterns. The calcium-carbonate matrix in the asbestos–cement dissolves in acid water, releasing asbestos fibres. Whether oral ingestion of asbestos is a significant health hazard is, however, uncertain. The data relating ingestion of asbestos to health effects, most notably colorectal cancer, are inconclusive (Homa *et al*., 1994; Browne *et al*., 2005). However, the potential for inhalation of asbestos fibres during showering may be a cause of concern.

Finally, it may be noted that acidification of soils and fresh water will also affect the bioavailability and toxicity of compounds that exist as weak acids or bases in the environment. Because essentially only the nonionized form of a lipid-soluble molecule will diffuse across biological membranes, acidification will

result in enhanced bioavailability (and hence potential for build-up in food chains and increased exposure for humans) for weak acids and decreased bioavailability for weak bases.

6 DRINKING WATER

6.1 Introduction

Since drinking water is not specifically treated in other chapters in this book, some human-health aspects of drinking water are discussed, both in this section and in parts of Section 5. The focus is on instances where toxic substances, at least partly, have their origin in soils, and where drinking water constitutes an important exposure pathway from soils to humans.

Soils fundamentally influence the chemical composition of drinking water in that the major part of most dissolved constituents in fresh water originates from weathering of soil minerals (Stumm and Morgan, 1996). Generally speaking, the main mechanisms or processes contributing to the chemical composition of drinking water are:

- Chemical weathering of the soils, bedrock and sediments in the drainage basins
- Atmospheric transport of salt particles from the sea
- Regional and local pollution
- Corrosion of the water pipes and plumbing systems
- Water treatment
- Decomposition of organic matter
- Hydrological variables (rainfall, soil depth, terrain slope, etc.).

The number of variables regulated by drinking water standards has increased rapidly during the last decades (WHO, 2008). It is evident that under special circumstances, the concentrations of a large number of substances, both natural and anthropogenic, may reach potentially toxic levels in drinking water. On the average, however, the contribution from drinking water to the total intake is small for most drinking-water constituents. There are a few exceptions, however, the best known probably being fluoride. Furthermore, the bioavailability of certain elements is probably higher in drinking water than in most foods. This could be the case for some elements with a complex chemistry in aqueous solution and which form compounds with low solubility, such as aluminium, chromium, cobalt, iron, manganese and molybdenum, but would be less probable for the alkali and alkaline-earth elements and the halogens, for example.

6.2 Fluoride

The dominating source of fluoride in fresh water is weathering of minerals in soil and bedrock (Edmunds and Smedley, 2005; Amini *et al*., 2008). Thus, differences in the chemical composition of the local soil will determine the concentration of fluoride in drinking water, and is clearly important for dental and skeletal health. Numerous studies dating back to World War II have clearly demonstrated that the prevalence of dental caries in children is strongly related to the fluoride concentrations in drinking water (WHO, 2002). An F^- concentration around $1\,mg\,l^{-1}$ is considered optimal, and many waterworks, notably in North America, add fluoride to drinking water to achieve this concentration in the treated water. Whereas a small amount of fluoride is beneficial, higher concentrations may have deleterious effects, notably mottled teeth (dental fluorosis) and, if the concentration is high enough, skeletal deformations and malformations (skeletal fluorosis). The concentrations necessary to produce these deleterious effects depend on the water intake. In warmer climates, people consume more water, and in parts of India, Sri Lanka (Dissanayake, 2005), China and the Rift Valley area in Africa, crippling skeletal fluorosis affects millions of people (Ayoob and Gupta, 2006). High drinking-water fluoride levels originating from the local soil and bedrock is therefore a major public-health problem.

6.3 Water Hardness and Cardiovascular Disease

The 'water story', that is, the possible association between cardiovascular diseases and the hardness of drinking water, has now passed its fiftieth anniversary (Kobayashi, 1957). In more than 50 ecological (geographical correlation) studies conducted in several countries up to 1978, the mortality or incidence of cardiovascular disease was found to be typically 5–15% lower in areas with hard drinking water than in areas where the drinking water is soft, that is, has low concentrations of calcium and magnesium (NRC, 1979). The majority of epidemiological studies published after 1978 have also indicated a protective effect (Monarca *et al*., 2006). However, the ample amount of research conducted has failed to clarify a biological mechanism; possible explanations behind the 'water story' include (NRC, 1979): (i) the principal constituents of hardness (calcium or magnesium) are protective; (ii) other elements that tend to be present in hard water (e.g. selenium, chromium, silicon, lithium or vanadium) are protective; (iii) harmful elements (e.g. lead or cadmium) are present in soft water, for example as a result of the corrosive action of soft water on the

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

water distribution system (cf. Section 5.6) and (iv) other (e.g. socio-economic) confounding factors are involved.

The main source of calcium and magnesium in drinking water is chemical weathering of soil minerals. Thus, differences in soil composition and soil depth dictate the concentrations of calcium and magnesium in drinking water, and would be the 'driving force' behind the 'water story'. Even at high concentrations, however, drinking water only contributes a minor fraction of the total intake of calcium and magnesium.

6.4 Arsenic

Arsenic has a complex chemistry in the environment and in biological systems. It occurs mainly in two oxidation states, +III and +V. In surface water and surface soil, most arsenic is pentavalent, while most of the arsenic introduced in the environment by human activities is trivalent. Trivalent forms are generally more toxic than pentavalent forms. Arsenic is biomethylated in nature, and may occur as many different organoarsenic species.

Arsenic exposure may cause toxic effects in many organ systems (WHO, 2001; Fowler *et al*., 2007). In Taiwan, extraordinarily high concentrations of arsenic in soil and water have been linked to an endemic peripheral vascular disease known as 'blackfoot disease', which in severe cases progresses to gangrene in the extremities (Tseng, 2005).

It is well established that ingestion of inorganic arsenic can cause skin cancer (WHO, 2001). In view of the increasing evidence that arsenic exposure may also cause other types of cancer and that its carcinogenic potency seems to be higher than previously thought (Fowler *et al*., 2007), WHO, in 1993, lowered its provisional guideline value for arsenic in drinking water to $10\,\mu g\,l^{-1}$ (WHO, 2008).

During the 1990s, endemic arsenic poisoning of enormous proportions was revealed in the Bengal alluvial delta region of Bangladesh and India (Mandal *et al*., 1996). This has been called 'the largest poisoning of a population in history' (Smith *et al*., 2000) and arsenic contamination of groundwater in general has been called 'the key environmental health problem of the twenty-first century' (Christen, 2001). In 2002, it was estimated that more than 300 000 people in the Bengal area had visible arsenic-related skin lesions, including melanosis, keratosis, nonpitting oedema, gangrene and skin cancer (Chakraborti *et al*., 2002). In the most seriously affected districts, more than 90% of the drinking water wells have arsenic concentrations above $50\,\mu g\,l^{-1}$, the highest concentrations being above $3000\,\mu g\,l^{-1}$ (Smedley and Kinniburgh, 2005). In total, an estimated 35 million people in Bangladesh and 6 million people in West Bengal are exposed to arsenic in drinking water at concentrations above $50\,\mu g\,l^{-1}$ (Smedley and Kinniburgh, 2002).

In the Bengal delta region, the traditional surface water sources for drinking were heavily contaminated with micro-organisms, causing a high burden of disease and mortality. During the 1970s and the 1980s, UNICEF worked with the local authorities to install tube-wells to provide what was presumably a safe source of drinking water for the population (Smith *et al*., 2000), and millions of wells were installed without testing the water for arsenic. The exact mechanism behind the high arsenic concentrations in the Bengal groundwater is not known, but the arsenic is generally accepted to be of natural origin. Development of strongly reducing conditions in the affected aquifers is likely the main factor controlling arsenic mobilization (Smedley and Kinniburgh, 2002). High arsenic concentrations in groundwater have later been reported in other river delta regions in Asia (Smedley and Kinniburgh, 2005), including the Red River delta in Hanoi, Vietnam (Berg *et al*., 2001) and the Mekong river floodplain in Cambodia (Buschmann *et al*., 2007). Globally, a wide variety of environmental conditions can give rise to arsenic concentrations in drinking water well above the WHO guideline of $10\,\mu g\,l^{-1}$ (Smedley and Kinniburgh, 2002).

6.5 Nitrate and Methaemoglobinaemia and Cancer

In many areas of the world, concentrations of nitrate in groundwater have been gradually increasing for several decades (Strebel *et al*., 1989; Spalding and Exner, 1993). The increase is seen mainly in agricultural areas, and is most probably due to addition of fertilizers to agricultural soils. Together with phosphorus and potassium, nitrogen is the main element in commercial fertilizers. The nitrate anion is only weakly bound in soils, and hence is fairly mobile. The mobility varies considerably with soil type and agricultural practices, and nitrate leaching from soils to groundwater may, in many cases, be efficiently controlled by agricultural practices (Strebel *et al*., 1989).

High concentrations of nitrate in drinking water was first reported to cause infant methaemoglobinaemia ('blue baby syndrome') in 1945 (Comly, 1945). Up to 1970, about 2000 cases of infant methaemoglobinaemia had been reported worldwide (Fan *et al*., 1987). This is the rationale behind drinking-water standards for nitrate, which in most countries is around $50\,mg\,l^{-1}$ of NO_3^-. Compliance with this standard seems to offer adequate protection against infant methaemoglobinaemia.

Some epidemiological studies have indicated that exposure of humans to high levels of nitrate is associated with an increased risk of several types of cancers, and later studies have indicated an increased risk for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat096
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

adverse pregnancy outcomes, but the evidence is inconclusive (Ward *et al*., 2005). The postulated mechanism is that bacteria in the alimentary tract reduce ingested nitrate to nitrite, which then reacts with nitrosatable substrates in certain foods to form carcinogenic *N*-nitroso compounds.

6.6 Chlorination By-Products and Cancer

Chlorination of drinking water, which was introduced about 100 years ago, has undoubtedly been one of the most important public health measures of the twentieth century (IARC, 1991). At present, water chlorination is still the most effective method for the control of waterborne infectious disease transmission. In 1974, it was discovered that chlorination of drinking water led to the formation of chloroform and other trihalomethanes (Rook, 1974). Since then, several hundred different halogenated organic compounds have been identified in drinking water (Richardson *et al*., 2007). However, the concentrations of even the most common chlorination by-products, chloroform and trichloroacetic acid, seldom exceed $100\,\mu g\,l^{-1}$. Most other by-products occur at levels typically below $1\,\mu g\,l^{-1}$. Several factors influence which compounds are formed, especially pH, chlorine-to-substrate ratio and the nature of the precursor compounds. The principal precursors of the chlorination by-products are humic substances, the natural products of decomposition of dead plants and animals in soil and water, which impart a characteristic yellow-brown colour to the water. Concentrations and types of humic substances vary widely in natural water, mainly as a result of local variations in soil conditions.

Among the chlorination by-products there are a number that are mutagenic and some, notably haloacetonitriles, chlorinated phenols, aldehydes and ketones, that are animal carcinogens. Practically all drinking water is mutagenic in Ames/*Salmonella* tests after chlorination, but seldom before, and mammalian cell and plant tissue assays generally give similar results (WHO, 2000; Richardson *et al*., 2007). The chlorination by-product 3-chloro-4-(dichloromethyl)-5-hydroxy-2[5 *H*]-furanone (MX) has attracted special attention, partly due to its extreme potency in the Ames mutagenic test. MX accounts for a major part of the mutagenicity in Finnish and other drinking water, although it is present in minute concentrations (below $100\,ng\,l^{-1}$) (Smeds *et al*., 1997).

More than 30 epidemiological studies of drinking water chlorination and cancer have been carried out, and although the results are not unequivocal, there is a clear tendency that cancers of the bladder, colon and rectum are associated with various measures of chlorination (Morris *et al*., 1992; Villanueva *et al*., 2004). More recently, a number of epidemiological studies have indicated that adverse pregnancy outcomes may also be associated with drinking-water chlorination (Bove *et al*., 2002; Savitz *et al*., 2006).

Although the current scientific evidence linking drinking-water chlorination to cancer and adverse pregnancy outcomes is inadequate to conclude that the relationship is causal, several waterworks have changed their treatment practices to reduce the amounts of chlorination by-products, or changed their source of raw water to one with lower concentrations of humic substances, thus reducing human exposure to chlorination by-products. One must not forget, however, that the primary public-health concern for drinking-water supplies is still waterborne disease transmission, against which chlorine provides very effective protection.

Biological Criteria for Water Quality in Relation to Human Health

Robert A. Howd

CONTENTS

1 INTRODUCTION

Maintenance of drinking water quality is vitally important to human health, and is too often taken for granted in the modern developed world. Providing clean water has become increasingly difficult as human populations have increased, with corresponding increasing demands for high-quality water supplies. Both natural constituents and man-made chemicals can cause problems, and both surface and groundwater supplies are at risk. But it is neither useful nor cost-effective to merely remove all chemicals from our drinking water. Distilled or ultrapure water from reverse osmosis filtration does not taste good and removes desirable minerals. Therefore water providers attempt to determine what to leave in and what to remove, and the best treatments to achieve these goals that do not add other undesirable constituents or traits to the water. Increasingly sophisticated tools are available for this purpose—not only water analysis techniques, but also methods for evaluation of health risks from contaminants.

Identification of water-quality problems and attempts to solve them began over 2000 years ago (Pontius, 2003a). The most notable example of this is the construction of the Roman aqueducts, bringing water to Rome from far upriver to avoid problems caused by human sewage and other activities polluting the Tiber, which flows through the city. The same strategy was followed in other cities throughout the world where feasible, but increasingly, as populations grew, more people relied on shallow wells and urban rivers and streams for their water supply (Okun, 2003). Contamination of water by human and animal wastes led to epidemics of cholera, amoebic dysentery and other diseases—although this was not recognized to be due to micro-organisms in the water until acceptance of Pasteur's germ theory in the late nineteenth century.

Filtration of water through sand helped protect its quality by removing both sediment and bacteria. However, as medical record-keeping improved in the late nineteenth and early twentieth century, the observed variation of illness rates with water source demonstrated the inadequacy of this strategy (Frost *et al*., 2003). Disinfection of water by chlorination was begun both in Europe and the United States to avoid these problems—and was wildly successful. Incidence of water-borne diseases plummeted. Chlorination was rapidly adopted throughout the developed world (for surface water and water from shallow wells).

Regulations intended to ensure optimum chlorination to limit residual coliform bacteria began in the USA with the Public Health Standards of 1914. A few chemicals were added in 1925 (lead, copper and zinc), more in 1942, and then still more in 1962, as advances in both analytical instrumentation and epidemiology revealed the need for enhanced control of water quality. Development of appropriately health-protective water quality standards has been a long process, with gradually increasing sophistication. In the US, health risk assessment procedures for chemicals were formalized in the 1970s and early 1980s, subsequent to the establishment of the Environmental Protection Agency in 1970

and the increased regulation of chemical contaminants in drinking water mandated by the Safe Drinking Water Act of 1974 (Howd, 2008). Risk assessment and management procedures were first comprehensively laid out in the groundbreaking publication, *Risk Assessment in the Federal Government: Managing the Process* (NAS, 1983). European Union (EU) water regulations began with the Surface Water Directive in 1975, followed by the Drinking Water Directive in 1980. The drinking water regulations were updated in 1998 with Council Directive 98/83/EC, which is still current (Hecq *et al*., 2006).

At the present time over 90 natural constituents and contaminants are regulated in the USA (US EPA, 2008a) and Canada (Health Canada, 2008a) and a comparable number are the subject of World Health Organization guidelines (WHO, 2006). The EU has promulgated standards for approximately 48 constituents or properties of drinking water in its current Directive (Hecq *et al*., 2006; EC, 2008). The UK water quality regulations are based on the 1998 European Community directive (EC, 2008), but some standards may be more stringent (DWI, 2008). Many of the standards are based on World Health Organization guidelines (WHO, 2006).

2 RISK-ASSESSMENT PROCEDURES

The policies and assumptions used in risk assessments for chemicals in drinking water have tended to converge in recent years among the USA, Canada and the EU. The US EPA guidelines and actual practice (US EPA, 2004a; 2005a; Donohue and Miller, 2008) are very similar for both carcinogens and noncarcinogens to the practices described by Health Canada (1995) and WHO (2006). The description of risk assessment below applies to all these jurisdictions except as specified.

2.1 Evaluation of Toxic Effects

For purposes of evaluating potential risks to human health associated with a chemical, several sources of data are considered, which are listed in order of general priority:

- Effects observed in humans
- Effects observed in animal studies
- Effects observed in isolated human or animal tissues
- Effects in simple cell tests such as cytogenetic assays in bacteria or yeast
- Structure–activity relationships.

2.1.1 Human Studies

Data on human effects of chemicals found in drinking water may be available from anecdotal reports (i.e. poisoning cases), from occupational epidemiology studies, from environmental epidemiology studies and, in a few cases, from purposeful administration of the chemicals to humans.

Data on the acute toxic effects of chemicals are of great interest for chemicals with prominent acute effects, such as acetylcholinesterase inhibitors (carbamate and organophosphate pesticides). Other examples include antimony and copper, for which the gastrointestinal effects (irritation, nausea and vomiting) are most obvious (Winship, 1987; Araya *et al*., 2003). Although chronic effects provide the lowest-dose responses for many chemicals, in other cases toxic effects could be most likely as a result of exposure during particularly sensitive periods and life-stages, such as pregnancy and foetal development, infancy, maturation of reproductive organs (puberty) or during senescence.

Excellent occupational studies are available for several common chemicals, including asbestos (Hodgson and Darnton, 2000), benzene (Rinsky *et al*., 1987; Lan *et al*., 2004), chromium (Park *et al*., 2004) and lead (Roels *et al*., 1994; Duydu *et al*., 2001). Good data are available for these chemicals because they have relatively specific toxic effects that can be distinguished from the general background illnesses in a study group. For example, the pulmonary mesothelioma caused by asbestos is virtually a specific diagnostic; non-asbestos-related mesothelioma is relatively rare. However, these data are not useful for risk assessment of asbestos in drinking water, because these lung effects do not occur with oral exposure to asbestos (OEHHA, 1997). Leukaemia and lymphoma caused by inhalation of benzene have been observed in several occupational studies. It is assumed for the purposes of risk assessment that the same effect will be observed after exposure to benzene in drinking water, because benzene is well-absorbed orally and this is a systemic effect. Actual concentrations of benzene found in drinking water are much lower than the concentrations in air which have been associated with leukaemia, so no confirmatory data exist.

Environmental exposures are generally to lower concentrations of chemicals than found in occupational situations. With the lower resulting doses, it is much more difficult to demonstrate specific effects of these exposures than has been the case for several occupational studies. Very large populations are required to provide statistical significance of changes in disease incidence, in the presence of many competing risk factors. Environmental epidemiology studies therefore mostly show an *association* of exposure with effects, rather than cause and effect. Even a compilation of multiple studies (often called a 'meta-analysis') may not provide compelling evidence of attributable disease. Some of the data on arsenic effects (i.e. skin keratosis) from exposure to drinking water are considered adequate to demonstrate causality because of the unique nature of the end point and the large populations studied, but data

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat098
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

on most other chemicals are not as clear. In addition to the lack of such a characteristic end point and many competing risk factors, the difficulty of quantitating relative exposures among the population(s) studied is a limitation for environmental epidemiology studies.

Studies involving specific dosing of humans with chemicals of concern do not suffer the limitation of variable or unknown exposures, but are limited to low doses that do not produce frank toxicity. Examples are studies on pesticides in support of registration (US EPA, 2007), hexavalent chromium for pharmacokinetics (Finley *et al*., 1997; Kerger *et al*., 1997) and perchlorate for evaluation of hormonal effects (Greer *et al*., 2005; Braverman, 2007). This type of human study, however, introduces two other difficult issues into the data interpretation: extrapolation of short-term effect to long-term exposures and extrapolations of the observed changes at low doses to potential toxic doses and effects. In addition, concerns have been raised (Oleskey *et al*., 2004; NAS, 2004; US EPA, 2007) about the ethics of exposing people to toxic chemicals when there is no health benefit to balance the risk (as there is for drug testing). Uses of these types of data in risk assessment are discussed in more detail below.

2.1.2 Animal Studies

Data obtained in animal models are valuable because the toxic effects and their mechanisms can be studied in detail. The more information that can be obtained on what a contaminant can do, and how it does it, the more accurately the potential effects on humans can be predicted. Many different types of studies are conducted, which are discussed elsewhere in this volume, usually involving rodents. Studies in dogs, rabbits, guinea pigs, cats or a few other species may be conducted for specific purposes, such as eye irritation in rabbits. Regulatory agencies have defined good laboratory practices (GLPs) and standard operating procedures (SOPs) for purposes such as pesticide registration or drug-safety evaluation, which then may be applicable for any risk-assessment purpose (US EPA, 2007; OECD, 2008).

All toxicity data obtained in the standard test protocols are deemed relevant unless the results are shown to be inapplicable to humans by compelling evidence that biochemical pathways or physiological regulatory systems differ in humans from those in the tested species. One example of such an effect is the observation of mammary tumours in female Sprague–Dawley rats, caused by exposure to atrazine (Morseth, 1998). In this case, the US EPA has accepted the argument that the mammary tumours result from an oestrogen-stimulatory mechanism in the rats that does not occur in the human menstrual cycle (US EPA, 2006a). The effect of this decision is to greatly increase the estimated safe dose of atrazine and other triazine herbicides in humans. Toxicity test results for chemicals found in water are also frequently available for several aquatic species, including fish, amphibians and insects. These are not utilized as the basis for a human-health risk assessment due to the increased uncertainty associated with cross-species extrapolation.

In general, the lowest relevant dose effects in the most sensitive mammalian species and strain are used in the risk assessment (US EPA, 2004a). The rationale for this is that, when human data are not available, it is most prudent to assume that humans are at least as sensitive as the most sensitive mammalian species. It is also customary to assume that systemic toxic effects observed by one exposure route would be observed by all routes, so that the most sensitive effect by any exposure route can be chosen. However, there are many exceptions to this assumption based on route-specific effects. Such effects include strong point-of-entry toxicity, high pulmonary, but low oral, absorption and substantial first-pass metabolism in the liver after oral administration. Also, when results of multiple tests are available and are considered to be equally representative of a particular effect, it may be appropriate to average critical doses or cancer potency factors to estimate the toxic potency of the chemical in animals.

2.1.3 Effects in Tissues In Vitro

Effects in isolated mammalian cells and tissues can be extremely valuable in interpreting potential toxic effects. For example, evaluation of metabolism of chemicals in human liver slices and microsomes can document production of reactive metabolites that may be associated with carcinogenicity (Steensma *et al*., 1994; Born *et al*., 2000). Determination of the potency of interaction with tissue receptors can also aid in the development of sophisticated physiologically based pharmacokinetic models (Evans and Andersen, 2000). On the other hand, demonstration of an effect *in vitro* at high, unphysiological levels is not particularly useful. This is especially relevant for studies on brain tissues, because the blood–brain barrier prevents or limits access to neural tissues for many chemicals *in vivo* (Garberg *et al*., 2005). Acute *in vitro* effects (release of a transmitter in brain slices, for instance), may also be the opposite of the chronic effects (tolerance and lowered reactivity in a neural circuit).

2.1.4 Cytogenetic Assays

The standard *in vitro* mutagenicity tests, such as the Ames assay using *Salmonella typhimurium*, provide relevant supporting data for determination of the carcinogenic potential of chemicals. However, the high concentrations used can lead to false positives secondary to cytotoxicity in such tests (Kirkland *et al*., 2007). On the other hand, some solvents found in drinking water have been tested without control of evaporation or assay of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat098
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the resulting concentrations on the test plates or culture medium, which can lead to false-negative results (Barber *et al*., 1981). The question of whether the metabolism of a chemical in an *in vitro* assay is relevant to human *in vivo* metabolism must also be addressed.

2.1.5 Structure–Activity Relationships

Literally hundreds of trace chemicals are found in drinking water, including a plethora of disinfection by-products (Zhang *et al*., 2005; Sultan and Gabryelski, 2006). No panel of toxicity test results is available for most of these chemicals (Richardson *et al*., 2007). Testing of relevant mixtures may demonstrate important adverse effects, such as mutagenicity or reproductive/developmental toxicity. Although the complexity of the mixtures may make correlations of effects with specific agents very difficult, predictions of effects and potencies through interpretations of structure–activity relationships can be quite useful. Relative toxicity values, such as for dioxins and furans, can be derived (Van den Berg *et al*., 2006; Wilkes *et al*., 2008). Thinking of such chemicals as a group may also result in methods for controlling them as a group, rather than as individual components.

2.2 Estimation of Safe Doses

Safe doses are estimated for exposure durations from acute (one exposure) up to an entire lifetime. Protection of public health requires a conservative approach, to minimize potential risk, especially for drinking water. The conventions applied to the risk assessments for individual chemicals are intended to be more likely to overestimate than underestimate potential hazards.

2.2.1 Noncancer Effects

All chemicals are evaluated for their general effects and expected toxic actions at various doses. The human and animal data are studied to determine the lowest doses associated with significant toxicity, called the lowest observed adverse effect level (LOAEL), and doses resulting in any biological effects of significance, called the lowest observed effect level (LOEL). It has been more common to derive a maximum acceptable dose using the LOAEL than the LOEL, but the public may not appreciate the distinction: they do not wish *any* unexpected effects, such as influence on thyroid hormone levels (Blount *et al*., 2006) from drinking tap water. The maximum acceptable dose is called the reference dose (RfD) by the US EPA (2004a) and tolerable daily intake (TDI) by Health Canada (1995) and WHO (2006).

Doses below the LOAEL or LOEL which result in no detectable effects are called the no observed adverse effect level (NOAEL) or no observed effect level (NOEL). From the highest NOAEL (or NOEL) associated with the lowest LOAEL (or LOEL) in a human or animal study (often called the critical dose), a virtually safe dose for the entire population is estimated by attempting to account for the uncertainty. If the critical dose level is derived from an animal study, an uncertainty factor (UF) of 1–10 is utilized to estimate what the no-effect level might be in a human. That is, assuming humans might be up to 10 times more sensitive, the animal NOAEL is divided by a number from 1–10. Ten is generally used, unless specific information is available to support a smaller number. This could include, for instance, information that the animals tested convert the chemical to a toxic metabolite much more efficiently than humans do. If the study did not identify a NOAEL, then the LOAEL may be divided by 10 to estimate the NOAEL (Alexeeff *et al*., 2002).

In addition, humans vary in many ways, including the ability to metabolize chemicals (Pelekis *et al*., 2001; Barton *et al*., 2007; Yang *et al*., 2008). For this reason, the NOAEL is divided by another UF of 1–10 to ensure that sensitive individuals and groups (such as foetuses and infants) are protected. The risk assessor would also consider the adequacy of the database, and whether the end point is a dire effect (such as death or cancer which cannot be modelled as described below), and could propose additional factors of 10 for each. These factors are multiplied together as a divisor for the NOAEL (or LOAEL). However, US EPA now limits the combined UF to 3000 for derivation of RfDs (US EPA, 2004a; Donohue and Miller, 2008). WHO designates any drinking-water value derived with a UF greater than 1000 as a provisional value, to emphasize the higher uncertainty (WHO, 2006). Guideline values with this high uncertainty are given higher priority for later re-evaluation as new information becomes available.

2.2.2 Carcinogenic Compounds

For carcinogens, a quantitative method is used to estimate human risks, which can be based on cancer incidence in either human epidemiology studies or animal experiments (Health Canada, 1995; US EPA, 2005a; WHO, 2006). Several mathematical models are available for this purpose, and can be downloaded free of charge from the US EPA web site at *http://www.epa.gov/ncea/bmds/*. The linear multistage model is most commonly used; its numerical output is cancer potency in the units of risk per $mg\,kg^{-1}\,day^{-1}$. The models calculate the maximum likelihood estimate (MLE), and upper 95th percentile confidence limit of the cancer potency slope, sometimes called the q1*. The q1* is chosen as a health-protective estimate of the cancer risk. Alternatively, the cancer model is used to calculate the lower 95% confidence

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat098
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

limit on the dose associated with a 10% cancer risk. This risk level divided by dose provides a cancer potency estimate in the same mathematical form as the q1* (i.e. 0.1/dose in $mg\,kg^{-1}\,day^{-1}$ = potency in units of $(mg\,kg^{-1}\,day^{-1})^{-1}$).

The cancer risk estimation is based on the assumption that there is no practical dose threshold for production of tumours for many carcinogens, at least those which produce tumours by direct reactions with DNA. This generally means that a straight-line extrapolation through zero dose is used to estimate low-dose risk. The justification for this is discussed elsewhere in this book. However, the extrapolation to low dose, over several orders of magnitude, inherently introduces much uncertainty. Uncertainty is also introduced in the default assumption that tumour rates observed in animals are directly applicable to humans (with a dose correction for body-weight scaling). Available data on pharmacokinetics and toxicodynamics may be incorporated into the estimates if available.

The US EPA uses the cancer potency factor to calculate the lifetime risk of drinking water, based on a water consumption value of $2\,l\,day^{-1}$ for a 70 kg adult (US EPA, 2004a; Donohue and Miller, 2008). The US EPA desirable level of the carcinogen in drinking water (the maximum contaminant level goal (MCLG)) is set at zero for carcinogens, while the regulatory value (the maximum contaminant level (MCL)) has a target value of a lifetime risk in the 10^{-4}–10^{-6} risk range. Health Canada (1995) defines a maximum acceptable concentration (MAC) as being in the 10^{-5}–10^{-6} range 'whenever achievable'. WHO (2006) determines a guideline value at the 10^{-5} risk level, and acknowledges that countries may choose to set their own standards at values 'more appropriate for their circumstances', hopefully in the range of 10^{-4}–10^{-6} lifetime risk.

It is important to note that these cancer risk levels refer to each carcinogen, whereas drinking water commonly contains many chemicals with carcinogenic properties. Additive or synergistic interactions among these chemicals are largely unknown and unexplored in toxicity studies. Thus while each cancer risk estimate may be considered to be based on conservative (health-protective) assumptions, the combined risk may be greater.

Chemicals that induce cancer through nongenotoxic mechanisms may be evaluated using the noncancer methods described above. This assumes a threshold for the toxic effect and incorporates the same UFs discussed above. However, evidence for a nongenotoxic mechanism must be quite clear. Chloroform represents the most striking example of this judgement in US EPA risk assessments. This chemical, a by-product of chlorine disinfection, has been judged to produce liver and kidney tumours secondary to cytotoxicity and regenerative hyperplasia (US EPA, 2001a). Several models which incorporate this conclusion into health-risk estimates have been published (Meek *et al.*, 2002; Tan *et al.*, 2003; Liao *et al.*, 2007). However, this mode-of-action decision does not extend to the other trihalomethanes (THMs) formed along with chloroform in drinking water disinfection with chlorine. Thus, efforts to limit total THM content of drinking water continue to be based on concerns about carcinogenicity (WHO, 2005; Health Canada, 2008b).

The widely used chlorotriazine herbicides (atrazine and simazine) represent another interesting example. These chemicals and their proximate metabolites induce mammary tumours in female Sprague–Dawley rats through disruption of the oestrus cycle, leading to overstimulation of mammary cells by endogenous oestrogens (O'Connor *et al.*, 2000; Gammon *et al.*, 2005). The production of mammary tumours is considered inapplicable to humans since the menstrual cycle in humans is quite differently regulated than the rat oestrous cycle. This toxicity re-evaluation would not likely impact the EU ban on the use of these chemicals, since it is based at least in part on concerns over potential environmental effects of the chemicals.

2.3 Calculation of Health-Protective Drinking-Water Levels

2.3.1 Exposure Estimates

Once a health-protective dose is established, an appropriate maximum level in drinking water can be estimated. The calculation is based on exposure to the chemical through the water. In many cases, exposure by the dermal and inhalation routes to chemicals in the water is considered, which is related to normal activities such as showering and bathing. For noncarcinogens, exposure to the chemical from nonwater sources is also considered, because all exposure must be counted, to judge whether the dose exceeds a threshold for toxicity. This is called the relative source contribution (RSC). For carcinogen risk assessment (where no threshold is assumed), only the 'extra' risk from the water needs to be considered. Exposures to the chemical in air or food are judged not to alter the risk from exposure to the chemical in drinking water, so no RSC is incorporated into the risk calculation.

A drinking-water intake value of $2\,l\,day^{-1}$ has traditionally been used for cancer, as well as for noncancer risk assessments in the US and by WHO. This was a somewhat arbitrary value, which was later shown to represent about a 75th percentile consumption value normalized to body weight, or a 90th percentile consumption, not normalized to body weight (Ershow and Cantor, 1989). Health Canada has derived its MACs using a water

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat098
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

consumption value of $1.5\,l\,day^{-1}$ (Health Canada, 1995). Values reflecting consumption by infants or children may be used when the critical end point refers to a potential effect in this group. Applicable values are $1\,l\,day^{-1}$ for a 10 kg infant or $0.75\,l\,day^{-1}$ for formula consumption for a 5 kg infant (WHO, 2006). More recently, the US EPA has considered the variability in drinking water consumption in various population groups (US EPA, 2004b; 2005b), with the intention of providing protection for a greater proportion of the population, especially infants and children. The California Office of Environmental Health Hazard Assessment (OEHHA) has incorporated the US EPA (2004b) upper 95th percentile drinking-water consumption rates into its recent risk estimates (Public Health Goals) for chemicals in drinking water for both children (OEHHA, 2008a; 2008b) and adults (OEHHA, 2009).

The additional exposures to a chemical from bathing, showering or swimming can be substantial, although dermal-uptake rates from water tend to be rather low (Thrall *et al*., 2000; Xu *et al*., 2002). Volatilization of chemicals from tap water in household uses can be significant for the small halogenated hydrocarbons like chloroform or trichloroethylene (Weisel and Jo, 1996), while inhalation of droplet mists in showering is so small that it could be relevant only for chemicals with a very high potency by inhalation compared to the oral route (Keating and McKone, 1993). US EPA (2001b) has estimated that liquid intake comprises only about 34% of the total daily dose of chloroform, with 31% from inhalation and 27% from the diet (not including tap-water uses); according to this US EPA report, Environment Canada produced similar estimates.

The US EPA guidelines for use of RSCs in their MCLG calculations specify default values in the range of 0.2–0.8 for fraction of exposure derived from water. Relatively stringent requirements for supporting data to estimate a 'true' value have been set (US EPA, 2000), and the default value of 0.2 has been most commonly used. WHO (2006) currently recommends RSC values in the range of 0.1–0.8 and also rarely uses a specific calculated value. The previous versions of the WHO guidelines recommended 0.01 for highly lipophilic chemicals, which may still be implemented in some chemical guidelines or regulations.

All of these authorities, however, make an exception in use of RSC when the data were derived from a human study of exposure to the chemical in drinking water. In this case, no RSC is used (or an RSC of 1.0), such as for barium, copper and fluoride. The rationale is that the human effects associated with consumption of a particular concentration of the chemical in drinking water were observed against a normal, usually unquantified, background exposure level, which is assumed to be about the same as current background exposures. Thus the background exposures cancel each other out.

2.3.2 Calculation Method

Using the US EPA terminology, the drinking-water guidance value for noncarcinogens is calculated as:

$$\mathrm{MCLG} = \frac{\mathrm{RfD}\times\text{body weight}\times\text{relative source contribution}}{\text{drinking water intake}} \qquad (1)$$

For carcinogens, US EPA sets the MCLG at zero as a matter of policy. However, a comparable risk-based value can be derived for carcinogens, as exemplified by the OEHHA approach, to calculate a health-protective concentration C at any particular lifetime cancer risk level, R:

$$C = \frac{R}{\mathrm{q1}^* \times \text{drinking water intake}} \qquad (2)$$

In both of these equations 'drinking-water intake' should be taken as including the dermal and inhalation exposures to chemicals derived from the tap water in normal household activities. The results (MCLG or C) are in units of $mg\,l^{-1}$.

2.3.3 Sensitive Populations

Recently increased efforts have been made to determine whether current risk assessment methods are protective of all identifiable portions of the human population, including, but not limited to, foetuses, infants and the elderly. One aspect of this question is whether the use of a 10-fold factor to account for variability among humans is adequately health-protective. For this evaluation, it is useful to separate variability in exposures from variations in susceptibility to a toxic effect.

Mean drinking-water consumption rates vary from about $13\,ml\,kg^{-1}\,day^{-1}$ in an older child (11–20 years) to $95\,ml\,kg^{-1}\,day^{-1}$ in an infant less than six months old (US EPA, 2004b), a factor of sevenfold. Other important factors, such as average breathing rate and volume vary almost as much by age (OEHHA, 2000). Acute changes associated with daily activities add variability on top of this, and long-term differences associated with lifestyle choices (physically active vs. sedentary) ensure that the mean values above underestimate the total exposure differences among a population. In addition, the effect of ambient temperature on drinking water consumption should not be overlooked. A current military operations manual notes that a person can sweat $1.5–2.5\,qt\,h^{-1}$ under desert conditions, and recommends that at least $4\,gal\,day^{-1}$ (over $15\,l\,day^{-1}$) be provided for drinking (Army Study Guide, 2005). This value is well over 10 times the average adult daily consumption of tap water documented by US EPA (2004b). For chemicals with health-protective levels estimated from relatively short-term effects, such a short-term high-level consumption could be very important, although it would be less

relevant for a chemical with risk estimated from chronic exposures.

Variations in susceptibility to toxic effects can occur because of life-stage, genetic variability and health and nutritional influences. Foetuses are uniquely sensitive to certain toxic insults because of their rapid development. If a short-term effect on cell division occurs during the first trimester, either teratogenicity or foetal death is likely (Faustman *et al*., 2000; Thrasher and Kilburn, 2001). If the transient effect on cell division occurs at a later stage, it might delay puberty, cause short-term hair loss or go unnoticed. Risk of exposure to carcinogens also varies with age, with the very young being apparently most susceptible (Hattis *et al*., 2005; US EPA, 2005c). Many toxic effects of chemicals vary with life-stage, such as the tooth-mottling caused by fluoride. Fluoride is incorporated into tooth enamel as tooth buds develop, so the first few years of life, when permanent teeth are formed, are the most critical for development of tooth mottling.

The ideal risk assessment would include tests covering each life-stage, and would be based on the effect in the most susceptible life-stage, as described above. Thus no additional consideration of a special susceptibility would be required. This thinking was incorporated into the US Food Quality Protection Act (1996), which mandates an additional UF of 10 for setting pesticide tolerance levels in food, unless adequate pre- and post-natal test data are available. This law does not apply to determination of health-protective levels of chemicals in drinking water, but the same considerations are appropriate. The maximum concentrations of pesticides allowed in drinking water in the EU are not health based. The EU parametric values for individual pesticides ($0.1\,\mu g\,l^{-1}$) and for total pesticides ($0.5\,\mu g\,l^{-1}$) are not science based. The member states of the EU and the European Commission that adopted the Drinking Water Directive 98/83/EC are of the opinion that pesticides should not be present in drinking water. The value of $0.1\,\mu g\,l^{-1}$ is a substitute for zero, not present in water or below the detection limit (Council of the European Union, 1998).

Genetically related variations in susceptibility to toxicants are not yet well-enough documented to establish the range and distribution of human variability for most chemical classes. A few well-known variations include polymorphisms in aldehyde dehydrogenase (Isse *et al*., 2005), glucose-6-phosphate dehydrogenase deficiency (Kaplan and Hammerman, 2004; Cappellini and Fiorelli, 2008) and Wilson's disease, a disorder of copper metabolism (Mak and Lam, 2008). It is important to note that even if the variations could produce a life-threatening illness in affected individuals exposed to otherwise healthy levels of a chemical, the incidence of the condition may be too low to be a matter of concern for drinking-water suppliers. For instance, Wilson's disease, with an incidence of 1 in 10 000 to 1 in 30 000 in various populations, is ignored in setting standards for copper in water (WHO, 2004). Affected individuals, it is reasoned, should have their disease treated by a physician rather than controlled much less efficiently by changes in control of copper in water.

In the same way, differences in susceptibility to toxicants due to illnesses, special conditions and nutritional inadequacies are generally presumed to be the responsibility of the individual. Various chemicals in water, such as aluminium and chloramines, are known to affect people on dialysis for kidney failure (Arduino, 2000), but the chemicals are not regulated based on this factor. Current discussions on control of perchlorate involve, in part, the question of whether dietary deficiencies in iodine (which result in sensitivity to thyroid hormone disruption) should be considered in determination of regulatory levels of perchlorate, an iodine uptake inhibitor (Blount *et al*., 2006; FDA, 2008). A decision might revolve around the prevalence of iodine deficiency in the population, particularly in women of child-bearing age. This involves the issue of whether a practical, statistically meaningful effect on human health could be made with a drinking-water standard. The same consideration applies to cases of allergy to common chemicals. Although allergies to metals such as beryllium and mercury may provoke a very high sensitivity to these elements, the prevalence of the sensitization response is low, and therefore no attempt is made to protect against these 'idiosyncratic' susceptibilities in determination of health-protective levels of the chemicals in drinking water.

3 ESTABLISHMENT OF REGULATORY LEVELS

In the USA, the Safe Drinking Water Act mandates the development of MCLGs and MCLs for chemicals of concern in municipal drinking water supplies (Donohue and Miller, 2008), for cases in which:

- The chemical may have an adverse health impact
- The chemical is known to occur at high levels frequently enough to be of concern
- Regulation would provide a clear opportunity for significant risk reduction.

The MCLG is defined as a level 'at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety'. The actual regulatory level, the MCL, must be set 'as close as feasible' to the MCLG, considering technology available, cost and feasibility. The levels are primarily measured leaving the water treatment plant.

A few chemicals are defined in law slightly differently. Standards for lead and copper are defined as

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

action levels, measured at the users' faucets. This distinction is primarily because lead and copper contamination is mostly derived from plumbing, not from the water-treatment plant. Control of their levels in drinking water may require changes in the chemistry of delivered water to alter its corrosivity in household pipes, as well as replacement of lead pipes and solder (by the user). This is regulated by 'treatment technique' (TT), which consists of a performance standard for techniques used by utilities to treat water and ensure control of contaminants. The TT regulatory mechanism also applies to acrylamide and epichlorohydrin, which are derived from materials used in water treatment (US EPA, 2008a).

The WHO (2006) Guidelines for Drinking Water Quality define a quite similar process, resulting in guideline values for contaminants. These are incorporated into specific regulations for chemicals in drinking water through European Union Drinking Water Directives. Member States of the EU 'can include additional requirements, for example, regulate additional substances that are relevant within their territory or set higher standards . . . [but] are not allowed to set lower standards' (EC, 2008).

3.1 Cost, Benefits and Feasibility

Cost, benefits and feasibility of specific regulations on drinking-water contaminants are defined in the USA through a quite lengthy process. This may involve development and laboratory validation of an improved analytical method for a chemical; conducting an extensive sampling programme, potentially in different seasons of the year; population exposure estimates; population impact assessment; evaluation of sources of the chemical (industry, agriculture, natural product, residential); investigation of methods and costs of removal of the chemical from water; and an integrated cost–benefit analysis of different control scenarios. Cost–benefit analysis is expertly described by Rauche (2003). The US EPA, as mandated by the 1996 Safe Drinking Water Amendments, has been attempting to develop an improved benefits analysis (US EPA, 2006b). Potential benefits that could be considered include: improvements in human health, enhanced aesthetic qualities, avoided costs of averting behaviour, avoided materials damages, avoided costs of market production, nonuse benefits and information benefits (US EPA, 2006b).

Feasibility of control of contaminants is a moving target, as new water-purification methods develop. Advances in ion-exchange resins, oxidation techniques and reverse-osmosis media, to list just a few, have greatly improved the ability of water suppliers to provide wholesome water supplies at moderate cost (Pontius, 2003b). One of the more exciting developments is the development of high-capacity, lower-pressure reverse-osmosis systems, which have enabled large-scale recycling and reuse of waste waters in several arid regions such as Israel and Southern California. US EPA has supported these efforts through the recent development of formal guidelines for water reuse (US EPA, 2004c). These improved technologies bring with them two further considerations: (i) are new contaminants introduced, both from new materials and from use of previously compromised water sources? (ii) as the cleanup methods improve, are cost–benefit analyses keeping pace, so that previously unattainable health goals can now be reconsidered and the higher-risk contaminant residues correspondingly reduced? Many current publications and conferences on 'emerging chemicals' address these issues, among others (Boyd and Grimm, 2001; Westerhoff *et al*., 2005; Krasner *et al*., 2006; Liebig *et al*., 2006).

3.2 Significant Impact on Public Health

The regulatory process imposes a significant burden, both in terms of the effort required to develop an appropriate regulation for a contaminant and in the monitoring and control required of water suppliers once a regulation is formalized. Therefore regulations should only be developed when the development and imposition of controls is judged to produce a significant beneficial effect. This is particularly true with regard to the WHO guidelines, since they may be applied in a wide variety of countries with greatly differing conditions (WHO, 2006).

The US EPA use of this criterion is explained in a Federal Register notice of regulatory actions for the second drinking-water contaminant candidate list, also known as CCL2 (US EPA, 2008b). US EPA did not develop new regulatory requirements for any of the 11 chemicals for which a determination was made in this particular notice, and included the justification that a regulation 'does not present a meaningful opportunity for health risk reduction', for several of the chemicals based on low incidence of detection at concentrations likely to have an impact on health. The notice acknowledges that individual states might see the situation somewhat differently (based on local problems) and that they should institute controls in their jurisdiction if needed. This does in fact occur; the state of California has developed regulatory levels (MCLs) for several chemicals that are not federally regulated, including methyl *t*-butyl ether (a gasoline additive), perchlorate (a component of rocket fuel and road flares), molinate (a rice herbicide) and others (DPH, 2008).

In this context it should also be noted that, since risk assessment is generally carried out one chemical at a time, cumulative exposures to a variety of chemicals could theoretically have a significant combined impact,

despite lack of a documentation of harm for any of the individual compounds. This has been most thoroughly explored for disinfection by-products in drinking water, for which studies indicate a potential for increased rates of bladder cancer and reproductive effects (Nieuwenhuijsen *et al*., 2000; Villanueva *et al*., 2003), although data are insufficient for assigning blame to any individual chemical. The conventions applied to the risk assessments for individual chemicals are generally considered more likely to overestimate than underestimate potential hazards, but thinking of water as an aggregate of a great many chemicals provides a rationale for considerable caution (Richardson *et al*., 2007).

It is to be expected that techniques for risk assessments will continue to improve with increased understanding of biological mechanisms and control systems. Potential impacts of environmental contaminants on public health should be less uncertain, and UFs should be decreased. This is the driving force for advances in physiologically based pharmacokinetic modelling, as well as attempts to improve structure–activity models (Gundert-Remy and Sonich-Mullin, 2002; Aitio, 2008; Thompson *et al*., 2008). Advances in high-throughput screening methods (genomics, proteomics, metabolomics) can also be expected to enhance the science of risk assessment, although these tools have not yet been adequately correlated with traditional toxic end points and biomarkers for regulatory use (Blaauboer, 2008; Cullen *et al*., 2008).

Interactions between Occupational and Environmental Factors in Toxicology, Hazard Evaluation and Risk Assessment

James Gomes and B. Meek

CONTENTS

1 INTRODUCTION

Occupational toxicology examines chemical, biological or physical hazards in the work environment and evaluates their relationship with the development of adverse health effects in the worker. Environmental toxicology, on the other hand, examines the impact of the quality of the environment on human health. The health and wellbeing of an individual is certainly affected by their occupation and environment, and additionally by the interactions between occupational and environmental factors, which may be synergistic or additive in nature. This chapter examines the nature of these interactions and relevant contributing factors and the subsequent impact on hazard evaluation and risk assessment. The factors that affect health outcomes, including personal and lifestyle factors, physiological characteristics, occupational and environmental factors, and genetic and ethnic characteristics are discussed in the context of hazard evaluation, risk assessment and management.

To establish the relationship between work and illness it is necessary to first confirm the exposure at the workplace or in the environment and second, to understand the timing and the nature of exposure. Causality (i.e. understanding that a particular exposure contributes to illness) is based on consideration of factors such as the biological plausibility of the relationship and the strength of the association. It is also necessary to examine the uptake, distribution, biotransformation or excretion of the absorbed dose as affected by intensity of physical activity at work, body composition, age, gender, ethnicity, diet, smoking history, drug treatment and coexposures to ethanol and other solvents. Therefore, at the outset, a few examples of interactions between occupational and environmental factors are presented. Workers who were exposed to trichloroethylene at work and who had stopped to have beer on the way home are described by Stewart *et al*. (1974) to have developed 'degreasers flush', a condition characterized by development of blotches on their faces caused by interaction of trichloroethylene at work and alcohol consumed after work. Interaction between tobacco smoking and occupational exposure to asbestos in the causation of lung cancer has also long been described (Steenland and Thun, 1986).

Several other examples of interaction between occupational and environmental or lifestyle-related exposures have been described in the scientific literature. The interactions could occur between: (i) two industrial organic solvents, (ii) ethanol and an industrial organic solvent,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

(iii) drug and industrial organic solvent and (iv) two drugs. Exposure to toluene and xylene results in increased solvent concentration in blood and delayed excretion of hippuric acid (Tardif *et al*., 1991). A number of interactions between exposure to industrial chemicals at work and ethanol have also been described. Exposure to hepatotoxic chemicals in an industrial environment could interact additively or synergistically with alcohol resulting in liver damage (Hills and Venable 1982). Drugs may affect the toxicokinetics of organic solvents by inhibiting or stimulating the metabolism. Some of the reported effects in humans from drug–solvent interactions include impacts on blood pressure, cardiac output and hepatic function (Holtzman *et al*., 1986; Rosenberg, 1990). Juurlink *et al*. (2003) have reported that patients previously treated with clarithromycin were more likely to be admitted to hospital with digoxin toxicity because of drug interactions.

The principles of occupational and environmental toxicity, and toxic interactions between occupational and/or environmental exposures are explored in this chapter. Interactions between different agents are examined and a range of adverse health outcomes are identified. Relevant factors and those which may play a role in precipitating adverse health conditions in the exposed individual are also described. Readers are presented with a systems biology approach and encouraged to view the situation holistically. Emerging evidence of newer health outcomes and use of newer technologies, including 'omics' are explored.

2 TERMINOLOGY FOR TOXICITY AND INTERACTIONS

Toxicity is defined as the ability of a substance to cause harm or damage to an organism or substructure of an organism. The toxic effect can be at the point of contact (topical) or to the whole system of an organism (systemic) and can either affect the whole organism, or certain organs (organotoxicity) or the cellular structure (cytotoxicity) of the organism. The toxic effects can be acute effects, which occur in the first 24 hours of single exposure, or chronic effects, which occur after a latency period over a prolonged period of time. Toxicity of a substance depends upon a number of factors, such the nature of the substance, dose of exposure, individual characteristics, such as age, gender, physiological functioning and genetic makeup. Toxicity of individual chemicals has been well characterized for most of the chemicals used in industry, commerce or household products. However, toxicity of chemical mixtures is complex and involves consideration of a number of factors. Individual susceptibility to toxic interactions is dependent upon genetic, physiological and environmental factors. Among the genetic factors, individual genotypes and phenotypes play an important role in the manifestation of clinical or subclinical conditions. Among the physiological factors, age, gender, pregnancy and immune-compromised conditions are important parameters in the development of signs and symptoms (Grandjean, 1995).

The fate of a toxicant in human biological systems is described using toxicokinetics and the effect of a toxicant on the human body is described using toxicodynamics. Quantitative translation of relevant information in toxicokinetics and toxicodynamics help to describe physiologically based pharmacokinetic (PBPK) models. Absorption, distribution, metabolism and excretion (ADME) of a toxicant in human biological systems have been described by PBPK models. The ADME of a toxicant is chemical- and mode-of-action-specific, and interactions occur in human biological systems when a toxicant is not completely eliminated or when biological changes induced by a toxicant persist over a period of time. Exposures to multiple chemicals in occupational and environmental settings modify the toxicokinetics and toxicodynamics of a toxicant and, therefore, the outcome for the PBPK model of a substance (Lof and Johanson, 1998). Four possible outcomes for interactions have been described for exposures to multiple chemicals: (i) independent, (ii) additive, (iii) synergistic and (iv) antagonistic. Interaction is independent when two or more chemicals act by different modes of action, different metabolic pathways and do not compete for receptors. Additive interactions occur when two chemicals act by different modes of action, but produce the same or similar effects. Synergistic interactions produce multiplicative effects where one chemical enhances the effect of another and the combined effect is greater than the sum total of each of the interacting chemicals. Antagonistic effects occur when each of the interacting chemicals reduces the effect of another because of competing metabolic pathways.

Terminology and methodology for considering the impact of combined exposures to multiple chemicals has recently been considered under the auspices of the World Health Organization (WHO) International Programme on Chemical Safety (IPCS) project on Harmonization of Approaches to the Assessment of Risk from Exposure to Chemicals (Meek *et al*., 2009). One of the barriers to the development of harmonized methodology for assessing the effects of exposure to multiple chemicals is variation in terminology adopted in different jurisdictions and associated understanding. Also relevant to the development of a framework for risk assessment of combined exposures to multiple chemicals is a common understanding of 'mode of action'. A postulated mode of action is a biologically plausible sequence of key events leading to an observed effect, supported by robust experimental observations and mechanistic data. Mode of action contrasts with 'mechanism of action' which generally involves an

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

understanding of the molecular basis for an effect so that causation can be established (Sonich-Mullin *et al*., 2001).

3 HEALTH OUTCOMES FROM INTERACTIONS

Health outcomes from interactions range from development of blotches on skin to severe adverse reactions, to developmental toxicity, to carcinogenesis. Shelley (1964) described dermatitis in a case from interaction between golf-course exposure to the fungicide thiram and alcohol consumption. A number of reports have described a range of interactions between exposure to ethanol and other industrial chemical exposures (Savolainen *et al*., 1980; Snyder *et al*., 1981; Hills and Venable, 1982). Interactions between over-the-counter drugs and alcohol have been described in animal models by Padmanabhan and Pallot (2005) as causing congenital malformations. Caffeine is also reported to produce toxic interactions with a number of drugs and in animal models teratogenic outcomes have also been reported (Beck and Urbano, 1993).

Congenital malformations and developmental effects have been observed for a number of single chemical exposures. For multiple chemical exposures, a range of effects from no interactions, to antagonistic, to additive, to synergistic, to potentiating effects have been observed (Nelson, 1994). Additive effects were observed when mean foetal weights in women were lower in those who had taken aspirin followed by alcohol (Guy and Sucheston, 1986). Wilson (1964) reported synergistic effects in animal models from coadministration of actinomycin, cyclophosphamide and fluorouracil by observing malformations in the embryos of the exposed dams. Similar results have been reported by Gomes and Lloyd (2008) when male and female mice were exposed to a mixture of organophosphorous pesticides premating and preconception. Synergistic effects were also observed in the form of increased incidence of malformations when ribavirin exposure was combined with adenine and guanine simultaneously (Willhite and Ferm, 1978). Potentiating effects are reported by Khera and Iverson (1981) when a teratogenic dose of ethylenethiourea was coadministered with *N*-methyl-2-thioimidazole.

The process of carcinogenesis is significantly affected by multiple chemical exposures and interactions between these exposures. Different exposures to a range of chemicals are reported to enhance the process of carcinogenesis through: (i) increased uptake of carcinogen, (ii) enhancement of carcinogenic activity, (iii) inhibition of DNA repair capacity and (iv) enhancement of DNA lesions (Williams, 1984). Upon exposure to several carcinogens, the observed effects are additive, and carcinogenesis could occur when exposures are sequential or concurrent (Odashima, 1959; MacDonald, 1959). On the other hand, initial exposures to agents not considered to be carcinogenic followed by subsequent exposures either sequentially or concurrently to carcinogenic agents could enhance the process of carcinogenesis (Williams and Furuya, 1984). For example, occupational exposure to ferric oxide enhances the uptake of benzo[a]pyrene, a known carcinogen, by the bronchial epithelium (Kennedy and Little, 1974) and pulmonary alveoli (Antrup *et al*., 1979). Ferric oxide also enhances the carcinogenic activity of dimethylnitrosamine (Feron *et al*., 1972). It is also reported that chemical exposures act to inhibit DNA repair in a nonspecific manner (Williams, 1984). Takahashi *et al*. (1982) reported that 3-aminobenamide acts on the DNA repair process to enhance the action of hetapcarcinogenic agents. Exposures (turpentine, chloroform) that cause hyperplasia also enhance the occurrence of tumours from exposure to methylcholantherene or tar through the process of tumour promotion (Rous and Kidd, 1941).

4 FACTORS THAT ENHANCE ADVERSE HEALTH OUTCOMES FROM INTERACTIONS

Interactions between occupational and/or environmental factors, including lifestyle exposures are adversely affected by a number of other associated factors. These factors include the following: (i) personal characteristics, such as age and gender; (ii) lifestyle characteristics, such as smoking profile, alcohol intake, drug-taking habits and so on; (iii) physiological function, including obesity, immune function, diabetes and so on; (iv) genetic make-up, including genotype and phenotype and (v) occupation or the residential environment, such as place of work, location of residence (proximity to industrial installations). These and other associated factors are discussed in this section of the chapter.

4.1 Personal Characteristics

Since enzyme function and hormone expression vary with age, manifestation of toxicity of chemicals and drugs is age dependent (Meydani, 1994). Drugs and chemicals are metabolized differently in children and adults, due to age-dependent expression of enzymes. Children are reported to more susceptible to lead exposure (Davis and Grant, 1992) then to paracetamol (acetaminophen) (Kauffman, 1992), in which case the toxicity in higher among adults. Since body fat increases during ageing, compared to lean mass, exposure to polar solvents leads to higher residual levels of polar solvents in the blood of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat100
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the elderly, while exposure to lipophilic solvents leads to lower levels in the blood because of higher retention of such compounds in the adipose tissues (Lof and Johanson, 1998). The storage of lipophilic solvents in the adipose tissues leads to sustained release over a longer period of time. Physiological changes in adult life and during the process of ageing lead to reduced hepatic clearance of drugs and solvents in the elderly (Woodhouse and Wynne, 1992; Tam, 1993). These physiological changes include reduction of cardiac output, liver blood flow and liver weight. Also glomerular filtration and tubular clearance decreases with age, leading to reduced clearance (Cody, 1993; Rowland and Tozer, 1995). The age-related decline in hepatic clearance and renal function is also believed to reduce biotransformation and excretion of solvents and related metabolites.

The age-dependent susceptibility to toxicity has also been shown in animal models. Young experimental rats are shown to be more susceptible to *n*-propanol toxicity (Nelson *et al*., 1988) and vinyl chloride toxicity (Swenberg *et al*., 1992). Age appears to decrease Phase I metabolism, because cytochrome P450 (CYP), aniline hydroxylation and *N*-demethylation are all decreased, while age has little impact on Phase II metabolism (James *et al*., 1985; Schmucker, 1985). The severity of hepatotoxicity of allyl alcohol was higher in older rats compared to younger rats, possibly because of decreased availability of glutathione in the former (Rikans, 1984). In rats, total glutathione levels are shown to decrease with age in the liver, blood, kidneys and intestinal mucosa, and, therefore, age-dependent increased drug toxicity may be observed in the elderly (Hazelton and Lang, 1980; Stohs *et al*., 1980). Levels of hepatic glutathione are also observed to be lower in mature rats compared to their younger counterparts (Schmucker, 1985). In the elderly, the decreased elimination of solvents is probably associated with the decreased size of the liver and decreased hepatic blood flow and to a lesser extent to the changes in enzyme activity.

Women and men generally differ in average body composition in that men have leaner mass while women have higher adipose tissue. Women, therefore, tend to have a higher body burden of lipophilic xenobiotics compared to men, given that the exposures are similar. Women also tend to be exposed over a longer period of time because of sustained release of these xenobiotics from the adipose tissues (Gleiter and Gundert-Remy, 1996). Drug disposition, including toxicokinetics and toxicodynamics, in women is influenced by the level of sex hormones, menstrual cycle and oral contraceptive use (Wilson, 1984). A number of reports on gender differences and ethanol metabolism are available. Women, due to their higher body fat content, tend to have smaller volumes of ethanol available for distribution; however, there seems to be small or no differences in metabolic rates in alcohol metabolism (Pikaar *et al*., 1988; van Thiel and Gavaler, 1988). Alcohol dehydrogenase (ADH) activity is higher in men than in women and this is believed to contribute to the observed differences in blood alcohol content (Frezza *et al*., 1990; Seitz *et al*., 1993; Gentry *et al*., 1994). Women are reported to have higher peak blood alcohol levels during ovulation and immediately before menstruation than at other times (Wilson, 1984).

In animal models it has been observed that both castration and oestradiol administration suppress the hepatic microsomal ethanol oxidizing system (MEOS) activity leading to decreased hepatic biotransformation of ethanol. The suppressed hepatic MEOS activity appears to be negated by administration of testosterone (Teschke and Heymann, 1982; Lof and Johanson, 1998). Davis (1992) has reported that the chloroform-induced hepatotoxicity and nephrotoxicity in females in enhanced by dichloro- and trichloroacetic acid exposures. Sex-based differences are reported in expression of cytochrome P450 enzymes (Waxman and Chang, 1995). Hepatic clearance of solvent metabolites is expected to be higher in men than in women because of higher glomerular filtration rates in men (Lof and Johanson, 1998).

4.2 Lifestyle Characteristics

Certain lifestyle habits are believed to interact with occupational and environmental exposures, resulting in enhancement of adverse health effects. An interaction between smoking and exposure to asbestos is reported to significantly increase the incidence of lung tumours (Steenland and Thun, 1986). Caffeine is reported to alter toxicity of a number of prescription and nonprescription drugs. In animal models, synergistic effects were observed for interactions between caffeine and acetazolamide, caffeine and cyclophosphamide, caffeine and 2-ethylhexanol, and caffeine and mitomycine, and antagonistic effects for interactions between caffeine and 5-azacytidine and caffeine and propranolol (Nelson, 1994). Alcohol consumption and smoking are also believed to interact with blood lead levels and urinary *o*-cresol excretion in workers exposed to toluene (Weyermann and Brenner, 1997; Inoue *et al*., 1994).

4.3 Physiological Function

Physiological functioning including coexisting diseases, immune status and obesity can affect the toxicity of occupational and environmental exposures. In patients with liver diseases, oxidative drug metabolism is impaired, while conjugation may not be affected, but plasma-protein binding is reduced. Impaired liver function affects distribution, clearance and elimination of toxicants (Welling and Pool, 1996). When renal function is impaired because of liver disease,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

elimination of drugs such as cimetidine, antipyrine, paracetamol (acetaminophen) and theophylline is prolonged (Hoyumpa and Schenker, 1982; Welling and Pool, 1996).

Many physiological functions, including sleep–wake cycles, blood pressure, renal function and urine volume are periodic and change during the 24 hour cycle (Rowland and Tozer, 1995). Many of the hormones also undergo cyclic changes. These cyclical changes in the physiological function and hormone levels alter the pharmcokinetics of drugs, including absorption, distribution, biotransformation and elimination of xenobiotic substances (Labrecque and Belanger, 1991). Diurnal variation in alcohol concentration has been observed in blood, liver, brain and urine in animal models exposed to ethanol at different times during the day (Soliman and Walker, 1979). The circadian variations in hepatic levels of reduced glutathione is believed to be the determinant of hepatotoxicity of 1,1-dichloroethylene (Jaeger *et al*., 1973), allyl alcohol (Hanson and Anders, 1978), chloroform (Lavigne *et al*., 1983) and styrene (Decarie and Chakrabarti, 1989). Advanced insulin-dependent diabetes is associated with defective carbohydrate metabolism, hormonal perturbations and reductions in circulating testosterone, thyroid hormone and plasma growth hormone. Alterations in these hormones disrupt many liver cytochrome P450 enzymes, including induction of CYP 2A1, 2B1, 2C7, 2E1, 4A2 and 4A3 and reduction of 2A2, 2 C11 and 2 C13 (Waxman and Chang, 1995).

Induction in cytochrome P450 induces detoxification, particularly when low to moderate levels of substrates are present. Induction, therefore, is a protective mechanism and the extent of induction is inversely related to the rate of biotransformation. Enzyme induction by one chemical may also lead to increased metabolism by other compounds (Whitlock and Denison, 1995). Inhibition of cytochrome P450 can also act as a metabolic inducer (Hodgson, 1980). Inhibition involves a direct interaction with active sites on the enzymes and is generally rapid. For example, intake of ethanol increases blood concentrations of toluene in one hour. However, induction could also be a slow process; for example, intake of ethanol the evening before, followed by exposure to *m*-xylene decreases the concentration of xylene in blood. Substrates that are metabolized slowly are also potent enzyme inducers; for example, 2,3,7,8-tetracholorodibenzo-*p*-dioxin (TCDD), a potent inducer of cytochrome P450, is metabolized slowly by the enzyme (Parke *et al*., 1991).

The induction of the enzymes depends on the level of exposure to the solvent, metabolic clearance and the flow of blood to the metabolizing organs. For low-dose exposures to solvents whose intrinsic clearance prior to enzyme induction is much larger than the hepatic blood flow, the toxicokinetics do not affect metabolic induction. However, for high-dose exposures, as metabolism approaches saturation, enzyme induction is dependent upon metabolic clearance and toxicokinetic pattern (Sato, 1991). The toxicity of a solvent could be increased by the formation of reactive metabolites post Phase I enzyme induction. This toxicity can be further enhanced if the reactive metabolites are not cleared by induction of Phase II enzymes (conjugation enzymes). The toxicity and the build up of toxic metabolites of a solvent are, therefore, dependent on the balance between the induction of Phase I and Phase II enzymes (Bock *et al*., 1990; Okey, 1990). Ethanol induces CYP 2E1 by a post-translational mechanism at low ethanol concentrations in blood, and a transcriptional or messenger-RNA-stabilization mechanism at high ethanol concentrations in blood. Ethanol also induces CYP 2E1 *in vivo* by protein stabilization (Roberts *et al*., 1995).

4.3.1 Induction by Solvents

A number of solvents induce cytochrome P450 in animals and humans. Ethylbenzene, *n*-propylbenzene and *m*-xylene are effective inducers of aromatic hydroxylation of toluene in rats (Backles *et al*., 1993). Methyl *n*-alkyl ketones and *n*-alkylbenzenes induce CYP 2B1 and CYP 2B2 (Imaoka and Funae, 1991). Occupational exposures to solvents sometimes enhance biotransformation of other solvents; for example, in workers exposed to styrene, a decrease in styrene concentration in blood and an increase in metabolic clearance was observed (Dolara *et al*., 1983; Dossing, 1983). In workers exposed to petroleum, increased antipyrene clearance was observed, indicating increased metabolism of petroleum components (Harman *et al*., 1981). In experimental animals, the excretion of xylene metabolites was higher and the concentration of xylene in adipose tissues was lower following repeated exposure to xylene (Liira *et al*., 1991).

Solvents also induce Phase II enzymes. In rats exposed to methyl-*t*-butyl ether a dose-dependent increase of liver uridine diphosphate (UDP)-glucuronyl transferase activity was observed in liver and kidney microsomes (Savolainen *et al*., 1985). Repeated exposure of experimental animals to limonene increased the activity of cytochrome P450, glutathione-S-transferase (GST) and UDP-glucuronyl transferase in the liver (Maltzman *et al*., 1991; Zheng *et al*., 1992). Enhanced hepatotoxic and nephrotoxic effects were observed from exposure to organic solvents such as carbon tetrachloride, chloroform, trichloroethylene and tetrachloroethylene following an earlier exposure to ethanol, but not to simultaneous exposure to ethanol. This is a function of the induction effect of ethanol being at maximum shortly after ethanol is cleared from the body (Cornish *et al*., 1977; Sato *et al*., 1981; Zimmerman, 1986). The hepatotoxic effects of chlorinated solvents are also potentiated by aliphatic alcohols, ketones and their precursors (Traiger and Plaa, 1971; 1974; Hewitt *et al*., 1980a; 1980b; 1987).

4.3.2 Induction by Ethanol

Chronic consumption of alcohol is shown to accelerate biotransformation of a number of organic compounds such as benzene, toluene, styrene, xylene, chloroform, trichloroethylene and carbon tetrachloride (Sato *et al*., 1980; 1981). The effects are not pronounced after 16–18 hours of consumption of alcohol and when ethanol has been cleared from the body. The effects disappear following a one day withdrawal of alcohol (Hetu *et al*., 1982). In toluene-exposed workers, it has been observed that the concentration of toluene in blood is lower with regular intake of alcohol than in nondrinkers (Waldron *et al*., 1983). However, it has been observed that drinking alcohol the evening before exposure to *m*-xylene decreases the concentration of *m*-xylene in blood and alveolar air during and after exposure (Tardiff *et al*., 1994). This effect was seen at high exposure levels only and not at low exposure levels, because biotransformation of *m*-xylene is catalysed by a high-capacity enzyme system (Lof and Johanson, 1998).

4.3.3 Induction by Drugs

Phenobarbital is reported to increase biotransformation of several solvents, including benzene, toluene, xylene, *n*-hexane, chloroform, carbon tetrachloride and trichloroethylene (Sato and Nakajima, 1985). Pretreatment of experimental animals with phenobarbital is reported to enhance the metabolism of methyl-*n*-butyl ketone (Abdel-Rahman *et al*., 1976; Couri *et al*., 1978). Although the excretion of *m*-xylene metabolites in urine increases in experimental animals following phenobarbital exposure, no increase was seen in humans from similar exposures (David *et al*., 1979).

4.3.4 Induction by Smoking

Tobacco smoke induces the cytochrome P450 system. In smokers, because of enhanced biotransformation, requirements of increased drug dosages and reduced clinical effects are observed for many pharmaceutical drugs (Miller, 1989). Tobacco smoke also enhances the metabolism of solvents. Smoking leads to a dose-dependent induction of CYP 1A2 and phenacetin transformation (Kalow and Tang, 1991; Pantuck *et al*., 1974). Decreased metabolism of toluene is reported in volunteers after three weeks of cessation of smoking (Hjelm *et al*., 1988).

4.3.5 Induction by Diet

Diet and nutritional status are believed to alter the metabolism of drugs and solvents and contribute to inter- and intra-individual variability. Diet and nutrition is reported to affect Phase I enzymes more than Phase II enzymes (Walter-Sack and Klotz, 1996). A high-protein and low-carbohydrate diet enhances metabolism and elimination of antipyrine, theophylline and phenacetin (Alvares *et al*., 1976a; Hoyumpa and Schenker, 1982). A high-protein diet is believed to increase enzyme activity (Mgbodile and Campbell, 1972; Paine and McLean, 1973). High-fat diets increase induction of CYP 2E1 (Yoo *et al*., 1990, 1991; Takahashi *et al*., 1992). High-carbohydrate and low-protein diets delay the clearance of antipyrine and theophylline (Kappas *et al*., 1976). Starvation, fasting and low-carbohydrate intake induce CYP 2E1 (Favreau *et al*., 1987; Hong *et al*., 1987). Starvation is believed to enhance the toxicity of carbon tetrachloride due to induction of metabolism (Krishnan and Stenger, 1966). Increased hepatotoxicity has been observed in fasting experimental animals exposed to halogenated hydrocarbons due to induction of CYP 2E1 (Jaeger *et al*., 1975; Diaz Gomez *et al*., 1975; Nakajima, 1997). Fasting reduces glutathione levels that increase following a high-protein or high-carbohydrate diet. However, glutathione levels continued to decrease when a higher fat diet was provided following starvation (Maruyama *et al*., 1968; Tateishi *et al*., 1974).

Diets rich in cruciferous vegetables induce CYP 1A2, leading to increased clearance of antipyrine and phenacetin in experimental animals (Loub *et al*., 1975; Vistisen *et al*., 1991). In other studies with experimental animals, cruciferous vegetables are observed to induce CYP 1A1, CYP 1A2, CYP 2B and CYP 2E1 enzymes (Vang *et al*., 1991). Charcoal-grilled meats induce CYP 1A2 and increase metabolite clearance of antipyrine, theophylline and phenacetin in humans (Kappas *et al*., 1978; Alvares *et al*., 1979). Concomitant administration of grapefruit juice is reported to increase the blood concentration of a number of drugs in humans, often resulting in adverse clinical effects. These effects are mediated by chemicals in grapefruit juice that inhibit CYP 3A4 in the gut (Bressler, 2006).

4.4 Work and/or Residential Environment

Occupational and/or environmental exposures to toxic substances cause either induction or repression of metabolizing enzymes. Toxic substances can cause inhibition of cytochrome P450 by either binding reversibly to the enzymes, or forming semi-irreversible complexes with the haeme iron atom, or by binding irreversibly to the protein or the haeme group. The toxicity of solvents from environmental and/or occupational exposures is dependent upon their interactive effects and their dosages. Metabolic interactions between solvents depend on the nature of the solvents, as well as the level of exposure and metabolic pathways through the enzyme system (Sato, 1991).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.4.1 Solvent–Solvent Interactions

Ethanol and methanol are both equally reactive in the peroxidative system, but ethanol is much more reactive in the ADH system. Both ethanol and 1-butanol are effective inhibitors of methanol oxidation in animal models (Makar *et al*., 1968). The accumulation of formic acid is remarkable after methanol ingestion and plays a major role in the metabolic acidosis and ocular toxicity observed in human subjects (Bergeron *et al*., 1982; Eells, 1992; Jacobsen *et al*., 1983; Medinsky *et al*., 1997). Pyrazoles (4-methyl pyrazole) also inhibit the oxidation of methanol in both animal models and humans (Jacobsen *et al*., 1996). Delayed metabolic inhibition and decreased urinary excretion of ethyl benzene and *m*-xylene metabolites have been observed following concurrent exposure to ethyl benzene and *m*-xylene (Angerer and Lehnert, 1979; Engstrom *et al*., 1984). Similarly, Shibata *et al*. (2002) and van Engelen *et al*. (1997) have reported decreased concentrations of 2,5-hexanedione in serum and urine following human exposure to *n*-hexane and methyl ethyl ketone. Concurrent exposure of methl ethyl ketone and xylene in humans is found to inhibit biotransformation of xylene by methyl ethyl ketone, but no inhibition effects have been observed following exposure to methyl ethyl ketone and toluene (Liira *et al*., 1988; Dick *et al*., 1984; Tolos *et al*., 1987). These examples show that solvent–solvent interactions generally decrease biotransformation rates, resulting in higher body burden and delayed excretion of urinary metabolites.

Competitive inhibitory effects have also been observed from exposure to two or more solvents in animal models. Sato and Nakajima (1979) have reported that toluene is an effective inhibitor of hydroxylation of benzene than benzene is of toluene side-chain hydroxylation. Another example is methyl ethyl ketone, which is a strong inhibitor of side-chain hydroxylation of *m*-xylene, but not of the benzene ring (Liira *et al*., 1991). Concurrent exposure to toluene and *n*-hexane reduces biotransformation of *n*-hexane to 2,5-hexanedione, decreases the urinary excretion of 2,5-hexanedione and decreases neurotoxicity in rats (Takeuchi *et al*., 1981; Perbellini *et al*., 1982). In a similar manner, concurrent exposure to *n*-hexane and methyl ethyl ketone causes potentiation of the neurotoxicity, although metabolites 2-hexanone and 2,5-dexanedione are reduced (Takeuchi *et al*., 1983; Shibata *et al*., 1990a; 1990b).

4.4.2 Ethanol–Solvent Interactions

Alcohol intake has a significant inhibitory effect on biotransformation of several solvents. The major (80–85%) metabolic pathway for alcohol is through ADH. The other pathways are MEOS (10–15%) and the catalase system (5–10%) (Teschke and Heymann, 1982; van Thiel and Gavaler, 1988). When blood alcohol levels are moderate, ethanol is metabolized by the ADH pathway, whereas when high blood ethanol levels are present, ethanol is metabolized by the MEOS system (Teschke and Gellert, 1986).

Ethanol–solvent interactions occur when blood alcohol levels are moderate or high. When blood ethanol levels are higher compared to the blood solvent levels, the inhibitory effects of the solvent on the biotransformation of ethanol are small, whereas when the blood levels of both ethanol and solvent are moderate or high, significant effects are observed in both animal models and humans. In animal models, high doses of ethanol and toluene inhibit biotransformation of both (Takahashi *et al*., 1987), and moderate doses of ethanol inhibit biotransformation of toluene (Dossing *et al*., 1984; Wallen *et al*., 1984). Also, moderate levels of ethanol inhibit biotransformation of *m*-xylene (Riihimaki *et al*., 1982a; 1982b), styrene (Wilson *et al*., 1983), trichloroethylene (Stewart *et al*., 1974), methyl ethyl ketone (Liira *et al*., 1990a) and 2-butoxyethanol (Dornow *et al*., 1991). Low doses of ethanol also inhibit the metabolism of toluene (Baelum *et al*., 1993). Concurrent smoking and alcohol drinking suppresses the conversion of xylene to methyl hippuric acid, as well as toluene to hippuric acid (Huang *et al*., 1994; Inoue *et al*., 1993a; Inoue *et al*., 1993b) primarily because of ethanol. Concurrent exposures to ethanol and carbon disulfide, diethyl sulphoxide, dimethyl formamide and chlorinated solvents could result in flushing, tachycardia, tachypnoea and sweat, caused by accumulation of acetyladehyde in the body (Cicero *et al*., 1980; Chadha *et al*., 1983; Kaplita and Smith, 1986).

4.4.3 Drug–Solvent Interactions

Drugs are reported to affect toxicokinetics of organic solvents through a number of pathways. Drugs unilaterally have been reported to affect hepatic blood flow (cimetidine, phenobarbital, propranolol), blood pressure (caffeine, propranolol, diuretics) and cardiac output (digitalis, propranolol) (Holtzman *et al*., 1986; Rosenberg, 1990). Drugs are also known to affect protein binding of solvent metabolites. For example, metabolites of trichloroethylene are displaced from plasma proteins by salicylates, sulfonamides and phenylbutazone (Rosenberg, 1990). Alcohol drinkers are believed to have elevated blood pressures compared to nondrinkers in a dose-dependent manner, while smoking is associated with lower blood pressure (Savdie *et al*., 1984).

Metabolic interaction of drugs and solvents occur when they are metabolized by the same enzyme. Antipyrine metabolism is delayed by the intake of cimetidine and propranolol because of competitive inhibition of cytochrome P450 (Feely *et al*., 1984). Intake of paracetamol delays the metabolism of toluene (Lof *et al*., 1990b) and acetylsalicylic acid delays the transformation of *m*-xylene to methyl hippuric acid (Campbell *et al*., 1988). Reduced biotransformation of ethanol has been

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat100
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

reported from chlorzoxazone intake, because of competitive inhibition of the CYP 2E1 enzyme (Peter *et al*., 1990). Both acetone and toluene delay the urinary excretion of chlorozoxazone (Ernstgard *et al*., 1998).

4.4.4 Metal–Solvent Interactions

Metals inhibit Phase I and Phase II xenobiotic-metabolizing enzymes. In animal models, it has been shown that cadmium, cadmium chloride, mercury and methyl mercury are inhibitors of cytochrome P450 (Schnell *et al*., 1979; Alvares *et al*., 1972). Acute exposure to lead has also been reported to inhibit drug metabolism in animal models (Alvares *et al*., 1976b; 1978). Alvares *et al*. (1975) has shown that in children, antipyrine metabolism is delayed in lead poisoning. Metals such as cadmium, chromium and mercury bind to plasma proteins. Since some of the solvents also bind to plasma proteins, they compete with metals for binding sites in concurrent exposures to metals and solvents (Rosenberg, 1990). The interactions between exposure to metals and solvents depend on the levels of exposure. Exposure to mercuric chloride and zinc chloride in animal models either increase or decrease the hepatotoxicity of bromobenzene, depending on the dose (Chakrabarti and Brodeur, 1985; 1986). Aitio *et al*. (1978) have reported that cadmium iodide and mercuric acetate inhibit hydroxylation of benzo[a]pyrene, de-ethylation of ethoxycourmarin, hydration of epoxide and conjugation of glutathione.

4.5 Genetic and Ethnic Characteristics

There is a wide variation in the response of individuals to environmental and/or occupational exposures. Similar differences are observed in drug responses. One of the reasons for these differences is physiological pharmacokinetic differences and metabolic capacity (Rowland and Tozer, 1995). A number of other factors such as age, diet, lifestyle habits, and occupational and environmental exposures have also been identified (Anderson *et al*., 1986). Jang *et al*. (1997) have shown that Caucasians have higher concentrations of perchloroethylene, but lower concentrations of styrene in exhaled air compared to Orientals, following exposure to perchloroethylene and styrene respectively. Orientals were also observed to have lower concentrations of trichloroacetic acid, methyl hippuric acid and phenyl glyoxylic acid in urine compared to Caucasians following exposures to perchloroethylene, xylene and styrene, respectively.

Intra-individual differences in response to occupational and environmental exposures could possibly be due to genetic polymorphisms in xenobiotic metabolizing enzymes (Wrighton and Stevens, 1992; Daly *et al*., 1993; Idle *et al*., 1992). It is believed that poor metabolizers are homozygous for a defective gene variant, while fast or moderate metabolizers are either homozygous or heterozygous carriers of the functional gene variants. Genetic polymorphisms have been reported for a number of Phase I and Phase II enzymes, including the ones for the enzymes CYP 2D6, GST M1, GST T1 and *N*-acetyl-transferase (NAT2) (Daly *et al*., 1993; Curran *et al*., 2000). Some of these polymorphisms give rise to defective phenotypes, however, other phenotypic polymorphisms have also been reported for CYP 1A1 for polyaromatic hydrocarbons, CYP 1A2 for phenacetin and caffeine, CYP 2C19 for mephenytoin, CYP 2A6 for coumarin, CYP 2E1 for ethanol and CYP 2C9 for tolbutamin (Daly *et al*., 1993; Hassett *et al*., 1994).

ADH and aldehyde dehydrogenase (ALDH) metabolize ethanol and other hydroxylated solvents. Ethnic differences have been reported for polymorphisms in ADH2 and ADH3 loci. Variant ADH2 is reported to be present in 5–20% of Europeans and 85% of Orientals (Stamatoyannopoulos *et al*., 1975). Variant ADH3 has been detected in 25% of black Americans. Both variants are associated with increased rates of catalytic activity, which help to explain the interethnic differences in ethanol metabolism rates (Daly *et al*., 1993). Among the different variants of ALDH, Caucasians have two major variants, ALDH1 and ALDH2, while 50% of the Orientals have only one (ALDH1) (Teng, 1981; Yoshida *et al*., 1983; 1989; Mizoi *et al*., 1985). Lack of ALDH2 leads to higher acetaldehyde levels in blood post alcohol consumption (Mizoi *et al*., 1983). Higher acetaldehyde levels in the Orientals who lack ALDH2 leads to higher frequency of alcohol intoxication and facial flushing (Harada *et al*., 1985). Similar flushing has been reported among Caucasians who lack or are polymorphic in ALDH1 (Daly *et al*., 1993). Native Americans also metabolize ethanol to acetaldehyde more rapidly than Caucasians resulting in higher intoxication and flushing rates (Segal and Duffy, 1992). Polymorphisms in ALDH2 are also believed to affect the oxidation of benzylalcohol to hippuric acid. Benzylalcohol levels are lower in individuals with inactive homozygous ALDH2 genotype compared with those with heterozygous or normal homozygous genotypes (Lof and Johanson, 1993).

Ethnic differences have also been reported for biotransformation by Phase II enzymes. Fewer numbers (50%) of Europeans and Africans express NAT2 than do the Orientals (100%) and Eskimos (95%) (Daly *et al*., 1993). The GST family of enzymes catalyse the conjugation of reduced glutathione to a variety of electrophilic and hydrophilic compounds. There are four generic classes of GST enzymes: α, μ, π and θ which contribute to Phase II biotransformation of xenobiotics (Meyer *et al*., 1991; Schroder *et al*., 1992). Polymorphisms have been observed in GST T1 and GST M1 classes of GST enzymes. The Chinese and Koreans are reported to have the highest prevalence of null genotypes for GST T

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat100
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Nelson *et al*., 1995). A number of substrates of GST T1 have been described, for example, methyl chloride, methyl bromide, methyl iodide, methylene chloride and ethylene oxide (Hallier *et al*., 1990; 1994; Fost *et al*., 1991). Lack of GST1 is reported to adversely affect solvent clearance for workers exposed to methyl bromide, for whom haemoglobin adduct levels were elevated (Iwasaki *et al*., 1989). Other studies have shown that workers exposed to methyl chloride had higher concentrations of methyl chloride in their blood and alveolar air (Nolan *et al*., 1985).

Phenotype studies have shown that 11% of the population lack conjugation activity of methyl chloride, whereas, 46 and 43% have intermediate and high activity (Warholm *et al*., 1994). In Europe, non-conjugators of methyl chloride are 11–12% in Sweden and Finland (Warholm *et al*., 1995), 30–40% in Germany (Peter *et al*., 1989) and 40% in Great Britain (Pemble *et al*., 1994). Interethnic differences in xenobiotic metabolism are supported by studies in North America in the Mexican population, where mutant allele frequency has been reported to be in the range of 30–43% (Mendonza-Cantü *et al*., 2004). Gene-dependent toxicokinetic studies have been well reported. Fast conjugators have high uptake, high metabolic clearance and lower concentration in blood, and rapid post-exposure decay, while nonconjugators show opposite effect and intermediate conjugators in between effects. Different solvent toxicokinetics have been reported for different ethnic groups.

Ethnic differences between Japanese and Chinese workers have been observed in the biotransformation of trichloroethylene (Inoue *et al*., 1989) and tetrachloroethylene (Seiji *et al*., 1989); the excretion of the metabolites in urine was lower for the Chinese workers. The concentration of hippuric acid and *o*-cresol in urine was half in Chinese and Korean workers compared to the Japanese workers, following their exposure to toluene (Inoue *et al*., 1988a; Liu *et al*., 1992). Increased susceptibility to cancer has been associated with ethnic differences for the genes NAT2, CYP 1A1, CYP 2D6, CYP 2E1, GST M1 and GST T1. Bladder cancer and gastric adenocarcinoma has been associated with genetic polymorphisms in NAT2, GST M1 and CYP 2D6 (Anwar *et al*., 1996; Brockmoller *et al*., 1996). The GST M1 null genotype is associated with increased risk of smoking-related cancers (Wolff *et al*., 1994). Polymorphisms in CYP 1A1 and CYP 2E1 are associated with lung cancers (Yu *et al*., 1995; Wu *et al*., 1997). Defective conjugation is associated with increased risk of lung cancer from cigarette smoking (Seidegarrd *et al*., 1986). The increased susceptibility to lung cancer in smokers with the GST M1 null genotype is believed to be due to nonclearance of carcinogen benzo[a]pyrene (Nakajima *et al*., 1995a).

5 RISK ASSESSMENT

In recent years, there have been advances in the development of more integrated approaches to consider the combined effects of toxins on cells, organs or organisms. This integrated approach is termed the systems-biology approach (Kitano, 2002) and allows for the examination of the modes of action, involving different targets within cells, tissues or organs. In the coming years, the systems-biology approach will be instrumental in assessing basic biology and in evaluating the conditions under which chemical stressors, either singly or in mixtures, may lead to clinically significant morbidity or toxicity in exposed population (Anderson and Denison, 2004). The systems-biology approach emphasizes the biology of organisms and dose-dependent relations for endogenous proteins and signalling molecules. The mode of action of xenobiotic chemicals is related to the endogenous perturbations of the endogenous signalling networks and manifestations of clinically relevant signs and symptoms. PBPK and physiologically based pharmacodynamic (PBPD) models of these perturbations may help to characterize the relationship between exposure and manifestation of adverse health effects.

With the development of omics (genomics, transcriptomics, proteomics and metabolomics), it has been suggested that these are potential technologies to study risk assessment of single or multiple toxicants and to predict interactions and combination effects. It is also believed that omics will provide the necessary tools needed to understand the mechanisms of action of toxicants at a molecular level (Cunningham *et al*., 2003; Bernauer *et al*., 2005). However, given the large number of chemicals in commerce and the endless combinations and complexity of interactions, a multifaceted approach may be needed, with contributions from computational technology, mechanisms of action, modes of action and mathematical modelling (El-Masri *et al*., 1995).

Current evolving frameworks for consideration of risk from combined exposures to multiple chemicals are proposed to be iterative, involving stepwise consideration of both exposure and hazard in several tiers of increasingly data-informed analyses. The approach involves decision-based analysis that takes into account relevant information at an early stage as a basis to scope the need or not for additional assessment and recommend any required data generation. Early consideration of potential for exposure (prior to any consideration of hazard) is essential in determining critical next steps, since there is no need for further assessment if there is no or minimal exposure (Meek *et al*., 2009).

The extent of assessment and nature of recommendations for generation of additional data are dependent upon the extent of the knowledge base, the magnitude of public-health concern (i.e. taking into account margins between exposure and effect) and the objective of the risk assessment (e.g. implications of potential

risk management decisions). It is envisaged, then, that approaches will range from predictive methodologies and conservative assumptions in early tiers, to more realistic estimates of risk and rigorous descriptions of uncertainties in later tiers, based on increasingly data-informed and probabilistic approaches.

This tiered approach is considered essential to ensure that the expenditure of resources is proportional to the public-health concern and consistent with regulatory objectives. This includes the purpose of the assessment, such as prioritization for assessment, screening for additional assessment and/or risk management (including bans, controls and other options, such as education).

The proposed framework for consideration of risks from combined exposures to multiple chemicals is also hypothesis driven, involving analysis of available information followed by a conclusion in which a hypothesis is developed and refined (as necessary). This enables transparent and systematic analyses in the context of a 'weight-of-evidence' approach consistent with the IPCS Framework for Analyzing the Relevance of a Cancer Mode of Action for Humans (Boobis *et al*., 2006) and the IPCS Framework for Analyzing the Relevance of Noncancer Mode of Action for Humans (Boobis *et al*., 2008). It also enables incorporation of data from evolving technologies, including systems approaches.

6 CONCLUSIONS

Interactions occur when concomitant exposures occur to multiple chemicals from occupational and/or ambient environments, diet, drugs or lifestyle habits. The type of response in interactions can range from rash to dermatitis, to severe acute condition, to cancer. The nature of the response depends on the nature of exposure to the chemical in question and the individual that is exposed. Among the exposure- or chemical- based factors, the type of chemical, the level of exposure and the type of exposure are important and need to be considered in assessing the risk. Among the individual-related factors, age, gender, dietary habits, drugs (both recreational and therapeutic), lifestyle habits (including alcohol consumption and smoking profile), physiological characteristics (concomitant and pre-existing health conditions, chronic diseases, immune status, etc.) and genetic characteristics (including genotype, phenotype and ethnicity) are important. Many normal physiological functions, including sleep–wake cycles, blood pressure and renal function, influence the interaction response or even the response to a single chemical exposure. Altered or perturbed hormones also influence the interactions. A number of approaches to more systematically assess risk associated with combined exposures to multiple chemicals, including stepwise consideration of both exposure and hazard in several tiers of increasingly data-informed analyses, including that from evolving integrated approaches in systems biology have been proposed.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the technical support provided by Mr. Linlu Zhao in preparing this manuscript. The authors gratefully thank Mr. Zhao for his systematic and meticulous literature search and compilation of the references.

Susceptibility of Children to Environmental Xenobiotics

Alan D. Woolf and Megan Sandel

CONTENTS

1 INTRODUCTION AND HISTORICAL PERSPECTIVE

The realization that the health of a child can be drastically affected by elements in his or her environment has only been appreciated relatively recently in history. However, the growth of interest in paediatric environmental health reflects a widespread recognition that the impact of the environment on children is of major importance, not only for this generation, but also for succeeding generations in the future. Such environmental exposures often have different determinants, mechanisms and consequences for children than for adults. Whereas more than 80 000 chemicals are in widespread commercial use, most of these were synthesized within the past 50 years and few have been adequately tested for their toxic effects on humans generally, let alone newborns, infants and children (Stein *et al*., 2002).

1.1 Scope of Environmental Impacts on Children's Health

Childhood is a time of rapid growth and development, with changes in anatomy, organ-system functioning, physiology, metabolic capacity, physical size, and cognitive, developmental, psychological and sexual maturation. Children have a greater vulnerability to many environmental chemicals and other toxins than do adults, by virtue of their smaller size, increased weight-adjusted intake of some toxicants, developmental differences in body systems and functions, overall physiological and toxicodynamic differences,

and differences in the environments they inhabit, the foods they eat and the behaviours they display every day. Even the prenatal environment and foetal exposures from placental transfer can determine foetal development and survival, as well as the child's postnatal health. **Table 1** illustrates some of the determinants of a child's health status that interact to contribute to a complex web of causation. The overall impact of such adverse effects, manifested by subsequent poorer health and the need for costly health careservices, is amplified by the longer lifespans of children and is associated with intergenerational transmission of harmful effects, to the detriment of mankind.

1.2 Protection of Children by Caregivers

Children are also subject to special risks by virtue of their dependencies and the social, cultural and economic circumstances of their families. A child relies on caregivers for his or her housing, water, sanitation, a healthy, nutritious diet, education, protection and nurturance. Parents must protect their children by controlling their environment: for example, by baby-proofing a home using gates and electrical outlet covers, by buckling toddlers into safety-engineered car-seats for each automobile ride and by using sun-block to protect them from overexposure to radiation from sunlight.

Caregivers can contribute to a child's risk, for example by exposing a foetus to alcohol or exposing a child to drugs of abuse or environmental tobacco smoke. Poor parenting techniques, social isolation, or aggressive and aberrant behaviours can contribute to a home atmosphere of unpredictability, disruption and violence, all of which will adversely affect the health and growth of a child. Some culturally contextual health practices may put children at risk for environmental exposures. For example, the use of tongue powders daily is promoted in certain Asian cultures to preserve infant good health. However if the tongue powder is contaminated with a heavy metal such as lead, then chronic poisoning of the infant can be significant (Woolf *et al*., 2008). Immigrant families using contaminated home remedies, herbs or even spices in cooking their food may also put their children at risk for heavy metals poisoning (Woolf and Woolf, 2005). Ayurvedic medicines, often used by people living in South Asian countries, are frequently contaminated with significant quantities of lead, arsenic, cadmium or other metals.

Disorganized families living under stress may have poor access to, or underutilize, available healthcare services, so that their children will not be afforded the preventive health programmes that contribute to healthy living. Children with underlying diseases, such as asthma or diabetes, may suffer exacerbations of their condition because of a lack of regular monitoring of their health status if families are not attentive to seeking out

preventive-care services. For example, the prevalence of physician-undiagnosed asthma among Detroit-area children was estimated to be 14.3% (Joseph *et al*., 1996).

Workers who do not practise good industrial hygiene can inadvertently contaminate their families by bringing home occupational chemicals clinging to tools, shoes, hair, skin and clothing. Numerous studies have documented elevated blood lead levels in children whose parents are employed in industries where lead contamination is an occupational hazard. Tissue mercury levels were found to be elevated in the children of parents who worked in a thermometer-manufacturing facility (Hudson *et al*., 1987). Some children of workers employed in the manufacture of synthetic oestrogens developed gynaecomastia and breast discomfort (Budzyńska *et al*., 1967). Contact with contaminated clothing produced chloracne in children whose parents worked in industries where there was exposure to dioxin and other polycyclic halogenated compounds (Mocarelli *et al*., 1991).

1.3 Prevalence and Costs of Environment-Associated Illnesses

The prevalence of some chronic childhood conditions is inexplicably increasing everywhere. Autism rates are estimated to be as high as 1 in 150 births (Stephan, 2008). The prevalence of asthma increased by almost 40% from 3.1% of children in 1981 to 4.3% in 1988 (Weitzman *et al*., 1992). At least part of this increased prevalence is speculated to result from children's inhalation of both indoor and outdoor airborne pollutants. Childhood lead poisoning is still a threat, with more than 300 000 children in the United States suffering elevated blood lead levels (Centers for Disease Control and Prevention (CDC), 2005c). In the case of some toxins, the threat may not become manifest for years. Environmental Protection Agency data suggest that a lifetime exposure to 1 ng kg^{-1} day^{-1} of 2,3,7,8 tetrachlorodibenzo-*p*-dioxin (TCDD) may account for 1560 additional cases of cancer per 10 000 population.

Conversely there is also great potential for averting such harmful effects by improving the quality of the environment and sparing children the consequences of exposure to harmful chemicals and toxins. One recent study estimated the economic gains and increased worker productivity to be anticipated from the reduction in environmental lead in the United States since 1976, based on population increases in cognitive abilities realized as blood lead level declines, to be in the range of $110–319 billion for each year's new cohort of two-year-old children (Grosse *et al*., 2002).

1.4 Historical Toxic Disasters: Examples Involving Children

Because of their physiological differences from adults, children are affected first and more intensely by environmental toxic spills and have higher morbidity and mortality rates than adults in such disasters. These factors are additive, marking children as the 'canaries' in much the same way that birds were lowered first into mine shafts to detect dangerous levels of toxic gases such as methane. If the birds died, than the miners would not enter the shaft. So too illness in children may be the first indication of a hazardous environment. Their casualties are disproportionately higher than those of adults because of their smaller size, their increased vulnerabilities, their dependency on adults for mature judgements and decision-making and their reduced ability to escape independently from such emergency situations.

1.4.1 Minamata Bay Mercury Poisoning

The chemical disaster that occurred at Minamata Bay in Japan in the 1950s was a watershed event in increasing the general public's awareness of the potential dangers inherent in environmental hazards having a widespread impact on children's health. Industrial discharges of very high concentrations of mercury into the bay from a vinyl-chloride-producing factory were incorporated into the flesh of fish which were subsequently caught and consumed by area residents. Neurological toxicity ensued with tremors and ataxia, paresthesias, constricted visual fields, impaired speech and hearing, and progressive neurological dysfunction. More than 3000 people were certified by the Japanese government as having 'Minamata disease' and at least 600 deaths were attributable to the contamination (Davidson *et al*., 2004). Pregnant women who ate the contaminated fish did not necessarily exhibit any symptoms themselves, but gave birth to infants with severe developmental disabilities, microcephaly, severe retardation, static encephalopathy and seizures, termed 'congenital Minamata disease'. This event alerted scientists, public-health officials and the general public to the potential greater sensitivity of the foetus to environmental chemicals conveyed via placental transfer.

1.4.2 Yusho, Japan Rice Oil PCBs Contamination

In Yusho, Japan, in 1968 it was discovered that a food staple, Kanemi rice, had been inadvertently contaminated with Kanechlor 400, a mixture of polychlorinated biphenyls (PCBs), polychlorinated dibenzofurans (PCDFs) and other dioxin-like compounds. PCBs and PCDFs comprise several hundred different chlorinated

hydrocarbon congeners varying in halogen content, but alike in their lipophilicity and persistence in food chains and the environment. Medical effects of exposure to these chemicals include acne-like facial rashes, hyperpigmentation and eye irritation. In children, growth retardation and triglyceride, immune and endocrinological disturbances are also suspected. By 1982 more than 1788 Japanese people had been certified as having been exposed to 'Yusho poisoning'. Even as late as 30 years after the incident blood levels of total dioxins and 2,3,4,7,8 pentachlorodibenzofuran in Yusho patients were 3.4–6.8 times higher and 11.6–16.8 times higher than matched controls (Furue *et al*., 2005). Long-term effects on Yusho women included a twofold increased rate of spontaneous abortion, a fivefold increased proportion of premature births, a twofold increased rate of pregnancy loss and a fivefold increased rate of induced abortion (Tsukimori *et al*., 2008). This event revealed the potential threat for long-term harm in children occasioned by their (or their mothers') relatively short-term exposures during environmental contamination events involving persistent organic pollutants (POP).

1.4.3 Bhopal, India Methyl Isocyanate Disaster

Methyl isocyanate (MIC) is a colourless liquid with a pungent odour that reacts violently with water and is highly flammable. In an incident on 3 December 1984, at the Union Carbide chemical plant in the city of Bhopal, India, water entered a storage tank containing 40 900 kg of MIC and produced an exothermic reaction. The explosion liberated about 24 545 kg of gaseous MIC, along with 12 800 kg of by-products such as carbon monoxide, monomethylamine gases and hydrogen cyanide, over the next two hours (Sutcliffe, 1985). The health effects of MIC, previously poorly studied in humans, included dermal and ocular irritation, metabolic inhibition, acute and chronic respiratory effects, including pulmonary oedema and death. Consequently more than 1000 people living within a perimeter close to the plant died within the first two hours after the gas release, 2500 people died within the first day and over 90 000 people required emergent medical evaluations for illness. There were hundreds of delayed deaths and thousands who suffered permanent lung damage and disability. A disproportionate number of children suffered coma, seizures, ophthalmologic and pulmonary toxic effects from their exposure, and a sizable number, 199 children, died within the first 12 days postexposure (Irani and Mahashur, 1986; Bharucha and Bharucha, 1987; Mehta *et al*., 1990). There are still many lingering questions regarding the long-term residual effects of the MIC exposure on the health of the children 25 years later.

1.5 Children, Communities and Environmental Justice

Economic disparities account for racial and ethnic disparities in childhood lead poisoning, with a disproportionate number of black and Hispanic children, who are exposed to lead-containing dust in older, dilapidated housing stock.

Because of socioeconomic and racial disparities, more children live in poverty than do any other age group. Their families are more likely to live in poorer, contaminated, unhealthy communities, in close proximity to toxic waste dumps, landfills and/or 'dirty' industries where environmental regulations are nonexistent, unmonitored or unenforced. For example, people living near air-polluting electricity-generating plants have higher rates of asthma and respiratory illnesses.

Children living in urban ghettos are exposed to the hazards of dilapidated housing, substandard sanitation and insufficient 'green space' areas to play. Benzene, a contaminant of gasoline and a known carcinogen, is a problem in poverty-ridden, urban settings. Benzene levels correlate with heavy automobile traffic, and children playing in the streets in poor neighbourhoods have disproportionately high exposures (Weaver *et al*., 1996). The prevalence of asthma among children living in the Bronx, New York, was estimated to be twice the national average, with disproportionately higher rates among both Hispanic and lower-income groups (Crain *et al*., 1994). There may be racial as well as socioeconomic determinants of childhood asthma, with black children being generally more affected than whites (Weitzman *et al*., 1992; Cunningham *et al*., 1996).

New immigrants and children of migrant workers are examples of other vulnerable groups whose socioeconomic circumstances force them into substandard housing stock and whose unfamiliarity with the local healthcare system, governmental programmes, education system and other community-based helping agencies may limit their children's access to services.

2 GENE–ENVIRONMENT INTERACTIONS

The central role of environmental genomics as the mediator of risk for many chronic disease processes is well established. Gene regulators and gene cascades may differ in their roles and expression from tissue to tissue and may differ in the timing of their activity in complex ways. Genetic differences dictate the number and functionalities of molecular transporters and tissue-specific receptor sites, protein structure and function, cell-signalling processes, enzyme efficiencies and many other molecularly mediated mechanisms of subcellular, cellular and organ function. Interindividual variation in both the effectiveness of drugs and the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

susceptibility to adverse drug reactions has long been known. For example, genetic polymorphisms associated with hepatic-enzyme efficiency (i.e. 'fast' or 'slow' acetylation) not only dictate the frequency of dosing necessary to achieve a therapeutic effect of isoniazid hydrochloride, but also determine the risk for developing some adverse effects to the drug. Likewise, such genetic polymorphisms may also dictate in part the individual's susceptibility to a chemical or toxin. Genetic differences in the efficiency of the alcohol dehydrogenase enzyme system account, in part, for the susceptibility of people of Asian descent to flushing and other adverse side effects of drinking ethanol.

The effects of environmental toxins in children are similarly mediated, in part, by their genetic make-up. The existence of genetic variants and polymorphisms confers relative vulnerability or resistance to molecular perturbations and cellular dysfunctions that are manifest downstream as phenotypic variation and, in some cases, clinical toxicity. Hopkins *et al*. (2008) genotyped 422 cord-blood samples in Mexican children for mis-gene variants in haemochromatosis and transferrin genes, which in part determine gastrointestinal absorption of the cationic metals, iron and lead. These researchers found that subjects carrying missense genes had blood lead levels 11% higher than those with wild-type genes, with a 50% higher risk of having a blood lead level greater than $10\,\mu g\,dl^{-1}$. Thus children with variant iron-transport and metabolizing genes may be especially vulnerable to low environmental exposures to lead sources.

Other disorders with significant environmental contributions besides lead may also be mediated by 'environmentally responsive' genes (Herbert *et al*., 2006). Researchers showed a modest correlation between single nucleotide polymorphisms (SNPs) of the airway inflammatory proteins, glutathione-S-transferase P1 and tumour necrosis factor, interacting with geocoded ambient levels of nitrogen oxides, in a case-cohort study of 542 asthmatic Swedish children, who developed clinical indicators of allergic disease at four years of age vs. 542 controls (Melen *et al*., 2008). Variants of the chromosome 17q21 were strongly associated with risk of early-onset (aged four years or younger) asthma in 1543 subjects tested in a replication study of SNPs (Bouzigon *et al*., 2008). Significantly the same SNPs on chromosome 17q21 and the same risks were also associated with early exposure to environmental tobacco smoke. Thus allelic variability may play a complex moderator role in the ability of children to adapt to environmental xenobiotics.

Such gene–environment interactions may also be evident in disease conditions in which the environmental influence or precipitant is still unclear. Abnormal alleles in the neurexin superfamily of genes, contactin-associated protein-like 2 (CNTNAP-2), are associated with autism spectrum disorders. CNTNAP-2 proteins have shown widespread expression in the brains of animal models, including limbic circuits implicated in social interactions, and are conserved across species (Bakkaloglu *et al*., 2008).

These may be 'environmentally responsive' genes involved in synaptic membranes as molecular chaperones inembryonic neuronal migration. Rare allelic variants may disrupt protein function and predispose the child to cerebral dysplasia (Arking *et al*., 2008; Bakkaloglu *et al*., 2008; Alarcon *et al*., 2008). The resulting loss-of-function proteins may affect the attachment of axons to glia and/or the alignment of ion channels within neurons so as to affect their infrastructure and function (Stephan, 2008). Such dysplasias may also render the axonal-glial system more sensitive to the effects of neurotoxic substances such as organophosphate pesticides (Herbert *et al*., 2006).

There may also be environmental influences on epigenetic factors that contribute to the variation in the functional expression of genes. Epigenetic events can be defined as the pattern and extent of post-transcriptional DNA modulation by methylation, phosphorylation or acetylation of genes or histones. The addition of such groups can change the three-dimensional conformation of DNA which, in turn, can influence its function. Addition of methyl groups typically reduces the activity of genes, whereas acetylation is an inducer. The role of phosphorylation remains unclear. Environmental effects on epigenetic phenomena in children are areas needing further intense scientific research.

3 DEVELOPMENTAL BASIS FOR SUSCEPTIBILITY TO ENVIRONMENTAL TOXINS

The absorption, distribution, metabolism and excretion of environmental chemicals in infants and children follow different kinetics than in adults due to the developmental maturation of organ systems and physiological processes with age. Such ontogenic considerations underlie the observation that children are often more susceptible to hazards in their environment and the adverse effects of toxins to which they are exposed.

For example, young infants may have milk-based formula as a single food source (as opposed to older infants, children and adults who have multiple food sources) and, proportionate to their size, infants have a higher fluid intake per body weight. Young infants have a higher gastric pH (greater than 4) than do older children, related both to lower basal acid output and lower gastric secretions (Agunod *et al*., 1969; Rodbro *et al*., 1967). This leads to colonization of the intestines with different bacterial flora than that which colonizes older children and adults. These bacteria have a greater capacity to convert ingested nitrates to more dangerous, oxidizing nitrites. Infants less than five

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

months also have reduced amounts (as little as 60% of adult amounts) of NADH-dependent methaemoglobin reductase, an enzyme responsible for reduction of potential oxidants in red blood cells. Thus if an infant's formula is made up using well water containing excess nitrates from agricultural fertilizer runoff, the infant drinking it may develop clinically significant methaemoglobinaemia (oxidized haemoglobin with impaired functional capacity to carry oxygen to cells), whereas older infants, children and adults drinking the same water experience no adverse effects (Comly, 1945).

3.1 Behavioural and Developmental Considerations

3.1.1 Pica and Oral Behaviours

Infants and young children have oral exploratory behaviours as part of their normal development, and they also put nonfood items in their mouth, defined as pica behaviours. Such hand–mouth activity of toddlers puts them at risk for ingestion of contaminant-laden household dust, paint chips, plaster, outside dirt and other nonfood items. Ingestion of outside dirt by young children from hand–mouth activity during play has been studied by several investigators. A wide range of estimates have been found: between 100 mg and 10 g of outside dirt, depending on the child's age and development (Kimbrough *et al*., 1984; Lepow *et al*., 1974; Day *et al*., 1975; Binder *et al*., 1986). Using aluminium, silicon and titanium tracers, Binder *et al*. studied 59 children one to three years old, finding a minimal estimate of 108 mg day^{-1} (maximum of 1834 mg day^{-1}) of soil intake, more than any other age group (Binder *et al*., 1986).

Such behaviours are known risk factors for oral exposures to dust-borne or paint-chip-borne toxins, such as lead, and account in large measure for the risk of childhood lead poisoning (Walter *et al*., 1980). Some groups of children are more vulnerable to toxic exposures from pica than are others. Both zinc deficiency and iron deficiency are known to be associated with increased pica behaviours in children. Children with pervasive developmental delays and autism have increased rates of pica, and may continue to display pica habits well into their school-age years (Hussain *et al*., 2007).

Children's blood lead concentrations are correlated with their intake of lead-containing dust from hand-to-mouth activities and oral exploration. This may result in appreciable absorption of lead from indoor sources, as well as from lead-contaminated soils outdoors (Walter *et al*., 1980). Arsenic contamination of residential soil in bare areas was found to correlate with urine and tissue levels of arsenic in children living near copper-smelting facilities (Binder *et al*., 1987; Hwang *et al*., 1997a; 1997b). Mean speciated arsenic concentrations in the first morning voids of 414 children less than 72 months was 9.1 $\mu g\,l^{-1}$ close to the smelter, 8.6 $\mu g\,l^{-1}$ at intermediate locations and 7.2 $\mu g\,l^{-1}$ in areas remote from the facility (Hwang *et al*., 1997b).

3.1.2 Hazards of Exploratory Play

Children generally spend more time outdoors than adults, engaged in vigorous play. This inevitably exposes them to toxins, such as chemical pollutants in the air and soil, and pesticides used on the lawn and garden. Play is the developmental 'work' of infants and young children, as the interaction with their social and physical environment teaches them, shapes their character and values, and enhances their cognitive growth through experience. However, such exploration and curiosity can also lead to injury or death from exposure to hazards. The highest death rate among children outside the newborn age period is due to injuries.

Young children play close to the ground, which places them at a high risk for exposure to pesticide applications inside the home, as well as on the lawn and garden. Exposures to household dust, which may contain hazardous particulates, biologic agents, mould spores, lead, dust mites and cockroach antigen, are more likely among children crawling on floors, pulling themselves up to windowsills and exploring indoors. Their often poor hand-washing technique exposes them to xenobiotics by ingestion.

Unintentional poisonings affect a disproportionately large number of young children. Children are developmentally at high risk for poisoning because they start walking (and running) during the second year of life, the same time at which they acquire the fine motor skills to open containers and the oral-exploratory habits of putting toys and everyday home products in their mouths. They also lack the cognitive skills and judgement to determine food vs. nonfood items, and so must rely on parents to safeguard their environment. Predictably, most childhood poisonings occur around mealtimes, when parents are preoccupied with meal preparation and distracted from the normal supervisory activities of monitoring their toddler. Of 2.4 million poison exposures recorded by poison-control centres in the United States in 2006, over 50% occurred in children aged five years and younger (Bronstein *et al*., 2007). In one analysis of costs, it was found that almost 3% of childhood hospitalizations were for the treatment of poisoning (Woolf *et al*., 1997).

The peak incidence of inadvertent poisonings is in children ages two to three years old and most such incidents occur in the child's own home. Of those poisonings that do not occur in a toddler's home, grandparents' homes are the next most common site. Thankfully most one-time potential toxic exposures in young children are medically

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

trivial and can be managed at home by a period of observation for any untoward behaviours or other symptoms and signs. While exposures to plants and over-the-counter medicines, such as cough and cold remedies, are among the most frequent toddler exposures, they are rarely serious. There are notable exceptions to this rule, such as exposures to caustic compounds, volatile hydrocarbons and pesticides, some chemicals, like cyanide and arsenic, toxic alcohols, such as ethanol, ethylene glycol or methanol, and some prescription medications.

Older children have imaginary play habits, an abiding curiosity and poor judgement borne of a lack of experience, that may put them at high risk for toxic exposures or physical injury and trauma. They are more likely to explore a variety of hazardous locales, such as quarries, toxic-waste dumps, sewer drains, contaminated streams and old abandoned buildings, ignoring printed warnings and barriers to entry. Electrocution, from climbing high-tension electrical towers, drowning, from swimming in abandoned quarries, vertical falls, from climbing unguarded precipices, and death, from walking along railroad trestles, are only a few examples of the calamities that can result from playing in unsafe environments. Pedestrian injuries are a common occurrence among older children. Motor vehicle accident-related injuries and death peak in their incidence through adolescence and young adulthood.

While one would not want to change opportunities of children for constructive play, increased supervision and modifications of the environment can reduce their exposure to hazards and toxins. For example, mitigation of lead hazard in homes can lower the risk of the contamination of young children (Haynes *et al*., 2002).

3.2 Reproductive Toxicology and Foetal Exposures

Following fertilization and implantation, foetal growth and development is a remarkable symphony of cellular proliferation, differentiation and migration, orchestrated by changes in cell cycling, complex signalling and cellular interactions, downstream events and apoptosis. The human conceptus is termed an embryo until eight weeks of gestation and is characterized by several distinct periods of development: pre-implantation, blastocyst formation, implantation, gastrulation and organogenesis. Despite its extraordinary plasticity and the built-in redundancy of systems allowing foetal adaptation to changes in intrauterine life, the foetus is still vulnerable to environmental insults. All of these periods of development are characterized by rapid cell division and differentiation, and they represent critical periods of susceptibility for the embryo. The human embryo is thought to be particularly sensitive to toxic and teratogenic effects of chemicals and radiation early in embryogenesis: organogenesis occurs between 18 and 60 days of gestation (Beckman and Brent, 1984). For example, arm defects only were associated with prenatal exposure to the drug, thalidomide, in the 27–30th day of gestation, whereas if the exposure was during the 30th to 33rd days, then both arm and leg abnormalities were seen in offspring (Beckman and Brent, 1984).

Sensitivity to carcinogens is theorized to be heightened during late foetal development. The initial peak of childhood cancer by five years of age may be due to prenatal exposure to mutagens from either parent (Autrup, 1993). Foetal cells are theorized to be particularly vulnerable to oncogenic cancer-formation due to their high rate of replication, the presence of pluripotential germ cells, and the relative lack of cellular DNA repair mechanisms. Examples of such critical windows for carcinogenesis in foetal development include exposure to diethylstilbestrol and later development of vaginal clear cell adenocarcinoma in young women and the association between prenatal exposure of the mother to ionizing radiation and the occurrence of leukaemia in offspring (Olshan *et al*., 2000).

The transfer of toxic chemicals to the foetus during pregnancy has long been recognized. Spontaneous abortions or congenital malformations are potential outcomes of maternal exposure to environmental toxins during embryogenesis. Chlorinated hydrocarbon insecticides can be detected in the organs of stillborn infants and the blood of newborns (Curley *et al*., 1969; Polishuk *et al*., 1977). During the pre-implantation period, embryo exposure to dichlorodiohentltrichloroethane (DDT), nicotine and methylmethane sulfonate resulted in deficits of body and/or brain weight and embryo lethality, but not malformations (Rogers and Kavlock, 1996). Physiological changes during pregnancy can mobilize stored toxins, such as lead from bone or PCBs from fat, resulting in foetal exposure.

Healthcare providers, such as anaesthetists, dental assistants and other hospital personnel, are often exposed to potentially embryotoxic hazards, such as ethylene oxide, anaesthetic gases, solvents, mercury and antineoplastic agents (Filkins and Kerr, 1993). Studies of these groups have revealed significant risks for spontaneous abortions and congenital malformations (Ahlborg and Hemminki, 1995; Hemminki *et al*., 1982). In a study of nurses and pharmacists with occupational exposure to antineoplastic agents, exposure of the mother or handling by the mother of antineoplastic agents during pregnancy resulted in a statistically significant increased risk of spontaneous abortions and combined risk of spontaneous abortion and stillbirth (Valanis *et al*., 1999).

Toxic exposures from the mother's habits pursued during pregnancy can be conveyed directly to the foetus. Maternal alcohol ingestion can lead to foetal alcohol syndrome. Transplacental transfer of carcinogens in smoke and smoke-related, adduct-induced injury to foetal

Table 2 Agents known or suspected to be reproductive hazards

Male reproductive toxins	Adverse pregnancy outcomes
Dibromochloropropane	Anaesthetic gases
Dinitrotoluene	Arsenic
Chloroprene	Carbon monoxide
Lead	Cytotoxic drugs
Chlordecone (Kepone)	Dibromochloropropane
Ethylene glycol ethers	Lead
Carbon disulfide	Methyl mercury
Naphthyl methylcarbamate (Carbaryl)	Organic solvents
	Ozone
Nitrous oxide	Organochlorines (DDT, DDE)
Caprolactam/Dinit	Phenoxyacetic acids (2,4,5-trichlorophenoxyacetic acid)
Alkyl mercury	
Ethylene dibromide	Polybrominated biphenyls
Toluenediamine	Polychlorinated biphenyls
Vinyl chloride	Tetrachloroethylene
	Toluene
	Vinyl chloride

Modified from Filkins and Kerr (1993).

tissues has been demonstrated (Autrup, 1993). Maternal smoking has been associated with lower birth weight and increased risk of foetal demise.

3.2.1 Fertility Issues

Parental exposure to chemicals while in the workplace or remodelling their homes, during recreational activities or while pursuing hobbies, and elsewhere poses the threat to their own fertility and can have intergenerational toxic consequences. **Table 2** presents some workplace chemicals known to be reproductive hazards. Parental exposures to chemicals may adversely affect their ability to conceive children at all. For example, endometriosis is a gynaecologic disease that often results in infertility. Dioxins have received attention as possible aetiologic agents linked to endometriosis, related to their toxicity as oestrogenic analogues (Zeyneloglu *et al*., 1997). The first study to demonstrate this possible relationship found higher levels of PCBs in 28 patients with endometriosis vs. 441 women without endometriosis in a population of women with infertility. In Belgium, the incidence of endometriosis approaches 60–80% in women with infertility and pain. Interestingly, a 1989 WHO report also found that dioxin concentrations in Belgium were among the highest in the world, providing suggestive evidence that high dioxin accumulation in Belgian women might contribute to the high incidence of endometriosis.

Male fertility can also be impaired from exposures to chemicals. One study of TCDD-exposed men with chloracne found them to have reduced libido 50% more often than either unexposed controls or exposed men without chloracne. In a longitudinal seven year follow-up study of workers exposed to the now-banned nematocide, dibromochloropropane (DBCP) in a California manufacturing plant in the 1970s, azoospermia occurred without recovery (Whorton *et al*., 1979). Differentiating spermatogonia (type B) are very radiosensitive cells, and ionizing radiation has been demonstrated to cause a significant reduction of sperm count (Giwercman and Bonde, 1998).

3.2.2 Foetal Physiology, Placental Transfer and Teratogenicity

As many as 5–8% of congenital malformations are thought to be caused by an environmental toxicant, and as many as 20% may be multifactorial, related to gene–environment interactions (Beckman and Brent, 1984). Environmental toxin exposure during the foetal period is more likely to result in impaired growth, disruption of organogenesis and poor functional maturation (Rogers and Kavlock, 1996). Thus exposure of the mother to a variety of chemicals, some of which may as yet be unrecognized as teratogens, presents, through placental transfer, an extraordinary risk to the sensitive, developing foetus. In the past the placenta has been thought to be an effective barrier to passage of toxicants, and it does have appreciable amounts of degrading enzymes such as catalase and superoxide dismutase. And yet many reactive chemicals are passed to the foetus; lipid-soluble organochlorine compounds, for example, are detectable in both mother and foetus (Polishuk *et al*., 1977). Adverse birth outcomes were correlated to maternal serum dioxin levels after the environmental disaster that released large amounts of the chemical contaminating the population in Seveso, Italy (Eskenazi *et al*., 2003). Pregnant women living in rural Sri Lanka, but not working in agricultural occupations, were studied for foetal effects of background amounts of organophosphate compounds during spray seasons (Samarawickrema *et al*., 2008). Cord blood taken from their newborn infants demonstrated inhibition of butyrylcholinesterase activity during the pesticide-spraying season; there was also evidence of associated foetal oxidative stress and DNA fragmentation.

Such environmental exposures can affect foetal outcomes at birth. For example, animal models have previously confirmed the capacity of PCB mixtures to cause reproductive dysfunction (Barsotti *et al*., 1976). PCB mixtures can induce premature uterine contractions in mice, mediated by activation of phosphorylase A2 enzymes which change intrauterine arachidonic acid levels (Bae *et al*., 1999). The metabolite of DDT, p,p′-DDE (1,1-dichloro-2,2 bis (p-chlorophenyl) ethylene), was measured in the serum of 2613 pregnant women with prospective follow-up of pregnancy outcomes in the Collaborative Perinatal Project (Longnecker *et al*., 2001). Higher DDE levels were correlated

with in a dose–response fashion with higher rates of preterm births, as well as a higher incidence of small-for-gestational-age infants, after other potential confounders were controlled for in multivariate models. The authors speculate that the adverse reproductive effects of DDE (and DDT) may be related to its adverse effects on the binding of androgens and/or progesterone to receptor sites. They also note that a major action of DDT is its ability to impair the closing of sodium channels in neurons. Since placental tissue has a large number of sodium channels compared to other non-neuronal tissues, it may be particularly vulnerable to neurotoxins. Exposures to tobacco smoke, either because of the cigarette smoking of the pregnant woman or her exposure to environmental tobacco smoke, can result in low birth weight. Reactive species of a multitude of chemicals in tobacco smoke can pass transplacentally to the foetus, including polycylic aromatic hydrocarbons, nitrosamines, 4-aminobiphenyls and cadmium. They are found in equal levels in both maternal and cord blood and may play a role in adverse foetal outcomes (Autrup, 1993).

The physiology of the foetus makes it particularly vulnerable to xenobiotics passing through the placenta. The foetus may in fact concentrate toxins, attaining higher blood levels than the mother. For example carboxyhaemoglobin concentrations in foetal blood are approximately 10–15% higher than those in the mother. The foetus is particularly susceptible to carbon monoxide because of several physiological factors. Foetal blood has higher concentrations of foetal haemoglobin, which binds carbon monoxide more tightly than haemoglobin A or A2. Gas exchange in foetal tissues takes place on the ascending slope of the sigmoid-shaped oxygen saturation curve, at about 75–80% arterial saturation, such that minor decrements in maternal pO_2 are magnified in the inability of the foetus to perfuse its own tissues and unload enough oxygen to cells. Even small reductions in maternal oxygen tension, such as the maternal carboxyhaemoglobin levels achieved by cigarette smoking, can drop the diffusion gradient across the foetal umbilical cord to hypoxic foetal stress (Hsia, 1998).

Cryptorchidism and hypospadias are teratogenic effects linked to prenatal oestrogen exposure in animal models. A case–control study in Denmark demonstrated that an increased risk of cryptorchidism occurred in the male offspring of women gardeners. The authors suggested that the increased risk was due to the use of farming and gardening chemicals that possess oestrogenic effects (Weidner *et al*., 1998). Infants born to Taiwanese mothers with exposure to PCBs during pregnancy exhibited numerous ectodermal teratogenic defects such as hyperpigmentation, carious teeth, poor nail formation and short stature (Rogan, 1995).

Periods within foetal life may represent distinct, critical windows of susceptibility to the neurotoxic effects of environmental chemicals. Effects on postnatal cognitive development have been linked to prenatal exposures to environmental PCBs (Jacobson *et al*., 1990; Ropgan *et al*., 1986). Prenatal mercury exposures have long been associated with seizures and developmental deficits in the newborn (Koos and Longo, 1976). Pregnant women exposed to methylmercury from the contamination of fish and shellfish at Minimata Bay in Japan gave birth to children with a number of congenital malformations, cerebral palsy and mental retardation (Powell, 1991). Pregnant women can mobilize significant amounts of lead from bone, which is then conveyed to the foetus via placental transfer during critical periods of neural development, resulting in prenatal lead poisoning and postnatal neurological dysfunction. Thus current screening standards suggest testing of the blood of both pregnant women and young children for evidence of lead contamination (U.S. Preventive Services Task Force (USPSTF), 2006).

Heavy-metal intoxication in the neonate from lead (Sikorski *et al*., 1989), mercury (Sikorski *et al*., 1989) and cadmium (Alessio *et al*., 1984) can occur from prenatal placental transfer of the metals. Maternal lead exposure during pregnancy has been documented from industrial exposures (lead smelting), lead-related hobbies (jewellery and stained glass making) and construction work (renovation of old dwellings with lead-based paint). Arsenic placental transfer can occur from maternal exposures when women are exposed as agricultural workers where arsenic is used as a pesticide, when they work in copper or other smelting operations, or when arsenic is present as a natural contaminant of their drinking water. Such metals are postulated to reduce glutathione levels and increase oxidative damage to foetal organs. Animal studies of arsenic-induced damage during early organogenesis targeted brain, sensory organs, pharyngeal arches and somites with dose-, time- and valency-related injury (Zelikoff *et al*., 1995). Human exposure to environmental sources of arsenic during pregnancy has been associated with a higher risk of neural-tube defects in offspring (Shalat *et al*., 1996). After heavy-metal exposures during pregnancy, postnatal neurodevelopmental injuries have been reported in their offspring (Ghafour *et al*., 1984; Sensirivatana *et al*., 1983; Shalat *et al*., 1996). Low-level foetal lead exposure (maternal lead levels $\leq 25\,\mu g\,dl^{-1}$) has been shown to result in mild developmental delays during the first several years of life (Dietrich, 1996).

3.3 Physiological Differences in Infancy and Childhood

Table 3 illustrates some of the physiological differences between infants and adults in the absorption, distribution and elimination of xenobiotics. Children differ from adults in many aspects of their physiology and this predictably may result in different toxic responses

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 3 Differences in toxicokinetics between infants and adults

Absorption	Neonate compared to adult
Gastric pH	Neutral at birth to <4 by 2–4 d
Gastric acid secretion	Adult levels by 3 mo
Gastric emptying	Variable until 6–8 mo
Digestive enzymes	Lower at birth
Bacterial flora	High concentration of nitrogen-splitting bacteria
Intestinal motility	Slow and irregular in infants
Distribution	
Body water	Higher (75% body weight at birth)
Fat	Higher in infants (25% by 6–9 mo)
Muscle	Lower mass
Brain	Higher relative mass; lower myelin; higher blood flow; more porous blood-brain barrier
Plasma proteins	Reduced binding of acidic/basic compounds
Elimination	
Liver mass	Higher relative mass
Glucuronidation	Absent at birth; adult levels by 4 wk
Oxidation	Lower cytochrome P450 activity
Ester hydrolysis	Depressed levels
Renal function	Reduced glomerular filtration rate
Renal tubular secretion	Adult levels by one year of age

Modified from **Table 2** (Renwick, 1998) and **Table 1** (Scheuplein *et al.*, 2002).

to environmental chemicals than those seen in adults. For example, the reaction to organophosphate pesticides may vary with age (Pope and Liu, 1997). One study of 36 children with carbamate intoxication and 16 children with organophosphate poisoning found that their symptoms and signs of poisoning were not often the 'classic' muscarinic signs of cholinesterase inactivation typically seen in adults, but were predominately changes in consciousness and hypotonia (Lifshitz *et al.*, 1999). The authors hypothesized that blood–brain permeability in younger children might facilitate organophosphate entry into the brain to produce central nervous system (CNS) toxicity, or, alternatively, that differences in affinity binding of such pesticides to the cholinesterase enzyme in central vs. peripheral nervous system targets might account for the clinical differences in the manifestation of toxicity. Thus the toxic injury to children attributable to an environmental agent is not entirely predictable from the adverse effects to the xenobiotic demonstrable in adults.

3.3.1 Size/Weight and Body-Composition Differences

The smaller size of a child exposes them to higher doses of a toxin per unit weight than an adult. The larger extracellular and total-body water spaces, coupled with a higher water/lipid fat composition, in infants and young children alter the dispersion of chemicals. Ontologic changes in carrier proteins such as albumen and α-1-glycoprotein and changes in membrane permeability with age will affect the distribution of drugs and chemicals, both throughout the body and at target organs.

3.3.2 Gastrointestinal Absorption

Absorption of xenobiotics and toxins in the paediatric age group differs from adults with respect to several physiologic processes, such as pH-dependent diffusion, gastric emptying time and gastrointestinal peristaltic activity. In the postnatal period, the amount and rate of gastric-acid secretion does not reach the lower limits of adult secretion until three months of age. During this period, newborns are vulnerable to absorption of xenobiotics whose pK_a will favour the formation of nonionized species in this less acidic milieu. In newborns, this relatively low acidity contributed to intestinal overgrowth of bacteria that caused an outbreak of methaemoglobinaemia from well water in Iowa. This well water was contaminated by nitrates that were converted to nitrites by the bacterial overgrowth (Luyens, 1987). In the newborn period, intestinal absorption of xenobiotics is also enhanced by a gastric emptying time that lags behind adult rates for the first six to eight months of life, as well as irregular and prolonged peristalsis relative to an adult's intestinal motility.

Lead is a classic example of an environmental toxin that is known to be preferentially absorbed in the small intestine of children to a much greater extent than in adults. A one- to two-year-old child will absorb 50% of ingested lead, whereas an adult will only absorb 10% of ingested lead (Royce, 1992).

3.3.3 Volume of Distribution

The apparent volume of distribution (V_d) for a xenobiotic is increased in the perinatal period due to several factors. Total body water (TBW) and extracellular fluid (ECF) comprise a greater percentage of body weight in the foetus and newborn vs. an adult. TBW and ECF do not decrease to adult levels until approximately one year of age. During the first year of life and *in utero*, this can result in an increase in the apparent V_d for water-soluble xenobiotics and thus potentially increase its elimination half-life. Increased apparent V_d in the foetus and newborn can also be attributable to decreased plasma protein binding of xenobiotics. Specifically, the most important proteins for binding xenobiotics in plasma (albumin, α-1-acid glycoprotein and lipoproteins) are decreased in infancy and do not reach adult levels until about one year of age. Decreased plasma protein-binding facilitates distribution of xenobiotics into tissues, where they bind to their receptors to exert their effect.

3.3.4 Respiratory and Cardiovascular Physiology

Heart and lung development begins very early in foetal life. The period of greatest risk for causing perturbations in cardiac development is during weeks 3–5 of embryogenesis, when cardiogenic cellular differentiation, neural crest cells and endocardial cushions all undergo complex and dynamic interactions resulting in organogenesis (Sadler, 2000). How environmental chemicals early in foetal life can produce congenital heart defects, or how pollutants in air, food and water can affect later cardiac function in childhood and adolescence is still largely speculative.

Children are at high risk for toxicity from inhaled toxins. The maturation of lung architecture has critical windows of vulnerability that extend from *in utero* changes, through the physiological transformation to air breathing that occurs at birth, and continues on with further development of new alveoli and greater degrees of lung volume and breathing capacity into childhood. Developmental changes in lung architecture and capacity (e.g. minute ventilation, vital capacity, respiratory rate) continue after birth and throughout childhood and alter the absorption and bioavailability of inhaled pollutants. Infants have a higher respiratory rate (40 breaths per minute in a newborn vs. 16–18 breaths per minute for an adult) and lung volume ($400\,ml\,min^{-1}\,kg^{-1}$ in a newborn vs. $150\,ml\,min^{-1}\,kg^{-1}$ in an adult), giving them higher doses of inhaled toxins relative to adults. In fact, an infant has double the amount of an inhaled chemical by body weight as compared to an adult. A higher pulse and more efficient cardiovascular system of tissue perfusion allows for more rapid dispersion of toxins absorbed across the alveoli into the blood.

Breathing zones are an important concept that can predispose a child to certain environmental toxins. Because a child's breathing zone is closer to the ground (1–3 ft compared to 4–6 ft for an adult), chemicals that are heavier than air (such as mercury, formaldehyde, pesticides, radon) will pose more of an environmental threat to them. Peak concentrations of air and surface chlorpyrifos concentrations after the pesticide's application indoors were substantially higher ($94\,\mu g\,m^{-3}$) in infant breathing zones than adult sitting zones ($63\,\mu g\,m^{-3}$), and remained higher whether or not the rooms were ventilated (Fenske *et al*., 1990). Dust also settles in infant breathing zones, exposing them to higher concentrations of a variety of biotoxins, including cockroach antigen, dust mites, other particulates and mould spores. Early exposures of crawling infants to such a variety of xenobiotics may have a role in sensitizing them, increasing the likelihood of later development of allergic reactions and reactive airway disease.

Paediatric lung development occurs in two phases: pulmonary alveoli and capillary proliferation until the age of five to eight years, followed by growth through alveolar expansion. By 12 years of age, children have nine times the number of alveoli that they had at birth. Such architectural changes of the anatomy also predispose children to anatomical damage occurring during the extended critical windows of lung maturation and development. Compared to unexposed controls, children exposed to environmental tobacco smoke experienced slower lung development and lower FEV_1 (forced expiratory volume in one second) (Tager *et al*., 1983). The combination of exposure to environmental tobacco smoke and the toxigenic mould, *Stachybotrys atra*, was possibly associated with an outbreak of acute pulmonary haemorrhage and haemosiderosis in 10 Cleveland infants in 1993–1994. Furthermore, it was felt that the rapidly growing lungs of these infants were more susceptible to the inhaled trichothecene mycotoxins produced by this mould (Committee on Environmental Health, American Academy of Pediatrics, 1998).

Bronchospasm and reactive airway constriction is more easily triggered in infants and young children compared to adults. This explains in part their propensity for wheezing as a pulmonary response to a variety of different environmental precipitants, including viruses, bacteria, dust mites, cockroach antigen and environmental tobacco smoke. Induced immunological hypersensitivity, coupled with hyper-reactivty of the airways, may explain in part the increased risk of childhood asthma (Etzel, 1995). Within the age group of children six years and younger, those with elevated blood IgE levels and a family history of allergies are an especially vulnerable group to the onset of wheezing (Martinez *et al*., 1995).

3.3.5 Neurodevelopmental Growth and Vulnerability

The paediatric brain and CNS are particularly susceptible to injury from environmental toxins. Brain development continues after a child is born, with neuronal proliferation completed only by the age of four to five years (Rodier and Cohen, 1994). Myelination continues into adolescence (Bearer, 1995). Additionally, the blood–brain barrier (BBB) prevents access of hydrophilic chemicals to the brain, but is not fully developed at birth. The maturation of the BBB occurs at different rates in different brain regions (Rodier and Cohen, 1994; Wenzel and Felfenhauer, 1976). The concentration and functionality of subcellular molecules, such as P-glycoprotein, a member of the adenosine triphosphate (ATP)-binding transporter series, can affect the cell's ability to form an effective protective barrier by extruding xenobiotics in a variety of tissue sites (e.g. BBB, hepatocytes, renal tubular sites). Limited data suggests the level of expression of P-glycoprotein in children is lower than that in adults (Tsai *et al*., 2001). The BBB may still be relatively porous until a child is three to four years old, making them more vulnerable to the injurious effects of neurotoxicants than older children and adults.

Clinical examples of the increased susceptibility of children during central nervous system development were the infamous outbreaks of mass methylmercury poisonings in Minamata, Japan, in the 1950s; infants exposed *in utero* and in early childhood were the most severely stricken (see Section 1.4.1).

Lead is a well-researched environmental toxin, long known to be associated with cognitive impairments in children, even at what could be considered exposures to background levels and low body burdens. Preschool children absorb higher amounts of lead from the gastrointestinal tract, distribute more of the metal to water-soluble, soft tissue compartments in the body, including the central nervous system, and have increased vulnerabilities of certain tissue sites for injury from lead than do adults (Woolf *et al*., 2007). Numerous studies have shown a direct dose–response relationship between increasing body burdens of lead accumulated during early childhood and decrements in intelligence quotient (IQ) (Needleman and Bellinger, 1990).

However while lead may be the most studied neurological toxin, it is not the only neurotoxicant that children commonly encounter. Using National Health and Nutrition Examination Survey (NHANES) III data in the United States, researchers have found inverse relationships between young children's exposure to environmental tobacco smoke, as measured by plasma cotinine levels, and their IQ scores (Yolton *et al*., 2005). Other researchers have defined the substantial costs and public health implications of the IQ decrement in the US population of children attributable to their methylmercury exposures, as defined by blood mercury levels greater than $5.8\,\mu g\,l^{-1}$ (Tresande *et al*., 2005).

Noise is often an unrecognized environmental hazard for sensorineural hearing development in the foetus and infant. The human hearing apparatus completes its normal development by 24 weeks of gestation, but has been shown to be sensitive to environmental noise *in utero* and postnatally. An American Academy of Pediatrics (AAP) Policy Statement, after a review of the literature, concluded that environmental noise poses a unique threat to the foetus and newborn in several ways: (i) excessive noise exposure *in utero* can result in high-frequency sensorineural hearing loss and have an association with prematurity and intrauterine growth retardation, (ii) excessive noise exposure in the neonatal intensive care unit (NICU) can result in cochlear damage and (iii) excessive noise exposure can disrupt normal growth and development of premature infants (Committee on Environmental Health, American Academy of Pediatrics, 1997).

Many studies have demonstrated an association of maternal smoking during pregnancy with subsequent subtle behavioural and neurocognitive developmental disorders in their children. Adverse behavioural effects that have been described include increased antisocial behaviour, conduct disorder, attention deficit, hyperactivity and anxiety/depression. Adverse neurocognitive developmental disorders that have been described include poor school performance and declining performance on achievement and speech/language tests, as well as declining performance on neuropsychologic assessments such as the Wechsler Intelligence Scale for Childre—Revised. Two possible mechanisms that are theorized to produce adverse neurodevelopmental disorders are: (i) nicotine in cigarette smoke reduces blood flow to the foetus and (ii) secondary carbon-monoxide exposure leads to higher levels of carboxyhaemoglobin. The common final pathway of both mechanisms is foetal hypoxia resulting in altered brain development (Eskenazi and Castorina, 1999).

Weiss (2000) has suggested that IQ loss resulting from exposure to neurotoxins in foetal life or in infancy and childhood represents, not only a measure of cognitive injury, but also a predictor of performance later in adulthood, expressed as a loss of income and discounted future earnings. Thus the economic consequences of a neurotoxic exposure on a population's IQ can be extrapolated to societal implications. Avoidance of such environmental neurotoxic exposures in the United States alone could result in an estimated potential savings of between $5.6 and $49.4 trillion (US) dollars.

3.3.6 Developmental Immunotoxicology

The developing immune system has been clearly identified as a target that is more sensitive to the damaging effects of xenobiotic exposure than the adult immune

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

system. Pluripotent stem cells are detectable early in foetal life, undergo waves of complex transformations and migrations, and are susceptible to exogenous insults. Critical stages of immune development unfold with exquisite precision to give rise to T- and B-cells, natural killer cells, macrophages and other components of the competent immune system. The neonate still has lowered amounts of complement; its neutrophils do not have effective chemotaxis and have little capacity to mount an inflammatory response.

Polycyclic halogenated hydrocarbons such as PCBs, PBBs (polybrominated biphenyls) and TCDDs, polycyclic aromatic hydrocarbons, pesticides such as DDT, chlordane and carbofuran, fungicides (hexachlorobenzene), metals (methyl mercury, lead, cadmium), hormonal substances, drugs, mycotoxins and irradiation are all environmental pollutants that can act as immunotoxicants in animal and/or human models (Holladay and Smialowicz, 2000).

TCDD is well characterized in terms of its differential, deleterious effects on the developing vs. adult immune system. TCDDs can be transferred to the foetus via the placenta. The persistent immunosuppressive effects of TCDD may be more pronounced if exposure occurs in the perinatal period vs. adulthood. Specifically, TCDD exposure during critical windows of foetal development of the immune system can result in various prolonged, postnatal impairments of cell-mediated immunity: suppression of T-cell mitogen responses, increased skin-graft rejection, increased graft-vs.-host reactivity, and increase delayed hypersensitivity.

In utero exposure to alcohol may also alter normal maturational events that occur during ontogenesis of the immune system. Specifically, children with foetal alcohol syndrome have lymphopenia, eosinophilia, decreased T-lymphocyte lymphoproliferative responses and increased vulnerability to infectious diseases (Holladay and Luster, 1999).

Immunological development continues in the newborn and throughout infancy, and competence is thought to be influenced, in part, by the timing and variety of *in utero* and neonatal exposures to environmental antigens. For example, postnatal TCDD exposure has been shown in experimental models to increase susceptibility to infectious agents.

Scientific modelling proposes that perinatal immune events involving the balanced reactions of two classes of T-helper cells (TH1 and TH2) and their cytokine milieus determine the later expression of allergen responder phenotypes. Conceptually the timing and variety of antigenic exposures in infancy, in the context of genotypic predispositions of the immune system, may determine later immune tolerance vs. responsiveness, including pathological responses manifested clinically as asthma, atopy and allergies (Boushey and Fahy, 1995; Holt, 1999). Complex interactions between cytokines, mediators of inflammation, immunoglobulins, and sensitized migratory and resident cells in the airways may predispose to the pathological responses to environmental antigens that characterize asthma in children. Different inhaled xenobiotics (e.g. air pollutants, viruses, bacterial endotoxins, moulds) may trigger varying pathogenic responses, some of which involve TH2 cells, eosinophils and IgE production, whereas others stimulate pathways involving mast cells and their cytokines. Persistent bronchial hyper-reactivity may thus be fundamentally mediated by imbalances in the cellular and subcellular mechanisms underlying the promotion and control of the inflammatory response (Boushey and Fahy, 1995).

3.3.7 Endocrine Growth and Environmental Hormonal Analogues

Foetal development is under tight hormonal regulation and various endocrine organs, such as the pancreas, hypothalamic-pituitary neuroendocrine axis, adrenal, and parathyroid and thyroid glands, have critical windows of susceptibility during prenatal organogenesis. Environmental toxins can possess the capacity to alter natural hormonal activity by acting as 'endocrine disruptors', and children have been shown to be susceptible to environmental toxins that mimic or inhibit the action of natural hormones. However, there still is little understanding of the full extent of perturbations of prenatal hormonal function possible by environmental exposures in humans.

There may be gene–environment interactions underlying the genesis of some cases of Type 1 childhood insulin-dependent diabetes. A cluster of cases of childhood diabetes was correlated with birth month in one study. Authors concluded that mothers had eaten a large amount of nitrosamine-containing cured, smoked mutton early in their pregnancies, and that this large intake of nitrosamine might have been linked to development of diabetes in their offspring (Helgason and Jonasson, 1981). They could replicate the finding in mice exposed to the same food additive (Helgason *et al*., 1982).

The foetal thyroid gland develops in the first trimester, and maternal thyroid transfer is the source of hormone through the first 12 weeks of gestation, during the critical time of cerebral neurogenesis and migration; foetal hormone thereafter regulates neuronal proliferation and differentiation (Sadler, 2000). Not only is thyroid hormone critical for CNS development, but also general foetal growth and cardiovascular and musculoskeletal development extending into the postnatal period. Elevated neonatal thyroid-stimulating hormone (TSH) levels were observed for up to three months in 200 Dutch children with a perinatal exposure to PCBs (Sauer *et al*., 1994). Another study correlated perinatal PCB exposure with elevated neonatal T4 levels (Pluim *et al*., 1993). Other environmental contaminants, including the plasticizers, bisphenol A and phthalates, have been shown in animal models to be capable of

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

interfering with normal foetal thyroid development and function.

Other environmental agents, such as the DDT metabolite DDE, interfere with androgen receptor function and are believed to act as endocrine disruptors. In animal models endocrine disruptors have been associated with an increased incidence of hypospadias and other abnormalities of sexual development (Kelce and Wilson, 1997).

3.3.8 Hepatic Detoxification Systems

Both Phase 1 (acetylation, oxidation processes) and Phase II (conjugation) hepatic metabolic enzymes undergo a developmental increase in their activity postnatally. The liver itself decreases in size disproportionately to the overall growth of the child. While there is scant information available on the ontogeny of Phase II reactions, there is considerable evidence that Phase I detoxification activity occurs at reduced levels in young infants. The majority of enzymes responsible for xenobiotic metabolism or detoxification are located in the smooth endoplasmic reticulum within the microsomal fraction of the cell (Reed, 1996). The cytochrome P450 system is perhaps the best understood of these mixed-function oxidase systems.

Phase 1 hepatic enzyme activity in infants one year of age is generally about one-third that of adults. Individual enzyme systems mature at different rates. For example, CYP 3A7, a cytochrome expressed in foetal life, can detoxify such foetoactive chemicals as retinoic acid (Chen *et al*., 2000) and dehydroepiandrosterone (Kitada *et al*., 1987). Cytochromes CYP 2E1 and 2D6 increase activity shortly after birth (Vieira *et al*., 1996; Treluyer *et al*., 1991), and CYP 2C9 and CYP 2C19 become active within the first week of life (Lacroix *et al*., 1997); whereas CYP 1A2 is not expressed until one to two months of age (Sonnier and Cresteil, 1998). Many of these cytochrome mixed-function oxidases do not achieve adult levels of activity until six months of age. During this lag phase, newborns will demonstrate prolonged body elimination of xenobiotics that depend on hepatic-based metabolic pathways for their detoxification. Conversely the young infant, with incomplete cytochrome activity, may tolerate better than older children and adults other environmental chemicals that require cytochrome-mediated oxidation to create more injurious active metabolites.

3.3.9 Dermal Absorption

Percutaneous absorption constitutes a major pathway of environmental toxin exposure in the newborn and child. The skin undergoes age-dependent changes in thickness, perfusion and extent of hydration, as well as changes in the relative size and ratio of skin area relative to body weight (Rutter, 1987; Okah *et al*., 1995; Fluhr *et al*., 2000; Amato *et al*., 1992; West *et al*., 1981).

After birth, the newborn requires about five days to acquire the normal dermal keratin layer to the integument. Without this barrier, newborns are susceptible to unique poisonings from environmental toxins. In addition, a newborn's ratio of skin surface area to body weight is about 2.7 times greater than an adult's (Selevan *et al*., 2000). Consequently, for an identical percutaneous dose of an environmental toxin, a newborn's systemic absorption (bioavailability) of that toxin will exceed an adult's by a threefold margin (Reed, 1996). Thus dermal absorption of chemicals previously used to clean newborn infants resulted in hypothyroidism from iodine in betadine solutions (Clemens and Neumann, 1989) and neurotoxicity from hexachlorophene (Shuman *et al*., 1974). Hyperbilirubinaemia in newborns resulted from washing with a hospital phenolic disinfectant detergent (Wysowski *et al*., 1978).

Dermal absorption of environmental toxins is inversely proportional to the integumentary thickness of the stratum corneum (Reed, 1996). Infants have more avid uptake of chemicals through their relatively thin dermis than older children and adults. This renders them more vulnerable to topical exposures. For example, aniline dyes used in the laundering of infant diapers caused an epidemic of infantile methaemoglobinaemia because of the oxidizing effects on red blood cells of aniline absorbed through their skin (Graubarth *et al*., 1945). Topical applications of high concentrations of the insecticide, *N*-,*N*-diethyl-*m*-toluamide (DEET), can cause neurological dysfunction because of systemic absorption in infants and children. Dysarthria, confusion, ataxia and seizures have all been documented in children after application of highly concentrated DEET products (Grybosky *et al*., 1961; Zadikoff, 1979; Roland *et al*., 1985), whereas such reactions are not observed in adults. Seizures also have been temporally related to dermal absorption of other chlorinated compounds such as the antiseptic agent, hexachlorophene or the pediculoside, γ-benzene hexachloride.

3.3.10 Renal Function

Chemicals absorbed by the newborn or young infant are not eliminated through the kidneys with the same efficiency as those same chemicals in adults. Nephrogenesis begins at about the ninth week of gestation and is complete by 36 weeks gestation, with changes in both renal and intrarenal blood flow occurring after birth. For example, renal blood flow if about five times lower in neonates than it is in adults, such that toxins carried in the blood are not as readily eliminated.

Postnatal maturation of renal function extends through the first 12 months of life. The glomerular filtration rate (GFR) doubles in the first two weeks of age (Guiguard *et al*., 1975). By two months of age the mean GFR is still only about $96\,\mathrm{ml\,min^{-1}}$ $1.73\,\mathrm{m^{-2}}$ (Schwartz *et al*., 1987) and it gradually rises to adult values by 8–12 months

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of age (Kearns *et al*., 2003) Tubular function undergoes a similar postnatal maturation process. Adult levels of renal concentrating ability are not achieved until about one year of age. Thus young infants may have a longer duration of exposure to those xenobiotics (or their active metabolites) that are primarily excreted by the kidneys.

3.4 Chronic Exposures and Remote/Latent Adverse Effects

Children can have late-appearing toxic effects of their exposures to environmental agents that accumulate or leave residues stored in body tissues. Cigarette smoking in adolescence can lead to significant lung dysfunction in adulthood and, in some cases, eventual induction of lung carcinoma perhaps 30–40 years later. Chronic exposures to elevated household radon concentrations during childhood is thought to be responsible for later cases of lung cancer that only become manifest in middle age. Exposure to lead in early childhood has been linked to academic performance later on in high school and to such adult maladies as hypertension and chronic renal disease. Lead previously stored in maternal bone reservoirs may be mobilized into blood and transmitted to the foetus during pregnancy.

3.4.1 Carcinogenicity

The risk of childhood cancer peaks within the first five years of life. This disproportionate risk may be related, at least in part, to prenatal environmental exposures and induced genetic changes. The foetus is very susceptible to carcinogenic agents due to its lack of some DNA repair mechanisms. The rapidly dividing cells involved in the differentiating systems characteristic of foetal development also make the potential risk of cancer-promoting mutational changes more likely. Examples of definite human transplacental carcinogenesis are scant, although the induction of vaginal adenocarcinoma following maternal exposure to diethylstilbestrol during the first trimester is proof of principle (Herbst *et al*., 1972).

Children are more susceptible than adults to the cancer-producing effects of chemicals by virtue of their longevity. Those chemicals which promote cancer only after a lengthy latency period, such as radon or asbestos, may not express their toxicity in adults who die for other reasons before the cancer becomes manifest. Children, however, will carry the toxic agent for a longer period, with a cumulatively higher risk of the clinical expression of disease. By combining contaminant data with food consumption data, researchers estimated that the one in one million benchmark for lifetime cancer risk was exceeded for such food contaminants as arsenic, chlordane, DDT, dieldrin, dioxins and PCBs by the time a child is 12 years old (Dougherty *et al*., 2000).

Background sources of radiation illustrate the relationship of environmental exposures to a child's lifetime cancer risk. An estimated 13 000 lung cancer deaths per year in the United States are attributable to residential long-term exposures to radon daughters. Several studies have confirmed that the cancer risks associated with radon increase in relation to both cumulative and time-weighted exposures (Pershagen *et al*., 1994; Jacobi and Paretzke, 1985). The Japanese longitudinal studies of atomic bomb survivors found that persons younger than 20 years at the time of radiation exposure were more susceptible to radiation-induced cancers. Thus it is plausible that children are more susceptible to lung cancer from chronic residential radon exposure than adults (Jacobi and Paretzke, 1985; Committee on Environmental Health, American Academy of Pediatrics, 1989).

Carcinogens generally target tissues undergoing rapid growth and differentiation due to changes occurring within DNA during cell growth and a shortened period for DNA repair. This may put children at a higher risk compared to adults. For instance, an epidemic of scrotal cancer occurred among adolescent chimney sweeps in Victorian England. Although adult occupational exposure at that time was also significant for soot and other cancer-causing materials, scrotal tumours were generally seen only in the adolescent chimney sweeps. Thus, it appeared that scrotal development during adolescence was particularly susceptible to the carcinogens in soot. An increased risk of paediatric brain tumours was associated with household flea/tick pesticide use from pregnancy to diagnosis (Pogoda and Preston-Martin, 1997). Paternal occupational exposure to pesticides was also found to have a statistically significant increased risk for Wilm's tumour in their offspring (Fear *et al*., 1998).

3.5 Children's Nutrition and Toxic Exposures

Differences in children's diet and metabolism from that of adults account in part for their greater susceptibility to environmental contaminants transmitted in food and water. Infants drink twice the amount of water and eat two to three times the amount of food per body weight as adults. The average milk intake of an infant per kilogram of body weight would be the equivalent of an adult drinking 50 glasses of milk daily. The growth velocity is accelerated in childhood, such that birth weight is increased 18 times over the first 20 years of life. Moreover the types of foods eaten by children may differ from the portions eaten by adults. The one-year-old child eats two to seven times more grapes, bananas, pears and carrots. Different preferences in food choices

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

may potentially lead to different risks of exposure to unacceptable daily intakes of pesticide residues and other food contaminants in children.

3.5.1 Breast Feeding, Lactation and Milk Formula

Table 4 presents some examples of environmental chemicals that can be concentrated in human breast milk. Drugs and environmental chemicals may concentrate in a mother's breast milk by many different mechanisms, including transcellular diffusion, intercellular diffusion, passive diffusion and ionophore diffusion (Berlin, 1992). Diffusion, a primary transport mechanism for toxins to enter breast milk from maternal tissues, is related in part to the lipid solubility of a chemical. The fat solubility coefficient will significantly influence the final concentration of the toxin in breast milk, as will protein-binding characteristics, low molecular weight and other factors. For example, the level of dieldrin, a widely banned pesticide, in the breast milk of a lactating woman is about six times higher than its concentration in her blood (Solomon and Weiss, 2002).

Table 4 Examples of lipophilic chemicals concentrated in human milk

Chemical	Commercial use
Aldrin	Pesticide
Benzene	Solvent, by-product
Benzene hexachloride	Pesticide
Carbon disulfide	Solvent
Carbon tetrachloride	Solvent
Chlordane	Pesticide
DDT (dichlorodiphenyl-trichloroethane)	Insecticide
Dieldrin	Pesticide
Dioxin	By-product
Furans	By-product
Heptachlor	Pesticide
Hexachlorobenzene	Pesticide, disinfectant
Hexachlorocyclohexane	Insecticide
Methylene chloride	Solvent, paint stripper
PBB (polybrominated biphenyls)	By-product
PBDE (polybrominated diphenyl ethers)	Flame retardant, manufacturing
PCB (polychlorinated biphenyls)	Flame retardant, electrical equipment
Styrene	Solvent
Trichloroethylene	Solvent
Tetrachloroethylene	Solvent
Toluene	Solvent
Xylene	Solvent

Wolff (1983); LaKind *et al*. (2001); Solomon and Weiss (2002); LaKind *et al*. (2004).

Thus, organochlorine insecticides and chlorinated hydrocarbons, such as dieldrin, heptachlor, lindane and DDT, halogenated solvents and other industrial compounds, and POPs such as PCBs, PBBs and furans concentrate in the 30% fat content of breast milk because of their lipophilicity. Women are exposed to the 17 most toxic congeners of dioxin and furan POPs (known as the 2,3,7,8 congeners) only by ingestion from dietary sources. Indeed milk expression may be the principal route of elimination of such xenobiotics from maternal tissues. Other industrial chemicals with high partition coefficients favouring breast milk vs. maternal blood include solvents such as tetrachloroethylene and carbon disulfide (Wolff, 1983).

Regional variability of exposure to POPs account in large measure for different levels of such chemicals detected in women from different countries and regions of the world (LaKind *et al*., 2001). With prohibition or declining use of a chemical in a country, a trend towards decreasing levels of the chemical in breast milk can sometimes be documented. Thus, countries such as Germany, Japan and Sweden have reported declining concentrations of hexachlorocyclohexane in human milk, and Sweden has observed declining concentrations of PCBs (LaKind *et al*., 2004). Concentrations of DDT in human milk declined from the 1970s to the 1990s in both Canada and the United States. Local use patterns of chemicals can also correlate with their concentration in milk. In Spain, a twofold difference in heptachlor epoxide levels was found in rural vs. urban women's breast milk, likely due to rural, agricultural usage patterns (Solomon and Weiss, 2002).

Rarely have environmental toxins to which an infant has been exposed been proven to have clinically important deleterious effects on the child's health directly, although any addition of xenobiotics to the background sources of overall exposure is deleterious. An association was found between transplacental and breast milk exposure to PCB and related compounds and developmental delays in young children (Gladen *et al*., 1988). And the strongest predictor of blood levels of organochlorine chemicals in a sample of 337 German seven-year-olds was whether or not they had been exclusively breast fed in infancy, with a dose-dependent relationship related to duration of lactation (Karnaus *et al*., 2000).

Lactating mothers exposed to cadmium, mercury and lead can secrete these metals into their breast milk, although since metals are not bound to proteins, this occurs only in trace amounts (Oskarsson *et al*., 1995). Breast-milk exposure of infants to methylmercury has resulted in significant neurotoxicity and has resulted in cautionary advice to lactating women against consumption of large amounts of mercury-containing fish. An epidemic of mercury poisoning occurred in Iraq in 1971–1972 after the mistaken consumption of methylmercury-contaminated grain used to make bread.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

It was subsequently confirmed that many infants developed neurotoxicity from exposure to methylmercury in breast milk (Amin-Zaki *et al*., 1976). These infants were longitudinally studied for the subsequent five years and found to develop progressively worsening hyper-reflexia, delayed motor development, mental retardation, and impaired motor, sensory and autonomic function (Amin-Zaki *et al*., 1981).

While milk formula might be considered less vulnerable to xenobiotic contamination than breast milk, this is not necessarily the case. Cows will secrete hormones, antibiotics and chemicals to which they have been exposed into their milk. During the processing of milk, contamination can occur. Milk contamination with the industrial chemical melamine in China in 2007–2008 resulted in illness in thousands of infants and death in some, due to melamine's renal toxicity. The use of contaminated water to reconstitute powdered formula is another route for the exposure of an infant to a variety of metals, biological agents and chemicals. Finally the use of lead-containing cans for milk storage or lead-containing cookware for the sterilization of milk formula is another source of potential contamination.

3.5.2 Dietary Preferences and Pesticide Residues

More than 1500 pesticides are used in the United States, and these can be combined to synthesize 50 000 commercial compounds (Needleman, 1995). It is estimated that £4.23 billion of pesticides were used in the USA in 1993 (Goldman, 1995), and worldwide the use of pesticides, including environmentally persistent, organochlorine compounds, is even higher. Such pesticide use is associated with the presence of pesticide residues detectable on many of the fruits and vegetables consumed every day by infants and children. Given the ubiquitous presence of pesticide use in agriculture, the National Resources Defence Council, Food and Drug Administration, and the US Department of Agriculture have estimated preschooler exposure to 23 different pesticides from the consumption of 27 different fruits and vegetables. Their data suggested that the pesticide residue intake of children exceeds daily allowances for a variety of organophosphates and other agricultural chemicals (Sewell and Whyatt, 1989).

Two unique features of the preschool diet also predispose them to pesticide poisoning: a greater rate of food consumption per unit weight, coupled with a dietary preference for fruits and vegetables. Due to an increased metabolic rate necessary for growth and development, infants and young children require 90–120 cal kg^{-1} daily of nutritional energy in their diets, more than twice the caloric needs for adults. Consequently preschool children generally eat three to four times as much food per pound of body weight as average American adults. Additionally, 34% of the preschooler's diet consists of fruits compared to 20% of the adult diet. The average toddler drinks 21 times more apple juice and 11 times more grape juice than adults, and eats 2–7 times more pears, bananas, grapes, carrots and broccoli (National Research Council (NRC), Committee on Pesticides in the Diet of Infants and Children, 1993). Thus children's diets differ from those of adults, exposing them to different doses of xenobiotic contaminants of food.

The combination of these two factors results in a child's daily average consumption of fruits (per kg of body weight) that is six times more than an adult woman. Consequently, children will have a proportionally greater dietary exposure to pesticides. A report from the National Research Council (NRC) concluded that consumption of pesticide residues on food products was higher in children; indeed the NRC estimated that 50% of the lifetime ingestion of pesticides occurs in the first five years of life (National Research Council (NRC), Committee on Pesticides in the Diet of Infants and Children, 1993).

3.6 Epidemiology of Special Populations of Vulnerable Children

Within the paediatric age group there may be special populations at higher risk from environmental contamination. Children with developmental delays and autism have been shown, by virtue of their continued oral exploratory behaviours, termed 'pica' for non food items, remain at risk for heavy-metal poisoning through childhood and adolescence (Hussain *et al*., 2007). Children with ataxia-telangiectasia, an inherited condition, have a defect in their DNA repair mechanisms. When exposed to conventional radiotherapy, these children may develop life-threatening complications from acute radiation poisoning (Cunlift *et al*., 1975). Children with xeroderma pigmentosa, another inherited condition, have DNA repair defects causing premature ageing, accelerated by radiation from exposure to sunlight. Children with underlying pulmonary diseases, such as bronchopulmonary dysplasia, asthma or cystic fibrosis, are more vulnerable to exacerbations of their chronic illness brought on by exposure to indoor or outdoor air pollution.

3.6.1 Example of a Special Population of Children: Childhood Asthma and Indoor Air Quality

Childhood asthma has grown at alarming rates, both in the United States and worldwide, over the last four decades, with large increases in asthma prevalence, hospitalization rates and mortality (Mannino *et al*., 1998). Allergens appear to play a critical role in the severity and chronicity of asthma, particularly in the inner city (Platts-Mills, 1994). Epidemiologic studies have established an association between elevated serum total IgE

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and asthma (Burrows *et al*., 1989), and skin-test positivity to indoor allergens, including those derived from dust mites, cockroaches, cats and dogs, is also a common finding in asthma (Eggleston *et al*., 1998).

Dust mites may be the best-studied allergen connected with asthma (Halken, 1994). From the genus *Dermatophagonides*, these mites deposit faeces onto many household places, including bedding, drapes, upholstered furniture and carpets (Lanphear, 2001). Dust mites are very potent allergens, with direct inhalation causing an immediate fall in FEV_1 and late-phase response in sensitized asthmatics (Sporik, 1990), though less prevalent in inner cities than the general population (Kattan *et al*., 1997).

Cockroach allergen is a well-described allergic trigger for asthma that is particularly important in low-income urban communities (Platts-Mills, 1994). Though many species of cockroach exist, the German cockroach (*Blattella germanica*), is the most common cockroach species infesting homes in cities in the United States and many other parts of the world, and is the best studied (Call *et al*., 1992). Children with the combination of a positive skin-test reaction to cockroach extract and a bedroom level of *Bla g* 1 exceeding 8 $U\,g^{-1}$ of dust had significantly more hospitalizations for asthma, unscheduled medical visits and parent-reported wheezing than other children (Rosenstreich *et al*., 1997). In addition to making asthma worse, recent data suggests exposure to cockroach allergen and sensitization is associated with an increased incidence of wheeze in the first year of life (Gold *et al*., 1999) and incident asthma among the siblings of the index children in a birth cohort (Litonjua *et al*., 2001).

In addition to cockroach allergen, a recent study has found connection with mouse allergen exposure (Phipatanakul *et al*., 2000a) and sensitization to severity of asthma (Phipatanakul *et al*., 2000b). There is also suggestive evidence of mouse allergen exposure as a potential contributor to the development of wheezing in the first year of life (Phipatanakul *et al*., 2005).

Mould exposure, particularly from damp housing, has been an important potential contributor to asthma as well (Strachan, 1989). Studies have suggested that exposure to dampness and mould can be a trigger for asthma symptoms (Jaakkola *et al*., 1993), as well a potential source for developing asthma in the first place (Institute of Medicine, 2004).

3.6.2 Example of a Special Environmental Toxin for Children: Bisphenol A, Phthalates

Recent concerns have been raised about the potential links between certain chemicals used in the manufacturing of plastics, and children's health.

Bis-Phenol A (BPA) is used to make polycarbonate, the plastic most commonly used for baby bottles and sippy cups. A known endocrine disruptor compound, BPA mimics oestrogen and has been linked with a range of health effects in animal and human studies (vom Saal and Hughes, 2005). It has chemical properties similar to oestradiol and can impact biological systems in very low doses (Claudio and Chace, 2006). BPA is more likely to leach from its polycarbonate matrix mainly during two instances: first, when the plastic is cracked or shows significant wear and tear; second when the contents of the actual plastic container are heated.

Phthalates represent a family of compounds with names like DEHP (diethylhexyl phthalate), DEHA (diethylhexyl adipate) and DINP (diisononyl phthalate). In 2003, the American Academy of Pediatrics in the United States came out with a consensus statement about where common sources are for children and the potential health effects (Shea, 2003). Phthalates are used to soften plastics called PVC (polyvinyl chloride), and are found in a range of products used by children, including toys. Like BPA, they are known endocrine disruptor compounds, acting as antiandrogenics and can adversely impact androgen-sensitive tissues during specific windows of development (Claudio and Chace, 2006). They have been linked with varied health effects in both animal and human studies (Sathyanarayana *et al*., 2008).

While the science regarding both BPA and phthalates is both emerging and controversial, there has been movement both in the United States and abroad to ban or limit children's exposure to both these chemicals based on the available animal and limited human epidemiologic data.

3.6.3 Child and Adolescent Workers

Over four million children and adolescents in the United States work outside the home; worldwide the figure may approach 200 million children. Entry-level, unskilled or menial jobs for which they qualify may bring them into contact with chemicals, gases and fumes, and other toxic hazards in the workplace environment. Exposure to heavy metals, pesticides, caustics and cleaning agents may be more of a risk to children working because they are not employed in regulated industries, will take greater risks to please an employer, and may not receive the appropriate training needed to work safely with dangerous chemicals. In the United States, 3% of 300 000 poison-centre occupational calls over a five year period involved adolescent workplace exposures (Woolf *et al*., 2001). The most common hazardous agents included corrosives, fumes and gases, bleaches, drugs, acids and hydrocarbons. In many cases, the exposure could have been prevented by proper training and the use of barriers, such as gloves and eyewear.

The NRC, citing the pesticide exposure risks of children working in agriculture and the risks of exposure to solvents and other chemicals to children employed in other industries, recommended in its book *Protecting Youth At Work* the development of a comprehensive plan

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

for monitoring work-related injuries to children, as well as monitoring the hazards to which they are exposed (National Research Council, Committee on the Health and Safety Implications of Child Labor, Board on Children, Youth and Families, Committee on Behavioral and Social Sciences and Education, Institute of Medicine, 1998).

Families in developing countries may rely on children's workplace earnings for economic support. In such circumstances, children may work in unregulated industries, such as mining, building materials fabrication, construction, agriculture and manufacturing, with high risk of poor health due to their exposure to toxic substances, physical hazards, repetitive motion strain and injury, and physical and mental demands. Injuries account for both morbidity and mortality among working children; unhealthy work conditions have long-term implications for their future productivity. Moreover, such labour may divert them from an education and the nurturing of their youth so as to enhance their chances to become productive citizens in the future.

3.6.4 Smoking, Solvent Abuse and Problem Experimentation

Children and adolescents are at high risk for a variety of environmental toxins through their developmental vulnerability to peer pressure and experimentation. Numerous studies have shown that the age of initiation of cigarette smoking is before age 18 years, and some adolescent smokers begin to develop architectural changes in lung anatomy and measurable decrements in lung function by the time they are young adults (Woolf, 1997). As many as 30% of young adolescents experiment with volatile inhalants. Such experimentation with 'gateway' substances of abuse in early adolescence may lead to chronic use and dependence. The adult sequelae of addictions initiated in adolescence are formidable for the individual, in terms of poor health, chronic illness and shortened lifespan, as well as for the public's health, include disproportionate use of costly health services, increased frequency of social pathology and disordered relationships, and loss of future productivity.

4 LABORATORY TESTING OF SUSCEPTIBLE POPULATIONS

Both environmental testing and biological tests of biomarkers in body fluids can be helpful in determining whether or not environmental toxins are associated with specific paediatric health complaints. However such testing must always be interpreted in the context of extant clinical data. In addition the clinical applications of some laboratory analyses remain controversial; specifically both chelation challenge testing and hair analyses have been disputed as lacking in adequate scientific evidence in some of their clinical applications to the assessment of children's exposures.

4.1 Tissue Matrix Testing

Both blood and urine testing are frequently used in some environmental exposures to confirm a child's contamination. However such testing is limited by a variety of parameters, including technical (e.g. detection levels, analytical reliability), clinical (e.g. validity of normative and/or 'no-effect' levels as applied to newborns, infants and children) and circumstantial (e.g. time lag between exposure and biological test performance) issues. Blood lead levels greater than $10\,\mu g\,dl^{-1}$ have been associated with neurodevelopmental delays in children, although some research has suggested that this threshold 'no effect' level has been set too high. Red blood cell cholinesterase levels are an indirect measure of recent exposure to organophosphate pesticides, since acute exposure levels of the enzyme will show marked decrements vs. baseline concentrations. A blood mercury level equal to $5.8\,\mu g\,l^{-1}$ has been used as a 'no-effect' level used in determining when methylmercury exposures can produce cognitive decrements (Tresande *et al*., 2005). A child's serum cotinine level has been used as a biomarker of exposure to environmental tobacco smoke.

4.2 Hair Testing

Siedel *et al*. (2001) assessed the reliability of data from hair analyses performed by commercial laboratories in the United States and found that designations of normal values for different metals and minerals varied greatly between laboratories, as did sample preparation techniques and quantitative analysis methodologies. These authors submitted split hair samples to different commercial laboratories; they found that the resultant hair content analyses varied widely and were unreliable for any clinical applications. Likewise Steindel and Howanitz (2001) found that hair analyses for trace metals gave discrepant results with wide coefficients of variability and a lack of uniformity in acceptable laboratory standards in methodology. Forensic toxicology studies of cadavers have found a lack of correlation between elemental concentrations in hair and that in other human organs (e.g. cerebrum, cerebellum, kidneys, heart and liver) (Yoshinaga *et al*., 1990). Contamination of hair by external environmental sources, a lack of sample homogeneity, variable collection methods and widely variant dispersion of metals within the hair matrix confound the clinical utility of analysing this matrix. And yet in carefully

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat104
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

controlled, experimental settings, using proper collection and analytic techniques, hair analysis has been found to be a valid biomarker of childhood exposures to environmental metal contaminants (Wright *et al*., 2006).

4.3 Chelation Challenge Testing

Prior to the advent of reliable blood lead testing, quantitative lead excretion in urine after an eight hour challenge with sodium calcium edetate (NaCaEDTA) was used to determine which children with suspected plumbism were candidates for five day hospital courses of parenteral chelation. With the development of very sensitive and specific whole-blood lead testing, this diagnostic test became outmoded and is no longer used clinically. The application of chelation challenge testing to other clinical uses, for example, in the determination of environmental exposures to metals of children with autism, has been disputed (Soden *et al*., 2007).

5 OTHER ENVIRONMENTS: BUILDING-RELATED ILLNESS

Children may spend much of their day out of the home, in daycare centres, nurseries or schools, where they may be exposed to indoor air and other pollutants. Building-related illness has occasionally been linked to volatile chemicals used in cleaning schools, chemicals off-gassing from newly installed floors and carpets or the routine indoor use of pesticides. Outdated and/or poorly maintained ventilation-exhaust and air-intake systems may contribute to poor air circulation and insufficient fresh air exchanges. Water damage to schools can create mould and mildew problems, old flaking ceiling tiles may expose children to asbestos and some schools are still contaminated with lead-containing paints.

Children react to indoor-air pollution from building-related causes, such as dust mites or moulds by wheezing (Etzel, 1995), or with burning eyes, headaches, sore throats and other irritant symptoms, depending on other aetiological agent(s).

6 INTERNATIONAL IMPLICATIONS

Children have long been recognized by international organizations as disproportionately affected by hazards in their environment. The World Health Organization estimates that more than 10 million children under the age of five die each year due to unhealthy environments (Gordon *et al*., 2004). More than 1.1 billion people in rural and underdeveloped areas, especially in Africa and Asia, do not have access to safe water; 2.2 billion do not have access to hygienic toilet facilities. Children are particularly susceptible to such poor sanitary conditions, which foster chronic diarrhoea, dehydration and such infections as typhoid and bacterial dysentery; more than 2 million succumb each year (Gordon *et al*., 2004). A disproportionate number of the world's children are malnourished and living in poverty, their futures prematurely shortened by the consequences of a marginal existence in a degraded environment.

Smith *et al*. (1999) employed consistent definitions and quantitative methodologies to estimate that 25–33% of all global ill health can be attributable to environmental risk factors, with children under five years of age bearing the largest environmental burden. Basic necessities, such as clean water, sanitary toilet facilities and safe food, are still out of reach in many poor, rural nations, especially in Asia and Africa. Such conditions foster childhood diseases such as diarrhoea and parasite infestations that exact a staggering toll in terms of lost lives and lost productivity. Biomass burning and indoor- and outdoor-air pollution contribute to high rates of respiratory illnesses among children living in developing countries. Globally, childhood poisonings and injuries account in large measure for high morbidity and mortality rates among infants and toddlers.

More than 200 million children worldwide between the ages of 5–14 years old forego any schooling to work outside the home, often in extremely hazardous occupations such as agriculture, construction, and mining and quarrying, to support their poverty-stricken families. Such environments expose them to physical injury, as well as to noxious chemicals, including solvents, glues, heavy metals and silica-containing dusts.

Such stark realities demand international answers addressing the pressing need for more healthful child environments.

7 RESEARCH DISPARITIES

An important context within which to consider the vulnerability of children to environmental toxins is the sparse knowledge we have of the toxicities such chemicals may produce in exposed children. Of the 3000 chemical pesticides produced in the United States at $\geq$1 million pounds annually, less than 7% have been fully studied for their effects on humans (Stein *et al*., 2002). Children are more vulnerable to xenobiotics because there is comparatively little that is known about the long-term outcomes of environmental exposures of children and the sequelae of such exposures in adult life. Much of what we know about such exposures is extrapolated from *in vitro* systems or animal studies, and such results may have errors in their extrapolation to humans, let alone to children. Often these are studies of acute

or subacute exposures of animals to single chemicals with such gross end points as relative lethality, rather than the more typical circumstances seen in children, involving chronic, low-dose background environmental exposures with subtle adverse-effect outcomes. Pope and Liu (1997) describe the relative sensitivity of adult vs. young rats to chlorpyrifos and other organophosphate pesticides and how such age-related differences can be obscured in improperly designed experimental studies that only examine lethality, instead of neurochemical changes, as an outcome.

Many studies of the effects of chemicals in humans have involved only healthy adults exposed to higher concentrations of these chemicals found in workplace settings. Adult safety standards derived from such studies may or may not be extrapolated to the safety of children. The circumstances of such exposures frequently assume eight hour workdays and five day workweeks of exposure. Those results are then further extrapolated to daily, lower-dose background levels of repetitive exposures in children to calculate tolerable exposure levels, often utilizing 10-fold uncertainty factors to account for differences in age and 3.2-fold uncertainty factors to account for toxicokinetic and toxicodynamic variability (Renwick, 1998). However, some have questioned the adequacy of such uncertainty factors, considering the range of variability in toxicokinetic and other differences between children and adults (Weiss, 2000; Ginsberg *et al*., 2002). It may be an error to assume that children of all ages will be equally protected by modelling their theoretical risk, some researchers have suggested that the estimates are perhaps adequate for between 60 and 100% of the population over the age of six months (Dourson *et al*., 2002).

There is little research directed at questions and hypotheses specifically involving children and their environmental exposures, and only a relatively small amount of funding and research resources is dedicated to such studies. Children have been called 'research orphans' because of the lack of private and public funding and a relative dearth of both governmental and academic institutional initiatives dedicated to children and their environmental risks.

Very few studies consider an 'integrated environmental risk', that is, synergistic and/or additive interactions effected by exposures to multiple chemicals. And yet children are exposed to background levels of varying mixtures of pollutants in their environment over time. Animal models suggest that such multiple, simultaneous exposures to pollutants and xenobiotics are far more damaging, or cause damage at lower levels, than do single agent exposures in experimental settings (Carpenter, 2002; Stein *et al*., 2002).

Moreover, research studies that are done in children often consider them as a homogeneous group, rather than as heterogeneous subpopulations by age and developmental stage or by ethnic, racial and socioeconomic differences. Very few studies have addressed in children any added risk to environmental toxins engendered by an underlying chronic illness, such as childhood diabetes, seizure disorders, mental retardation or cystic fibrosis.

Thus, a new research agenda specific to paediatric environmental health concerns is of paramount importance, since the questions and challenges are so different from those of adults. There is a compelling need for better research into the health implications of children's exposures to environmental toxins, especially regarding high prevalence conditions, such as childhood cancer, asthma, endocrine and sexual disorders, and neurobehavioural toxicants (Landrigan *et al*., 1998).

Clinical Toxicology

Alister Vale and Sally Bradberry

CONTENTS

1 INTRODUCTION

This chapter defines the specialty of clinical (or medical) toxicology and the components that should make up a comprehensive clinical toxicology service; it describes the presentation and complications of poisoning and details the general assessment and management of the poisoned patient; the chapter concludes with a discussion of the role of toxicovigilance.

2 CLINICAL TOXICOLOGY

Clinical toxicology is that discipline within toxicology which is concerned with the impact of drugs and other chemicals on humans. Some define this discipline as medical toxicology. For example, the American College of Medical Toxicology, a nonprofit association of physicians mostly from an emergency-medicine background, defines medical toxicology as a 'medical subspecialty focusing on the diagnosis, management and prevention of poisoning and other adverse health effects due to medications, occupational and environmental toxins and biological agents'. The present authors, who are physicians who have practised the discipline for several decades, believe the term clinical toxicology should be employed rather than medical toxicology to reflect the fact that clinical toxicology is both a discipline of toxicology and a medical subspecialty. This view also takes account of the fact that in North America in particular, a number of distinguished clinical toxicologists hold a PharmD and offer a professional opinion either via a poisons information centre or at the bedside. It is acknowledged, however, that in Europe most, if not all, clinical toxicologists are medically qualified.

The role of the clinical toxicologist encompasses the traditional therapeutic role, including the development of effective treatment strategies for the management of acute and chronic poisoning, the provision of expert advice via a poisons information service and the evaluation of the adverse effects of drugs and other chemicals on the body. The clinical toxicologist must be able to apply relevant kinetic and biochemical data so that treatment strategies can be developed and refined, based on the likely mechanisms of toxicity (Vale, 1992). In addition, an understanding of pathological appearances is necessary if the results of toxicity tests are to be extrapolated accurately to man and the results of forensic

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

examinations are to be interpreted correctly. The clinical toxicologist will also need to be aware of the limitations of analytical methods, both as regards their sensitivity and specificity.

The increased public awareness and concern regarding the potential effects of pesticides and other chemicals means that a clinical toxicologist must be familiar with the occupational and environmental impact of a wide range of agents. A clinical toxicologist can be expected to be involved in the development of strategies for the management of major chemical disasters, including the chemical contamination of drinking water, the evaluation of antidotes used against chemical warfare agents and in the assessment of the adverse effects of pesticides, whether resulting from a single exposure or chronic low-level exposure.

Thus, clinical toxicologists will need to possess a detailed knowledge and understanding of the clinical, biochemical, kinetic, analytical, forensic, occupational and environmental aspects of toxicology if they are to play the important role that is now expected of them in today's society. They will also need to be committed to research and training.

3 A COMPREHENSIVE CLINICAL TOXICOLOGY SERVICE

It has been suggested previously that poisons centres need to offer a comprehensive clinical toxicology service if they are to survive and meet the challenges of the twenty-first century (Vale and Meredith, 1993). The combination of intensive treatment facilities for poisoned patients and substance abusers, a poisons information service and supporting laboratory is, we believe, the model that should be adopted. A comprehensive clinical toxicology service, embracing a clinical and advisory service, analytical support, research and training, with due emphasis on the occupational and environmental aspects of toxicology is needed if clinical toxicologists are to address adequately current toxicological challenges and opportunities.

3.1 A Poisons Information Service and an Expert Advisory Service to Physicians

A poisons information service must be available 24 hours a day, 365 days a year to provide expert advice to medical and paramedical staff, and, in most countries, to the public, on the toxicity of drugs and other chemicals, plants and animals. Such a service could also serve as a community resource so that health professionals and the general public can be advised both on ways to decrease the risk of poisoning and the measures to take if it occurs.

Physicians using the service must have every confidence that the advice given is evidence-based and up-to-date. To be credible such a service must include those with extensive training in clinical toxicology so that specific advice on the management of cases of poisoning can be given. It is a major advantage if these clinical toxicologists are also directly responsible for the management of patients suffering from the effects of acute or chronic poisoning. Such expertise is necessary if all the available information, circumstantial, clinical, laboratory and from other sources, is to be assessed accurately in relationship to the substances involved and the circumstances of exposure. Only in this way can a detailed plan for clinical management be developed which will maximize the chances of the patient surviving and minimize the risk of short- and long-term sequelae. This expert advice will need to be supported by a comprehensive collection of reference works and original papers, as well as by access to on-line retrieval systems.

3.2 An In-Patient Treatment Service

An in-patient service, of necessity, must be available at all times and be staffed by physicians with extensive training in clinical toxicology, who are respected for their professional competence and authority and who are capable of furnishing reliable opinions, as well as being adept at differential diagnosis. If possible, these physicians should also be responsible clinically, not only for the management of patients suffering from the effects of acute or chronic poisoning, but also for the detoxification of substance abusers. If logistically possible, it is a major advantage if the in-patient beds are in a dedicated area to act as a focus for the provision of expert medical, psychiatric and social care. It is also advantageous if the psychosocial assessments are undertaken by psychiatrists who have a specific commitment to the service.

3.3 An Out-Patient Clinical, Occupational and Environmental Toxicology Service

Many chronic medical problems are alleged to have a toxicological basis, be it occupational or environmental. Patients with such suspected toxicological problems should be assessed by an experienced clinical toxicologist to determine whether the patient's clinical features are due to a toxic exposure or not. In some countries, poisons centres are part of a much larger occupational medicine unit. Where they are not, there

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

should be a close working relationship between clinical toxicologists and occupational physicians, particularly if the former are not appropriately trained in occupational medicine. Only in this way can a first-class occupational toxicology service be offered. A clinical toxicology centre should also play a major role in providing advice on environmental toxicological problems, such as on the chemical contamination of drinking water, the environmental impact of pesticides and on the management of major chemical disasters.

3.4 Advice to Government, Regulatory and International Bodies

Clinical toxicology centres will wish to play a full part in providing advice and support to Government Departments, Regulatory Authorities and Intergovernmental Bodies such as the International Programme on Chemical Safety (IPCS).

3.5 Analytical Support

Whether analytical support is provided 'in-house' or by contract with an outside laboratory is less important than the quality and speed of the service offered. In-house facilities allow a close working relationship to develop between clinical and analytical toxicologists, which will strengthen and improve the quality of the overall analytical service even further.

3.6 Research and Training in Toxicology

However outstanding its clinical service, no clinical toxicology centre can have a major impact without being closely involved in toxicological research. It is equally true that without a well-organized and relevant research programme an outstanding clinical service is unlikely to be offered. A commitment to research not only provides a stimulating environment for more senior faculty members, but also helps attract younger colleagues who are highly motivated and committed. Furthermore, a centre which is 'spearheading' clinical advances is likely to be widely consulted and have a substantial number of patient referrals.

Training programmes should ensure that those in training are able to apply relevant kinetic and biochemical data, so that treatment strategies can be developed and refined, based on the likely mechanisms of toxicity. Trainees will also need to recognize the limitations of analytical methods and be trained in the occupational and environmental aspects of toxicology.

4 POISONING

Exposure to a substance is often equated with poisoning. However, absorption is necessary for there to be a toxic effect and, even if this occurs, poisoning does not necessarily result, because the amount absorbed may be too small. In developed countries, poisoning causes approximately 10% of acute hospital medical presentations. In such cases poisoning is usually by self-administration (that is the act is deliberate) of prescribed and over-the-counter medicines, or illicit drugs. Rarely, deliberate poisoning may be the result of criminal intent (homicide). Sometimes inappropriate treatment of a patient by a doctor (iatrogenic poisoning) is responsible for the development of poisoning, for example, in the case of digoxin toxicity.

Poisoning in children aged less than six months is most commonly iatrogenic, and less frequently accidental by the parents, and involves over-treatment with, for example, paracetamol. Children between eight months and five years of age also ingest poisons accidentally, or they may be administered deliberately to cause harm, or for financial or sexual gain.

Occupational poisoning as a result of dermal or inhalational exposure to chemicals is a common occurrence in the developing world and still occurs in the developed world. As a result of changes to manufacturing processes, which may be due to criminal intent or incompetence, substantial morbidity and mortality has resulted. A famous example is the outbreak of diethylene glycol poisoning in 1937 due to the contamination of sulfanilamide (Geiling and Cannon, 1938); in recent years other outbreaks of diethylene glycol poisoning have occurred in Australia, Bangladesh, Haiti, India, Nigeria and South Africa following its inappropriate use commercially.

The type of agent taken in overdose is also heavily influenced by availability and culture. In the UK, paracetamol poisoning is responsible for approximately one third of all admissions (Bateman *et al.*, 2006), whereas in Sri Lanka, for example, the agents ingested are more often pesticides or plants such as oleander (Eddleston *et al.*, 2005). In addition, ingestion of heating fuels, antimalarials, antituberculous drugs and traditional medicines are reported frequently in the developing world.

The toxicity of a substance, and therefore the features of poisoning, can generally be predicted from its physicochemical properties, its pharmacological or toxicological actions, the route of exposure and the dose to which an individual has been exposed. The features of poisoning are classified as either local or systemic. Local toxicity is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

confined to the site of contact of the substance with body surfaces. The route of exposure (eye, skin, respiratory or gastrointestinal (GI) tract) determines the anatomical location of the interaction; the physicochemical characteristics of the substance (solubility, volatility, pH) define its nature and extent. Systemic toxicity depends on the fraction of the dose of the poison that is absorbed into the circulation; systemic toxicity is generally dose related, may be organ-specific, or may involve several organs.

While the pharmacological and toxicological effects of the poison are generally proportional to the amount that has been absorbed, the effects are modulated by variations between individuals. Some individuals react in a non-dose-dependent, idiosyncratic manner to some agents (such as metoclopramide, and some phenothiazines and butyrophenones). The speed with which features appear depends partly on the route of exposure; it is greater with inhalation and injection than with dermal exposure and ingestion.

4.1 Assessment and Management of the Poisoned Patient

The assessment and management of an acutely poisoned patient involves the following approach:

1. Taking an appropriate history
2. Assessing vital functions (the level of consciousness, ventilation, circulation and temperature) and correcting any impairment
3. Examining the patient and observing features (**Tables 1** and **2**) that help to identify the substance(s) to which the patient has been exposed
4. Identifying complications and treating them:
   (a) Fluid, acid–base and electrolyte abnormalities
   (b) Skin blisters
   (c) Convulsions
   (d) Rhabdomyolysis
   (e) Methaemoglobinaemia
   (f) Serotonin syndrome
5. Requesting appropriate investigations
6. Assessing the patient psychiatrically and offering appropriate management.

Diagnosis is based on the history, circumstantial evidence, the features present (if any) and, occasionally, on the results of haematological, biochemical and toxicological analyses.

4.2 Taking a History

About 80% of adults who have ingested an overdose are conscious on arrival at hospital and the diagnosis of self-poisoning can usually be made from the history. In unconscious patients, a history from friends or relatives is helpful, and the diagnosis can often be inferred from tablet bottles or a 'suicide note' brought by the paramedics, or made by exclusion of other causes. Self-poisoning must always be considered in the differential diagnosis in any patient with an altered consciousness level, even if relatives claim that the individual would never take an overdose.

Table 1 Features of poisoning

Features	Likely poisons
Constricted pupils (miosis)	Opioids, organophosphorus and carbamate insecticides, nerve agents
Dilated pupils (mydriasis)	Tricyclic antidepressants, amphetamines, cocaine, anticholinergic drugs
Divergent strabismus	Tricyclic antidepressants
Nystagmus	Carbamazepine, phenytoin
Loss of vision	Methanol, quinine
Papilloedema	Carbon monoxide, methanol
Convulsions	Tricyclic antidepressants, theophylline, opioids, mefenamic acid, isoniazid, amphetamines
Dystonic reactions	Metoclopramide, phenothiazines
Delirium and hallucinations	Amphetamines, anticholinergic drugs, cannabis, recovery from tricyclic antidepressant poisoning
Hypertonia and hyper-reflexia	Tricyclic antidepressants, anticholinergic drugs
Tinnitus and deafness	Salicylates, quinine
Hyperventilation	Salicylates, phenoxyacetate herbicides, theophylline
Hyperthermia	Ecstasy (MDMA), salicylates
Blisters	Usually occur in comatose patients

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106

Table 2 Feature clusters in acute poisoning

Feature clusters	Poisons
Coma, hypertonia, hyper-reflexia, extensor plantar responses, myoclonus, strabismus, mydriasis, sinus tachycardia, convulsions	Tricyclic antidepressants; less commonly antihistamines, orphenadrine, thioridazine
Coma, hypotonia, hyporeflexia, flexor or nonelicitable plantar responses, hypotension	Barbiturates, benzodiazepine and alcohol combinations, tricyclic antidepressants
Coma, miosis, reduced respiratory rate	Opioid analgesics
Nausea, vomiting, tinnitus, deafness, sweating, hyperventilation, vasodilation, tachycardia	Salicylates
Hyperthermia, tachycardia, delirium, agitation, mydriasis	MDMA (ecstasy) or other amphetamine
Miosis, hypersalivation, bronchorrhoea	Organophosphorus and carbamate insecticides, nerve agents

Acutely poisoned patients may be emotionally and psychiatrically distressed, and require competent, sympathetic assessment if essential information is not to be missed. It is pertinent to try to establish the nature of the substance taken, the amount involved, the route (ingestion, injection, inhalation or dermal) and the time of exposure, so that the clinical course can be anticipated and the risk assessed. However, statements about the nature and amount of what has been taken should be regarded with clinical suspicion, because these are often inconsistent with laboratory analysis of blood or urine (Mahoney *et al*., 1990; Pohjola-Sintonen *et al*., 2000). When the time of exposure is important (e.g. paracetamol poisoning), the accuracy can be improved by relating events to activities of daily life (e.g. the time of a television programme).

4.3 Assessment of Vital Functions and Their Management if Impaired

The level of consciousness, ventilation and circulation should be assessed in all patients.

4.3.1 Level of Consciousness

The Glasgow Coma Scale (GCS) is the most commonly used method to assess the degree of impairment of consciousness. The AVPU (Alert, Voice, Pain, Unresponsiveness) scale is a simplified version of the GCS (alert, responsive to verbal stimulation, responsive to painful stimulation and unresponsive) and corresponds well to GCS scores when assessing level of consciousness in the poisoned patient (Kelly *et al*., 2004). A GCS score of ≤ 8 (not obeying commands, not speaking, not eye opening) should prompt careful respiratory assessment, particularly if the laryngeal (gag) reflex is lost.

4.3.2 Ventilation

In any case of poisoning the priority is to assess and, if necessary, treat impairment of respiratory function. Food, vomit, secretions and dentures should be removed from the patient's mouth and pharynx, and the tongue prevented from falling back. The patient should be nursed with their head down in the left lateral position to minimize the risk of aspiration of the gastric contents into the lungs.

Pulse oximetry can be used to measure oxygen saturation. The displayed reading may be inaccurate when the saturation is below 70%, when peripheral perfusion is poor, and in the presence of carboxyhaemoglobin or methaemoglobin. If the patient has an arterial oxygen saturation of less than 95% (by pulse oximetry), is comatose (GCS $\leq$ 8) and/or the laryngeal (gag) reflex is absent, arterial blood gases should be measured. Only measurement of arterial blood gases indicates the presence of both hypercapnia (an increase in the arterial partial pressure of carbon dioxide) and hypoxia (a decrease in the arterial partial pressure of oxygen). The presence of ventilatory insufficiency (as determined by arterial partial pressure of oxygen ≤ 9 kPa on air and/or arterial partial pressure of carbon dioxide ≥ 6 kPa) should lead to intubation and mechanical ventilation if the central respiratory depression cannot be reversed by administration of a specific antidote, such as naloxone (see Section 4.7.2.2). Even when ventilation is satisfactory on presentation, it must be reassessed periodically

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

because deterioration is well recognized (e.g. after ingestion of a sedative drug).

4.3.3 Circulation

Pulse, blood pressure and temperature (core and peripheral) should be measured to assess cardiovascular function. An electrocardiogram (ECG) should be undertaken in moderately or severely poisoned patients, particularly when a drug with a cardiotoxic action (e.g. a tricyclic antidepressant that produces QRS prolongation) has been ingested (Thanacoody and Thomas, 2005). Although hypotension (systolic blood pressure $\leq$80 mmHg) is a recognized feature of acute poisoning, the classical features of shock (tachycardia and pale, cold skin) are seen rarely, because only a minority of patients are severely poisoned.

Hypotension and shock may be caused by:

1. A direct cardiodepressant action of the poison (e.g. β-blockers [DeWitt and Waksman, 2004], calcium-channel blockers [DeWitt and Waksman, 2004], tricyclic antidepressants [Thanacoody and Thomas, 2005]);
2. Vasodilation and venous pooling in the lower limbs (e.g. angiotensin-converting enzyme (ACE) inhibitors [Lip and Ferner, 1995], phenothiazines);
3. A decrease in circulating blood volume because of GI losses (e.g. profuse vomiting in theophylline poisoning [Vale, 2007b]), increased insensible losses (e.g. salicylate poisoning [Chapman and Proudfoot, 1989]), increased renal losses (e.g. poisoning due to diuretics) and increased capillary permeability.

Hypotension may be exacerbated by coexisting hypoxia, acidosis and dysrhythmias. Young patients are generally not at risk of cerebral or renal damage unless their systolic blood pressure falls below 80 mmHg. In older patients, it is preferable to maintain systolic blood pressure above 90 mmHg. As a first step, the patient should be placed in a head-down position by elevating the foot of the bed by 15 cm. If this measure fails to produce improvement, plasma volume should be expanded by infusion of a crystalloid such as sodium chloride solution 0.9%. Invasive haemodynamic monitoring to confirm that adequate volume replacement has been administered may be appropriate. Dobutamine $2.5-10\,\mu g\,kg^{-1}\,min^{-1}$, or epinephrine $0.5-2.0\,\mu g\,kg^{-1}\,min^{-1}$, is indicated if hypotension is resistant to these measures; dopamine $2-5\,\mu g\,kg^{-1}min^{-1}$ is an alternative. A vasoconstrictor sympathomimetic drug (e.g. norepinephrine) may be necessary in severe cases, but it must be recognized that blood pressure may be raised at the expense of perfusion of vital organs, such as the kidneys.

A few drugs when taken in overdose may produce systemic hypertension. If this is mild and associated with agitation, a benzodiazepine such as diazepam may suffice. In more severe cases, for example, those due to a monoamine oxidase inhibitor, there may be a risk of arterial rupture, particularly intracranially. To prevent this, intravenous (iv) isosorbide dinitrate $2-10\,mg\,h^{-1}$ up to $20\,mg\,h^{-1}$ if necessary, or an α-adrenergic blocking agent (e.g. phentolamine, 5 mg iv every 10–15 minutes), or sodium nitroprusside $0.5-1.5\,\mu g\,kg^{-1}\,min^{-1}$ by iv infusion, may be administered until blood pressure elevation is controlled.

4.3.4 Abnormalities of Temperature

A core (rectal) temperature below 35 °C is often present in older patients who are comatose, particularly if they have been exposed to cold temperatures for several hours. Placing the patient in a room with moistened air at a temperature of 27–29 °C and covering him or her with a foil space blanket to minimize heat loss is the best way to treat hypothermia. In addition, iv and intragastric fluids at normal body temperature may be used. Local radiant heat should not be used.

Rarely, body temperature may increase to potentially fatal levels after poisoning with central nervous system (CNS) stimulants such as cocaine, amphetamines, including 3,4-methylenedioxymethamphetamine (MDMA) (ecstasy) (Freedman *et al*., 2005), monoamine oxidase inhibitors or theophylline. In such cases, muscle tone is often increased (hypertonia) and convulsions (see Section 4.5.3) and rhabdomyolysis (see Section 4.5.4) are common. Cooling measures should be instituted, sedation with diazepam should be given and, in severe cases, dantrolene 1 mg (kg body weight)$^{-1}$ should be administered intravenously.

4.4 Examination and Identification of Poison-Induced Features

Physical signs (features) are particularly important when trying to elucidate the cause of unexplained coma. A diagnosis of acute poisoning can only rarely be made on the basis of a single physical sign, but there are clusters of features that make a diagnosis of poisoning with specific drugs very likely (**Table 1**). General observations may also reveal useful information. For example, solvents or alcohol may be smelt on the breath, track marks may reveal undisclosed illicit substance abuse, atypical bruising may warn of domestic or other violence, and the signs of alcoholic liver disease may be revealed.

Inequality of the pupils is not uncommon in poisoned patients. Widely dilated pupils that react poorly to light may be caused by poisons with anticholinergic actions (e.g. tricyclic antidepressants) or sympathomimetic effects (e.g. amphetamines). Miosis (constricted pupils) is usually caused by opioid analgesics or poisons

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

with cholinergic or anticholinesterase actions (e.g. organophosphorus or carbamate insecticides, nerve agents). Visual impairment (blindness) is associated most commonly with quinine (Mackie *et al*., 1997) and methanol (Barceloux *et al*., 2002) poisoning.

Strabismus (squint), internuclear ophthalmoplegia (paralysis of the muscles inside the eye that control the iris and ciliary body) and total external ophthalmoplegia (paralysis of the muscles that control eye movements) have been described in poisoning by various drugs (Hotson and Sachdev, 1982). Transient and variable strabismus (usually with the optic axes divergent in the horizontal plane) has been attributed to phenytoin, carbamazepine and tricyclic antidepressants. Although loss of oculocephalic and oculovestibular reflexes is usually regarded as evidence of severe brain-stem damage, poisoning with carbamazepine, phenytoin and tricyclic antidepressants can be associated with loss of these reflexes, but patients recover completely.

Hypertonia, hyper-reflexia and extensor plantar responses are commonly found in tricyclic antidepressant poisoning, and with other drugs with marked anticholinergic actions (e.g. the older antihistamines). However, all of these signs may be abolished in deep coma. Decerebrate and decorticate movements of the limbs often occur in unconscious poisoned patients but, in most cases, there is no irreversible brain damage and the patient recovers fully. Acute dystonic movements (muscle dysfunction characterized by spasm) are also observed in poisoning due to metoclopramide (Bateman *et al*., 1985), or less commonly haloperidol, droperidol, prochlorperazine or trifluoperazine.

4.5 Complications of Poisoning and Their Management

4.5.1 Fluid, Acid–Base and Electrolyte Imbalance

Patients who are vomiting, sweating excessively or passing large quantities of urine should be given fluids intravenously to replace GI, dermal and renal losses.

Acid–base abnormalities, particularly respiratory and metabolic acidoses, are common presentations in acute poisoning. Respiratory acidosis due to CNS depression or pulmonary toxicity, and metabolic acidosis due to lactic acidaemia or derangements of intermediary metabolism are common features of poisoning (Jones, 2007). Respiratory alkalosis is a feature of early salicylate poisoning (Chapman and Proudfoot, 1989). Some common poisons that cause metabolic acidosis are shown in **Table 3**. After correction of hypoxia and hypotension, metabolic acidosis should be treated by the administration of sodium bicarbonate 50–100 ml as a bolus dose with further boluses being given as required.

Table 3 Poisons causing metabolic acidosis

- Carbon monoxide
- Cocaine
- Cyanide
- Diethylene glycol
- Ethanol
- Ethylene glycol
- Iron
- Methanol
- Paracetamol
- Salicylates
- Tricyclic antidepressants

Information about the nature of poisons ingested can occasionally be obtained from standard haematological and biochemical investigations, and from arterial blood gas analysis (**Table 4**). Measurement of a full blood count is generally of little diagnostic value, though prolongation of the prothrombin time (international normalized ratio (INR)) may be caused by anticoagulants or by liver necrosis in paracetamol or hepatotoxic mushroom poisoning. Routine biochemistry and arterial blood-gas analysis are of value in the differential diagnosis of coma or the detection of poison-induced hypokalaemia, hyperkalaemia, hypoglycaemia, hyperglycaemia and hepatic and renal failure or of acid–base disturbances. Measurement of carboxyhaemoglobin, methaemoglobin and cholinesterase activities are of assistance in the diagnosis and management respectively of cases of poisoning due to carbon monoxide, methaemoglobin-inducing agents such as nitrites, and organophosphorus or carbamate insecticides.

Hypernatraemia can be caused by ingestion of salt and is well recognized as a nonaccidental injury in children. Urine sodium concentration is elevated in salt poisoning, but this finding does not exclude hypernatraemia caused by dehydration; measurement of the fractional excretion of sodium and water is needed to distinguish the two causes (Coulthard and Haycock, 2003). Hyponatraemia is a recognized complication of the use of MDMA ('Ecstasy'). It is caused by inappropriate secretion of antidiuretic hormone (ADH) (Henry *et al*., 1998), which impairs renal water excretion. This is often exacerbated by such patients drinking large amounts of water. It is managed by restricting the amount of fluid given to the patient.

Unless renal function is impaired or rhabdomyolysis is severe, hyperkalaemia is a relatively uncommon metabolic complication of poisoning. In contrast, marked hypokalaemia is a more common problem and may have serious sequelae. Most potassium disturbances in acute poisoning are due to disruption of extrarenal control mechanisms, notably the activity of Na^+/K^+ ATPase (adenosine triphosphatase) and potassium channels.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 4 Nontoxicological investigations

- Serum sodium concentration (e.g. hyponatraemia in MDMA poisoning or hypernatraemia after salt ingestion)
- Serum potassium concentration (e.g. hypokalaemia in theophylline poisoning and hyperkalaemia in digoxin poisoning)
- Plasma creatinine concentration (e.g. renal failure in ethylene glycol poisoning)
- Prolongation of the prothrombin time (increased International Normalized Ratio—INR) (e.g. in paracetamol or anticoagulant poisoning)
- Acid–base disturbances, including metabolic acidosis and respiratory alkalosis
- Blood glucose (sugar) concentration (e.g. hypoglycaemia in insulin poisoning or hyperglycaemia in salicylate poisoning)
- Serum calcium concentration (e.g. hypocalcaemia in ethylene glycol poisoning)
- Serum phosphate concentration (e.g. hypophoshataemia in paracetamol poisoning)
- Transaminase or aminotransferase (ALT (alanine) and AST (aspartate)) activities (e.g. increased in paracetamol poisoning)
- Carboxyhaemoglobin concentration (increased in carbon monoxide poisoning)
- Methaemoglobin concentration (e.g. increased in nitrite poisoning)
- Erythrocyte cholinesterase activity (e.g. reduced in organophosphorus and carbamate insecticide and nerve agent poisoning)

Hypokalaemia occurs because of increased Na^+/K^+ ATPase activity (e.g. β_2- agonist, theophylline or insulin poisoning), competitive blockade of potassium channels (e.g. barium or chloroquine poisoning), GI losses and/or alkalosis. Hypokalaemia results in generalized muscle weakness, paralytic ileus, ECG changes (flat or inverted T waves, prominent U waves, ST segment depression) and cardiac arrhythmias (atrial tachycardia ± block, atrioventricular (AV) dissociation, ventricular tachycardia (VT), ventricular fibrillation (VF)). Severe and clinically significant hypokalaemia (e.g. that caused by theophylline (Vale, 2007b) or β_2-agonist poisoning (Vale, 2007c) should be corrected by infusing potassium to prevent arrhythmias (Bradberry and Vale, 1995).

Hyperkalaemia follows inhibition of Na^+/K^+ ATPase activity (e.g. by digoxin), increased uptake of potassium salts, disruption of intermediary metabolism (e.g. cyanide poisoning), activation of potassium channels (e.g. fluoride poisoning) and the presence of acidosis and rhabdomyolysis, particularly if the latter is complicated by renal failure. Hyperkalaemia is associated with abdominal pain, diarrhoea, muscle pain and weakness, ECG changes (tall peaked T waves, ST segment depression, prolonged PR interval, QRS prolongation) and cardiac arrhythmias (VT, VF).

Hypocalcaemia is a specific feature of ethylene glycol and hydrogen fluoride poisoning, in which calcium is deposited as insoluble oxalate and hydroxyapatite crystals, respectively.

Hypophosphataemia may contribute to morbidity and mortality in paracetamol poisoning by inducing mental confusion, irritability and coma (Jones *et al*., 1989; Schmidt and Dalhoff, 2002). Phosphaturia appears to be the principal cause of hypophosphataemia in paracetamol poisoning; it may occur in the absence of fulminant hepatic failure and indicates paracetamol-induced renal tubular damage (Jones *et al*., 1989; Florkowski *et al*., 1994). More recently, hyperphosphataemia has been shown to be a highly specific and sensitive predictor of nonsurvival in patients with severe paracetamol poisoning (Schmidt and Dalhoff, 2002). It has been suggested that hyperphosphataemia is caused by renal dysfunction in the absence of hepatic regeneration (Schmidt and Dalhoff, 2002).

Hypoglycaemia may follow an overdose of insulin, sulfonylureas or ethanol, and may occur in paracetamol-induced liver failure. It is corrected by infusing 10% dextrose, if necessary, after a bolus injection of 50% dextrose (50 ml).

4.5.2 Skin Blisters

Skin blisters may be found in poisoned patients who are, or have been, unconscious (Beveridge and Lawson, 1965; Hoffbrand and Ridley, 1972). Such lesions are not diagnostic of specific poisons, but are sufficiently

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

common in poisoned patients (and sufficiently uncommon in patients unconscious from other causes) to be of diagnostic value. Unconscious patients should be turned at least every 2 hours. Bullous lesions should be left intact until they burst, to reduce the risk of infection. Deroofing should be performed when the blister bursts; a nonadhesive dressing is then applied.

4.5.3 Convulsions

These may occur, for example, in poisoning due to tricyclic antidepressants (Bateman, 2005), mefenamic acid or opioids. Usually the seizures are short-lived but, if they are prolonged, diazepam 10–20 mg iv or lorazepam 4 mg iv should be administered. Persistent fits must be controlled rapidly to prevent severe hypoxia and brain damage and should be treated with a loading dose of phenytoin 18 mg kg^{-1} administered intravenously at a rate not more than 50 mg min^{-1}, with ECG monitoring. Theoretically, phenytoin is contraindicated in poisoning due to tricyclic antidepressants as it may exacerbate sodium-channel blockade and increase the risk of cardiac arrhythmias. Rarely, muscle relaxation and mechanical ventilation are required in addition to phenytoin.

4.5.4 Rhabdomyolysis

Rhabdomyolysis is a condition in which there is dissolution of striated muscle fibres, with leakage of muscle cell contents (enzymes, myoglobin, potassium and phosphate) (Vale, 2007a). In patients who are poisoned, nontraumatic rhabdomyolysis may be caused by a direct insult to the cell membrane, affecting its ability to maintain ion gradients or be secondary to local muscle compression as a result of coma or seizures. Two clinically important complications are observed: acute renal failure (which may be nonoliguric) and peripheral nerve damage (secondary to compartment syndrome), resulting predominantly in wrist or foot drop.

Rhabdomyolysis accounts for 5–9% of all cases of acute renal failure (Grossman *et al*., 1974; Thomas and Ibels, 1985) and 5–30% of patients with rhabdomyolysis develop acute renal failure (Gabow *et al*., 1982; Ward, 1988). Three main mechanisms are involved (Holt and Moore, 2001). First, tubular necrosis occurs by free-radical-mediated lipid peroxidation. This involves redox cycling between two oxidation states of myoglobin haem: Fe^{3+} (ferric) and Fe^{4+} (ferryl) (Holt and Moore, 2000). The formation of ferryl myoglobin requires the presence of lipid hydroperoxides (LOOH). Once formed, the ferryl species reacts with lipids and LOOH to form lipid alkyl (LOO) and lipid peroxyl (L) radicals that progressively damage renal tubular membranes. Thus, ferryl myoglobin can initiate lipid peroxidation.

Secondly, renal vasoconstriction occurs due to activation of the sympathetic nervous system and the renin–angiotensin system in response to reduced effective circulating blood volume, scavenging of the vasodilator nitric oxide (NO) by myoglobin and release of isoprostanes (particularly 15-F2t and 15-E2t, which are potent vasoconstrictors), formed as a result of free-radical damage to phospholipid membranes.

Thirdly, tubular obstruction occurs due to the formation of tubular casts formed by binding of free myoglobin to Tamm–Horsfall protein (uromodulin), a renal glycoprotein (Zager, 1989), and as a result of urate crystal deposition.

Experimentally, urine alkalinization (see Section 4.7.3.2) has been shown to suppress the rate of conversion of ferryl (Fe^{4+}) myoglobin to ferric (Fe^{3+}) myoglobin. Thus, alkalinization inhibits the cyclical formation of lipid peroxide radicals and limits lipid peroxidation (Moore *et al*., 1998), so reducing tubular damage. Isoprostane release is also reduced by alkalinization, thereby lessening vasoconstriction. In addition, binding of myoglobin to Tamm–Horsfall protein is reduced under alkaline conditions, so that tubular casts are not formed (Zager, 1989). The administration of 8.4% sodium bicarbonate 225 ml should produce urine alkalinization; further boluses of sodium bicarbonate will be required to maintain the urine pH greater than 7.5. However, limited experimental and clinical data (Eneas *et al*., 1979; Homsi *et al*., 1997; Brown *et al*., 2004) suggest that early volume replacement is more important than urine alkalinization in preventing rhabdomyolysis-induced renal failure.

4.5.5 Methaemoglobinaemia

Methaemoglobin is formed when ferrous haemoglobin iron (II) is oxidized to ferric iron (III), which cannot participate in oxygen transport. Methaemoglobin concentrations are normally maintained at around 1% total haemoglobin by the action of a nicotinamide adenine dinucleotide (NADH)-dependent methaemoglobin reductase for which the physiological electron carrier is cytochrome b5 (Bunn and Forget, 1986). Excess methaemoglobin causes tissue hypoxia, not only because methaemoglobin is incapable of binding oxygen, but also because the oxidation of one or more iron atoms in the haem tetramer distorts the tetramer structure, so that the remaining nonoxidized haem subunits bind oxygen avidly, but release it less efficiently (Bunn and Forget, 1986).

Poisoning with a number of oxidizing drugs and chemicals may be complicated by methaemoglobinaemia (Bradberry *et al*., 1994a; 1994b; 2001; Bradberry, 2003). Two important chemical groups in this regard are organic nitrites (e.g. amyl and isobutyl nitrite) and amino or nitro derivatives of benzene (e.g. aniline, dapsone and lidocaine). Organic nitrites are sold as 'room odourizers'. Inhalation causes profound, though transient, vasodilatation with the intent of enhancing sexual pleasure

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

or inducing a transient 'high'. Substantial absorption, which may occur after prolonged inhalation or ingestion, precipitates methaemoglobin formation. Amino and nitro derivatives of benzene are particularly potent methaemoglobin-formers because once absorbed they are activated to a metabolite that enters a cyclical process of methaemoglobin production such that even small exposures can result in clinically significant methaemoglobinaemia (Bradberry, 2007).

Even though methaemoglobin cannot bind oxygen, it is appropriate to administer high-flow oxygen to symptomatic patients with methaemoglobinaemia to maximize oxygen saturation of residual normal ferrous haemoglobin. In addition, methylthioninium chloride (methylene blue), which acts as an electron donor to reduce methaemoglobin, should be employed. In otherwise healthy individuals, methaemoglobin concentrations less than 30% usually do not require specific therapy, since such patients have only minor or no symptoms and methaemoglobin will be reduced over several hours by the intrinsic activity of methaemoglobin reductase. However, an anaemic patient may experience symptoms of hypoxia at methaemoglobin concentrations below 30%, since even in the absence of methaemoglobinaemia their overall oxygen transporting capacity is reduced. Such patients, or otherwise healthy individuals with methaemoglobin concentrations greater than 30%, warrant treatment with methylthioninium chloride $1-2\,mg\,kg^{-1}$ (the dose depending on the severity of features) intravenously over 5–10 minutes as a 1% solution. If the methaemoglobin concentration is greater than 50%, methylthioninium chloride $2\,mg\,kg^{-1}$ should be administered. Symptomatic improvement usually occurs within 30 minutes.

If there is evidence of continuing chemical absorption or prolonged methaemoglobin formation, a second dose of methylthioninium chloride $1-2\,mg\,kg^{-1}$ may be required. High doses (typically in excess of $20\,mg\,kg^{-1}$) of methylthioninium chloride can initiate severe intravascular haemolysis and doses as low as $4\,mg\,kg^{-1}$ may exacerbate the haemolytic effect of oxidizing chemicals. Severe renal impairment is an absolute contraindication to methylthioninium chloride administration, since it is eliminated predominantly renally. Methylthioninium chloride will also be less effective where nicotinamide adenine dinucleotide phosphate (NADPH) availability is reduced, as occurs in the presence of glucose-6-phosphate dehydrogenase (G-6-PD) deficiency and haemolysis, and when the chemical initiating methaemoglobin formation itself utilizes NADPH in cyclical methaemoglobin production, as occurs with, for example, dapsone and aniline.

4.5.6 Serotonin Syndrome

Serotonin toxicity results from an excess of serotonin in the CNS, which can be due to inhibition of the metabolism of serotonin (monoamine oxidase inhibitors), prevention of the reuptake of serotonin in nerve terminals (serotonin reuptake inhibitors), increased serotonin precursors (tryptophan) or increased serotonin release (serotonin-releasing agents such as amphetamines, fenfluramine, MDMA) (Isbister *et al*., 2007).

Serotonin toxicity occurs insidiously and is characterized by the development, within hours, of a triad of altered mental status (approximately 40% of patients), neuromuscular hyperactivity (approximately 50% of patients) and autonomic instability (approximately 40% of patients), though diagnosis does not depend on all parts of the triad being present (Sternbach, 1991; Isbister and Buckley, 2005; Boyer and Shannon, 2005; Thanacoody, 2007; Isbister *et al*., 2007). Features of altered mental status include agitation, confusion, delirium and hallucinations. Drowsiness and coma may occur in severe cases. Neuromuscular features include profound shivering, tremor, teeth grinding, myoclonus and hyper-reflexia. Features of autonomic instability include dilated pupils, sinus tachycardia, fever and hypertension or hypotension. Flushing, diarrhoea and vomiting are also common. In severe cases seizures, hyperthermia, rhabdomyolysis, renal failure and coagulopathies may develop.

The Hunter Serotonin Toxicity Criteria (Dunkley *et al*., 2008) have refined Sternbach's criteria and proposed seven features which are considered to be more sensitive and specific in making the diagnosis: clonus (spontaneous, inducible and ocular), agitation, diaphoresis, tremor, hyper-reflexia, hypertonicity and hyperthermia ($T^0 > 38\,^{\circ}C$). Clonus is the most important diagnostic sign.

The precipitating drug(s) should be discontinued and supportive care instituted. The control of agitation with benzodiazepines is essential. If hyperthermia supervenes, cooled iv fluids, tepid sponging and use of fans may help; paralysis and assisted ventilation should be employed if these measures do not to reduce muscle activity (Boyer and Shannon, 2005). Seizures should be controlled with diazepam 10–20 mg in an adult. Myoclonic jerks may be helped by clonazepam 1 mg intravenously over 2 minutes. The 5HT2A (5-hydroxytryptamine (serotonin) receptor 2A) antagonists, cyproheptadine 4–12 mg orally (up to 12–32 mg has been proposed during a 24 hour period (Boyer and Shannon, 2005)) and chlorpromazine 50 mg parenterally, have been used to treat serotonin syndrome following overdose, but there are no controlled trials to support the use of either agent (Isbister *et al*., 2007).

4.6 Investigations

Measurement of the concentration of a specific poison in the blood, or toxicological screening of blood or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

urine, can be used to establish a diagnosis of poisoning, particularly in severely poisoned patients in whom the cause of coma is unknown. However, although identification of a poison may reassure the clinician, this is not a good reason for the request. Before proceeding, the clinician should consider how the result of a screen will alter management. The pattern of drugs involved in poisoning in most developed countries is such that specific treatment is unlikely to be available and management will therefore be supportive. There are a small number of cases where emergency measurement of the plasma concentration will assist clinical management and/or help to determine prognosis: aspirin (salicylate), carbamazepine, digoxin, ethylene glycol, iron, lithium, methanol, paracetamol, paraquat, phenobarbital, quinine and theophylline.

Routine radiology is of little diagnostic value. It can be used to confirm ingestion of metallic objects (e.g. coins, button batteries) or injection of globules of metallic mercury. Rarely, hydrocarbon solvents may be seen as a slightly opaque layer floating on the top of the gastric contents with the patient upright, or outlining the small bowel. Some enteric coated or sustained-release drug formulations may be seen on plain abdominal radiographs, but, with the exception of iron salts, ordinary formulations are seldom seen. Ingested packets of illicit substances may be discernible on a plain radiograph, but computed tomography (CT) or magnetic resonance imaging (MRI) is more reliably able to detect such objects. Radiology may be particularly helpful in confirming some of the complications of poisoning, for example, aspiration pneumonia, noncardiogenic pulmonary oedema (salicylates), bronchiolitis obliterans (nitrogen oxides), acute respiratory distress syndrome (ARDS) and lung fibrosis (paraquat).

Performing an ECG is also of limited diagnostic value, though it should be undertaken in those ingesting potentially cardiotoxic drugs; continuous ECG monitoring may be appropriate in such patients. Sinus tachycardia with prolongation of the PR and QRS intervals in an unconscious patient should prompt consideration of tricyclic antidepressant poisoning. With increasing cardiotoxicity, VT may supervene. ECG changes in association with poison-induced potassium disturbances are discussed in Section (4.5.1). QT interval prolongation is a recognized adverse effect of several drugs in overdose (e.g. quetiapine, terfenadine and quinine) and predisposes to ventricular arrhythmias, notably *torsade de pointes*.

4.6.1 Psychiatric Assessment and Management

In adults, self-poisoning is commonly a 'cry for help'. Common precipitants include relationship problems, often in the context of depression and alcohol abuse. Those involved are most often females under the age of 35 who are in good physical health. They take an overdose in circumstances where they are likely to be found, or in the presence of others. In those older than 55 years of age, men predominate and the overdose is usually taken in the course of a depressive illness or because of poor physical health. The risks of repetition of self-harm and of suicide following self-poisoning are substantial (Hawton, 2007).

All patients require a sympathetic and caring approach, a psychiatric and social assessment and, sometimes, psychiatric treatment. Psychosocial assessment should include investigation of the events and problems preceding the act, suicidal intent and other motives for the act, psychiatric disorders, personality traits and disorders, family and personal history, psychiatric history, including of self-harm, risk of further self-harm and suicide, and coping resources and support (Hawton, 2007).

4.7 Management of the Poisoned Patient

As explained above, initial management involves the treatment of any potentially life-threatening conditions, such as airway compromise, breathing difficulties, haemodynamic instability, serious dysrhythmias and convulsions. Thereafter, fluid, acid–base and electrolyte abnormalities should be corrected and temperature disturbances treated appropriately.

Further management is aimed at:

1. Reducing absorption of the chemical(s) to which the individual has been exposed;
2. Employing a specific antidote, if appropriate;
3. Using methods to increase the elimination of the poison, if relevant.

Expert advice can always be obtained from a poisons information service.

4.7.1 Reduction of Poison Absorption

Poisons may be absorbed through the lungs, skin or from the GI tract. To reduce absorption through the lungs and skin, the exposed individual should be moved from the contaminated area, contaminated clothing should be removed and the skin thoroughly washed with soap and water.

While it appears logical to assume that removal of unabsorbed drug from the GI tract ('gut decontamination') will be beneficial, the efficacy of current methods remains unproven and efforts to remove small amounts of 'safe' drugs are clearly not worthwhile or appropriate.

4.7.1.1 Activated Charcoal

Activated charcoal adsorbs a wide variety of drugs and toxic agents; the exceptions are acids and alkalis,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

ethanol, ethylene glycol, iron, lithium and methanol. In studies in volunteers given 50 g activated charcoal, the mean reduction in absorption was 40, 16 and 21% at 60, 120 and 180 minutes, respectively, after ingestion (Chyka *et al*., 2005). Based on these studies, activated charcoal should be considered in those who have ingested a potentially toxic amount of a poison (known to be adsorbed by charcoal) up to one hour previously. There are insufficient data to support or exclude its use after one hour. There is no evidence that administration of activated charcoal improves the clinical outcome.

4.7.1.2 Gastric Lavage

Gastric-emptying studies in volunteers provide no support for the use of gastric lavage. In the single clinical study in which benefit was claimed for lavage within one hour of overdose, patients also received activated charcoal (Kulig *et al*., 1985). There was also selection bias, and hence conclusions based on these data are limited. Thus, gastric lavage should not be used routinely in the management of poisoned patients, as there is no evidence that it improves outcome, and it may cause significant morbidity (Kulig and Vale, 2004). The efficacy with which lavage removes gastric contents decreases with time. Therefore, lavage should be considered only in patients who have ingested life-threatening amounts of a toxic agent up to one hour previously.

4.7.1.3 Emesis with Syrup of Ipecacuanha

Syrup of ipecacuanha is derived from the dried roots of *Cephaelis ipecacuanha* and *C. acuminata* and contains the active alkaloids emetine and cephaeline. Emetine has a direct irritant action on the gastric mucosa, which causes vomiting within 30 minutes of administration; subsequent vomiting results from the central action of both alkaloids. Although syrup of ipecacuanha is an effective emetic, there is little evidence that its use prevents significant absorption of toxic material and, moreover, its adverse effects (e.g. persistent vomiting, diarrhoea, lethargy, drowsiness) may complicate diagnosis (Krenzelok *et al*., 2004). It should be abandoned.

4.7.1.4 Whole-Bowel Irrigation

Theoretically, the more quickly a poison passes through the gut, the less it is absorbed. Whole-bowel irrigation using polyethylene glycol electrolyte solutions does not result in absorption of fluid and electrolytes, even though large volumes are administered rapidly via a nasogastric tube. Some volunteer studies have shown substantial decreases in the bioavailability of ingested drugs, but no controlled clinical trials have been conducted and there is no evidence that whole-bowel irrigation improves outcome (Tenenbein and Lheureux, 2004). Based on volunteer studies, whole-bowel irrigation may be considered following potentially toxic ingestion of sustained-release or enteric-coated drugs and in body-packers (Hoffman *et al*., 1990).

4.7.1.5 Cathartics

Cathartics have been used alone and with activated charcoal. Two general types of osmotic cathartics have been used: saccharide cathartics (sorbitol) and saline cathartics (magnesium citrate, magnesium sulfate, sodium sulfate). Cathartics are intended to decrease the absorption of substances by accelerating the expulsion of the poison from the GI tract. Since most drug absorption occurs rapidly in the upper GI tract, the use of cathartics is most likely to benefit patients who have ingested drugs that are absorbed slowly. In volunteers, cathartics did not alter significantly the serum concentrations of lithium and salicylate when administered 30 minutes after dosing (Sørensen and Lindkær-Jensen, 1975) or change significantly the urine recovery of the metabolites of paracetamol (Galinsky and Levy, 1984) or salicylate (Mayersohn *et al*., 1977). In other studies, there was no difference in the mean area under the curve (AUC) of theophylline between the sorbitol-treated and control groups. No clinical studies have been published to investigate the ability of a cathartic, with or without activated charcoal, to reduce the bioavailability of drugs or to improve the outcome of poisoned patients. For these reasons it has been concluded that cathartics alone have no role in the management of poisoned patients. In addition, based on available data, routine use of a cathartic with activated charcoal has not been endorsed either (Barceloux *et al*., 2004).

4.7.2 Antidotes

There is no generally agreed definition of an antidote. The Shorter Oxford English Dictionary (2007) defines an antidote as a 'medicine given to counteract the action of a poison'. A WHO Working Party suggested an antidote was a 'therapeutic substance used to counteract the toxic action(s) of a specified xenobiotic' (Meredith *et al*., 1993), which could include substances such as activated charcoal. Flanagan and Jones (2001) have defined an antidote as a 'substance used to treat poisoning which has a specific action depending on the poison'. Bateman and Marrs (see **Antidotal Studies**) have adopted a similar definition.

Antidotes exert their beneficial effects by a variety of mechanisms, including forming an inert complex with the poison, accelerating detoxification of the poison, reducing the rate of conversion of the poison to a more toxic compound, competing with the poison for essential receptor sites, blocking essential receptors through which the toxic effects are mediated and bypassing the effect of the poison. These actions are described more fully in **Antidotal Studies**.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There are only a small number of poisons for which there is a specific antidote (**Table 5**) and few antidotes are employed regularly in clinical practice. Those that are include *N*-acetylcysteine, naloxone and flumazenil, and these are described below.

4.7.2.1 Acetylcysteine

Acetylcysteine acts by replenishing cellular glutathione stores. Acetylcysteine may also repair oxidation damage caused by *N*-acetyl-*p*-benzoquinone imine (NAPQI), either directly or, more probably, through the generation of cysteine and/or glutathione, and may also act as a source of sulfate and thereby 'unsaturate' sulfate conjugation (Jones, 1998). IV therapy with acetylcysteine is preferred, if available, because in overdose paracetamol induces vomiting and oral therapy may not be absorbed. The iv regimen employed involves a 20 hour 15 min to 21 hour regimen (Prescott *et al*., 1979a; Buckley *et al*., 1999; Kerr *et al*., 2005) and involves the administration of acetylcysteine 150 mg kg^{-1} over 15–60 minutes, then 50 mg/kg over the next four hours and 100 mg kg^{-1} over the next 16 hours; (total dose, 300 mg kg^{-1} over 20 hours 15 min to 21 hours). An oral regimen (Smilkstein *et al*., 1988) used only in the USA and now largely superseded by the iv preparation involved the administration of acetylcysteine 1330 mg kg^{-1} over 72 hours. Acetylcysteine must be administered within 8–10 hours of ingestion if hepatic damage is to be minimized or prevented (Vale and Proudfoot, 1995; Kerr *et al*., 2005; Prescott, 2005).

Approximately 10% of patients treated with iv acetylcysteine (20 hour 15 min regimen) develop rash and bronchospasm within the first hour of commencing treatment; the reaction is probably the result of histamine release caused by acetylcysteine in a concentration-dependent manner (Dawson *et al*., 1989; Sandilands and Bateman 2009). These reactions are seldom serious, but infusion of acetylcysteine should be discontinued for 30–60 minutes. Antihistamines are not usually required.

4.7.2.2 Naloxone

Naloxone is a pure opioid antagonist and has been used to make a rapid clinical diagnosis of opioid poisoning in those whose clinical presentation suggests inadequate

Table 5 Antidotes of value in poisoning

Poison	Antidotes
Aluminium (aluminum)	Desferrioxamine (deferoxamine)
Arsenic	Dimercaprol, succimer (DMSA[a])
Benzodiazepines	Flumazenil
β-Adrenoceptor blocking drugs	Atropine, glucagon
Calcium channel blockers	Atropine
Carbamate insecticides	Atropine
Carbon monoxide	Oxygen
Copper	D-Penicillamine, unithiol (DMPS[b])
Cyanide	Dicobalt edetate, hydroxocobalamin, oxygen, sodium nitrite, sodium thiosulfate
Diethylene glycol	Ethanol, fomepizole
Digoxin and digitoxin	Atropine, digoxin-specific antibody fragments
Ethylene glycol	Ethanol, fomepizole
Hydrogen sulfide	Oxygen
Iron salts	Desferrioxamine (deferoxamine)
Lead (inorganic)	Sodium calcium edetate, succimer (DMSA[a])
Methaemoglobinaemia	Methylthioninium chloride (Methylene blue)
Methanol	Ethanol, fomepizole
Mercury (inorganic)	Unithiol (DMPS[b])
Nerve agents	Atropine, HI-6, obidoxime, pralidoxime,
Oleander	Digoxin-specific antibody fragments
Opioids	Naloxone
Organophosphorus insecticides	Atropine, obidoxime, pralidoxime,
Paracetamol	Acetylcysteine
Thallium	Prussian (Berlin) blue
Warfarin and other anticoagulants	Phytomenadione (Vitamin K)

[a]Dimercaptosuccinic acid.
[b]Dimercaptopropanesulfonate.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

ventilation caused by an opiate. It causes no adverse effects when given in opioid-naive individuals, though even in small doses may produce withdrawal symptoms in addicts. The dose of naloxone is titrated until the effects of the opioid have been reversed to a clinically detectable extent within 1–2 minutes. Typically, this dose of naloxone is 1.2 mg intravenously, followed by naloxone 2 mg if the response is only partial; a further 2 mg may be given 2–5 minutes later, if full resuscitation is not achieved. In patients who have not responded to naloxone 4 mg, the diagnosis of opioid poisoning should be reconsidered.

As naloxone has a half-life of some 45 and 90 minutes, which is much shorter than the half-life of opioids, repeat doses of naloxone are often required to maintain opioid reversal (Meredith *et al*., 1993). Alternatively, an infusion of naloxone may be commenced with the dose infused over one hour being 60–100% of the resuscitative dose. For slow-onset acting agents, such as methadone, the patient will need careful monitoring for several hours after the start of the infusion to ensure that appropriate levels of reversal are achieved.

Since naloxone reverses the effect of opioids on the gut there may be an increase in absorption of an orally ingested compound which leads to unexpected increases in opioid effects.

4.7.2.3 Flumazenil

Flumazenil is the specific antidote for benzodiazepines and may be given to avoid ventilation in patients with chronic obstructive pulmonary disease. Although flumazenil will reverse the respiratory and CNS depressant actions of a benzodiazepine, caution should be exercised in patients who have coingested a tricyclic antidepressant and in those known to suffer from epilepsy, because seizures and arrhythmias could be precipitated by its use. Flumazenil has a short half-life (about one hour) (Meredith *et al*., 1993). Therefore, patients with severe poisoning in whom it is indicated should be administered flumazenil 0.5 mg intravenously over one minute; flumazenil 1.0 mg should be given if there is no response or only a partial response. Once the patient has been resuscitated fully, an iv infusion ($0.5–1.0\,mg\,h^{-1}$) may be commenced, if necessary, to maintain reversal of the respiratory and CNS depressant actions of the benzodiazepine. Flumazenil is also effective, though less so, in reversing sedation in overdose from the nonbenzodiazepine hypnotics zopiclone, zolpidem and zaleplon.

4.7.3 Methods to Increase Elimination

4.7.3.1 Multiple-Dose Activated Charcoal

Multiple-dose activated charcoal is thought to produce its beneficial effect by interrupting the enteroenteric and, in some cases, the enterohepatic and the enterogastric circulation of drugs. In addition, any unabsorbed drug still present in the gut will be adsorbed onto the activated charcoal, thereby reducing drug absorption. Human volunteer studies have demonstrated that multiple-dose activated charcoal increases the elimination of many drugs, the most important clinically being carbamazepine (Neuvonen and Elonen, 1980), dapsone (Neuvonen *et al*., 1980), phenobarbital (Neuvonen and Elonen, 1980), quinine (Lockey and Bateman, 1989) and theophylline (Berlinger *et al*., 1983; Mahutte *et al*., 1983). Clinical studies have confirmed these volunteer studies and shown that the elimination of carbamazepine (Boldy *et al*., 1987; Montoya-Cabrera *et al*., 1996), dapsone (Neuvonen *et al*., 1980; 1983), phenobarbital (Pond *et al*., 1984; Boldy *et al*., 1986), quinine (Prescott *et al*., 1989) and theophylline (Mahutte *et al*., 1983; True *et al*., 1984; Amitai *et al*., 1986) is enhanced by multiple-dose activated charcoal. Based on these studies, multiple-dose activated charcoal should be considered if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine or theophylline. However, this therapy has not yet been shown in a controlled study in poisoned patients to reduce morbidity and mortality (Vale *et al*., 1999). Further studies are required to establish the role of multiple-dose activated charcoal and the optimal dosage regimen of charcoal to be administered. It is suggested that, after an initial dose of 50–100 g given to an adult, charcoal be administered hourly, every two hours or every four hours at a dose equivalent to $12.5\,g\,h^{-1}$ (Vale *et al*., 1999).

4.7.3.2 Urine Alkalinization

Urine alkalinization is a treatment regimen that increases poison elimination by the administration of iv sodium bicarbonate to produce urine with a $pH \geq 7.5$ (Proudfoot *et al*., 2003; 2004). The administration of 8.4% sodium bicarbonate 225 ml should produce alkalinization; further boluses of sodium bicarbonate will be required to maintain the urine pH greater than 7.5. The term urine alkalinization emphasizes that urine pH manipulation rather than a diuresis is the prime objective of treatment. Administration of bicarbonate to alkalinize the urine may rarely result in alkalaemia (an increase in blood pH or reduction in its hydrogen ion concentration), but there is no evidence to suggest that relatively short-duration alkalaemia (no more than a few hours) poses a risk to life in normal individuals. Hypokalaemia is the most common complication of urine alkalinization but can be corrected by giving potassium supplements. Alkalotic tetany occurs occasionally, but hypocalcaemia is rare.

Urine alkalinization increases the urine elimination of chlorpropamide, 2,4-dichlorophenoxyacetic acid, diflunisal, fluoride, mecoprop, methotrexate, phenobarbital and salicylate (Proudfoot *et al*., 2004). Based on volunteer and clinical studies, urine alkalinization should be considered as first-line treatment for patients with moderately severe salicylate poisoning (Prescott *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat106
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1982) who do not meet the criteria for haemodialysis. Urine alkalinization cannot be recommended as first-line treatment in cases of phenobarbital poisoning, as multiple-dose activated charcoal is superior (Ebid and Abdel-Rahman, 2001). Supportive care, including the infusion of dextrose, is invariably adequate in chlorpropamide poisoning. A substantial diuresis (approximately $600\,ml\,h^{-1}$) is required in addition to urine alkalinization if the chlorophenoxy herbicides, 2,4-dichlorophenoxyacetic acid and mecoprop, are to have their elimination enhanced in a clinically significant way (Prescott *et al*., 1979b).

4.7.3.3 Haemodialysis, Haemodialfiltration and Haemoperfusion

Haemodialysis, haemodialfiltration and haemoperfusion are of little value in patients poisoned with drugs with large volumes of distribution (e.g. tricyclic antidepressants), because the plasma contains only a small proportion of the total amount of drug in the body. These methods to increase poison elimination are indicated in patients with both severe clinical features and high plasma toxin concentrations.

Haemodialysis significantly increases elimination of ethanol, ethylene glycol, isopropanol, lithium, methanol and salicylate, and is the treatment of choice in all cases of severe poisoning with these agents (Vale, 1990). Haemodialfiltration is more widely and readily available and increases elimination of poisons such as ethylene glycol and methanol, though it is less efficient than haemodialysis. Charcoal haemoperfusion can significantly reduce the body burden of phenobarbital, carbamazepine and theophylline, but multiple-dose activated charcoal is as effective and simpler to use.

5 TOXICOVIGILANCE

The concept of toxicovigilance encompasses the active detection, validation and follow-up of clinical adverse events related to toxic exposures in human beings (Descotes and Testud, 2005). WHO has defined toxicovigilance as the 'active process of identifying and evaluating toxic risks in a community in order to reduce or remove them' (IPCS, 1997). Descotes and Testud (2005) have extended this definition and proposed that toxicovigilance 'primarily encompasses the active detection, validation and follow-up of clinical adverse events related to toxic exposures via household, occupational or environmental chemicals and products'. Drug-induced clinical adverse events are dealt with by a related process of pharmacovigilance (postmarketing drug surveillance).

Descotes and Testud (2005) believe that, 'Toxicovigilance is essentially based on the medical assessment of acute or chronic intoxications on an individual basis, which requires validated information that epidemiologists either do not look for or cannot analyse as comprehensively on a large scale'. Toxicovigilance primarily involves the collection of medically validated data from case reports, preferably using a consistent structured format to allow for the aggregation of information for global risk assessment. Thus, toxicovigilance 'generates signals that can be used to elaborate pathogenic hypotheses, and this in turn can serve as an impetus for epidemiological studies' (Descotes and Testud, 2005).

The IPCS has stated that the main goal of toxicovigilance is prevention. 'Toxicovigilance consists of the active observation and evaluation of toxic risks and phenomena in the community—an activity that should result in measures aimed to reduce or remove risks' (IPCS, 1997).

The IPCS believes that the role of poisons information centres in toxicovigilance includes (IPCS, 1997):

1. Identifying serious poisoning risks in the local community, and the substances, circumstances and population groups involved;
2. Identifying changes in the incidence of poisoning, for example, different substances of abuse, application of new pesticides and seasonal variations in the incidence of poisoning, such as carbon monoxide poisoning from heating appliances;
3. Monitoring the toxicity of commercial products, such as household, industrial and agricultural chemicals, as well as pharmaceuticals (by any route of administration), for acute, medium-term and chronic effects, with particular regard to new products and formulations (e.g. overuse of analgesics, occupational exposure to solvents);
4. Monitoring the toxic effects of drug overdosage;
5. Identifying substances that cause significant morbidity and mortality, and specific effects on organs (e.g. high incidence of renal insufficiency, foetal malformations);
6. Reporting to health authorities and other relevant bodies situations that demand preventative corrective action, and, where appropriate, calling an alert;
7. Monitoring the effectiveness of preventative measures.

Similarly, Volans *et al*. (2007) have suggested that, 'In practise, toxicovigilance is achieved through a range of activities, undertaken mainly, although not exclusively, by poisons centres. Clinical adverse events and hazards can be identified by a retrospective analysis of detailed case reports from poison centre databases to identify new patterns in cases of poisoning, or by prospective observation studies designed to answer specific questions, for example, to identify hazards associated with products and their use that can result in recommendations to improve drug safety'.

The most well-developed national poisons surveillance system is that coordinated by the American Association of Poisons Control Centers (AAPCC). It was formerly called the Toxic Exposure Surveillance System (TESS) but is now referred to as the AAPCC National Poison Data System (NPDS). Automated, real-time toxicovigilance of the database was initiated in March 2003 as a surveillance process to identify exposures that may have public health and safety implications (Watson *et al*., 2005). The goal was to provide early identification of new product hazards, water, food or product contamination, chemical/biological terrorism incidents and emerging substances of abuse. Watson *et al*. (2005) have suggested that the methods were designed to detect:

1. Increases in total or human exposure case volume at each poison center;
2. Increases in national reporting of individual toxic (clinical) effects;
3. Cases that meet a surveillance-case definition.

These toxicovigilance tools were applied to incoming data on both real-time and near-real-time (1 to 24 hour interval) basis (Watson *et al*., 2005). The results were reviewed by clinical toxicologists with public health expertise to determine if further investigation or dissemination of findings was necessary. Clinical (toxic) effect data were collected using a list of 131 unique clinical effects, laboratory and diagnostic findings (Watson *et al*., 2005). Medical outcomes were categorized as no effect, minor effect, moderate effect, major effect and death using standardized definitions.

The medical outcomes of TESS/NDPS cases have been used to calculate a hazard factor (serious outcomes per 1000 poison exposure cases) (Watson *et al*., 2005). Hazard factor analysis provides a method for comparisons of the relative toxicity of products. An early use of hazard analysis compared the relative toxicity, defined as the rate of either major outcome or death associated with different poison exposure substance categories in children (Litovitz and Manoguerra, 1992). The hazard factor was calculated as the number of major medical outcomes and deaths per 1000 poison exposures with a documented medical outcome. This analysis showed that the three categories of substances most commonly involved in unintentional paediatric poisoning exposures, cosmetics and personal-care products, cleaning products and plants, had low hazard factors, indicating that the most common exposures were associated with minimal toxicity. Hazard-factor analysis identified a number of less frequently reported poisoning exposures that had more significant toxicity. Exposures with high hazard factors included hydrocarbons and pesticides. It was found that products containing yohimbe or ephedra were more likely to be associated with severe medical outcomes than other botanical products when risk ratios were compared (Watson *et al*., 2005).

The TESS/NDPS database has also been utilized for product safety assessment and to identify changes in substance-reporting patterns (Litovitz, 1998). Data have been used to support regulatory actions such as child-resistant closures on ethanol-containing mouthwashes, topical preparations of dibucaine and lidocaine, and acetonitrile-containing cosmetics. TESS/NDPS data have supported the reclassification of prescription medications to over-the-counter status and the cancellation of the registration of relatively more toxic pesticides, such as mevinphos and arsenical ant baits (Watson *et al*., 2005).

As Descotes and Testud (2005) have concluded, 'So far very few countries have set up structured toxicovigilance systems and it is hoped that in the future, national and international initiatives will help bridge this gap in our knowledge of the toxicity of many chemicals and commercial products to human beings'.

Occupational Toxicology

Chuanfang Jin, Charles M. Werntz, III and Alan M. Ducatman

CONTENTS

1 INTRODUCTION

Occupational diseases are both over- and underdiagnosed. Both problems are important, but underdiagnosis in populations dwarfs the intermittent problem of occasional overdiagnosis in individuals. A Venn-diagram approach to occupational disease includes: (i) a correct clinical diagnosis (specific ICD (International Classification of Diseases) code or else a clear description of the clinical presentation), (ii) an understanding of the patient's exposure history (toxic exposures, including some sense of 'dose') and (iii) an understanding of the actual human toxicology/epidemiology of the exposure(s) in question (evidence-based exposure–outcome assessment). Incomplete understanding of the clinical presentation or failure to understand the exposure explains the large background of missed diagnoses. Fanciful attributions of exposure–outcome relationships explain intermittent overdiagnoses. Following an overview of the occupational history and laboratory testing, this chapter surveys the literature covering a broad range of toxic exposure–outcome information.

2 APPROACH TO A PATIENT WITH A CONCERN

2.1 Definitions

- Symptom—a change reported by the patient (example—pain)
- Sign—a deviation from 'normal' identified by the physician (example—a lump felt during palpation, or reddening of the skin).

2.2 Exposure History

2.2.1 Occupational History

A comprehensive occupational history starts with the first job and runs forward in time, noting approximate employment dates, job title and significant duties. Each job has a 'riskiest part', as well as most common toxic exposures or physical risks. The use and adequacy of personal protective equipment should be noted for jobs which involve toxic exposures.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

A comprehensive occupational history is a substantial effort. A single worker may be exposed to allergens, carcinogens, central or peripheral neurotoxins, and important pulmonary or dermatologic irritants, including chemicals, dusts and biohazards, in a day's work or in a working career. The pace of the modern physician's office visit makes it increasingly hard to do justice to the need for understanding patient exposures. Available office time and inadequate knowledge base are the major obstacles to good exposure histories (Harber, 2001). Sometimes, it is adequate to focus on just the aspect of a current or past job that likely relates to an abnormal pathology. (Example 1: Subacute disease. The auto body painter with asthma works with toluene diisocyanate-based paints. Example 2: Chronic disease. The retired policeman with a malignant mesothelioma helped his father, the stonemason, to mix asbestos and concrete, 60 years ago. Even these obvious, common relationships can take substantial time to elicit.) In the time-constrained environment of modern clinical practice, it is useful to consider when the patient deserves a referral to an occupational physician for purposes of comprehensive history-taking.

Electronic medical records may improve the ability to use standardized forms for exposure history-taking. Examples of job elements in a standard format would include: employer(s) listed sequentially, dates worked, hours, industry type, job duties, known health hazards, presence of protective equipment, and acute injuries/illnesses and chronic diseases attributed to work, for each job. Beyond that is a list of exposure types (e.g. acids, aerosols, biologics, zeolites) and specific toxins (e.g. asbestos, dyes, zinc chloride, smoke). There are excellent resources for finding forms and formats online. The Agency for Toxic Substances and Disease Registry (ATSDR), a part of the US Centers for Disease Control and Prevention, provides one that is attractive and has the advantage of considering home exposures and 'social' exposures, such as second-hand cigarette smoke (Centers for Disease Control, 2008). This resource is linked to a useful case study with teaching points.

While a form can adequately serve screening needs, our information technology is not yet so well developed that a formulaic approach can outperform an expert for diagnostic purposes. There are so many toxins, with so many outcomes that can be caused by toxic exposures, or by other causes. For example, in most specialty clinics, the most common cause of toxic-metabolic peripheral neuropathy referral will be diabetes, not workplace toxins. Cases of lead poisoning or other toxic causes of peripheral neuropathy can be missed easily against this background. The thought process for the occupational and environmental history resembles the thought process for creating a differential diagnosis for chronic infectious disease. What is the differential diagnosis of the symptoms and findings? Where has the patient been and what are the associated exposures? The Venn diagram of the expert thought pattern links exposure history, to clinical expert different differential diagnosis, to the epidemiology of the relationships of exposures and outcomes. Knowledge of all these characteristics is essential.

The three challenges faced by experts are these: (i) the many things we do not know about toxins; (ii) the many powerful, non-evidence-based concepts imposed on the field by (usually) well-meaning but non-evidence-based practitioners and (iii) both the patient's desire to achieve social justice and the clinician's need to perform evidence-based clinical decision-making. Patient concepts of social justice and clinician concepts of evidence are easiest to act upon when they are aligned. When they are not aligned, the clinician is obligated to the evidence. The goal of the occupational and environmental history is to link exposure evidence to clinical findings to literature evidence, or, rarely, but importantly, to propose new disease relationships in a testable fashion.

New disease relationships are rare, yet it is important to be alert that the history can uncover new aetiologic agents. Two disease relationships recently uncovered by astute observers through good history-taking include 'popcorn alveolitis' (a bronchiolitis obliterans caused by diacetyl in butter flavourings) and 'progressive inflammatory neuropathy' among slaughterhouse workers (probably caused by 'something' in aerosolized pig brains). These conditions are among the recent, new aetiologic associations whose existence was detected by astute history-taking.

Table 1 points out some common associations. It is necessarily incomplete by topic, by exposures for each topic and by outcomes for exposures. It merely demonstrates the potential role of biological, as well as chemical, agents in the workplace.

2.3 Examination

2.3.1 Confirming a Condition Suggested by the Exposure or Symptoms

The purpose of most examinations is to look for additional data to aid the physician in reaching a diagnosis. The diagnosis is an essential precursor to the further consideration of causes of disease. The occupational medicine examination is focussed upon signs of the diseases associated with the exposure, while considering the potential for new or unreported diseases, especially with novel exposures. Most physicians are adept at identifying clinical abnormalities; however, determining their environmental cause is often a less familiar activity.

A third type of occupational examination related to toxins determines fitness for specific duties, including respirator users, transporters of hazardous materials, hazardous waste operations workers and emergency

Table 1 Exposure associations

Occupation	Exposure	Outcome
Agriculture, farm, silviculture	Pesticides, dusts, sunlight, vibration	Neurotoxic, respiratory, skin cancer, vascular
Animal handler	Pathogens, anaesthetic gases, allergens	Infections, reproductive effects, allergy
Auto body	Specialty paints and putties, isocyanates	Asthma, hypersensitivity pneumonitis, contact dermatitis
Baker	Flour, dusts	Allergy, asthma
Blaster	Nitrate explosives	Headache, sudden death
Bridge repair	Lead, silica	Neurotoxicity, pneumoconiosis
Custodian	cleaning fluids	Asthma, allergy
Degreaser, drycleaner	Solvents	Contact dermatitis, neurotoxicity, chemical hepatitis
Foundry	Heat, silica, metals	Heat stress, silicosis
Greenhouse	Mold, pesticides	Allergy, neurotoxicity
Insulator, electrician	Asbestos, manmade fibres	Pneumoconiosis, lung cancer, malignant mesothelioma
Miner	Coal dust, silica dust, radiation	Pneumoconiosis, lung cancer
Painter	Solvents, paints, lead	Central and peripheral neuropathy
Oil field or gas field	Hydrogen sulfide	'Knockdown', death
Sand-blaster	Silica	Pneumoconiosis

responders. Entry examinations for job applicants and periodic examinations for persons in these positions are intended to assure that there is not a medical condition present that would compromise critical activities or put the public at risk. In practice, incumbents who have demonstrated their ability to do the job may be less severely scrutinized.

2.3.2 Phases of an Examination

2.3.2.1 Complete History

The medical history for the occupational-exposure patient is not different from the history of other patients. There should be a chief complaint and a history of events of the present illness. Physicians who permit patients to start with exposures make the critical error of accepting a patient perspective of diagnosis and aetiologic relationships; the patient can get that without the visit. A review of systems should have a strong focus on risk factors such as tobacco and alcohol. These data are not intended to be oppositional to a patient-centred perspective; they are evidence-based.

2.3.2.2 General Examination

Vital signs, generally consisting of height, weight, pulse, respirations and blood pressure, are measured. General inspection should include abnormalities in movement, appearance, dress, speech and attention. The physician will typically assess the patient's mental function while taking their history, and may follow up on detected abnormalities during the examination. For example, if the patient provides a clear story and recalls details appropriately, then little additional testing for cognition is usually needed. On the other hand, a patient who cannot relate the story, who cannot recall details, or who reports memory problems should have further testing.

2.3.2.3 Examination of the Ears, Eyes, Nose and Throat

- Goal: ensure normal vision, including visual acuity and visual fields.
- Many chemicals can injure the eyes via desiccation or from changes in pH, especially when mixed with the tears.
- Caustics are well known to opacify the cornea, which can lead to blindness.

2.3.2.4 Inspection, Palpation and Auscultation (Listening with a Stethoscope) of the Neck

Examination of the throat and nares (nose) can reveal irritation, especially following inhalation of water-soluble chemicals or gasses, which form irritating liquids on contact with the mucosal surfaces.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2.3.2.5 *Examination of the Chest: Heart Sounds, Lung Sounds*

Auscultation of (listening to) the heart assists the examiner to identify irregularities in rhythm, abnormal flow through the heart's valves and congenital defects. Auscultation of the lungs can find evidence of lung disease, including asthma and dust-related diseases, as well as other lung diseases. Occasionally, chest-wall percussion will reveal additional information, such as the presence of free fluid within the chest, or fluids/pus within the lung tissues.

2.3.2.6 *Inspection, Auscultation and Palpation of the Abdomen*

Although other abdominal organs are occasionally involved, the liver, with its central role in metabolism, can be affected by many toxins. Enlargement of the liver can be detected by palpation or auscultation to locate the liver edge, and can be confirmed by ultrasound. Other concerns are steatohepatitis due to abnormalities of lipid metabolism, and cirrhosis, which is the replacement of liver tissue with non-functioning scar tissue. Interestingly, this can lead to enlargement of the liver early in the disease, and then shrinking of the liver later in the disease. While hepatitis and cirrhosis are commonly associated with voluntary ingestion of ethanol, liver damage can also follow inhalation exposure to most solvents and many other chemicals.

2.3.2.7 *Neurologic*

The neurologic system consists of the brain, spinal cord and peripheral nerves that go from the spinal cord to innervate the muscles, organs and senses. The peripheral nervous system can be subdivided into the sensory-somatic nervous system, which controls the muscles and reports sensation back to the central nervous system (CNS), and the autonomic nervous system, which oversees most of the internal and basal functions of the body. Additionally, the cranial nerves exit from the brain directly, and primarily innervate the face and head, including the special senses (hearing, vision, taste and smell).

Toxins can affect all portions of the nervous system, but some toxins are specific in their actions. For example, lead prominently causes extensor muscle weakness at the wrists, as well as CNS effects, including cognitive and behavioural problems, especially following childhood exposure. Toxic peripheral neuropathies are more commonly sensory (touch, vibration).

2.3.2.7.1 Distribution of Signs/Symptoms from Neurotoxins

Most systemic toxin-related effects on the nervous system should be symmetric, meaning that they should affect the left and right sides approximately equally. Significant asymmetry should prompt consideration of nontoxic causes. However, neurotoxins often affect nerve axons based upon the length of the nerve, starting at the brain. A condition could therefore affect the feet (longest nerve pathway in the body) before affecting the hands. The common example of this is the peripheral neuropathy of diabetes, which may present with a burning sensation of the feet, then progress to affect areas closer to the brain.

A portion of the examination involves testing the patient's strength, usually by opposing the strength of the examiner. While there is some variation in strength between patients, asymmetry is an abnormal finding, either between sides (right vs. left) or between muscle groups (normal extension, then weak flexion of a muscle group).

2.3.2.7.2 Sensation (via Light Touch or Sharp Stimuli)

The skin contains many nerve endings that report stimuli to the CNS. Loss of this signal can come from impaired nerve transmission, or increase in the 'noise' from the generation of alternate signals, such as pain or 'pins and needles' sensations. Sensory loss can occur in several patterns. A dermatomal pattern follows the nerves from a specific nerve root coming out of the spine (and is usually not caused by toxins); a distal, nondermatomal pattern such as 'stocking' or 'stocking and glove' peripheral neuropathy is a common presentation in toxic exposures.

2.3.2.7.3 Reflexes

A reflex tests a complex set of functions in the nervous system. Starting with the muscle which normally pulls on the tendon relaxed, the tap from the hammer stretches the tendon, sending a signal to the spinal cord which then must be processed by the spinal cord, generating a new signal telling the muscle to contract. This tests that the sensory 'organs' are detecting the stretch, the sensory nerves between the tendon and the spinal cord, the spinal cord signal processing and then the motor nerve conduction from the spinal cord to the muscles that contract. A limited number of reflex circuits that can be tested in this way, including knee, ankle and elbow. Similar 'reflex arcs' can be tested more completely and objectively using an electrical test called an electromyelogram, typically performed by a neurologist or physiatrist.

2.3.2.7.4 Cognitive (Mini Mental-Status Exam)

Cognitive effects are associated with a variety of toxic exposures, including mood, memory (especially with solvent exposure), thought processes, reaction speed, learning and problem-solving.

The mini mental-status exam (MMSE) is a quick office test that seeks relatively profound decrements of orientation, understanding, memory registration, memory recall, calculation or spelling and the ability to follow simple directions. It will miss some subtle deficits. More detailed testing is available in formal neuropsychiatric

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

testing, a test battery of several hours' duration performed by a psychologist.

Comparison of the pattern of a patient's deficits to known patterns from a variety of toxins may enable the examiner to propose a specific cause for impairments.

2.3.2.8 *Focussed Exam of the Body Part of Concern Based Upon Exposures or Symptoms*

Patient complaints about a specific body region or organ system can help the physician to provide a focus for the examination aimed at documenting findings or if there are no findings, to reassure the patient. Additional laboratory testing or imaging of the affected area may also be needed, and the examination helps guide test selection.

2.3.2.9 *Limitations*

An examination can provide only a temporal snapshot of the patient's condition. Today's normal exam inadequately predicts the presence or absence of future disease. The presence of identifiable risk factors is useful for predicting the future, but must not be overestimated. Even marked increase in risk may still describe uncommon events, if the baseline risk was already small. Patients with pleural rubs and radiographic evidence of asbestos have markedly increased risk of asbestos-related disease, yet malignant mesothelioma in any such high-risk patients is still not the most common cause of death. There are only a few exceptions, such as current urinary arsenic predicting future risk of urinary system cancers.

2.4 Laboratory Tests and Other Ancillary Tests in Occupational Medicine Practice

Laboratory tests confirm or rule out evidence of disease not detectable on examination. Tests done in connection with occupational practice are classified into several categories.

2.4.1 Tests to Assess Health Status and Potential Disease Aetiologies

Evaluation of suspected intoxication should routinely include basic laboratory tests, such as complete blood count, basic blood chemistry and urinalysis. Additional tests should depend on clinical presentation or nature of exposure. Common aetiological causes should be ruled out.

2.4.2 Nonspecific Tests of Exposure

Depending on clinical symptoms, tests are generally focussed on the nature of exposure and involved organs or systems. Examples are mean corpuscular volume; mean corpuscular haemoglobin concentration (MCHC) in case of exposure to haemotoxic agents; aspartate aminotransferase (AST-SGOT); alanine aminotransferase (ALT-SGPT) in exposure to liver toxins; erythrocyte protoporphyrin (EP), which can be measured as free erythrocyte protoporphyrin (FEP) or zinc protoporphyrin (ZPP) to help assess time course in suspected lead poisoning. Pulmonary disease might be detected by a reduction in forced expiratory volume 1 second (FEV1) for potential occupational asthma evaluation, sometimes with methacholine challenge test for recurrent asthma, or chest X-ray/computed tomography (CT)/magnetic resonance imaging (MRI) to evaluate pulmonary disorders. Neurologic tests might include electroneurodiagnostic testing for peripheral neuropathy, sensory-evoked potentials and neuropsychologic tests for central neurotoxin exposures and neuropsychologic testing for CNS damage. It should be emphasized that these tests are nonspecific for a particular exposure. An abnormal test indicates anatomical or physiologic alteration with a variety of causes, including occupational exposures.

2.4.3 Tests of Direct Biologic Indicators for a Specific Exposure

Exposure to some workplace chemical agents can be assessed through biologic testing of the exposed chemical compound or its metabolites. The chemical substance itself or a metabolite may be measured in end-exhaled air, blood or urine to detect and monitor the chemicals present in the body. Hair and nails may be useful for past exposures; these require very specific laboratory expertise. The result often represents the internal or biologic index of an exposure, referred to by many authors as internal exposure markers. For example, blood lead is elevated immediately following lead exposure, and gradually resolving evidence of elevated blood lead level can be found for many red-cell half-lives following exposure. Exposure to toluene may be detected by analysis of hippuric acid in urine, and exposure to trichloroethylene (TCE) may be ascertained by urine trichloroacetic acid or by breath analysis of the chemical compound. In contrast to lead, direct tests for solvent and pesticide exposures are valuable only for hours or days after exposure. However, abnormal tests for acetylcholinesterase inhibition following exposure to certain organophosphate pesticides may persist for a red-cell half-life (weeks or months). **Table 2** lists common tests for chemical exposures.

Table 2 Tests for specific chemical exposures

Exposed chemicals	Test of chemicals or metabolites	Medium of testing samples	Comments
Solvents			
Styrene	Mandelic acid	Urine	Represent current exposure
Toluene	Hippuric acid	Urine	Represent current exposure
Xylene	Methylhippuric acid	Urine	Represent current exposure
Trichloroethylene	Trichloroethanol and trichloroacetic acid	Urine	Represent current exposure
1,1,1-Trichloroethane	Trichoroethanol and trichloroacetic acid	Urine	Represent current exposure
Perchloroethylene	Trichloroacetic acid	Urine	Represent current exposure
n-Hexane	2,5-Hexanedione	Urine	Represent current exposure
Benzene	Phenol	Urine	Represent current exposure
Metals			
Lead	Lead	Blood	Current exposure (screen)
	Lead	Urine	
	Zinc protoporphyrin (ZPP)	Blood	Measure body burden after EDTA (ethylenediaminete-traacetic acid) injection Elevated on lead poisoning and stayed high after cessation of exposure
Mercury (inorganic)	Mercury	Blood	Recent exposure
	Mercury	Urine	Biological monitoring
Beryllium	Lymphocyte (BeLPT (beryllium lymphocyte proliferation test))	Blood	Beryllium sensitization
	Lymphocyte (BAL (bronchoalveolar) BeLPT)	Bronchoalveolar lavage	Beryllium lung sensitization
Platinum	Pt salt (Prick test)	Skin	Pt allergic hypersensitivity
	Pt	Blood (plasma)	Monitoring treatment
Arsenic (inorganic)	Total arsenic	Urine	Affected by seafood ingestion
	Methylated derivatives	Urine	Correlate with airborne exposure
	Arsenic	Blood	Poor correlation with arsenic exposure
Cadmium	Cadmium	Blood	May reflect cadmium level in the entire body
	Cadmium	Urine	Exam kidney toxicity
	Retinol-binding proteins	Urine	Assess kidney toxicity
	β-2-microglobulin	Urine	
Gas			
Carbon monoxide	Carboxyhaemoglobin	Blood	Exposure
Chromium	Chromium (trivalent)	Urine	Biologic monitoring
	Chromium (hexavalent)	Erythrocytes	Determine body burden
Others			
Organophosphates	Cholinesterase	Plasma	Diagnosis of phosdrin poisoning
	Cholinesterase	Erythrocytes	Dx[a] of phosmet toxicity
	Cholinesterase	Plasma	Dx[a] of chlorpyrifos toxicity
	Cholinesterase	Erythrocytes	Dx[a] of dimethoate toxicity

[a]Dx: diagnosis.

2.4.4 Tests of Genetic or Acquired Susceptibility

An increasing number of tests have been developed to establish susceptibility to a condition that may be predisposed, precipitated or aggravated by occupational exposure. For example, hereditary serum α1-antitrypsin deficiency is found to be associated with chronic obstructive pulmonary disease; glucose-6-phosphate dehydrogenase deficiency with hypersusceptibility to haemolytic agents; diaphorase deficiency with susceptibility to nitrite exposure and HLA-DPB1Glu69 is associated with beryllium sensitization, as well as development of chronic beryllium disease (McCanlies *et al*., 2004). The correct interpretation of test results requires a thorough understanding of the properties of the test. Use of the tests requires expertise in legal requirements and ethical standards in the practice setting.

Every test has a detection limit. The accuracy of a test declines as the measured value approaches the detection limit. Laboratories can report abnormal cut-offs unconventionally, including the lowest level of detection above the abnormal limit. Laboratories which report abnormals near, at, or below their detection limits are problematic.

Many occupational exposures involve essential trace elements. These substances are normally present in the body, and homeostatic mechanisms exist to regulate concentrations within a narrow range. Except in the setting of overt toxicity, measurements of elements such as zinc, copper, manganese and aluminium are of limited value in the diagnosis of occupational exposure for individual patients. (There may be population uses, a completely different topic.) In addition, many laboratories are willing to report on substances that they are ill-prepared to measure.

Many nonoccupational sources can lead to abnormal test readings of unclear significance. For example, smoking causes an increased level of cadmium, consumption of shellfish (and some shellfish-derived supplements) increases the arsenic level and some beauty products contain mercury. Some nonoccupational diseases may also affect certain test results; iron deficiency and haemoglobinopathy affect ZPP levels used to test for persistence of lead poisoning, and several heritable or disease conditions affect plasma and red-cell cholinesterase concentrations used to test for cholinesterase-inhibiting pesticide exposure.

Most tests indicate only the absorption of the substance into the body and/or its metabolism. Due to the variability of individual response, tests results do not necessarily indicate intoxication. It is important to be aware of the half-life of exposed substances, as well as natural processes that may create an appearance of exposure. Detection of chemical compounds with a short half-life suggests recent exposure, as in solvent exposure. A negative test result may be false if the sample is collected too long after exposure cessation. On the other hand, very small amounts of detected solvents may be from normal metabolic processes in the absence of exposure. The timing of sample collection for substances with a long half-life is not as critical as that of chemicals with a short half-life. Depending on toxicokinetic characteristics of exposed substances, absorption, distribution, biotransformation and elimination, these chemicals can be detected in different biological media. The half-life varies by biological medium; mercury, for example, has a 60-day half-life in urine, but approximately three days in whole blood. Marked interspecies variations in half-lives may limit the ability to generalize human outcomes from animal toxicity data.

The key to the diagnosis of occupational toxicity or toxic exposures is history. Laboratory tests and/or other tests are useful under some circumstances to confirm or exclude common nonoccupational aetiologies. Laboratory testing results should be carefully interpreted within the context of the clinical findings, including history and physical examination. Diagnoses should not be based on test results alone. When patients demand biomonitoring tests after implausibly long time periods, it is better to explain why the test is inappropriate than to try to deal with the strong likelihood of inappropriate results. Very few biosurveillance tests work well for patients outside of a workplace population context. The notable exception is blood lead, especially for children living in older homes in societies that permitted the past use of lead paints. **Table 2** lists tests for specific chemical exposures.

2.5 Common Agents by Disease or Affected Organ

2.5.1 Cancer

Cancer is a feared diagnosis, associated with a number of occupational exposures. In this section we will provide a general overview of the common toxin-associated cancers, however it is important to understand that there are many others. Excellent sources to look into these associations include the International Agency for Research on Cancer (IARC), The US Environmental Protection Agency (EPA) and the ATSDR, a part of the US Centers for Disease Control and Prevention. These agencies regularly assess the literature supporting the carcinogenic effects of various chemicals, and offer opinions both to the carcinogenic nature of the exposure, as well as the cancers that they feel support their opinion about carcinogenicity. The three sources occasionally differ in their opinions.

For any carcinogen, there may be some threshold before the exposure becomes carcinogenic. However, it is technically difficult or impossible to identify a specific level that will not lead to developing cancer.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2.5.1.1 *Occupational Cancer*

Occupational cancer has been recognized since the eighteenth century, starting with scrotal cancer in chimney sweeps. The cause is now known to be hydrocarbons, and there are more modern jobs with similar skin cancer issues. Because of long latencies in the development of cancer, it is rare for poison centres to field calls or to feature expertise in occupational cancer. This topic is the province of the occupational physician, or less commonly, the pulmonologist, urologist or other organ-system specialist.

Table 3 links work populations with aetiologic agents and organ-system outcomes. It is intended to be illustrative, not exhaustive.

2.5.1.1.1 Lung Cancer

Lung cancer has been associated with a number of exposures, including cigarette smoke, arsenic, cadmium, silica, asbestos, radon and other uranium daughters and many more. Most of these are IARC Category I carcinogens.

Lung cancer challenges clinicians with variable treatment options, depending on the stage of disease at diagnosis. Historically, screening using chest X-ray and sputum samples has not been successful. Recent proposals to screen for lung cancer using single-breath-hold low-dose CT scans of the chest hold future promise for identifying early lung cancers (Bach *et al*., 2007). There are high costs, and yet there is still no clear survival benefit from early detection. There may be risks from the radiation needed to do the screening. At the time of writing, screening for lung cancer is not yet a recommended standard of care, not even in high-risk patients.

2.5.1.1.2 Scrotal Cancer

Scrotal cancer was identified as a hazard in chimney sweeps by Sir Percival Potts, centuries ago. This specific exposure–disease relationship is not known to occur in modern times. Requiring coke-oven workers to shower at the end of each work day has eradicated similar outcomes. The irritant properties of soot, and their carcinogenic potential, are clear.

2.5.1.1.3 Liver Cancer

There are several types of liver cancer. Angiosarcoma of the liver is associated with vinyl chloride exposure. A variety of exposures, including arsenic, are associated with hepatocellular carcinoma. Liver cancers are often asymptomatic until the patient is quite sick. While partial hepatectomy is usually survivable, many liver cancers will have spread to the point that surgical treatment is not practical when they are discovered.

2.5.1.1.4 Colon Cancer

Colon and rectal cancer are common. It is estimated that in 2008 in the US there will be 108 070 cases of colon cancer and 40 740 cases of rectal cancer diagnosed, with approximately 49 960 deaths (National Cancer Institute, 2008). Colon cancer has been associated with diet and inactivity. Some studies have associated colon cancer with chemical exposures, but these effects are often small and most of the associations are inconsistent.

2.5.1.1.5 Brain Cancer

Primary brain cancers are fairly uncommon, (as opposed to cancers from other organs that spread to the brain). There is mixed evidence for the association between brain cancers and exposures. Several associations have been proposed, including mixtures such as petrochemical exposure (Liu *et al*., 2008), but none are strongly supported. The population study of environmental mixtures as possible causes of death is important, difficult to perform or replicate, and expensive.

2.5.1.1.6 Prostate Cancer

Prostate cancer is the most common cancer in men. Many cases are indolent, some are invasive. While most prostate cancers remain confined to the prostate, the lifetime risk of developing invasive prostate cancer has increased from 7.3 to 19.6% for whites and from 8.5 to 18.6% for blacks (Merrill *et al*., 1997). A number of jobs have been associated with small increased risk of prostate cancer, but in the face of the large background rate of development of this common cancer, it is unknown whether small differences in the rate of prostate cancer are due to an exposure. The most suspect occupation is farming, and the specific concern is pesticide use, yet aetiologic causation is not established for any occupation.

2.5.1.1.7 Malignant Mesothelioma

Malignant mesothelioma is a cancer of the lining around the lungs and abdomen. It is histologically distinct from lung cancer, rarer and even more lethal. Mesothelioma was identified as an occupational disease in an asbestos-exposed cohort in the 1950s. Since that time, the connection has been repeated in many other settings. Mesothelioma, like many other cancers, develops following a period of latency, often 40 years from initial exposure. Unfortunately, mesothelioma may occur following fairly short (and often intense) asbestos exposures. It remains very difficult to treat this disease, with poor prognosis and short survivals.

2.5.1.1.8 Skin Cancer

Skin cancers have been associated with arsenic, including squamous cell (ATSDR, 2008), basal cell (ATSDR, 2008) and melanoma (Beane Freeman, 2004) types of skin cancers. For all skin cancers, early diagnosis is important, and greatly reduces the risk of spread. Some jobs may be associated with repeated episodes of sunburn, which increases the risk of skin cancer. Jobs which permit year-round tan may be less hazardous.

Table 3 Aetiologic agents and organ-system outcomes

	Agent (where known)
Bladder cancer	
Dye workers	Arylamine
Chemical workers	β-naphthylamine
Aluminium smelters	Benzedine
	4,4′-Methylenedianiline (MDA)
	o-Toluidine
	4,4′-Methylene-bis-(2-chloraniline)
	Other aniline dyes
	3,3′-Dichlorobenzedine
	Other polyaromatic hydrocarbons
Hospitality and other	Secondhand cigarette smoke
Rubber workers	4-Aminodiphenyl
Environmental drinking water	Arsenic
Aluminium workers	Hydrocarbons
Machinists, mechanics	Hydrocarbons
Hairdressers	Hydrocarbons
Kidney Cancer	
Potroom workers, solvent exposure	Tetrachloroethylene (perc)
	trichloroethylene
Hospitality industry	Sidestream smoke
Liver Cancer	
Exposure to poor-quality foods	Aflatoxin
Exposure to animal products	Hepatitis B
	Hepatitis C
Body builders	Anabolic steroids
Plastics chemicals	Vinyl chloride (angiosarcoma)
Exposure to thorotrast (historic)	Thorium dioxide
Laryngeal Cancer	
Insulators, electricians	Asbestos
Lung Cancer	
Insulators, electricians, miners	Asbestos, and asbestos-like fibres, including some manmade fibres
Miners, sandblasters	Silica
Uranium miners, or those living in affected homes	Radon
Pleural and other mesothelial cancer (malignant mesothelioma)	
Insulators, miners, others	Asbestos
Nasal Cancer	
Forestry, wood products, textiles, nickel refining	Wood dusts, organic dusts, nickel
Skin Cancer	
Wood preservative, other	Coal tar
	Anthracene
	Coal tar and pitch
	Dibenzanthracene
	Methylcholanthracene
Chimney sweeps	Soots
Contaminated water	Arsenic
Mule spinners, oil field workers	Shale oils, crude oils, paraffins
Machinists	Mineral oils, machine oils
Fishermen, other sun-exposed	Ultraviolet light

2.5.2 Haematopoietic Disease

Lead affects haemoglobin synthesis. The route of exposure is generally inhalation for adults, and both inhalation and ingestion for children. Children do not need to exhibit pica in order to ingest lead. When they crawl or toddle in a contaminated area, they breathe lead and they get dust on fingers, and then put fingers into mouths. Lead inhibits several enzymes along the pathway to haemoglobin synthesis. It also inhibits the synthesis of pyrimidine 5′-nucleotidase, which promotes the catabolic reuptake of RNA precursors in the immature red cell. This inhibition, combined with impairment of haeme synthesis, explains the 'basophilic stippling' seen in Wright stains of blood smears, once lead poisoning is moderately advanced. In vulnerable populations, that is, exposed children and workers, it is essential to provide surveillance in order to detect lead poisoning before it gets to this point, as multiple organ systems are affected before the classic changes of anaemia occur.

Benzene, present in gasoline and numerous other organic products, is a potent haematologic poison with demonstrable physiologic effects following respiratory exposure, even at currently permissible occupational standards. It causes epoxidization, leading to defective DNA. Exposure leads to acute bone-marrow depression, and may result in acute and chronic myelogenous leukaemia, myelodysplastic syndromes and several haematolymphopoietic cancers.

Arsine (AsH_3) is used in specialty microelectronic applications and may be generated as an undesirable by-product of soldering or galvanizing operations, or as an undesirable gas in mining. Arsine exposure induces red blood cell haemolysis. Treatment includes emergency exchange transfusions and urine alkalization to protect the kidneys from haemoglobin precipitation.

Naphthalene, an active ingredient of mothballs, causes haemolysis, which is seen most often in patients with G6PD deficiency. (Patients of African, Mediterranean and Pacific-rim ancestry are most at risk of G6PD deficiency or carrier status.) Naphthalene also causes methaemoglobinaemia (described in greater detail below). Trimellitic anhydride, a strong pulmonary irritant and allergen that is one of a variety of anhydrides used to cure resins, can cause an antibody-mediated haemolytic anaemia (associated with fever and dyspnoea). Usually, recognition and cessation of exposure is adequate to treat the condition.

Table 4 lists several toxins that can interfere with oxygen delivery into the red blood cell, or within the red blood cell, or from the red cell to tissues. (Carbon monoxide (CO) is an example of a multilevel toxin.) Of the topics addressed in the table, methaemoglobinaemia causes cyanosis and is often asymptomatic until levels are quite high. Sulfhaemoglobinaemia is uncommon in occupational settings (hydrogen sulfide usually causes other problems first). Carboxyhaemoglobinaemia is well known, as is the toxicity of cyanide; both are covered elsewhere in this text.

2.5.3 Liver Disease

Solvents have been the historic cause of occupational liver disease. Much of the evolution of industrial solvent use has been an effort to replace hepatotoxic solvents, such as carbon tetrachloride, perchloroethylene, TCE and chloroform, with lower-toxicity solvents. Nevertheless, small studies of general exposure to solvents and solvent mixtures show positive correlations of total and recent solvent exposures, serum aminotransferases and cholesterol. Of potentially great significance, the positive correlation also exists with serum glucose (Kaukiainen *et al*., 2004). In addition, liver anatomic changes can occur following solvent exposure, before there are detectable changes in 'liver enzymes' such as alanine aminotransferase (ALT) and aspartate aminotransferase (AST) (Brodkin *et al*., 1995).

Less commonly, settings other than solvent exposure have been associated with liver damage. Vinyl chloride, the monomer used to produce polyvinyl chloride, causes both hepatic fibrosis (Hsiao *et al*., 2004) and angiosarcoma of the liver. **Table 5** notes work settings and classes of chemicals known to be associated with hepatotoxicity. This list is meant to be instructive, not all-inclusive. Many agents can cause different types of hepatopathology at different doses, and infectious hepatitis may be associated with some occupations. It is certainly associated with the sex trade internationally.

2.5.4 Neurologic Disease

Many substances in the environment and workplace are capable of damaging the human central nervous system; a smaller number are known to damage the peripheral nervous system. Chemicals that cause peripheral damage are known to cause central damage.

Occupational toxin-induced neurologic diseases arise from exposure to metals, solvents and pesticides. A single toxin can produce a number of nonspecific syndromes and the resulting dysfunction is rarely specific to or pathognomonic of the exposure. Hence, the aetiologic diagnosis is easily overlooked, unless the clinician vigilantly pursues the role of workplace factors.

Toxic neurologic disease can be classified based on affected anatomic sites or toxic mechanisms. **Table 6** lists a classification of occupational toxic neurologic disorders.

2.5.4.1 Central Nervous System

2.5.4.1.1 Toxic Encephalopathy

2.5.4.1.2 Acute

Many toxic exposures may lead to acute or subacute onset of an altered state of consciousness, often appearing as vague malaise and eventually as a

Table 4 Agents that interfere with red blood cell oxygen delivery

Outcome and Agent	Mechanism	Clinical
Methaemoglobinaemia[a] Aniline (percutaneous) Nitrates (including explosives) Naphthalene Dyes	Haemoglobin is oxidised by the nitrate (Fe^{++} to Fe^{+++})	Cyanosis, often asymptomatic
Sulfhaemoglobinaemia Hydrogen sulfide Pharmaceuticals	Sulphur in porphyrin ring reduces oxygen affinity	Cyanosis, often asymptomatic Loss of consciousness
Carboxyhaemoglobinaemia Carbon monoxide	Carbon monoxide binds to haemoglobin more avidly than does oxygen. 'Shifts' dissociation curves and starves tissues of oxygen.	Headache, nausea, palpitation, normal oxygen levels can be deceptive until breathing is depressed
Disrupt cellular respiration Cyanide	Disrupts electron transport	Rapid progression to death

[a]: the group of chemicals that oxidizes the iron atoms in haemoglobin from ferrous iron (Fe^{++}) to ferric iron (Fe^{+++}), rendering it unable to carry oxygen and causing metheamoglobinemia. It can lead to hypoxemia in organ tissue.

Table 5 Chemicals associated with hepatotoxicity

Chemical or class	Job type example	Outcome
Carbon disulfide	Rayon manufacture	Elevated lipids
Chlorofluorocarbons	Solvent, refrigerant	Hepatitis
Dimethyl acetamide	Industrial waste worker	Hepatitis
Hexachloroethane	Military, smoke bomb	Hepatitis
Nonhalogenated solvents; dimethyl formamide; naphthalenes	Skin exposure	Elevated enzymes, hepatitis
	Halowaxes (historic)	Cirrhosis
Paraquat	Agricultural field workers	Necrosis
Phosphorus	Matches (historic)	Osteopathy
Products of combustion	Coke oven	Elevated enzymes
Solvents (especially halogenated)	Spray paint, dry cleaning	Range: elevated enzymes to fatty liver to fulminant hepatitis
Trinitrotoluene (TNT)	Explosives	Subacute necrosis
Trivalent arsenic	Vintners	Cirrhosis
Vinyl chloride	PVC (polyvinyl chloride) manufacture	Fibrosis

confusional state. Symptoms may range from headaches, irritability, nausea, and incoordination upon mild exposure, to seizures, coma and death, with severe poisonings. Diffuse injury may affect not only the cerebral cortex (cognitive function) but also the cerebellar cortex (coordination). While symptoms are generally nonspecific, certain toxins affect specific areas of the brain. CO, manganese and carbon disulfide can generally damage the basal ganglion (Chuang *et al*., 2007; Huang *et al*., 1996; Brunssen *et al*., 2003; Prabhakaran *et al*., 2008), whereas organic mercury damages the cerebellum and occipital cortex (Chang, 1990). CO can cause diffuse frontal-lobe damage in addition to its effect on basal ganglia. Other agents, such as lead or organotins (Chang, 1990), may cause increased intracranial pressure with headaches, nausea, vomiting, seizures and papilloedema.

Table 6 Classification of occupational toxic neurologic disorders

By affected anatomic site	By toxic mechanism
Central Nervous system	Axonopathy
Toxic encephalopathy	Myelinopathy
• Acute	Neurotransmission-associate neuropathy
• Chronic	
Movement disorders	
Peripheral Nervous system	
Toxic polyneuropathy	
Neuromuscular junction blockade	

2.5.4.1.3 Chronic

Chronic encephalopathy can take many forms. Typically, mood, memory and psychomotor function deteriorate slowly, and cognitive dysfunction becomes evident, eventually resulting in dementia.

Organic solvents commonly cause chronic encephalopathy, also known as solvent syndrome or painter's syndrome (initially reported among painters in Scandinavian literature during the 1970s). The condition comprises a constellation of CNS abnormalities, including loss of short-term memory, diminished ability to concentrate or problem-solve, change in personality, headaches, fatigue and decreased performance on neuropsychological tests.

Since the symptoms of organic solvent syndrome are nonspecific, the diagnosis depends on an accurate history of repeated exposures over the years, usually punctuated by episodes of acute intoxication characterized by transient light-headedness, headaches, a sensation of drunkenness and exclusion of other toxic-metabolic aetiologies. Standardization of a diagnostic approach to the solvent syndrome has been attempted by the World Health Organization (WHO) and summarized by Rosenberg (1995), as follows:

- Type I: symptoms only. Complaints of nonspecific symptoms; considered reversible if exposure is discontinued.
- Type 2A: Sustained personality or mood change. Complaints of nonspecific symptoms, which are not reversible.
- Type 2B: Partially irreversible impairment in intellectual function. Symptoms are accompanied by objective evidence of impairment on neuropsychological tests.
- Type 3: Dementia. Global deterioration in intellectual function; neurologic signs evident; poorly reversible, if at all. This is generally nonprogressive once exposure has ceased. However, there is emerging evidence that populations with 'mild cognitive dysfunctions' are more likely to be diagnosed with Alzheimer's disease at a later time.

Heavy metals, such as lead and mercury, may cause CNS disturbance. Relatively nonspecific clinical features, including irritability, difficulty concentrating, insomnia, inappropriate excitement, hallucinations and confusion, characterize initial presentations, depending upon the extent of poisoning. In addition, mercury poisoning (erethism) characteristically manifests as extreme timidity, shyness, embarrassment and discouragement. Other manifestations of mercury intoxication include ataxic intention tremor (also known as the 'Danbury shakes'), suggestive of a toxic mechanism beyond the cerebrum.

2.5.4.1.4 Movement Disorders

The term 'movement disorders' refers to motor dysfunction related not to weakness but to abnormalities of muscle tone, voluntary movement and posture. Movement disorders encompass involuntary movements, including tremors, dystonia, chorea, athetosis, dyskinesia, myoclonus and ballismus. The most common syndrome is parkinsonism.

Parkinson's disease, manifested with tremor, bradykinesia and rigidity caused by injury to the basal ganglia, occurs commonly in the elderly population and also, rarely, in younger patients. Occupational exposures to manganese, CO and methyl phenyl tetrahydropyridine (MPTP, a 'designer drug' contaminant not used by industry) produce syndromes that may resemble idiopathic parkinsonism, although specific differences in presentation and in anatomic variations have been described for each (Kurz *et al*., 2007). These exposures, as well as the potential role of any new or unusual compound, should be considered when evaluating patients with new-onset symptoms, especially if the patients are relatively young. At low exposure levels, manganese creates a less specific, but increasingly well-studied constellation of neuropsychologic problems, including population decrements in hand–eye coordination, hand–face arm movement, visual reaction time and tremor (Integrated Risk Information System, 2008).

2.5.4.2 Cranial Neuropathy

The cranial nerves are rarely the target of neurotoxic assault. The best-known toxic syndrome of the cranial nerves is trigeminal neuropathy related to exposure to TCE (Annau, 1981), which was once used as an anaesthetic agent. Trigeminal neuropathy is rare with current industrial practice. TCE-related trigeminal neuropathy may be caused in whole or in part by the decomposition product dichloroacethylene (Annau, 1981) since pathologic studies do not reveal such

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

neuropathologic conditions after exposure to TCE alone.

2.5.4.3 Peripheral Neuropathy

Many toxins are capable of producing peripheral neuropathy. Most are primarily toxic to the axon, and the myelin sheath is affected secondarily. Presentation varies, depending on the agent and the degree of exposure. Acute polyneuropathy is rare, although it can occur with exposure to hexacarbons (such as *n*-hexane and methyl *n*-butyl ketone (MnBK)), which can be confused with acute polyradiculitis or Guillain–Barré syndrome. Repeated lower-level exposures cause polyneuropathy with mild symptoms, sometimes with only electrophysiologic abnormalities accompanied by minimal or no symptoms. Depending on whether or not the agent can cross the blood–brain barrier, the peripheral nervous system may be involved alone, or in concert with the central nervous system. **Table 7** lists toxic chemical compounds associated with peripheral neuropathies.

Table 7 Toxic chemical compounds associated with peripheral neuropathies

Chemical compounds	Clinical characteristics
Metals	
Lead	Motor deficit predominant; often asymmetric
Arsenic	Sensory, symmetric, often painful
Mercury	Often mixed neural deficits, symmetric
Thallium	Often mixed neural deficits, symmetric
Solvents	
Hexacarbons, including *n*-hexane, methyl *n*-butyl ketone (MnBK)	Often mixed neural deficits, symmetric
Trichloroethylene	Sensory deficit, featuring with trigeminal neuropathy
Carbon disulfide	Mixed neural deficits, symmetric
Styrene	Mixed neural deficits, symmetric
Gas	
Carbon monoxide	Mixed neurological deficits, may be asymmetric
Ethylene oxide	Mixed neurologic deficits, symmetric
Plastics	
Acrylamide	Mixed neurological deficits, symmetric
Pesticides	
Chlordecane	Mixed neural deficits, symmetric
Organophosphates	Delayed mixed neural deficits, symmetric

Typically, the onset of symptoms is insidious, with numbness and paresthesias of feet and hands, with progression to distal weakness. Most toxic-induced peripheral neuropathies are symmetric with distal nerve involvement. Clinical features usually present with sensory loss early on, and motor and sensory deficits as the neuropathy progresses. Sensitivity to light touch, pinprick and temperature are reduced in a stocking-and-glove distribution. Vibration and position sense are usually reduced in the distal legs prior to involvement of the arms. Cranial nerve function is usually preserved, and CNS function may or may not be clinically apparent depending on the nature of the toxic agents. Motor involvement typically shows decreased muscle tone and weakness, usually symmetric and more commonly seen in the lower extremities, such as toe extensors (extensor digitorum brevis), and foot dorsiflexors (anterior tibialis); the extensor muscles in the hands (hypothenar or dorsal interossei) (Rosenberg, 1995) may also be involved. Reflexes may be reduced or absent. Gait can be affected, likely related to neurosensory impairment, but ataxia is usually absent. Rapid alternating movement is generally intact. Clinically, large-fibre neuropathies can be distinguished from small-fibre neuropathies during neurologic testing; large fibres carry sensation for vibration and proprioception, while small fibres carry sensation for pain and temperature. Sensation for light touch is carried by both large and small nerve fibres.

Small-fibre involvement presents with painful polyneuropathy and can be associated with autonomic neuropathy. The most common example is alcoholic neuropathy (Koike and Sobue, 2006).

Although peripheral neuropathy has multiple aetiologies, the nerve has a limited number of ways to respond to injury. The damage can occur at the level of the axon (i.e. axonopathy). A disruption of the axons (e.g. trauma) results in degeneration of the axon and the myelin sheath distal to the site of the injury (i.e. Wallerian degeneration). In most toxic injuries, the most distal portion of the axons degenerates, with concomitant breakdown of the myelin sheath (known as 'dying-back', or length-dependent, neuropathy) (Edwards *et al*., 1991).

Neuronopathies occur at the level of the motor neuron or dorsal root ganglion, with subsequent degeneration of their peripheral and central processes. Because the injury is at the level of the cell body, recovery is often incomplete.

Myelinopathies occur at the level of the myelin sheath, and can be inflammatory or hereditary. In acquired demyelinating neuropathies, the injury is often patchy or segmental. Because the axons are relatively less damaged,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

recovery is often rapid (weeks to months) and complete. Hereditary abnormalities of myelin are usually diffuse, with a slowly progressive course.

Aetiologies for peripheral neuropathy are numerous; occupational toxic exposures occupy in only a small piece of a larger puzzle. Other causes of peripheral neuropathy should be ruled out, including, but not limited to, diabetes mellitus; alcohol abuse; medications in common use, such as vincristine (Citak *et al*., 2008), cisplatin (Krarup-Hansen *et al*., 2007), and podophyllin (O'Mahony *et al*., 1990), including over-the-counter agents and 'herbal remedies'; nutritional deficiency and collagen vascular diseases. Although it is important to consider other aetiologies, the presence of common risk factors such as diabetes mellitus and alcohol abuse does not exclude a sole or contributing role of workplace neurotoxins. Judgement about attribution is ultimately based on the assessment of the exposure (nature, intensity, duration), the likelihood of contribution by nonoccupational factors (for example, the nature of the presentation and the extent of alcohol use), and the nature of the process (a predominant motor neuropathy with associated new-onset joint pain in a diabetic with documented lead exposure in the workplace is likely caused by the lead). In some instances, both occupational and nonoccupational factors may be considered significant in an already susceptible patient.

2.5.4.4 Neuromuscular Junction Blockade

Certain toxins, such as pesticides or additives in plastics and petroleum products, cause blockage of the neuromuscular junction. Organophosphate pesticides inhibit acetylcholinesterase and create a cholinergic excess, preventing normal function of the neuromuscular junction. Weakness and fasciculations occur. The central and autonomic nervous systems are involved, so other manifestations include miosis, blurred vision, abdominal cramps, nausea, sweating, salivation, and confusion.

2.5.5 Respiratory

Warning properties are sensory effects of exposure; they are often unpleasant. Some chemicals, such as acid gasses, will cause burning and choking, which are very strong warning properties. These tend to be corrosives with dramatic effects. If a person is exposed to a chemical with strong warning properties, they will normally try to escape. Other chemicals, such as CO, asbestos, hydrogen cyanide and nitrogen, have essentially no odour or warning properties. These chemicals are equally dangerous, and there is even less tolerance for industrial error because there may be no human perception of exposure before harm is done.

2.5.5.1 Pneumoconiosis

Pneumoconiosis (literally 'rock lung') follows from accumulation in the lungs of one or more substances that cannot easily be removed by the immune system, either because the material cannot be dissolved by macrophages (the scavenger cells in the lungs), or the extent of the exposure is to more material than can be efficiently removed. The lung reacts with an inflammatory response, leading to fibrosis. The common pneumoconioses are asbestosis, coal worker's pneumoconiosis ('black lung') and silicosis.

The presence of pneumoconiosis can best be identified through radiographs (X-rays or high-resolution CT scans) of the lungs, whereas the extent of damage is assessed by radiographs and pulmonary function tests together. The current International Labour Organization (ILO) system for interpreting chest radiographs for the pneumoconioses is based upon the interpretation of plain posterior to anterior (PA) chest X-rays. Systems are currently being developed to provide ILO classification for digital chest X-rays and CT scans of the chest.

Unfortunately, once pneumoconiosis starts to develop, treatment is limited to preventing infections (pneumonia and flu vaccines) and controlling symptoms (for example, by providing supplemental oxygen). The disease process is not reversible; however, the rate of progression can be affected by removing the worker from further exposure. This opportunity for secondary prevention (removing a worker from exposure after they have started developing a disease, before symptoms develop) is the basis of programmes that monitor for disease development in exposed workers. The 'gold standard' of prevention programmes is to prevent disease in the first place. This goal is variably achieved.

2.5.5.2 Coal Dust (Black Lung)

Coal dust exposures include mining, both above and below ground, coal transport and coal processing. Exposure is characteristically intense at the 'face', where the coal is being cut from the earth, and is greater for underground miners. In the United States, national health surveillance programmes have found that the rate of miners with 'rapid progression', that is, >2 subcategory progression within five years, seems to be geographically based, with a 'hot spot' in central Appalachia (Antao *et al*., 2005). The current theory is that both total dust exposure and coal 'rank' (related to purity and BTUs (British thermal units)) play a role.

2.5.5.3 Asbestos (Asbestosis)

Asbestos fibres move into the distal lungs following exposure. The 'aspect ratio' of the asbestos fibres may contribute to the risk of disease development. A longer, skinny fibre may penetrate the lung tissues more deeply and may thus cause more disease than a shorter, fatter fibre. Asbestosis involves fibrosis of the lower lung parenchyma and the lung pleura. Asbestos also causes lung cancer and malignant mesothelioma. The risk of lung cancer is potentiated by concomitant cigarette smoking. Different types of asbestos fibres have

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

varying capability to precipitate malignant mesothelioma. However, the concept that there is a relatively safe asbestos is a commercial concept and not well related to epidemiologic findings.

2.5.5.4 Silica (Silicosis)

Silicosis causes fibrotic changes in the lung, predominantly in lower lung fields. Although the radiologic findings within the lung tissue are similar to coal dust, there is increased frequency of calcification of the lymph nodes, with eggshell calcifications being a classic finding. Silicosis may also progress to 'complicated' disease with cascading areas of lung emphysema.

2.5.5.5 Byssinosis (Cotton Worker's Lung)

Although frequently lumped with the pneumoconioses, byssinosis is physiologically quite different. Cotton-dust exposure precipitates an asthma-like condition via immunologic response leading to constriction of the air passages, rather than the scar tissue that is a hallmark of coal, silica and asbestos exposure. The precise agent within the cotton plant that causes byssinosis is not clearly known, although a role for endotoxins is certainly indicated.

2.5.5.6 Asthma

Asthma is a manifestation of allergic disease in which the airways in the chest become reactive. Sensitization can occur to any protein and to many other smaller chemicals. Following sensitization, if there is additional exposure to the trigger, the airways are reactive to inflammation, with decreasing flow of air to the lungs. Sensitization can occur to many plant (pollen), animal (dander) and insect (scat) proteins. Additionally, some industrial exposures, such as certain sawdusts, colophony (solder flux), isocyanates and cotton dust have been associated with asthma. Irritant mixtures such as cleaning materials may also provoke reactions. Avoidance of the trigger is the most effective treatment, although there are medications available that can treat disease and even decrease event frequency.

2.5.5.7 Reactive Airway Dysfunction Syndrome (RADS)

High-dose exposure to a strong irritant can cause virtually instantaneous airway obstruction, very similar to asthma. Once reactive airway dysfunction syndrome (RADS) occurs, victims may react to a wide variety of other irritant triggers, at lower exposure levels. Patients may gradually return to normality over the course of several years. Strong irritants such as chlorine or ammonia may provoke this rapid response.

2.5.5.8 Irritants

There are several respiratory exposures which can directly irritate the respiratory tract, causing airway reactivity and lung damage. Examples include acid mists, products of combustion and any of the water-soluble acidic or basic gasses. Following exposure, responses can range from mild irritation to scar formation anywhere in the respiratory tree, including the alveoli and the lungs themselves. The only effective treatment is avoidance, either through product substitution, personnel controls or the use of personal protective equipment.

2.5.5.9 Asphyxiants

Asphyxiants block the effective use of oxygen by cells of the human body. There are four mechanisms to consider: simple, blood, cellular and central. All forms of asphyxiants can cause death. Removal to fresh air and supportive care is sufficient care for simple and central asphyxiants; additional medical care is needed for the other forms.

A simple asphyxiant merely changes the concentration of oxygen in inspired air by displacement. An example is argon gas in an enclosed space. This lethal problem is avoided by testing confined spaces for oxygen content before entry.

A 'blood' asphyxiant interferes with the transport of oxygen in the blood. An example would be CO, which preferentially binds with haemoglobin, and also interferes with the release of oxygen to tissues, thus preventing normal oxygen transport in the blood. Hyperbaric oxygen is the treatment of choice for CO poisoning.

The third mechanism is the 'cellular' asphyxiant, which uncouples oxidative phosphorylation, and thus interferes with the function of the mitochondria, blocking cells from effective utilization of oxygen. The prototype of this mechanism is cyanide. Treatment recommendations following cyanide exposure vary from supportive care only, to specific antidotes such as large doses of hydroxocobalamin to bind the cyanide.

A central asphyxiant interferes with the drive to breathe. The well-known example is hydrogen sulfide, nicknamed the 'knockdown gas' for its propensity to cause exposed oil-field workers to rapidly lose consciousness.

2.5.5.10 Bronchiolitis Obliterans

Diacetyl is used as the butter flavouring in most microwave popcorn. In 2001, bronchiolitis obliterans was noted in several workers at a plant manufacturing microwave popcorn. The greatest exposures to diacetyl and most of the disease occurred among workers in the mixing room, where large vats of heated diacetyl were added to the other ingredients. Work is ongoing to look for other exposures in the flavourings industry.

2.5.6 Skin

There are four types of exposure-related skin disease: dermatitis, allergic reaction, pigment changes and skin cancers. Each will be discussed (see above for discussion of skin cancers).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The most common skin conditions are irritation or allergy of the skin. Both conditions are called dermatitis, although the mechanism of rash is different. Contact dermatitis can result from mechanical damage, such as exposure to acids or alkalis. Either type of dermatitis can result from a variety of exposures. Other than noting the pattern/distribution, a physician cannot identify the cause by inspection. Sometimes the pattern/distribution of a dermatitis is helpful. For example, a sharply demarcated boarder matching the edge of a pair of gloves might suggest a reaction to the gloves in one distribution, or to a chemical for which the gloves provide the barrier in another.

Allergic reactions can occur to nearly any ingredient or product. Allergic reactions can be localized (to the area of exposure) or generalized. Generalized allergic reactions may progress well beyond a skin reaction, to hives or even anaphylaxis, which can be fatal.

The third major type of skin reaction is discolouration. Populations drinking arsenic-laden water develop a dark discolouration of the feet and legs called 'blackfoot disease'. Many pigmented chemicals can leave a sometimes permanent 'tattoo' if they penetrate the skin. Other chemical exposures can lead to either darkening or lightening of the skin.

2.5.7 Renal and Urinary Tract Diseases

A wide range of occupational toxins has been implicated in causing urinary tract and kidney disease. Chemical compounds affect different sites in the urinary system. **Table 8** summarizes chemical agents that have been found to be associated with kidney diseases as well as urinary-tract disorders.

Table 8 Industrial chemical compounds associated with renal and urinary tract disorders

Condition	Offending chemical agents
Acute renal disease	
Tubulointerstitial	Halogenated hydrocarbons (carbon tetrachloride, ethylene glycol) Pesticides: Organophosphate (parathion) Organochlorine (dichlorodiphenyl-trichloroethane; DDT) Bipyridyl (paraquat) Heavy metals (arsenic, chromium, mercury, lead)
Glomerular	Hydrocarbon solvents Heavy metals
Indirect	Haemolytic agents (arsine) Rhabdomyolitic agents (ethylene glycol)
Chronic renal disease	
Tubulointerstitial	Heavy metals (cadmium, lead, beryllium)
Glomerular	Heavy metals (lead, mercury) Hydrocarbon solvents Silica and silicon compounds
Bladder dysfunction	
Bladder irritation	Pesticide (formamidine)
Sacral neuropathy	Plasticizer (DMAPN)

2.5.7.1 *Kidney Disorders*

2.5.7.1.1 Tubulointerstitial disease

The tubule is the most common site of acute nephrotoxic injury. Acute or chronic injury depends on the exposed dose and duration, with acute renal damage often occurring following high-dose, short-duration exposure. Halogenated hydrocarbons, such as carbon tetrachloride, chloroform and tri- and tetrachloroethylene, may cause acute injury to the liver and renal tubular necrosis. The primary cellular target of chloroform is the proximal tubule, with no primary damage to the glomerulus or the distal tubule. Proteinuria, glucosuria and increased blood urea nitrogen levels are all characteristic of chloroform-induced nephrotoxicity (Sinicrope *et al*., 1984). The mechanism of chloroform nephrotoxicity is related to its metabolite, trichloromethanol. This unstable, biotransformed product from chloroform releases hydrogen chloride (HCl) to form phosgene, which injures proximal tubular cells.

The effects of halogenated hydrocarbons appear to depend on dose and possibly on route of absorption. Inhalation exposures seem more likely to induce acute renal failure as the most prominent manifestation, whereas ingestion predisposes patients to hepatocellular necrosis (Lauwerys *et al*., 1985; Phillips *et al*., 1988). The difference may be explained by the first-pass effect of ingested chemical compounds cleared into the enterohepatic circulation. Solvent renal and hepatic effects are probably caused by metabolites.

Ethylene glycol is a component of commercial antifreeze. It can cause acute tubular injury following a large-dose exposure. The mechanism combines deposition of calcium oxalate crystals in renal tubular cells and lumen with direct cytotoxic effects. Glomerular proliferative changes may also be seen pathologically. The toxic metabolite of ethylene glycol, oxalic acid, is formed by alcohol dehydrogenase. Competitive inhibition of the alcohol dehydrogenase enzyme site (Guo *et al*., 2007) by (intravenous) ethanol or by 4-methylpyrazole is an effective treatment.

Heavy metals, such as inorganic mercury, arsenic, cadmium, chromium, gold, iron, silver and uranium, cause renal toxicity. Mercury is capable of inducing acute renal failure secondary to proximal tubular necrosis. The pathogenesis is partially related to mercury's affinity to membrane sulfydryl groups, resulting in alterations in cellular permeability. Damage occurs when the serum

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

binding protein (metallothionein) is saturated (Barbier *et al*., 2005).

The principal target organ of chronic exposure to cadmium is the kidney. Following longstanding low-dose exposures, workers may develop proximal tubular dysfunction heralded by the excretion of β-2-microglobulin and other tubular low-molecular-weight proteinuria, as well as albuminuria. Hypercalciuria with nephrolithiasis is common. Fanconi syndrome with amino aciduria, glycosuria, phosphaturia and renal tubular acidosis can be seen in more severe cases. Osteomalacia may occur in severe cases. The changes are usually irreversible, but removal from exposure often halts disease progression.

Chronic lead exposure leads to progressive damage to the proximal tubular epithelium, followed by interstitial scarring and loss of glomeruli. Hyperuricemia, an early sign of lead nephrotoxicity, results from enhanced proximal reabsorption of urate. Subsequently, decreased glomerular clearance with hypertension may appear, usually after years of lead exposure.

Tubulointerstitial diseases can be secondary to haemolysis or rhabdomyolisis effects of primary toxins, leading to both acute and chronic forms of kidney disease.

2.5.7.2 Glomerular Diseases

Toxic insults to the glomeruli result in clinical manifestations similar to those seen in non-toxin-induced glomerulopathies, including proteinuria, reduced glomerular infiltration rate, oedema and hypertension. Organic and inorganic mercury has been found to be associated with acute glomerular injury, histologically identified as a membranous glomerulopathy.

A number of solvents used in industry, such as halogenated hydrocarbons, may increase the risk of glomerulonephritis, particularly antiglomerular basement-membrane antibody-mediated disease, resembling Goodpasture's syndrome (Churchill *et al*., 1983). A number of hydrocarbon mixtures and specific chemicals, for example, organic solvents, hairdressing solvents, gasoline, glues, trichloroethane or tetrachloroethane, have been associated with antiglomerular basement-membrane disease.

Many nephritic toxins, such as mercury and hydrocarbon solvents, are associated with chronic glomerulopathies or glomerulonephritis.

2.5.7.3 Bladder Dysfunction

2.5.7.3.1 Sacral Neuropathy

Lower urinary tract dysfunction can result from the neuropathic effects of workplace exposures. Dimethylaminopropionitrile (DMAPN), a catalyst in polyurethane foam manufacture was found to be associated with isolated urinary dysfunction. The symptoms are manifested with micturition abnormalities including retention, dysuria and delayed micturition time (Keogh, 1983). The pathogenesis is thought to be related to sacral neuropathy. DMAPN has been removed from sale and use.

2.5.7.3.2 Chemical Irritation

Pesticides of the formamidine group and toluidine are associated with bladder irritation. The exact mechanism is unclear.

2.5.8 Cardiovascular Disease

Heart diseases are leading causes of morbidity and mortality in the developed world, and they are advancing problems everywhere that 'Western' diets are adopted. Although many cardiovascular deaths may be accounted for by the known risk factors of hypertension, diabetes, cigarette smoking, hyperlipidaemia and genetic factors, many other cardiovascular deaths are not explained by these risk factors. The role of occupational risk factors and of their potential contributions, alone or in combination with other risks, to the overall burden of cardiovascular diseases, is insufficiently studied. Nevertheless, exposure to toxic chemicals in the workplace and in nonoccupational environments is clearly associated with cardiovascular disease.

Chemical compounds affect the cardiovascular system at a variety of sites. Cardiovascular toxins are generally classified by nature of abnormality or by anatomic injury location/injury mechanism (see **Table 9**).

2.5.8.1 Ischaemia

Atherosclerotic vascular disease causes cardiac ischaemia, an imbalance between the heart's demand for oxygen and the delivery of oxygen to the myocardium. Chronic exposure to carbon disulfide has been definitely linked to cardiac ischaemia (Kotseva and De Bacquer, 2000). Population investigation associates that outcome with alterations in lipid metabolism and increases in diastolic blood pressure (Kotseva and De Bacquer, 2000; Kotseva, 2001). Carbon disulfide was also found to alter thyroid function, glucose tolerance and fibrolytic activity (Cavalleri, 1975; Candura *et al*., 1979). These physiologic processes accelerate vascular atherosclerosis. Because the cardiovascular risk of carbon disulfide exposure remains after adjusting for hypertension and serum cholesterol, it is suggested that carbon disulfide may affect the cardiovascular system through other, as yet unknown, toxic mechanisms (Nurminen *et al*., 1982).

Cardiovascular diseases caused by carbon disulfide are clinically indistinguishable from nontoxic atherosclerotic vascular diseases, with one possible exception. Abnormal ocular microcirculation, characterized by microaneurysms and haemorrhages resembling those of diabetic retinopathy, is an early sign of chronic carbon disulfide poisoning (Karai *et al*., 1983a; 1983b). Laboratory tests are also generally nonspecific for individuals. There is population evidence of decreased

Table 9 Occupational toxic cardiovascular diseases and agents

Condition	Causation		
	Definite	Probable	Possible
Cardiac ischaemia secondary to atherosclerosis	Carbon disulfide	—	Carbon monoxide, methylene chloride, nitrites, arsenic
Nonatheromatous ischaemic heart disease	organic nitrates, carbon monoxide	Methylene chloride	—
Dysrhythmias/arrhythmias	Fluorocarbons, chlorinated hydrocarbons, nitrates, organophosphates, arsenic and arsine, particulates	Antimony	—
Hypertension	—	Lead, arsenic	Cadmium, carbon disulfide
Cardiomyopathy	Arsenic, arsine, cobalt	—	Antimony, organic solvents, lead
Peripheral vascular disease		Arsine, lead, carbon disulfide	—
Alterations to lipid mechanism	Carbon disulfide, alcohol	Perfluorocarbons	—

thyroxin level and an increase in serum cholesterol level. Carbon disulfide can be measured in blood by gas chromatography-mass spectrometry; however, testing is not readily available for routine examination. A conjunction product of carbon disulfide and glutathione is excreted in urine proportionally to exposure and can be measured to monitor exposure.

Dramatically increased risk for ischaemic heart disease was also reported in large populations exposed to arsenic via contaminated well water in Taiwan (Wu *et al*., 1989; Chen *et al*., 1996). Chronic exposure to arsenic at the workplace was also found to be associated with cardiovascular disease in copper-smelter workers (Hertz-Picciotto *et al*., 2000; Axelson *et al*., 1978), including increased mortality with dose-related outcome.

Nitrate esters, of which nitroglycerine is the best known, have long been used as pharmaceuticals and as explosives. In addition to their oxidant properties and potential to induce methaemoglobinaemia, nitrates have immediate effects of variable onset and duration as arterial vasodilators. Withdrawal from nitrates will cause rebound vasospasm. Since chronic exposure to nitrates produces tolerance, acute symptoms such as severe headaches characteristically recur during withdrawal or more commonly on re-exposure after absence from work for several days (i.e. the so-called 'Monday morning headaches'). Re-exposure to nitrates after a period of nonexposure can cause paradoxic cardiac arrest. Sudden ventricular fibrillation is the likely cause (Lange *et al*., 1972; Morton, 1977).

CO causes cardiac ischaemia through several mechanisms, including avid binding to haemoglobin, with a resultant decrease in tissue oxygen delivery, as well as shifting of the haemoglobin–oxygen dissociation curve. CO exposure decreases myocardial contractility by binding to the cytochrome oxidase system in the mitochondria of cardiac muscle (Chance *et al*., 1970). Acute toxicity with high-dose exposure is common, especially in developing countries where stoves are the main means of heating in winter, or following disaster-recovery efforts with indoor use of temporary gas- or kerosene-powered generators. CO is suggested to cause ischaemic heart disease following repeated low-dose exposures (Teculescu *et al*., 2007; Koskela *et al*., 2000; 1994). Following CO exposure, workers with underlying coronary artery disease may experience exacerbation of angina and arrhythmias, even with a blood carboxyhaemoglobin of less than 10% (Sheps *et al*., 1990). The exact blood concentration of CO sufficient to produce permanent pathologic changes in humans is unknown, and likely subject to substantial variability depending on victim fitness and genetic susceptibility. At higher levels of carboxyhaemoglobin, usually above 25%, manifestations of ischaemia, dysrhythmias and electrocardiographic abnormalities are likely to be observed in otherwise healthy individuals (Prockop and Chichkova, 2007).

Methylene chloride was commonly used in paint thinner, and still persists in some products. It has cardiotoxicity, partly because of its metabolic conversion to CO. The biologic half-life of CO from this source is longer than that of inhaled CO. Carboxyhaemoglobin levels have been used to monitor methylene chloride exposure.

2.5.8.2 *Dysrhythmias*

A number of chemicals have been associated with atrial and ventricular dysrhythmias by mechanisms unrelated to ischaemia. The agents of concern include organic

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

solvents, with both halogenated (particularly fluorocarbons) and nonhalogenated chemicals implicated. Cases have been reported for sudden death in solvent sniffing or inhalant abuse, especially in toluene abusers (Soden *et al*., 1996). The causes for sudden death include cardiac dysrhythmias and hypoxia-induced heart block. The toxic mechanism of sudden death is thought due to sensitization of the myocardium to circulating catecholamine. The range of solvents and solvent mixtures capable of this mischief is likely broad; an adult woman developed ventricular fibrillation and cardiopulmonary arrest after prolonged exposure to concentrated vapours from mineral spirits. Dilated cardiomyopathy and myocardial fibrosis are also reported in solvent-abuse populations.

2.5.8.3 Cardiomyopathy

Cobalt exposure has been linked directly to the development of cardiomyopathy. The association was first observed in the 1960s in drinkers of beer containing cobalt added to stabilize the foam (Bonenfant *et al*., 1967; Alexander, 1972). Occupational exposure to cobalt was observed in the production of metal alloys used especially in the manufacturing of drills and bits. A study of tungsten carbide workers exposed to cobalt-containing dust found a weak, but statistically significant, inverse correlation between resting left ventricular ejection fraction and duration of exposure (Horowitz *et al*., 1988). The findings support a possible role for cobalt in causing myocardial disease. The probable mechanism of cobalt cardiac toxicity is depression of oxygen uptake by heart mitochondria and interference with energy metabolism. It is similar to the effects of thiamine deficiency (Alexander, 1969). Antimony has also been anecdotally linked with the development of cardiomyopathy and electrocardiographic abnormalities.

Hypertension, a commonly seen chronic disease, is a major risk factor for premature atherosclerotic coronary vascular disease, cardiomyopathy and stroke. Several industrial agents can induce or aggravate hypertension. Epidemiologic studies consistently show that low-level lead exposure can chronically elevate blood pressure (Sharp *et al*., 1987; Skoczyńska *et al*., 2007). A positive relationship is reported between lead concentration and systolic blood pressure (Pirkle *et al*., 1985; Menditto *et al*., 1994). In animal studies, the mechanism of hypertension by lead is likely related to increased vascular resistance, possibly through increasing plasma renin activity, either by inhibiting angiotensin-converting enzyme or by enhancing responsiveness of vascular smooth muscle to the pressor effects of endogenous vasoconstrictors, and/or directly contracting vascular smooth muscles (Carmignani *et al*., 2000). Lead also affects calcium in tissues by inhibiting sodium-potassium-adenosine triphosphate (ATPase) and calmodulin-mediated calcium transport (Carmignani *et al*., 2000).

Other chemicals found to be associated with hypertension include carbon disulfide and organic solvents, and metals, such as cadmium and arsenic.

2.6 Other Topics

2.6.1 Indoor Air Quality

The energy crisis of the 1970s prompted efforts to increase the energy efficiency of buildings by increasing insulation and decreasing incursions of outdoor air. This trend may deepen. These laudable activities increase the risk for accumulation indoors of the products of human activity (office machines, outgassing from furniture, dust in ducts and construction materials). Decreased ventilation and increased dust are associated with a constellation of effects including nose and throat irritation, headaches, lethargy and difficulty concentrating. The exact cause of these symptoms is unclear, and removal of single constituents from the environment may not alter the effects.

Carbon dioxide is not the causative agent in indoor air problems. It is a product of human respiration that can be fairly easily monitored, and increased carbon dioxide levels in an inhabited building suggests a problem with ventilation and air quality. Thresholds ranging from 800 to 1000 ppm have been suggested. Abatement efforts typically consist of increasing the proportion of outside air that is added to the indoor environment, and retrofitting exhaust fans where they have been omitted.

2.6.2 Mould

Mould is a ubiquitous, common exposure. Human exposure has been a health concern for millennia, with instructions for removing mould from houses dating from antiquity (The Holy Bible, Revised Standard Version, 1952). Funguses do have the ability to elaborate toxins, which can be harmful to humans. For example, T-2 mycotoxin is a potential chemical weapon.

There is much lay literature focussed on the ill effects of various mould species, with most allegations of direct toxicity regarding 'black mould', especially *Stachybotrys* species. A report associated S*tachybotrys* with pulmonary haemorrhage in infants (MMWR, 1997); this report has been rescinded (MMWR, 2000). There have been no other similar reports.

Case reports following exposure to mould have also claimed a variety of direct toxic cognitive effects; these have not so far been supported by larger studies.

Allergic symptoms, including rhinitis and asthma, are mould-exposure outcomes that are clearly supported by the medical literature. People can clearly become sensitized to moulds (and to bacterial endotoxin as bacteria grow next to mould), with allergy symptoms following

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

further exposure. Treatment with medications can limit these effects; however, avoidance of exposure is more effective. Removing first sources of moisture and then the mould is more effective than treating the resultant allergy. The toxicology of indoor air pollution is further discussed in **Indoor Air Quality**.

2.6.3 Nanotechology

Nanotechnology refers to materials which have a length scale between 1 and 100 nanometres (National Nanotechnology Initiative (NNI), 2008). Various geometries have been created, including single- and double-wall tubes, pyramids and fullerenes (soccer ball-like spheres, previously known as Bucky balls). There are also older products that occur in this size range, such as carbon black and titanium dioxide. There are multiple theoretical reasons for concern and, to date, scant information reporting on actual health effects associated with manufactured other geometries or materials. This is an area of active research at the US National Institute for Occupational Safety and Health. When nanomaterials are an unintended pollutant, rather than a product, they are regarded as 'ultrafine' air pollution. Ample epidemiologic evidence supports respiratory, cardiovascular and mortality outcomes. The toxicology of nanmaterials is further discussed in **Nanotoxicology-The Toxicology of Nanomaterials**.

2.7 Clinical Syndrome Presentations

Nonspecific clinical syndromes are common in the developed world. They primarily include chronic fatigue, chronic fibromyalgia and irritable bowel syndrome in the United States. Variants of these and many other syndrome presentations are found throughout the world. Less common is the nonspecific syndrome with a reference to work. Three important syndrome presentations which may be attributed to work are 'sick building', multiple chemical sensitivity (MCS), and electrical sensitivity.

'MCS' has a more than a century-old history of antecedent sociomedical history in the United States, and the recast diagnosis from the 1980s has been exported internationally. Its formal requirement, that the disorder be acquired in relationship to documented (albeit low-level) exposures, is rarely met in practice, yet such exposures are highly plausible for most of the world's population, so there is little chance to 'rule out' the diagnosis based on exclusion of minute exposures. This clinical syndrome diagnosis is therefore equally applicable across the spectrum of workers and the unemployed, in theory. In practice, the diagnosis has been historically less common in industrial-exposure groups and more common in teachers, office workers and the previously employed.

The research diagnosis involved symptoms that can be thought of as referring to more than one organ system and which recur following predictable stressors (from many unrelated chemical classes). Objective organ-system findings are not part of the syndrome and implicate other diagnoses (Cullen, 1987). Many authors have pointed out that patients who present with MCS to occupational providers typically have other practitioners who may have diagnosed 'overlap' syndromes of medically unexplained symptoms, such as chronic fatigue, chronic fibromyalgia, chronic candidiasis, chronic Epstein–Barr virus and chronic tick-borne infectious disease. The North American histories of international syndrome diagnoses, past and present, could be a book chapter in a different kind of text. Among these medically unexplained diagnoses, MCS is unique in the patient expectation that the problem is caused by other humans' behaviour with chemicals.

MCS patients present with reversible symptoms of paralyzing pain, strange skin sensations, evanescent rash, and rapid-onset and rapidly reversed episodes of confusion/memory loss, as primary examples. Triggers are odours, often starting with a single exposure and then often generalizing to a plethora of odours. Patients who perceive these triggers seek to minimize them without additional clinician guidance.

Taking an occupational-exposure history is important for all exposure patients; however, it is equally an exploration of frame of mind and historic treatment options for MCS patients. Unusual exposures from non-evidence-based remedies ranging from enemas to chelation therapy should be sought. Unusual symptoms, such as sudden paralysis or loss of consciousness are critical to understanding social risk. The patient is likely to express a goal of restored social function, and to simultaneously perceive that goal as unattainable for many details of lifestyle normalization.

In the United States, these MCS (and 'overlap') patients frequently present very unusual laboratory tests from an array of unconventional biologic media (often with brightly coloured graphics and very unconventional ways of expressing normal ranges). The quality of these tests is far from assured. Several ways to deal with these tests are to repeat the tests in a reputable lab if cost is no object, to repeat only the tests with plausible abnormalities if the usual fiscal constraints pertain to patient care or to ignore the tests if the patient is already at the point of changing belief systems. Accepting these tests at face value is the error with the largest social cost for these unfortunate patients.

It is useful to know that surveys of US populations find surprisingly high endorsement of belief systems, but actual work impairment is much rarer, and designed trials to establish aetiology either find no evidence of environmental causation, or implicate psychologic causes (Ducatman, 2007). It is nevertheless wise to remember that psychologic causes have physiologic consequences.

For the MCS patient, careful, nonjudgemental listening is far more important than therapeutic suggestion or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

further extension of already implausible test batteries. The patient may demand physiologic explanations and treatment advice, with a focus on environmental interventions. Be alert, however, that actual needs are different than those expressed. An innocent suggestion to 'avoid exposure' can further enforce an obsessive response and help this patient travel still further down the road to unconventional medical practice, social isolation and economic deprivation. And, an affirmative response to the question 'Is it all in my head?' is all it takes to send this patient back to the least evidence-based, most economically abusive provider. It is better to point out that all pain and all fatigue are experienced in our heads, and that we have not found the cause of the particular symptoms that affect our patient.

The goals of care are modest: address alarming, nonstandard lab testing as needed (and affordable); establish trust that you care; assure the patient that you do not know the physiology of the problem and create routine appointments so that medical contact can be retained in the absence of new and more alarming symptoms. Let the patient know that in this circumstance, the patient is her own best doctor, with a treatment goal to gradually improve exercise tolerance and social integration. Do not be in a hurry to make this suggestion.

Throughout Europe, MCS patients have a second manifestation of 'electrical (or electromagnetic) hypersensitivity'. The presentation is generally similar to, but less dramatic than, that of the MCS patient. Similar symptoms include headache, fatigue, weakness, lethargy and skin sensations (Lotz, 2007). The physiologic evidence basis for electrical hypersensitivity is similar to that of MCS; designed studies do not find a physiologic basis, unless it is psychologic (Ducatman, 2007; Lotz, 2007). A less challenging and more common situation is the patient who wants to be tested 'for everything' to 'prove it's safe.' In this circumstance, the goal is to be informative and believable about the limits of medical science.

2.8 Causation and Aetiology

Discussions of causation generally start with a discussion of the work of Sir Austin Bradford Hill, who proposed what are now known as 'Hill's criteria'. These points must all be considered in establishing an opinion about causation; however, it is not mandatory that all of the criteria be met to establishing causation.

2.8.1 Hill's Criteria

2.8.1.1 Temporal Relationship

The exposure must always precede the development of disease, and this must also include an appropriate latency period. While other criteria are relative, this one is absolute.

2.8.1.2 Strength

Review the epidemiological evidence, looking at the number of studies showing an association, the strength of that association and the presence or absence of studies with alternate results.

2.8.1.3 Dose–Response Relationship

This concept can have three different interpretations. The concept of dose will be reviewed, the types of dose–response relationship discussed and the application of dose–response in various settings explored.

First, consider the concept of dose. For medications, this is milligrams per tablet, times how often the tablets are taken. Applied to environmental exposures, the dose is comprised of the exposure per unit of time, times the duration of the exposure. As an example, for cigarette smokers, this would be how many packs of cigarettes a day times how many years they have smoked, yielding an exposure history expressed in pack-years. The cigarette-related diseases correlate to the pack-year total of the smoker. Expert-rated assessments start with measured or inferred contaminant levels, and then apply models to extend the measurements and estimate human exposure.

Dose–response relationships can be stochastic or deterministic. Stochastic relationships vary with the level of the exposure. An industrial example might be skin exposure to sulfuric acid, in which the amount of damage to the skin would correlate directly with the strength of the acid and the contact time. This contrasts with a deterministic dose–response relationship, in which there may be no effect at lowest doses, based upon reaching a threshold (which can vary considerably between individuals.) Most cancer outcomes are thought to be deterministic. Unfortunately, we cannot discern most workers' susceptibility to any exposure. Protective levels are necessarily set well below the level at which most individuals would develop the outcome, and still fail to be fully protective. In many cases of failure-to-protect, the problem stems from short-term excursions that are unaccounted in a larger model of total dose.

There are two types of dose–response relationship. The first of these considers the individual patient, and the second the effect on populations. In much of medicine we apply the dose–response concept to the individual patients. For example, we expect that a higher dose of a blood-pressure medicine would result in a greater lowering of blood pressure in a patient. This would apply to any stochastic toxic exposure.

Applying the dose–response concept to populations is different, and applies primarily to deterministic exposure–disease relationships. For an exposure without a threshold effect, the rates of development of disease will be highest in populations with the greatest exposure. That is not to say that all persons in the most exposed group will develop disease, just that the rate of disease in this most exposed group will be greater than in less

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat107
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

exposed groups. And, as more susceptible individuals often fail to thrive as workers for health reasons, the puzzling finding of an outcome, without a strong dose–response, should not be dismissed as meaningless. While the identification of a dose–response relationship adds strength to a causation determination, this can be difficult to calculate in some exposed populations, especially if the numbers exposed are small.

2.8.1.4 Consistency

An association between an exposure and a disease should be repeatable. Multiple studies using different epidemiological methods and settings are desirable when possible. One study, even if very positive, is usually not enough to reach a conclusion. There are important exceptions for rare diseases with striking outcomes. Similarly, single negative studies should give one pause in evaluating conclusions, yet negative studies often receive less scrutiny.

2.8.1.5 Plausibility and Coherence

Plausibility is a common-sense evaluation of a scientifically reasonable association between the exposure and the disease. While current knowledge is essential to support or rule out connections between exposure and disease, one must be willing to consider novel associations that will, from time to time, change the way we think about things.

Coherence relates to findings in similar studies. This resembles thinking about drug classes that affect specific receptors. If there are similar exposures that cause similar outcomes, strength is added to the potential association. Recall that novel associations surprise us all too often, and that 'known' associations can be wrong.

2.8.1.6 Specificity

A specific exposure should cause a specific outcome. For example, reports that exposure to X causes 'cancers' or causes 'female problems' are very difficult to interpret. This is not to say that an exposure cannot cause more than one outcome; however, one should expect there to be a very short list of outcomes associated with the exposure. A problem with this criterion is that many exposures are to mixtures, so the exposure–outcome relationship becomes very complex. An inability to identify the specific component within a mixture of exposures does not mean that the exposure mixture is harmless.

2.8.1.7 Experimentation

While not one of Hill's original criteria, experimentation can offer the strongest evidence of an association. Animal testing can suggest a risk, but animal metabolic systems are somewhat different from human ones, so there may be effects from chemicals seen in animals, but not in humans, and vice versa. Recent work with perfluorocarbons illustrates the importance of choosing animals whose receptors and metabolism resemble the species of interest. Obviously, experimental exposure of humans is neither ethical nor appropriate. Commonly, we learn about human toxicity from inadvertent 'natural' experiments. There is a long industrial history of learning much from unintended consequences.

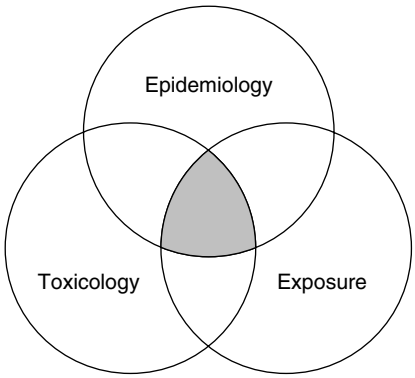

Figure 1 Discipline inputs to aetiologic decisions.

2.8.2 Consideration of Alternate Explanations

While this is really a subset of the plausibility and coherence criteria, one must always consider alternate sources of causation for the disease. If the alternate source of causation is more likely, then that should be stated. For example, a worker at a chemical plant with infrequent low-level exposure to a possible lung carcinogen who develops lung cancer may have been a two-pack-per-day smoker for the past 40 years. In this circumstance, causation is usually associated with the smoking.

2.8.3 Causation beyond Hill's Criteria

Another way to think about assessing causation is shown in the Venn diagram in **Figure 1**. Only situations where there is concurrence of exposure, toxicology and epidemiology, shown by the shading, can a causative connection be determined.

The most clinically challenging aspect of this is assuring oneself that there is a plausible exposure pathway. Mere proximity to a potential contaminant is *not* sufficient for causation; it is important to assure that the exposure pathway is completed.

Occupational Toxicology and Occupational Hygiene within the European Union (EU) Chemicals Regulation

Steven Fairhurst and Elanor Ball

CONTENTS

1 CONTEXT

The purpose of this chapter is to discuss the interplay between the disciplines of toxicology and occupational (or industrial) hygiene in understanding and controlling the hazards and risks to health posed by chemicals, in an occupational setting.

Ten years ago, the chapter 'Industrial Toxicology and Hygiene', produced for the second edition of *General and Applied Toxicology*, offered a perspective on the main approaches, roles and responsibilities that, in a regulatory context, had held for a considerable period of time within chemical legislation. This updated chapter is written from within the European Union (EU) at a time when it is embarking on a new era of chemicals legislation that promises to change things profoundly. On 1 June 2007 the Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) regulation came into force in the EU (EC, 2006). This legislation changes the nature and balance of roles between industry and regulatory

authorities—and modifies the conventional approaches to, and interplay between, toxicology and occupational hygiene—in regulating industrial and commercial chemicals within the EU.

In its information requirements for registration purposes, REACH creates a tension between desires to improve the extent and quality of data available on chemicals, but also to minimize experimental animal testing. In relation to toxicology, this poses challenges to all concerned. REACH removes the distinction and associated data-expectation requirements between 'new' and 'existing' substances within the EU. REACH also expands and reinforces the 'customer care' principle that suppliers of chemicals take responsibility for understanding the uses to which their chemicals are to be put and specifying the risk management measures that should be followed in such uses. This will be a big challenge to the occupational hygiene profession. And all of this also comes at a time when the EU is in the process of adopting the globally harmonized system (GHS) of classification and labelling (C&L) of chemicals, which will modify the EU C&L system that has operated for the previous several decades.

So it is a time of change—and no one is quite sure how things will work out in the next 10 years. This chapter attempts to portray how these recent developments build on, or change, what has gone before, and discusses some of the key issues that are ahead for the toxicology and occupational hygiene fields, operating in this new regulatory context.

2 INTRODUCTION—BASIC PRINCIPLES

Occupational or industrial toxicology focusses on gaining an understanding of the hazardous properties of chemicals encountered at work and the risks of these properties being manifested under working conditions. Occupational or industrial hygiene, in relation to chemicals, addresses the exposure conditions created during the manufacture, formulation and use of chemicals, and the potential means of controlling and protecting against exposure. The manner in which the two disciplines interact is brought out by considering the familiar 'risk-assessment paradigm' (**Figure 1A** and **B**). Toxicology deals with the assessment of toxicological hazards and the risks of expression of such hazards under defined exposure conditions. Occupational or industrial hygiene deals with exposure assessment and the control of exposure and thereby risk. It seeks to define what exposure conditions could or will be encountered at work and addresses the technical and practical issues arising in considering and applying appropriate risk-management measures. The shared aim of both specialisms is to develop a sound scientific and technical basis for good standards of health, and effective and appropriate control measures in the workplace. There are, of course, other disciplines, such as occupational medicine and epidemiology, which make substantial contributions to achieving this goal.

Almost every chemical substance involved in modern society has an occupational exposure context and hence falls under the scrutiny of occupational toxicology and hygiene. Beyond the vast array of chemicals, such as reactants in synthetic processes, solvents, metals, oils, coatings, colourants and polymers, and the manufacturing and use situations in which they arise, conventionally thought of as 'industrial', there are other occupational exposure situations that should not be forgotten. Pharmaceuticals are made, formulated and used by medical staff in their work. Foods are processed, additives are added and cooking is done by people at work. Pesticides are made, formulated and applied by workers. Overall, there are tens of thousands of substances present in the occupational environment in most industrialized countries.

For most chemical substances the workplace is the situation where there is the potential for higher exposure than in other sectors of life. The two modes of exposure of primary interest in the workplace are inhalation of the airborne substance and surface (skin, eyes) contact with the substance. Ingestion can also be an issue, arising from contamination of material entering the mouth (food, drink, cigarettes), poor personal hygiene (hand-to-mouth transfer of chemicals) or swallowing of mucous containing inhaled substance being cleared from the respiratory tract by the mucociliary escalator).

The occupational environment holds several exposure possibilities—single, short-term exposure under normal operating conditions; single short-term exposure under uncontrolled (i.e. spillage, accident) conditions; occasional, but repeated, exposure; regular daily exposure under normal operating conditions and combinations of these. Exposure concentrations and time periods will fluctuate and exposure can also occur via more than one route. The occupational hygienist needs to give consideration to all of these aspects in making exposure assessments and contemplating control measures. The occupational toxicologist needs to consider all exposure scenarios and their potential impact on health in order to gain a full appreciation of the risks of ill-health arising from encountering a substance at work.

A particular feature of occupational toxicology is the consideration of site-of-contact effects. This can be a problem, in that much conventional toxicology has been and continues to be performed using the oral (and sometimes parenteral) route(s). Alongside the possibilities arising from the absorption, distribution around the body and metabolism (to more or less toxic derivatives) of a substance, significant occupational toxicology concern surrounds the local consequences of inhalation or skin/eye contact at and around the initial point of impact. Sensory irritation (nerve stimulation), tissue inflammation

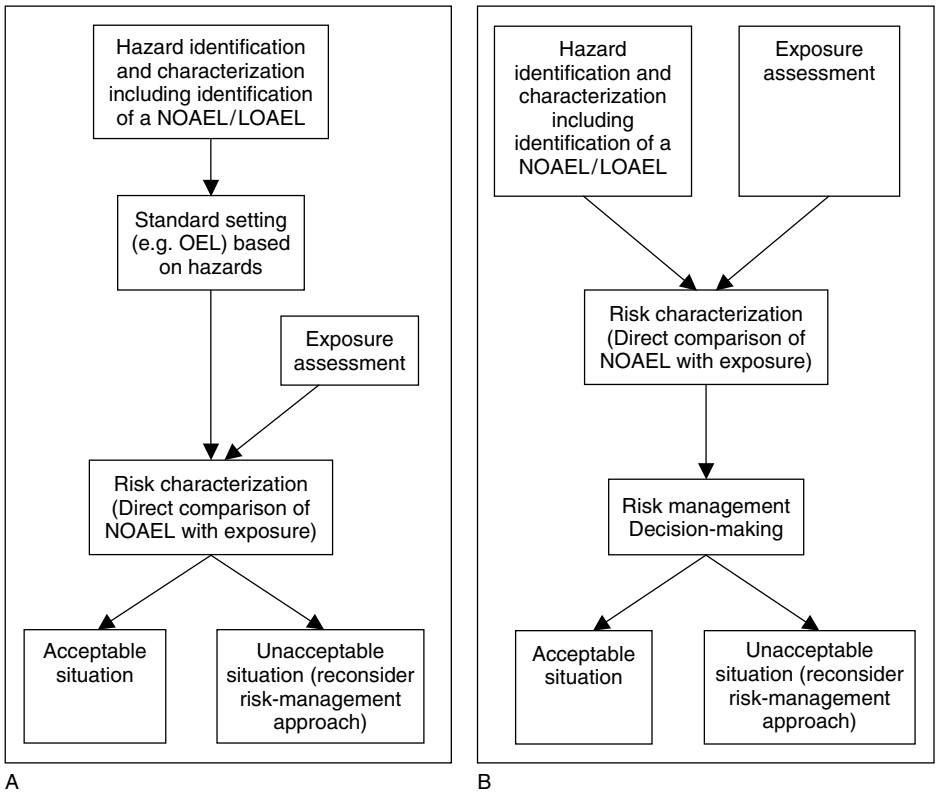

Figure 1 The interplay between hazard, exposure and risk assessment, leading to risk-management decision-making; two alternative pathways.

and damage, sensitization, mutation and cancer can arise in the lung or skin as a result of direct exposure to some reactive industrial chemicals or their locally produced metabolites. Additionally, pH effects and particle effects in the lungs (some related more to the physical than the chemical properties of a substance) are important considerations for local toxicity. The need to form a view of the potential local consequences of occasional or regular deposition of a substance in the respiratory tract and on the skin is an essential requirement in occupational toxicology.

3 HISTORICAL DEVELOPMENT

Observation of the adverse effects on health of occupational exposure to chemicals has a long history; brief allusions can be found in texts from ancient Greece and Rome. Classical figures of early toxicology and occupational medicine—Paracelsus, Ramazzini, Pott and others established their reputations from the sixteenth to the end of the eighteenth century in making the observations for which they are famed.

During the nineteenth and then the twentieth century, industrialization and the development of chemistry and the chemical industry brought about many benefits to society, but also problems, including occupational ill-health arising from exposure to industrial chemicals. The number of substances known to have produced some manifestation of occupational ill-health, be it skin inflammation, damage to internal tissues or cancer, stretches into the hundreds. It should also be acknowledged that there have been and continue to be many other, less well-substantiated claims made for evidence of manifestations of toxicity arising in the working environment.

Until well into the twentieth century there was a general acceptance or tolerance by society that where such chemical-induced ill-health at work was apparent, it was an unfortunate, but largely inescapable, feature of the world of work. Observations of affected workers were made, but there was little or no predictive toxicological testing of industrial chemicals, exposure assessment or pre-emptive action based on judgements of potential risks to health and aimed at prevention of toxicity arising from workplace exposures.

The first rudimentary toxicity testing of chemicals for the purposes of better understanding and controlling the risks to health involved in their industrial use was carried out by Lehmann in Germany in the late nineteenth century. These studies, principally on gases, involved only short-term exposure of animals and humans and were primitive in their design and conduct, but they did establish a baseline, which was important to later investigators. Similar studies were performed by others in the early part of the twentieth century, although the range

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of substances covered remained small. The findings were laid out in standard textbooks of the time (Henderson and Haggard, 1927; Flury and Zernik, 1931).

Toxicology investigations on industrial chemicals became more regular and refined from the 1940s. Nevertheless, it is generally true that the enormous and rapid expansion in the last 60 years in the number of chemical substances potentially in the occupational environment occurred largely in the absence of programmes specifically requiring the gathering and critical assessment of detailed and comprehensive toxicological data. Hence, even in the early 1970s, the American Conference of Governmental Industrial Hygienists (ACGIH) recommended a threshold limit value for vinyl chloride as high as 500 ppm (eight hours time-weighted average), commensurate with a substance being viewed as of low toxicity. Soon afterwards, vinyl chloride was clearly shown to be genotoxic and unfortunately to have already produced cancer in humans (Purchase *et al*., 1987). The situation with asbestos is even more salutary, with the tragedy still being played out of many tens of thousands of deaths from cancer, a consequence of inadequate understanding of toxicological hazard, potential exposure situations and the appropriate stringency of control necessary to secure negligible risk.

Although the field of occupational health is replete with historical accounts of industrial chemical toxicity that are both fascinating, but also tragic from a worker-health standpoint, much has been done in recent times to improve the understanding and control of risks to health posed by occupational exposures. Nevertheless, it is still true to say that the toxicology of industrial chemicals has been examined in a patchy fashion. A minority of substances have been well investigated. However, most substances of interest in relation to occupational exposure do not have extensive, detailed toxicological data on them and many have received little investigation (National Academy of Sciences, 1984; Allanou *et al*., 2000). One of the key objectives of REACH is to greatly improve this situation (see Section 7 in this chapter).

A significant consideration is the relative cost–benefit balance of pursuing better understanding of a situation as against settling immediately for tight control of that situation. Where only small quantities of a substance are being manufactured and used, and risk management to secure avoidance of ill-health is the goal, it is often more realistic to approach risk management by applying very stringent controls to achieve negligible exposure, rather than investing the time, effort and money necessary to acquire a clear understanding of the toxicology.

4 LEGISLATIVE FRAMEWORK

Since the late 1960s, a progressively increasing amount of legislation has been introduced in what is now termed the European Union, currently comprising 27 Member States; aimed at the appropriate identification and control of threats to human health (and safety, and the environment) posed by industrial chemicals. Prior to the introduction of REACH, the complex legislative framework that had developed over the last 40 years was anchored to the following general philosophy:

- *Suppliers* were deemed to be responsible for understanding the hazardous properties of the chemical(s) being supplied, toxicological information being conveyed, in a suitably interpretable manner, to recipients/users of the chemical(s). In this context *regulatory authorities* have developed classification systems that provide criteria by which to allocate substances to particular hazard categories denoted by symbols and phrases appearing on labels.
- *Users* have been held responsible for understanding the intended local conditions of use of the chemical and setting this knowledge, with its implications for levels, routes and frequencies of exposure, alongside the hazard information. In doing so, the user has been required to make a situation-specific risk assessment and draw conclusions regarding the appropriate risk management measures to apply—and then to apply them. In attempting to help the user, *regulatory authorities* have established some general risk-management measures, chiefly by extolling adherence to specified occupational exposure limits (OELs) for the airborne substance.

Although key aspects of these principles still hold now and will persist into the future, trends have been established in the EU over the last 10 or so years that have shifted things in several ways. The appearance of the new REACH legislation promises to change the picture still further, in ways that are described below. However, first we should appreciate what has been the regulatory framework for industrial chemicals up to now. This is done in the next section.

5 TOXICOLOGICAL HAZARD IDENTIFICATION: CLASSIFICATION AND LABELLING

A number of classification or categorization systems have been developed by different institutions in various parts of the world. Such systems are used to denote that a chemical belongs to a group sharing either a specified degree of toxicological hazard or a specified weight of evidence of a toxicological property (e.g. carcinogenicity) of relevance to human health. We concentrate here on the current EU system. In addition, since the mid 1990s there has been an initiative to develop a 'GHS' aimed at standardizing C&L across the world. At the time

of writing this chapter, a new EU regulation is being negotiated that will bring the GHS into the EU (see Section 5.2).

5.1 The EU Classification and Labelling System

Since the mid 1960s, for the supply of chemicals to be used in workplaces (and elsewhere) in the EU, there has been a regulatory requirement to classify and label substances, and combinations thereof ('preparations'), in accordance with an EU-wide system described in EC Directives (and their Amendments) on the Classification and Labelling of Dangerous Substances and Preparations, together with their accompanying Annexes (EEC, 1967; EEC, 1988). This system has been implemented in each EU Member States via each country's national legislation.

The aim of this system is to harmonize understanding of the hazardous properties of any particular substance or preparation, across all of the EU Member States and across different companies with a shared interest in the same material, such that trade, and health, safety and environmental matters that might be connected with such hazardous properties are considered, based on this common currency.

This EU C&L system has required that identified hazardous toxicological properties, from whatever test situation used or observations made, are considered in terms of their relevance to human health and the C&L ultimately derived should reflect this relevance. All the data available on the chemical, including both experimental animal and human findings, needs to be taken into account. The system encompasses all toxicological end points:

- Acute toxicity arising from single exposure
- Skin, eye and respiratory tract irritancy
- Skin and respiratory sensitization
- Longer-term toxicity arising from repeated exposure
- Mutagenicity
- Carcinogenicity
- Reproductive toxicity, covering both effects on the developing foetus and newborn offspring.

Detailed criteria against which the toxicological (and physicochemical and ecotoxicological) properties of a substance are compared in order to determine its C&L are given in an annex to the directive dealing with substances. Preparations containing one or more hazardous (i.e. classified) substances are classified either by comparing the toxicological properties of the preparation against the same criteria, or by a series of rules based on the concentrations of individual substances present in the preparation.

The label that emerges from the process has three components—danger symbols, in the form of pictograms, phrases indicating hazardous properties ('R' phrases), such as 'toxic if swallowed', 'irritating to eyes' or 'may cause cancer' and phrases indicating basic advice for safe use.

The application of the C&L criteria to toxicological data available on a substance is in some instances quite straightforward. In other cases the findings of extensive and complex toxicological investigations need to be understood and considered before an appropriate judgement is reached. To take one aspect, within the current EU C&L system there are three categories of 'positively' classified carcinogen; there are detailed criteria and guidelines available to steer assessors towards the most appropriate position, within a framework in which the general meaning of the categories is as follows:

- Category 1—confirmed (i.e. directly observed) carcinogen in humans
- Category 2—presumed human carcinogen, that is, carcinogenic potential in humans judged to be likely, based on the available evidence
- Category 3—possible human carcinogen, that is, some evidence for carcinogenicity of potential relevance to humans, but surrounded by significant uncertainty.

Much toxicological endeavour and extensive and sometimes contentious regulatory debate has been expended to resolve matters of the type illustrated in **Table 1**.

Finalized positions on C&L have become ever more important, because classification now enjoys much more significance than merely information transfer. The act of classification represents a gateway beyond which there may be a large number of downstream consequences for a chemical. These are set out in legislation such as the Preparations Directive, the Carcinogens Directive, the Safety and Health at Work of Pregnant Workers Directive, the Chemical Agents Directive and the 'Seveso Directive' on control of major accidents (EC, 1999; 1998; 1996; EEC, 1990; 1992b). Thus, hazard classification can lead directly to risk management stipulations in several different spheres of chemical manufacture and use. For example, substances classified as Category 1 or 2 carcinogens, mutagens or reproductive toxicants are not allowed in consumer products, and Category 1 and 2 carcinogens and mutagens are subject to the strict risk-management specifications of the Carcinogens Directive (definitions of the categories used for classification for carcinogenicity within the EU are given above; classification for germ-cell mutagenicity and reproductive toxicity is based on similar principles).

However, the C&L scheme in itself does not specify an information requirement. Rather, it provides a set of criteria against which the observed or predicted

Table 1 Carcinogenicity classification assigned to three substances found to produce malignant neoplasms in experimental animals

Substance	Findings in carcinogenicity studies in experimental animals	Carcinogenicity classification conclusion
Propylene oxide	Malignant respiratory tract neoplasms in rats	Category 2 carcinogen
Aniline	Malignant spleen neoplasms in rats	Category 3 carcinogen
Diethyl hexyl phthalate	Malignant liver neoplasms in rats	Not classified as a carcinogen

toxicological properties of a substance should be compared, however extensive or sparse the available data. For some substances, a regulatory C&L position has been agreed for legal implementation across the EU. However, for many others the responsibility has fallen on each individual company supplying the substance to 'self-classify' by interpreting the available data against the general criteria and guidance. This situation has (inevitably) led to inconsistency. One such example that our authority has become aware of relates to the substance 3,3′-diaminobenzidine in respect of its carcinogenicity classification.

Benzidine (**Figure 2**) is an established human (bladder) carcinogen and, as such, has a formally agreed regulatory classification in the EU as a Category 1 carcinogen.

3,3′-Diaminobenzidine (**Figure 3**) does not have a formally agreed EU classification and hence the responsibility has fallen on each supplier to self-classify. This substance has a limited toxicological database. It is genotoxic *in vitro* and no *in vivo* genotoxicity studies have been identified. In relation to carcinogenicity, no studies have been performed to current internationally accepted protocols; the results of some rather old and nonstandard studies in small groups of rats and mice do not yield a clear picture of the carcinogenic potential of 3,3′-diaminobenzidine (DFG, 1992).

Information available from a number of different suppliers indicates that 3,3′-diaminobenzidine has been marketed within the EU in recent years with self-classification verdicts for carcinogenicity of not classified, Category 3 carcinogen, or category 2 Carcinogen!

Looking ahead, one key feature of REACH, that of collaboration between companies sharing a common interest in the same substance, holds the promise of eradicating such inconsistency. This is discussed in the REACH section later in this chapter.

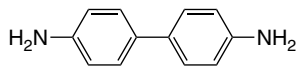

Figure 2 Chemical structure for benzidine.

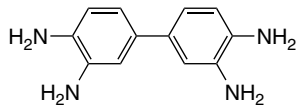

Figure 3 Chemical structure for 3,3′-diaminobenzidine.

5.2 Globally Harmonized Scheme

Stimulated by the 1992 United Nations Conference on Environment and Development (UNCED), the last 15 years have seen the development by the United Nations (UN) of a globally harmonised system (GHS) for the classification and communication of the hazards of substances and preparations (mixtures) (OECD, 2001). The model scheme for the GHS was agreed at the UN level in 2003 (UN, 2003).

The EU has recently embarked on a new regulatory initiative to bring into EU law much of the GHS, via a proposed new 'Regulation… on classification labelling and packaging of substances and mixtures…' (EC, 2007). The detail of this new regulation is under negotiation at the time of writing this chapter. It is currently envisaged that from the end of 2010 substances in the EU will be dual-classified under the stipulations of the existing EU C&L system and the new GHS rules, but labelled and packaged according to the requirements of the new legislation. From mid 2015 all substances and mixtures thereof will be classified, labelled and packaged according to the new regulation only.

5.3 (Material) Safety Data Sheets

Closely associated with C&L, the key component of information transfer from the supplier of a chemical substance or preparation to the recipient/user is the (material) safety data sheet ((M)SDS). In the EU, prior to the arrival of REACH the content of an SDS has been stipulated in the European Union Safety Data Sheets (EU SDSs) Directive (EC, 1993). The disciplines of occupational toxicology and occupational hygiene should come together to summarize the key hazard and control alerts presented in the SDS.

The REACH legislation has subsumed the EU SDS Directive and now stipulates what is required of an safety data sheet (SDS) in the EU. The degree of change in structure from what has gone before is minimal (see

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Section 8). However, experience of SDSs to date is that the quality of their content has been highly variable, with many examples of gaps, errors or ambiguities in information. Under REACH, SDSs will remain a key component of information transfer along the supply chain. It is hoped that the quality of information they contain will improve substantially in future years.

6 USER-SIDE RISK ASSESSMENT AND RISK MANAGEMENT FOR INDUSTRIAL EXPOSURE TO CHEMICALS

To reiterate points made above (see Section 4), the regulatory framework applying to workplaces in the EU has held users of chemicals responsible for understanding the intended local conditions of use of the chemical and setting this knowledge, with its implications for levels, routes and frequencies of exposure, alongside the hazard information. In doing so, the user has been required to make a situation-specific risk assessment and draw conclusions regarding the appropriate risk management measures to apply—and then to apply them. This philosophy is captured within the EU Chemical Agents Directive, implemented in each EU member state by national legislation, such as the Control of Substances Hazardous to Health (COSHH) Regulations (EC, 1998; COSHH, 2004) in the United Kingdom.

In attempting to help the user, *regulatory authorities* have specified some risk-management measures, in earlier years chiefly by extolling adherence to specified OELs for the airborne substance. This picture has started to change somewhat in recent years and the advent of REACH promises further changes. The progression to this situation is discussed below.

6.1 Occupational Exposure Limits (OELs)

6.1.1 General Principles of OELs

An OEL serves to indicate an 'appropriate' (this could be defined in a variety of ways) level for the control of exposure to an airborne substance in the workplace.

A very strong traditional representation of the process and impact of establishing OELs would run as follows. For an individual substance under consideration, the occupational toxicology profession would examine the toxicological profile of the substance to ascertain its toxicological hazards, their associated dose–response characteristics and the surrounding issues of route, frequency and duration of exposure connected with the possible appearance of the hazardous properties. Then, against a criterion for an OEL being, for example, the highest level of exposure at which no adverse effects on health would be anticipated, a toxicological judgement is made to derive the OEL value. Then the occupational hygiene profession comes in. The concept is that the OEL value is used to establish the control regime that would bring exposure to a level at or below the OEL. The associated imagery is that the occupational hygiene profession will be engaged on monitoring the airborne exposures arising in the manufacture and use of the substance, to ensure that the control of exposure to the OEL is being secured.

A variation on this process is where consideration of the practical and economic consequences of securing control to a particular airborne level is an integral part of the OEL-setting process. This approach has been used in the UK in situations where, for example, there is doubt about where a no-effect level for human exposure might lie, such as for a poorly investigated substance; or where it has not been possible to identify with confidence a no-effect level for humans, such as for a genotoxic carcinogen. In such circumstances occupational-hygiene expertise comes in earlier, to assess contemporary exposure levels and the cost and achievability of control to one or more possible lower levels of exposure, leading ultimately to determination of the eventual OEL.

These concepts and approaches have been the basis of the practice of setting OELs, an activity that has been a central plank of occupational toxicology and occupational hygiene thinking and work for more than half a century.

6.1.2 Emergence of Early OEL Lists

The first published OEL is held to be the value of 500 ppm carbon monoxide, put forward by Max Gruber in the late nineteenth century and derived from studies involving 12 rabbits, two hens and himself! (Paull, 1984). The basis was the avoidance of immediately recognizable acute effects, as it was in the first lists of harmful concentrations of substances in air that began to appear in the first quarter of the twentieth century, mainly from toxicological work performed in Germany (see Section 3).

Almost no toxicological information beyond acute toxicity and irritancy was available for substances at this time. From the 1920s, some information became available on dose–response relationships for long-term exposure to a few familiar toxicants—lead, mercury, crystalline silica, benzene—and the stated purpose of listing 'maximum allowable concentrations (MACs)' gradually changed to one of protecting the workforce against ill-health when exposure was occurring daily over a working lifetime.

Perhaps the single most significant development in this area was the establishment, in the 1940s, of the Threshold Limits Committee of what was first the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

National, and then became the American Conference of Governmental Industrial Hygienists (ACGIH), in the USA. This committee used pre-existing information and its own experience to construct and adopt its first list of MACs, comprising limit values for 160 substances, in 1946. The list of what soon became known as threshold limit values (TLVs) was first published in 1950 (ACGIH, 1950). Over the subsequent 60 or so years the TLV list has grown, as has the amount of supporting information documented in support of the rationale for the values listed.

6.1.3 Proliferation of OEL Lists

The ACGIH TLVs were extremely influential in the USA and also across the world in the second half of the twentieth century. Many countries used the values either as guidance or as the basis for national legal standards. Even now, when other systems have come and, in some cases, gone or are on the way out, listings of OELs persist in many parts of the world and contain values inherited directly from TLV lists of the past.

From about 40 years ago, institutions in various parts of the world started to establish their own systems for producing OELs, via assessment of the available toxicology and, in some cases, occupational exposure data. The first such system developed in Germany. In 1968 Germany ceased to adhere automatically to the ACGIH list and began a programme of generating its own OELs under the Maximale Arbeitskonzentrationen (MAK) Commission. Since then the MAK Commission has produced its own annual listing of limit values (DFG, 2007).

Other systems then developed, including those in the Netherlands, the UK, Nordic countries, Australia and Japan. Alongside these systems, the USSR (as was) had its own system of establishing OELs that began in the 1930s, largely based on Russian literature with findings somewhat at odds with the western world consensus at the time (Sanotsky *et al*., 1986).

From the beginning of the 1990s the EU, via one of its Directorates General (DGs) now known by the summarized title of DG Employment, developed a system for introducing EU-wide OELs (details are provided on the DG Employment web site; a link is given under Further Reading). The EU system has the potential for two types of OEL to be introduced, under the umbrella of the Chemical Agents Directive (EC, 1998). The indicative occupational exposure limit value (IOELV) is envisaged to be health-protective, in that there is confidence that adherence to it will avoid any ill-health consequences of exposure to the substances in question. The binding occupational exposure limit value (BOELV) is envisaged to reflect a balanced judgement between health, practicality and socioeconomic considerations, for substances where a health-based limit cannot be identified and/or control of such a limit cannot be achieved.

To assist it in the process of establishing EU OELs, DG Employment has its Scientific Committee on Occupational Exposure Limits (SCOEL). This committee of prominent EU experts in the field of chemicals and occupational health examines and debates the toxicological evidence and analytical methods available for a substance, and endeavours to make OEL recommendations to DG Employment. IOELVs are negotiated and implemented via EU Directives.

6.2 Effectiveness of OELs; Control-Banding Approaches

In the last 10–15 years, in the UK and some other countries, there has been some serious questioning of the reality of the above picture (see Section 95.6.1.1), and the effectiveness of tabulated lists of OELs for hundreds of individual substances. It could be argued that, to a large extent, the difference between what happens in reality and the standard representations made earlier in this section is a consequence of limitations in the availability of occupational hygiene resource, particularly at sites of receiving and using chemicals. Research conducted in the UK in the mid-1990s, in relation to the list of regulatory OELs in the UK at that time, indicated a disappointing lack of awareness and utilization of these OELs in company decision-making about chemical control (Research International, 1998). Two other key themes emerged at about this time: many smaller companies wanted to be instructed in how to secure appropriate control, rather than have to work out for themselves the control solutions; and for very many substances relatively little monitoring of exposure was occurring—and the extent of exposure monitoring seems to have been diminishing still further in recent times.

The consequence of these influences has been the development of 'control-banding' schemes. One such scheme developed in the UK is 'COSHH Essentials' which can be accessed at *www.coshh-essentials.org.uk*. Another scheme based on similar principles is the Dutch 'Stoffenmanager' scheme which can be accessed at *www.stoffenmanager.nl*.

Control-banding schemes operate on the principle that the identified toxicological hazards of a substance define its allocation to a particular category, group or band that is associated with an approximate level of occupational exposure deemed to be appropriate for substances possessing such properties. For any substance within a particular group, associated knowledge of how and in what quantities it is being used, together with its propensity to become airborne, is then used to determine the appropriate control strategy to be applied to the use of that substance in a particular industrial setting.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The two major advantages of such schemes are that: (i) they can embrace every substance, rather than be limited to those substances for which a position (OEL) is listed and (ii) they provide users of substances with practical control advice, rather than (simply) an exposure level to be achieved.

The concept has become a gradually increasing focus of attention during the last 10 years. It has had a major influence on the concept of 'exposure scenarios' under REACH; this is discussed further in the section on REACH.

6.3 Biological Monitoring and Biological Limits

In a manner that can complement the measurement of airborne exposures and the use of OELs as control standards for airborne exposure, biological monitoring involves the measurement of a substance and/or its metabolite(s) in body fluids (usually urine or blood) or exhaled breath. A closely related concept is that of biological-effect monitoring, the measurement of a biochemical change in the body caused by exposure to a substance, the degree of change being below that associated with frank ill-health.

Biological limits are standards, based on biological monitoring or biological-effect monitoring, against which the results of biological (effect) monitoring can be compared to assess adequacy of control.

In general, biological (effect) monitoring gives a more accurate assessment of individual intake of a substance, compared with atmospheric monitoring, and is particularly useful in the following respects:

- To assess the extent of substance intake via routes other than inhalation (skin, ingestion)
- To track the potential accumulation of substances in the body resulting from long-term repeated exposure
- To examine the effectiveness of personal protective equipment (PPE) in guarding against exposure to and intake of substances.

The two most productive systems establishing biological limits are those of the ACGIH in USA and the MAK Commission in Germany, with their biological exposure indices (BEIs) and biological tolerance values (BATs), respectively. Other systems for setting biological limits exist, including the system for establishing Biological Monitoring Guidance Values (BMGVs) in the UK. The EU Chemical Agents Directive and derivative legislation also makes provision for EU biological limits, but as yet there has been little attempt to see such values introduced.

Throughout the world, the number of substances for which biological limit values exist (with associated reliable measurement methods) is less than 100. The approach is potentially very useful in some circumstances involving exposure to particular substances; for example, it has a long history of compulsory use in relation to monitoring occupational intake of lead. However, its practical use is restricted to a modest number of specified substances.

The above section has discussed the manner in which the 'user' side of industry has been required to assess and manage the risk involved in chemical exposure at its worksites. In so doing, a user company has needed to make the best of whatever information has come through the supply chain, alongside any stipulations and guidance from regulatory authorities. The next section looks at some initiatives that have been taken in the EU in the recent past to put more responsibility on to supplying companies to better assess and meet the information needs of user companies.

7 PREVIOUS (PRE-REACH) SUPPLY-SIDE DATA-GATHERING AND RISK-ASSESSMENT PROGRAMMES IN THE EU

7.1 EU 'New Substances' Legislation (1979–2008)

In its first initiative to improve the information available on industrial chemicals, the EU introduced, at the beginning of the 1980s, legislation requiring a package of data to be generated for industrial chemicals new to the EU market. The extent and quality of this information had to be deemed satisfactory by the relevant regulatory authorities before the substance could be marketed. This has been known as the 'Sixth Amendment', and later the 'Seventh Amendment' legislation, these being amendments to the original 1967 European Directive on substance C&L (EEC, 1979; 1992a). Each member state has been required to have its own national legislation and associated competent (regulatory) authority to implement the requirements of the Directive. These regulations covering *new* substances operated until the middle of 2008, whereupon they were supplanted by the advent of the REACH regulations (see Section 8).

In their first 'Sixth Amendment' form, the regulations concentrated on information generation and the communication of hazardous properties using the EU C&L system. Toxicity testing, in accordance with standard OECD test guidelines, was required, the extent being tiered according to tonnage to be placed on the EU market. Conformity with expectations was checked by Member State Competent Authorities (MSCAs). The principle was that new substances, and preparations

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

containing them, being supplied to workplaces (and elsewhere) arrived for the first time with some of their toxicological (and physicochemical and ecotoxicological) properties having been explored. Where indicated by the findings of such exploration, the relevant hazardous properties would be shown on the label and in the (material) safety data sheet. Subsequently, if the quantity of the new substance on the market increased, more extensive testing was considered, embracing a wider range of toxicological end points and/or a greater depth of exploration of individual issues.

The 'Seventh Amendment' expanded the ambition of this *new substances* legislation, in that the focus became, not only hazard identification, but also risk assessment. This has required suppliers of new substances to take increased responsibility for understanding the potential exposure and therefore risk situations that could be created in the downstream use of the supplied substance, and to ensure that appropriate advice was transmitted to recipients to facilitate adequate exposure control and risk management. This development ushered in an important new feature, that of suppliers of substances taking responsibility for securing their safe use by recipients, a crucial principle that has come through into the REACH era (see later). Delivery of such a responsibility clearly requires collaboration between the disciplines of toxicology and occupational hygiene.

For *new* substances notified to the regulatory authorities at the premarketing stage, the obvious problem arises that experience has not yet been gained from which to measure directly the characteristics of exposures in use. Hence there has been a need to develop the means of predicting exposure by way of modelling. Within the EU, several approaches have been developed to meet this requirement for occupational exposure prediction, such as the knowledge-based system Estimation and Assessment of Substance Exposure (EASE) (HSE, 1995). Such models use information on the physicochemical properties of a substance and the intended characteristics of any use situation (type and scale of use, intended exposure controls, such as local exhaust ventilation) and make predictions of likely exposure either by matching such information to pre-existing knowledge of exposures created in other comparable circumstances, or by making a prediction from first principles. The occupational hygiene profession has always stressed that the predicted numerical values or ranges obtained from such models represent rough initial estimates that, as a description of any particular situation, should be considered and interpreted by an experienced occupational hygienist. The use of such exposure modelling techniques has come through into the guidance for fulfilling some responsibilities under REACH (see later).

In three decades of operation of the new substances legislation, the number of known cases of toxicity arising from exposure to a new substance within the EU is very small. This could be taken to be a strong vindication of the value and effectiveness of the legislation. However, there was always a view from industry, sometimes also voiced by others, that the legislation was too onerous—bureaucratically, in terms of the interactive process with regulatory authorities, and financially, because of the cost of commissioning toxicity (and other) testing. Associated with the latter point was a feeling that there was too much use of experimental animals to test substances that regularly showed (and, with hindsight, might have been predicted to show) little or no significant toxicological potential. Certainly the UK regulatory authority encouraged and made ever-increasing use of grouping, read-across and other structure–activity approaches, and other types of arguments, waiving the need for a test to be conducted, wherever the predictions appeared valid and beneficial in economizing on animal experimentation.

In the late 1990s the desire to change the new substances legislation grew to an extent that it has been supplanted by the REACH regulation, developed and implemented over the subsequent 10 years, in which there is no distinct identification of *new* substances. Nevertheless, many of the features of REACH are adaptations of the principles and approaches of the former new substances legislation. Importantly for toxicology, the sociopolitical pressure in the EU to minimize experimental-animal testing has continued to grow, such that REACH provides strong encouragement for imaginative alternative ways of compiling toxicological profiles of substances that are sufficiently dependable to permit appropriate regulatory judgements, without recourse to undertaking new animal experimentation.

7.2 EU Existing Substances Regulation (ESR)

In the early 1990s the EU introduced the Existing Substances Regulation (ESR) (EEC, 1993). ESR embraced similar principles to those of the 'Seventh Amendment' legislation for new substances, in that suppliers of substances (but this time substances already familiar to the EU market) were held responsible for working with regulatory authorities to address the hazardous properties of substances, and the exposure conditions and risks (to human health and the environment) that could arise in the manufacture and use of the substance. The objective was to secure appropriate exposure control and risk management of important existing industrial chemicals by instructions and measures applied through the supply chain. As for new substances legislation, ESR required each EU member state to appoint a national competent (regulatory) authority (CA).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

ESR required:

1. Collation by industry of all relevant, reliable data already available on an existing substance, including toxicological and exposure data, in a computerized proforma called a harmonized electronic dataset (HEDSET), to be sent to a central regulatory point, the European Chemicals Bureau at Ispra in Italy.
2. Storage of this information on a database called IUCLID (International Uniform Chemical Information Database) and use of the knowledge of and concerns about individual existing substances by the European Commission and EU member states' CAs to select priority substances for regulatory assessment.
3. For a selected priority substance, compilation by a *rapporteur* EU member state of an extensive document detailing the hazardous properties of the substance, its dose–response characteristics, exposure assessment and assessment of the risk judged to be involved for various sectors of the human population, including all workplace situations (and the environment) encountering the substance.
4. For each priority substance assessed, to arrive at an ultimate conclusion about the acceptability or otherwise of the risk of adverse consequences in every situation in which the substance could arise to a significant extent; wherever it was deemed that an unacceptable risk might arise, risk reduction measures to mitigate the risk were brought into play. A third, interim conclusion was also possible, that further information was required, possibly including the need for suppliers to commission additional toxicity testing in experimental animals, before a final conclusion could be reached about the risk posed in any particular situation in which the substance was present.

The features of ESR clearly indicate the need for toxicology and occupational hygiene to work in close collaboration, in addressing workplace exposure situations. It was found that occupational exposure measurements for many of the circumstances that needed to be considered were often sparse or nonexistent, necessitating the use of the predictive modelling skills of occupational hygienists to fill such gaps.

Some major difficulties arose with ESR. One was the lack of preparedness and apparent inability of industry to identify and characterize from the point of supply all of the potential workplaces, working practices and associated exposure situations that could arise with a particular substance. This led to a related, but even more general problem that the demands placed on individual ESR competent authorities to compile the extensive documents required, including the coverage of issues that supplying companies had been unable to address satisfactorily, defeated the resources available within these authorities. The rate of progress of priority substances within the ESR process and the numbers of substances that had completed their passage through the process in the 15 years of its operation were well below what was desired by the EU regulatory system when the legislation was being developed. The slow progress was identified in the late 1990s, and ESR has now been supplanted by the REACH regulation which, conceptually, aims to remedy the deficiencies that emerged under ESR.

8 REACH—A NEW ERA

REACH stands for the Registration, Evaluation, Authorization and Restriction of Chemicals. In total it replaces about 40 pieces of chemicals legislation in the EU and is intended to streamline and improve the way chemicals are regulated. It removes the arbitrary division of chemicals into 'new' and 'existing' substances and aims to place all chemicals under the same regulatory framework. REACH places important obligations on suppliers, but also imposes duties on downstream users and will have a much more direct influence on the way the risks arising from the use of chemicals are managed.

The key aims that the EU hopes to achieve with REACH are:

- To improve the protection of human health and the environment from risks posed by chemicals
- To promote alternative methods for hazard assessment
- To enhance the competitiveness of the European chemicals industry
- To ensure free circulation of substances on the internal market of the EU.

These are ambitious aims that carry within them the apparently conflicting public desires for a better understanding and control of risks arising from the use of chemicals and a move away from the use of animal models for toxicity testing. One way the European Commission hopes to achieve this is by requiring industry to share test data obtained from animal studies. In the longer term it is hoped that these aims will stimulate the development of new and better approaches to hazard evaluation.

8.1 Scope of REACH

REACH is very broad in scope. It deals with substances; substances used on their own and as they are used in preparations and in articles. REACH applies to most chemicals and it applies to most uses of chemicals. Very few chemicals are exempted from all of the provisions of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

REACH but exemptions from certain aspects are given to substances that have undergone extensive evaluations under other legislative programmes, or where limited exposure can be demonstrated; or where substances have been demonstrated to be of intrinsically low hazard. Exemptions from certain aspects of REACH are also granted for the purpose of product and process oriented research and development (PPORD) to facilitate the development of alternative substances and processes. Exemptions are described in the legislation.

8.2 Elements of REACH

There are four key elements to REACH:

Registration —is the process by which manufacturers and importers into the EU provide information on the substances that they supply to a new central coordinating body, the European Chemicals Agency (ECHA), based in Helsinki, Finland.
Evaluation —encompasses the various checks on this information from the simple completeness checks performed on all registration dossiers to the in-depth reviews that will be carried out by MSCAs on priority substances according to a rolling plan of action.
Authorization —is the mechanism by which substances with properties deemed to be of the highest concern will be phased out of use, if the risks involved in their continued use are judged to be unwarranted.
Restriction —is the mechanism by which MSCAs and the European Commission can identify and further limit the manufacture, supply and/or specific uses of substances where the risks involved in current situations are judged to merit more stringent control.

8.3 Registration and Evaluation

All manufacturers and importers of substances who supply to the EU market in quantities of 1 tonne per annum or more are required to register their substances with ECHA in order to be able to continue to supply (for substances already on the market) or in advance of supply (for substances new to the market). In order to register, manufacturers and importers need to provide a dossier of information on that substance. The amount of information that each manufacturer or importer is required to provide depends on the tonnage that the manufacturer or importer supplies, with stepwise increases in data requirements for the four tonnage bands (1–10 tonnes per annum, 10–100 tonnes per annum, 100–1000 tonnes per annum and >1000 tonnes per annum). This reflects the data-gathering process that was successfully used to gather hazard information under the previous 'new substances' legislation (see Section 7.1). There is also a requirement for suppliers to consider how their substances are being used within their own company and for all downstream uses (including consumer uses) and whether there are potential releases to the environment at different life-cycle stages. The life cycle covers all stages from manufacture to eventual disposal, including all workplace and consumer uses. If the substance is present in articles it may be necessary to consider the service life of those articles. It may also be necessary to consider the potential for human and environmental exposure during recycling. Where potential risks to human health or the environment are identified, suppliers must determine the measures necessary to adequately control those risks and must disseminate information on the operating conditions and risk management measures necessary to secure adequate control through the supply chain. This is done by means of exposure scenarios describing appropriate control strategies which are incorporated into extended safety data sheets (e-SDSs).

In the model envisaged under REACH, the onus is placed on suppliers (manufacturers and importers at the top of the supply chain) to detail the hazards and appropriate control strategies for the substances that they supply. The onus is on downstream users to apply the control strategies correctly in their respective workplaces, taking into account workplace-specific factors that might influence the efficacy of the control measures that are recommended. Downstream users are also required to communicate information on experience in use back up the supply chain to enable suppliers to optimize their risk assessments.

It is intended that the regulatory process under REACH will be transparent. To this end, ECHA will make publicly available via its web site as much information as possible from registration dossiers and the regulatory decision-making process, without compromising the need to protect confidential business information. The ECHA web site can be accessed at: *http://echa.europa.eu*.

The duty to register chemicals new to the EU market came into force on 1 June 2008. Owing to the large number of chemicals that are currently placed on the EU market in quantities of 1 tonne per annum or more (estimated to be around 30 000) the duty to register chemicals that are currently on the market is being phased in over a 10-year period. The timescales are illustrated in **Figure 4**. In order to take advantage of the phase-in deadlines, suppliers must have 'pre-registered' the substances they currently supply by 30 November 2008. The final deadline for registration of substances currently on the market is 1 June 2018, so by this time there should be core information on hazards and potential risks for every chemical that is supplied onto the EU market in quantities of 1 tonne per annum or more. Registration of chemicals new to the market is envisaged to be a continuing requirement beyond 2018.

In order to encourage harmonization of the hazard and risk management information that individual

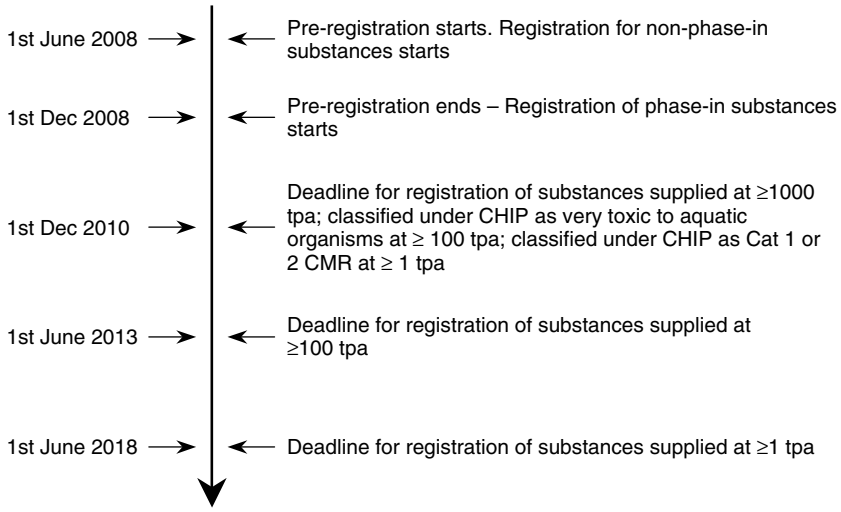

Figure 4 Timeline for implementation of registration requirements. CHIP: Chemicals (Hazard Information and Packaging for Supply) Regulations 2002; CMR: carcinogenic, mutagenic or toxic to reproduction; tpa: tonnes per annum.

suppliers disseminate through their respective supply chains, companies wishing to register a particular chemical are encouraged to 'pre-register' their interest in the substance. ECHA will then facilitate each such company joining with other companies wishing to register the same chemical in groups called Substance Information Exchange Forums (SIEFs). SIEFs enable companies to collaborate on the preparation of registration packages and share the costs. Registrants are legally obliged to share data obtained from animal test models and are encouraged to share data obtained by other types of test. In this way it is hoped that there will be a shared understanding of the hazardous properties of substances between suppliers and that this will lead to harmonization of the hazard information, C&L and recommended risk-management measures that each company provides addressing the current problems with inconsistent information between suppliers (see Sections 5.1 and 5.3).

The core data requirements for chemicals supplied in quantities of 1–10 tonnes per annum are light, at least for toxicity and ecotoxicity data. However, if it is available, companies must also submit any extra information beyond the core data requirements for their tonnage band. For example, if a carcinogenicity study had been published in the open literature this will need to be included, even if a particular registrant is only supplying at 1 tonne per annum.

The registration package for the 1–10 tonnes per annum band comprises a dossier, covering the identity of the registrant and the substance being registered plus the technical information outlined below. Registrants supplying at 10 tonnes per annum or more must also provide a chemical safety report (CSR). This documents the hazard assessment and, if required, exposure assessments and risk characterization that the supplier has performed and is the tool for identifying measures necessary to control the risks that have been identified. The chemical safety assessment (CSA) and report is discussed in more detail below.

8.3.1 1–10 Tonnes Per Annum

At the 1–10 tonnes per annum band, the minimum hazard data set includes extensive information on physicochemical properties. Toxicity data includes: information on skin and eye irritation potential based on pH or *in vitro* data; if there are no existing skin sensitization data, a local lymph node assay (LLNA) is required; registrants need to submit an *in vitro* mutagenicity test in a bacterial test system and an acute oral or acute inhalation toxicity test needs to be provided. Some ecotoxicological data are also required.

Suppliers must assign appropriate hazard C&L to their substance, based on all available data. Initially this will refer to the criteria laid out in Directive 67/548/EEC, but in the future it will refer to the criteria developed for the GHS, to be implemented within the EU as the Classification, Labelling and Packaging (CLP) Regulations, (see Section 5). It is hoped that there will be a greater degree of harmonization in the hazard C&L assigned by suppliers through collaboration in the preparation of registration dossiers. It is intended that EU regulatory committees and authorities will debate and agree harmonized C&L positions for substances only for carcinogenicity, mutagenicity and reproductive toxicity end points.

Within a registration dossier there is a requirement to provide general descriptive information on manufacture and use covering:

- Use categories for industrial, professional and/or consumer uses

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- A brief description of the manner in which it is being used, for example, in closed systems, or included into a matrix, nondispersive and dispersive uses
- An indication of significant routes of exposure for humans (i.e. oral, dermal and inhalation) and the environment (i.e. water, air, solid waste and soil)
- Patterns of exposure (i.e. will exposure be accidental or infrequent, occasional or continuous/frequent).

The supplier will also identify uses advised against. These are uses that the supplier is aware of, but is not prepared to support due to concerns for safety. The use information that is required will be sufficient to identify uses where there is the greatest potential for exposure, but will not be sufficient for the quantitative exposure assessment that is required at higher tonnages. It is anticipated that control measures will be implemented where there is a potential for exposure and limited information on potential hazards, which might well be the case for low-tonnage substances.

The technical dossier will also include guidance on safe use. This is the information that would typically appear within an SDS. SDSs are intended to provide: information on the hazards of the material being supplied; some generic advice on risk-management measures for handling, transport and storage; action to be taken in the event of a fire or spill and information on any regulations, for example, OELs that may apply to that material. Until now, information provided in SDSs has often been incomplete, risk-management advice has been generic and very basic and SDSs from different suppliers have not always been consistent (see Section 5.3). Under REACH, SDSs will continue to be a vehicle for communicating hazard information and risk-management advice along the supply chain. However, it is hoped that the need to generate core data sets and the collaborative approach encouraged for registration will improve the quality and consistency of the information included in SDS. Furthermore, there is a requirement for all SDSs to include contact information for the person responsible for its content, enabling recipients to seek clarification if required. Where exposure scenarios have been prepared these must be appended to the SDS, forming the e-SDS.

8.3.2 10–100 Tonnes Per Annum

Registrants supplying at 10 tonnes per annum or more are required to provide additional data on toxicological and ecotoxicological hazards. At the 10 tonnes per annum threshold this will include, in most cases, short-term repeated-exposure toxicity data and a screening test for reproductive/developmental toxicity. It is possible for a registrant to argue against the need to conduct repeated-exposure and reproductive toxicity testing at this level of supply, if they can confirm that there will be no human exposure arising from any of their own uses and any downstream uses. This may be the case for substances that are used in a limited number of industrial processes for which there is a high level of control and where there is no release to the environment, such as a catalyst that is consumed entirely in a chemical process.

8.3.3 100 Tonnes Per Annum and Above

Longer-term toxicity data are required once supply reaches the 100 and 1000 tonnes per annum thresholds. However, if such data are not already available, companies must not automatically conduct new experimental animal tests, but must submit testing proposals to ECHA. The testing proposal should take account of the hazardous properties that have already been identified and should focus on obtaining information necessary to clarify uncertainties in the data, rather than simply conducting tests because it is an automatic regulatory requirement. Each testing proposal submitted to ECHA will be evaluated to determine whether the tests being proposed are the most appropriate to obtain the information that is required. In evaluating the testing proposal, ECHA will consider whether sufficient information can be obtained from existing studies or whether the information could be obtained by other means, for example, *in vitro* methods, read-across to similar substances, use of structure–activity relationship information and so on. It will also be possible to use arguments based on limited or tightly controlled exposure to justify nonconduct of long-term repeated-dose and reproductive toxicity testing. In order to justify this waiver, a registrant must demonstrate that there is 'no significant' human exposure. This is done by generating exposure scenarios to allow exposures during use to be quantified, and comparing this to a level of exposure at which risks are expected to be minimal (this process is described in more detail below). For low-hazard materials, there is no need to generate any additional exposure information beyond the general descriptive information outlined above. Registrants may therefore need to weigh up the costs of conducting long-term toxicity tests against the costs of quantifying exposure during use to demonstrate that adequate control is being achieved. In the case of carcinogenicity, new testing should only be proposed for substances with widespread dispersive use, or uses that are likely to lead to long-term human exposure, and where there is evidence for mutagenic activity or effects indicating potential carcinogenic activity have been seen in repeated-exposure studies. By adopting this approach it is hoped that suppliers will be prompted to take a scientific-need-based approach to data generation and that the scientific community will be encouraged to develop alternatives to the traditional animal-based methods to complete toxicity profiles.

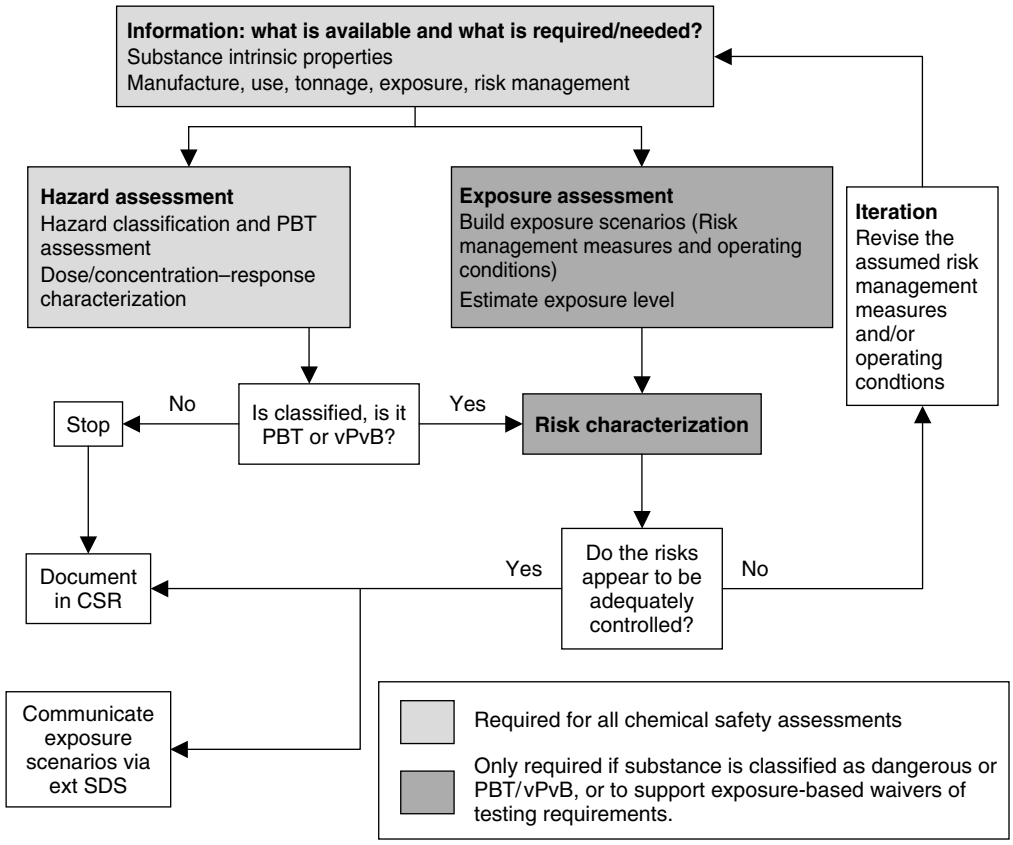

Figure 5 Illustration of the risk assessment process under REACH (based on ECHA, 2008a). PBT: persistent, bioaccumulative and toxic; vPvB: very persistant and very bioaccumulative.

8.4 Chemical Safety Assessment and Report

A CSR is required for all registrations for chemicals supplied in quantities of 10 tonnes per annum or more. It provides a written record that the registrant has undertaken a CSA and documents the outcome of the assessment. The CSA is the process by which a supplier characterizes the risks that their substance poses in any of the situations in which it will arise and determines the measures that are necessary to control those risks. An illustration of the risk-assessment process that will be followed under REACH is given in **Figure 5**.

The CSA is a two-stage process. The first stage involves an assessment of the hazardous properties of the substance and identification of the levels of human and environmental exposures that are deemed to be acceptable. If no hazards are identified there is no need to progress beyond this stage. If a substance is determined to be hazardous, that is, it meets the regulatory criteria for hazard classification for any end point, or is of concern because it is determined to be persistent, bioaccumulative and toxic (PBT) or very persistent and very bioaccumulative (vPvB) in the environment, the supplier moves to the exposure assessment and risk characterization stages. The following text focuses on the human-health risk-assessment process. A similar approach is followed for the environmental risk assessment. Detailed guidance on all aspects of the CSA process has been published on the ECHA website (ECHA, 2008b).

8.4.1 Hazard Assessment and Identification of Acceptable Levels of Exposure

Under REACH, acceptable levels of exposure are determined from data on the hazardous properties of the substance. In the case of human exposure, the acceptable levels are referred to as derived no-effect levels (DNELs). Depending on the hazards and uses for a substance, it may be necessary to derive DNELs for oral, dermal and inhalation exposure, for local and systemic effects arising from short-term/peak exposures and long-term exposures and for workers, consumers and for indirect exposures via the environment. These DNELs will then be compared with the exposures that are assessed to occur during various uses and life-cycle stages. Although the DNEL is intended to act as a benchmark against which the estimated levels of exposure will be judged, it will not have the same regulatory status as, for example, an OEL. For hazardous properties for which it is not possible to identify with confidence a no-effect level, such as is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

often the case with mutagenicity or genotoxic carcinogenicity, REACH has the concept of a derived minimal effect level (DMEL). A summary of the processes by which the DNEL and DMEL are derived is given in Box 1.

Where measured or predicted exposures are found to be below a DNEL or DMEL they will be deemed to be acceptable. If exposures are initially anticipated to be above the DNEL or DMEL then the situation appears unacceptable. However, first the registrant should look to refine their exposure and possibly also hazard assessments, in the latter case particularly if uncertainty in the hazard data has caused the registrant to introduce a number of multiplicative factors in deriving the initial DNEL value. Such a reconsideration might bring about a change in the position. The ultimate goal is to bring the situation to one where control of exposure is adequate, defined by measured or predicted exposures under the control regime advocated being below the relevant DNEL (or DMEL) value.

Box 1 Derivation of a DNEL or DMEL

- The first stage in the derivation of a DNEL is the identification of the critical health effect(s) that are relevant for the exposure pattern that is being assessed. For example, irritation may be the most relevant effect for short-term peak exposures. It is also necessary to identify whether the critical effect is mediated by a mode of action for which a threshold could be anticipated or whether the effect is a mutagenic or carcinogenic effect for which it is not possible to identify with confidence whether or not a threshold dose exists. Having identified the critical effect and mode of action it is then necessary to identify the most appropriate dose descriptor (e.g. a no (lowest) observable adverse effect level (N(L)OAEL), a benchmark dose (BMD), an LC50 or LD50, or a risk estimate obtained from an epidemiological study or some other descriptor). For threshold-based effects, for example, respiratory tract irritation, the dose descriptor is modified using assessment factors to take account of differences in the exposure patterns used for the key study and the anticipated pattern of human exposure, for example, to extrapolate from a six hour experimental exposure to an eight hour working day or to take account of differences in bioavailability if route-to-route extrapolation has been used. Additional factors are used to take account of inter- and intraspecies differences, differences in the duration of exposure (for example to extrapolate from a 90-day study to an anticipated lifetime exposure) and uncertainties in the data to arrive at the DNEL.
- In a situation where the critical effect is considered to arise through a mode of action for which it is not possible to identify with confidence whether or not a threshold dose exists, the aim is to define a level of exposure at which there is anticipated to be a minimal residual risk. This is referred to as the derived minimum effect level (DMEL) and it is determined using a semiquantitative approach. The starting point will normally be a T25 or BMD10 value. As before, it may be necessary to modify the starting point to take account of differences in exposure patterns. Two approaches may be taken to covert the modified dose descriptor to the DMEL. The first method involves linear extrapolation from the modified dose descriptor to a dose that is estimated to give a particular level of risk for the effect (e.g. 10−4, 10−5, 10−6, etc.). The actual level of risk that would be used is a matter for policy-makers to decide. Where this approach is followed, assessment factors to take account of inter- and intraspecies differences are generally not recommended because of the very conservative nature of the approach. An alternative method might involve the use of an assessment factor in the region of 10 000 to take account of inter- and intraspecies differences, uncertainties in understanding of the nature of the carcinogenic process and the fact that there is an identified risk at the starting point (i.e. the BMD10 or T25 values reflect levels of effect rather than NOAELs). Such a large assessment factor would move one to a relatively very low exposure, at which one might expect that the risk of an adverse effect occurring would also be very low.
- If it is not possible to identify a suitable dose descriptor, then a qualitative approach may be used. The qualitative approach involves selection of risk-management measures that are anticipated to provide a stringent level of control for the identified risk. Further information is available in the Chemical Safety Assessment Guidance (ECHA, 2008b)

8.4.2 Exposure Assessment, Risk Characterization and Identification of Appropriate Operating Conditions and Risk-Management Measures

The exposure assessment needs to consider each identified use and all life-cycle stages that are relevant to the identified hazards. In order to characterize exposure, detailed information needs to be obtained for each use

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and life-cycle stage on the factors that determine exposure by all relevant routes (including skin, inhalation and possibly also the oral route).

Determinants of exposure include:

- Substance-specific factors, such as volatility, particle size, chemical reactivity, and so on
- Factors relating to the operating conditions for the process, such as the type of activity, the scale, how frequently it is carried out, the process temperature, and so on
- Factors relating to any risk management measures that may be in place, for example, local exhaust ventilation (LEV) or personal protective equipment (PPE) and the effectiveness of these measures. Product packaging may also be designed to limit exposure during use and this will also need to be considered.
- Factors relating to the surroundings in which the task is performed; for example, is the task performed indoors or outdoors, in small or large spaces, what levels of natural ventilation may be present and so on.

Once assembled, the information will be used to construct exposure scenarios. The format used to describe an exposure scenario is illustrated in **Figure 6**. Exposure scenarios describe a set of process-operating conditions and risk-management measures that may be applied for a particular task and enable exposure under that particular set of circumstances to be quantified. Measured data may be available that are representative for the operating conditions and risk-management measures that are described. However, in many cases the absence of reliable exposure measurements for the situation of interest means that it will be necessary to use models.

The occupational-exposure models that are currently recommended to estimate workplace exposure are deterministic models that rely on conservative assumptions. They provide a 'reasonable worst-case' estimate of exposure. The preferred model is the targeted risk assessment (TRA) tool developed by the European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) (ECETOC, 2004) which can be accessed at *www.ecetoc.org*. This is based on the EASE model (see Section 7.1) and provides estimates of inhalation and skin exposure. It does not take account of the use of PPE. If it is not possible to use this model, a German control-banding tool 'EMKG' based on the COSHH Essentials scheme developed in the UK (see Section 6.2) may be used where inhalation exposure is of concern; it can be accessed at *www.baua.de* (BAuA, 2006). These models can be used as the basis for a conservative 'Tier 1' assessment. A more sophisticated model is the updated version of 'Stoffenmanager', (version 3.5, due to be published during 2009). This will provide quantitative estimates for inhalation exposure to vapours, aerosols of low-volatility liquids and dusts, and will also provide quantitative skin-exposure estimates. At present, a complete, validated 'Tier 2' exposure assessment tool is not available, though work is underway to develop appropriate tools. The provision of better models to predict exposure is an early goal for the European Commission and the chemicals industry to facilitate the implementation of REACH.

Exposure models are also available that address exposures arising from the use of consumer products or estimate indirect human exposure via the environment.

The generation of exposure scenarios is likely to be an iterative process requiring good communication between suppliers drafting the exposure scenarios and downstream users, who have a much better understanding of the conditions within their workplace. Where an exposure scenario has been shown to produce an unacceptable level of exposure, the registrant (with input from downstream users) must rework the exposure scenario, including a more stringent set of controls. The goal is to identify the operating conditions and risk management measures that are required to achieve levels of exposure at or below the DNEL or DMEL. Looking at the process by

1	Short title of the exposure scenario
2	Process and activities covered by the exposure scenario
Operational conditions of use	
3	Duration and frequency of use
4.1	Physical form of substance or preparation; surface-volume ratio of articles
4.2	Concentration of substance in preparation of article
4.3	Amount used per time or activity
5	Other relevant operational conditions of use
Risk-management measures	
6.1	Risk-management measures related to human health (workers or consumers)
6.2	Risk-management measures related to the environment
7	Waste-management measures
Information on estimated exposure and downstream user guidance	
8	Exposure estimation and reference to its source (i.e. was the estimation based on measured or modelled data and which modelling tool was used)
9	Guidance to the downstream user to evaluate whether they work within the boundaries set by the exposure scenario

Figure 6 Information contained within an exposure scenario for a typical workplace use (ECHA, 2008b).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

which DNELs are derived and the way the DNEL is used in the risk-characterization process, it becomes clear that DNELs based on limited or uncertain data will be very conservative and it will be necessary to implement stringent control measures in order to achieve these levels of exposure. This will provide a strong impetus for industry to obtain an accurate understanding of the inherent hazards of the materials that they supply and this may, at least in the short term, prompt an increased demand for toxicity testing.

Once a set of operating conditions and risk-management measures that secure adequate control have been identified they are documented in the CSR, which forms part of the registration package. They are also appended to the SDS to form the e-SDS. When a downstream user receives an e-SDS they are obliged to check that the operating conditions and risk-management measures at their workplace comply (i.e. provide an equivalent level of control) with the measures described in the exposure scenario. To help ensure that the correct exposure scenarios are referred to, each exposure scenario is given a short title based on standardized 'use descriptors' for various tasks and processes that have been specifically developed for this purpose. In addition, standardized phrases will be used to identify process-operating conditions and risk-management measures. Further details of these phrases and use descriptors are provided in the CSR guidance. It is the duty of suppliers to ensure that the information in their SDS is provided in a form that can readily be understood by downstream users. In this way, REACH reflects the philosophy of control-banding schemes that users should be given clear and comprehensive control advice. However, downstream users still have the responsibility to ensure that the way they implement the advice within the exposure scenario is appropriate to the specific circumstances of their workplace. It is considered that the exposure scenarios provided under REACH should not obviate the need for employers to conduct the workplace risk assessments required under legislation such as the EU Chemical Agents Directive (98/24/EC) (see Section 6).

8.5 Authorization and Restriction

The remaining two elements of REACH are authorization and restriction. Chemicals that may be subject to *authorization* are referred to as substances of very high concern (SVHC). SVHC include known and probable human carcinogens, mutagens and reproductive toxicants (substances classified as Category 1 or 2 carcinogens, mutagens and reproductive toxicants under the current EU C&L scheme), substances that are PBT in the environment (i.e. those meeting the criteria for PBT or vPvB) and 'substances of equivalent concern'. Substances that are subject to the authorization regime will be listed in Annex XIV of the REACH Regulation. Each substance listed in Annex XIV will be allocated a 'sunset date'. Once this date has passed it will no longer be possible to use that substance unless a specific authorization has been granted for that use. Authorization will only be granted providing industry can demonstrate to the satisfaction of the REACH regulatory authorities that the risks are being adequately controlled or can demonstrate that the societal need for the use of a particular substance in a particular process outweighs the risks. Within the authorization process, industry will need to consider the availability of alternative substances or processes and may need to assess the risks to human health and the environment associated with those alternatives. Even where granted, authorizations will be time-limited and will impose requirements on industry to actively seek less hazardous alternatives.

The *restriction* element of REACH is designed to cater for substances that do not meet the criteria for SVHC, but on analysis are considered to pose unacceptable risks because of the way they are being used. Where these are identified, member states can propose limitations ('restrictions') on the manufacture, supply and/or specific uses for the substance. In this case, the onus is on member states to consider the availability of alternatives and to consider the effects that implementing the restriction will have on society.

9 ISSUES FOR THE FUTURE

The new EU REACH legislation will change things. The regulation is broad in scope, covering a very large number of the chemicals present in the workplace (and elsewhere). It imposes responsibilities on all actors in the supply chain for substances and preparations containing those substances—on those who make or import substances and those who receive and use them in their business. It also has ambitious objectives (see Section 8) and these objectives and some of the features of the regulation reflect political will; the practical achievability of some of the objectives has not yet been tested.

For occupational toxicology, a major challenge is posed by the objective to promote alternative (to animal experimentation) methods for the assessment of the hazards of substances. This is coupled with regular exhortations throughout the REACH text and associated guidance to minimize the extent of additional experimental-animal testing. In the field of toxicology, in 2008, we feel that it is fair to say that the balance of opinion supports a statement that our ability to predict the toxicological profile of a substance by such alternative means is limited. Hence there is an apparent tension between the desire to have a good understanding

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat108
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of the toxicological properties of a substance and the desire to minimize experimental animal testing. It has to be hoped that this tension will motivate all concerned to produce and deploy intelligent and innovative ways of making toxicological assessments. Optimistically, the next decade might see satisfactory new approaches to gaining sufficient understanding of the toxicological properties of chemicals, such that appropriate exposure control can be applied in the workplace and beyond, without recourse to extensive new animal experimentation. Pessimistically, satisfying solutions might be difficult to find.

Several features of REACH are designed to contribute to the overall objective to improve the protection of human health and the environment from the risks that can be posed by chemicals. It will be interesting to see how the following aspects work out.

Firstly, will the registration data requirements and industry collaboration mechanisms produce more complete, accurate and consistent (between different suppliers) classification and labelling of substances and preparations (mixtures) containing them? It is hoped that this will be the case, such that labels and accompanying safety data sheets contain better quality warnings about the hazardous properties of materials.

Then, alongside hazard information, REACH intends for safety data sheets to be the means by which appropriate risk-management information is conveyed from supplier to user. It will be a huge challenge to chemical manufacturers and importers to understand all of the downstream uses of their chemicals and the associated conditions of use, in order to develop and supply appropriate risk-management advice. It remains to be seen whether or not business knowledge and the occupational hygiene community can meet this challenge.

It is also anticipated that some chemicals and/or particular uses of chemicals will disappear from the scene in the EU. The extent to which this happens and the reasons for such disappearances are issues for the future. In its design, REACH has the intention of exposing to authorization decisions the uses of chemicals deemed to be 'SVHC' and the promotion of substitution of such substances with alternatives possessing milder toxicological and/or ecotoxicological hazards. This is one way in which substances and their uses might change. However, it is also possible that commercial decisions by potential registrants of substances mean that a company decides to no longer manufacture or import into the EU that substance, for purely economic reasons. What effect such decisions might have on the pattern of chemical availability and use in EU workplaces and beyond is as yet unknown.

A final point concerns the traditional roles of chemical suppliers and chemical users and the toxicological and occupational hygiene thinking and tools that each has conventionally deployed. REACH pushes suppliers to address not only hazard, but also downstream exposure, risk and risk management. To a very large extent, it is expected that under REACH chemical users should follow the instructions given to them by their supplier. This raises important issues about the future role of user-side risk assessment, and about the future of OELs and risk-management tools and guidance generated by regulatory authorities and governmental systems.

REACH is not 'big bang' legislation. Rather, the results of duty holders delivering their responsibilities will accumulate gradually over the next decade (2008–2018). It will be very interesting and very important for occupational toxicology and occupational hygiene disciplines, particularly in the EU, to monitor how things progress.

Forensic Toxicology

Erkki Vuori and Ilkka Ojanperä

CONTENTS

1 INTRODUCTION

An extensive definition of forensic toxicology is given by the American Board of Forensic Toxicology as 'the study and practice of the application of toxicology to the purposes of law'. The definition encompasses the scope of the discipline, which involves not only science, research and theory, but also their practical application in the service of law.

By definition, forensic toxicology is always tied to the legal system of a given country. Of course, analytical methods and principles coincide internationally, and pharmacological principles apply to all human beings universally, but the legal and social contexts vary. Thus, the interpretation of the significance and the consequences of a given toxicological finding can also vary.

It is possible to divide forensic toxicology in several ways. Nevertheless, the three established specialties are postmortem toxicology serving cause-of-death investigations; clinical forensic toxicology covering drugs and driving, other 'under the influence' issues and drug-facilitated crime; and urine tests for drugs of abuse in workplaces, prisons, armed forces and so on. Additional application areas can be found within occupational, veterinary and environmental toxicology and in the investigation of terrorism. Clinical toxicology and therapeutic drug monitoring are also connected with forensic toxicology as they share similar target substances and methodology.

Forensic toxicology serves the individual, who may be a victim, an offender, a relative or a beneficiary, by providing information about accidental poisoning, malpractice, suicide and criminal offences. Revealing homicide by poisoning is the ultimate dimension of the discipline. For society as a whole, forensic toxicology provides evidence for the administration of justice, and evidence-based information for drug enforcement and other administrative purposes. Forensic

toxicology combines the scientific principles and methods of analytical chemistry, pharmacology and epidemiology. Successful interpretation of forensic toxicological results necessitates detailed information about the case in question and a thorough understanding of the methods used to produce the results.

2 HISTORY

Poisonings, especially murder by poisoning, have troubled humanity throughout history. The toxicity of some plants and minerals was known in ancient Mesopotamia, Egypt and India. Hippocrates (460–370 BC) also mentioned poisonings by herbs and food. Plato's account of Socrates' execution by hemlock poisoning (399 BC) is a well-known example. However, it was not until the science of chemistry had developed sufficiently that the testing for toxic substances in humans could be used as evidence in court. M. J. B. Orfila (1787–1853) is often cited as 'the Father of Forensic Toxicology'. His principal work, *Traité des poisons ou Toxicologie Générale*, was published in 1814 and included a division of poisons into six categories. Orfila was the first to be able to prove the presence of a toxic substance, arsenic, in samples taken from a human body, namely that of the murdered husband in the famous Marie Lafarge case. He also established the principles for giving expert opinion in court.

Since then, many scientists have made significant contributions to the development of forensic toxicology in their respective localities and countries (Sunshine, 1998). Some chemists and forensic toxicologists of previous generations have won international recognition. Among these are J.-S. Stas (1813–1891) of Belgium and F. Otto, (1809–1870) of Germany, who developed a method for extracting alkaloids from organ samples, and E. M. P. Widmark (1889–1945) of Sweden, a pioneer in the detection and determination of alcohol in body fluids and the pharmacokinetics of ethanol. The Widmark oxidation method for determination of alcohol in capillary blood samples, although not specific to ethanol, was long a routine method for alcohol measurement in drink-driving cases in Scandinavia and Germany. He also introduced the statistical approach of triplicate measurements to confirm the final results, later expanding his method to include postmortem samples. He developed the Widmark equation (**Box 1**), which is still used to estimate the amount of alcohol consumed and the corresponding blood alcohol concentration. R. K. Bonnichsen (1913–1986) of Denmark developed the alcohol dehydrogenase enzyme method and evidential breath analyser for the determination of alcohol. A. S. Curry (1925–2007) of Britain introduced the use of ultraviolet spectroscopy, paper and thin layer chromatography (TLC) and glass column gas chromatography. His handbooks, detailing his findings, were highly influential. I. Sunshine (1916–2006) of the USA established a large international network of forensic toxicologists. He was a founding member of The International Association of Forensic Toxicologists (TIAFT) in 1963, and active in Poison Center programmes. He also made a positive impact through his lectures, workshops, scientific papers and books.

Box 1 Widmark's formula

The uncertainty associated with the use of the formula has been calculated and discussed by Alha (1951) and Gullberg (2007).

$$A = p \times r(C_t + b \times t)$$

A = amount of alcohol consumed, in grams
r = volume of distribution ($0.731\,kg^{-1}$ for males)
p = body weight in kilograms
C_t = blood alcohol concentration at time t
b = elimination rate for blood alcohol (average $0.148\ ‰\,h^{-1}$)
t = time since consumption started, in hours

3 POISONING

In forensic toxicology, a poison is defined as any substance which, when present in the organism in sufficiently high concentrations, can cause illness, be otherwise harmful, or eventually result in death by a chemical mechanism. It can exist in gaseous, liquid or solid form. Chemically, poisons range from simple inorganic compounds, such as metals and metal salts, to complex synthetic organic molecules or natural toxins.

Poisoning can occur intentionally or accidentally. Intentional poisoning can be self-inflicted or murder by poisoning. In both cases, it is possible that the original intention was not to kill but to cause harm or injure. However, dangerous mistakes are likely when administering a potentially toxic substance. Typical accidental poisonings are caused by intoxicants such as alcohol and drugs of abuse, ordinary drugs, household chemicals, pesticides, toxic plants or venoms (**Table 1**). Accidental poisonings can also be due to food, occur in pharmacotherapy or be occupational. Chemical warfare agents, although prohibited, are also potential poisons, and in countries with capital punishment, some poisons are used for the purpose of execution.

The cause of accidental poisoning is typically ignorance, carelessness or negligence. To prevent accidental poisoning in children, it is vital to provide information to parents, and that parents supervise their children closely. The means available for preventing accidental

Table 1 Common substances constituting the most important finding in fatal poisonings

Industrialized countries
Typically found in accidental deaths
Ethanol
Opioids: heroin, morphine, codeine, propoxyphene, tramadol, fentanyls, oxycodone, buprenorphine
Cocaine
Amphetamines
Neuroleptic drugs: methotrimeprazine, promazine
Benzodiazepines: diazepam, oxazepam, alprazolam
Other analgesic drugs: paracetamol
Typically found in suicides
Antidepressants: amitriptyline, doxepin, dothiepin, mirtazapine, venlafaxine
Hypnotics: zopiclone, zolpidem, temazepam
Cardiac medicines: digoxin, propranolol, metoprolol
Insulin
Carbon monoxide: exhaust gas
Other substances: cyanide, pesticides
Developing countries
Insecticides
Rodenticides
Opiates
Benzodiazepines
Plant and animal poisons
Metals: thallium, arsenic

and suicide poisonings differ. For example, information on the risks of potentially toxic chemicals commonly found in the home may be used by unstable individuals who are considering suicide.

4 SAMPLES

Regardless of whether a sample originates from a living or deceased subject, the principles and procedures in the laboratory are identical and should conform to quality requirements. The basic procedures are the same regardless of whether the laboratory is big or small. In order to keep the quality of results reliable and to make it possible to present and defend the results in court, the *chain of custody* must be kept unbroken. This includes following written instructions for sampling, transporting, storing, analysing and calculation, and for interpreting results. In addition, careful documentation during all the phases of sample handling is vital.

The prerequisite for a forensic toxicological investigation is the justification of sampling. If the subject is a victim, the investigation is for the benefit of the individual, and it is in the subject's own interest to give the sample voluntarily. In such cases, the subject's consent should be documented. If the subject is suspected of committing a crime, sampling may be involuntary, although by law coercive measures depend on the severity of the suspected crime. The legislation in force in the country in question must be followed. Cases sometimes involve minors, and the question of the age at which a child has sovereign rights over his or her own body can be difficult to resolve. In some countries, the views of the child have to be heard if he or she is aged 12 years or older.

As to postmortem toxicology, the choice of samples is far less restricted. In addition to the usual blood and urine samples, samples are routinely taken from the stomach, liver and vitreous humour. There are several other possibilities, including hair, haematoma and bile. Not infrequently the deceased is badly injured, burned or in a state of putrefaction. In such cases, the forensic pathologist collects any sample that is available, such as 'central blood' from cavities and muscle tissue, which endures postmortem changes for a considerable time. The results in such cases must be interpreted with caution, while the condition of the samples must also be considered.

4.1 Blood

What samples are needed for forensic toxicological analysis depends on what question is to be resolved. If the objective is to establish whether a subject has been under the influence of a substance, a blood sample is obligatory. Before sampling, the skin must be cleaned, which is also the case with cadavers, but organic solvents, including alcohols, should be avoided. Although the risk is minimal, the possibility of contamination can affect the integrity of the samples (Pendlington *et al*., 2001). In living persons, blood is collected by venipuncture, usually from a cubital vein, utilizing vacuum tubes containing oxalate or EDTA (ethylenediaminetetraacetic acid) as anticoagulant, and sodium or potassium fluoride as enzyme inhibitor and to inhibit bacterial growth and activity. In a living person, all venous blood is equally acceptable. However, this is not true with blood samples from a cadaver, where the sampling site may affect concentrations. Postmortem changes may take place for a variety of reasons, such as diffusion, liposolubility, the volume of distribution of a given drug, instability and putrefaction. It is known that liver and lung tissues can have high concentrations of drugs, and of course the gastric contents can show very high amounts of substances in suicide cases involving overdoses. It is not surprising, therefore, that the concentrations in central blood can be more than 10 times higher than in corresponding femoral blood samples (Prouty and Anderson, 1990; Pounder and Jones, 1990; Rodda and Drummer, 2006). The biggest differences have been detected with tricyclic antidepressants, chloroquine,

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

amphetamine, amiodarone, propoxyphene and digoxin. For this reason it is recommended that blood samples for postmortem toxicological investigations be collected from peripheral veins, for example from the femoral vein, avoiding the siphon effect which can contaminate the sample with central blood. Even if blood is correctly collected from the periphery, some redistribution is still possible, especially in the case of lipid-soluble drugs (Drummer, 2007). In order to avoid postsampling degradation, forensic samples should always be stored refrigerated or frozen (Peters, 2007). If cell-free samples are needed for biochemical investigations, for example determination of insulin and C-peptide, serum separation tubes can be used, but for optimum results the sample must be collected as soon as possible after death (Winston, 2000).

4.2 Urine

Urine samples are preferable if the question to be answered is, 'has the subject used a substance or has he/she become predisposed to a substance?' The concentrations of many drugs are high in urine and the window of detection can be long, especially in the presence of metabolites. Fast, simple immunological screening methods can therefore be used.

Free drugs that are not bound to proteins are excreted to a greater or lesser extent in urine, but only polar or ionized drugs are found in high concentrations. Most drugs are excreted as their metabolites. During biotransformation (metabolism), a drug goes through a process which exposes or adds a functional group to the parent molecule (Phase I). In Phase II the exposed functional group reacts with substances present and forms glucuronide, sulfate or glycine conjugates, which are usually more polar than the parent substance and are excreted in urine. For example, after a single dose of codeine, in Phase I the drug is *O*- and *N*-dealkylated to morphine and norcodeine, respectively. After Phase II reactions, in addition to codeine, morphine and norcodeine, the corresponding 3- and 6-glucuronides of all three substances can be found in urine (Baselt, 2004). Because some functional groups, especially phenolic and alcoholic hydroxyl groups, form conjugates, urine samples are normally treated enzymatically, for example using glucuronidase, before extraction prior to analysis.

4.3 Alternative Samples

Other common samples that can be obtained from a living subject are saliva (oral fluid), hair and gastric contents (vomit or gastric lavage).

4.3.1 Oral Fluid

The fluid present in the oral cavity has several origins. Most is secreted by the major salivary glands, but a portion is secreted by numerous accessory salivary glands and by gingival tissue. Some stems from oronasopharyngeal secretions, or possibly from food (Aps and Martens, 2005). This fluid also contains cells, bacteria and viruses, and can be contagious. Different saliva glands secrete different types of saliva: under normal conditions, submandibular saliva accounts for most of the volume, but the parotid glands when stimulated can secrete up to half of the saliva. The pH of unstimulated saliva is acidic to neutral, but stimulated saliva can be neutral to basic. The change in acidity affects the saliva/plasma ratio of those drugs that have a pK_a value close to seven.

Drugs present in the blood enter saliva by passive diffusion and are in balance with the un-ionized, unbound and thus active fraction of a given drug in blood. This is why oral fluid is the best alternative to a blood sample if 'being under the influence' has to be evaluated (Langman, 2007). However, the distribution of a particular drug between oral fluid and blood is not constant; also, many drugs may be present due to oral deposition, for example by smoking, snorting or from sublingual or buccal dosing. Hence the interpretation of the laboratory results meets numerous considerations (Cone and Huestis, 2007).

Oral fluid has several advantages over blood and urine samples in testing for drugs of abuse. Collection is noninvasive and can be performed observed but without embarrassment right away at the scene of the incident or accident. Samples can be taken without the need for medical personnel. Oral fluid has disadvantages, too. Many common drugs have an anticholinergic effect and can cause hyposalivation and dry mouth; in these cases, collection of the sample can be difficult or impossible. As with blood samples, the period during which drugs are detectable is short and the results indicate recent use only. There are several commercial devices available for collecting and analysing oral fluid samples.

4.3.2 Hair

Hair has been described as 'a recording filament' that records and preserves information about the drugs present in blood during the formation of the hair shaft in the germination centre of the hair follicle. Drugs can be incorporated via diffusion from blood, or transfer can take place via sweat, sebaceous and apocrine gland secretions (Henderson, 1993). Hair grows in cycles, and in the anagen (growing) phase, drugs are incorporated. After this active phase comes the catagen phase and then the telogen phase, when shedding occurs. In humans, each follicle has its own independent cycle of growth, and on average 85% of scalp hairs are in the growing phase

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat109
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and 15% in the resting phase at any given time (Harkey, 1993).

Hair samples are collected from the back of the head, that is, the *posterior vertex* area, where hair growth averages about 1 cm month^{-1}. In order to keep the individual hair strands synchronized, and to make segmental analysis possible, it is recommended that a bundle of hairs be tied together with a cotton thread and the sample cut close to the scalp with scissors.

Hair testing has many advantages: it increases the window of drug detection, allows resampling if the results are disputed and can discriminate a single exposure from long-term use (Kintz, 2007). External contamination of hair is always possible, and the analytical procedures used must include washing. Cosmetic treatments, such as bleaching and dyeing, can interfere by removing drugs. Hair is an excellent sample if the extent of the use of a given drug has to be evaluated in history, but has no immediate value when acute fatal poisoning is suspected. However, hair testing is also useful in clarifying a single exposure in the examination of drug-facilitated crimes. In these cases, it is recommended that samples be taken four to five weeks after the incident (Kintz, 2007).

4.3.3 Gastric Content

Analysis of gastric content or vomit shows which drugs have been last ingested, but not necessarily which drug caused the poisoning.

4.3.4 Muscle

The alcohol concentration in muscle has been shown to follow closely that in blood in cases where blood alcohol is higher than 100 mg per100 ml; at lower levels, muscle alcohol seemed to be higher (Garriott, 1991). Studies comparing drug concentrations in skeletal muscles with drug concentrations in blood have, generally speaking, produced similar findings. However, the results are not unanimous. In one study (Christensen *et al*., 1985), in which the results from skeletal muscle and venous blood from an extremity were compared, the concentrations were of the same magnitude for acidic drugs, while, with a few exceptions, good correspondence was also found for basic and amphoteric drugs. On the other hand, sometimes the reference blood is not always collected from the periphery (Garriott, 1991), which makes it difficult to assess the value of muscle as a sample. Variations have also been shown also to occur between different sampling sites of the same muscle (Christensen *et al*., 1985; Williams and Pounder, 1997). One interfering factor might be the length of survival time between dosing and death.

5 ANALYTICAL PRINCIPLES

It is convenient to divide forensic toxicological analysis according to the scope of the investigation into *targeted analysis*, including testing for drugs of abuse in various instances, and *comprehensive analysis*, which comprises postmortem toxicology and many facets of clinical forensic toxicology. Drug-testing laboratories manage with more modest equipment such as immunoassay and possibly a confirmatory technique, while expert laboratories performing comprehensive analysis and confirmation require state-of-the-art analytical instrumentation (Penders and Verstraete, 2006).

Drug testing typically involves an initial analysis (screening), and in positive cases a confirmatory analysis, of several of the following abused substances in urine: amphetamines, barbiturates, benzodiazepines, buprenorphine, cannabinoids, cocaine, ecstasy, fentanyl, LSD, methadone, methaqualone, opiates, oxycodone, phencyclidine and propoxyphene. The initial analysis is usually performed by urine drug immunoassay. Several types of immunoassay techniques are available for the substances mentioned above and for many additional drugs, such as β agonists, tramadol and tricyclic antidepressants (Verstraete and Heyden, 2005). Administrative cut-off values are used to distinguish between positive and negative results. Immunoassay seldom differentiates between individual drugs within a group, and members of the group often possess different responses to the assay in spite of the nominal cut-off limit. Homogeneous immunoassays are easy to use, while heterogeneous immunoassays offer a larger selection of tests. In positive cases, confirmation of findings in the same urine sample is usually carried out by gas chromatography-mass spectrometry (GC-MS). The procedure involves extraction and derivatization of the compounds and GC-MS analysis in the selected ion-monitoring mode, using deuterated internal standards. The cut-off limits are usually lower than those used in screening.

Comprehensive toxicological analysis is required in many areas of clinical forensic toxicology, such as in cases of drugs and driving, drug-facilitated crime and violent crime, child welfare and doping in sports. Postmortem toxicology necessitates the broadest scope of analysis, as the investigation should cover every exogenous substance potentially contributing to death. Terms like systematic toxicological analysis (STA) and general unknown screening (GUS) have been given to the organized approach of using one or several methods in search of drugs and poisons (de Zeeuw, 1998; Hartstra *et al*., 2000). A major forensic toxicology laboratory might have to have around 500 reference standards to perform its work properly. Maintaining an up-to-date reference standard collection is one of the biggest challenges facing such laboratories. **Table 2** shows the groups of drugs and poisons relevant in forensic toxicological investigations,

Table 2 Drugs and poisons relevant in forensic toxicological investigations and the analytical techniques commonly used for their detection

Substance	Analytical technique	Approximate number of compounds
Alcohols	Head space GC	5
Volatile substances	Head space GC, head space GC-MS	50
Glycols	GC, GC-MS	5
Acidic and neutral drugs screening	TLC, GC, GC-MS, LC, LC-MS	50
Basic drugs screen	TLC, GC, GC-MS, LC, LC-MS	350
Drugs of abuse screen	Immunoassay	20
Drugs of abuse confirmation	GC-MS, LC-MS	20
Drugs related to chemical submission	GC-MS, LC-MS	50
Digoxin	Immunoassay	1
Insulin	Immunoassay	1
Salicylate	Spectrophotometry	1
Carbon monoxide	CO-oximetry, spectrophotometry	1
Cyanide	Spectrophotometry, GC, GC-MS	1
Pesticides	GC, GC-MS, LC-MS	50
Anticholinesterases	Cholinesterase activity assay	30
Metals	AAS, ICP-MS	10

GC—gas chromatography; MS—mass spectrometry; TLC—thin-layer chromatography; LC—liquid chromatography; AAS—atomic absorption spectrophotometry; ICP—inductively coupled plasma.

and the instrumental techniques commonly used for analysis.

A urine specimen is the first choice for comprehensive qualitative drug screening, as most drugs and metabolites appear in urine at higher concentrations than in blood, and as urine also possesses a longer time-window of detection (Verstraete, 2004). **Table 3** gives suggested detection times for a range of drugs of abuse in urine. Drug concentration in venous blood (plasma, serum) reflects the current level of drug action, and consequently large compilations of therapeutic, toxic and fatal concentrations in blood are available to aid interpretation (Musshoff *et al*., 2004). A good practice in forensic toxicology is to perform the analysis on two different specimens, for example urine and blood, using two independent analytical techniques. A limit of detection (LOD) and a limit of quantification (LOQ) should always be established for qualitative and quantitative analysis, respectively, and an administrative cut-off value can also be applied. Full bioanalytical method validation involves a range of additional measures, including accuracy, precision, range of measurement and uncertainty of measurement.

In recent years, much attention has been given to the development of comprehensive drug screening methods based on GC-MS and liquid chromatography-mass spectrometry (LC-MS). Large spectral libraries of organic substances are available for GC-MS, making this technique most suitable for the identification of unknown substances (Maurer, 2006). Many novel drugs, however, are polar or thermolabile in nature and therefore more amenable to LC analysis. Thus the most recent advances in GUS are related to LC-MS techniques that employ triple quadrupole or ion trap mass analysers (Mueller

Table 3 Time windows of detection for drugs of abuse in urine. The time interval depends on the cut-off level selected and also individually according to factors such as the size of the dose and the duration of the abuse[a] (Baselt, 2004; Drummer, 2001; Verstraete, 2004)

Drug	Days
Amphetamine[b]	2–9
Methamphetamine[b]	2–6
MDMA	1–2

et al., 2005). Liquid chromatography coupled with time-of-flight mass spectrometry (LC-TOFMS), which is based on accurate mass measurement, allows tentative formula-based substance identification without reference standards. While retention times are always applied when available, target libraries containing as many as 1000 compounds can be regularly updated with fresh numerical data on new drugs, designer drugs and metabolites from the literature or other sources (Ojanperä *et al*., 2006). Quantitative analysis methods rely on the same GC- and LC-based technology, but being strictly dependent on reference standards and instrument calibration, they do not allow simultaneous quantification of more than 50–100 substances (Rasanen *et al*., 2003).

Advances in drug screening techniques have resulted in an increasing number of drugs and poisons routinely found in forensic toxicology cases. **Table 4** presents a typical postmortem case of alcohol and drug poisoning with multiple findings in urine by LC-TOFMS and subsequent quantification of the relevant findings in blood. Interpreting such findings requires both a pathologist and a toxicologist, the former being acquainted with the case history and autopsy results, and the latter being able to evaluate the drug findings against epidemiological and toxicological information.

Table 4 Example of the comprehensiveness of an initial urine analysis with a novel liquid chromatography-time-of-flight mass spectrometric method. A total of 18 drugs and metabolites, representing a vast chemical variety including basic, acidic and neutral drugs, were detected in a single run (DNo. 070764). Confirmation and quantitative analyses in blood were performed using various listed methods

Initial analysis in urine by LC-TOFMS	Blood analysis ($mg\,l^{-1}$)
Tramadol	3.8 (GC)
Nortramadol	ND (GC)
O-Desmethyltramadol	ND (GC)
Venlafaxine	1.7 (GC)
Metoclopramide	0.2 (GC)
Amitriptyline	0.2 (GC)
Carbamazepine	6.1 (GC)
Oxazepam	0.5 (GC)
Warfarin	Positive (GC-MS)
Metoprolol	0.21 (LC-MS/MS)
Oxycodone	0.16 (GC-MS)
Noroxycodone	ND (GC-MS)
Gabapentin	27 (GC-MS)
Nicotine	ND (GC)
Cotinine	ND (GC)
Hydroxycotinine	ND (GC)
Ketoprofen	ND (GC-MS)
Ranitidine	NA

ND—not detected; NA—not analysed; TOFMS—time-of-flight mass spectrometry;
MS/MS—tandem mass spectrometry.
Alcohol concentrations in blood and urine were 2.4 and 2.8‰, respectively.
Ketoprofen, nicotine, nicotine metabolites and tramadol metabolites were not detected in blood. Ranitidine was not quantified, but the substance was included in the medical history of the deceased.
The forensic pathologist classified the cause of death of the 48-year-old man as combined poisoning with alcohol and drugs, but the mode of death remained obscure.

6 INVESTIGATIONS ON LIVING PERSONS

The services of forensic toxicology are increasingly needed in today's society. This is true because, in addition to the traditional tasks (such as blood alcohol analysis in cases of drunk drivers), new duties such as workplace testing have become more frequent during the last few decades. Expertise in clinical forensic toxicology is needed for investigating the victims and offenders in cases of assault, in obstetric wards if a mother is suspected of drug abuse or a newborn baby shows withdrawal symptoms, in other child welfare cases, and in cases of drug-facilitated crimes. The contexts are often delicate and emotional, and the appropriate legislation concerning sampling and civil rights must be strictly followed.

6.1 Drunk and Drugged Drivers

Alcohol, common drugs and drugs of abuse can cause impairment of driving skills and predispose the driver to accidents. Deaths in road traffic are a serious public health problem all over the world, and driving under the influence of drink or drugs is usually penalized by law. The legally permitted limit for blood alcohol concentration varies between different countries from zero (Hungary) to 80 mg per 100 ml (USA and Canada). In most European countries and in Australia, the limit is 50 mg per 100 ml. In many countries, being under the influence of alcohol is assessed after initial breath testing with simple roadside devices or impairment tests, using evidential breath analysers. Standardized field sobriety tests typically include one-leg stand, walk and turn, and horizontal gaze nystagmus testing. If the impaired driver is not able to blow correctly, or if drugs are suspected, a blood sample is necessary. Blood alcohol concentration is usually measured using head space GC with flame ionization detection. The method is accurate, and international proficiency testing programmes typically prove a low deviation between laboratories.

Many drugs of abuse have deleterious effects on driving. For example, amphetamines and cocaine can

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat109
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cause aggressiveness and unpredictable behaviour; benzodiazepines are known to slow reaction times and cause impairment of cognitive and psychomotor functions, even at therapeutic doses (Drummer, 2001). The recognition of an impaired driver is difficult at the roadside, and new methods have therefore been developed to identify those driving under the influence of drugs. Immunoassays for testing oral fluid (saliva) are now available (Drummer *et al*., 2007), and advances in testing will produce new instruments and methods which, in turn, will increase the range of testable substances (Walsh *et al*., 2007; *www.rosita.org*). Of course, before legal penalties can be imposed, an initial positive result must be confirmed by analysis of a blood sample by confirmatory methods, preferably by MS. Some countries, such as Belgium, Germany, Finland, France, Sweden and Switzerland, apply zero tolerance in traffic, and the concentration of any drug of abuse in blood samples must be under the agreed limit. In some other countries, such as in Denmark, the UK and Norway, the simultaneous impairment of driving skills must also be proven. The legislation is exceptionally strict in Iceland, where merely a single positive urine sample will deprive the driver of his or her driving licence.

6.2 Workplace Drug Testing

Workplace drug-testing programmes have spread worldwide following drug-related accidents in transportation and aviation in the USA in the 1980s. Workplaces in transportation, the nuclear industry and aviation in particular have adopted testing programmes. In the USA, federal employees are also routinely tested. The list of tested substances varies from country to country, as do the cut-offs for positive results, but usually the Mandatory Guidelines for Federal Workplace Drug Testing Programmes of SAMHSA (Substance Abuse and Mental Health Services Administration) are followed (Federal Register, 2004; **Table 5**). Substances typically tested for in the USA include amphetamines, cannabis, cocaine, opiates and phencyclidine. In Europe, phencyclidine is not routinely tested for, but benzodiazepines are usually included. In workplace testing, adulteration of a void urine sample is always possible, and the laboratory responsible for the initial or confirmation analysis must check the samples for foul play. Normally the appearance and colour of the urine sample is checked, as well as temperature, pH, specific gravity or creatinine level, and the sample screened for

Table 5 Cut-offs for Mandatory Guidelines for Federal Workplace Drug Testing in urine, and proposed cut-offs for initial testing of alternative specimens by Substance Abuse and Mental Health Services Administration (SAMHSA), US Department of Health and Human Services (HHS) (*http://workplace.samhsa.gov*, Bush, 2008)

Initial drug-test level	Urine ($ng\,ml^{-1}$)	Hair ($pg\,mg^{-1}$)	Oral fluid ($\mu g\,l^{-1}$)	Sweat (ng $patch^{-1}$)

the presence of known adulteration substances, such as nitrite or glutaraldehyde. Any final positive result must be inspected by a medical review officer (MRO), who will be able to exclude any confounding factors, such as the correct use of justified prescribed drugs or common over-the-counter drugs. Drug-testing programmes reveal many drugs of abuse, but not all. Special methods are needed to detect and determine some amphetamine derivatives, tryptamines, gammahydroxybutyrate, buprenorphine and several synthetic opioids. This is why a negative test result excludes only the substances tested for, not all possible drugs of abuse, and thus testing programmes can actually give a false feeling of safety.

6.3 Drug-Facilitated Crimes

Drug-facilitated sexual assaults often involve the use of alcohol together with short-acting benzodiazepines, hypnotics like zopiclone or zolpidem, or drugs having psychedelic or empathogenic effects (like ecstasy, cannabis or gammahydroxybutyrate). Anticholinergic drugs, like scopolamine, are associated with anterograde amnesia. Potential other substances include drugs that lower blood pressure and cause unconsciousness, like clonidine or tetryzoline, in addition to any drug affecting the central nervous system. This is why the investigation of suspected cases is always a challenge for the laboratory. No single method covers all possible substances, and a variety of analytical methods is therefore needed.

6.4 Doping

From a forensic toxicological point of view, doping means the use of banned substances to enhance performance in sports. Doping is banned for ethical, legal and health reasons. The World Anti-Doping Agency (WADA) issues annually a list of prohibited substances and methods (*www.wada-ama.org*). Some drugs are prohibited in-competition, while others are prohibited out-of-competition or in particular sports. Totally prohibited substances include anabolic agents, hormones and related substances, β_2 agonists, agents with antioestrogenic activity, diuretics and other test-masking agents. In competition, stimulants, narcotics, cannabinoids and glucocorticosteroids are also banned. In particular sports, such as shooting, alcohol and β blockers are also prohibited. The collection of urine samples for doping analysis must be supervised and follow a given protocol; for example, the tested person has the right to choose the vials for taking and storing the samples, and the original sample must be split into A and B subsamples, which are sealed and stored under the same conditions. If an A sample turns out positive, the person tested has the right to be present when the confirmation analysis of the B sample takes place. Doping analysis can be performed only in laboratories having both WADA and ISO/IEC 17025 accreditation.

7 POSTMORTEM FORENSIC TOXICOLOGY

The suspicion of poisoning normally arises from the circumstances surrounding the death. Medicines are missing or present at the scene; bottles, tablets, syringes and needles or other paraphernalia indicating abuse have been found, or the deceased is a known abuser. Sometimes the deceased has left a farewell letter with a description of the manner of intended suicide or has revealed to relatives the intention of committing suicide. Scene investigation and history do not in all cases reveal intoxicants, and routine screening for alcohol and drugs of abuse is recommended in all medicolegal cases (Gruszecki *et al.*, 2007).

An external inspection of the body can reveal stains of drugs around mouth or nose, or injection marks, while the colour or odour of the deceased can also be indicative. At autopsy, tablets or remains of drugs may be found in the gastric contents, or corrosive changes in the alimentary tract may be present. The colour of lividity is reddish in carbon monoxide and cyanide poisoning, and the blood is abnormally flowing. Congestion and oedema of the inner organs is a typical finding in cases of poisoning. However, no finding, except a recognizable odour, is fully pathognomonic; the finding may be attributable to other conditions related to sudden and unexpected death, such as asphyxia or exposure to a cold environment.

According to the classification of causes of death issued by the World Health Organization (WHO), poisoning can be an underlying cause of death (Ic), an immediate cause of death (Ia), or a contributing cause of death (II). The underlying cause of death is always the event that 'initiated the train of morbid events leading directly to death'. Opiates, cocaine, tricyclic antidepressants, neuroleptic drugs, alcohols and carbon monoxide are frequent causes of fatal poisonings in the industrialized countries, while pesticides are often involved in developing countries (**Table 1**).

Revealing a murder by poisoning is of course one of the main assignments of forensic toxicology. Toxicological information can also be decisive in solving other homicides. Drugs or alcohol may have been used to facilitate the offence, or a fire may have been started to eradicate clues or to destroy the corpse. In the latter case, no elevated carboxyhaemoglobin or cyanide will be found in the blood sample,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat109
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

which indicates that the victim had not inhaled toxic fumes.

Compared to clinical forensic toxicology, postmortem investigations suffer from several shortcomings. The samples are often far from ideal, and resampling is not usually possible. Neither the anamnesis nor the symptoms of the poisoned patient point suspicion in any particular direction, and the laboratory is left having to search for the unknown substances. On the other hand, the selection of suitable sample sites is larger than with a living person, and very sophisticated autopsy sampling is possible when needed; for example, from known sections of the brain (Stimpfl and Reichel, 2007).

It is worth remembering that the same rules do not apply to the deceased as to the living. For example, an opiate abuser may die suddenly while injecting heroin, and if the urine was originally free of opiates the abuser may have died before the opiates were secreted in the urine in detectable amounts, thus making the urine opiate concentration less than the corresponding cut-off value for the method (**Case 1**). This is why a negative urine screen in postmortem samples does not guarantee a negative blood analysis. If the background information indicates possible poisoning, a blood sample must also be screened.

Case 1 DNo. 990525

A 30-year-old man was found dead in a public toilet. At the scene on the floor, a syringe with a needle was found. The pocket of the deceased contained a small package, which was suspected to contain a single dose of an unknown drug of abuse.

An external inspection revealed two fresh injection marks. At autopsy, a fatty liver and a few minor bruises were noted. Samples of urine, blood from the femoral vein, vitreous humour, the liver, gastric contents, hair and from the injection sites were collected and sent for toxicological analysis.

No alcohol was detected in the blood or urine samples. Drug screening for common drugs was conducted on a liver sample by TLC, and temazepam was detected. The urine was screened for drugs of abuse with an immunological method. Amphetamine was positive, but the sample was negative for cannabinoids, opiates and cocaine. Quantitative analysis with a dual column gas chromatographic method revealed a blood oxazepam concentration of $0.9\,mg\,l^{-1}$ (reference value $0.1–1.4\,mg\,l^{-1}$) and a temazepam concentration of $0.4\,mg\,l^{-1}$ (reference value $0.4–0.9\,mg\,l^{-1}$). The amphetamine finding was confirmed by MS, and the amphetamine concentration in blood was found to be $0.1\,mg\,l^{-1}$ (reference value $0.03–0.6\,mg\,l^{-1}$). The blood sample was also found to contain morphine at a concentration of $0.22\,mg\,l^{-1}$ (reference value $0.08–0.12\,mg\,l^{-1}$). In urine the amphetamine concentration was $1.2\,mg\,l^{-1}$, and the sample was found to contain 6-acetylmorphine (6-AM) $0.12\,mg\,l^{-1}$ and morphine $0.07\,mg\,l^{-1}$. Amphetamine and morphine were detected at both injection sites. The hair sample represented the period of the last two months of life and was found to be positive for amphetamine and negative for cannabinoids and opiates.

Interpretation

On the basis of positive hair and urine analysis, the deceased had a history of amphetamine abuse but was naive in relation to opiates. He had obviously injected a mixture of amphetamine and heroin. He had no tolerance to opiates and had expired shortly after the last injection. Opiates can cause respiratory depression and sudden death, the risk being increased by the simultaneous presence of benzodiazepines. The combined concentration of morphine and 6-AM was less than the cut-off value for the screening method, which is $0.3\,mg\,l^{-1}$, and thus the opiates were not seen in urine with the method used for the initial analysis.

The forensic pathologist excluded other causes of death and classified the cause of death to be poisoning with heroin plus benzodiazepines, and the manner of death to be accidental.

With the standard head space GC method, it is possible to detect and quantitatively determine ethanol, isopropyl alcohol, methanol and acetone in a single run (**Figure 1**), (**Case 2**).Because of the danger of postmortem production of alcohol by microbiological activity (Zumwalt *et al*., 1982; Vuori *et al*., 1983), it is recommended to include alcohol analysis of samples other than blood (Kugelberg and Jones, 2007). Urine and vitreous humour are good alternative samples, and the results can support the blood alcohol result. The quantitative relationship between urine alcohol and blood alcohol can also be used to judge the phase of alcohol absorption at the time of death. A blood alcohol level higher than that of urine suggests incomplete absorption and recent drinking as well as the probable presence of nonabsorbed alcohol in the gastric contents. In the opposite case, the absorption and distribution of alcohol is supposed to be complete. If the deceased's body is putrefied, analysis of alcohol in the vitreous humour can lend support to the blood alcohol result. Vitreous humour alcohol correlates more closely with blood alcohol than does urine alcohol. However, in individual cases this may not be the case. If the blood sample is not available or the deceased is badly putrefied, as exhumed bodies usually are, alcohol can also be determined from a muscle tissue sample.

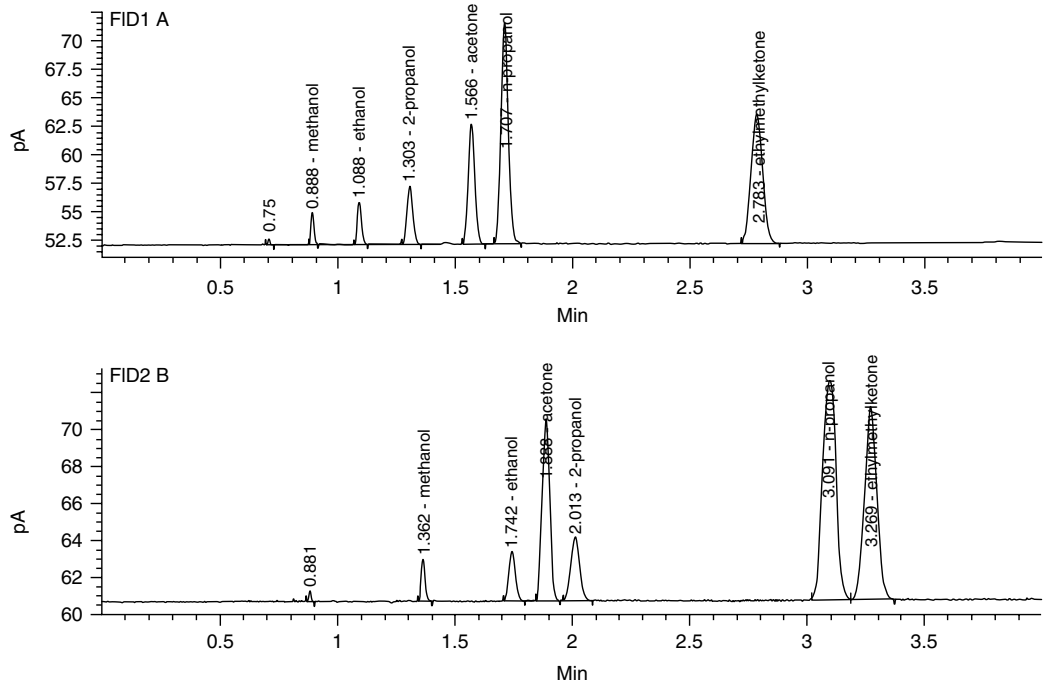

Figure 1 The detection of alcohols and some volatiles in a single run utilizing head space chromatography with flame ionization detectors and a dual column approach. Analysis of a standard mixture; the concentration of each analyte is 0.2‰, isothermic 40°C. Column A Restek Rtx-BAC1 30 m × 530 μm × 3 μm. Column B Restek Rtx-BAC2 30 m × 530 μm × 2 μm.

Volatile organic compounds (VOCs) other than ethanol are rare but important findings in postmortem toxicology (**Case 3**).Whole blood is the specimen of choice: VOC detection is as sensitive as with lung tissue and levels can be quantified. Volatile compounds usually require a dedicated head space GC or GC-MS analysis method. The terms *glue sniffing* and *solvent abuse* have now been replaced by *volatile substance abuse* (VSA). Most VSA deaths are due to gaseous fuels and aerosol propellants, especially butane. Cigarette lighter refill is a typical individual source of butane. The victims of accidental VSA death are predominantly young males. Analysis of VOCs also reveals other fuels, solvents from glues, aerosol propellants and fire extinguishers, and inhalation anaesthetics (Flanagan and Ives, 1994).

8 BIOCHEMICAL ANALYSIS

Many of the clinical chemistry investigations routinely used in clinics to diagnose disease disorders are not available postmortem. This is because postmortem blood is inevitably haemolysed and clotted, and it is impossible to recover serum or plasma. Haemolysis interferes with and precludes most investigations of blood. Hence alternative samples, such as vitreous humour and cerebrospinal fluid, which in most cases are free from contamination with blood and hence from haemolysis, have been used instead of blood. If a blood sample is to be used, the sample should be drawn very soon after death. This is often impossible, however, as the deceased may not be found for several days, weeks or even months after death. Due to postmortem changes, the opportunity to conduct several of the usual blood investigations will be lost; for example pH, oxygen tension, osmolality, sodium and potassium (Coe, 1993).

8.1 Glucose

Obtaining information on blood glucose concentrations postmortem is one of the challenges normally faced by laboratories. Hypoglycaemia can be fatal, develop rapidly and cause sudden death. The external reasons for the condition are injected insulin or excess of a given oral antidiabetic drug. Murder by poisoning with insulin is a reality, unfortunately also in hospitals and nursing institutions. So far there is no method for establishing hypoglycaemia postmortem. In addition, blood levels of insulin are normally measured using an immunological technique, and only certain laboratories can determine insulin by using chemical methods, typically LC-MS. Chemical methods can separate human, porcine and bovine insulin in postmortem blood (Darby *et al*., 2001). At present, however, recombinant human insulin or short-,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat109
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

intermediate- and long-acting human insulin analogues are used, and the old methods are no longer useful. New methods have been developed and have been validated for insulin and its degradation products in the analysis of urine and serum samples in cases of suspected doping (Thomas *et al*., 2007; Van Uytfanghe *et al*., 2007). However, these methods require ideal and nonhaemolysed samples. Immunological tests are handicapped by the fact that they merely yield the sum of all of the insulin-like active substances present: human, human analogue and antibody–insulin complexes, which may be present if external insulin has been used in treatment. One possibility is to analyse the insulin content at the alleged injection site, in which case a comparable control-site sample must be included.

Case 2 DNo. 080790

A 48-year-old man had been drinking alcohol for several days. He was brought to hospital in bad condition. The patient was restless and had a breath alcohol level of 3.78‰. He was given haloperidol to treat the restlessness. He died a few hours later.

At autopsy, no obvious cause of death could be established, and the forensic pathologist took samples for forensic toxicological investigations: blood, urine, liver, gastric contents, vitreous humour and cerebrospinal fluid.

Head space gas chromatographic analysis revealed the presence of methanol in the samples: blood 5.5‰, urine 8.4‰ and spinal fluid 7.8‰. No ethanol was detected in any of the samples. Urine was found to contain metoclopramide, the corresponding concentration in blood being $0.09\,mg\,l^{-1}$ (reference value $0.04–0.1\,mg\,l^{-1}$).

Interpretation

In methanol poisoning, symptoms arising from depression of the central nervous system are common, and the patient's restlessness could therefore have been due to methanol poisoning. Simple breath alcohol testing devices do not differentiate between methanol, ethanol and acetone, and in this case, the result of the initial test was misleading, and no other reasons for the condition were considered at hospital. The patient died shortly after administration of haloperidol and thus this drug was not detected. Metoclopramide is used in the treatment of nausea, which is also a frequent symptom of methanol poisoning. In this case, the finding has no additional forensic toxicological value.

The forensic pathologist considered accidental poisoning with methanol to be the cause of death.

Case 3 DNo. 990407

A 69-year-old man was found burned on the ice of a lake. Only a single set of footprints were noted leading to the scene. It was suspected that the man had committed suicide by burning himself with gasoline.

At autopsy, no other obvious cause of death was detected apart from burning, and the forensic pathologist took blood, urine, liver, gastric content and hair samples for forensic toxicological investigations.

No alcohol was detected in the blood or urine samples. Citalopram was detected in the liver sample by TLC. The blood citalopram concentration was found to be $0.2\,mg\,l^{-1}$ (reference value $0.04–0.4\,mg\,l^{-1}$). The blood sample also contained therapeutic, or less than therapeutic, concentrations of temazepam, oxazepam, diazepam and desmethyldiazepam plus paracetamol. The carboxyhaemoglobin content of the blood was 17%. The hair sample contained no amphetamines, cannabinoids or opiates. Purge-and-trap GC combined with Fourier transform infrared detection revealed the presence of methyl *tert*-butyl ether (MTBE) in the blood sample.

Interpretation

Citalopram is prescribed to depressed patients. Suicidal thoughts and suicide attempts are common symptoms of depression. MTBE is added to gasoline as an antiknock agent and to regulate the octane number of fuel products. It is absorbed through skin, and its presence in blood is a typical finding if gasoline has been used as burning fluid. The presence of carboxyhaemoglobin in the blood proves that, before death, the deceased had inhaled the toxic fumes produced by his burning clothes.

The forensic pathologist classified the death as suicide by burning.

On the other hand, it is possible to get information on hyperglycaemia, which is also potentially life threatening. This condition develops more gradually and typically causes ketoacidosis. In these cases, ketone bodies and acetone are usually detected in the blood or vitreous humour of the deceased. Information on the past glucose balance can be gained by determining glycosylated haemoglobin in the blood, HbA_{1c}, which remains stable postmortem and is not affected by haemolysis. The use of the combined value of glucose and lactate in the vitreous humour is a proven method for distinguishing hyperglycaemic from normal conditions postmortem (Sippel and Möttönen, 1982).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

8.2 Insulin and C-peptide

The pancreas secretes proinsulin in response to carbohydrate load. Active insulin is formed when proinsulin loses its C-peptide. Thus, in a living person, there is normally an equimolar relationship between secreted insulin and C-peptide. If someone has been exposed to external insulin, the imbalance in this ratio can be used to verify the external exposure. In postmortems, blood insulin and C-peptide are both unstable (Winston, 2000), and the ratio between them can no longer be used. The vitreous humour is not a suitable sample site since insulin and C-peptide penetrate the blood–vitreous barrier only minimally (Coe, 1993).

8.3 Potassium

The intracellular potassium concentration is higher than that of extracellular fluid. After death, cell membranes no longer maintain this difference in concentration. The serum potassium concentration therefore rises rapidly after death, making it impossible to assess the premortem potassium level (Coe, 1993). However, in the vitreous humour the rise in potassium concentration happens more slowly and is linear with respect to the time interval after death. There are several external and internal factors that need to be considered. The ambient temperature during the period postmortem has an effect, as does the age of the deceased and some metabolic conditions (Coe, 1993). Several mathematical formulas have been developed to estimate the postmortem time interval (Madea *et al*., 1990). Excluding unusual circumstances, the accuracy of the method is typically plus or minus 20 hours in the first 100 hours postmortem (Coe, 1993).

8.4 Tryptase

In an anaphylactic episode, an allergen (e.g. a medicinal substance, food or the venom of a bee or snake) releases enormous amounts of histamine and other active compounds from mast cells. The reaction is usually mediated by an interaction between an allergen-specific antibody (immunoglobulin (IgE)) and the allergen. The release and turnover of histamine are swift, and the measurement of histamine concentrations in anaphylactic deaths postmortem is not informative (Coe, 1993). It is possible to measure specific IgE allergens postmortem. A positive result means that the individual has a given allergy, but not that death is due to an allergic episode. Among many other active chemicals, the mast cells contain abundant tryptase enzyme, which is also released during an allergic episode. The release of tryptase is slower than that of histamine and peaks at 15–30 minutes survival time after exposure to the allergen. This is why, if death due to anaphylactic mechanism happens immediately after exposure, the tryptase concentration is not necessary elevated. The tryptase activity stays most stable if the sample is preserved in a freezer, but elevated levels can still be detected after several days of storage at room temperature (Yunginger *et al*., 1991). Suitable samples for the measurement of tryptase activity must be cell free. They can be obtained using serum separation tubes.

9 TERRORISM

Forensic toxicological services have also been needed for working out the possible consequences of terrorist attacks. In such cases, the use of unusual and unexpected substances has been detected, such as ricin in the Georgi Markov case in London (1978), the nerve agent sarin in Matsumoto (1994) and in the Tokyo subway (1995), a fentanyl derivative in resolving the siege by Chechen terrorists of the Dubrowka theatre in Moscow (2002), and dioxin in an attempt to murder the then presidential candidate Viktor Yushenko in Ukraine (2004).

Also exceptional was the Tylenol tampering incident, when someone replaced the original product with cyanide-containing capsules in Chicago (1982). This kind of crime is difficult to solve, and the offender was never caught.

10 ENVIRONMENTAL TOXICOLOGY

Environmental pollution can cause illnesses and can also result in death by poisoning. A typical example is air-pollution episodes, when higher than expected mortality can statistically be shown to occur. The problem in these cases is that the victims are people already suffering from cardiac and respiratory problems, primarily the elderly. However, it is impossible to prove in individual cases that the deceased is the victim of, say, a smog episode. In other environmental accidents, such as paralytic shellfish poisoning (PSP) and a disaster in a dialysis centre in Caruaru, Brazil (1996), the causative substances (algal neurotoxin in the first case and hepatotoxin in the second) have been determined. Other notorious environmental disasters have been caused by methyl mercury, other heavy metals like lead, cadmium or arsenic, polychlorinated biphenyls, dioxins and methylisocyanate.

11 NEW PERSPECTIVES

Postmortem forensic toxicology produces evidential information that is valuable in determining the cause of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat109
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

death of an individual. Together, single cases form a larger set of information, which can be useful for other purposes, for example in revealing trends in illicit drug abuse and in improving drug safety in general. To be able to utilize the information, the target population, the autopsy rate and the comprehensiveness of the data must be known as well as the analytical principles and the quality of the laboratories involved.

If the number of prescriptions or sales of drugs in an area is known, this information can be used to relate fatal poisonings to the consumption of drugs in the population. Thus, it is possible to calculate a fatal toxicity index (FTI) for a single drug or categories of drugs, and to compare the drugs with each other (Cassidy and Henry, 1987). The comparison of FTIs may reveal more dangerous drugs in a given therapeutic group of drugs. This kind of comparison has shown that, in terms of fatal poisonings, the old tricyclic antidepressant are more dangerous by far than the newer drugs, and that selective serotonin reuptake inhibitors (SSRIs) are clearly the safest of all antidepressants (Koski *et al*., 2005).

With the help of a sufficient database, the interaction between alcohol and drugs can also be established. It is known from case reports that the combination of propoxyphene and alcohol is especially fatal. With statistical methods, it has been possible to point out that the hazard is actually different with different drug–alcohol combinations (Koski *et al*., 2003). The greatest risk was identified if alcohol and promazine were present simultaneously. Amitriptyline or doxepin together with alcohol carries a similar risk to that of propoxyphene and alcohol, while the combination of alcohol and citalopram had practically no major effect.

Database studies can be extended to other combinations of drugs. It is known that there are potentially adverse drug combinations, and every effort is made to avoid these combinations in treatment. Such combinations include several serotonin-active drugs simultaneously, or a serotonin-active drug together with a monoamine oxidase inhibitor like moclobemide. These combinations are likely to cause serotonin syndrome, which can be fatal. Interaction databases are available to help avoid dangerous combinations in the treatment of patients. The most risky combinations found postmortem are medicines that together can cause serotonin syndrome, and β blockers together with verapamil or diltiazem (Launiainen *et al*., 2009). However, it is sometimes impossible to determine whether these incompatible combinations were prescribed or due to an accidental dosage by the deceased.

Traditionally, the concentrations of a particular drug found postmortem are compared with reported therapeutic, toxic and fatal concentrations, and a decision is then made on the importance of the finding. Lists have usually been collected from many sources, such as case reports over a period of several decades, and with no precise information on the site of collection, the quality of the samples or the methods of analysis. The best way so far to produce a reliable compilation is to use statistical methods for a single laboratory that has standard procedures and a large database. A Swedish group has given medians and 10–90 percentiles to several drugs found in fatal poisonings involving one drug only; to poisonings with the drug together with other drugs or alcohol; to concentrations of the drug found in fatalities other than poisonings; to concentrations detected in living drunk drivers; and to the results derived from therapeutic drug monitoring (Druid and Holmgren, 1997; Reis *et al*., 2007). In any case, a sound forensic toxicological interpretation cannot be given simply on the basis of the concentration found. Adequate background information (including possible clinical information) together with knowledge and understanding of the laboratory practices and possible analytical pitfalls are always needed (Flanagan and Connally, 2005).

Pharmacogenetics may play a role in individual cases of forensic interest. The polymorphic cytochrome P450 (CYP) enzymes, mainly CYP2D6 and CYP2C19, are involved in the metabolism of several toxicologically important drugs. Thus postmortem genotyping is recommended if statistically abnormal drug : metabolite ratios are found together with background information. As an example, a low doxepin : nordoxepin ratio has been associated with a defective CYP2D6 genotype, contributing to death from doxepin poisoning without an acute overdose (Koski *et al*., 2007).

Veterinary Toxicology

Frederick W. Oehme and Wilson K. Rumbeiha

CONTENTS

1 INTRODUCTION

Veterinary toxicology is a diverse discipline with many subspecialities dealing with the health and care of animals, the relationship of animals in studying human disease and the concern for domestic and wild animals in the environment. As these themes cannot all be addressed adequately in the space of one chapter, the focus of this tome will be the classic role of veterinary medicine in understanding and managing chemically induced disorders of domestic animals. Animals have

basic anatomical, physiological and biochemical differences between species and it is, therefore, not surprising that each species, including human beings, often react differently to the same toxicant. Those interspecies differences will be emphasized in this chapter.

Daily veterinary clinical practice is largely devoted to the diagnosis and treatment of poisonings in animals, although in recent years an increasing effort is devoted to zoonotic disease and public-health concerns protecting human health. The range of animals seen by practising veterinarians vary with individual specialists, but can range from small domestic animals, that is, cats and dogs, to food-producing animals (i.e. dairy and beef cattle and swine), to horses, pocket pets, pet birds, zoo animals and even wild game, such as tropical birds, caged reptiles and tropical fish. The small animals react to chemicals more or less in the same way as humans because the species are all monogastrics. The ruminants (i.e. cattle and sheep), however, react differently from the monogastrics. The ruminants have evolved a unique digestive tract structure and microbial flora which play a major role in the fermentation and digestion of the forage ingested. The ruminant's microflora is usually capable of biochemically altering foreign chemicals. As an example, cattle are more susceptible to nitrate poisoning than the horse, while dogs and cats are very resistant. Cattle are very susceptible to nitrate poisoning because the microbes in their digestive tract can convert nitrates to the proximate toxic metabolite, nitrite. Dogs, because of their relatively small gastrointestinal microbial population, are resistant to nitrate poisoning. The horse may still succumb to nitrate poisoning because of the micro-organisms in the caecum in its posterior digestive tract. However, by the time nitrate reaches the caecum, more than 70% will have been absorbed in the proximal digestive tract and little will be available for biotransformation into the toxic nitrite ion. Horses therefore require approximately threefold higher nitrate concentrations in their diet to be poisoned than do cattle.

Physiological differences among species also markedly alter the susceptibility of animals to toxicants. Birds, including pet birds, are more sensitive to toxic vapours and gases than mammals because of their respiratory-system structure and functioning. Canaries have been used in mines to test for the presence of poisonous gases because their unique respiratory system makes them succumb to lower concentrations of toxic gases than humans. Biochemical differences also contribute to differential susceptibility between and within species. Cats are more susceptible to paracetamol (acetaminophen) poisoning than are other domestic animals (Welch *et al*., 1966). The cat's ability to employ glucuronyl transferase activity for conjugating paracetamol (acetaminophen) is much lower than that of other domestic species, and feline haemoglobin is more susceptible to oxidation than that of other animals (Rumbeiha and Oehme, 1992a). Therefore, cats given what would be considered a therapeutic dose for small humans will die of methaemoglobinaemia. Biochemical differences are also found within the same species; for example, the Bedlington terrier is much more susceptible to copper poisoning than other species of dogs. These biochemical differences are of genetic origin and thus specific for animal species and breed.

Adequate comprehension of the variability in toxicity from chemicals in the domesticated species requires an understanding of the anatomy, physiology and biochemistry of the affected animals. The other general factors that affect the toxicity of chemicals must also be considered when dealing with clinical toxicities in domestic animals. These factors include the animal's age, sex, health and nutritional status, concurrent exposures to other chemicals, and the environment in which the animal lives (Osweiler *et al*., 1985). The effects of these and other factors in modifying the outcome of poisoning are of vital importance in determining the clinical outcome, and markedly affect consideration of appropriate management options. Ultimate therapy and prognostic decisions thus rely upon these overlapping insights. There is a vast literature in this area which interested readers may consult for further detailed discussions (Osweiler *et al*., 1985; Hayes, 1991; Gwaltney-Brant, 2007).

2 COMMON TOXICOSES OF DOGS AND CATS

Dogs and cats are commonly poisoned by pesticides, household products such as antifreeze and bleaches, and by human medications to which they have become accessible or with which they have mistakenly been dosed. By far the most commonly reported toxicities in these pets involve insecticides because of overzealous use of these products by owners in controlling fleas and ticks on their pets (Trammel *et al*., 1989).

2.1 Insecticides

The insecticides most commonly involved in poisoning dogs and cats are organophosphates, carbamates, pyrethrins and pyrethroids. The organophosphate and carbamate insecticides have a common mode of action in the inhibition of acetylcholinesterase (Fikes, 1990). Acetylcholinesterase is an enzyme which breaks down acetylcholine, a neurotransmitter in autonomic ganglia and at cholinergic nerve endings. The inhibition of acetylcholinesterase by organophosphate and carbamate compounds causes acetylcholine to accumulate and results in persistent firing of cholinergic nerve fibres.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat110
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Affected animals are overexcited and show increased respiratory rates, muscle tremors and excessive salivation. Treatment of animals poisoned by organophosphate compounds involves administration of atropine and pralidoxime. Cases involving carbamates should only be treated with atropine. The organophosphate and carbamate compounds have a relatively high acute toxicity compared with chlorinated hydrocarbon (CH) insecticides, but have a lower residual activity. As such, organophosphate compounds have largely replaced the organochlorines for insecticide use because of environmental concerns.

The CHs were among the first insecticide compounds to be used, but have fallen into disfavour because of their persistence in the environment (Smith, 1991). Typical examples include dichlorodiphenyltrichloroethane (DDT) and lindane. The toxicity of these compounds in all animal species is characterized by excessive central nervous system (CNS) signs including ataxia and convulsions. Small animals are usually poisoned accidentally by being sprayed or by drinking concentrates of CH intended for spraying on crops. Although most of the organochlorines are banned or their use is highly restricted in developed countries, they are still widely used in developing countries. Therefore, cases of CH insecticide poisoning are still present in countries outside of North America.

Another class of insecticides which is increasingly commonly involved in small animal poisoning involves plant products: pyrethrins and their synthetic congeners the pyrethroids. These products are currently enjoying a resurgence because of their selective insecticidal properties and absence of environmental persistence (Valentine, 1990). These compounds are metabolized in the body mainly in the liver by glucuronidation. The cat is the most sensitive domesticated animal to pyrethrin toxicity because of the low activity of the glucuronide conjugating system in this species. Young cats, less than six weeks of age, are the most sensitive. We see frequent toxicosis in felines from pyrethroid products when they are used enthusiastically on cats for flea control or when products formulated for dogs are applied to cats or cats sleeping with treated dogs lick the pyrethroid product from their companion dog's haircoat. Pyrethroid compounds formulated with the insect repellent diethyltoluamide (DEET) were responsible for numerous deaths in cats and dogs in the early 1980s. Pyrethroids interfere with sodium channels in nerves causing them to fire repetitively (Casida *et al*., 1983). Clinical signs of pyrethroid poisoning in small animals include muscle fasciculations and tremors, ataxia and excitement. There is no antidote for pyrethrin poisoning, but treatment consists of symptomatic treatment, such as decontamination procedures and sedation (Valentine, 1990).

The more recent group of chemicals used to control ticks, fleas and other vectors on household pets are formulated with considerably reduced toxic risk and to work on insects on the pet through novel molecular or reproductive-interfering mechanisms. Fipronil is distributed in the pet's surface skin layers and is selectively neurotoxic to vertebrates and invertebrates, but less so to mammals. Imidacloprid has no systemic absorption and after topical application resides in the fatty layer of the skin. It is effective in insect control by mimicking acetylcholine and interfering with stimuli transmission in insect nervous systems. Sulfluramid is used as an ant and roach control agent, and produces potent uncoupling of insect mitochondrial respiration; the loss of ATP (adenosine triphosphate) causes insect toxicosis and death in 24–48 hours.

2.2 Rodenticides

Rodenticide poisoning is commonly encountered in small animals. They are widely used in homes and around farm houses to control rodents such as rats and mice, which destroy property and invade farm produce. Several classes of rodenticides are currently in use. These include the anticoagulant rodenticides (warfarin and the second generation rodenticides such as brodifacoum), zinc phosphide, strychnine, compound 1080 and arsenic compounds. Small animals are poisoned either by consuming baits directly or through consumption of carrion of animals which have died of rodenticide poisoning. The clinical signs will vary with the compound involved and in the majority of cases occur in dogs because of their indiscriminate eating habits. Strychnine and anticoagulant rodenticides are the most frequently reported offenders. Strychnine poisoning in dogs is a rapidly developing syndrome characterized by tonic-clonic seizures. These signs are a result of strychnine competitively blocking the inhibitory neurons in the brain (Heisser *et al*., 1992). The animals start showing signs within 20 minutes to one hour of ingesting strychnine, and if the animal has ingested a sufficient amount, death from anoxia occurs acutely. Anoxia results from paralysis of respiratory muscles. Treatment of strychnine poisoning is symptomatic and involves general decontamination procedures. Use of sedatives such as phenobarbital (phenobarbitone) and diazepam, maintenance of adequate urine output and respiratory support are supportive measures. The sedatives control the seizures and cause muscles to relax (Maron *et al*., 1971; Boyd and Spyker, 1983).

The anticoagulant rodenticides have been in use for a fairly long time. Because of the long time required to take effect, some strains of rats became genetically resistant to the so-called first-generation anticoagulant rodenticides, such as warfarin. This led to the introduction of second-generation rodenticides, such as brodifacoum. Unlike the first-generation rodenticides which took at least 24–48 hours to take effect, the second-generation

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat110
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

rodenticides act fairly acutely; clinical signs can be evident within a few hours and have a long residual action. These anticoagulant rodenticides act by inhibiting vitamin K-dependent factors (VII, IX and X), decreasing prothrombin synthesis and by directly damaging blood capillaries (Coon and Wallis, 1972). Clinically, animals poisoned by anticoagulant rodenticides are weak, have swollen joints because of bleeding into the joint cavities, can show bleeding from the nostrils and may pass blood-stained faeces. Treatment of anticoagulant rodenticide poisoning involves blood transfusions if the bleeding is severe or vitamin K_3 injections. Early intervention involves general decontamination procedures to limit further absorption of toxicants, especially in the case of exposure to the potent second-generation rodenticides, followed by vitamin K_1 therapy (Pelfrene, 1991).

The toxicity of zinc phosphide is due to phosphine gas which is produced by acid hydrolysis in the stomach. Animals with partially filled stomachs are more sensitive to zinc phosphide poisoning than those with empty stomachs because of higher gastric acid secretion precipitated by the presence of food. Phosphine gas is then absorbed systemically and exerts its effects in the lungs. Poisoned animals exhibit respiratory difficulties because of the build-up of fluid in the lungs. The cause of death is respiratory failure (Stephenson, 1967). Supportive therapy, including respiratory support, is recommended in cases of zinc phosphide poisoning, but the prognosis is poor as no effective antidote is available.

Compound 1080 (sodium fluoroacetate) is a highly lethal toxicant which acts by blocking the Embden–Meyerhof pathway, thereby depriving cells of energy. *In vivo,* fluoroacetate is metabolized to fluorocitrate, which inhibits mitochondrial aconitase. This blocks ATP production (Buffa and Peters, 1950). Affected animals are initially uneasy, become excitable and will run in one direction and finally fall down in seizures and die of anoxia. There is no antidote to Compound 1080 and, invariably, poisoned animals die.

Cholecalciferol (Quintox) is a rodenticide which has been reported to be widely involved in the poisoning of dogs. The compound alters calcium homoeostasis by promoting calcium absorption from the gut and also by mobilizing calcium from bones. Consequently, poisoned animals have elevated blood calcium levels. The calcium is subsequently deposited in soft tissues, such as lung, intestinal mucosal cells, muscle, liver, heart and kidneys. Mineralization of soft tissue interferes with normal functioning of these organs. Clinically the animals do not show toxicity until 24–48 hours after ingestion of the bait. The affected animals are depressed, and have reduced urine production with low urine specific gravity. Severely poisoned animals have haematemesis, azotaemia and cardiac arrhythmias (Dorman, 1990). Animals with renal impairment are more susceptible to cholecalciferol poisoning than those with normal renal function. Cholecalciferol poisoning requires protracted treatment which may last as long as three weeks in severe intoxications (Livezey *et al.*, 1991). The treatment consists of fluid therapy to assist kidney excretion of calcium, corticosteroids to depress inflammation and calcitonin to enhance calcium resorption into bones.

Several other rodenticides can cause poisoning in small animals but do so less frequently because these rodenticides are used less often. Red squill and thallium have been used as rodenticides for a very long time. Red squill acts as a cardiotoxicant and causes death by cardiac arrest. Red squill also causes convulsions and paralysis. Thallium is a general systemic toxicant. It has a high affinity for sulfhydryl groups throughout the body. Thallium causes cracking at the corners of the lips and also hair loss. *n*-Naphthylthiourea (ANTU) causes death by inducing lung oedema, subsequently leading to anoxia. White phosphorus is a hepatorenal toxicant. Animals poisoned by white phosphorus have severe abdominal pain, hepatomegaly and signs of hepatic insufficiency, such as prolonged bleeding and hypoglycaemia.

In general, cases of rodenticide poisoning in small animals should be regarded as emergencies. General decontamination procedures such as vomiting induced with either hydrogen peroxide or apomorphine, use of activated charcoal to bind the unabsorbed toxicants or enterogastric lavage should be employed to minimize absorption of the poisons.

2.3 Household Chemicals

Antifreeze is one of the household products most commonly involved in small animal poisoning. The active ingredient in antifreeze is ethylene glycol. The characteristic sweet taste of this compound makes it very attractive to small animals. Ethylene glycol is metabolized in the liver by the alcohol dehydrogenase pathway into glycolic acid and oxalate, and the former contributes to the characteristic acidosis of ethylene glycol poisoning. The oxalate binds with calcium in the blood to produce calcium oxalate crystals, which are filtered in the renal tubules causing toxic damage to the tubular epithelium and leaving crystals that produce blockage of the renal tubules (Grauer and Thrall, 1982). Consequently, affected animals have renal failure characterized by anuria and uraemia. The binding of blood calcium to oxalate causes hypocalcaemia which, if severe, can lead to acute death. Ethylene glycol poisoning is traditionally treated by giving ethanol if the animal is presented within 4–8 hours of suspected ingestion and by giving fluids containing sodium bicarbonate to facilitate flushing the calcium oxalate crystals from the kidneys and also to correct the acid–base imbalance. Alcohol dehydrogenase, an enzyme which breaks down ethanol to acetic acid and water, prefers ethanol to ethylene glycol and in the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

presence of both substrates will selectively metabolize ethanol, leaving ethylene glycol to be excreted unchanged in the urine. 4-Methylpyrazole has more recently been confirmed to have excellent antidotal properties against ethylene glycol toxicosis in dogs (Connally *et al*., 1996). It has fewer side effects than ethanol and works by reversibly blocking the conversion of ethylene glycol to glycolic acid and oxalate by alcohol dehydrogenase. It is effective if administered up to 8–12 hours after the consumption of antifreeze, but because of species differences in enzyme specificity it is of considerably lesser benefit to cats poisoned with ethylene glycol, leaving ethanol as still the preferred treatment for ethylene glycol intoxication in cats (Dial *et al*., 1994).

Household products such as sink cleaners, dish-washing detergents and toilet cleaners are not uncommon causes of poisoning in household pets. The majority of the cleaning detergents are corrosive compounds which contain either strong alkalis, acids or phenolic compounds (Coppock *et al*., 1988). These compounds therefore act as contact poisons, causing coagulative necrosis of the tissues which they contact. Following ingestion of these products the dog or cat will vomit, have severe abdominal pain and may have diarrhoea. The vomitus and faeces may be bloody. Animals may also show other signs depending on the specific ingredients of the offending products. For example, products containing phenolic derivatives will cause acidosis and hepatotoxicty. In general, treatment following ingestion of household products is symptomatic and involves the administration of dilutants (milk or water), adsorbents, such as activated charcoal, gastrointestinal protectants such as peptobismol or egg whites, and correction of acidotic systemic disturbances which often accompany the poisoning. Animals so poisoned should be provided abundant glucose and quality protein diets.

2.4 Unusual Household Materials

The average home and household contains many materials and chemicals that could cause injury or poisoning to pets that consume them. Each year veterinarians and toxicologists are asked to deal with dogs and cats that have been exposed to one or more of such products in rooms, garages or backyards. Many induce mild to moderate effects; some are more toxic, and on being informed that illness is due to application or ingestion of the hazardous material, the animal owner usually responds with, 'I didn't know that would cause any problem!'

The materials and products that attract pets are often novel and induce the animals to play with them and in the process swallow all or a portion of them. In some instances owners offer the material to their pets believing they are harmless playtoys or snacks.

Examples of some of these products are glow jewellery, gorilla glue, super glue, homemade play dough, ice melts, fireworks and matches, mothballs, paint balls, xylitol-containing gum, macadamia nuts, grapes and raisins, hops, onions and garlic, commercial 'Greenie' treats and the numerous and varied herbal products. Each is capable of inducing unique toxic risks in pets. The extent and characteristics of each intoxication is usually a diagnostic and then management challenge that is appropriately handled by an experienced veterinarian.

2.5 Garbage Poisoning

Garbage poisoning is a frequently encountered problem in small animals. This condition is also referred to as enterotoxicosis or endotoxaemia, depending on whether poisoning is from bacterial infection or ingestion of bacterial endotoxins. Dogs that are not well fed and/or not closely supervised may seek out and eat garbage. Cats may also be affected, but only rarely because they are discriminate eaters. The bacteria most commonly involved are the coliforms, *Staphylococci*, *Salmonella* and occasionally *Clostridium botulinum*. Enterotoxaemia-affected animals develop a bacteraemia after eating infected carrion, with clinical signs normally appearing at least 24–48 hours after ingestion. The condition is characterized by severe abdominal pain, anorexia, fever, vomiting and infrequent bloody diarrhoea. In endotoxaemia the poisoning results from the bacterial endotoxins which are normally present in bacterial cell walls. The clinical signs are generally indistinguishable from those of enterotoxaemia except that with endotoxaemia there is no bacteraemia (which can be confirmed by blood culture). Although rare in occurrence, botulism is a rapidly developing fatal disease which can result from ingesting bones contaminated with *Clostridium botulinum*. In small animals the disease is characterized by an ascending paralysis. At first there is weakness and incoordination in the muscles of the hind limbs and as the paralysis progresses anteriorly there is dyspnoea and convulsions.

Garbage poisoning is rarely a severe condition in small animals because the animals invariably vomit and reduce the amount of toxicant ingested. However, in severe cases medical attention will be required. If the cat or dog is presented early after ingestion then general decontamination procedures should be instituted. Anti-inflammatory corticosteroids and antibiotics should be given, with further treatment involving supportive therapy.

2.6 Pet Food and Dietary Hazards

2.6.1 Numerous Sources

Pets are at the mercy of their owners or care-providers for appropriate feeding and other care. Those pets that also have outdoor access may also have opportunity to browse their neighbourhood or to have material thrown into their outdoor pens if exposure to harmful substances is intended. The latter situation usually involves dogs and cats being maliciously exposed to pesticides, toxic baits or known poisons such as strychnine. The effect of these recognized toxins are discussed in separate sections.

Accidental dietary poisonings may also occur with pets gaining access to spoiled food, materials undergoing fungal growth and producing mycotoxins, and in general consuming discarded wastes that may even contain outdated drugs and discarded household materials such as coffee grounds, breads/cakes, pizza and even old chocolate pieces. As noted elsewhere in this chapter, consumption of these products is also hazardous.

Of recent additional concern has been the intentional inclusion of unidentified chemicals in commercial dietary formulations for economic gain without warning of their presence and potential toxic effects.

2.6.2 Industrially Contaminated Pet Foods

These purposely added compounds to pet diets have had confusing and largely unexpected consequences to the consuming pets. Their illegal dietary presence did not warn the veterinary and general public of potential dangers, and when clinical problems developed considerable analytical diagnostic efforts over significant timeframes impacted the ability to provide appropriate management and prevention efforts. Such was the case with the 2007 melamine contamination of dog and cat branded dietary products by the inclusion of contaminated raw ingredients from Asian suppliers.

In the Spring of 2007 observations from a small pet-food feeding study showed an incidence of adverse kidney effects. Followup investigations identified the contamination of an ingredient in the experimental diet as being melamine, cyanuric acid and related chemicals. Clinical effects were associated with the ingestion of dietary products containing melamine and cyanuric acid, producing composite crystals in the renal tubules and dose-related kidney toxicity. Both chemical contaminants were required to induce the kidney disorder.

Clinical lesions and outcomes were clearly related to the dosage of each chemical in the diet, producing an interesting classic dose–response phenomena.

2.6.3 Mixtures and Interactions Between Contaminants

Similar risks may develop by animals ingesting chemicals in mixtures or from the intentional or accidental contamination of animal foods. Owners may offer left-over table scraps to pets, not recognizing that the tasty human dietary additions may produce hazards when mixed and consumed by nondiscriminating pets. Left-over spices, onions, garlic, fruits, sweets and nuts become risky foods when eaten by animals metabolically challenged to metabolize and excrete such unaccustomed materials. The risk is increased when unknown compounds are substituted or used to replace the ingredients usually present, such as occurred in the melamine-cyanuric acid episode.

Unfortunately, testing of mixtures or unusual dietary additions is a complex effort and not on the immediate radar screen of most researchers. Industry is further compromised by not always being aware of what dietary components are most likely to be included in the mix. The result is that toxicologists and cooperating scientists are usually working with developing events as they unfold and playing 'catch-up' to identify and deal with the most prominent concerns. Identification of the issues in question is often the first priority.

2.6.4 Regulatory Actions in the Future

Since public as well as animal safety is frequently affected on the occasion of such dietary contaminant happenings, state and Federal regulatory action may result from these situations. When dietary contamination of purchased supplements is found, mandatory inspection of feed ingredients and manufacturing facilities may be an early action. Assurances from suppliers of expected quality and the meeting of ingredient standards, supported by the necessary analytical assays and attested-to documents become a part of the new manufacturing and formulating paradigm. Such regulatory requirements and oversights have intensified in response to the recent series of commercial pet food and dietary indiscretions.

2.7 Mycotoxins

Some of the mycotoxins of veterinary interest include aflatoxins, deoxynivalenol (DON). Diacetoxyscirpenol (DAS), T-2 zearalenone, ochratoxins and fumonisin B_1 (Cheeke and Shull, 1985; Keller *et al*., 1990). Mycotoxins especially are a common problem in warm climates where high temperatures and relative humidity support fungal growth and favour mycotoxin production. All animals are susceptible and clinical signs will depend on the mycotoxins involved. Rarely is only one mycotoxin

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat110
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

involved because several species of fungi, for example, *Fusarium*, *Penicillium* and *Aspergillus*, coexist and often produce more than one type of mycotoxin.

The common sources of aflatoxins to pet and food-producing animals include corn and oats. When aflatoxins are ingested in parts per million quantities acute death can occur, with the affected animals showing severe gastrointestinal pain and haemorrhage. Aflatoxins are severe hepatotoxicants: therefore hepatomegaly and jaundice may be observed in severe subacute cases. Quite often, however, aflatoxin poisoning is insidious following a chronic intake of parts per billion concentrations of aflatoxin over a prolonged period of time. Clinical signs include poor weight gain, decreased milk production and poor reproductive performance, including abortions. Virtually every organ function is affected by aflatoxins. The immune system of affected animals is impaired and they succumb to infectious diseases (Pier, 1981).

Toxicity due to T-2 mycotoxins has been reported in North America and some other parts of the world, including Germany, Hungary, France and South Africa. It is less common than aflatoxin toxicity. T-2 acts by interfering with the blood-clotting mechanism. Affected animals have gastrointestinal bleeding and will pass blood-stained faeces. The animals will perform poorly, lose appetite, have low weight gain and productivity and chronic decreased food intake. T-2 is also an immunosuppressant. All animals are susceptible to T-2 mycotoxicosis. Treatment consists of withdrawal of the contaminated feed and supportive care.

Zearalenone is an oestrogenic mycotoxin which often causes toxicity in young animals, prepubertal swine being mostly affected. Consuming diets containing contaminated corn is the usual source. Affected females show swelling of the vulva and excessive straining which may cause vaginal prolapse. In male animals zearalenone will cause decreased libido. There is no effective treatment apart from withdrawing the contaminated feed.

Other mycotoxins, including deoxynivalenol (DON), diacetoxyscirpenol (DAS) and ochratoxin, are not of major economic importance, although they can be toxic and economically disruptive to food-producing animals. DAS causes necrosis and erosion of the oral mucous membranes. Consequently, affected animals may refuse to feed and have impaired growth. DON also induces vomiting and feed refusal in swine. Ochratoxins cause renal problems, including hydronephrosis.

Ergot poisoning is occasionally encountered in livestock fed diets containing grain screenings contaminated with *Claviceps purpurea*. The active ingredients are ergotoxin and ergotamine, which are vasoactive compounds. These compounds cause vasoconstriction of the peripheral vessels, especially those of the extremities, causing necrosis and gangrene of extremities. Abortions and agalactia have been reported. Therapy consists of discontinuation of the source of the toxicant and antibiotics to prevent secondary bacterial infection in necrotic tissues (Cheeke and Shull, 1985).

Fumonisin B_1 is produced by *Fusarium moniliforme*, a worldwide fungus which predominantly grows on corn. Fumonisin B_1 causes pulmonary oedema and respiratory distress in swine and other monogastrics. Deaths have been reported in swine fed contaminated corn screenings (Colvin and Harrison, 1992). This mycotoxin is also responsible for numerous sporadic outbreaks of CNS disease in horses characterized by an encephalomalacia and is epidemiologically associated with high incidences of human oesophageal cancer in cultures that have corn as a dietary staple.

2.8 Heavy Metals

Lead, zinc and arsenic are the heavy metals most frequently involved in small animal poisoning, although zinc intoxication is unique and seen in dogs with increasing frequency.

Lead poisoning is more commonly reported in the dog than the cat, but both are susceptible. The sources of lead poisoning in the dog include ingested lead objects such as lead weights and paint chips in old houses that are being renovated. The clinical signs of lead poisoning in the dog primarily involve the CNS. The dogs often present with abdominal pains, diarrhoea and CNS involvement. Lead poisoning is a chronic disease in dogs, but the overt central nervous signs may appear suddenly. Lead poisoning causes blood dyscrasia characterized by reticulocytosis and occasionally anaemia. Similar clinical signs are elicited in the cat. Treatment consists of giving chelating agents such as calcium disodium EDTA (ethylenediaminetetraacetic acid), dimercaprol (BAL), succimer (DMSA) or D-penicillamine. Identifying and removing the source in the home is important, but often is a challenge.

The playful mouthing and swallowing behaviour of dogs results in their ingesting coins that, in the acidity of the stomach, release zinc. The absorbed zinc causes chronic liver damage and red-blood-cell destruction, presenting as a haemolytic anaemia. The often puzzling clinical illness responds quickly to removal of the dissolving coins from the stomach and appropriate supportive care for several days.

Arsenic is the active ingredient in some insecticides, rodenticides and herbicides. Inorganic arsenic and the aliphatic organic arsenicals are rapidly absorbed from the gut, skin and lungs and are more toxic than cyclic organic arsenicals which are used as feed additives (Furr and Buck, 1986). Trivalent arsenic is the proximate toxicant of the pesticide arsenicals

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat110
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and it reacts with the sulfhydryl groups of proteins throughout the body. It is therefore a general poison, inhibiting all sulfhydryl-containing enzymes. The clinical signs of inorganic arsenic poisoning in dogs include severe abdominal pain, bloody diarrhoea, anorexia and hair loss, and so on, as discussed under herbicides. Treatment involves decontamination, chelation therapy with BAL and supportive therapy.

2.9 Herbicides

Herbicides are not widely involved in small animal toxicity despite their frequent use around farms. However, toxicity in dogs arising from consumption of concentrates of herbicides during mixing is occasionally reported.

The triazine herbicides act by inhibiting photosynthesis and are generally safe products. The LD_{50} of these compounds in the rat is at least 1900 mg (kg body weight)$^{-1}$. Therefore, toxicity in dogs can only occur following ingestion of large doses of the concentrated product. In experimental situations, triazine-herbicide-poisoned dogs become either excited or depressed, have motor incoordination and may show clonic-tonic spasms.

Some inorganic arsenic compounds are used as herbicides. Inorganic arsenicals are general protoplasmic poisons and therefore are hazardous to both plant and animal life. Affected dogs have severe abdominal pain, bloody diarrhoea and vomiting, and the vomitus may contain mucous shreds from erosion of the intestinal epithelium.

Paraquat, although restricted in use in most Western countries, is a very toxic herbicide which is readily available in developing tropical locales. Following intake, paraquat is rapidly metabolized in the liver and lungs with secondary oxygen-radical production. It is these secondary radicals which cause injury to tissues, especially the lungs. Poisoned animals die of acute respiratory failure.

Unlike other animals, the dog appears sensitive to chlorphenoxy herbicides such as 2,4-dichlorophenoxyacetic acid (2,4-D). The oral LD_{50} for the dog is 100 mg (kg body weight)$^{-1}$. Ventricular fibrillation is the cause of death in severely poisoned dogs. Ingestion of sublethal doses induce myotonia, stiff extremities, ataxia, paralysis, coma and subnormal temperatures (Stevens and Sumner, 1991).

Chlorate herbicides have been used on roadsides. Chlorates are rapidly metabolized in the liver to the chlorate ion, which induces methaemoglobinaemia in both cats and dogs. Cats, however, because of the greater susceptibility of their haemoglobin molecule to oxidation, are more susceptible to induced chlorate poisoning than dogs.

Organophosphate herbicides, for example, glyphosate and merphos, are weak cholinesterase inhibitors and are of moderate toxicity in dogs and cats. Carbamate herbicides are not inhibitors of acetylcholinesterase and are also moderately toxic to dogs. The LD_{50} of most of the carbaniate herbicides is at least 5000 mg (kg body weight)$^{-1}$.

2.10 Plant and Mushroom Poisonings

Although one would not expect dogs and cats to eat plants (toxic or nontoxic), plant poisoning is surprisingly often reported in these species (Fowler, 1981; ASPCA, 2008). Because of their exploratory nature, puppies and kittens are most often involved. Boredom and change of environment are some of the predisposing factors to plant ingestion in dogs and cats.

Poisonous ornamental plants, for example, *Rhododendron*, and plants used around fences such as cassia and oak are mostly involved. The subject of poisonous plants is a vast one and because the clinical signs are similar in food-producing and small animals, this subject is dealt with extensively under food-producing animal toxicoses (see **Tables 1–8**). In addition, interested readers may consult a good overview of plant poisonings in small companion animals (Fowler, 1981), as well as current online listings of common plant poisonings in pets (ASPCA, 2008).

Occasionally dogs or cats will eat or be fed poisonous mushrooms by uninformed owners. *Amanita muscaria* and *A. pantherima* are acutely toxic and induce signs within 15–30 min of ingestion. These two mushroom species cause nervous signs, which also include salivation, pupillary constriction, muscular spasms, drowsiness or excitement and eventually coma and death in severe intoxications. Ibotenic acid and muscimol are the active toxins.

However, *A. phaloides*, *A. virosa* and *A. verna* induce gastrointestinal signs which are evident 6–12 hours after ingestion. The signs include violent vomiting, diarrhoea, dehydration and muscle cramps. These mushrooms also cause hepatic insufficiency. Phalloidin and α- and β-ainanitine are the principal poisons in this group (Fowler, 1981).

3 COMMON TOXICOSES IN FOOD-PRODUCING ANIMALS

This section will address toxicoses commonly encountered in cattle, sheep, goats and swine. Swine differ from all other animals in this category in that they have a simple stomach (monogastrics), whereas the rest have a compound (four-compartment) stomach.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat110

Table 1 Toxic plants affecting the gastrointestinal tract of food-producing animals

Scientific name	Common name	Species commonly affected	Toxic parts and principle(s)	Clinical signs
Ricinus communis	Castor oil plant	Cattle, pigs	Seeds, leaves Ricin	Abdominal pain, vomiting, convulsions, dullness
Robinia pseudocacia	Black locust	Cattle, sheep	Bark, foliage, seed Robin, robitin, phasin	Anorexia, lassitude, posterior paralysis, cold extremities, dilated pupils
Phoradendron spp.	Mistletoe	Cattle, sheep	Berries. β-Phenylethylamine, choline, tyramine	Vomiting, diarrhoea, bradycardia, sudden death
Ranunculus spp.	Buttercup	Cattle, goats, swine	Fresh foliage Protoanemonin	Blisters on lips, salivation, diarrhoea, tucked abdomen
Phytolacca dodecandra	Pokeweed	Cattle, sheep, swine	Foliage, unripe berries. Oxalic acid, phytolaccotoxin, phytolaccin	Diarrhoea, dyspnoea, spasms, reduced milk, convulsions, ataxia
Sesbania spp.	Rattlebox	All	Seeds, foliage Sesbanine	Haemorrhagic diarrhoea, severe abdominal pain, coma, death
Agrostemma githago	Corn cockle	Cattle, swine	Seeds. Githagenin	Diarrhoea, arched back
Quercus spp.	Oak	Cattle, sheep, swine	Acorns, buds, young leaves, flowers, seeds, stem Tannic acid, gallic acid	Abdominal pain, constipation or bloody diarrhoea
Euphorbia spp.	Spurge	Cattle, sheep	Whole plant Euphoron, euphorbin, cyanide	Diarrhoea (haemorrhagic or not), blisters of skin and oral mucous membranes, salivation, abdominal pain
Xanthium spp.	Cocklebur	Pigs, cattle, sheep	Seeds, cotyledons Carboxyatractyloside	Anorexia, vomiting, tucked abdomen, depression, severe hypoglycaemia, weakness, convulsions

Most of the toxicants discussed under small animals also affect food-producing animals, but there are some toxicants which are peculiar or predominantly seen only in food-producing animals. Those frequently encountered in ruminants include nonprotein nitrogen toxicoses, copper, lead, arsenic, mycotoxicoses, nitrite poisoning, pasture-plant poisonings and algae poisoning. In swine, salt poisoning, mycotoxicoses, organic arsenic, small pasture- and feedlot-plant poisoning and gases generated in swine-confinement operations are often involved.

3.1 Poisoning by Nonprotein Nitrogen Compounds

Nonprotein nitrogenous sources in food-producing animals include urea, biuret and ammoniated feeds. These compounds are cheap sources of nitrogen, which is required by the animals for protein synthesis. Nonprotein nitrogen poisoning is a common problem and is often seen in animals that are not gradually introduced to diets containing these compounds.

Table 2 Toxic plants primarily affecting the liver of food-producing animals

Scientific name	Common name	Species commonly affected	Toxic parts and principle(s)	Clinical signs
Senecio spp.	Groundsel	Cattle, sheep, goats	Foliage Several alkaloids, for example, jacobine, jacodine	Dullness, aimless walking, weakness, increased pulse, rapid respiration
Crotolaria sagitallis and *C. spectabilis*	Rattlebox	Cattle and swine mainly, but all species affected	Foliage and seeds Monocrotaline	Loss of appetite, weakness, emaciation incoordination, excitability, nervousness
Amsinkia intermedia	Fiddleneck	Pigs mainly but also sheep and cattle	Seeds Intermidine, lycopsamine, sincamidine	Unthrifty, icteric, haemorrhages of the gastrointestinal tract and subcutaneous tissues
Echium plantagineum	Viper's bugloss	Sheep mainly but also cattle and pigs	All parts are toxic Echiumine, echimidine	As for *Amsinkia*, contact dermatitis
Heliotropium	Heliotrope	Sheep	All parts Heliotrine, lasiocarpine, heleurine	As for *Amsinkia*; secondary photosensitization
Trichodesma europeum	—	All	Foliage Unidentified pyrolizidine alkaloids	As for *Amsinkia*
Lantana camara	—	Cattle, sheep, goats	All parts but especially foliage and berries Lantadine A and B	Severe gastroenteritis, bloody watery faeces, jaundice, secondary photosensitization
Helenium spp.	Sneezeweeds	Sheep and goats mainly but also cattle	All parts but especially leaves and flowers Helenaline, helanine, dugaldine	Severe abdominal pain, bloating, CNS involvement, for example, head pressing
Hymenoxys	Bitterweed	Sheep, cattle, goats	All parts. Hymenoxon	Unthriftiness, inappetance, salivation
Kochia scoporia	Kochia	Cattle	Foliage Unidentified alkaloids + oxalates, nitrates and a thiamine antagonist	Unthriftiness, CNS signs, bleeding disorders, photosensitization
Agave lechuguilla	Agave	Sheep, goats, but also cattle	Foliage Unidentified saponins	Listlessness, primary photosensitization
Trifolium hybridum	Alsike clover	Pigs, sheep, cattle	Foliage. Unidentified saponins	Listlessness
Lotus corniculatus	Birdsfoot trefoil	Cattle	Foliage. Unidentified principles	Listlessness, bloat

Table 3 Toxic plants primarily causing CNS effects in food-producing animals

Scientific name	Common name	Species commonly affected	Toxic parts and principle(s)	Clinical signs
Dicentra cucullaria	Dutchman's breeches	Cattle	All parts but especially leaves and bulbs. Isoquinaline-type alkaloids, for example, apomorphine	Initially abdominal pain and diarrhoea; ataxia, trembling, respiratory distress, convulsions
Cicuta spp.	Water hemlock	Cattle, sheep, goats, pigs less often	Roots, stem base Cicutoxin, cicutol	Muscular spasms and spasmodic convulsions
Corydalis spp.	Fitweed	Sheep mostly but also cattle	Foliage Unidentified alkaloids	Clonic seizures, twitching of facial muscles
Asclepsia spp.	Milk weed	All	Foliage Cardenolides	Severe depression, ataxia, dilated pupils, laboured respiration
Gelsemium spp.	Carolina jessamine	Cattle, sheep, goats	Foliage, flowers Gelsemine and other strychnine-related alkaloids	Depression, muscle weakness, respiratory failure, convulsive movements preceding death
Calycanthus spp.	Sweet shrub	Cattle	Seeds Calycanthine	Seizures, severe tetanic spasms, muscular fasciculations
Eupatropium rugosum	White snakeroot	Young cattle, sheep	Foliage, passes in milk Tremetol	Depression, listlessness, trembling, laboured breathing
Haplopappus heterophylus	Rayless goldenrod	Cattle, sheep, goats	Foliage Tremetol	Depression, trembling, rare limb weakness
Sophora spp.	Mescal beans	Sheep mostly but also cattle and goats	All parts but seeds especially Cytisine, sophorine and nicotinic alkaloids	Nervousness, exercise-induced violent tremors, stiff gait
Xanthium spp.	Cocklebur	Pigs mostly but also cattle and sheep	Seeds, cotyledons Carboxyatractyloside	Depression, prostration, hunched posture, severe hypoglycaemia, extreme hyper sensitivity, convulsions when recumbent
Ranunculus spp.	Buttercup	Cattle mostly but also sheep, goats, pigs	Fresh foliage Protoanemonin	Irritation of oral tissues, salivation, nervousness, paralysis, depression or excitement and convulsions

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat110

Table 4 Toxic plants affecting the autonomic nervous system of food-producing animals

Scientific name	Common name	Species commonly affected	Toxic parts and principle(s)	Clinical signs
Datura stramonium	Jimsonweed, thorn apple	Pigs mostly; sheep goats, cattle	All parts but especially seeds Atropine, scopolamine, hyoscyamine	Anticholinergic signs, for example, dilated pupils, dry mouth, muscle twitching, incoordination, paralysis
Hyoscyamus niger	Henbane	All	Seed. Hyoscyamine	As for *D. stramonium*
Solanum spp.	Nightshades	Pigs mostly; sheep, goats	Foliage, berries Solanine, dihydrosolanine, chaconine	Apathy, depression, dilated pupils, trembling, incoordination, muscular weakness, paralysis, convulsions
Physalis spp.	Groundcherry	Sheep	Tops and unripe berries. Solanine and atropine-like alkaloids	Diarrhoea, trembling, hyperthermia, weakness, paralysis
Gelsemium spp.	Carolina jessamine	Cattle, sheep, goats	(see 'plants causing CNS effects')	
Lycium spp.	Matrimony vine	Calves and sheep	Foliage Unidentified solanaceous alkaloids	Excitement, convulsion
Lobelia spp.	Wild tobacco	Sheep, cattle, goats	Foliage and green fruits Lobeline and lobelidine	Profuse salivation, dilated pupils, narcosis
Conium maculatum	Poison hemlock	Cattle, pigs	Seeds most toxic; fresh Nicotinic alkaloids, for example, conline	Muscle tremors, ataxia, muscle weakness, frequent urination and defecation, respiratory failure
Lupinus spp.	Lupine	Sheep	Pods (seeds) Nicotinic alkaloids, lupinine, lupanine	Laboured breathing, depression, salivation, ataxia, seizures
Sophora spp.	Mescal beans	(see 'plants causing CNS effects')		

It is an acute fatal condition characterized by bloating, intense abdominal pain, ammonia on the breath, frequent urination and frenzy. Often several animals will be affected at once. In ruminant animals the rumen microflora normally converts urea to ammonia, and the ammonia is rapidly utilized by the liver for protein synthesis. However, in cases of excess ammonia production, the blood ammonia concentration builds up to toxic levels very quickly and induces CNS derangement (Lloyd, 1986). Therefore, in addition to gastrointestinal signs, the animals will show fulminating central nervous effects. Treatment of the condition involves giving a weak acid, such as vinegar, and plenty of cold water orally. The rationale behind giving cold water and acetic acid is to slow the action of urease, the enzyme responsible for breaking down urea to ammonia, which requires high temperature and pH for optimal function. The cold water lowers the temperature and the acetic acid lowers the pH. Infusions of calcium and magnesium solutions should be given to alleviate tetany (Osweiler *et al*., 1985; Lloyd, 1986).

Other sources of nonprotein nitrogen (urea) poisoning in ruminants involve accidental ingestion of nitrogen-based fertilizers, such as ammonium phosphate (Gosselin *et al*., 1976. Occasionally cattle break into drums or bags of fertilizers containing these nitrogen-based compounds. Prognosis is grave in most cases if several animals are affected. In cases where only a few valuable animals are affected, a rumenotomy can be performed.

Although small ruminants have the same anatomical predisposition to suffer from nonprotein nitrogen poisoning, they are rarely involved, probably because

Table 5 Toxic plants affecting the reproductive system of food-producing animals[a]

Scientific name	Common name	Species commonly affected	Toxic parts and principle(s)	Clinical signs
Veratrum californicum	False hellebore	Sheep	Roots and rhizomes mainly, but all parts are toxic. Jervin, veratrosin, cyclopamine	Cyclopian-type congenital malformation, anophthalmia, cleft palate
Festuca arundinacea	Tall fescue	Sheep, cattle	Foliage. Endophyte alkaloids, for example, perlolidine, perloline	Abortion, still births, agalactia
Pinus ponderosa	Ponderosa	Cattle, sheep	Pine needles Unidentified	Last trimester abortions, stillbirths, premature deliveries, retained placenta
Gutierrezia microcephala	Broomweed	All	Foliage Unidentified saponins	Abortions, premature delivery, swelling of vulva
Cupressus macrocarpa	Monterey cypress	Cattle	Foliage Unidentified	Last trimester abortions, weakness, ataxia, death
Iva augatifolia	Sumpweed	Cattle	Foliage Unidentified	Abortion in last half of gestation

[a]Other plants that cause abortion include those containing nicotinic alkaloids (such as poison hemlock and tobacco), nitrate-accumulating plants (such as locoweed), cyanogenic plants (such as sorghum) and oestrogenic plants (such as clovers and wheat germ).

they are not often fed rations containing these compounds.

3.2 Nitrate/Nitrite Poisoning

Excessive exposure of ruminants to nitrates causes nitrite toxicity, an acute, rapidly fatal disease. The commonest source of nitrates in ruminants is through consumption of forage grown on heavily fertilized fields that have accumulated a lot of nitrate compounds (Ridder and Oehme, 1974). All common animal feeds, such as sorghum, alfalfa and milo and so on, can accumulate excessive amounts of nitrates (Clay *et al*., 1976). Another common source of nitrates is contaminated drinking water. Nitrates are highly water soluble and underground water contamination can occur from heavily fertilized fields (Menzer, 1991). Run-off from fertilized fields is another source of contamination to surface pools and ponds.

Nitrates are reduced to nitrites by rumen microflora. Under normal circumstances the nitrite ion is rapidly utilized for ammonia synthesis, but in cases of excessive acute intake of nitrate and its rapid reduction, the nitrite ion is absorbed into the bloodstream where the nitrite ion reacts with haemoglobin to form methaemoglobin. Methaemoglobin is incapable of oxygen transport and the animal compensates for the anoxia by increasing its respiratory rate. Therefore, affected animals will be hyperventilating, have brownish mucous membranes, and will be weak. Chronic intake of nitrates has been reported to cause reproductive problems, such as abortion, but experimental results are inconclusive (Osweiler *et al*., 1985). Besides reacting with haemoglobin, the nitrite ion also replaces iodine in the thyroid gland, thereby interfering with the function of the thyroid hormone.

Treatment of nitrate/nitrite poisoning involves intravenous infusion of 1% methylene blue at a dose of 1.5 mg (kg body weight)$^{-1}$ and removal of the offending feed.

3.3 Copper/Molybdenum Poisoning

Sheep are more susceptible to copper poisoning than cattle, but cattle are more sensitive to molybdenum poisoning than sheep. The *in vivo* relationship between copper and molybdenum is well understood, with copper excess inducing molybdenum deficiency and copper toxicity and *vice versa.* The most frequent cause of copper poisoning in sheep is uninformed farmers, feeding them rations formulated for cattle. Copper is an essential element for cattle and is usually added to their feeds, but molybdenum is not considered highly essential and is therefore not added. Cattle feeds therefore have high copper and no molybdenum and feeding this ration

Table 6 Toxic plants affecting the cardiovascular system of food-producing animals[a]

Scientific name	Common name	Species commonly affected	Toxic parts and principle(s)	Clinical signs
Digitalis purpurea	Foxglove	All (see 'plants causing CNS effects')		
Nerium oleander	Common pink oleander	All	Foliage and flowers Several digitoxin-like glycosides	Cardiac arrhythmias, unconsciousness, hypotension, dyspnoea
Convalaria spp.	Lily-of-the-valley	All	All parts, convallarine, convallatoxin, convallamarin	Tachycardia, diarrhoea, anorexia
Apocynum spp.	Dogbane	Cattle, sheep	All parts. Cardiac glycosides, for example, apocynamarin	Cardiac arrhythmias, fever, gastrointestinal pain, fever, gastric upset
Taxus spp.	Yew	All, but swine most sensitive	Foliage, bark, seeds Taxine	Acute heart failure (bradycardia)
Zygadenus spp.	Death camas	Sheep, cattle	All parts. Zygacine	Lowered blood pressure, salivation
Brassica spp.	Kale, rape	Cattle, sheep, goats	Foliage S-Methylcysteine sulfoxide	Haemolytic anaemia, weakness, fast respiration, haemoglobinuria, staggering, collapse
Onion	Onion	All	All parts. *n*-Propyl disulfide	As for *Brassica* spp.

[a]Several nitrate-accumulating plants, for example, *Astragalus*, sudan grass, sorghum, com and pigweed, cause methaemoglobinaemia. Some other plants, including sudan grass and sorghum, affect the cardiovascular system by virtue of their cyanogenic properties (see text).

to sheep upsets the copper/molybdenum ratio *in vivo* for sheep.

Copper toxicity in sheep is an acute condition which develops after a period of chronic copper intake. During the chronic phase copper is stored in the liver until a critical concentration is reached. Following stressful conditions such as transportation or insufficient feed or water intake, a massive hepatic release of copper may be triggered, producing a haemolytic crisis (Osweiler *et al*., 1985). Affected sheep have haemoglobinuria, are weak and death occurs acutely. The massive release of haemoglobin may induce renal failure. The prognosis is poor for animals already showing clinical signs. Chelation therapy using D-penicillamine is recommended for exposed animals not showing clinical signs. The recent availability of injectable ammonium tetrathiomolybdate effectively reduces liver copper levels and improves the prognosis of sheep accumulating low to moderately elevated concentrations of copper (Ensley, 2004).

In cattle molybdenosis is characterized by foamy diarrhoea which may be bloody; affected cattle also have depigmented hair. Molybdenosis is a subacute to chronic condition and occurs when the dietary copper:molybdenum ratio is 2 : 1 or less. The condition has a geographical distribution and occurs in areas deficient in copper or where there is excessive soil molybdenum, in parts of the USA (California, Oregon, Nevada and Florida) (Buck, 1986). Treatment of this condition calls for careful copper supplementation in the animals' feed.

3.4 Lead Poisoning

Despite an awareness of the dangers of lead poisoning in humans and domestic species, it is surprisingly the most frequently encountered heavy metal toxicity in food-producing animals. Lead poisoning is more commonly seen in cattle than in other food-producing animals.

Young animals are mostly affected because of their curiosity and indiscriminate feeding habits. There are several sources of lead for cattle, and discarded batteries and leaded water pipes are the commonest. Often uninformed owners will discard or store old batteries in farm environments and cattle will chew on them. Discarded

Table 7 Toxic plants affecting renal function of food-producing animals

Scientific name	Common name	Species commonly affected	Toxic parts and principle(s)	Clinical signs
Beta vulgaris	Beet	Sheep and cattle	Sugar beet tops. Oxalates	Muscle tetany, renal failure
Rheum rhaponticum	Rhubarb	All	Foliage Oxalic acid, oxalates	Irritation of oral cavity and digestive tract, renal failure, death in convulsions
Halogeton spp.	Halogeton	All	Foliage and seeds Oxalates	Renal failure, dullness, weakness, slobbering
Sarobatus vermiculatus	Black grease-wood	Sheep, cattle	Foliage. Oxalates	As for *Halogeton*
Rumex spp.	Curlydock	Sheep, cattle	Foliage.Oxalic acid	As for *Halogeton*
Chenopodium spp.	Lambsquarters	All	All parts. Oxalic acid	As for *Halogeton*
Amaranthus spp.	Rough pigweed	Pigs, cattle, sheep	Foliage. Unidentified	Non-specific but related to perirenal oedema and nephrosis
Quercus spp.	Oak	Cattle, sheep	Young leaves, acorn, flowers, stem.Tannic acid, gallic acid	Abdominal pain, constipation, frequent urination, renal failure

Table 8 Toxic plants causing primary photosensitization of food-producing animals

Scientific name	Common name	Species commonly affected	Toxic parts and principle(s)	Clinical signs
Hypericum perforatum	St. John's wort	Cattle, sheep, goats	Foliage Hypericin	Acute: increased respiration and heart rate, mild dermatitis Chronic: photosensitization of unpigmented areas of the skin, photophobia
Agave lechuguilla	Agave	Sheep, goats, cattle	Foliage. Unidentified	As for *H. perforatum*
Fagopyrum esculantum	Buckwheat	All	All parts and seeds. Fagopyrin	As for *H. perforatum*
Cymopterus watsonii	Spring parsley	Sheep, cattle	Foliage. Psolalens	As for *H. perforatum*
Trifolium hybrium[a]	Alsike clover	Pigs, sheep, cattle	Foliage and seeds. Unidentified	As for *H. perforatum*

lead pipes, especially those used around oil wells, are a common source of lead poisoning (Blood and Rodostits, 1989).

Lead interferes with haem synthesis and causes prominent CNS damage. Affected animals are initially anorectic. They may become belligerent and blind at the terminal stages of the disease. Once the CNS signs have appeared the prognosis is poor, but treatment with chelating agents, for example, calcium disodium EDTA and DMPS (2,3-dimercapto-1-propane sulfonate), may be of value.

3.5 Arsenic Toxicities

Arsenic poisoning is second to lead as the most frequently reported heavy metal toxicant in food-producing animals. Arsenic is present in the environment in two forms: inorganic and organic. Inorganic arsenic is often incorporated into pesticides, which are the most common sources of arsenic poisoning in cattle. Inorganic arsenicals are also used as herbicides and cattle are sometimes exposed by eating grass clippings from recently sprayed forage. Inorganic arsenic poisoning is a rapidly developing and fatal

disease (Radeleff, 1970). Affected animals show severe gastrointestinal abnormalities with minor CNS involvement, and have severe abdominal pain, haemorrhagic diarrhoea and depression. Usually these signs appear 24–36 hours after exposure.

Phenylarsonic arsenicals are less toxic to mammals than the inorganic arsenicals. Phenylarsonic compounds are usually incorporated into swine and poultry feed for disease-control purposes and also to improve weight gain. Examples of these compounds include arsenilic acid, 3-nitroarsenilic acid and 4-nitroarsenilic acid. Organic arsenicals are also available as trivalent and pentavalent compounds, the trivalent forms being more toxic than the pentavalent compounds. These phenylarsonic compounds are peripheral nervous system (PNS) toxicants. They cause demyeination of the peripheral nerve fibres leading to ataxia and paralysis of the hind quarters. The condition occurs frequently in swine kept on feed containing 10 000 ppm arsenic for at least 10 days or 200 ppm arsenic for 30 days or more. Therefore, unlike inorganic arsenic poisoning, which is an acute expression of the toxicosis, poisoning by phenylarsonic compounds has an insidious onset. In addition, organic arsenic is commonly involved in toxicities in swine because of its incorporation into swine feeds, whereas inorganic arsenic poisoning is more commonly seen in cattle.

Treatment of inorganic poisoning is by decontamination procedures and application of BAL chelation. Use of demulcent, to coat the gastrointestinal tract, and antibiotics is also recommended. Treatment of organic arsenic poisoning involves prompt withdrawal of the feed involved. Severely affected pigs should be culled and often cannot be used for food because of remaining arsenic residues.

3.6 Selenium Poisoning

Selenium poisoning is a regional problem in areas where the selenium content in soil is high. Selenium is absorbed and concentrated by selenium-accumulating plants such as *Astragalus*. Cattle, sheep, goats and swine consume these indicator plants; acute selenium poisoning occurs when animals consume plants containing more than 10 000 ppm. This is characterized by sudden death or the animal may have laboured breathing, abnormal movements and posture, frequent urination, diarrhoea and death. Because plants containing high selenium concentration are unpalatable, they are rarely consumed by animals, so that acute selenium poisoning is rare.

However, chronic selenium poisoning is common. Chronic consumption of plants containing as low as 50 ppm selenium can cause poisoning after weeks or months of ingesting the selenium-containing forage. Affected animals are anorectic, have impaired vision, wander, salivate excessively, are emaciated, lame and lose hair, particularly the long mane and tail hairs. Hooves are also affected resulting in overgrown hooves and difficulty walking. Removal of animals from pastures and forage that have high selenium concentrations is necessary to initiate recovery (Muth and Binns, 1964).

3.7 Blue-Green Algae

Blue-green algae poisoning occurs late in summer and early autumn when algae form a scum on pond waters. The toxicity has been prominently reported in North America and the UK. Because of husbandry practices cattle are most frequently involved. Algae of the genus *Anabaena* are commonly involved.

There are two distinct syndromes in blue-green algae poisoning: hepatotoxicity and neurotoxicity. The neurotoxic effect is peracute. Cattle that drink water containing the neurotoxic principle anatoxin-*a* can die within a few minutes and are found close to the waters with the toxin source. On the other hand, the hepatotoxic type causes a less acute poisoning characterized by lethargy and jaundice (Beasley *et al*., 1989), and death, which may occur several days or more after drinking contaminated water. Affected cattle not dying earlier become unproductive and are usually eventually culled.

Treatment involves supportive therapy for animals affected with the liver syndrome. Because of the peracute nature of the blue-green algae-induced neurological syndrome, there is hardly time for treatment, and the prognosis is poor.

3.8 Toxic Gases

Toxic gases are of primary concern in closed animal housing, especially confinement swine operations. In these intensive operations, with buildings designed to save on energy, toxic gases can accumulate causing serious health consequences in cases of ventilation failure or overstocking. These toxic gases are generated from the decomposition of urine and faeces, respiratory excretions and the operation of fuel-burning heaters. The most common and health threatening gases are ammonia, carbon monoxide, methane and hydrogen sulfide. A number of vapours from manure decomposition, such as organic acids, amines, amides, alcohols, carbonyls and sulfides, are also produced. Respirable dust particles may be loaded with endotoxins and are also a major health problem in swine and animal caretakers in confinement operations (Osweiler *et al*., 1985).

Ammonia is highly lipid soluble and will react with the mucous membranes of the eyes and respiratory passages.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat110
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

At 100 ppm or greater, ammonia toxicosis will show as excessive tearing, shallow breathing and clear or purulent nasal discharge. The irritation of the respiratory tract epithelium leads to bronchoconstriction and shallow breathing.

Hydrogen sulfide poisoning is responsible for more animal deaths than any other gas and, at 250 ppm and above, hydrogen sulfide causes irritation of the eyes and respiratory tract and pulmonary oedema. Concentrations of hydrogen sulfide above 500 ppm cause marked nervous system stimulation and acute death (O'Donaghue, 1961). To prevent hydrogen sulfide poisoning, manure pits should be agitated when pigs are not in the premises and proper ventilation should always be in place.

Carbon monoxide is produced by the incomplete combustion of hydrocarbon fuels. Poisoning by carbon monoxide is caused by operating improperly vented space heaters or furnaces in poorly ventilated buildings. Carbon monoxide binds to haemoglobin, forming carboxyhaemoglobin, thereby reducing the oxygen-carrying capacity of the blood and subsequently causing hypoxia. Concentrations of carbon monoxide greater than 250 ppm cause hyperventilation and respiratory distress; still births have been reported (Carson and Dominick, 1982).

Nitrogen dioxide is a very poisonous gas which is responsible for causing silo-fillers' disease in humans; the gas is also very toxic to animals. Nitrogen dioxide is produced during the first two weeks after silage has been cut and put in the silo. Highest concentrations of the gas are reached during the first 48 hours after filling the silo. Nitrogen dioxide dissolves in water to form nitric acid, which is very corrosive to the respiratory tract and the lungs. As low as 4–5 ppm nitrogen dioxide can cause respiratory-system disturbances (Osweiler *et al*., 1985).

Exposure to sulphur dioxide at 5 ppm or higher causes irritation and salivation in swine. The gas is soluble in water, forming the more toxic sulfuric acid, which causes eye and nasal irritation, and in severe cases haemorrhage and emphysema of the lungs (Osweiler *et al*., 1985).

The effect of these toxicants singly and in combination is a hypofunctional respiratory system, and affected animals are predisposed to respiratory tract infections. The end result is retarded performances of the affected animals. It is therefore important to ensure that animal housing is adequately ventilated to provide animals with a healthy and productive environment.

3.9 Salt Poisoning

Salt poisoning is frequently encountered in swine operations, but can also occur in feedlot cattle. The causes of this condition are twofold. Most commonly, the animals will be on a ration containing the recommended concentration of sodium chloride, but management failure can favour conditions that will cause salt poisoning to occur. These poor management conditions include the sudden absence of water, for example, by freezing in winter or breakdown of the water supply, and the possibility of accidental addition of excessive amounts of salt to the ration.

Salt poisoning has also been reported in swine operations, even when the management situation was satisfactory, the only change being that the animals were moved into a new housing facility, as occurs after weaning. Apparently, the animals were not used to the different watering facilities in the new buildings; they did not know how to obtain fresh water and went without adequate water while feeding on a normal ration. Clinically, salt poisoning is an acute neurological disorder. Affected pigs will spin on their hind limbs and fall down in convulsions. The pigs will also show a characteristic rhythmic pattern of convulsions which occur every 5–7 minutes. Several pigs are affected at the same time. The condition is corrected by providing adequate, but restricted, amounts of water for several hours, while the animals adjust to the rehydration (Dunn and Leman, 1975).

3.10 Toxic Plants

Plant poisoning is very common in areas where open grazing is practised, such as in the Great Plains of the US, the prairies of South America and the vast spaces of Africa. In North America plant poisoning is widely reported as a seasonal event during periods of drought and forage shortages.

The subject of poisonous plants is a wide-ranging one, which cannot be adequately summarized in the few pages of this chapter. The toxic potential of selected common poisonous plants is summarized in **Tables 1–8**. In these tables the plants are grouped according to the organs most prominently affected and the clinical syndromes observed. It is important to realize, however, that plants rarely affect only one biological organ, and multiorgan effects are often seen in field outbreaks of toxicity.

This presentation is an attempt to summarize the vast amount of literature on this subject. Readers interested in more extensive discussions should consult the abundant relevant literature available in numerous sources, such as the comprehensive reviews by Kingsbury (1964), Cheeke and Shull (1985), Burrows and Tyri (2001) and others.

It is important to remember that the toxicity of any given plant can vary widely depending on the prevailing natural environmental conditions of temperature, moisture, sunlight, stage of growth and nutrition. It is therefore not surprising that a given plant may be toxic under certain conditions, for example, during stressful drought

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

conditions, but relatively nontoxic during other seasons and conditions.

4 COMMON TOXICOSES OF HORSES

In comparison with cats, dogs and food-producing animals, horses are less frequently poisoned. The most commonly encountered equine toxicoses involve pesticides, snake bites, arsenic, selenium, monensin, cantharidin and mycotoxins (Oehme, 1987a). Most plants discussed earlier with regard to food-producing animals are also toxic to horses, but are less frequently exposed to horses because of closer owner surveillance. However, horses are very uniquely sensitive to toxicities from monensin and cantharidin.

The pesticides most frequently encountered in equine poisoning are the organophosphate, carbamate and CH insecticides. Both the organophosphates and the carbamates are acetylcholinesterase inhibitors, and offer clinical presentations similar to those seen in food-producing animals. Affected animals salivate profusely, and develop muscle incoordination and ataxia prior to recumbency. The CHs are CNS stimulants and affected horses become excited, hyperalert and in extreme cases go into convulsions. In the vast majority of cases the exposure to pesticides is through topical application (Oehme, 1987b).

Horses are highly susceptible to monensin poisoning in comparison with other domesticated animals. Monensin and other ionophores are commonly incorporated into cattle and poultry feeds to provide improved growth efficiency by improving the movement of calcium and sodium from the gut. Horses are easily poisoned by accidentally consuming cattle or poultry feed containing amounts of monensin, recommended for those species, but detrimental for horses. Affected horses can die suddenly without any premonitory signs. Monensin affects the cardiac and skeletal muscles, and heart failure is the cause of death (Amend *et al*., 1980).

Cantharidin is the toxic agent in blister beetles. Several species of blister beetles are known and only a few contain toxic concentrations of cantharidin. Blister beetles are abundant in July–September at the time that hay is harvested in North America. Horses are poisoned by eating hay containing trapped swarms of blister beetles. Affected horses have severe colic and will kick at their belly and roll; they may die of shock. There is no effective therapy for affected horses, but treatment involves the use of pain killers such as banamine hydrochloride (Schmitz and Reagor, 1987) and intensive electrolyte therapy.

Lead poisoning in horses is characterized by neurological abnormalities. Affected horses may be either depressed or excited. Colic and diarrhoea are also observed. Horses poisoned by lead also have difficult respirations with 'roaring' because of laryngeal nerve paralysis. Abortions are also common.

Arsenic poisoning in horses is caused by consumption of foliage which has recently been sprayed with arsenic herbicides. The condition is normally acute and characterized by intense colic and haemorrhagic diarrhoea. As in food-producing animals, inorganic arsenic poisoning does not involve the nervous system, which helps differentiate this condition from organophosphate or carbamate poisoning.

4.1 Toxic Plants

Selenium is an essential element, but is toxic when excessive quantities are ingested from plants that have accumulated significant quantities from the soil. Exposure is usually through consumption of seleniferous (indicator) plants, for example *Astragalus.* Exposure to high quantities of selenium over a short period of time causes diarrhoea, which may be foul smelling and contain air bubbles. Neurological, cardiovascular and respiratory signs may also be present. Death in these animals is from respiratory failure. Chronic exposure to excessive selenium is characterized by hoof abnormalities at the coronary bands and discolouration and loss of hair. The hoof deformities and the resulting pain cause lameness (Hultine *et al*., 1979).

Other plant poisonings commonly encountered in horses are those that cause gastrointestinal problems (**Table 1**), liver damage (**Table 2**), primary or secondary nervous-system involvement (**Tables 3** and **4**) and sudden death. Plants such as castor bean, oleander and bracken fern cause colic and diarrhoea; oleander also causes heart failure.

Prolonged ingestion of some plants for several weeks can lead to liver damage and hepatic cirrhosis. Examples of commonly involved hepatotoxic plants include *Amsinckia*, *Senecio* and *Crotolaria* (Rumbeiha and Oehme, 1992b). Liver damage may compromise the ability of the horse to detoxify ammonia which accumulates *in vivo,* leading to CNS involvement.

Plants that commonly cause CNS stimulation include larkspur, locoweed, lupine, water hemlock and fitweed. Common plants that cause CNS depression include black locust, bracken fern, horsetail, milkweed and white snake root.

Like ruminants, horses will avoid eating toxic plants because they are not palatable. Therefore, consumption of poisonous plants will occur during drought conditions when the animals lack suitable pasture. Sudden death in horses can be caused by the consumption of cyanide-containing plants such as sorghum. The cyanide ion forms a complex with cytochrome oxidase, which prevents transportation of electrons and utilization of oxygen by tissues throughout the body. As a consequence, blood is well oxygenated and cherry red in colour. Treatment for this condition is an emergency and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat110
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in the USA involves giving both sodium thiosulfate and sodium nitrite intravenously (other antidotes are used in other countries).

Horses, like other monogastrics, are more resistant to nitrate/nitrite poisoning than ruminants. However, horses can reduce nitrates to nitrites in the caecum, but require approximately three times as much nitrate to produce a similar effect as in the ruminant.

4.2 Mycotoxins

Contaminated grains are sources of mycotoxin exposure in horses. The effects are similar for the horse as for food-producing animals. The most commonly involved mycotoxins are aflatoxins, T-2 and fumonisin B_1.

Aflatoxins will cause nonspecific signs, such as not thriving, haemorrhages and abortions. T-2 is a trichothecene mycotoxin which causes prolonged bleeding time in affected animals.

A specific mycotoxin uniquely affecting horses is fumonisin B_1 which is produced by *Fusarium moniliforme*. It is responsible for the condition called equine leucoencephalomalacia. Horses are affected by the consumption of mouldy corn and become anorectic and initially depressed, but as the condition progresses animals become blind, walk aimlessly and may show head pressing. They have difficulties with swallowing and eventually die (Wilson *et al*., 1990).

5 COMMON TOXICOSES OF POULTRY

This section will mainly address toxicoses in chicken, ducks and turkeys. However, there is much interest in the toxicology of wild birds, especially those kept in zoos and wildlife parks, as well those poisonings affecting pet birds. This discussion will emphasize toxicoses encountered in poultry. Readers interested in the general subject of avian toxicology are referred to LaBonde (1991).

5.1 Chemotherapeutic Drugs

Sulfonamides have been used as coccidiostats in poultry for several decades. Although sulfonamides have inhibitory action against coccidia and other pathogenic agents, they can also be toxic to the host under certain conditions. In poultry, sulfonamide toxicity is characterized by blood dyscrasia, and renal and liver dysfunctions. Feeding chickens a mash containing only 0.2% sulfonamides for two weeks is toxic. Clinically affected birds have ruffled feathers, are depressed, pale, icteric and have poor weight gain and prolonged bleeding times. In laying birds, sulfonamides cause a marked decrease in egg production, thin, rough egg shells and depigmentation of brown eggs. The temperature of affected birds is often elevated. At post mortem, haemorrhages are found under the skin, in muscles (especially those of the thighs and breast) and in internal organs. Once these signs are noticed, the concentration of sulfonamides in the various rations should be determined and the feed involved withdrawn (Peckham, 1978).

Other chemotherapeutic agents sometimes involved in poisoning poultry include coccidiostats such as nicarbazine, zoalene (3,5-dinitro-*o*-toluamide), nitrophenide and the ionophore monensin. As little as 0.006% dietary nicarbazine causes mottled egg yolks and 0.02% produces a depressed rate of growth and depressed feeding efficiency. Feeding 0.025% nicarbazine to day-old chicks for one week results in dullness, listlessness, weakness and ataxia. Feeding zoalene at twice the recommended level of 0.025% induces nervous signs and depressed growth and feeding efficiency. The nervous signs resulting include stiff neck, and staggering and incoordination when the birds are excited. Nitrophenide possesses marked electrostatic properties and thus adheres to the sides of the feed mixer. The last portion of feed in the feed mixer will normally contain a high concentration of nitrophenide and feeding this has caused disturbances in posture and locomotion, retarded growth and significant mortality in chickens. Postural disturbances resulting include a tilted position of the head, tremors of the neck and difficulty in the righting reflex (Peckham, 1978).

In general, poultry are more resistant to nionensin toxicity than mammals. There have been reports of monensin toxicity in turkeys accidentally fed rations containing 250 ppm monensin. There is a big difference in species susceptibility among various poultry to monensin poisoning. Chickens and turkeys less than two weeks old are more resistant than older birds, but keets (young guinea fowl) seem more susceptible than adult guinea fowl and young animals of other species. For example, monensin at 200 ppm was not toxic for poults whereas 100 ppm poisoned keets.

5.2 Cresol

Cresol was previously employed as a commonly used disinfectant in poultry houses, but has been withdrawn from use and replaced by safer disinfectants. Nevertheless, cresol is still found in use in some countries. Cresol poisoning usually occurs in chickens at three to six weeks of age. Affected chicks are depressed and have a tendency to huddle. There are signs of respiratory problems, such as rales, gasping for breath and wheezing. In instances of prolonged exposure oedema of the abdomen will develop.

DOI: 10.1002/9780470744307.gat110
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

5.3 Sodium Chloride

All poultry and pigeons are susceptible to salt poisoning. Young birds are more susceptible than adults. Although both acute and chronic forms of salt poisoning occur, the chronic form is more commonly encountered and results from prolonged ingestion of feed containing a high salt content. Sodium levels of 0.5% or more in drinking water or 5–10% in feed cause death in baby chicks. Signs of salt poisoning in poultry are anorexia, thirst, dyspnoea, opisthotonos, convulsions and ataxia. Increased water consumption may be the most significant early indicator of salt poisoning in poultry (Peckham, 1978).

5.4 Insecticides

Chlorinated hydrocarbon insecticides and organophosphate compounds are sometimes used inappropriately around poultry houses to control external poultry parasites (LaBonde, 1991). Commonly involved organochlorine insecticides include chlordane, dieldrin, DDT, heptachlor and lindane. Occasionally birds are also exposed by gaining access to sprayed fields, such as golf courses.

Chlordane causes chicks to chirp nervously, rest on their hocks and lie on their sides. The birds then become hyperexcitable as the condition progresses. In mildly affected adult birds there is reduced food consumption, decreased body weight and a fall in production.

Consumption of grain seeds dressed with dieldrin has been a source of exposure in wild birds. Affected birds are listless, have coordination problems while alighting, and severely poisoned birds show nervous signs characterized by lateral movements of the head and tremors of the head and neck. Birds die of violent convulsions.

DDT toxicity in chickens is characterized by hyperexcitability and fine tremors in severe cases. Moderate cases are characterized by loss of weight, moulting and reduced egg production.

Lindane dust is frequently used in chicken houses. Adult chickens poisoned by lindane become anorectic, manifest opisthotonos, flapping of the wings and clonic muscle spasms and they die in a coma (Peckham, 1978).

The organophosphate compounds commonly involved in poultry poisoning include diazinon, malathion and parathion. Diazinon is used for chicken premises, but is very toxic to ducklings; when used at rates recommended for chickens, 100% mortality occurred in one to two-week-old ducklings. Experimental studies suggest that goslings are three times more sensitive than ducks, chickens or turkeys. Poisoned birds are unable to stand, salivate profusely and manifest tremors of the head and neck. Brain cholinesterase levels in birds that die of organophosphate poisoning are on average 69% less than controls.

Other organophosphate compounds commonly used on chicken premises include dichiorvos, malathion and parathion. Birds poisoned by these compounds manifest signs similar to those produced by diazinon. Other signs that may be encountered include birds being depressed, ataxic and reluctant to move, paralysis, lachrymation, gasping for breath, diarrhoea, crop stasis and dyspnoea (Mohan, 1990). In general, ducks are more sensitive to organophosphate poisoning than chickens, and care should be exercised when using these products on premises holding ducks (Mohan, 1990).

The carbamate insecticide carbaryl is widely used as a poultry insecticide. This compound is relatively safe to use, but deaths have been reported in turkey poults kept in premises where the product has been applied at 10 times the recommended rate. The clinical signs are similar to those caused by organophosphate compounds.

5.5 Heavy Metals

Lead poisoning is not as common in poultry as in wild birds. Lead poisoning is the most common toxicity reported in the avian species (LaBonde, 1991). Lead shot has caused losses in waterfowl populations in North America. All birds are susceptible to lead poisoning, but most losses are reported in waterfowl because their feeding habits predispose them to ingestion of lead shot.

Characteristic signs of lead poisoning are those related to CNS derangement, such as ataxia, depression, paralysis of wings or convulsions. In some cases the birds present as anaemic, emaciated, regurgitating and weak. Green diarrhoea has also been reported in some birds affected with lead poisoning (LaBonde, 1991).

5.6 Rodenticides

Yellow phosphorus is a highly toxic element used as a rodenticide. Poultry and wild birds can be intoxicated by consumption of bait intended for rodents. Fragments of fireworks containing phosphorus are also a common source of poisoning in free-range birds. Affected birds are depressed, anorectic, have increased water consumption and manifest diarrhoea, ataxia, paralysis, coma and death (Peckham, 1978).

All rodenticides are potentially toxic to poultry and other birds. The clinical signs caused by rodenticides are similar to those that occur from similar compounds in small animals.

Birds occasionally consume baits containing anticoagulant rodenticides. The more potent second-generation rodenticide-containing baits, such as brodifacoum, are

especially dangerous to birds. These coumarin-like anticoagulants act by interfering with vitamin K_1 recycling, causing bleeding because of depletion of vitamin K_1-dependent clotting factors. Poisoned birds bleed from the nares and subcutaneously, with oral petechiae. They often are weak and depressed.

Of special interest, however, is secondary intoxication from consumption by free-range birds of carrion of animals that died of rodenticide poisoning. Strychnine and sodium monofluoroacetate are compounds commonly involved because they cause acute death in primary victims and are thus present in high concentrations in carrion. Strychnine-poisoned birds manifest clinical signs within two hours of ingesting the product. The birds become apprehensive, nervous and show violent tetanic convulsions, which cause the birds to become exhausted and die of hypoxia. Sodium monofluoroacetate causes overstimulation of the CNS and also myocardial depression. Cardiac failure is the cause of death, occurring within one hour of consuming the product or portions of the contaminated carcasses (Peckham, 1978).

5.7 Mycotoxins

Mycotoxicoses are a common problem in the poultry industry in developing tropical countries. Aflatoxins are of primary concern because of the public-health risk, from consuming aflatoxin residues in eggs and meat, as well as interfering with productivity. Poultry are normally exposed by consumption of contaminated feed, especially corn. Some developing countries lack the resources to screen potentially contaminated corn adequately. Poultry feed is often made from poor quality corn rejected for human consumption; this poor quality feed may be contaminated with the aflatoxin-producing fungi, *Aspergillus flavus* and *Penicillium* spp.

Aflatoxicosis in poultry can be either acute or chronic depending on the exposure dose. Ducklings are more susceptible to aflatoxin than turkeys, pheasants or chickens (Butler, 1974). In acute cases affected birds become lethargic, their wings droop and they manifest nervous signs, such as opisthotonos. Affected birds frequently die with their legs rigidly extended backward. Chronic consumption of at least 2.5 ppm aflatoxin in the diet causes a significant drop in performance with reduced weight gain and egg production. Perhaps more important is the increased susceptibility of the affected flock to infection because chronic consumption of aflatoxins lowers the immunity of the birds. Aflatoxicosis is therefore a disease of serious economic consequences to the poultry industry in developing countries such as Uganda, both through lowered productivity and the death of affected birds.

Ergot poisoning has been reported in Europe where rye is commonly used as a feed. In acute ergot poisoning the birds' combs are cold, wilted and cyanotic. The birds are weak, thirsty and have diarrhoea. In severe cases they develop convulsions and paralysis, with death following. Ochratoxin mycotoxins have uniquely been reported to cause renal toxicity in poultry.

6 SUMMARY

In this brief chapter we have summarized the broad discipline of veterinary toxicology. We have given overviews of selected common toxicities from the various animal species so as to draw the attention of the reader to similarities and differences in their reaction to toxicants. Because some animals are more sensitive than others to the same toxicant, absolute diagnosis of some toxicoses may require the help of specialists within the veterinary profession.

This chapter is not intended as a detailed source of reference for the diagnosis and treatment of animal poisonings, nor is it meant to be all inclusive. Rather it is a summary of the commonly encountered toxicoses in the veterinary and animal health profession. Interested readers should consult the relevant references given to gain more in-depth knowledge on poisonings of interest.

From this general overview it should be clear that all animals are susceptible to some toxicants and that many toxicants are poisonous to all animals (including humans). It is therefore important to be cautious when handling chemicals around animals to avoid unnecessary risk. Animal caretakers should also provide chemically clean environments to their animals. Rations should provide well-balanced and nutritionally sound quality feed from reputable sources, and suspect feed should be avoided or atleast checked for suspected toxicants before being fed. It is also vitally important to remember that all chemicals become poisons if their exposure dose is great enough. Therefore, even some of the valuable compounds used around animals, for example, growth promoters, can be fatal if used excessively or if given to species for which they are not intended. The susceptibility of sheep to feed containing copper intended for cattle, or of poultry feed supplemented with monensin and offered to horses, are frequently tragic cases in point.

Essentials of Epidemiology for Toxicologists

David Coggon

CONTENTS

1 INTRODUCTION

Epidemiology is concerned with the distribution and determinants of health in populations. The earliest epidemiological research provided simple descriptions of variations in mortality and in the occurrence of disease by time and place, but as its methods have evolved, epidemiology has progressed to more detailed investigation of disease causation, and extended its scope to other health outcomes, such as illness (including symptoms that occur in the absence of demonstrable underlying disease), disability and biomarkers relevant to future health. In addition, similar techniques have been used to investigate patterns of disease in animal populations (veterinary epidemiology).

Table 1 Applications of epidemiological research

• Development of policy to maintain or improve health	This includes the identification of factors that cause disease, illness or disability, and assessment of how risks vary according to the circumstances and levels of exposure to these factors.
• Evaluation of interventions aimed at maintaining or improving health	This may be through experimental trials of preventive measures and treatments, or through observational studies.
• Characterization of prognosis and prognostic indicators	Systematic follow-up of appropriately defined populations can provide information on prognosis and its predictors. This may be useful in clinical care, and also, for example, in determining fitness for different types of work.
• Planning of health care services	Epidemiology can help in estimation of the numbers of patients who will require different treatments, and for how long.
• Determination of causal attribution for purposes of compensation	Epidemiology can help to establish whether cases of disease can reasonably be attributed to alleged causes, both in the courts and under social security regulations.

Epidemiological research has various applications (**Table 1**), but of most relevance to toxicology are its uses in the identification and characterization of toxic hazards, the assessment of risks from toxic exposures, and the evaluation of measures designed to control such risks. The contribution of epidemiology in these areas is complementary to that of experimental toxicology.

Epidemiology has the great strength that it provides direct information about determinants of health in human populations, avoiding the uncertainties that are inherent in extrapolation between species. Some toxic hazards, such as the carcinogenicity of benzene and arsenic, have been clearly apparent in epidemiological studies, but have proved difficult or impossible to demonstrate in laboratory animals. Others, such as the hepatic carcinogenicity of peroxisome proliferators in mice, appear not to extend to humans. And some health outcomes—for example, those relating to higher cerebral function and to immune sensitization—are difficult to model in the laboratory. Also, because epidemiological studies can include very large numbers of subjects (often thousands and sometimes even millions), they may be able to discern small effects from low exposures to a toxicant that could not be predicted with confidence from the laboratory. A good example is the small but important risk of cardiorespiratory disease from particulate pollutants in outdoor air.

Against this, however, epidemiology is limited by the practical and ethical constraints on research involving human subjects. Studies cannot be designed and conducted with the same rigour that is possible in the controlled environment of the laboratory, and this leads to uncertainties in interpretation.

This chapter introduces the main concepts of epidemiology, describes the most frequently employed study designs, and outlines the considerations that must be taken into account when interpreting epidemiological findings.

2 QUANTIFICATION OF HEALTH OUTCOMES

Fundamental to epidemiology is the quantification of health outcomes in populations. Various metrics are used for this purpose, but first the health outcome must be defined.

2.1 Definition of Health Outcomes

As in toxicology, measures of health outcome in epidemiology can be dichotomous, ordinal or continuous. Dichotomous outcomes usually distinguish between cases and noncases of illness or disease. For example, people might be classified according to whether or not they meet specified criteria for a diagnosis of myocardial infarction. This approach is most satisfactory for disorders that are relatively all-or-none in nature. However, it can also be applied to outcomes that occur in a spectrum of severity with no clear distinction between normality and abnormality. This requires specification of somewhat arbitrary criteria for case definition. Thus, a case of hypertension might be defined as having a systolic blood pressure >140 mm Hg and/or a diastolic blood pressure >90 mm Hg on each of three consecutive measurements over a period of three weeks.

Alternatively, an outcome such as blood pressure could be characterized by a continuous measure—for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat111
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

example, the mean systolic pressure from three consecutive readings over a three-week period. Other examples of continuous outcome measures are bone mineral density, hearing threshold on audiometry and erythrocyte acetyl cholinesterase activity.

Ordinal outcome measures are less often encountered. Examples include scales that have been devised to grade pneumoconiosis (International Labour Office, 2002) and osteoarthritis (Kellgren and Lawrence, 1957) on radiographs.

In practice, the best available measures of health outcomes are often only approximate. This may be because of inaccurate or imprecise methods of measurement (e.g. in a biochemical assay), or because indirect markers of outcome are employed—for example, in the epidemiological study that first established the human carcinogenicity of 2-naphthylamine (Case *et al*., 1954), mortality from bladder cancer as recorded on death certificates was taken as an indirect index of bladder cancer incidence. Any approximations in the assessment of health outcome must be taken into account carefully when results are interpreted. For example, when a study found elevated mortality from lobar pneumonia in occupations involving exposure to metal fume (Coggon *et al*., 1994), one possible explanation was that fume increased susceptibility to pneumonic infection. Another possibility, however, was that it increased fatality from pneumonia (i.e. the risk of death in people who have already developed pneumonia), while not influencing whether people initially acquired the disease.

Whatever the measures of health outcome that are adopted in an epidemiological study, they should be explicitly and unambiguously defined. Otherwise, results cannot be properly interpreted.

2.2 Rates of Disease[a]

As described above, most epidemiological investigations classify people dichotomously according to whether or not they are cases of a disease. In order to draw useful conclusions about the distribution and determinants of a disorder, the number of cases that occur in a population or group of people must be related to the size of the population. Several measures of disease occurrence are commonly used.

2.2.1 Incidence

The incidence of a disease is the rate at which new cases occur in a population over time. For example, the incidence of breast cancer among women aged 65–69 years in England during 2005 was 395 per 100 000 per year.

2.2.2 Mortality

A mortality or death rate is the incidence of death in a population that is attributable to one or more specified causes. For example, mortality from breast cancer among women aged 65–74 in England and Wales during 2005 was 91 per 100 000 per year.

2.2.3 Prevalence

The prevalence of a disease is the proportion of a population who are cases at a specified time or during a specified period. For example, in a survey of rural residents, the prevalence of tiredness and lack of energy during the past month among men aged 24–69 years who had at some time worked with insecticides was reported as 17.3% (Solomon, 2007), and the prevalence of Down's syndrome among babies born in 17 states of the USA during 1983–1990 was reported as 9.2 per 100 000 live-born infants (Department of Health and Human Services, 1994). The prevalence of a disorder depends both on its incidence and on the time for which it persists before recovery or death. Thus chronic diseases such as rheumatoid arthritis and multiple sclerosis have a higher prevalence relative to incidence than those that are short-lived (e.g. influenza) or rapidly fatal (e.g. pancreatic cancer).

In studies of causation, incidence is the most relevant measure of disease frequency. This is because mortality may be influenced by determinants of fatality, as well as of incidence, while prevalence depends on factors that influence disease persistence, as well as its first development. Mortality and prevalence are often used as proxy measures of incidence, but findings must then be interpreted with appropriate care.

2.2.4 Crude, Stratum-Specific and Standardized Rates

Measures of disease frequency may apply to the whole of a population (crude rates) or to specified subsets of a population defined, for example, by sex and age. Because the occurrence of most diseases varies importantly by sex and age, use of sex- and age-specific rates usually enables more meaningful comparison between populations than can be achieved with crude rates. However, the elaboration of multiple sex- and age-specific rates can sometimes be rather unwieldy, especially when data cover a large number of sex and age 'strata' (where a population is partitioned into multiple categories defined by levels of one or more variables, the categories are often termed strata of the population). In these circumstances, an alternative is to 'standardize' rates for the stratifying variables. Two methods of standardization are commonly employed.

Direct standardization entails the calculation of a weighted average of stratum-specific rates, where the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat111
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

weighting factors are derived from a defined (real or theoretical) population. Effectively, this gives the crude rate of disease that would apply in the standard population if it experienced the same stratum-specific rates that are observed in the population under study. Directly standardized rates, whether of incidence, mortality or prevalence, allow simple summary comparisons of populations that are meaningful, provided that the underlying stratum-specific rates differ consistently between the populations. However, where this condition is violated (e.g. one population has higher rates than another at older ages, but lower rates in the young), useful information will be lost. In fact, depending on the weighting factors applied, either population could be made to have the higher directly standardized rate.

In indirect standardization, the number of cases in a study population is compared with the number that would have been expected had that population experienced the same stratum-specific rates as a specified standard population (e.g. the national population of a country in a specified time period). The comparison is summarized as the ratio of observed to expected cases (often expressed as a percentage), which may be termed a standardized incidence ratio (SIR), standardized prevalence ratio or standardized mortality ratio (SMR), depending on the measure of disease frequency to which it refers. Strictly, indirect standardization is valid only as a method for comparing the study population with the chosen standard population. In most circumstances, however, comparison of standardized ratios for two or more populations (in relation to the same standard population) gives a reasonable summary of their relative frequency of disease.

2.2.5 Proportional Mortality and Morbidity

Sometimes it is not possible to derive incidence, mortality or prevalence rates for a disease because, although cases can be enumerated, the size of the population from which the cases derived is not known. For example, the number of deaths each year from sinonasal cancer among cabinet-makers in England and Wales can be established from death certificates. However, the total number of cabinet-makers nationally cannot be estimated reliably, except near the time of a national census.

In these circumstances, an alternative to the calculation of disease rates is to derive proportions. Thus, the proportion of deaths among cabinet-makers that were ascribed to sinonasal cancer might be compared with the corresponding proportion in all occupations combined, the latter information also being obtained from death certificates. Similarly, the proportions of emergency admissions that were for bleeding duodenal ulcer might be compared between two hospitals for which the exact catchment populations could not be enumerated. As for rates of disease, proportions can be directly or indirectly standardized for sex and age. For example, sex- and age-standardized proportional mortality ratios (PMRs) are often used in national or regional analyses of mortality by occupation.

Special care is needed, however, in the interpretation of proportions. This is because they depend, not only on the frequency of the disease of specific interest, but also on the overall rate of disease that provides the denominator for the proportion. For example, in England and Wales, teachers have been found to experience high proportional mortality from multiple sclerosis (Coggon *et al*., 1995). This could be because teachers are abnormally susceptible to the disease, but it is also possible that they have unusually low overall mortality, while their death rate from multiple sclerosis is unremarkable.

3 MEASUREMENT OF RISK FACTORS

As well as the measurement of health outcomes, epidemiology requires ascertainment of 'risk factors' that are known or suspected to influence or predict the occurrence of health outcomes. Risk factors for health outcomes include demographic characteristics (e.g. sex and age), genetic constitution, aspects of lifestyle, such as dietary, smoking and sexual habits, and exposure to various chemical, physical and biological agents and to psychological stressors. They may be categorical (e.g. ever or never treated with a particular drug), ordinal (e.g. level of education) or continuous measures (e.g. 24 hour urinary excretion of cadmium). Some of the methods that are commonly used to ascertain risk factors are listed in **Table 2**.

Like the assessment of health outcomes, ascertainment of risk factors is often liable to error, either because it is based on an indirect marker (e.g. job title is used as an index of exposure to a chemical in the workplace) or because of shortcomings in measurement techniques (e.g. inaccurate recall in a questionnaire). The scope for such errors can often be reduced by good study design, but the potential for residual inaccuracy must be taken into account when results are interpreted.

4 MEASURES OF ASSOCIATION BETWEEN RISK FACTORS AND HEALTH OUTCOMES

Much of epidemiology is concerned with assessment of associations between risk factors and health outcomes. Various statistics are used to summarize such associations, and their nomenclature is not yet fully standardized. The terms and definitions that follow are quite widely adopted, but not all are universally agreed.

Table 2 Common methods for ascertainment of risk factors in epidemiological studies

• Questionnaires	Self-administered or completed at interview
• Physical examination	For example, measurement of height, weight or blood pressure
• Clinical investigation	For example, genotyping
• Measurement of biomarkers of exposure	For example, metabolites of DDT in adipose tissue, benzene in exhaled breath, or cotinine in saliva
• Personal or environmental exposure-monitoring	Using active or passive samplers

4.1 Attributable Risk

Attributable risk is the absolute difference in the risk (or probability) of a health outcome between someone who is exposed to a risk factor and someone who is unexposed or exposed at a different level. For example, a study might estimate the difference in the incidence of hepatic angiosarcoma between people who have and have not worked with vinyl chloride monomer, or the differences in the prevalence of limb reduction abnormalities between babies born to mothers who took thalidomide at different times during pregnancy. Attributable risk is the measure of association that is most relevant when making decisions for individuals. For example, when deciding whether or not to use hormone replacement therapy, a woman needs to weigh the benefits against the absolute increases in risk that she would incur for adverse effects such as breast cancer.

4.2 Relative Risk and Odds Ratio

Relative risk (RR) is the ratio of the risk of a health outcome in someone who is exposed to a risk factor to that in someone who is unexposed or exposed at a different level. For example, use of aspirin by children with acute infections has been estimated to increase the risk of Reye's syndrome by a factor of 11.5 (Halpin *et al*., 1982). Closely akin to RR is the corresponding odds ratio, defined as the ratio between the odds of the health outcome in an exposed person and the odds in someone who is unexposed or exposed at a different level (a risk of $1/N$ corresponds to odds of $1/(N-1)$). RRs lie closer to the null value of one than the corresponding odds ratios, but the difference is small for health outcomes with a risk of less than 10% in each of the exposure categories under comparison.

The relation between RR and attributable risk depends on the frequency of the health outcome. The RR of hepatic angiosarcoma from work with vinyl chloride is high (>10 000), but because the disease is extremely rare in unexposed persons, the attributable risk is modest.

4.3 Population Attributable Risk

Population attributable risk is the excess frequency of a health outcome in a population that is associated with a risk factor. In other words, it is the difference between the population's incidence, mortality or prevalence rate and that which would apply if the risk in all persons exposed to the risk factor were reduced to that of people who are unexposed (or exposed at some specified lower level). It depends on both the (individual) attributable risk and also the prevalence of exposure in the population of interest. Thus, although the individual attributable risk of mortality and serious morbidity from particulate pollution in outdoor air is small, large numbers of people are exposed, and the population attributable risk is sufficiently large to have warranted controls on sources such as motor vehicle exhaust.

4.4 Attributable Proportion

Attributable proportion (also known as population attributable fraction or aetiologic fraction) is the proportion of cases of illness or disease in a population that would be eliminated if the risk in exposed persons were reduced to that of people who were unexposed (or exposed at some specified lower level). For example, the proportion of lung cancer cases in a population that are attributable to smoking might be estimated as 80%. This would imply that if everyone in the population had the risk of a lifelong nonsmoker, 80% of lung cancer cases would be eliminated. Like population attributable risk, attributable proportion is used to inform decisions in risk management at a population level.

It should be noted that where multiple causes of a disease have been identified, their attributable proportions will often sum to more than 100%. This is because causes act in concert rather than in competition, and in persons who develop a disease following exposure to a combination of two causes, avoidance of either one of the causes would often have sufficed to prevent the disease. To give a specific example, phenylketonuria is 100% attributable to genetic constitution, but it is also 100% attributable to diet, and can be completely prevented by elimination of foods containing phenylalanine during infancy.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat111
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.5 Attributable Fraction in Exposed

The attributable fraction in exposed (AF_{exp}) is the proportion of cases among exposed persons that would be eliminated if their risk were reduced to that of people who were unexposed (or exposed at some specified lower level). It relates to the RR by the formula $AF_{exp} = (RR - 1)/RR$. The main application of AF_{exp} is in the determination of attribution to exposures for purposes of compensation. For example, in Britain, one justification for the classification of an occupational disease as compensatable under social-security provisions is the demonstration that a specified occupational exposure carries an AF_{exp} of at least 50%. This implies that cases of the disease in exposed persons can be ascribed to the exposure 'on the balance of probabilities'.

5 BIAS, CHANCE AND CONFOUNDING

Central to the design and interpretation of epidemiological research are the concepts of bias, chance and confounding. These terms are best understood if an epidemiological study is conceived as collecting information about a sample of people with the purpose of estimating one or more parameters in a (theoretically infinite) population from which the sample derived. For example, the odds ratio for the association between Parkinson's disease and previous work with pesticides in a general population sample might be used to estimate the odds ratio for this association more generally. Here the odds ratio in the study sample is known as a sample statistic, and serves as an estimator for the corresponding population parameter, the odds ratio in the population at large.

5.1 Bias

Bias is a systematic tendency to underestimate or overestimate a parameter of interest because of a deficiency in the design or execution of a study. Epidemiological textbooks have distinguished and named many different categories of bias, but broadly, bias can arise from two sources.

Firstly, the way in which subjects are recruited to a study may render them systematically unrepresentative of the population about which conclusions are to be drawn. The problem may arise in the specification of who is eligible for inclusion in the investigation, or from incomplete recruitment of those who are eligible for inclusion (e.g. because of missing records or unwillingness to participate).

Secondly, bias may result from inaccuracies in the information that is obtained about subjects, concerning risk factors, health outcomes or both.

Almost all epidemiological studies are liable to biases of one sort or another, and one of the arts of epidemiological research is to design and carry out studies in a way that minimizes bias, and makes it easier to gauge the potential impact of those biases that cannot be eliminated. When assessing possible effects of biases, it is important to consider in which direction they might affect parameter estimates, and to what extent. The same source of error may produce major bias in the estimation of one parameter, but have little effect on estimates of another. For example, in a survey to assess the prevalence of high alcohol consumption in a general population sample, incomplete participation might lead to serious underestimation if heavy drinkers were less willing to take part than moderate, light or nondrinkers. However, if the aim of the study were to assess the association of heavy drinking with a biomarker of liver function, this differential participation would be of less concern. Bias would only arise if the association between heavy drinking and the biomarker were systematically different in nonparticipants as compared with those who opted to take part, which seems less likely.

5.2 Chance

Even where a study sample is recruited in a way that is not systematically unrepresentative, it may still be atypical by chance. Larger samples of people are less likely to be atypical by chance than smaller samples, and the potential for chance variation in sample statistics can be quantified by methods of statistical inference.

5.2.1 Hypothesis Testing and p-values

The earliest approach to be developed was that of hypothesis testing, in which a 'null' hypothesis is assumed to apply in the theoretically infinite population from which the study sample was drawn. For example, the null hypothesis might be that in this source population there is no association between an exposure and a health outcome (or put another way, that the RR associated with the exposure is one). The probability (p-value) is then calculated of obtaining a result as or more extreme from this null hypothesis than that observed in the study sample, in a sample of the same size selected at random from the source population. If the p-value is sufficiently low, the null hypothesis may be rejected in favour of an alternative (e.g. that in the source population, the exposure and health outcome are related).

5.2.2 Statistical Power

The p-value depends on the extent to which findings in the study sample deviate from the null hypothesis, but it is also influenced by the size of the study sample. In

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat111
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

a very large study sample, even a small deviation from the null hypothesis can be highly significant statistically (i.e. associated with a very small p-value). On the other hand, a large deviation from the null hypothesis could be associated with an unremarkable p-value if the study sample were small. This reflects the notion of 'statistical power'. Other things being equal, larger study samples have the capacity to discriminate smaller deviations from the null hypothesis.

When a study is being planned, the statistical power for a specified sample size can be calculated. This requires various stipulations, according to the study design. For example, in a study comparing rates of a health outcome in people with and without exposure to a risk factor, the expected rate of the outcome in people unexposed to the risk factor would be specified. In addition, the investigator would choose the lowest RR in the source population for which they wished to be confident of finding a p-value below some stated threshold (e.g. 5%). With these specifications, the probability of obtaining a p-value below the threshold could then be calculated for different sizes of study sample.

5.2.3 Confidence Intervals

In practice, decisions in the management of risks to health depend not so much on whether or not a hypothesis is true as on the estimated magnitudes of relevant parameters. For example, a decision whether or not to use a drug is determined, not simply by whether or not it is efficacious, but by the estimated extent of benefits from the treatment, and how they weigh against the costs of the drug and any risk of adverse effects. For this reason, statistical inference in epidemiology these days has largely moved away from hypothesis testing, instead focussing on the derivation of confidence intervals around estimates of parameters.

A confidence interval can be viewed as a range within which, in the absence of bias, the true value for the population parameter of interest would normally be expected to lie. Most often, 95% confidence intervals are calculated. The formula for a 95% confidence interval is specified in such a way that, on average, (in the absence of bias), 95% of such intervals will include the population parameter to which they relate. Other confidence intervals (e.g. 90% confidence intervals) are defined analogously.

Confidence intervals give an indication of the statistical uncertainty around estimates of population parameters. Other things being equal, larger samples of subjects will give tighter confidence intervals, reflecting the fact that they are less likely to be unrepresentative by chance. Once a study has been completed, the confidence interval around a parameter estimate gives the simplest and most easily interpreted index of its statistical power.

5.2.4 Statistical Inference in Context

Although p-values and confidence intervals quantify the statistical uncertainty in epidemiological findings, a final assessment of the likely contribution of chance to an observation must also take account of what is known from sources external to the study. For example, if a new epidemiological study indicated a statistically robust protective effect of smoking against lung cancer, in the absence of other explanations, one might nevertheless attribute the result to chance, given the extensive body of evidence from elsewhere that smoking is in fact a potent cause of the disease.

5.3 Confounding

Confounding is a potential source of error when conclusions about causation are inferred from statistical associations between risk factors and health outcomes. It occurs when the risk factor of interest is associated with another exposure (a confounding factor), which independently determines the risk of developing the health outcome. Depending on whether the confounding factor makes the health outcome more or less likely, confounding can cause the observed association to overestimate or underestimate the causal impact of the risk factor of primary interest. This sometimes extends to the generation of spurious associations with risk factors that in fact have no causal impact whatsoever on the health outcome. For example, several epidemiological studies have demonstrated statistical associations between higher consumption of coffee and cancer of the pancreas. However, these observations may be completely explained by a confounding effect of smoking—high consumers of coffee are more likely to be smokers and smoking is an independent cause of pancreatic cancer.

Where an exposure is recognized in advance as a potential confounding factor (e.g. because it is a known cause of the health outcome and could plausibly be associated with the risk factor of primary interest), its possible effects can be taken into account in study design. Methods include: restriction of the study to subjects with identical exposures to the confounding factor (e.g. limitation to nonsmokers), matching the groups under comparison for their exposure to the confounding factor, or measurement of the confounding factor as part of data collection and then adjusting for it in statistical analysis (by techniques such as stratification or regression modelling). However, control for identified confounding factors may be incomplete (e.g. because they are not ascertained with complete accuracy), and there is the possibility of other confounding factors of which the investigator is unaware. Therefore the potential for residual confounding is always a consideration in the interpretation of observed statistical associations.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat111
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

It should be noted, however, that in order completely to explain an observed association between a risk factor and a health outcome, a confounding factor must carry an RR for the outcome at least as high as that found for the risk factor. To this extent, higher RRs are harder to explain by unrecognized confounding.

6 STUDY DESIGNS

6.1 Descriptive Studies

Most of the earliest epidemiological research was concerned simply with summarizing disease frequency by time and place. The data generated were used, for example, to track the evolution of epidemics of infectious disease. Descriptive epidemiology of this sort remains an important source of information that is used for various purposes (**Table 3**).

Most descriptive studies use routinely collected data—for example, on death registrations, cancer registrations or hospital admissions—but more rarely, descriptive data are generated through specially designed *ad hoc* investigations. As well as analyses by time and place, the frequency of disease may be broken down according to other characteristics such as sex, age, social class, ethnic origin, place of birth and occupation.

In addition to data on health outcomes, descriptive studies may be used to quantify and monitor the occurrence of risk factors that influence health, such as smoking habits and alcohol consumption.

Table 3 Uses of descriptive epidemiology

• Planning health services	Descriptive studies can provide information about the numbers of cases of disease in a population that will require treatment.
• Surveillance for newly emerging health problems	For example, descriptive epidemiology has drawn attention to large, and as yet unexplained, increases in the incidence of testicular cancer over the past century in a number of countries.
• Monitoring the impact of preventive measures and treatment	Analysis of trends in mesothelioma in England and Wales has highlighted a failure of controls on exposure to asbestos in the 1970s.
• As a source of clues to previously unrecognized causes of disease	The discovery that dust from vegetable-tanned leather causes sino-nasal cancer arose from the observation of a cluster of cases in the English county of Northamptonshire, using routinely collected cancer registration data.
• As a source of data for use in other types of epidemiological study	For example, routinely collected data on cause-specific mortality and cancer incidence have been used as a control for comparison with rates in occupational populations exposed to known or suspected carcinogens.

6.2 Ecological Studies

Ecological studies investigate statistical associations between risk factors and health outcomes across populations—that is, with populations or groups of people as the units of analysis rather than individuals. For example, mortality from Parkinson's disease in counties of Nebraska has been correlated with rates of pesticide usage in those counties (Strickland *et al*., 1996). The populations that are compared in ecological studies may be defined in various ways, including by country or region of residence, occupation or time period.

An advantage of ecological studies is that they often exploit data that have already been collected for other purposes and therefore are relatively cheap. Against this, their capacity to adjust for potential confounding factors is usually less than that of studies focussed on individuals. Nevertheless, ecological studies have sometimes generated findings sufficiently persuasive to influence health policy. For example, a major component of the evidence underpinning national policies on particulate pollution in outdoor air has come from ecological studies that correlated daily fluctuations in mortality and hospital admissions for cardiorespiratory disease in defined urban populations with changes in airborne concentrations of particulate matter recorded at local monitoring stations.

6.3 Cohort Studies

In a cohort study, individuals who differ in their exposure to known or suspected risk factors are identified and followed up over time with systematic ascertainment

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat111
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of relevant health outcomes. Rates of health outcomes can then be compared according to levels of exposure to risk factors, allowing estimation of RR and/or attributable risk. The design is analogous to that of an animal bioassay, except that the subjects are more heterogeneous (they do not all come from the same genetic strain) and the investigator studies them as they happen to have been exposed rather than allotting the exposure that they receive (i.e. the design is observational rather than experimental). A consequence of these differences is the possibility of confounding because people with higher exposure to a risk factor of interest may be systematically different in their exposures to other determinants of the relevant health outcome. Therefore, where possible, potential confounders should be identified in advance, and taken into account by restriction, matching or statistical adjustment.

Methods of follow-up depend on the health outcomes under investigation. They include linkage with routinely collected data (e.g. on cause-specific mortality or cancer registrations), and periodic questionnaires, physical examinations (e.g. to measure blood pressure) or clinical investigations (e.g. radiography or biochemical assays). The duration of follow-up is influenced by the time period over which risk factors are expected to exert their effects (e.g. whether there is likely to be a long induction period between first exposure and eventual manifestation of a disease), and also by the incidence of health outcomes (if incidence rates are low, longer follow-up may be needed in order to have sufficient cases for meaningful statistical analysis).

Examples of cohort studies include investigations that have followed up women who differed in their use of contraceptives, to compare their incidence of diseases such as breast cancer, myocardial infarction and stroke; and studies in which serial measurements of lung function have been carried out in coal miners over a number of years and changes in their forced expiratory volumes in one second (FEV_1) have been related to their smoking habits and exposures to coal-mine dust.

Cohort studies have the advantage that they normally incorporate relatively reliable information on exposure to risk factors and potential confounders (since the assessment of exposures is the starting point for the investigation). Also, they can often be used to study multiple health outcomes simultaneously, with little additional effort. For example, studies of workers exposed to suspected carcinogens have used linkage with cancer registration records to provide information about the risk of a range of different cancers. Against this, however, in order to achieve adequate statistical power, cohort studies may need to follow up large numbers of subjects for prolonged periods, making them relatively expensive.

Sometimes this limitation can be partially countered by carrying out a cohort study retrospectively. Subjects are identified who had differing exposures to risk factors in the past, and their subsequent health outcomes over the period up to the time that the investigation is conducted are systematically ascertained and compared. For example, studies have used prescription data to identify retrospectively patients who had been treated with different nonsteroidal anti-inflammatory drugs, and then compared their subsequent incidence of myocardial infarction as ascertained from healthcare records (Garcia Rodriguez *et al*., 2004; Dick, 2000). A prerequisite for retrospective designs of this sort is that ascertainment of the study 'cohort' should not be influenced in any way by the health outcomes under study. This could be a problem, for example, if the exposure records of people who had subsequently died had been selectively deleted, leading to their exclusion from the study sample. Another requirement is that relevant health outcomes should be ascertainable retrospectively with sufficient reliability. This is most often achieved when outcomes are derived from routinely collected records (e.g. of mortality, cancer registration or hospital admission).

Another modification that may make cohort studies more efficient is to use routinely available rates of mortality or cancer incidence in the general population as a comparator for rates in an exposed cohort, thus eliminating the cost and effort of recruiting and following up internal controls. This is appropriate where exposure to the risk factor of interest in the population at large is trivial in comparison with that in the study cohort. The method has been applied, for example, to examine risks of incident (i.e. newly occurring) and fatal cancer in cohorts of workers with high occupational exposures to chemicals such as styrene (Kogevinas *et al*., 1994) and formaldehyde (Coggon *et al*., 2003). Importantly, the health outcome should be ascertained by the same method in the study cohort as in the general population. Otherwise, bias may occur. For example, if rates of cancer in the general population were derived only from cancer registrations, whereas those in the cohort took account also of cases identified from detailed review of clinical records (some of which may not have been picked up by the registration system), risk estimates could be spuriously elevated.

Where the general population provides comparison rates of mortality or cancer incidence, risk estimates are often presented in the form of an SMR or SIR. This is the ratio of the number of cases observed in the cohort during the follow-up period to the number that would have been expected had the cohort experienced the same sex-, age- and calendar period-specific rates as the general population.

6.4 Case–Control Studies

In a case–control study (also known as a case–referent study), people who have developed a health outcome of interest (cases) are identified, and their past exposure to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat111
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

known or suspected risk factors is compared with that of controls (referents) who do not have the outcome. The method is best conceived as a way of sampling efficiently from a (usually hypothetical) cohort study. In most cohort studies, information about exposure is collected for a relatively small number of people who go on to become cases and a much larger number who do not. This imbalance is statistically inefficient. In effect, a case–control study aims to characterize exposures in all the cases that occur in a cohort, but in only a representative sample of noncases. By comparing the prevalence and patterns of exposure in this way, it is possible to estimate odds ratios (usually a good proxy for RRs) and also attributable proportions. However, attributable risks cannot be estimated directly from case–control studies. Allowance for potential confounding factors is made by restriction, by matching controls to cases (either individually or in groups) according to their exposure to confounders, or by collecting information about subjects' exposures to confounders and then adjusting for them statistically. Where matching is employed, statistical analysis must be modified to take the matching into account—otherwise risk estimates may be biased.

Methods for ascertaining exposures will depend on the nature of the risk factors and potential confounders under investigation. It may be possible to determine exposures from stored records (e.g. on prescriptions or hospital treatments) or from a persistent biomarker that is not modified by the development of the health outcome (e.g. measurement of the metabolite, DDE (dichlorodiphenyldichloroethylene), in adipose tissue or blood has been used as an index of past exposure to the insecticide, DDT (dichlorodiphenyltrichloroethane) in case–control studies of breast cancer (Snedeker, 2001). Most often, however, exposures are assessed through questionnaires that are either completed at interview or self-administered.

The most challenging aspect of case–control design is usually the choice of suitable controls. The aim is that (within matching strata if there are any) controls should have exposures to risk factors and potential confounders that are representative of those in the (real or hypothetical) cohort from which the cases derived. In other words, exposures should be representative of those in people who would have been included in the study as cases, had they developed the health outcome of interest during the period of study. At the same time, it is desirable that exposures be ascertained with similar accuracy for cases and controls (ideally exposures would be established with complete accuracy in both groups, but if this is not possible, similar accuracy for cases and controls will normally ensure that any resultant bias is towards the null—that is, associations will tend to be obscured rather than exaggerated).

In practice, however, it is rarely possible to achieve both of these objectives simultaneously, especially when exposures are ascertained by questionnaire. If controls are sampled from the source population at random (or by some pseudorandom algorithm), their exposures to risk factors and confounders should be fairly representative of those in the source population. However, it is likely that they will be less motivated than cases to remember past exposures, leading to a bias that tends to inflate risk estimates. Recall bias of this sort is less likely if, for example, patients with other diseases are employed as controls. However, the exposures of such patients may not be representative of those in the source population. For example, in a case–control study of bladder cancer and smoking, controls collected from a chest clinic could give a highly unrepresentative picture of smoking patterns in the population that gave rise to the cases. Again, bias would result.

Therefore, the choice of controls in a case–control study is often a compromise. Bias can only be minimized and not totally eliminated.

Case–control studies vary in their ratio of controls to cases. If both cases and controls are readily available and can be studied at similar cost, statistical efficiency will be greatest with equal numbers of cases and controls. If, however, there is a limit to the number of cases available for study (e.g. because the disease under investigation is rare), then statistical power can be increased by recruiting more than one control per case, although the gain in power diminishes as the ratio of controls to cases increases. Therefore, unless it is very cheap and easy to enrol additional controls, it is rarely worth including more than four or five controls per case.

Case–control studies have the advantage that they are usually cheaper than cohort studies of the same statistical power, especially for the investigation of rare health outcomes. However, they are less efficient when the exposures of interest are rare in the population under study (for a dichotomous risk factor, statistical power is greatest when the prevalence of exposure in the study population is 50%, and diminishes substantially if exposure is very rare or very common). Furthermore, because of the potential for inflationary recall bias, case–control studies often give less reliable estimates of risk than cohort studies.

6.5 Cross-Sectional Studies

In a cross-sectional study, information is collected at a point in time or over a relatively short period, in a defined population, about the prevalence of current, recent or past health outcomes and/or exposure to risk factors. If only health outcomes or only risk factors are ascertained, then the study is purely descriptive (see above). However, cross-sectional studies can also be used to examine associations between risk factors and health outcomes. For example, cross-sectional

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat111
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

designs have been employed to explore the relation between exposure to genotoxic chemicals and the prevalence of cytogenetic abnormalities in circulating lymphocytes.

Where cross-sectional surveys are used to investigate questions about causation, care is needed that associations are not distorted by selective exclusion of potential participants as a consequence of the study design. For example, a cross-sectional study of sheep farmers looking for a relation of previous work with organophosphate sheep dip to impaired performance on neuropsychological testing, might underestimate an adverse effect if individuals with organophosphate-related illness were more likely than others to have left farming, and therefore to be excluded from the study sample. This type of selection effect would be of less concern, however, if the study sample comprised men living in defined rural areas, who were selected solely on the basis of their age and place of residence, and not according to whether they were currently working in agriculture. Selection effects are also less likely when the health outcome of interest is asymptomatic or associated with only minor symptoms.

In addition to selection bias and possible confounding, interpretation of cross-sectional studies must sometimes give consideration to the possibility of 'reverse causation'. For example, an association between use of analgesics and dyspeptic symptoms could occur because the drugs cause gastric irritation, but might also arise because people take analgesics to relieve their dyspepsia. Reverse causation is less of a concern in cohort and case–control studies where risk factors are usually ascertained in a way that ensures they precede health outcomes in time.

6.6 Randomized Controlled Experiments

In a randomized controlled experiment (also known as a randomized controlled intervention study), eligible subjects who agree to participate are randomly assigned to receive one of two or more treatments or exposures. Subsequent health outcomes are then systematically ascertained and compared between the treatments or exposures. Studies of this sort provide the strongest evidence of causation that is possible from investigation of statistical associations in human populations. This is because if randomization is carried out on a sufficiently large scale, important confounding, even by unrecognized causes of the health outcome, becomes statistically unlikely. Randomized controlled experiments are used most commonly to assess the benefits and risks of drug treatments, but can also be applied to assess risks of minor, reversible, toxic effects of chemicals. For example, randomized controlled experiments have been used to investigate the effects of food-colouring agents on hyperactive behaviour in children (McCann *et al*., 2007).

6.7 Nonrandomized Experiments

Even where it is ethically acceptable deliberately to expose human subjects to a chemical, investigation of its effects by a randomized experiment may not be practical. For example, studies have been conducted in the past to assess the impact of fluoridating drinking water on rates of dental caries in children. However, because the intervention was at the level of the water supply systems to communities, and only a few communities could be included in a single investigation, there would have been no benefit in allocating exposures randomly. Just by chance, potentially confounding factors, such as poor dental hygiene, could have ended up being distributed unevenly between the communities assigned to fluoridation and the control communities. In this situation, a stronger design was a nonrandomized experiment, in which allocation of communities to fluoridation was done in a purposive way that balanced as far as possible the distribution of potential confounding factors between fluoridated and control communities. In addition, the design could be further strengthened by collecting information on rates of dental caries in all communities both before and after the intervention. Analysis would then compare the change in rates of dental caries following fluoridation in the communities that received the intervention with that in the control communities over the same period. Important confounding would only occur if exposure to major causes of dental caries changed differentially over the course of the study in the intervention as compared with the control communities.

The major strength of nonrandomized experiments as compared with cohort studies is that the investigator controls the exposure that is delivered through the intervention. However, like observational studies, nonrandomized experiments are liable to unrecognized confounding effects.

7 INTERPRETATION OF EPIDEMIOLOGICAL STUDIES

Unlike toxicological experiments in the laboratory, epidemiological studies, especially if observational rather than experimental, generate relatively 'dirty' data. Their findings must therefore be interpreted with care. Two studies that apparently address the same question can sometimes generate results that are quite different. In evaluating epidemiological studies and considering why findings are discrepant, six points of interpretation should be considered.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

7.1 Classification of Exposure

One reason for apparently discrepant findings may be that the exposures studied were not identical. In some cases, the differences may be clear from the way in which exposure was defined. For example, work for at least 12 months in the manufacture of boats from glass-reinforced plastics gives substantially different cumulative exposure to styrene from short-term employment in a styrene-producing chemical plant. In other cases, differences may be less obvious. Thus, two studies might both derive risk estimates for cumulative exposures to styrene in the range 10–90 ppm-years, but in one, most of the individual exposures so classified might be at the lower end of the range, whereas in the other, they were near the upper end.

7.2 Classification of Health Outcome

In the same way, two studies, although seemingly addressing the same health outcome, may differ importantly in the mix of cases investigated. For example, one case–control study of nasopharyngeal carcinoma and exposure to wood dust might include predominantly patients with squamous cell tumours, while in another, most of the cases had anaplastic cancers. If wood dust affected the risk of these histological types differentially, then the two studies could produce quite different estimates of risk.

7.3 Bias

Sources of bias and their possible impact on parameter estimates are always a major consideration in the interpretation of epidemiological data. If two studies differ importantly in their biases, this could lead to substantial differences in their results.

7.4 Chance

Chance is another possible explanation for apparently discrepant findings. The confidence intervals around parameter estimates give a good indication of their associated statistical uncertainty, and when this is taken into account, discrepancies may seem less remarkable. Sometimes formal statistical tests are carried out to explore whether heterogeneity of parameter estimates between studies is greater than might reasonably be expected by chance.

7.5 Confounding

Differences in the impact of confounding factors are another reason why studies may give different results.

7.6 Effect Modification

Effect modification occurs when the RR associated with a risk factor varies according to the presence or level of another exposure (an effect modifier). For example, the risk of bladder cancer from occupational exposure to aromatic amines has been found to vary according to genetically determined differences in activity of the enzyme, *N*-acetyl-transferase (Yuan *et al*., 2008). In other words, acetylator status modifies the effect of aromatic amines on risk of bladder cancer.

Differences in the distribution of effect modifiers are another reason why risk estimates for an association between a risk factor and health outcome can vary between studies.

If these six points of interpretation are carefully considered, it is normally possible to draw useful conclusions from epidemiological data, even when there are clear limitations in study designs. Importantly, however, results should always be viewed in context, taking into account the biological plausibility of different possible explanations for what has been found. Thus parallel toxicological findings are often a major consideration in the evaluation of epidemiological observations. Similarly, relevant epidemiology, where available, can substantially enhance the interpretation of some toxicological research.

NOTES

[a.] Diseases are the health outcomes most commonly studied in epidemiology, and unless otherwise stated, the discussion in this section assumes that disease is the health outcome of interest. Rates of other dichotomous health outcomes such as illness and disability can be defined analogously.

Aviation Toxicology

Thomas C. Kupiec and Vishnu Raj

CONTENTS

1 INTRODUCTION

Air travel has become an increasingly popular modality of long-distance travel for the majority of people. In recent years, a source of concern with the increase in civil and military aviation traffic is the effect of the exponential rise in the use of prescription medications. The detrimental effect of drugs and alcohol on driving performance is well documented. The complexities of aviation tasks create potentially more devastating consequences, with subtle errors by an impaired pilot. Both prescription and illicit drugs can lead to impaired performance and subsequent accidents. In addition, the medical condition for which a drug is prescribed may itself lead to accidents. Presence of drugs in biological specimens obtained from aircraft accidents may indicate exposure to drugs, as well as the possible medical conditions for which the medication might have been taken (Chaturvedi and Canfield, 1997).

The field of aviation toxicology addresses the impact of prescription and illicit drugs on pilot performance, as well as the putative role of these agents in the cause or manner of death in aviation fatalities. Applications of aviation toxicology are vast, and range from human performance to accident reconstruction efforts. Toxicological analysis of the post-mortem specimens usually includes identification of illicit drugs, controlled substances, including Schedules I–V (SI–V), prescription and nonprescription (over-the-counter (OTC)) drugs and ethanol (Chaturvedi *et al*., 2005). Examples of SI–II substances include amphetamines, cocaine and marijuana and SIII–V substances include benzodiazepines, phentermine and propoxyphene (Chaturvedi *et al*., 2005). Antidepressants, antihypertensives and anticonvulsants are example of prescription drugs, and antihistamines, antipyretics and decongestants are examples of nonprescription drugs (Chaturvedi *et al*., 2005).

In aviation toxicology, analysis of the relative levels of hydrogen cyanide and carbon monoxide (CO) among passengers and crew, may help establish fire patterns (Rainford and Gradwell, 2006). Additionally, in several situations, owing to the severity of physical trauma, toxicological examination may provide the only evidence of pathological conditions that could produce sudden incapacitation, such as hypertension and epilepsy (Rainford

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and Gradwell, 2006). Toxicological analysis of specimens from aviation accident victims necessitates a thorough investigation for the presence of prescription, OTC and illicit drugs, environmental contaminants and toxins, as well as the identification of artifacts such as post-mortem ethanol. This investigation could assist in the elucidation of human factors that contributed to the aviation accident.

Contrary to conventional forensic toxicology, drugs in aviation forensic toxicology are usually found in therapeutic to subtherapeutic levels (Chaturvedi and Canfield, 1997). Therefore, owing to their longer window of detection, the identification and determination of drug metabolites assumes a critical role in air-accident investigations. In some cases, the levels of parent drug and active metabolites may also help establish degree of intoxication.

2 ANALYTICAL TECHNIQUES

Drugs and chemicals that are commonly analysed include ethanol, stimulant and depressant drugs including prescription and illicit drugs, CO, hydrogen cyanide, solvents, fuels and insecticides. Screening for the presence of pesticide or herbicides and cholinesterase inhibition may help establish accidental exposure during crop spraying (Rainford and Gradwell, 2006). The collection of a variety of tissues and fluids is integral to successful testing. In aircraft fatalities, the availability of fluids is often impossible due to high impact forces, however; whenever possible, an adequate quantity of blood from two separate sites, sterile urine from an intact bladder and bile and vitreous humour (VH) should be obtained (Rainford and Gradwell, 2006). **Table 1** provides a listing of specimen suitability characteristics for analyses of different drugs. Samples should preferably be obtained from all accident victims. Specimens from passengers may help serve as controls for specimens obtained from flight crew, especially in instances of post-mortem ethanol production (Rainford and Gradwell, 2006).

Specimens may be subjected to various extraction techniques such as liquid–liquid and solid-phase extraction. Various techniques are available to extract drugs from tissue and these usually involve the physical breakdown of tissue with a homogenizer or blender, followed by protein precipitation, direct solvent extraction or further tissue breakdown by acid hydrolysis Mayes (1982). Osseleton introduced an extraction technique using a nonspecific proteinase to digest tissue proteins and release the drug into solution. A far higher yield was evident for the enzymatic method relative to acid hydrolysis Mayes (1982).

Headspace gas chromatography (GC) is used for the analysis of ethanol and screening for volatile compounds (Rainford and Gradwell, 2006). CO concentrations may be estimated by the spectrophotometric analysis of carboxyhaemoglobin (COHb) using a CO-oximeter (Instrumentation Laboratories (UK) Limited, Warrington, UK). However, with contaminated samples or decomposed blood, GC or derivative spectrophotometry is required. Cyanide (CN^-) is separated from acidified blood using Conway diffusion and analysed by colorimetry or GC.

Specimens are screened for drugs using immunoassay, GC and high-performance liquid chromatography (HPLC) technologies. Confirmation is performed using gas chromatography/mass spectrometry (GC/MS) and liquid chromatography/mass spectrometry. Mass-selective detection is essential for the identification of certain drugs (Rainford and Gradwell, 2006). Urine is preferred for the screening of prescription and OTC drugs using HPLC and GC/MS. Certain additional drugs—for example, paracetamol (acetaminophen), salicylates, quinidine, theophylline, phenytoin and propoxyphene—are also screened in urine by fluorescence polarization immunoassay (FPIA) (Chaturvedi *et al*., 2003). In the absence of urine, other specimens are screened for drugs of abuse using radioimmunoassay (RIA). The order of specimen preference for the RIA-based abused-drug screening is bile, blood, liver, kidney and other tissues (Chaturvedi *et al*., 2003).

Drugs of abuse including amphetamines, methamphetamine, phencyclidine, cocaine, opiates, cannabinoids, barbiturates and benzodiazepines are commonly screened by FPIA. The difference between the drug screen in forensic toxicology and aviation toxicology is that the forensic toxicologist is principally concerned with drugs at the overdose level (Mayes, 1982). In aviation toxicology, many drugs may impair performance at or below therapeutic levels and therefore the drug screen in aviation toxicology must be capable of detecting and identifying drugs at very low levels nanogram or picogram (Mayes, 1982).

Depending on the types and quantity of received samples, COHb, blood CN^-, alcohol/volatile, glucose and haemoglobin A1c (HbA1c) analysis and drug screening batches are prepared and submitted for analysis. Batches are prepared by transferring an aliquot of the specimens into test tubes (Chaturvedi *et al*., 2003). Batches also contain aliquots from at least two quality assurance/quality-control (QA/QC) blind samples—one negative control and one positive control (Chaturvedi *et al*., 2003). The controls are consistent with batch types, case aliquot matrices and analytes (Chaturvedi *et al*., 2003). Analysts are blinded to the location and the type or quantity of analyte(s) present in the QA/QC blind aliquots of a particular batch, and if the initial screening analysis is positive, the specimens are confirmed and quantitated (Chaturvedi *et al*., 2003).

Table 1 Specimen characteristics for toxicological analysis (Civil Aerospace Medical Institute (CAMI))

Specimen type†	Optimal amount‡	Analysis type suitability
Blood	40 ml	Green-top tube blood for carboxyhaemoglobin (COHb), blood cyanide CN^-, haemoglobin A_1c HbA_1c) and drug analyses Gray-top tube blood for ethanol and drug analyses
Urine	100 ml	Ethanol, drug and glucose analyses
Vitreous humor	2 ml	Ethanol and glucose analyses
Spinal fluid	Available amount	Ethanol and, perhaps, drug analyses
Bile	10 ml	Abused drug radioimmunoassay (RIA) screening, when urine is not available
Gastric contents[P]	100 g	Need-based drug analysis
Liver	500 g	Ethanol and drug analyses
Muscle	300 g	Ethanol and drug analyses
Spleen	150 g	Ethanol and drug analyses
Lung	100 g	Ethanol and drug analyses
Kidney	100 g	Ethanol and drug analyses
Brain	100 g	Ethanol and drug analyses
Heart	50 g	Ethanol and drug analyses

† Drugs/substances (tablets, caplets, capsules, powder, and/or liquid) found at the accident scene are also occasionally submitted. Analyses of drugs/substances may be helpful in the investigation of accidents, particularly when they are also found in the submitted biological samples.

‡ An adequate amount considered is half of the optimal amount. Any specimen submitted in the amount less than the adequate amount is considered to be inadequate.

3 ETHANOL

Ethanol-induced impairment and the incompatibility of operating a motor vehicle under the influence of ethanol are both well recognized. The effect of ethanol may be more deleterious in aviation, where slight errors have potentially lethal consequences. In addition, effects of ethanol may also be more pronounced at higher altitudes. Alcohol use by pilots is a highly contentious matter, especially during the investigation of aviation disasters (Li *et al*., 2005). Pilot performance has been shown to be impaired at blood alcohol concentrations (BACs) as low as $0.01\,g\,dl^{-1}$, and the number and magnitude of errors increases in proportion to the BAC. **Table 2** delineates the adverse effects of alcohol on piloting performance (Cook, 1997).

A study by Canfield *et al*. (1993) reported 79 ethanol-positive ($>0.04\,g\,dl^{-1}$) specimens among 975 specimens of victims of fatal aircraft crashes, received by the US Civil Aeromedical Institute during 1989–1990 (Canfield *et al*., 1993). Based on the distribution of ethanol in urine, vitreous, blood and tissue it was determined that 21 of the positive cases could be attributed to post-mortem synthesis of ethanol, whereas 22 reflected alcohol consumption, and 36 could not be interpreted satisfactorily (Canfield *et al*., 1993). Two of the cases reported had post-mortem ethanol levels as high as $0.15\,g\,dl^{-1}$ (Canfield *et al*., 1993). Aviation fatalities present several difficulties during the recovery of the bodies and sample collection for toxicological analysis (Kugelberg and Jones, 2007). The post-mortem examination and the toxicological analyses are complicated due to extensive trauma, including stomach rupture and bursting of the bladder (Kugelberg and Jones, 2007).

Ethanol concentration measured in blood drawn from different sampling sites tends to exhibit greater variation than expected from inherent variations in the analytical methods used. It has been reported that ethanol concentrations in heart blood are generally higher than in blood from a peripheral vein, although in any individual case there are likely to be considerable variations (Kugelberg and Jones, 2007; Pelissier-Alicot *et al*., 2006; Chikasue *et al*., 1988). Femoral blood is least susceptible to post-mortem changes, and is hence the preferred specimen. The collection of additional specimens, such as urine and VH, is preferable whenever possible (**Table 1**). Blood from the intact chambers of the heart is considered suitable as a supplementary specimen to compare with femoral BAC or when the volume of the latter specimen might be limited. (Kugelberg and Jones, 2007). The worst possible specimen is a blind-stick into the chest or

blood scooped from the chest cavity on opening the body (Kugelberg and Jones, 2007).

Specimen collection tubes should contain preservative such as sodium or potassium fluoride to ensure a final concentration of 1–2% w/v (Kugelberg and Jones, 2007). The fluoride ion is seemingly effective in inhibiting the activity of several kinds of enzymes, such as enolase, an enzyme important for the fermentation initiated by yeasts, fungi and so on. All containers used to collect autopsy blood specimens should be carefully labelled with the type of material, the anatomical site of origin, the date and time and important details of the case including identification of the deceased. Fluid specimens intended for determination of volatiles like ethanol should have a small air-space to minimize evaporation. Finally, the containers should be made airtight with tamper-proof seals and, if possible, transported to the laboratory refrigerated (4–8°C). Maintenance of accurate specimen chain-of-custody is integral to future legal proceedings (Kugelberg and Jones, 2007).

Alcohol is typically analysed by headspace GC which offers the benefit of protecting the chromatographic column from overloading with nonvolatile blood constituents (Kugelberg and Jones, 2007). Headspace GC entails the removal of a portion of the vapour phase in equilibrium with the biological specimen, which is kept in an air-tight glass vial at a constant temperature of 50 or 60 °C (Kugelberg and Jones, 2007). Matrix effects are minimized by diluting the blood specimen 1:5 or 1:10 using an aqueous solution of a suitable internal standard, such as *n*-propanol or *t*-butanol. Trace amounts of volatile substances may be analysed by saturating both the biological specimens and the aqueous standards with an inorganic salt such as sodium chloride or sodium sulfate. This salting-out technique raises the vapour pressure of nonelectrolytes (e.g. ethanol) in the flask and boosts the sensitivity of the headspace GC analysis. Standard addition may be performed to minimize matrix effects, when ethanol or other drugs are determined in a complex or unusual matrix (Kugelberg and Jones, 2007).

Using highly specific gas chromatographic methods of analysis, ethanol can be determined reliably even in the presence of potential interfering substances (e.g. acetaldehyde, ethyl acetate, *n*-propanol, isopropanol, *n*-butanol), that might be produced during decomposition. The biological specimens sent for analysis of ethanol should be analysed in duplicate on two different chromatographic systems, thus providing different retention times for ethanol and internal standard. The use of dual internal standards (e.g. *n*-propanol and *t*-butanol) to dilute autopsy blood specimens, has also been recommended. The tertiary alcohol (*t*-butanol) is recommended because under some circumstances small amounts of *n*-propanol might be produced during decomposition and putrefaction processes (O'Neal *et al.*, 1996).

The precision of routine blood-alcohol analysis is high and interlaboratory coefficients of variation (CVs), according to several studies, are only 3–5% compared with within laboratory CVs of less than 1% (Kugelberg and Jones, 2007). However, higher CVs are evident upon comparison of blood-ethanol concentrations from different sampling sites, and this may be partly explained by the varying fluidity of the specimens and the amounts of plasma, red cells and clots present (Kugelberg and Jones, 2007). Therefore, this site-related uncertainty needs to be considered during interpretation of post-mortem alcohol concentrations and comparison with statutory levels. The significance of a relatively low post-mortem BAC ($<0.03\,g\,dl^{-1}$) in the absence of corroborating evidence from analysis of ethanol in urine or VH, is debatable. A post-mortem BAC of less than $0.01\,g\,dl^{-1}$ should be reported as negative and is close

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to the limit of quantitation of most routine headspace GC methods.

3.1 Post-Mortem Ethanol Formation

Although the qualitative and quantitative determination of ethanol in post-mortem specimens is a relatively simple analytical procedure, the interpretation of post-mortem BAC and the consequent extrapolation of ante-mortem concentration and the individual's degree of impairment is fraught with difficulties (Kugelberg and Jones, 2007). Post-mortem diffusion of alcohol from the stomach to central blood-sampling sites is a complicating factor if a person died shortly after a period of heavy drinking (Kugelberg and Jones, 2007). In certain situations, especially involving decomposed bodies, ethanol might be produced post-mortem, due to microbial activity and fermentation of glucose. The question of post-mortem ethanol production often occurs during the investigation of mass transportation fatalities. Therefore, findings of positive BAC need to be interpreted with caution because of the heightened risk of post-mortem synthesis (Kugelberg and Jones, 2007).

Extensive trauma to a body has been known to increase the potential for spread of bacteria and heightens the risk of ethanol production after death (Kugelberg and Jones, 2007). Blood-ethanol concentrations as high as $0.19\,\mathrm{g\,dl^{-1}}$ have been reported in post-mortem blood after traumatic events such as explosions, with no evidence supporting ante-mortem ingestion of ethanol (Kugelberg and Jones, 2007). In these situations, the comparison of ethanol concentrations in blood from different sampling sites, as well as in alternative body fluids, such as urine, VH and cerebrospinal fluid (CSF) can help resolve the origin of ethanol in dead bodies (Kugelberg and Jones, 2007).

Following death, the integrity of cell membranes and tissue compartments gradually disintegrate through the action of various digestive enzymes (autolysis) (Kugelberg and Jones, 2007). During this process, bacteria from the bowel invade the surrounding tissue and vascular system. Glucose concentrations increase post-mortem, therefore providing a substrate for microbial synthesis of ethanol. Low concentrations of ethanol ($\leq 30\,\mathrm{mg\,(100\,ml)^{-1}}$) are more likely to be formed post-mortem than high concentrations (Kugelberg and Jones, 2007). Speedy recovery and refrigeration of the bodies helps to prevent microbial synthesis of ethanol.

Urine can be beneficial for alcohol analysis, owing to its high water content and a lower risk of post-mortem microbial invasion of the urinary bladder, relative to blood specimens. Additionally, the urine produced by healthy individuals does not contain significant amounts of glucose (the substrate for post-mortem ethanol synthesis). The use of urine is contraindicated if the deceased suffered from diabetes and glycosuria. An elevated urinary ethanol concentration in a specimen from a diabetic, and a negative blood ethanol concentration, is usually indicative of post-mortem urinary synthesis of ethanol due to the fermentation of glucose. If available, the determination of glucose in vitreous fluid is useful to corroborate the hypothesis of glycosuria.

Urine should be sampled directly from the intact bladder by penetrating the organ with a sterile syringe and needle and transfering to a container with a fluoride preservative present (1–2%) before shipment for analysis of ethanol (Kugelberg and Jones, 2007). Calculation of the ratio of UAC (urine-alcohol concentration)/BAC furnishes useful information about the status of alcohol absorption at the time of death. A ratio less than or close to unity suggests incomplete absorption of alcohol in all body fluids at time of death, therefore implying fairly recent drinking, with some of the ingested alcohol probably remaining unabsorbed in the stomach (Kugelberg and Jones, 2007). A ratio of 1.25 or more suggests that absorption and distribution of ethanol was complete by the time of death.

Vitreous fluid is a useful specimen for the post-mortem analysis of ethanol, drugs and endogenous biochemical constituents of the body. The main advantage of the vitreous over blood, is that anatomically it is remote from the gut and therefore less prone to bacterial contamination, especially in severe trauma and decomposition cases.

The mean vitreous humor/blood ratio of ethanol has been reported to be very close to values expected from the distribution of water in these two biological specimens, namely about 1.15–1.20:1 (Kugelberg and Jones, 2007). Correlation coefficients between VH and blood have been reported to be range between $r = 0.936$ and $r = 0.979$.

In the absence of traditional specimens, other biological specimens such as liver, brain, skeletal muscle, spleen, bone marrow, CSF and synovial fluid, as well as bile, may be used for toxicological analysis (**Table 1**) (Kugelberg and Jones, 2007). The water and lipid content of these more unusual body fluids and tissues and the stability of ethanol after sampling are important to consider, for better interpretation of the results. Organs such as liver and kidney may retain some enzymatic activity after death as the body cools, and depending on ambient temperature and availability of cofactor nicotinamide adenine dinucleotide (NAD^+) ethanol might be metabolized to some extent after death (Kugelberg and Jones, 2007). Some body organs and tissue are probably more susceptible than others to putrefaction processes, depending on their glucose and glycogen content and proximity to the bowel, thus facilitating spread of bacteria and fungal growth. In decomposed or exhumed bodies, skeletal muscle is probably the most appropriate specimen for forensic analysis of ethanol and other drugs (**Table 1**) (Kugelberg and Jones, 2007).

3.2 Biochemical Markers

In order to distinguish between ante-mortem ethanol ingestion and the post-mortem synthesis of ethanol, biochemical indicators such as nonoxidative metabolites of ethanol have been used. Trace quantities of ethyl glucuronide (EtG), a minor metabolite of ethanol, are produced during enzymatic metabolism of ethanol (<0.1% of dose) but more importantly, EtG is evidently not produced by the action of microbes and yeasts on glucose. EtG, if present in measurable quantities, would imply that the ethanol had been metabolized during life. However, an implication of an elevated ante-mortem BAC may not be drawn from the presence of EtG, because the elimination half-life of EtG is more prolonged relative to ethanol. Analyses of EtG and ethyl sulfate are of special interest in occupational medicine for proof of abstinence among individuals performing highly skilled tasks and safety-sensitive work, for example, surgeons or airline pilots (Kugelberg and Jones, 2007).

Depending on the dose ingested, urinary EtG can disclose recent drinking for about 6–10 hours after ethanol is no longer measurable. This presence of EtG and its longer elimination time could be misinterpreted if post-mortem ethanol had been produced, and the ante-mortem BAC had reached zero due to metabolism. This scenario could probably be incorrectly interpreted to mean that the individual had alcohol in the blood at the time of death (Kugelberg and Jones, 2007). A study by Schloegl *et al*. found that EtG concentrations remained fairly constant in urine samples held in air-tight containers when these were stored at room temperature for five weeks (Schloegl *et al*., 2006). An important finding was that when EtG-free blood and liver samples were spiked with ethanol ($100\,mg\,(100\,ml)^{-1}$) there was no new *in vitro* formation of EtG during storage (Schloegl *et al*., 2006).

The urinary metabolites of serotonin, namely 5-hydroxytryptophol (5HTOL) and 5-hydroxyindoleacetic acid (5HIAA) have also been used to resolve whether a positive BAC stems from ante-mortem ingestion of ethanol or post-mortem synthesis. Finding an elevated urinary ratio of 5HTOL:5HIAA (>15) indicates that ethanol has undergone metabolism, which points to ante-mortem ingestion (Kugelberg and Jones, 2007). An article by Johnson *et al*. describes the accurate determination of the origin of ethanol origin in post-mortem urine samples, using an improved GC/MS method for simultaneous determination of 5HTOL and 5HIAA (Johnson *et al*., 2004). This approach has been used for investigating the origin of ethanol in victims of civil-aviation disasters (Johnson *et al*., 2004)

The microbial synthesis of endogenous ethanol can lead to the production of other low-molecular-weight volatiles, including higher aliphatic alcohols (isoamyl alcohol, *n*-propanol, isopropanol, *n*-butanol), acetaldehyde and propionic acid, as well as other organic acids (Kugelberg and Jones, 2007). Among these, *n*-butanol and isobutyric acid are considered to be reliable indicators of putrefaction, and their presence in blood may question the concentration of ethanol (Kugelberg and Jones, 2007; Caughlin, 1994). The use of *n*-propanol as an indicator of putrefaction, has been proposed; however, the quantitative relationship between *n*-propanol detected and the amount of ethanol produced in post-mortem blood was not strong, with the concentrations of *n*-propanol 15–20 times less than that of ethanol (Moriya and Hashimoto, 2004).

3.3 Interpretation

Traditional dose : plasma concentration relationships are not practicable for use in post-mortem toxicology owing to protein binding, drug sequestration in tissue depots and ill-defined volumes of distribution (Kugelberg and Jones, 2007). A well-recognized source of concern in post-mortem toxicology is the post-mortem redistribution of ethanol and drugs, due to passive diffusion through the stomach wall, thereby falsely increasing the concentration of these substances in surrounding tissues and blood (Kugelberg and Jones, 2007; Iwasaki *et al*., 1998). Therefore, the concentration of a drug determined during autopsy may not necessarily reflect the concentration present at the time of death (Kugelberg and Jones, 2007). Post-mortem displacement of a relatively small amount of substance from a tissue depot, for example, the liver, into the vascular system could produce a substantial change in the drug concentration determined using central blood. The passive diffusion of alcohol across a mucous membrane depends on the concentration gradient across the membrane and its permeability.

In cases of traumatic deaths, such as in an air crash, there is an increased risk of gastric alcohol contaminating the surrounding tissues. However, post-mortem diffusion and redistribution appears to be more of a concern with drugs rather than ethanol, especially those drugs with large volumes of distribution, such as tricyclic antidepressants (TCAs). Drugs that are sequestered in a particular tissue or when concentrations are sensitive to changes in pH after death are especially problematic (Kugelberg and Jones, 2007).

However, post-mortem ethanol production is of significant concern, especially in mass transportation and aviation disasters. Two methods used to establish whether measured ethanol resulted from consumption or post-mortem formation, are by the analysis of multiple specimens and the analysis for other volatile substances (Klette *et al*., 1992). Comparing the concentrations of ethanol in different specimens, such as cardiac and femoral blood, urine and VH, is integral to the rule out endogenous ethanol production. A positive blood ethanol, in combination with a negative VH or urine ethanol, two specimens resistant to the putrefaction

process, would usually indicate that the ethanol was formed post-mortem (Klette *et al*., 1992). In addition, various biomarkers have been developed to help establish whether a positive blood ethanol arose from post-mortem synthesis or ante-mortem ingestion. Klette *et al*. in their study, reported the presence of acetaldehyde and/or *n*-propanol, two volatiles which have been observed in decomposing specimens (Klette *et al*., 1992).

4 INHALATION TOXICOLOGY

Upon exposure of aircraft cabin occupants to fire effluent, the first hazard encountered is usually smoke, containing particulates and toxic gases, causing immediate visual obscuration and painful irritation of the eyes and respiratory tract (Purser, 1996). In smouldering or small, confined, in-flight fires, where the yields of organic irritants and acid gases are likely to be high and exposure times long, the distressing effects of irritants, lung inflammation and asphyxia induced by CO are likely to be the main hazards. Types and amounts of combustion products generated depend upon the chemistry of the materials involved and the environmental conditions present during a particular fire (Chaturvedi and Sanders, 1996). Post-crash fires tend to develop rapidly into a flashover, and provide very limited time for escape before the onset of lethal conditions due to the effects of toxic smoke and heat. Combustion of cabin lining and seating materials increases the concentrations of toxic gases, especially CO and hydrogen cyanide, thereby incapacitating any remaining cabin occupants (Purser, 1996).

Besides visual obscuration, smoke components produce adverse biological effects. Exposure to CO and hydrogen cyanide, two components of smoke, may lead to incapacitation and eventual death (Chaturvedi and Sanders, 1996). CO binds haemoglobin and thus interferes with oxygen transport, whereas hydrogen cyanide inhibits oxygen utilization at the cellular level. Simultaneous exposure to both gases can produce a combined effect of severe hypoxia (Chaturvedi and Sanders, 1996). Carbon dioxide increases the respiratory rate and results in an increased uptake of the more toxic gases. The diminished oxygen at fire scenarios reduces oxygen availability and utilization (Chaturvedi and Sanders, 1996).

5 CARBON MONOXIDE AND CYANIDE

CO and CN^- are combustion products, and are often investigated in aviation accident investigations. CO in the flight crew may suggest a causal contamination possibly due to faulty heat exchangers (Rainford and Gradwell, 2006). Relative to oxygen, CO has approximately 200 times higher affinity for haemoglobin and binds it to form COHb, therefore leading to hypoxia. COHb has a half-life of 4–5 hours, and increased levels of COHb are usually attributable to smoke inhalation. CO is analysed as COHb and hydrogen cyanide as CN^- (Canfield *et al*., 2005).

Analysis of CO may help determine if the accident victim was exposed to an in-flight/post-crash fire or faulty heating/exhaust system (Lewis *et al*., 2004). Concentrations of haemoglobin in nonsmokers may be as high as 3%, while smokers may achieve levels up to 10%. Therefore, 10% saturation is a useful cut-off to separate those who have inhaled toxic atmospheres from those who have not. The fatal threshold for fire deaths has been taken as 50%, but fatalities may occur with saturations ranging from 10 to 90%. The toxic effect of high concentrations of CO in inhaled air may manifest by the inhibition of the cytochrome systems (Rainford and Gradwell, 2006).

COHb concentrations above 30% and CN^- concentrations above $1\,\mu g\,ml^{-1}$ have been reported to cause toxic effects resulting in the incapacitation of pilots (Canfield *et al*., 2005). However, the mere presence of COHb and CN^- in blood, even in potentially toxic or lethal concentrations, does not necessarily indicate that exposure to CO and hydrogen cyanide caused the death (Canfield *et al*., 2005). Elevated COHb and CN^- levels in post-mortem blood of individuals who died on impact would imply an in-flight fire, because CN^- is not produced from an exhaust leak (Canfield *et al*., 2005). An exhaust leak would be suspected in those cases with no fire, no CN^-, and blood COHb levels above 30% (Canfield *et al*., 2005).

A study on military aircraft fatalities from 1986–1990 reported greater than 10% CO saturation levels in 4% of the 535 cases where appropriate specimens were collected (Klette *et al*., 1992). These relatively low levels of COHb saturation are characteristic of most noninstantaneous deaths in post-crash fires involving military aircraft (Klette *et al*., 1992).

Canfield *et al*. investigated the presence of COHb and CN^- in 5945 aircraft fatalities, and found 223 (4%) of the cases with COHb of $\geq$10% (Canfield *et al*., 2005). Of the 223 cases, fire was reported in 201, no fire in 21, and undetermined fire status in one (Canfield *et al*., 2005). CN^- concentrations were at or above $0.25\,\mu g\,ml^{-1}$ in 103 of the 201 fire-related cases (Canfield *et al*., 2005). All nonfire cases with COHb $\geq$30% were associated with exhaust leaks (Canfield *et al*., 2005).

CO may be analysed by spectrophotometry or GC (Klette *et al*., 1992). Spectrophotometric methods of analysis are based on the comparison of COHb to reduced haemoglobin. A reducing agent is commonly employed in the spectrophotometric analysis of COHb to reduce any oxyhaemoglobin and methaemoglobin (MetHb) present in the blood, thereby eliminating their potential interference with the absorbance of COHb (Lewis *et al*., 2004). However, very low levels of haemoglobin in the fluids may increase the likelihood of an artificially

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat112
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

elevated COHb. In addition, with aged or putrefied post-mortem blood, the resistance of conversion of some of the haemoglobin pigments to reduced haemoglobin, may invalidate these methods.

GC is another technique that may be used for the analysis of CO, and there are several different GC methods available for the determination of CO in blood. Although GC methods are more time-consuming than spectrophotometric procedures, their utility is unparalleled when analysing samples that are unsuitable for ultraviolet (UV) methods because of post-mortem deterioration, coagulation or the presence of a substance that obscures the UV absorption pattern of COHb (Lewis *et al*., 2004). The most common and rapid GC method determines %COHb from a ratio of the CO peak area of CO-unsaturated blood to CO-saturated blood (Lewis *et al*., 2004). While this method works very well with preserved blood samples, it does encounter limitations when analysing post-mortem blood that may have experienced some degree of deterioration (Lewis *et al*., 2004).

Post-mortem deterioration due to a lack of timely preservation, exposure to heat and as a result of the freezing of a blood sample at and above temperatures of $-30\,^{\circ}C$ can result in the oxidation of haemoglobin to MetHb (Lewis *et al*., 2004). MetHb does not bind CO, and since %COHb is calculated as a ratio of peak areas of the unsaturated and saturated samples, elevated levels of MetHb in a sample will result in a loss of CO-binding capacity, and will produce an erroneously high %COHb value (Lewis *et al*., 2004). Treating the sample with a reducing agent, such as sodium dithionite, will convert the MetHb back to haemoglobin, thus restoring the total CO binding capacity of the sample (Lewis *et al*., 2004).

6 GLUCOSE

The analysis of glucose may be a critical factor in helping establish the cause of the aviation fatality, especially among individuals with a history of hyperglycaemia. Hypoglycaemia may be a factor in aircraft accidents; however, the accurate determination of the glucose level in the blood of a fatally injured crew member may be difficult (DeHart and Davies, 1996). Depending on the location of collection, post-mortem variations in glucose levels may be evident. Glucose levels in the vitreous fluid of the eye do not change as rapidly, and therefore the vitreous is a suitable source for the estimation of post-mortem glucose (DeHart and Davies, 1996).

In addition, the VH constitutes an isolated pool of material suitable for many analyses and is far less susceptible to rapid chemical changes or contamination than the blood. Glucose concentration in VH is of particular interest when fatal hypoglycaemia or diabetes is suspected (Sippel and Möttönen, 1982). However, studies on VH have demonstrated occurrence of post-mortem glycolysis (Sippel and Möttönen, 1982).

The determination of both CSF glucose and lactic-acid values, has been proposed for the diagnosis of fatal diabetes mellitus and hypoglycaemia, since this method takes into account the breakdown of glucose to lactic acid after death (Sippel and Möttönen, 1982). The diagnosis of ante-mortem hypoglycaemia must be made with caution, owing to erratic and occasionally very marked post-mortem reduction in the vitreous glucose (Sippel and Möttönen, 1982). Sippel and Mottonen reported a rapid and irregular increase in the lactic acid content of VH after death, and therefore, the determination of vitreous glucose and lactate values may be valuable in the exclusion of hypoglycaemia as a contributory cause of death (Sippel and Möttönen, 1982). High levels of vitreous glucose and lactate are indicative of ante-mortem hyperglycaemia (Sippel and Möttönen, 1982). Relatively low glucose concentrations, on the other hand, may be suggestive of lactic acidosis. Therefore, the determination of VH glucose shortly after death (less than two hours), or the combined vitreous glucose and lactate values at one to 10 days post-mortem may be a valuable tool for diagnosing ante-mortem hyperglycaemia (Sippel and Möttönen, 1982).

Establishment of cause of death in hypoglycaemic or diabetic coma should be made in conjunction with anamnestic response, morphology, biochemical (glucose, lactate, HBA1c, ketonic bodies, insulin and C-peptide) and toxicological findings (Karlovsek, 2004). High glucose levels in VH (more than $234\,mg\,dl^{-1}$) or combined values of glucose and lactate in VH or in CSF over threshold values of 427 and $422\,mg\,dl^{-1}$ respectively, can be an indicator of the pre-mortem hyperglycaemic state with fatal outcome (Karlovsek, 2004). The determination of glycated haemoglobin, acetone and other ketone bodies improve the diagnostic values of the whole procedure (Karlovsek, 2004). Diabetic ketoacidosis (blood acetone $>0.3\,g\,l^{-1}$) is more often the cause of death of diabetic patients than the nonketotic hyperosmolal state. Hypoglycaemia is deemed fatal if the combined values are lower than $5.5\,mmol\,l^{-1}$ ($100\,mg\,dl^{-1}$) and cannot be excluded if they are lower than $8.9\,mmol\,l^{-1}$ ($160\,mg\,dl^{-1}$).

7 ANTIDEPRESSANTS

Antidepressant drugs are among the most widely used prescription medications, and they include selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs) and TCAs. Among these groups of antidepressants, SSRIs are the most frequently encountered. SSRIs have the potential to affect the central nervous system (CNS), and thus might impair performance and ultimately compromise aviation safety (Akin and Chaturvedi, 2003). Therefore, with the exception of a few, most of these drugs are not approved by aeromedical regulatory authorities for use by aviators,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat112
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

due to their potential for impairing performance and causing drug interactions (Akin and Chaturvedi, 2003). However, as shown in **Table 3**, SSRIs and antidepressants featured prominently among a list of medications detected in pilots following aviation accidents. As of 2003, five drugs—fluoxetine, sertraline, paroxetine, fluvoxamine and citalopram were classified as SSRIs (Akin and Chaturvedi, 2003).

Although SSRIs are relatively safe compared to other groups of antidepressants, they have the potential for drug interactions. All five SSRIs are extensively metabolized by the cytochrome P450 (CYP) enzyme system. SSRIs are known to inhibit CYP2D6-mediated metabolism with paroxetine exerting the greatest degree of inhibition and fluvoxamine the least (Mozayani and Raymon, 2004). Excluding citalopram, at higher concentrations, SSRIs have been know to inhibit their own metabolism by saturating their metabolizing CYP enzymes (Akin and Chaturvedi, 2003). Since patients with depression are frequently treated with multiple drugs, the inhibition of the metabolism of these drugs by SSRIs can lead to drug interactions, toxicity and even death (Akin and Chaturvedi, 2003). Blood concentrations of those other drugs could be higher than their typical therapeutic blood levels because of the SSRI-caused inhibition of their metabolism, and thereby their accumulation in the blood.

Fluoxetine is metabolized by CYP2D6, with CYP2C9 and CYP3A4 playing a contributory role (Hemeryck and Belpaire, 2002). Fluoxetine is a potent inhibitor of CYP2D6 and norfluoxetine has a moderate inhibitory effect on CYP3A4. Fluoxetine used concurrently with alprazolam may lead to a decrease in alprazolam clearance and concomitant increase in plasma levels plausibly due to reduction in alprazolam metabolism. Fluoxetine has also been known to inhibit the metabolism of carbamazepine by the liver, presumably due to CYP2D6 inhibition. Certain side effects of fluoxetine, including drowsiness, dizziness, abnormal vision, diarrhoea and headache, and so on, could affect pilot performance and become a factor in an aviation accident (Johnson *et al*., 2007).

A study by Johnson *et al*. determined the distribution of fluoxetine and its desmethyl metabolite, norfluoxetine, in various post-mortem tissues and fluids from 10 fatal aviation accident cases. Blood fluoxetine concentrations in these 10 cases ranged from 0.021 to 1.48 $\mu g\,ml^{-1}$ (Johnson *et al*., 2007). Akin *et al*. investigated the prevalence of SSRIs in pilot fatalities of civil-aviation accidents, using post-mortem samples from pilots involved in fatal civil-aircraft accidents (Akin and Chaturvedi, 2003). Samples were received from 4184 fatal civil-aviation accidents, and there were 61 accidents in which pilot fatalities had detectable levels of SSRIs

Table 3 Drugs detected in post-mortem specimens of pilots in aviation accidents

Psychotropic	#	Cardiovascular	#	Neurological	#
Alprazolam	8	Amlodipine	8	Carbamazepine	3
Amitriptyline	10	Atenolol	33	Phenytoin	11
Bupropion	14	Bisoprolol	4	Selegiline	1
Buspirone	1	Clonidine	1	Total	15
Chlordiazepoxide	5	Diltiazem	23		
Citalopram	13	Doxazosin	1		
Clomipramine	1	Flecainide	1		
Desalkylflurazepam	3	Labetalol	4		
Diazepam	29	Metoprolol	24		
Doxepin	2	Moricizine	1		
Fluoxetine	40	Nadolol	4		
Imipramine	10	Procainamide	3		
Lorazepam	1	Propranolol	9		
Mirtazapine	2	Verapamil	33		
Nefazodone	1	Total	149		
Nordiazepam	16				
Norfluoxetine	1				
Oxazepam	2				
Paroxetine	21				
Sertraline	26

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat112
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Akin and Chaturvedi, 2003). Blood concentrations of SSRIs in the fatalities were 11–1121 ng ml^{-1}, for fluoxetine; 47–13 102 ng ml^{-1} for sertraline, 68–1441 ng ml^{-1} for paroxetine and 314–462 ng ml^{-1} for citalopram (Akin and Chaturvedi, 2003). In 39 of the 61 pilots, other drugs, such as analgesics, antihistamines, benzodiazepines, narcotic analgesics and/or sympathomimetics—and/or ethanol were also present (Akin and Chaturvedi, 2003). The authors noted that pharmacodynamic and pharmacokinetic interactions of SSRIs and their active metabolites with other drug(s) and ethanol could realistically lead to performance impairment and unpredictable pharmacological effects (Akin and Chaturvedi, 2003). Reduced oxygen availability at higher altitudes might lead to increased performance impairment and potential for adverse effects (Akin and Chaturvedi, 2003).

SSRIs have been known to inhibit their own metabolism, thereby altering the parent drug : metabolite ratios (Akin and Chaturvedi, 2003; Goeringer *et al*., 2000). These ratios are less at low SSRI doses in comparison with the ratios at high SSRI doses (Akin and Chaturvedi, 2003). Post-mortem blood concentrations of SSRIs may not necessarily reflect ante-mortem blood levels, owing to extensive post-mortem redistribution that occurs with these basic drugs (Pounder and Jones, 1990). During investigations of aviation accidents involving SSRIs, the post-mortem blood levels of SSRIs should be carefully evaluated and interpreted, particularly in the presence of other drug(s) and/or ethanol (Akin and Chaturvedi, 2003). Levels of SSRIs in other biological sample types cannot be accurately correlated with the degree of impairment or adverse effects, since such levels merely indicate the exposure of those victims to SSRIs (Akin and Chaturvedi, 2003).

8 ANTIHISTAMINES

First-generation H1-receptor antagonists are popularly used for alleviating allergy and cold symptoms, but these antihistamines cause drowsiness and sedation, thereby potentially impairing pilot performance (Sen *et al*., 2007). First generation antihistamines also depress the CNS, causing dizziness and sedation, diminished alertness, slowed reaction times and impaired performance on flight tasks, resulting in slowed reaction times, memory difficulties and impaired vigilance (Sen *et al*., 2007). Owing to these adverse effects, the first-generation antihistamines are not approved for use by civilian aviators (Silberman, 2003).

A recent study investigated the presence of the first-generation antihistamines in 5383 pilot fatalities of civil-aircraft accidents that occurred over a 16-year period. Specimens from 338 pilot fatalities were found to contain brompheniramine, chlorpheniramine, diphenhydramine, doxylamine, pheniramine, phenyltoloxamine, promethazine and triprolidine (Sen *et al*., 2007). Antihistamines alone were detected in 103 fatalities and present in combination with other drug(s) and/or ethanol, in an additional 235 fatalities. 191 fatalities was associated with diphenhydramine, followed by 112 with chlorpheniramine, and 50 with doxylamine (Sen *et al*., 2007). Antihistamines were determined to be the cause of 13 and a factor in 50 of the 338 accidents (Sen *et al*., 2007). Blood levels of the antihistamines were in the subtherapeutic to toxic range (**Table 4**). The detection of other psychotropic medications may imply concurrent use, with the potential for additive impairment of motor skills (Sen *et al*., 2007).

Interpretation of blood antihistamine concentrations must be made in conjunction with consideration of other parameters, such as the relationship between the plasma (serum) and the whole-blood drug concentrations, as well as potential for post-mortem redistribution of the antihistamines. In addition, the presence of other drugs and/or ethanol in the fatalities could also potentially affect antihistamine concentrations.

9 DRUGS OF ABUSE

Screening of blood or urine for drugs of abuse is mandatory following a fatal aviation accident. Positive

Table 4 Antihistamine concentrations found in civil aviation pilot fatalities

	Blood Concentration (ng ml^{-1})	
Antihistamines	Without other substance	With other substance(s)[a]
Brompheniramine	200 (n = 1)	5–100 (n = 7)
Chlorpheniramine	7–151 (n = 14)	4–6114 (n = 53)
Diphenhydramine	14–3800 (n = 38)	9–806 (n = 87)
Doxylamine	64–300 (n = 3)	10–1309 (n = 30)
Pheniramine	—	—
Phenyltoloxamine	—	4 (n = 1)
Promethazine	—	—
Triprolidine	—	—

[a]Includes other antihistamines, drugs and/or ethanol.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat112
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

screening results should always be confirmed and quantitated using GC/MS, to eliminate crossreactivity and false-positive results. Psychoactive drugs of abuse can be divided into:

- Narcotic analgesics such as morphine and heroin
- Stimulants such as cocaine and amphetamines
- Sedatives and hypnotics including barbiturates and benzodiazepines
- Psychedelics and hallucinogens, including cannabinoids and lysergic acid diethylamide (LSD)
- Antidepressants and antipsychotic agents.

Analysis of drugs of abuse in post-mortem cases requires certain special precautions, especially with regard to drug stability in various biological matrices.

In aviation disasters, it is highly plausible that tissues are exposed to the elements for protracted periods of time. Post-mortem chemical changes or metabolism may affect the interpretation of results (Drummer, 2004). The most common specimens used for the post-mortem analysis of drugs of abuse are blood, liver and urine. Other specimens such as VH and hair may also have important applications, whereas brain, muscle, fat, bone and pleural effusions have more specialist applications (Drummer, 2004). All drugs of abuse are detectable in bile, although buprenorphine, tramadol, other opioids, and benzodiazepines and colchicine appear to be present in higher concentrations than in blood (Drummer, 2004). **Table 5** provides a list of specimens and their relative advantages for the analysis of drugs of abuse.

Hair analysis has specialized applications for the analysis of drugs of abuse in order to establish evidence of long-term exposure. Segmental hair analyses have been used to determine degree of exposure to heroin and assess the risk of heroin use (Drummer, 2004). However, drug incorporation into hair is a complex phenomenon influenced by a number of factors, and therefore caution is advised during the interpretation of hair results (Drummer, 2004). Gastric contents may be used to establish a possible time of drug administration and to delineate oral from other routes of administration (Drummer, 2004).

Canfield *et al*. (2006), in a recent study, analysed specimens from 4143 deceased pilots who died as a result of an aviation accident. Psychotropic medications were found in 5%, cardiovascular medications found in 4% and neurological medications were found in 0.4% of the pilots in this study (**Table 3**) (Canfield *et al*., 2006). The accuracy of required reporting of medications by pilots was low. Of the 387 samples reviewed, only 8% had accurately reported the medications they were taking (Canfield *et al*., 2006). No medications were reported by 74% of the pilots found to be positive for drugs by post-mortem toxicology, and 18% had reported medications different from what was detected (Canfield *et al*., 2006). The authors also found that pilots taking psychotropic or neurological medications rarely reported the medication or medical condition on their employment medical application (Canfield *et al*., 2006).

9.1 Cocaine

Cocaine is a strong CNS stimulant that blocks the reuptake of catecholamines, particularly the excitatory neurotransmitter dopamine. Cocaine undergoes rapid absorption following smoking, snorting and intravenous administration, and is extensively metabolized to a variety of compounds, including the centrally inactive benzoylecgonine (BE), ecgonine and ecgonine methyl ester (Couper and Logan, 2004). The concurrent ingestion of cocaine and ethanol leads to the formation of cocaethylene, an

Table 5 Relative merits of post-mortem specimens for drugs of abuse

Specimen	Particular advantages
Blood/plasma/serum	Preferred specimen for most substances
Bile	Morphine, buprenorphine, tramadol, benzodiazepines, MDMA
Bone	Qualitative analysis of morphine, benzodiazepines, amphetamines
Brain	Centrally acting drugs, for example, morphine, cocaine, limited literature data
Fat	THC, and other drugs, but little literature to interpret results
Gastric contents	Orally administered drugs/poisons
Hair	All substances, particularly basic substances, and most metals
Muscle	Most drugs, however literature contains little data to interpret concentrations
Pleural effusion	Most drugs, but drugs subject to concentration changes, hence difficult to interpret
Vitreous humour	Ethanol, some biochemistries, for example, glucose, urea, creatinine

DOI: 10.1002/9780470744307.gat112
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

active metabolite (Couper and Logan, 2004). Cocaine has a very short half-life of approximately 0.8 ± 0.2 hours, whereas BE has a longer half-life of six hours (Couper and Logan, 2004). Cocaine concentrations in blood are not usually associable with a degree of impairment, owing to factors such as drug tolerance and artifactual changes in cocaine upon storage (Couper and Logan, 2004).

Specimens from 3235 fatal aviation accidents over a 10 year period were analysed, among which 24 tested positive for cocaine and 17 tested positive for methamphetamine (Lewis *et al*., 2006; Botch *et al*., 2006). Among the 24 cocaine-positive fatalities, cocaine or a combination of cocaine and other drugs was found to be the probable cause of five accidents and a factor in four additional accidents (Lewis *et al*., 2006). On 12 September 1994, an airplane crashed onto the South Lawn of the White House, killing the pilot. Both cocaine and alcohol were detected in the pilot's blood (*http://www.fas.org/irp/agency/ustreas/usss/t1pubrpt.html*).

9.2 Amphetamines

Amphetamines constitute a group of sympathomimetic amines with strong stimulant properties. Stimulants drugs typically act by increasing the dopamine concentrations in the synaptic cleft. In contrast to cocaine, which blocks the reuptake of dopamine into the presynaptic neuron, the amphetamines stimulate presynaptic production and release of dopamine into the cleft (Logan, 2001). Amphetamines act both centrally and peripherally, resulting in increased pulse and blood pressure, pupillary dilation, excitation, increased alertness, anorexia, hyperactive reflexes and ataxia. Amphetamines are commonly used as recreational drugs, and chronic use results in sleep loss with associated exhaustion and sleepiness, anxiety, irritability, poorer psychomotor performance, exhaustion, depression, confusion, suspiciousness, paranoia, delusions, hallucinations, irrational behaviour and diminished attention and concentration (Logan, 2001).

Relative to other drugs, illicit amphetamine use does not appear to be as significant among pilots. Emonson and Vanderbeek (1995) studied the effects of amphetamines on pilot performance, and reported that as many as two-thirds of the pilots issued a 5 mg +-amphetamine pill every four hours to combat fatigue resulting from sustained flying operations, stated that they felt it made for safer flying operations (Emonson and Vanderbeek, 1995). Amphetamine (30 mg in divided 10 mg doses at four hour intervals) has been reported to sustain helicopter pilot performance during periods of sleep deprivation (over 48 hours without sleep) (Logan, 2002). Specimens from 3235 fatal aviation accidents over a 10 year period were analysed, among which 24 tested positive for cocaine and 17 tested positive for methamphetamine (Lewis *et al*., 2006; Botch *et al*., 2006). Fourteen of the 24 pilots tested positive for additional disqualifying substances including six for ethanol, five for methamphetamine, three for tetrahydrocannabinol (THC), two for benzodiazepines, one for methylenedioxymethamphetamine (MDMA) one for propoxyphene, two for fluoxetine and one for paroxetine (Lewis *et al*., 2006). Among the 17 methamphetamine-positive fatalities, methamphetamine or a combination was reported to be the probable cause of 12 accidents (Botch *et al*., 2006). Ten of the 17 tested positive for other disqualifying substances including seven for marijuana, five for cocaine, one each for ethanol, benzodiazepines, MDMA, fluoxetine and tramadol (Botch *et al*., 2006).

9.3 Cannabinoids

Cannabis (marijuana), a drug with psychedelic properties, is known to impair cognitive processes, divided attention and perceptual motor performance involving tasks such as fine motor performance and target tracking (Rainford and Gradwell, 2006). In a toxicological examination of 2326 occupants of aircraft mishaps, marijuana was the third most frequently detected drug as reported by DeHart and Davies, 1996. At recreational doses, effects include relaxation, euphoria, relaxed inhibitions, sense of well-being, disorientation, altered time and space perception, lack of concentration, impaired learning and memory, alterations in thought formation and expression, drowsiness, sedation, mood changes, such as panic reactions and paranoia, and a more vivid sense of taste, sight, smell and hearing (Couper and Logan, 2004). Short-term effects of marijuana use include problems with memory (**Table 6**) and learning, distorted perception, difficulty in thinking and problem-solving, and loss of coordination (Couper and Logan, 2004). Marijuana use also decreases the ability to concentrate and maintain attention, and leads to a dose-related impairment of hand–eye coordination (**Table 6**) (Couper and Logan, 2004).

A Federal Aviation Administration (FAA) report in 1973 indicted that in a two year period, 500 out of 1 000 000 applicants for a medical certificate admitted to previous marijuana use (Newman, 2004). Lewis *et al*. reported that marijuana and altitude could produce cumulative effects on some cognitive tasks, and found a reduction in work output and speed of response at altitudes of 8000 and 12 000 ft, as the dose of Δ^9-tetrahydrocannabinol (THC) increased (Newman, 2004). A study by Meacham *et al*. evaluated the performance of six pilots classed as infrequent marijuana users (Meacham *et al*., 1974). The pilots were given either a controlled dose of marijuana or a matched marijuana placebo, and each pilot operated a flight simulator sequence under both marijuana and placebo

Table 6 Simulator studies on the effect of marijuana on pilot performance

Findings	THC levels[a, b]	Dose[a]
Impairment short term memory, attention and concentration up to 4 h	N/A	0, 0.9 mg kg^{-1} THC SM
Performance decrements up to 24 h; pilots no awareness of impairment	N/A	19 mg THC SM
Impairment with turbulent flight after high dose; impairment increased as task difficulty/complexity and pilot age increased	Serum THC 7 ng ml^{-1} at 1 h after high dose SM	0, 10, 20 mg THC SM
24 h impairment; pilots no awareness of decreased performance	N/A	0, 20 mg THC SM

[a]THC = Δ^9-Tetrahydrocannabinol.
[b]N/A = Not applicable; SM = Smoke.

conditions (Meacham *et al*., 1974). Each pilot exhibited a significant deterioration in flying performance during the 30 minute period after taking marijuana, but not after taking placebo. The decrease in flight performance involved an increase in major errors (such as navigational errors, major altitude deviations, stalling and loss of control events) (Meacham *et al*., 1974). In a similar experiment, Janowsky *et al*. reported gross impairment of flying skills and performance, reflected in a greater number of both major and minor errors (Janowsky *et al*., 1976). Alterations in concentration, loss of orientation and temporal distortion, were noted among the affected pilots (Janowsky *et al*., 1976).

Ten experienced pilots exhibited significant impairment in number and size of aileron changes, size of elevator changes, distance off centre on landing and vertical and lateral deviation on approach to landing, 24 hours after marijuana usage (Yesavage *et al*., 1985). Leirer *et al*. studied pilots in a flight simulator, after a moderate social dose of marijuana. Pilots flew just before smoking, and 15 minutes, 4, 8, 24 and 48 hours after smoking. Marijuana impaired performance of flying tasks for up to 24 hours after smoking (Leirer *et al*., 1991). Drug dosage, time interval between drug intake and flight, pilot age and the task complexity were all reported to affect the pilot's performance (Leirer *et al*., 1991). Impairment of performance and skills appears to be at a maximum during the first four hours after taking marijuana, with some residual impairment over the subsequent 24 hours (Newman, 2004). Therefore, this combination of residual impairment at 24 hours and some other performance-reducing factors, such as increased task difficulty can result in significant deterioration of performance in pilots (Newman, 2004). Results of flight simulator studies on the effects of marijuana on piloting performance are provided in **Table 6**.

Concentrations of THC and metabolites are dependent on the pattern of use as well as dose, with THC concentrations typically peaking during smoking, while peak 11-OH-THC concentrations occur approximately 9–23 minutes after the start of smoking (Couper and Logan, 2004). Concentrations of both analytes decline rapidly and are often <5 ng ml^{-1} at three hours. Chronic users may exhibit mean plasma concentrations of THC-COOH of 45 ng ml^{-1}, 12 hours after use; corresponding THC levels are, however, less than 1 ng ml^{-1} (Couper and Logan, 2004).

One of the concerns with marijuana is the interpretation of impairment based on drug concentrations in urine or blood. Marijuana is highly lipophilic, and serum and blood concentrations are much lower relative to tissue concentrations, and therefore may not reflect degree of impairment. The time of marijuana exposure may be estimated within a 95% confidence interval using mathematical models by Huestis. (Couper and Logan, 2004). Knowing the time interval from last marijuana exposure may be used to predict impairment with concurrent cognitive and psychomotor effects based on data in the published literature (Couper and Logan, 2004). Presence of THC metabolites in urine is only indicative of prior THC exposure and not necessarily impairment. Low concentrations of THC have also been measured in OTC hemp oil products, and consumption of these products may produce positive urine cannabinoid test results (Couper and Logan, 2004).

Johnson *et al*. analysed specimens from 3235 fatal aviation accidents over a 10 year period, of which 74 tested positive for THC (Johnson *et al*., 2006). Among these 74 cases, THC was reported as a probable cause or factor in 32% of the accidents (Johnson *et al*.,

2006). In addition to a positive THC, 24 of the 74 pilots tested positive for other disqualifying substances including seven for methamphetamine, six for SSRIs, five for ethanol, five for benzodiazepines, three for cocaine and one each for tramadol, meperidine and olanzapine (Johnson *et al*., 2006).

9.4 Opiates

Opiates comprise a group of commonly used and highly addictive drugs used for pain relief. The most commonly prescribed opiate-type compounds are hydrocodone, dihydrocodeine, codeine, hydromorphone, oxycodone and morphine (Lewis *et al*., 2005). Side effects of opioid use include drowsiness, dizziness, hypotension, unconsciousness or mental clouding, all of which can lead to significant impairment. The presence or absence of opiate compounds in post-mortem fluids and/or tissues derived from fatal civil aviation accidents may have serious medicolegal consequences and may help establish the cause of impairment and/or death (Lewis *et al*., 2005). Heroin (diacetylmorphine), is a commonly abused illicit opioid drug. Heroin is metabolized to 6-monoacetylmorphine (6-MAM), which is then metabolized to morphine. 6-MAM has not been detected following the use of morphine or other opiate compounds or the ingestion of poppy seeds and is only present following heroin use. Therefore, 6-MAM is considered a heroin-specific metabolite and is legally defensible evidence of heroin use (Lewis *et al*., 2005).

In a study by Lewis *et al*., post-mortem fluid and tissue samples obtained from eight separate civil aviation fatalities over three years that had previously been screened positive for opiates by GC/MS were re-examined. Morphine was found in three of the eight cases examined and was the only opiate detected in two of these cases (Lewis *et al*., 2005). Morphine concentrations in the various fluids and tissues ranged from 0 to 260 ng ml^{-1}, 122 to 526 ng g^{-1}, 0 to 870 ng g^{-1}, 121 to 1786 ng g^{-1} and 21 to 120 ng g^{-1} in blood, urine, liver, kidney and muscle respectively. Morphine concentrations were highest in urine and lowest in muscle.

Codeine was identified in two of the eight cases investigated at concentrations of 13 ng ml^{-1}, 78 ng g^{-1}, 68 ng g^{-1} and 19 ng g^{-1} in blood, liver, kidney and muscle, respectively; urine levels ranged from 47 to 154 ng ml^{-1}. One of the codeine-positive cases also tested positive for morphine and thebaine, while the other case tested positive for hydrocodone and dihydrocodeine. Thebaine, morphine and codeine were identified in one of the cases examined, at urinary concentrations of 22, 122 and 47 ng ml^{-1}, respectively. The relatively higher morphine, as well as the low concentration of both opiates and the presence of thebaine, was indicative of poppy seed consumption. It is important to note however, that following poppy seed ingestion, morphine and codeine may be detected in urine, without the detection of thebaine. Therefore, the absence of thebaine cannot preclude poppy seed consumption as the source of morphine and codeine (Lewis *et al*., 2005).

Hydrocodone and dihydrocodeine were detected in four of the eight cases examined at blood concentrations ranging from 18 to 102 ng ml^{-1} and 13 to 270 ng ml^{-1}, respectively. Urinary concentrations for hydrocodone and dihydrocodeine ranged from 35 to 1447 ng ml^{-1} and 78 to 2023 ng ml^{-1}, respectively. No apparent correlations were evident between hydrocodone and dihydrocodeine concentrations within specimen types.

Hydromorphone was found in one of the hydrocodone/dihydrocodeine-positive cases. Hydromorphone was below the limit of quantitation in all specimens except urine, in which it was found to be 178 ng ml^{-1}. Oxycodone was found in one of the eight cases examined with urinary concentrations being the highest, and blood concentrations the lowest (Lewis *et al*., 2005).

9.5 Post-Mortem Degradation and Redistribution

Drugs of abuse undergo post-mortem changes; however, the extent of these changes varies significantly between drugs (Drummer, 2004). Heroin and cocaine undergo rapid hydrolysis during life, as well as after death. Depending on environmental factors and the time interval between the crash and discovery of the body, varying degrees of tissue decomposition may be observed. Blood specimens containing cocaine and BE exhibited poor stability and were shown to degrade over time even when stored at ambient temperature and even when stored in fluoride/oxalate tubes (Giorgi and Meeker, 1995).

Anaerobic bacterial activity can lead to the conversion of nitrazepam, flunitrazepam and clonazepam to their respective 7-amino metabolites (Drummer, 2004). Other benzodiazepines, such as diazepam and temazepam, may also undergo degradation under putrefying conditions (Drummer, 2004). The concentration of THC in blood has also been shown to decrease with time, particularly when stored at −20 °C (Drummer, 2004). In frozen specimens, morphine is relatively stable, however, significant losses are evident when stored at 4 °C or higher for more than a few days, or in post-mortem specimens (Drummer, 2004).

Post-mortem redistribution may affect drug concentration due to drug diffusion from an area of higher concentration to an area of lower concentration. Post-mortem redistribution is a particular concern with drugs having high volumes of distribution.

Methadone, a drug with a high volume of distribution exhibits a moderate increase in post-mortem blood concentration ranging up to fourfold, although there is

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

significant site-to-site variability (Drummer, 2004). In contrast, morphine, a drug with a lower volume of distribution, shows little change in post-mortem blood concentration (Drummer, 2004).

Methamphetamine has been known to exhibit a twofold variation between drug concentrations in femoral and heart blood specimens, apparently due to diffusion of drug from pulmonary circulation into the left cardiac chambers (Drummer, 2004). Although peripheral sites, such as femoral blood might show fewer changes than blood taken from the thoracic and abdominal areas, it too will show higher concentrations of drugs following a post-mortem period (Drummer, 2004). Site variability may occur due to other factors, such as differences in hematocrit, influences of other fluids and other factors affecting the quality of blood, even in the absence of significant putrefaction (Drummer, 2004). Variations in heart:femoral blood concentration ratios greater than twofold have been reported with the SSRIs fluoxetine, paroxetine, sertraline, venlafaxine and risperidone (Rodda and Drummer, 2006).

10 POST-MORTEM DNA ANALYSIS

The accuracy of analytical data on biological evidence for toxicological interpretation is imperative in order to establish the cause and manner of death.

This perspective is magnified during aircraft accident investigations, wherein multiple types of post-mortem specimens are collected for analysis from the victims, and depending upon the nature of an aircraft accident, victim bodies are frequently scattered, disintegrated, commingled, contaminated and/or putrefied (Chaturvedi *et al*., 1999). Identification of multiple specimens may be effectively resolved using deoxyribonucleic acid (DNA) profiling. However, environmental and biological factors responsible for putrefaction may also lead to degradation in the post-mortem samples that are generally obtained from aviation accident sites (Chaturvedi *et al*., 1999).

Two techniques commonly used to analyse DNA include restriction fragment length polymorphism (RFLP) and the polymerase chain reaction (PCR)-based method. Analysis of degraded DNA using the conventional RFLP technique is not as effective as the PCR-based method, which has been successfully used for the analysis of low quantities of degraded and low-molecular-weight DNA, in contaminated and putrefied samples (Chaturvedi *et al*., 1999).

Besides the identification of victims and post-mortem tissues, DNA analysis may be applied to resolving issues, such as tissue mismatching/commingling, unacceptable batch analysis and unusual analytical findings (Chaturvedi *et al*., 1999). Chaturvedi *et al*. reported the presence of atropine at unusual toxic concentrations in the blood and lung samples, but absent in the other tissue specimens, obtained from an aircraft accident victim. Three possible scenarios were postulated: intentional or accidental atropine poisoning, atropine administration by emergency healthcare providers into the thoracic cavity to modify the vasovagal activity and tissues originating from different subjects (Chaturvedi *et al*., 1999). DNA analysis performed on the blood and liver revealed tissue mismatching/commingling between the specimens, thus explaining the presence of atropine in select tissues.

11 FUTURE OPPORTUNITIES—GENOTYPING AND PHARMACOGENOMICS

In aviation fatalities, the interpretation of drug concentrations is often compounded by genetic variability in drug disposition. Pharmacogenomics is the study of the association between an individual's genotype and their response to drugs (Kupiec *et al*., 2006). Interindividual variations in drug response are often associated with polymorphisms in genes encoding for drug-metabolizing enzymes, transport proteins and drug receptors (Kupiec *et al*., 2006). The Cytochrome P450 2D6 (CYP2D6) enzyme metabolizes 25–30% of all drugs, and is also the most polymorphic CYP enzyme (Kupiec *et al*., 2006).

Based on the genetic polymorphisms of CYP2D6, three metabolizer types are recognized: ultraextensive metabolizers (UMs), extensive metabolizers (EMs) and poor metabolizers (PMs). Individuals with a UM phenotype generally have multiple copies of a gene, will metabolize drugs more rapidly, and therapeutic plasma drug levels will not be achieved at ordinary drug dosages. In contrast, individuals with a PM genotype may require substantial dose reduction to prevent toxicity. For example, in the metabolism of the tricyclic antidepressant nortriptyline, PMs have zero copies of the CYP2D6 enzyme, intermediate metabolizers have one copy, EMs have two copies and UMs have more than two copies (Kupiec *et al*., 2006). Clinical manifestations of these genetic drug metabolism profiles could range from therapeutic inefficacy to toxicity for the same dose of a drug (Kupiec *et al*., 2006).

Several commonly used prescription drugs are metabolized by CYP enzymes, for example, CYP2D6 metabolizes numerous SSRIs and opioids. SSRIs and other antidepressants have been associated with suicides and accidental deaths, and delineating a suicidal from an accidental death based on plasma drug concentrations alone might be misleading (Kupiec *et al*., 2006). An individual with a PM genotype might exhibit toxic drug concentrations at therapeutic or subtherapeutic dosages. Therefore, in aviation fatalities, caution must be exercised during interpretation of drug concentrations of drugs associated with polymorphic enzymes. Genotyping of post-mortem specimens has been proposed in order to distinguish

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

drug overdose from accidental deaths due to reduced enzymatic capacity (Druid *et al*., 1999). Future research in aviation toxicology may be focussed on predictive genotyping for aviators, in order to establish optimal drug dose–response relationships, as well as identifying susceptible genotypes.

Aviation toxicology has evolved through the years into a highly specialized area of toxicology with several unique perspectives on the cause and manner of death. However, some analytical challenges, such as the paucity of samples, complexity of air-crash specimen separation and identification and decomposition issues, still remain. Toxicological interpretation is routinely complicated by putrefied or aged samples, relative to conventional forensic toxicology. Advances in related disciplines such as inhalation toxicology, pharmacogenomics and forensic toxicology have all led to a better understanding of issues in aviation toxicology. In addition, the prospect of ever-burgeoning air traffic creates an avenue for new areas of research, especially in the area of predictive genomic markers of aviation performance, as well as the potentially impairing effects of new drugs that are introduced into the market. These investigations can be expected to contribute to large-scale improvements in aviation safety with positive financial and societal ramifications.

The Toxicologist as Expert Witness

Ira S. Richards and Marie M. Bourgeois

CONTENTS

1 INTRODUCTION

> *Science alone of all the subjects contains within itself the lesson of the danger of belief in the infallibility of the greatest teachers in the preceding generation … As a matter of fact, I can also define science another way: Science is the belief in the ignorance of experts.*
> *Richard Feynman (Root-Bernstein, 1999).*

Toxicology is the science which deals with the adverse effects of chemicals in biological systems. It has long been viewed as the first forensic science (Ramsland, 2008). Mathieu Joseph Bonaventure Orfila who published *A Treatise of General Toxicology* is widely regarded as the 'Father of Forensic Toxicology'. James Marsh in the 1830s, tested the coffee of a suspected victim of poisoning, but was unable to effectively explain to a lay jury how he had found the arsenic. This inability to effectively communicate his findings inspired him to improve his methods and make them more demonstrative for a court of law. His method became known as 'The Marsh Test' and was used extensively by contemporaries such as Orfila, to analyse both exhumed bodies and surrounding soil samples for arsenic, to assist in determining whether or not the decedent was poisoned. Dr. William Willcox in the early 1900s further developed methodologies to quantify arsenic in body tissues.

Although toxicologists initially restricted their testimony to cases of suspected poisonings, experts today offer opinions across a broad range of criminal and civil litigation (Kupferschmidt, 2004). In many ways, the science has evolved alongside the legal system and the toxicology expert witness is a commonplace legal figure today. We can define an expert witness as one who by virtue of either specialized education, experience, training, specific skills or through a combination of these, well-above those of the 'average person', may provide legal opinions, conclusions or other information that the court deems necessary to assist in clarifying the issues under specific legal consideration.

While the term forensic toxicologist may typically conjure up images of high technology laboratories and individuals gathering information from body fluids and chemical tests which will be used in a court of law, the toxicologist that serves as an expert witness, for *any* issue related to the broad discipline of the science, by definition becomes a forensic toxicologist (Kier, 1977). Today, the toxicology expert witness is involved in legal issues as diverse as driving while intoxicated, accidental or intentional poisonings, occupational toxic exposures and worker's compensation claims, product liability, regulatory proceedings, toxic torts and personal injury, environmental exposures and class-action litigation (Ellenhorn, 1978).

As science has become increasingly complex, so has the toxicologist's role as an expert witness. The ultimate

goal is to help translate the complex scientific theories and evidence of a case to the court, so that rational decisions and recommendations can be made by a judge and jury. The problem for any expert and their legal team is that there may be, and most often are, opposing experts and their legal team who will tell a judge and jury, and often very convincingly, that your opinions are wrong. At times an expert may strongly believe that an opposing expert is embracing perhaps 'junk science' and should not have even been qualified to offer expert opinion. It would certainly not be in the best interests of an expert to tell the judge that he/she made a poor decision in qualifying that expert. Unfortunately, sometimes what makes a good expert is how convincing they are to a judge or jury. Beyond being credible in court, your testimony must always be based upon good scientific evidence. Furthermore, to be an expert witness requires your understanding and acceptance that the way the legal world determines if science is good may be different from yours (Mosteller, 2007). You may have fine credentials, are well published and even may be involved in cutting-edge research, your testimony as an expert must abide by the legal ruler for measuring good scientific evidence (Jasanoff, 2005). Remember, your expert opinions constitute an important form of evidence which can ultimately determine the outcome of a case. At times this legal ruler may seem to use a scale that is foreign to you or difficult to accept. This is especially important in courts operating under the *Daubert* standard of acceptability. The proponents of *Daubert* cited widespread scientific ignorance of the public. They maintained such ignorance had costly, sometimes catastrophic effects and led to acceptance of 'junk science' (Thigpen, 1995). A naïve jury could be swayed by anecdotal evidence (Ozonoff, 2005). This ruling established judges as 'gatekeepers', granting them sole authority over the approval of experts and their theories.

2 THE SPECTRUM OF LEGAL PROCEEDINGS

Public concern about the adverse effects from chemical exposures has risen steadily in the past few decades. This awareness can be seen on two somewhat disparate legal fronts; toxic tort litigation and regulatory proceedings. Toxicological evidence plays an integral role in both of these arenas. The courts have become burdened with cases ranging from real causation-injury to perhaps a somewhat offensive odour as responsible for producing neurologic injury. There has been a significant increase in the number of civil lawsuits and criminal prosecutions, in federal and state courts, that present evidence and theories requiring the consideration of basic and advanced science. At the same time, there has been a growing ignorance of the fundamentals of science by the public. This is not limited to advanced theoretical concepts; rather, the gap includes basic scientific principles like what constitutes anecdote and what constitutes credible evidence.

A toxic tort is the name given to a body of laws and procedures that establishes the circumstances under which individuals or companies may be held liable for the injury of a person(s) from exposures to chemicals either intentionally or accidentally and provides remedies to recover damages for those injuries (Benjamin, 1993). An important issue in tort law is to determine whether negligence was involved in the injury or not, typically what the legal profession defines as determining the 'standard of care'. The burden of proof for those who claim injury is to prove negligence sufficient to cause injury; otherwise, tort law will not compensate them.

Toxic torts typically involve pharmaceutical, consumer product, environmental or occupational exposures (Marchant, 2002). Pharmaceutical toxic tort cases are often litigated against drug manufacturers and distributors, as well as prescribing physicians. Unlike medical malpractice, pharmaceutical cases are essentially product-liability cases with the defective product being the drug. Most pharmaceutical and consumer-product toxic injury cases involve large numbers of individuals and are typically stimulated by drug and product recalls. Unlike the general population, industrial workers are often exposed to chemicals at higher concentrations and duration than the general public and therefore have a greater risk of developing disease from particular chemical exposures than the general population. Occupational exposures to chemical agents have often provided the most reliable information on chemical injury causation in humans. Probably the best example that can be provided is that of asbestos exposure. Occupational toxic tort cases differ from a worker's compensation claims which are directed against the worker's employer, while an occupational toxic tort case is usually filed with the courts against 'third parties', companies and individuals other than the employer who either manufacture or distribute chemicals and equipment for their application that can expose the workers or bystanders to these chemicals.

The role of the toxicologist is slightly different in regulatory proceedings; here, the testimony is used in support or opposition of proposed federal or state regulations with regard to a specific chemical or class of chemicals. The toxicologist uses their expertise to describe the effect of a potential exposure on a population rather than answering questions about causation.

3 QUALIFICATIONS AND ROLE OF THE TOXICOLOGY EXPERT WITNESS

Unlike other witnesses who simply relay their version of a specific event, expert witnesses are expected to evaluate the facts of the case and render a thoughtful opinion. In the eyes of the judge and jury, credentials often equal credibility. The legal community has developed a general level of expectation outlining the professional attributes for one to qualify as an expert witness. Toxicologists base their expert opinion, in part, on a thorough review of relevant research literature. They must be capable of weighing the strengths and weaknesses of each study before they can make a determination of its value. The expert also considers fundamental precepts of toxicology before forming an opinion. This requires a thorough understanding of the actions of chemicals in biological systems. No single academic degree, research direction or career path uniquely qualifies a toxicologist as an expert.

A well-qualified toxicologist would satisfy the majority of the following:

- Possesses a graduate degree, preferably a doctorate in toxicology or a related field
- Has published papers in their discipline
- Has edited a journal or book
- Has written a book
- Has contributed chapters to a book
- Is board certified in their field
- Has practical experience in an industrial or educational environment
- Is a member of professional societies with credentialing requirements
- Has served as an advisor to a local, state or federal agency
- Has not been disqualified as an expert previously.

The role of the toxicologist in the legal arena can take many forms, including:

- Consultant
- Teacher
- Interpreter
- Investigator
- Reporter
- In-house expert
- Witness for the defence or plaintiff
- Court-appointed witness.

Toxicologists serving as legal consultants may advise attorneys regarding the development of factual evidence and the strengths or weaknesses of the opponents' case, help frame the issue, reduce wasted time and effort, guide the attorney on the relevance of documents and testing, determine cause-and-effect relationships, act as an advisor on the nature and effects of a toxicant, craft questions for an interrogatory, evaluate the theory of the case and help establish foundation (Muller, 2008).

In law, a foundation is sufficient preliminary evidence of the relevance and authenticity of evidence to admit to the court for consideration. The evidence provided by the expert can be material evidence in the form of exhibits or testimony, and its importance may greatly determine the outcome of a case (Simington, 2006). Lack of foundation by an opposing legal team is a valid objection that can be and is often used to greatly reduce the effectiveness of opposing legal counsel. Experts retained in investigatory or technical roles may conduct independent testing or research.

Consider, for example, the toxicologist called upon to offer expert opinion as to whether or not an individual was impaired through the consumption of alcohol during the operation of a motor vehicle. This witness may assume a role as an expert for either the defence of the individual or for the prosecution, by serving as a reporting witness, interpreting witness or teaching witness.

The expert may have been involved in performing or supervising the laboratory tests which were conducted to determine the blood ethanol concentration for the individual in question. The toxicologist may describe the nature of these tests to a jury, the procedures involved and the quality control standards that were in place to ensure both the accuracy and reliability of the tests which were used. The court in turn may wish to determine the qualifications of the witness to conduct such testing, which is generally satisfied by the expert qualifying by virtue of skills gained through education, experience and training. The expert must be prepared to provide convincing testimony that:

- The correct tests were done
- The equipment was in proper working order
- The sample tested was obtained through an acceptable chain of custody.

The same or another toxicologist may serve as an interpreting witness to explain the results of the tests even when a test result is self-explanatory, pass/fail or involves a statutory presumption. An opposing expert may offer opinion as well. The same or another expert witness may be called upon to offer instruction to the court on the metabolism of alcohol and its effects upon the human body and to render an opinion as to the level of impairment which would be expected at a certain blood alcohol concentration and whether or not the individual in question was impaired while operating the motor vehicle. An opposing expert may have different opinions.

Attorneys may employ in-house toxicologists as expert witnesses under certain circumstances. Such an expert has the advantage of familiarity with the product or industrial process at the heart of the lawsuit. The expert's

employer will need to be consulted to determine the scope of allowable testimony. There may be restrictions on testimony of this sort in an effort to control the release of work-product details or detrimental information.

Occasionally, the court will appoint its own expert. The court-appointed expert is permitted under Rule 706 in the Federal Rules of Evidence. This expert can have a major impact on the outcome of the case because the jury will see him/her as an especially impartial expert. The court-appointed expert is subject to examination by the plaintiff and the defence attorneys. An expert may not be compelled to accept the request from the court to act as a court-appointed expert witness. There may be many reasons that a toxicologist may wish to decline, including commonly their time commitments and the issue of compensation, which may be problematic as the amount is fixed by the court. In civil lawsuits, attorneys from both sides are often required to contribute to their fees. This is not true in criminal cases (Federal Rules of Evidence, 2008a).

4 MARKETING YOURSELF AS AN EXPERT WITNESS

Once you have made the decision to become an expert witness, you might wonder about marketing strategies. You may wish to contact your colleagues that do expert witness consulting, as one expert may recommend another if they feel the case match to their own background and interests are weak, or they have other time commitments or potential conflicts of interest, to name a few. A strong *curriculum vitae* with an appropriate cover letter targeted to attorneys in the field of personal injury, toxic torts, worker's compensation and other areas can be extremely effective in obtaining initial assignments. You might also consider asking attorneys with whom you are acquainted to assist you in 'getting the word out' as to your areas of expertise and your interest in forensic work. The majority of attorneys find experts through colleagues, web sites and agencies which maintain databases of experts. Self-promotion, such as advertising in law journals or web sites can be counterproductive, especially if you derive most of your income as a consultant. The advertisement may appear at trial as an exhibit with the unstated implication you are a 'hired gun'.

A comprehensive *curriculum vitae* may be the most important tool at your disposal. It can be used to qualify your testimony. It will be submitted to every attorney with whom you come into contact. It can show that you constantly update your skills, detail specific accomplishments and list basic and advanced skills. It must also have a complete publication list and some references to previous testimony.

5 THE ATTORNEY–EXPERT RELATIONSHIP AND PROTECTING YOUR INTERESTS

An attorney will initially contact a potential expert witness to discuss a particular case. Most times it is relatively early in the litigation process, although there are times when trial has already been scheduled and there is a feverish rush to find and disclose an expert and complete the discovery process. Sometimes the latter is the result of poor planning by the legal firm and sometimes new information develops late and there is an urgent need for an expert witness at the eleventh hour. In either event, it is commonplace to spend some time either over the telephone or at a scheduled visit at the expert's office. Having established a collegial tone, and provided some very preliminary thoughts, the attorney may then ask if they can designate you a 'possible expert'. An important question to always ask in your initial discussion is how did your name come up as a potential expert witness? If you are an experienced witness then it might have been through a referral. Commonly, a legal assistant did a web-based search for toxicologists in the area and your name came up. In any event, a point will be reached in the discussion where you may be requested to forward a complete resume, fee schedule and perhaps the names of other attorneys with whom you have worked. An attorney should never formally disclose you as an expert without first contacting and retaining you. In some venues, misrepresenting an expert as retained to pre-empt the other side from using their services can lead to sanctions against the attorney and law firm.

You should discuss compensation as soon as feasible to avoid disagreements later. A potential expert witness should confirm whether the attorney or the client will be responsible for paying their fees and should be satisfied that the firm has adequate resources available to pay for your time, especially if it is anticipated that many hours of your time may be involved. Additionally, the expert should review any information about the attorney that he will be working with, and the legal firm, to better address concerns that they have a demonstrated record of producing the best legal efforts on behalf of their client(s) whether that will be for the defence, plaintiff or claimant (worker's compensations proceedings). It is important to provide a statement of understanding to the attorney prior to being retained. This statement of understanding should note types of billable expenses and what your retainer amount will be. Your fee structure needs to explicitly state the costs associated with research, active experimental investigation, file review and report generation, consultation and testimony at deposition or trial. Developing a fee structure can be difficult; consult with other professionals to make sure your rates are reasonable and will not price you out of the market. Higher rates are generally reserved

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat113
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

for more experienced experts with a proven record of satisfaction by different legal firms. Professional societies such as the Society of Toxicology and the American Chemical Society provide legal and educational resources for their members. There are also multiple organizations of expert witnesses that can provide interested parties with stock contracts for expert witness services, consultation agreements and other necessary documents. These documents can be tailored for your individual situation; for example, an expert unwilling or unable to travel may not need an agreement that sets reimbursement rates for rental cars and hotel rates. Never accept a case with the understanding that it is on a contingency basis. You must be paid for your work whatever the final disposition of the case; win, loss, or settlement.

Once retained it is the responsibility of your attorney is to provide you with all pertinent information, including that which might be damaging to their own case. It is imperative that you have this information provided to you before you enter into deposition or trial testimony. Remember that your sworn testimony, as obtained by opposing counsel during deposition and trial, will be a meticulous and diligent probing of you as an expert to discover and emphasize your weakness to the court, including a lack of all the relevant information which may bear upon your opinions as an expert. Either your poor preparation or that of your attorney, including failure to provide all the documents needed to form your opinions, will have a negative impact upon you professionally. In either case, it may be viewed in the future as poor preparation for deposition or trial on your part.

It is your professional and sometimes personal reputation at stake; all that you say in sworn testimony is public record and available at a later time by the legal profession that may be considering retaining you on another case as their expert. It is important early on to let your attorney know that in the absence of reviewing adequate records, your full opinions cannot be formed. Sometimes following the record review, an expert may indicate to the attorney that the case is weak, and a clear basis for causality cannot be established. An excellent approach that can be taken is to let the attorney initially retain you as a consultant to evaluate the case and educate the legal team regarding strengths and weaknesses. Do not have the attorney disclose you as an expert witness until it is agreed among all concerned parties that your testimony will constitute a vital component of their legal efforts.

Expert testimony is not for the faint of heart. Your professional judgement, research skills, employment history, academic background, publications and previous testimony may all be harshly scrutinized by opposing counsel. An expert witness should be prepared to explain discrepancies between current testimony and that offered in prior depositions or trials. Meticulous recordkeeping makes this easier. It has become popular in the past few decades to accuse innovative scientific experts of practising 'junk science'. These charges can be effective because 'junk science' is a nebulous term with many possible interpretations. The adoption of *Daubert* was intended to minimize claims of this nature; however, the standard is not uniformly applied. Reliance on accepted methodology is the easiest way to avoid 'junk science' accusations.

Attacks on your credibility can be distressing, but they are rarely considered abusive. Defensiveness can be perceived by the judge and jury as an unspoken confirmation of the accusations made by opposing counsel. An expert witness should deflect hostility during questioning with a calm and professional demeanour. The expert witness should also be aware that background checks are commonplace, so potential problems should be disclosed up front. One common avenue of credibility attack is when an expert witness almost exclusively works for either the defence or the plaintiff. Your selection of which cases to consider should always be driven by your interests, experience, time commitments and other factors; however, it is best to be an expert witness who has been seated on both sides of the fence.

It should be noted that toxicologists operating in certain legal capacities may not need to be disclosed to the opposition. The scope of disclosure requirements differs greatly. Communications with experts who are not retained may be protected by work-product doctrine or disqualification. Although delaying disclosure can provide the attorney with a tactical advantage under certain conditions, there are several reasons that the toxicologist should be retained as an expert by the attorney as soon as it is feasible.

Some of the questions asked of the toxicology expert witness may centre on ethical issues related to the discipline (Elvins and Stephens, 1999). Responses should be consistent with those accepted by the profession. Toxicology, as well as other professional societies, has codes of ethics; a toxicologist interested in becoming an expert witness should be familiar with the ethical code of the societies to which they belong (Bouma, 2001). The Society of Toxicology, as an example, has such a code:

> *The Society of Toxicology is dedicated to developing and communicating knowledge to improve the health and safety of living beings and to protect the environment upon which we depend. To attain this objective, each member must maintain high ethical standards, recognize a duty to share this knowledge with the public, and be a thoughtful advocate for human, animal, and environmental health. To this purpose, this code requires a personal commitment:*
>
> - *Conduct their work with objectivity and themselves with integrity. Being honest and truthful in reporting and communicating their research.*

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat113
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- *Hold as inviolate that credible science is fundamental to all toxicological research and is the basis for communicating results.*
- *Recognize a duty to communicate information concerning health, safety, and toxicity in a timely and responsible manner, with due regard for the significance and credibility of the available data.*
- *Give due consideration to the ethical, legal, social and policy implications of their research and communications.*
- *Be a thoughtful advocate for human, animal and environmental health.*
- *Abstain from professional judgments influenced by undisclosed conflict of interest, disclose any material conflicts of interest and avoid situations that imply a conflict of interest.*
- *Observe the spirit, as well as the letter of laws, regulations, and ethical standards with regard to the conduct of human and animal research.*
- *Practice high standards of environmental and occupational health and safety for the benefit of themselves, their co-workers, their families, their communities, and society as a whole.*

Code of Ethics Adopted by the Society of Toxicology on 31 January 1985, Revised on 1 June 2005 (http://www.toxicology.org/AI/ASOT/ethics.asp).

Safeguarding your professional reputation is vital; there is no coming back once you acquire the 'hired gun' label or are viewed as an expert that is poorly prepared for sitting a deposition. An expert witness should never tailor their opinion to please the attorney. You must be capable of objectively evaluating the case and rendering an independent opinion. An expert should stress this to the attorney during their first conversation. This does not mean your judgement cannot evolve with new information.

Your attorney will also be responsible for preparing you for testimony at deposition and trial (Babitsky and Mangraviti, 1999). The testimony that you provide is a form of evidence that is obtained following the taking of a sworn oath or affirmation under penalty of perjury. It is a statement or declaration of fact, opinion, inferences or personal information that will be used in a legal action. The testimony may be oral, written or videotaped.

The rehearsals will help familiarize you with the pertinent case law, alternate theories that may be presented by the opposing counsel, and the overall process (Babitsky and Mangraviti, 1999). Depositions are almost always conducted by the opposition so they can be protracted, confrontational affairs (Hawkins, 2005). Your attorney will advise you on the nuances of testimony and perhaps even provide you with some insight about any 'tactics' likely to be used by the lawyer who will be deposing you, especially if there is familiarity from other depositions (Catto, 2008). Much advice may seem common sense:

- Know the legal issues
- Be well prepared
- Dress in a professional manner
- Answer only the question you have been asked—don't volunteer information
- Take your time
- Avoid overstatements of any kind
- Feel free to consult your notes
- Stay calm, professional and polite
- Don't be afraid to admit ignorance
- Be wary of potential traps—opposing counsel will try to damage your credibility
- Realize your testimony will be used to sway a judge or jury so use everyday language when appropriate (Gorney, 2008a)

6 TRIAL PREPARATION

According to the National Center for State Courts, 15 million civil cases are filed annually in the United States (*http://www.ncsconline.org/WC/Publications/Res_CtComm_CJRIPub.pdf*). Fewer than 5% of these will ever make it to trial. Litigation is a lengthy and complex process governed by the Rules of Civil Procedure and the Rules of Criminal Procedure (Federal Rules of Civil Procedure, 2008; Federal Rules of Criminal Procedure, 2008). An expert witness may be involved in any or all phases of the process and although there may be significant overlap, it is convenient to the litigation process in preparation for trial and the trial itself.

The expert witness is not a surprise witness who suddenly appears at trial, but rather Rule 26 of the Federal Rules of Civil Procedure outlines the details of expert testimony disclosure, and the scope of discovery and privilege (Federal Rules of Civil Procedure Rule 26, 2008). The identity of an expert who may be presenting evidence during trial must be disclosed to the opposition at least 90 days before the trial date. This is accompanied by a written report prepared by the witness. The report contains:

- A statement of opinions the expert is expected to offer
- Data used to form the aforementioned opinion
- The witness's qualifications
- A list of all cases, dating back four years, in which the expert has been deposed or testified
- A statement of compensation.

These are rules as they relate to federal court; however, they may not all be strictly applicable to state courts (e.g. there is no requirement at the state level for an expert to list all cases dating back four years for which he/she was deposed or testified), although it could be requested from

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat113
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the expert by subpoena from opposing legal counsel prior to deposition.

The pretrial is a conference held prior to trial whereby all of the interested parties may outline discovery proceedings and work with a neutral mediator in an attempt to avoid a trial, which can add significantly to overall litigation cost. Discovery is the means of obtaining information in preparation for trial (Simington, 2006). An expert witness who has been disclosed to the opposition may be required to submit copies of all of their relevant documents, reports, research and experimental data. The proposed discovery plan generated in the pretrial is submitted to the court for approval; the plan establishes the scope and limitations of the discovery process. It will also address issues of privilege or protection. Privilege refers to an immunity that allows a witness to refuse to divulge information (NOLO, 2008).

Interrogatories, depositions and production of document requests and requests for admission into evidence are tools of discovery. Interrogatories are written questions designed to elucidate the opposing party's case (Garner, 2000). Attorneys may use form interrogatories that cover typical situations, or they may write their own questions. They may also enlist the help of an expert to generate the questions. In a deposition, the opposing counsel questions the expert witness. This can be a lengthy and sometimes very heated event, which at times may be deemed by the expert as little outside of a personal attack on their professional accomplishments and opinions. All the questions are answered under oath and a transcript is recorded by the court reporter. An expert is free to consult notes or utilize PowerPoint presentations. Depositions are frequently videotaped so they may be read to or played for the jury should the witness be unavailable for trial. Deposition testimony may be used to impeach a witness during trial; witness preparation is therefore very important (Busse, 2005). Production of document requests are requests for specific documents thought to have relevance. An expert may receive a *subpoena duces tecum* from opposing counsel. This may require that the expert produce the entire file for deposition. The expert may be required to go through the file, page by page and copy documents. The time spent doing this at the request of opposing counsel should be billed to them at the normal hourly rate. Requests for admissions are statements served to get opposing counsel to stipulate to facts or documents.

7 TRIAL

A toxicologist wishing to serve as an expert witness will be required to qualify their testimony (Schroeder, 1980). *Voir dire*, from the French 'to see and speak', refers to the process used to qualify the witness. This process will differ depending on the acceptance test used by the court. Briefly, the court will apply its own standard of acceptability to the witness; it may be as simple as relevance or it might be far more stringent. The relevant statutes governing the acceptance tests are discussed elsewhere in the chapter.

Despite the differences between criminal and civil procedure, both types of trials have the following stages:

- The judge gives the jury some preliminary instructions and then the lawyers present opening statements; sometimes the opening statements on behalf of one or more parties are omitted
- Plaintiff calls witnesses and produces evidence to prove its case
- Defendant may call witnesses and produce evidence to disprove the plaintiff's case and to prove the defendant's claims
- Plaintiff may call rebuttal witnesses to disprove what was said by the defendant's witnesses
- Closing arguments are made by the lawyer on each side
- The judge instructs or charges the jury as to the law
- The jury retires to deliberate
- The jury reaches its verdict and returns to the courtroom where the verdict is announced.

(*http://www.flnd.uscourts.gov/jurors/jurySelection.cfm*)
(*www.abanet.org/publiced/practical/books/family_legal_guide/chapter_2.pdf*)

Testimony is as much an art as it is a skill. An attorney will frequently request from the expert witness a rehearsal(s) of their testimony. The direct examination should flow logically and conversationally. Your attorney may simply ask a series of open-ended questions that allow you to engage the jury. Cross examination by opposing counsel may be far more of an ordeal. The deposition should have prepared the expert for the line of questions which will be asked in court, but it can still be quite confrontational. Responses during cross examination will be much briefer than they were during direct examination. The opposing counsel will try to catch contradictory statements, impugn integrity or intellect and attempt to fluster the expert. Take time to reflect on questions before responding and do not be afraid to say 'I don't know'. Your attorney may redirect questioning following the cross examination, allowing for a further clarification of a response to opposing counsel's questions and to shore up any damage inflicted during cross examination. Opposing counsel will get one more chance to question the expert in re-cross. The expert needs to connect with the judge and jury. If the proceedings are a bench trial, that audience is the judge. Bench trials require a slightly different approach to a jury trial. The demeanour of the attorneys may change as well. Jury trials are a performance of sorts, and attorneys on both sides will play to the audience. An expert must connect

to the audience or their testimony will not be effective.

8 RULES GOVERNING ACCEPTANCE OF EXPERT TESTIMONY

Perhaps because scientific knowledge is extremely influential in litigation, courts continue to struggle with admissibility of scientific evidence. There is still no national standard test of acceptance for the admission of expert scientific testimony (**Table 1**). In the early 1900s, courts used the commercial marketplace test. This simply held that a person capable of earning a living based on their expertise or knowledge could be considered an expert. The *Frye* test was named for the ruling in Frye vs. United States of 1923 (Frye vs. United States 293 F. 1013 (DC Cir. 1923)). This test is also referred to as the 'general acceptance rule'. The test did not specify the scope of the expert's field, nor did it welcome innovative scientific methods. Frye was the predominant rule for the United States until the early 1990s.

Table 1 State positions on *Daubert*

Adopted	Rejected	Under consideration
Alaska	Arizona	Alabama
Arkansas	California	Hawaii
Connecticut	Colorado	Illinois
Delaware	District of Columbia	Minnesota

The *Daubert* standard is a legal precedent set in 1993 regarding the admissibility of expert witnesses' testimony during federal legal proceedings (Daubert vs. Merrell Dow Pharmaceuticals, 509 US 579 (1993)). The Supreme Court ruled that the 1923 Frye test was superseded by the 1975 Federal Rules of Evidence, particularly Rule 702. Rule 702 states:

> *If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise.*

The *Daubert* standard was further refined by two more Supreme Court rulings. These three cases are commonly referred to as the '*Daubert* trilogy'. The Supreme Court held in General Electric Co. vs. Joiner, 522 US 136 (1997) that an abuse-of-discretion standard of review was the proper standard for appellate courts when reviewing a trial court's decision on the admissibility of expert testimony (Bernstein and Jackson, 2004). This meant that appellate courts should defer to the decision of the lower-court decision. The Supreme Court held in Kumho Tire Co. vs. Carmichael, 526 US 137 (1999) that the judge's gatekeeping function identified in *Daubert* applies to all expert testimony (Nordberg, 2007). *Daubert* established that judges are the 'gatekeepers' of good science and has granted them the sole authority to either approve or disapprove the use of any particular expert and their opinions in their court.

The four tenets of the *Daubert* trilogy are:

- Has the theory been tested?
- Is there a known or potential error rate?
- Has it been subjected to peer review and published?
- Is it generally accepted within the field?

As you can see, the last tenet is the *Frye* test (Waters and Hodge, 2004). Even in states that use the *Daubert* standard, there is uneven application. Few states use the entire trilogy. The results have been mixed. Proponents of *Daubert* argued that it would reduce the acceptance of 'junk science' in courtrooms by allowing the judge to act as a 'gatekeeper' (Berger, 2005). Opponents have argued that judges are ill-prepared to act as amateur scientists. Prior to *Daubert's* adoption, judges were inclined to let the issue be sorted out during cross examination. Application of *Daubert* has led to an increase of *motions in limine* and in summary judgments; however, the overall effect appears to be changing the way trials are managed by attorneys (Haack, 2005). *Daubert* challenges to expert witnesses are used as leverage in many civil disputes (Melnick, 2005). Loss of a key expert's testimony late in the trial generally leads to a summary motion against them. Acceptance tests

are not the last word on admissibility of expert witness testimony. The Federal Rules of Evidence, specifically Rules 602, 701–706 and 803, provide guidance for criminal and civil law (**Table 2**).

9 BURDEN OF PROOF

The burden of proof is the requirement to prove those allegations which are presented in a legal action. The toxicologist as an expert witness will be called upon to address these issues. The burden of proof rests upon the one who complains: '*maxim necessitas probandi incumbit ei qui agit*'. The burden of proof simply means responsibility. In a criminal trial, it is the state's responsibility to prove the defendant's guilt. In a civil trial claiming a personal injury from a medication that was prescribed, it is the plaintiff's responsibility to show causation (Frankel, 1986). In a toxic tort alleging that an individual user of a household cleaning product was injured during the course of its use, for example, the toxicologist may serve as a expert witness for the plaintiff who used the product in question, assisting in the legal burden of proof that would be required to provide convincing evidence to the plaintiff legal team and the court in order to prevail in a claim of personal injury.

The toxicology witness must be prepared to discuss the probability that the injury was caused from exposure to the product.

The question becomes what is the level of proof or the 'standard of proof' required to satisfy the court? Typically, most nations have two levels of proof:

- Preponderance of evidence, which is used mainly in civil trials and worker's compensation claims, represents the lowest level of proof
- Beyond a reasonable doubt, which is used in criminal trials and represents the highest level of proof.

In addition to these, the USA introduced a third standard called clear and convincing evidence. This level of proof is sometimes required in civil cases for the plaintiff to prevail. It means that the court must be persuaded that the evidence is highly probable, thus providing a heavier burden than the preponderance of the evidence standard, but less than beyond a reasonable doubt.

The preponderance of the evidence, also referred to as the balance of probabilities, is the standard required in most civil cases and is met if the conclusion is more likely to be true than not true. Essentially, the standard is satisfied if there is greater than 50% chance that the proposition is true or 'more probable than not'. Beyond a reasonable doubt means 'to the exclusion of'. That is, the state must exclude any and all reasonable doubt as to the defendant's guilt. Simply put, the phrase means that if a juror has a reasonable doubt it is their duty to return a verdict of not guilty. On the other hand, if a juror does not have a reasonable doubt then the state has met its burden of proof and it is the juror's duty to return a verdict of guilty.

Beyond a reasonable doubt is the standard required by the prosecution in most criminal cases and represents the highest level of burden of proof. This simply means that there is no 'reasonable doubt' in the mind of any reasonable person that the defendant is guilty. There can still be a doubt, but only to the extent that it would not affect a 'reasonable person's' belief that the defendant is guilty. A toxicologist may be called upon as an expert, for example, to render an opinion which may require that this standard be applied. A prosecutor may ask the toxicology expert if is it their opinion, beyond any reasonable doubt, that the decedent's death was directly caused from ingestion of this chemical. The toxicologist must recognize that the opinion is concerning the chemical and not how or who may have given the chemical to the decedent. The toxicology expert witnesses may be asked to explain the difference between scientific standards legal standards of certainty. Scientific certainty is a probability that data have sufficient statistical significance at a certain confidence level. Legal certainty merely establishes that a complaint has met the minimum amount in controversy required for a court to have jurisdiction to hear the case. Legal certainty is built on scientific certainty.

10 TRANSLATING SCIENCE IN COURT

As a part of your responsibilities as an expert witness, you will no doubt be called upon to explain to your legal team and to educate judge and jury on what you would consider to be very basic toxicological principles (Omenn, 1994). If this disturbs you in any way then perhaps you should consider not becoming an expert witness. A jury can clearly sense when an expert is trying to educate them so that they will be able to make informed decisions and when an expert is merely demonstrating their wealth of knowledge, which they may not be in a position to even actually evaluate or appreciate in the first place. Some of the concepts that the toxicology expert witness will most commonly refer to in court and those that will be directly relevant to their specific case will include:

- Dose and the dose–response relationship
- Pathways, routes, frequency and duration of exposure
- Exposure assessments and how they are determined
- Relationships between exposure and dose
- Sites of chemical action in the body
- Threshold vs. nonthreshold exposures
- What is risk?

Table 2 Federal rules related to expert witness testimony

Rule 602. Lack of Personal Knowledge	A witness may not testify to a matter unless evidence is introduced sufficient to support a finding that the witness has personal knowledge of the matter. Evidence to prove personal knowledge may, but need not, consist of the witness' own testimony. This rule is subject to the provisions of rule 703, relating to opinion testimony by expert witnesses.
Rule 701. Opinion Testimony by Lay Witnesses	If the witness is not testifying as an expert, the witness' testimony in the form of opinions or inferences is limited to those opinions or inferences which are (a) rationally based on the perception of the witness, and (b) helpful to a clear understanding of the witness' testimony or the determination of a fact in issue, and (c) not based on scientific, technical or other specialized knowledge within the scope of Rule 702.
Rule 702. Testimony by Experts	If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods and (3) the witness has applied the principles and methods reliably to the facts of the case.
Rule 703. Bases of Opinion Testimony by Experts	The facts or data in the particular case upon which an expert bases an opinion or inference may be those perceived by or made known to the expert at or before the hearing. If of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject, the facts or data need not be admissible in evidence in order for the opinion or inference to be admitted. Facts or data that are otherwise inadmissible shall not be disclosed to the jury by the proponent of the opinion or inference unless the court determines that their probative value in assisting the jury to evaluate the expert's opinion substantially outweighs their prejudicial effect.
Rule 704. Opinion on Ultimate Issue	(a) Except as provided in subdivision (b), testimony in the form of an opinion or inference otherwise admissible is not objectionable because it embraces an ultimate issue to be decided by the trier of fact. (b) No expert witness testifying with respect to the mental state or condition of a defendant in a criminal case may state an opinion or inference as to whether the defendant did or did not have the mental state or condition constituting an element of the crime charged or of a defense thereto. Such ultimate issues are matters for the trier of fact alone.
Rule 705. Disclosure of Facts or Data Underlying Expert Opinion	The expert may testify in terms of opinion or inference and give reasons therefore without first testifying to the underlying facts or data, unless the court requires otherwise. The expert may in any event be required to disclose the underlying facts or data on cross examination.
Rule 706. Court Appointed Experts	(a) Appointment. The court may on its own motion or on the motion of any party enter an order to show cause why expert witnesses should not be appointed, and may request the parties to submit nominations. The court may appoint any expert witnesses agreed upon by the parties, and may appoint expert witnesses of its own selection. An expert witness shall not be appointed by the court unless the witness consents to act. A witness so appointed shall be informed of the witness' duties by the court in writing, a copy of which shall be filed with the clerk, or at a conference in which the parties shall have opportunity to participate. A witness so appointed shall advise the parties of the witness' findings, if any; the witness' deposition may be taken by any party; and the witness may be called to testify by the court or any party. The witness shall be subject to cross examination by each party, including a party calling the witness. (b) Compensation. Expert witnesses so appointed are entitled to reasonable compensation in whatever sum the court may allow. The compensation thus fixed is payable from funds which may be provided by law in criminal cases and civil actions and proceedings involving just compensation under the Fifth Amendment. In other civil actions and proceedings the compensation shall be paid by the parties in such proportion and at such time as the court directs, and thereafter charged in like manner as other costs. (c) Disclosure of appointment. In the exercise of its discretion, the court may authorize disclosure to the jury of the fact that the court appointed the expert witness. (d) Parties' experts of own selection. Nothing in this rule limits the parties in calling expert witnesses of their own selection.

Table 2 (*continued*)

Rule 803. Hearsay Exceptions; Availability of Declarant Immaterial	The following are not excluded by the hearsay rule, even though the declarant is available as a witness: (18) Learned treatises. To the extent called to the attention of an expert witness upon cross examination or relied upon by the expert witness in direct examination, statements contained in published treatises, periodicals, or pamphlets on a subject of history, medicine, or other science or art, established as a reliable authority by the testimony or admission of the witness or by other expert testimony or by judicial notice. If admitted, the statements may be read into evidence but may not be received as exhibits.

- Risk perception
- Toxicological causation and how it is established
- Chemical exposure and development or exacerbation of disease
- Cancer risk
- Mechanisms of chemical carcinogenesis
- The uses and limitations of animal toxicity testing
- The use of toxicological data to assess risk in individuals and populations
- The use of toxicological data to establish acceptable levels of exposure for populations
- Populations at special risk
- Regulatory guidelines as they relate to protecting individuals and populations.

11 THE EXPERT'S ROLE IN CLARIFYING THE CONCEPT OF RISK

In court, it is often necessary in many cases for the toxicologist to explain what constitutes risk to an individual of injury from a chemical exposure. This is often a challenging task, as it is necessary to clearly explain to the judge and jury the differences in risk perception and risk assessment. The concept of real risk vs. perceived risk must be emphasized when possible (Richards, 2007). Risk perception is the sensation of danger associated with an exposure. Clearly there can be no risk, whatever the toxicity of the chemical in question, if there is no opportunity for exposure.

Unlike the current Chinese infant formula crisis, where measurable amounts of melamine have been found in both cans of the powdered formula and serum samples taken from stricken children (Macartney and Yu, 2008), chemical injuries in humans rarely permit quantitative determination of exposure doses. Clinical toxicologists rely instead on case reports, case series and occasionally experimental study data to elucidate probable dose–response relationships and mechanisms of action (Chamberlain, 1996). For example, occupational and environmental exposures to polychlorinated biphenyls (PCBs) prior to usage restrictions have been assessed to determine absorption, distribution, metabolism and excretion. Human exposures occur predominantly in occupational settings, as was the case for industrial exposures to lead and asbestos (Richards, 2007). It can be difficult, if not impossible, to quantify an exposure, even one that occurs under controlled circumstances. Moreover, humans are exposed to multiple chemicals over the course of a single day. This can make it difficult to affix blame for an adverse outcome to a single specific chemical.

People may tend to overestimate or underestimate the risks of exposure for a number of different reasons. Risk assessment is a procedure used to quantify the danger of exposure. It is typically broken down into four, sequential steps:

- Hazard identification
- Dose–response assessment
- Exposure assessment
- Risk characterization.

The concepts of threshold and nonthreshold exposures are important in toxicological testing. The expert witness must be sure to differentiate between the terms; it may be simplest to define them based on carcinogenicity. Jurors should be able to understand that regulatory agencies develop guidelines based on the theory that there is no safe threshold for exposure to carcinogens. Depending on the lawsuit, the expert may then need to explain that regulatory agencies tend to exaggerate risk to keep the maximum number of people safe. Zero threshold should not be construed as unavoidably hazardous.

12 TOXICOLOGICAL CAUSATION

As an expert witness you must be prepared to render opinions as to the use of toxicological data in the assessment of individual causation. You will be required to render opinions as to:

- Whether or not the chemical(s) in question can produce or exacerbate the type of illness claimed in this case
- Whether or not an exposure to the chemical or chemicals in question had actually occurred

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat113
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Whether or not an exposure to the chemical or chemicals in question was of a sufficient duration to produce the illness in question
- Whether or not an exposure to the chemical(s) was of a magnitude sufficient to produce the illness in question
- Whether or not medical records support the health effects of the chemical or chemicals in question
- Whether or not there are other explanations that can account for the development or exacerbation of the illness in question
- Whether or not other individuals who have been similarly exposed developed comparable illness.

In his 1965 Presidential address to the Royal Society of Medicine, Sir Austin Bradford Hill opined that:

> *All scientific work is incomplete - whether it be observational or experimental…*
>
> *(Hill, 1965)*

He went on to delineate nine criteria for assessing causation from chemical exposure:

- Strength of the association between a specific chemical exposure or process and a specific injury
- Consistency of effect among individuals similarly exposed
- Specificity of the type of injury or injuries that are produced
- Temporality between the exposure and subsequent development of an injury
- Biological gradient or dose–response should be evident from available studies
- Plausibility of the biological effect must be supported by available information
- Coherence with available experimental information should be apparent
- Experiments may support or modify current observations if available
- Analogy from other chemicals or sources of information may be enlightening.

These came to be known as Hill's Criteria of Causality and they have had a profound impact on science and law.

Interrogatories typically refer to causality criteria; an expert witness should expect a question that asks if associations are proof or are they are anecdotal events. A causal hypothesis cannot be literally proven or disproven (Cole, 1997). The role of the expert is to evaluate the facts of the case as he or she knows them and use that knowledge to generate an opinion.

Establishing causality is one of the most challenging aspects of scientific research. Toxicologists who serve as expert witnesses are frequently asked to establish or disprove causality. A controlled study is the most effective means of evaluating a causal relationship between an exposure and an outcome. '*Correlation does not imply causation*' is one of the basic tenets of statistics. Simply put, it means that the existence of a correlation between variables does not prove a causal relationship. As an expert witness, you will be called upon to provide opinions addressing a number of questions which will be asked of you. You must be prepared to answer them.

Does a temporal progression support causality? Obviously, the appearance of symptoms prior to exposure would rule out causality; however, a strong temporal relationship between exposure and symptom/sign onset is insufficient evidence of a causal relationship. In an acute injury, the time period between exposure and the appearance of symptoms is generally short and may support cause and effect, but in and of itself is not reasonable proof. Frequently though, the onset of symptoms is delayed by the number or duration of biological processes that occur as a result of the exposure. One only needs to consider a delayed inflammatory response, or acute myelogenous leukaemia as a result of benzene exposure, to support the idea of the delayed onset model. There is a latency period of approximately two years between exposure to radiation, benzene or chemotherapy drugs and the appearance of clinically recognizable acute myelogenous leukaemia. Any toxic tort claim that alleges a shorter timeframe is scientifically untenable. Asbestos is another example of a significantly delayed disease onset; symptoms of mesothelioma may not be detectable for more than 20 years following the initial exposure to asbestos fibres.

Is the medical history of the plaintiff consistent with the type of exposure alleged? A thorough medical history can be an invaluable asset in allowing you to form your opinions. Occasionally the signs and symptoms themselves are suggestive of a specific exposure. For example, acute exposure to organophosphate pesticides typically elicits complaints of headaches, nausea, dizziness, anxiety, restlessness, muscle fasciculation, diaphoresis, salivation and lacrimation.

There is currently no standardized patient information questionnaire for the toxicologist which is capable of providing all the information desired and it is often difficult to read through volumes of medical records and reports to gather the information that you deem as especially important for you to reach your conclusions. This means it is often up to the medical professional to ask the correct questions and gather the pertinent medical records. The following is a list of information that you should request from your attorney, if not provided to you:

- Past and present occupational history
- Environmental history of exposure to toxic agents
- Lifestyle characteristics (e.g. use of nicotine and alcohol)
- Family medical history (e.g. medical conditions, diseases of relatives)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat113
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Personal medical history (e.g. present symptoms, lab test results, past injuries, current medical conditions, diseases, surgical procedures and medical test results).

Are the complaints specific or nonspecific? Acute exposures can trigger a constellation of nonspecific symptoms, including headaches, nausea, lightheadedness and fatigue. These symptoms can be considered part of the 'human condition', something everyone has experienced at one time or another. They are triggered by a host of physical, biological and psychological factors and may be mistakenly attributed to an exposure based solely upon a temporal association. Careful medical histories require a sharp focus on patterns in the emergence of signs and symptoms. It is far easier to establish causation or lack of causation when the observed signs and symptoms that are typically seen with a specific exposure such as vinyl chloride and hepatic angiosarcoma, for example, are either present or absent respectively. Unfortunately, the vast majority of cancers and other conditions are associated with multiple causative factors.

Do laboratory tests results support exposure? Routine tests are used to detect changes in normal body status and can provide clues as to consistency with exposure to toxicants. One only needs to think of blood gases and carbon monoxide exposure as a simple example or serum cholinesterase levels for organophosphate exposure. Other routine tests, such as complete blood count, basic metabolic panels and urinalysis may be important in providing additional insight for the toxicologist. More often than not, tests to determine the specific levels of the exposure chemical(s) of concern are either unavailable or have not been performed in a timely fashion.

What other explanations could account for a given illness? Collecting a meticulous medical and occupational history is often the only way both physician and toxicologist can perform this assessment. Additionally, the medical experts may provide a differential diagnosis which either supports or fails to support that the illness in question was directly attributed to the exposure (Muller, 2008). Failure to produce such a differential diagnosis by the physician and a toxicological assessment to support this diagnosis would leave any causal connection in doubt. Careful examination of the available data, coupled with deductive reasoning, can allow the expert to determine a causal relationship between exposure and symptoms. Animal studies, pharmacological research on mechanisms of toxicity, *in vitro* studies and epidemiological data, if available, may either provide or not provide support for the toxicity of a particular compound in this case, thus influencing the expert's opinion on causality. It is considerably more difficult when the available data is scant or conflicting. In cases such as these, the expert must be prepared to explain how these results impact their reasoning.

Regulatory Toxicology

H. Paul A. Illing and Timothy C. Marrs

CONTENTS

1 INTRODUCTION: TOXICOLOGICAL RISK ANALYSIS AND REGULATORY TOXICOLOGY

Toxicological risk analysis includes all forms of risk analysis involving effects on human health and environmental pollution. It is the process of assessing, evaluating and managing risks. Risk analysis may be conducted by the individual, the legal entity (company), national governments or supragovernmental international organizations (such as the European Union (EU) or the United Nations (UN)). This national and international toxic risk analysis is conducted on behalf of society, because decisions have been taken that the nature and type of risk management required by society is too complex to be left to the individual (*caveat emptor* cannot be adequately sustained as the buyer is so disadvantaged by a lack of relevant knowledge and experience). Furthermore, in international risk management, leaving risk management to individual governments may raise the possibility of use of spurious risk management as a nontariff barrier to trade. Legislation is introduced to regulate the ways in which these risk assessments are conducted. When toxic risk analysis is conducted by or on behalf of governments or intergovernmental organizations, the toxicology contained within the risk assessments and evaluations is referred to as 'regulatory toxicology'.

Regulatory toxicology is the process whereby information relevant to assessing and evaluating the toxicity of agents, which may be biological, chemical or physical in nature, is obtained and evaluated by or on behalf of governmental or international organizations. The aim is to protect workers, consumers, the public generally and the environment. The intention is either to provide information for the management of risks, usually in an easily understood form so that untrained individuals can manage the risks, or actively to manage the risks. It has been said that regulatory toxicology is to toxicology as military music is to music. This is because the requirements of many regulatory systems are closely defined in terms of both the studies required and the interpretations to be placed upon the results obtained, so that there is little scope for originality.

Essential to a consideration of regulatory toxicology are the concepts of risk and hazard. The latter is the inherent property of an agent or situation having the potential to cause adverse effects when an organism, system, population or subpopulation is exposed to that agent. Risk is the probability of an adverse effect in an organism, system, population or subpopulation caused under specified circumstances by exposure to that agent.

1.1 General Principles

Regulatory toxicology does not take place in a vacuum; a legislative framework is required. Society has perceived

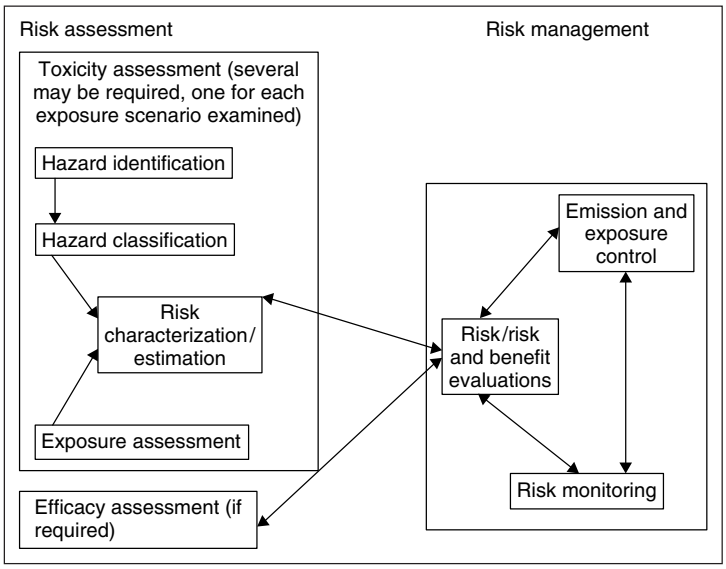

Figure 1 Risk assessment and risk management. Note: the risk analysis process is undertaken within a societally derived framework, represented by the outer box. (Adapted from Illing, 2009.)

that there is a problem and has framed a system for examining that problem. This system therefore develops from the sociological and psychological perceptions of the risks associated with the particular class of agent. Legislative frameworks have developed piecemeal, as society has seen the need to manage specific uses. The first toxicology regulation in the UK is often said to be the Alkali Act of 1863 (Alkali Act, 1863), which was intended to control pollution by heavy industry. Other early regulatory schemes were concerned with drugs and food contaminants, and regulation was later extended to pesticides and other groups of compounds.

In this chapter the regulatory systems associated with chemicals and human health will be examined, but those concerned with physical agents, such as radiation, and biological agents, such as organisms used to control pests, will not be examined further. In addition, in the main, the purely environmental risk evaluations are not included in this chapter, although risks to human health via the environment are included.

Within the legislative framework it is traditional to have separate regimes for different end uses; for example, human medicines, veterinary products, medical devices, 'cosmetics' (otherwise called personal care products), foods, food additives and contaminants, and pesticides, subdivided into plant protection products and biocides. More recently, reserve schemes have been developed for chemicals placed on the market and not included in these specific use schemes. For all of these schemes, there is a clearly identifiable entity seeking to place the chemical on the market and it is usually possible to insist that they accept the costs of premarketing and postmarketing testing and, sometimes, postmarketing monitoring and surveillance. Additional regulatory schemes deal with indoor and outdoor air quality, water quality (drinking and environmental) and soil contamination. Generally, it is difficult to identify a nongovernmental entity to underwrite testing and controlling risk when dealing with these latter schemes. Consequently, in such circumstances, the government is frequently both regulator and provider of research funds to acquire new knowledge. Another group of substances where it may be difficult to identify an entity other than the government to underwrite testing is food contaminants such as aflatoxins.

The process by which toxicological risks are assessed and managed is illustrated diagrammatically in **Figure 1**. It was first set out in two documents, one a report of a UK Royal Society Study Group (Royal Society Study Group, 1983), and the second a report of the US National Research Council (National Research Council, 1983). Many definitions for the elements of the process and of the stages in the process have recently been agreed internationally (OECD, 2003; IPCS, 2004). The definitions for several key terms associated with **Figure 1** are given in **Table 1**.

Two key terms: emission and exposure control, and risk perception, were not defined in the OECD (Organisation for Economic Co-operation and Development)/IPCS (International Programme on Chemical Safety) list of key definitions. Emission and exposure control is associated particularly with industrial hazards—the control of emissions from stacks to the atmosphere or discharges to waste water. However, it also applies to most sources of exposure to chemicals, including drugs. Drugs are controlled through designating those authorizing the obtaining of the medicine (doctors, and so on, with prescribing rights) and through designating the outlets from which they may be obtained (e.g. pharmacy only, or any supermarket). Most other regulatory schemes control emission, for example, for foods there are emission limits

Table 1 Key definitions for use in toxicological risk analysis

Term	Definition
Exposure assessment	Evaluation of the exposure of an organism, system, population or subpopulation to an agent (and its derivatives). Exposure assessment is the third step in the process of risk assessment. (IPCS (2004) Part 2 states 'The process of estimating or measuring the magnitude, frequency and duration of exposure to an agent, along with the number and characteristics of the population exposed. Ideally it describes the source, pathways, routes and uncertainties in the assessment'.)
Hazard	The inherent property of an agent or situation having the potential to cause adverse effects when an organism, system, population or subpopulation is exposed to that agent.
Hazard characterization	The qualitative and, wherever possible, quantitative description of the inherent properties of an agent or situation having the potential to cause adverse effects. This should, where possible, include a dose–response assessment and its attendant uncertainties. Hazard characterization is the second stage in hazard assessment, and the second step in risk assessment.
Hazard identification	The identification of the type and nature of adverse effects that an agent has an inherent capacity to cause in an organism, system, population or subpopulation. Hazard identification is the first stage in hazard characterization, and the first step in risk assessment.
Risk	The probability of an adverse effect in an organism, system, population or subpopulation caused under specified circumstances by exposure to that agent.
Risk analysis	Process for controlling systems where an organism, system or population or subpopulation could be exposed to a hazard. The risk analysis process consists of three components: risk assessment, risk management and risk communication.
Risk assessment	A process intended to calculate or estimate the risk to a given target organism, system, population or subpopulation, including identification of attendant uncertainties, following exposure to a particular agent, taking into account the inherent characteristics of the agent of concern as well as the characteristics of the specific target system. The risk assessment process includes four steps: hazard identification, hazard characterization (related term: dose–response assessment), exposure assessment and risk characterization. Risk assessment is the first component in a risk analysis process.
Risk characterization	The qualitative and, wherever possible, quantitative determination, including attendant uncertainties, of the probability of occurrence of known and potential adverse effects of an agent on a given organism, system, population or subpopulation, under defined exposure conditions. Risk characterization is the fourth step in the risk assessment process.
Risk communication	Interactive exchange of information about health or environmental risks among risk assessors, managers, news media, interested groups and the general public.
Risk evaluation	Establishment of a qualitative or quantitative relationship between risks and benefits of exposure to an agent, involving the complex process of determining the significance of the identified hazards and estimated risks to the system concerned or affected by the exposure, as well as the significance of the benefits brought about by the agent. It is an element of risk management. It is synonymous with risk–benefit evaluation.[a]
Risk management	Decision-making process involving consideration of political, social, economic, and technical factors with relevant risk assessment information relating to a hazard, so as to develop, analyse and compare regulatory and nonregulatory options, and to select and implement appropriate regulatory response to that hazard. Risk management comprises three elements: risk evaluation, emission and exposure control, risk monitoring.
Risk monitoring	Process of follow-up of decisions and actions within risk management in order to ascertain that risk containment or reduction with respect to a particular hazard is assured. Risk monitoring is an element of risk management.

[a]Technically this definition confuses risk and risk–benefit. Risk alone is the criterion when dealing with an equity-based system for examining risks, risk–benefit is the criterion employed when dealing with tolerable risks in a system that can employ utility and technical-feasibility criteria when examining risks (see below).
From OECD (2003) and IPCS (2004) (Part 1) with minor textual amendments, unless otherwise noted.

from packaging and maximum residue levels (MRLs) for additives and contaminants in foodstuffs.

Monitoring includes inspection to ensure that conditions of control are being met in the field. It also includes procedures, such as those associated with pharmacovigilance, designed to ensure that previously unidentified effects do not go unrecorded.

Risk perception was also not defined. However, the Royal Society Study Group (1983) called perceived risk the combined evaluation that is made by an individual of the likelihood of an adverse event occurring in the future and its likely consequences. In the introduction to the chapter on risk perception in the 1992 report of the Royal Society Study Group (1992), risk perception (from the perspective of the social sciences) involves peoples' beliefs, attitudes, judgements and feelings, as well as the wider social or cultural values and dispositions that people adopt towards hazards and their benefits. When aggregated, individual beliefs, attitudes, and so on, become the societal beliefs, attitudes, and so on, that both drive legislation and drive concerns about decisions taken by public bodies set up to administer and enforce the legislation.

Central to any toxicological risk analysis is the risk evaluation. There has been debate over whether it is part of risk assessment or part of risk management. It was notable that the Royal Society Study Group (1983) placed risk evaluation as part of the risk assessment, whilst the US National Research Council (1983) placed it as the first stage of risk management. In practice, risk evaluation is the key link between the two elements of risk analysis. Although in the simplest cases this risk evaluation can be conducted by individuals using guidelines on how to interpret the tests, in Europe, the more complex situations evaluations are often conducted on behalf of society by scientific committees consisting of relevant experts (and ideally some lay ('stakeholder') participation), and their recommendations implemented by the regulatory authority.

1.1.1 Basis of Risk Evaluation (Equity, Utility and Technical Feasibility Criteria)

The confusion between risk evaluation and risk/benefit evaluation in the OECD/IPCS definitions concerning risk evaluation can be examined further. It arises because of confusion about the basis of the risk evaluation. Decisions can be reached using one or more of three 'pure' criteria (HSE, 2001). These are:

- An equity-based criterion, which starts from the premise that all individuals have unconditional rights to certain levels of protection. This leads to standards, applicable to all, held to be usually acceptable in normal life. In practice this leads to fixing a limit to represent the maximum level of risk above which no individual can be exposed. If the risk characterization indicates that the risk is above this limit, the risk is held to be unacceptable—whatever the benefits.
- A utility-based criterion, which applies to the comparison between incremental benefits of measures to prevent the risk of injury or detriment, for health effects, ill health and the cost of the measures. The utility-based criterion compares the relevant benefits (e.g. statistical lives saved, life-years extended, reduced ill health and better quality of life) obtained by adoption of a particular risk prevention measure, with the net cost of introducing it, and requires that a balance be struck between the two. This balance can be deliberately skewed towards benefits by ensuring gross disproportion between costs and benefits.
- A technology-based criterion, which essentially reflects the idea that a satisfactory level of risk prevention is attained when state of the art control measures (technological, managerial, organizational) are employed to control risks, whatever the circumstances.

These criteria underlie the regulatory process first outlined by the Royal Society Study Group (1983). The scheme is based on:

- an upper limit of risk which should not be exceeded for any individual (unacceptable);
- further control, so far as is reasonably practicable, making allowances if possible for aversions to the higher levels of risk or detriment (tolerable);
- a cut-off in the deployment of resources below some level of exposure or detriment judged to be trivial (broadly acceptable).

The scheme is outlined in **Figure 2**.

In most fields of use requiring preauthorization, regulatory toxicology attempts to be protective, that is, to use a pure equity criterion and to include some disproportion in order to be conservative (Illing, 1999). This has been called gatekeeping. Thus, with pesticides it is assumed that, for most uses, no individual benefit will arise from exposure of people to pesticides. It is however realized that this is not always the case, as a benefit may arise when a pesticide is used, for example, to prevent exposure to fungal toxins in food. Risk–benefit considerations are major factors when evaluating human medicines, because of the need to balance risk of side effects against the benefit of the therapeutic effect in the patient. Risk–benefit considerations may also be appropriate when investigating occupational exposures, as it may be necessary to allow a tolerable risk to those exposed occupationally in order for society to gain great benefit from the products. In these circumstances, more explicitly considered societal judgements

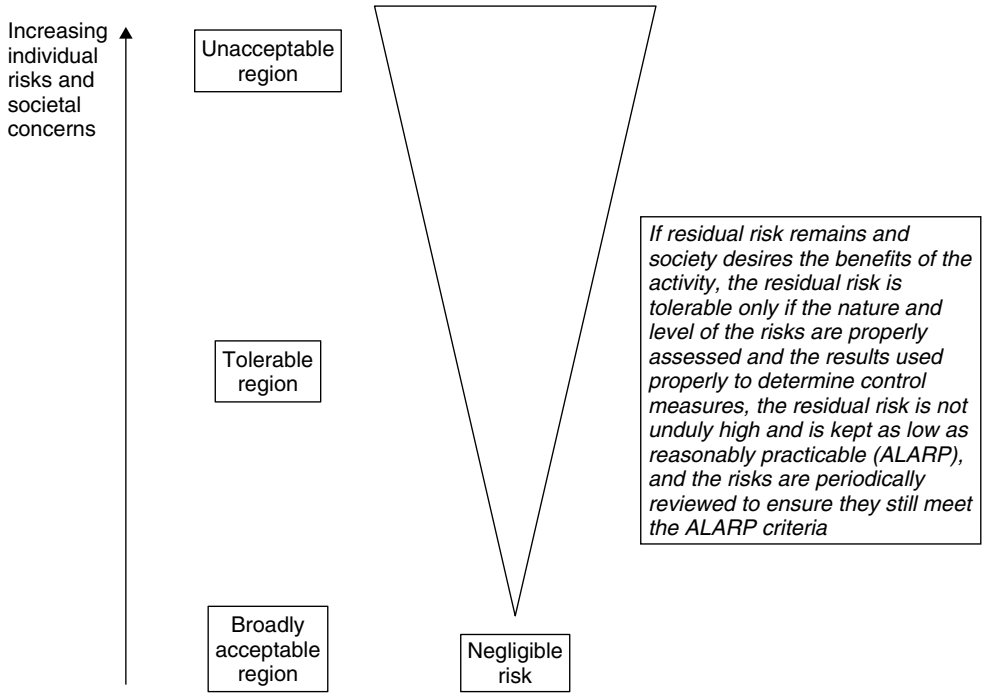

Figure 2 Outline of the Royal Society approach to risk management/tolerability of risk framework. (Based on HSE, 2001.)

concerning what constitutes 'broadly acceptable' and 'tolerable' risk criteria are required. They may also be relevant when considering the toxicity of essential nutrients, including vitamins and minerals, if the margin of exposure (MoE) between the essential minimum requirement and the level at which toxicity is seen is low. Often, air quality guidelines are set on technology-based criteria, with deadlines for requirements to meet tighter standards.

Generally, in the first instance, regulatory risk assessments are based on achieving a 'broadly acceptable' level of risk (a 'safe' level of exposure). Two processes may be used to evaluate data. These are the 'uncertainty factors (UFs)' approach and the 'margin of exposure' approach. The former mixes risk characterization with risk evaluation. In the latter, the decision concerning the acceptability is technically purer as the decision concerning the acceptability of the MoE (the risk evaluation) is independent of the evaluation of the data in the risk characterization.

1.1.2 Procedures for Regulatory Assessment and Risk Evaluation

The simpler regulatory assessments and evaluations are often conducted by an individual using guidelines. Complex regulatory evaluations may be carried out by expert committees. Before dealing with specific procedures it is necessary to set out some general principles that underlie the procedures employed.

1.1.2.1 Source–Pathway–Receptor

Many regulatory assessments have to take into account where the chemical comes from and how it is released (the source of the exposure), the passage of the chemical from the source of the exposure to the receptor (the pathway) and the receptor, at which the chemical exerts its effect, when analysing risks and setting standards (**Figure 3**). Standards may be set at various points in the transfer from source to receptor, thus risk evaluations involving toxicological input may be required at several points during this transfer. These can include limits at source such as maximum inputs into the environment from a factory, often called emission limits or discharge limits, or maximum residue levels in food. Alternatives to limits at source are intake standards measured in one or all the appropriate media (air, water, food or soil). Occasionally, as with occupational lead exposure in the EU, uptake standards may be preferred.

Modelling is required to relate input to intake and uptake. There are many types of models, usually specific to the particular exposure circumstances, and hence to the particular regulatory scheme, so they will not be considered further here.

1.1.2.2 Dose Effect and Dose Response

Most adverse effects follow a continuum of severity, from normal, through homeostatic adjustment, to compensation by input of reserve capacity with possibility of repair, to breakdown (disability and death). In the individual, severity of effect increases with increasing dose. Biological variation in the sensitivity of individuals to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

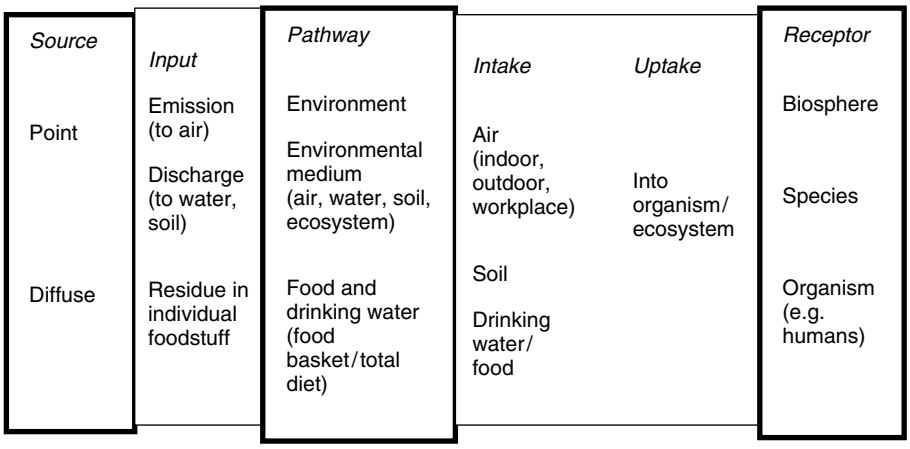

Figure 3 The passage of a chemical from source to receptor. (Reproduced with permission from Illing, 2006. © Royal Society of Chemistry.)

these effects means that the frequency of occurrence of a specific level of response can be represented by a dose–response relationship. If the individual variation in severity of effect with dose is small, a population dose–effect curve can be derived (see **Figure 4**), with its associated confidence limits, and the dose–response relationship is derivable from the statistics of the dose–effect curve.

Some substance/effect combinations (e.g. teratogenicity) are severe effects for which it is difficult to describe a dose–effect relationship, but for which there is a clear threshold. For these substance/effect combinations it is possible to set an equity-based safe limit (a broadly acceptable risk) or a utility/technological-feasibility base limit (a limit based on a tolerable risk).

Some harmful effects are quantal (all-or-nothing), appear random (stochastic) in terms of who they affect in the exposed population, and may be considered to be without threshold. Usually genotoxic substances that may cause cancer or heritable genetic damage are included in this category. Occupational asthmas are also occasionally included on grounds of very wide interindividual variations in susceptibility. Usually, the effect is considered to be 'all-or-nothing', and without a no-observed-adverse-effect level (NOAEL). A dose–effect relationship cannot be set out, but a dose–response relationship is clearly feasible and is assumed to have no threshold. In the USA, there have been attempts to describe a broadly acceptable risk for carcinogens, and methods have been developed for determining safe levels of exposure. However, these methods are not universally accepted. In other circumstances, the risk characterization, evaluation and management of these effects is based on the principle that there is no safe level of exposure; that is, that, under an equity-only-based risk management system, the substances must be banned. When present as contaminants, it may not be possible to ban the substances, and approaches based on the 'virtually safe' level of exposure have been adopted to deal with the problem. These approaches are based on utility and technological feasibility, and are therefore tolerable, rather than broadly acceptable, risks.

Approaches to toxic risk characterization and evaluation depend on whether the response is considered to have a threshold or not.

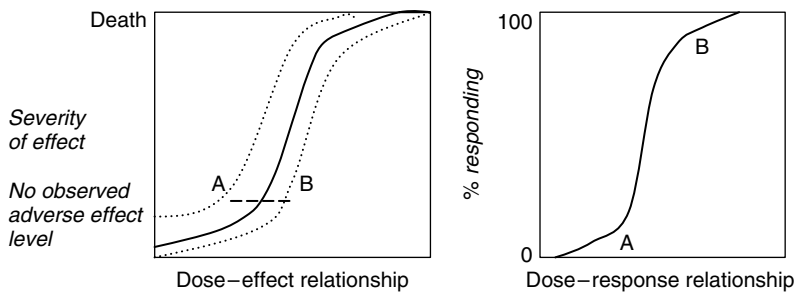

Figure 4 The relationship between dose effect and dose response. The dotted lines indicate the 95% confidence limits for the dose–effect relationship; taking the values for a fixed level of effect (AB) they can be transformed into the 5 and 95% dose values for the dose–response curve for that particular level of effect. 1.1.2.3 Testing Strategies, Test Methods and Evaluation Procedures

From the point of view of the notifier or registrant, a premarketing regulatory scheme includes four key elements:

- when to conduct which test (testing strategies);
- the protocols considered appropriate for that test (test methods);
- an audit process (such as Good Laboratory Practice (GLP))
- the procedures for evaluating the tests and, where necessary, inserting the results into the appropriate exposure model.

Testing strategies depend on the end points of interests for the particular regulatory scheme, and this may change with intended use. Hence, for example, there are core requirements and requirements related to specified uses in the EU scheme for biocides. Testing strategies may include staged testing, and, once some data have been evaluated, in particular areas (notably human medicines and personal care products) testing in humans becomes permissible.

Test methods may cover physical chemistry and structure–activity evaluation, acute and short-term toxicity (including skin and eye irritation and skin sensitization), repeated-dose toxicity, carcinogenicity, reproductive toxicity and studies examining specific aspects of toxicity, such as neurotoxicity or immunotoxicity. Regulatory schemes tend to divide into two groups when looking at test methods. One group follows the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) route, the other the OECD route. The biggest divergence is over reproductive toxicity testing, where the protocols are incompatible with one another. However, the emergence of these two blocks has considerably reduced the need to test for the same end point using a variety of marginally different protocols to satisfy different national regulatory bodies.

The advent of GLP and Good Clinical Practice (GCP), both audit systems, has reduced substantially the amount of duplicate testing, by making a test undertaken in one country and audited in accordance with agreed internationally accepted guidelines acceptable to other countries. These audit procedures were introduced following incidents concerning the accuracy of data submitted to regulatory authorities (see **Quality Assurance in Toxicology Studies**).

The procedures for evaluation may be kept in house by a regulatory authority, or they may be carried out by an independent body or by the notifier, depending on the regulatory scheme. If they are carried out externally from the regulatory authority, then guidance is published concerning how to interpret the results.

Regulatory toxicity tests are coarse screens for toxicity. Subtle effects may not be detected. Some toxic effects are well characterized ('known knowns'), others are identified but poorly characterized ('known unknowns') and others may not be detected by regulatory testing ('unknown unknowns'). Although any regulatory scheme seeks to minimize the known unknowns and unknown unknowns, it is unlikely that they can be eliminated entirely. Thus, for the last two groups of effects it is essential to include risk monitoring and re-evaluation, either periodically or on the basis of new information/new interpretations, in any regulatory scheme.

In the case of schemes not involving prior notification (e.g. for air or drinking water quality), the chemical is already present and the risk evaluation is based on available evidence, including, significantly, often much greater availability of human epidemiological data than there would be with a new chemical entity for use as a drug or pesticide. If further studies are required, usually the regulator has to fund them.

In recent years the ability of analysts to detect extremely low levels of chemicals (usually contaminants) has considerably increased. There is a level of presence of a chemical below which it is not considered worthwhile testing. Thus the concept of a threshold of toxicological concern has been developed. However, numerical thresholds usually depend to some extent on structure–activity relationships, as they vary for different end effects. In addition, some schemes include arrangements whereby there are levels of contamination for which only reduced testing of the contaminant is required. This is a useful tool in discouraging unnecessary testing of contaminants.

1.1.2.4 Methods for Effects That Have a Threshold

1.1.2.4.1 Uncertainty-Factor Approach for Intake/Uptake

In regulatory toxicology there are two ways of conducting the risk assessment and risk evaluation. In the first way, used for standard settings, the risk characterization is combined with the risk evaluation. In one procedure, the uncertainty-factors (UFs) (formerly called safety factors) approach, the risk characterization is set against standard, predefined risk evaluation criteria, and a maximum safe (however defined) level of exposure determined (the reference dose (RfD, also called the health-based guidance value), or, for the EU REACH (Registration, Evaluation, Authorisation and restriction of CHemicals) regulation, the derived no-effect level). The definition of an uncertainty factor is:

> *A reductive factor by which an observed or estimated NOAEL is divided to arrive at a criterion or standard that is considered safe or without appreciable risk.*
> *(OECD, 2003; IPCS, 2004)*

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The UFs approach can be described by the equation:

$$\text{RfD} = \frac{\text{NOAEL (or LOAEL or BMD)}}{\text{Uncertainty and modifying factors}} \qquad (1)$$

Where LOAEL is the lowest-observed-adverse-effect level; BMD is the benchmark dose—these and NOAEL essentially are dose levels at which no or very minor adverse (and, usually reversible) effects are seen. The BMD is a statistically based procedure favoured in the USA. The critical effect is that which, under the exposure conditions, yields the NOAEL, from which the RfD is calculated. The pivotal study is the study from which the critical effect NOAEL is derived.

In this process, hazard identification, hazard characterization and risk evaluation criteria are combined to produce a maximum safe level of exposure. The hazard identification and hazard characterization includes determination of relevant physicochemical and toxicological properties through testing and, where available, appropriate human or other target-species studies (experimental studies, clinical trials and epidemiology). The specific mix of studies depends on the particular regulatory scheme. Although variants are employed by the different regulatory authorities, the actual procedure used for the combined risk characterization and evaluation is essentially that set out in EHC (environmental health criteria) 170 (IPCS, 1994), and is given in **Figure 5**.

Data packages will usually generate many NOAELs, depending on the duration, type of exposure and type of study; some studies, for example studies of developmental toxicity, will generate more than one (in this case for the dams and the offspring). Thus it may be necessary to adjust from one route to another, or from, say, a 28-day repeated-dose study to a 90-day repeated-dose study. Assumptions (usually worst-case, in the absence of information) are usually made concerning the route-to-route extrapolation. Thus, ideally, such extrapolation should be avoided. Generally NOAELs decrease with duration of exposure, so UFs may be used to adjust a NOAEL from a study of one length of duration to a NOAEL at another duration.

The original pragmatic uncertainty factor for an equity-based broadly acceptable level of risk (safe exposure) was set at 100, over 50 years ago (Lehman and Fitzhugh, 1954). It has remained at this value when a complete set of good-quality studies is available to the regulator, even though what constitutes a complete set of studies has been greatly extended. Where good experimental human data are used to derive the RfD, a UF (usually 10) is used to cover variability in the human population, and where animal data are used a further UF (often 10, making $10 \times 10 = 100$ *in toto*) is used. The 10-fold UF for extrapolation from animals to humans is used because there are often no data on the relative sensitivity of humans and animals. Both 10-fold factors have been divided, more or less arbitrarily, as being partly due to toxicokinetics and partly due to toxicodynamics (IPCS, 1994; 1999). Although detailed examinations have been conducted to validate these assumptions *post hoc*, they remain no more than pragmatic judgements based on experience. If actual data for toxicokinetics and toxicodynamics are available (e.g. from physiologically based toxicokinetic modelling or from biologically based dose–response modelling), such data can be substituted for the pragmatic assumption. A further pragmatic assumption, application of an extra factor of 10 for seriousness of effect, is often used when dealing with teratogens and nongenotoxic carcinogens; that is, when there is a severe effect for which it is difficult to describe a dose–effect relationship.

Although there have been a number of attempts to put UFs onto a more scientific basis, they remain pragmatic assumptions. This use of pragmatic assumptions means that, where the RfD is breached, it cannot be assumed that an adverse effect will occur.

One reason why pragmatism is likely to persist is that UFs may also have to take into account societal judgements (Illing, 1999). It is notable that, in the past, occupational exposures, which have to allow for utility/technical feasibility criteria as well as equity criteria, and therefore cannot afford the same level of disproportion, have tended to use smaller uncertainty UFs (Fairhurst, 1995).

1.1.2.4.2 Margin-of-Exposure Approach for Intake

The MoE approach is technically purer than the uncertainty-factors approach as it separates the risk characterization (and hence the risk assessment) from the risk evaluation.

The margin of exposure is defined as: ratio of the no-observed-adverse-effect level for the critical effects to the theoretical, predicted or estimated exposure dose or concentration (OECD, 2003; IPCS, 2004).

The margin-of-exposure approach can be described by the equation:

$$\text{MoE} = \frac{\text{NOAEL (or LOAEL or BMD)}}{\text{Predicted or estimated exposure}} \qquad (2)$$

The ideal is to use measured exposure, but predicted exposure often is the only exposure data available. Models are often used to obtain predicted exposure. These may include models for route-to-route extrapolation as the data available may be for the wrong route of exposure (e.g. oral, rather than inhalation), as well as models for predicting the frequency and dose (exposure level and duration). There are many types of models, usually specific to the particular exposure circumstances, so they will not be considered further here.

With the MoE approach, social, political and other factors affecting the risk evaluation are separated from the scientific and technical process of risk assessment.

For some experts the 'margin of safety' is an alternative term and has the same meaning as the MoE (OECD,

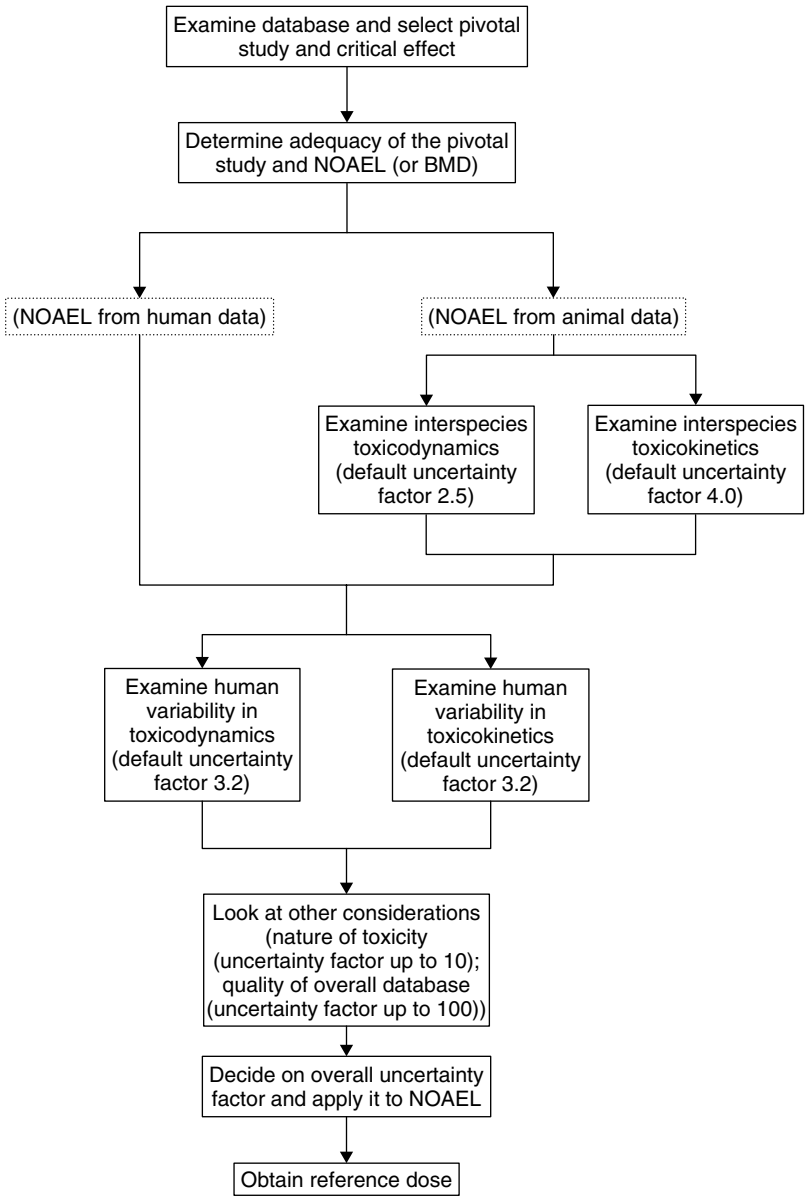

Figure 5 Procedures for the derivation of exposure standards—'uncertainty-factors' approach. NOAEL—no observed adverse effect level; BMD—benchmark dose. (Reproduced with permission from Illing, 1999. © Elsevier.)

2003). For others, the margin of safety means the margin between the RfD and the actual exposure or concentration. Thus, if the term 'margin of safety' is employed it is important to know how it has been defined.

1.1.2.5 Extrapolation for Nonthreshold Effects—Cancers and Heritable Genetic Effects

The biggest divide in toxicological risk analysis occurs in respect to attitudes to the evaluation of carcinogens. In the USA and elsewhere, extrapolation is undertaken using numerical approaches based, if necessary, on animal studies and mathematical modelling. The currently favoured model is linear extrapolation from the low 95% confidence limit for a dose associated with a 10% extra risk (LED_{10}) (IPCS, 1999). In essence the mathematical model is a device for obtaining a safe level of exposure (a broadly acceptable risk).

In the UK, regulators do not generally accept such procedures. They deem that:

- the methods are not validated;
- they are often based on incomplete or inappropriate data;
- they are derived more from mathematical assumptions than from a knowledge of biological mechanism;
- they demonstrate a disturbingly wide variation in the risk estimates, depending on the models used.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Thus exposure is eliminated, where possible, or reduced 'as low as is reasonably practicable' (IGHRC, 2002). This approach is based, where possible, on applying an equity-based criterion for evaluation of the toxicity, and where a contaminant cannot be eliminated, applying utility and technological-feasibility criteria to establish a standard based on a risk sufficiently low as to be unquantifiable (Maynard *et al*., 1995), effectively a minimal tolerable risk.

This difference between the mathematical approach and the pragmatic approach probably arises from cultural differences associated with the acceptability of mathematical modelling, and legislative differences concerning how carcinogens should be treated.

1.1.2.6 Inputs and Input Standards

Input standards include discharge limits from factories to air or sewerage systems, and MRLs in meat or fruit and vegetables, or maximum amounts of toxic chemicals in cosmetics. Input information may also be required for prediction when dealing with the toxicity associated with major accident hazards. Modelling is required to relate input to intake. There are many types of models, usually specific to the particular exposure circumstances, so they will not be considered further here.

1.1.2.7 A Cautionary Note

In recent years the development of guideline exposure standards has become increasingly internationalized. Although international guideline standards have been set, they are usually based on first world attitudes to risk and life expectancy, thus they may be appropriate for first world nations but wholly inappropriate when dealing with other conditions. What constitutes adequate evaluation and control depends on attitudes to risk and background morbidity and mortality data. When agriculture is involved, the problems associated with the background agroecosystems also have to be taken into consideration. Hence, although the underlying hazard characterization (and toxicology) remains relevant, there is a need to adapt the risk characterizations and risk evaluations, together with the approaches to risk management, to reflect particular exposure circumstances.

1.1.2.8 Hazard Characterization

In certain regulatory schemes, notably those for chemicals based on the OECD approach, substances may be classified solely on their hazardous properties. Classifications based on simple tests, clear end points and definite criteria may be deterministic (classifiable/not classifiable) or more quantitative (grade as very toxic, toxic or harmful). When tests are complex, end points difficult to interpret and criteria difficult to define, classification is a simple deterministic statement based on quality and type of evidence. This information is then passed through the supply chain, through, for example, information sheets or safety data sheets. The various recipients conduct appropriate risk evaluations at the different stages of the supply chain. This classification is becoming more international as countries and supranational blocks, such as the EU, are implementing the UN Globally Harmonized System (GHS) for classification of the hazardous properties of a chemical (European Parliament and Council, 2008).

2 TYPES OF REGULATORY SCHEMES

Thus there are numerous regulatory systems worldwide, most concerning particular groups of compounds, for example drugs, pesticides, industrial chemicals, and originally, at least, covering one country. The tendency over the last few years has been for trading groups such as the EU and the North American Free Trade Area (NAFTA) to centralize procedures; further there have been attempts to harmonize data requirements, within and between trading blocks. The various systems fall into a few patterns (Diggle, 1999) (**Table 2**). Note that the difference between these schemes is often one of degree, and the EU schemes for pesticides and, for example, food additives are quite similar on paper, the main difference being that new pesticides are common and new food additives less common.

In the UK, pesticides were formerly regulated by a voluntary scheme (the Pesticides Safety Precaution Scheme), as were novel foods. In addition to formal regulatory mechanisms, the law of tort may apply in common law countries, if untoward effects are attributable to a substance.

Table 2 Type of regulatory framework

Type of scheme	Effect	Examples
Premarketing authorization	The marketing of the product can be authorized only after the regulatory body has examined safety and efficacy	Human and veterinary pharmaceuticals; pesticides
Allowed/proscribed lists	There are official lists of allowed and/or proscribed ingredients; individual authorization is not necessary	Cosmetics; food additives
Notification schemes	The individual substance does not need to be authorized, but its use/sale/manufacture has to be notified, together with the basic properties of the compound.	Industrial chemicals (REACH)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

It should be remembered that strict regulation is not a win–win situation in all circumstances. Thus fungal toxins are a major cause of mortality and morbidity in some countries (Wang *et al*., 1998), as are parasites in food of animal origin (Kraft, 2007); insect vectors are a major cause of disease in human populations and control is usually at least partially by chemical means. Further, large companies can deal with regulations more easily than small companies, so that regulation may inhibit competition and drive small businesses from the market (Booker, 2008).

Below are discussed some of the regulatory systems for the main groups of chemicals, using the systems in the EU and USA as exemplars.

2.1 Premarketing Authorization Systems

These systems are used most notably for human and veterinary pharmaceuticals and for pesticides. In such systems, safety and efficacy data are presented by the applicant (usually the organization wishing to market the substance) to the regulatory body, which, in the United Kingdom (UK), may rely upon the advice of an expert committee (the Committee on the Safety of Medicines, the Veterinary Products Committee and the Advisory Committee on Pesticides (ACP), respectively). In each case, national systems have largely been subsumed into an EU system. With a very few exceptions data have to be generated according to GLP.

2.1.1 Regulation of Pharmaceuticals for Use in Humans

Most countries have a system for regulating pharmaceuticals based on safety, quality and efficacy, in which the regulator has to make a judgement weighing risk against benefit for the patient.

2.1.1.1 In the European Union

In the EU, Directive 65/65 (Council of the European Economic Community, 1965) as amended, provides the legal basis for the regulation of human pharmaceuticals ('medicinal products'). Other directives established standards for testing the products. Furthermore a committee, the Committee for Proprietary Medicinal Products (CPMP), was established as well an agency, the European Medicines Evaluation Agency (EMEA) in London, UK.

The notice to applicants is a guide from the European Commission intended primarily for the pharmaceutical industry, but the notice gives a detailed overview of the system. Volume 2A covers the procedures for marketing authorization (European Commission, 2005–2007), Volume 2B covers presentation and content of the dossier (European Commission, 2006a), while Volume 2C covers the regulatory guidelines themselves (European Commission, 2003–2007). These documents are regularly updated. The format of applications for marketing authorization has been standardized throughout the EU (European Commission, 2006a).

2.1.1.1.1 Preclinical Data Requirement

The toxicological data requirements depend on a number of factors, including proposed duration of dosing and the population, for example whether the drug will be used in women of child-bearing age. Acute and repeated-dose toxicity studies are required, the latter with a duration depending on the proposed duration of human treatment. Studies of reproductive, developmental and perinatal toxicity are usually required as well as mutagenicity tests *in vitro* and *in vivo,* and carcinogenicity. Omission of particular studies needs to be justified.

2.1.1.1.2 Clinical Trials

An essential feature in bringing a new drug to market is the clinical trial. Clinical trials in the UK are regulated under the Medicines for Human Use (Clinical Trials) Regulations (2004). Studies must be in accordance with the Declaration of Helsinki (1964), which set out ethical guidelines for human volunteer studies (see also WMA, 1996). Directive 91/507/EEC (Commission of the European Communities, 1991) lays down that clinical trials should be carried out according to GCP.

2.1.1.1.3 Marketing Authorizations

To obtain a marketing authorization, there are two routes that can be followed, a centralized procedure, and the mutual recognition procedure. In the former, the application is made to the EMEA. A rapporteur, who is a CPMP member, is appointed to lead the scientific evaluation. The CPMP gives an opinion on whether a marketing authorization should be granted. This is passed to the European Commission and thence to the standing committee on medicinal products (SCMP) for human use, which comprises representatives of the member states. If the SCMP's decision is favourable, the Commission makes the final decision (or in certain circumstances the European Council). In the mutual recognition procedure, a pharmaceutical company with a marketing authorization in one member state can ask one or more other member states to recognize a marketing authorization granted by the first member state. There are procedures for objections by member states and for arbitration.

2.1.1.1.4 Pharmacovigilance

The holder of a marketing authorization has certain responsibilities after the granting of the authorization. These include gathering and acting upon information bearing on the safety of the drug, comprising, for example, suspected adverse reaction reports and

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

published literature, including clinical reports and epidemiological studies.

2.1.1.2 In the USA

The basis of the regulation of pharmaceuticals in the USA is the Food, Drug and Cosmetic Act (1938), passed in the wake of a therapeutic disaster in 1937, in which a Tennessee drug company marketed a sulfonamide as an elixir for paediatric patients (Elixir Sulfanilamide). The solvent in this untested product was a highly toxic compound. Initially the requirement was for evidence of safety, but the Kefauver–Harris Amendments imposed additional requirements for evidence of efficacy. The agency regulating pharmaceuticals is the Food and Drug Administration (FDA).

2.1.1.2.1 New Drug Applications (NDAs)

The first stage after a drug development programme is the investigational new drug (IND) application. This is not an application for marketing approval. US federal law prohibits movement from one state to another of pharmaceuticals, without an approved marketing application. Because a sponsor will probably want to ship the investigational drug to clinical investigators in many states, the IND is needed for clinical trials. Approval for marketing is based on the new drug application (NDA). This now requires evidence of safety and efficacy and the information is presented in a standardized format (Applications for FDA approval to market a new drug. Content and format of an application, 1999).

Application for the IND and NDA is made to the FDA, and the toxicological data requirements are similar to those in the EU.

2.1.1.3 International Conference on Harmonisation (ICH)

The ICH brings together the regulatory authorities of Europe, Japan and the United States, together with experts from the pharmaceutical industry in the three regions, with the aim of making recommendations on ways to harmonize interpretation and application of technical guidelines and requirements. One result of this is to obviate the need for duplicating studies for guidelines that may be only slightly different, and thereby, for example, reduce experimental animal usage. The process has proceeded well, and the sixth International Conference on Harmonisation took place in Osaka, Japan, in November 2003. The main focus of the technical discussions at the conference was on the implementation of the Common Technical Document, that had been adopted at the previous conference in 2000 and which has become the required format for submissions in the EU and Japan, and the strongly recommended format in the USA.

2.1.2 Veterinary Pharmaceuticals

As with human pharmaceuticals, most counties have a system for regulating veterinary pharmaceuticals based on safety, quality and efficacy, in which the regulator has to make a judgement weighing risk against benefit for the animal. However there are two additional considerations for veterinary medicines. The first is that, in food-producing animals, human safety must be considered, in addition to that of the animals. The reason for this is that the use of veterinary medicines may give rise to residues in food. A second consideration is that, with companion animals, human exposure may be important; this is especially the case with ectoparasiticides used on cats and dogs. An additional consideration is that some veterinary medicines (e.g. sheep dips) may have a significant environmental impact.

2.1.2.1 In the European Union

In the EU, Directive 65/65 (Council of the European Economic Community, 1965), as amended, provides the legal basis for the regulation of veterinary pharmaceuticals ('veterinary medicinal products'), as with human medicines. Other directives established standards for testing the products. Furthermore a committee, the Committee for Medicinal Products for Veterinary Use (CVMP[a]), was established and this responsible for preparing the opinions of the EMEA[b] on all questions concerning veterinary medicinal products, under Regulation EC 726/2004 (European Parliament and Council, 2004a). The CVMP meets at the EMEA in London.

2.1.2.1.1 Preclinical Data Requirement

The toxicological data requirements depend on a number of factors, most importantly whether the product will be used in food-producing animals. In such animals, maximum residue limits need to be established for human safety purposes (see below). The veterinary equivalent of the clinical trial in humans is the animal trial, which may be a tolerance study (i.e. to show that the animal tolerates the drug, without unacceptable adverse effects). In addition, in food-producing animals, the safety of residues left in foods to be eaten by human consumers must be demonstrated, taking account of pharmacological, toxicological and microbiological end points, and also residue depletion studies will be required for the product. Where maximum residue levels have been set, withdrawal periods may need to be set for the product to ensure that none of the MRLs for different foods derived from the treated animal are exceeded.

2.1.2.1.2 Marketing Authorizations

As with human drugs, to obtain a marketing authorization, there are two routes that can be followed, a centralized procedure and the mutual recognition procedure.

In the former, the application is made to the EMEA and the outcome is binding on all the member states. A rapporteur, who is a CVMP member, is appointed to lead the scientific evaluation. The CVMP gives an opinion

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114

on whether a marketing authorization should be granted. This is passed to the regulatory committee (the standing committee on veterinary medicinal products (SCVMP)), which comprises representatives of the member states. If the SCVMP's decision is favourable, the Commission makes the final decision; the outcome, if favourable, being an EU-wide marketing authorization. In the mutual recognition procedure, a pharmaceutical company with a marketing authorization in one member state can ask one or more other member states to recognize the authorization granted by the first member state. There are procedures for objections to be made by member states and for arbitration, in which the opinion of the CVMP will be sought.

2.1.2.1.3 Maximum Residue Levels (MRLs) and Food Safety

MRLs are levels of veterinary drugs that may not be exceeded in foods of animal origin. The legal basis for pan-EU MRLs is regulation EEC 2377/90 (Council of the European Communities, 1990a). This has four annexes:

Annex I: Substances with full MRLs
Annex II: Substances which do not require MRLs
Annex III: Substances with provisional MRLs
Annex IV: Substances where MRLs cannot be established on human safety grounds.

The fundamental effect of this is that only substances on Annexes I, II and III can be used in food-producing animals. The basis for establishing the MRLs is a full toxicological data package, similar to that required for other food contaminants, including studies of acute and repeated-dose toxicity (including chronic toxicity), reproductive and developmental toxicity, genotoxicity and carcinogenicity. Additionally, pharmacokinetic and pharmacodynamic studies in laboratory animals are required as well as in the target species. The full list is given in Regulation EEC 2377/90 (Council of the European Communities, 1990a). The Commission has published a draft regulation to replace Regulation EEC 2377/90, available at *http://eurlex.europa.eu/LexUriServ/site/en/com/2007/com2007_0194en01.pdf* (see below). Risk assessment is carried out using the toxicological data. For some substances, it is also necessary to consider the pharmacodynamic effects that might occur at lower doses than those causing toxicity. The general pattern is that the appropriate NOEL, generally the lowest NOEL in the most sensitive species (known as the critical NOEL), divided by a safety factor (often 100) is used to calculate an acceptable daily intake (ADI). For microbiologically active substances, the effects on the human gut flora are also taken into account when setting the ADI. The MRLs are then based upon the fact that the ADI should not be exceeded and this must take into account distribution of the substance in the animal, the data on distribution coming from residue depletion studies in the target animal. The other data needed to elaborate MRLs from ADIs are 'food factors'; these are daily consumption quantities for animal products.

2.1.2.2 *In the USA*

In some ways, the regulation of veterinary drugs is simpler in the USA than the EU, but a major difference is that veterinary ectoparasiticides are regulated by the United States Environmental Protection Agency (US EPA) under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) (Federal Insecticide, Fungicide and Rodenticide Act, 1947; see also Protection of Environment: Part 152—Pesticide Registration and Classification Procedures, 2001), as pesticides. Vaccines are regulated by the United States Department of Agriculture (US DA). The basis of the regulation of all other veterinary pharmaceuticals in the USA is the Food, Drug and Cosmetic Act (1938), as amended (see above), and the agency responsible is the FDA, as for drugs for human use.

2.1.2.2.1 New Animal Drug Applications (NADAs)

The first stage after a veterinary drug development programme is the investigational new animal drug (INAD), which is the counterpart of the IND for drugs for use in humans. An INAD is needed for trials in animals. Approval for marketing is based on the new animal drug application (NADA). The NADA is the counterpart of the NDA.

Applications for INADs and NADAs are made to the FDA, and the toxicological data requirements are similar to those in the EU.

2.1.2.2.2 Tolerances and Food Safety

Tolerances in the USA are levels of veterinary drugs that may not be exceeded in foods of animal origin. A full toxicological database is required to assure consumer safety for veterinary products used on food-producing animals, similar to that required in the EU. Guidelines on the studies required are available and are periodically updated: these are available at the Center for Veterinary Medicine on *www.fda.gov/cvm*. Risk assessment is carried out using the toxicological data. The general pattern is that the appropriate NOEL, generally the lowest NOEL in the most sensitive species (known as the critical NOEL) is divided by a safety factor, which is often 100, but more if the database is defective or certain toxicological end points are seen. This procedure produces the ADI. A safe concentration of the drug is calculated from the ADI and a food factor (1 for muscle, higher for some offal), and a meat intake factor (500 g in an adult).

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2.1.2.3 International Activities

2.1.2.3.1 Veterinary International Cooperation on Harmonisation (VICH)

International Cooperation on Harmonisation of Technical Requirements for Registration of Veterinary Medicinal Products (Veterinary International Cooperation on Harmonisation (VICH)) is the veterinary counterpart of ICH for human pharmaceuticals and was launched in 1996. The aim of VICH is to make recommendations on ways to harmonize interpretation and application of technical guidelines and requirements. VICH is a series of meetings of officials from regulatory authorities of Europe, Japan and the United States together with experts from the pharmaceutical industry in these three regions/countries. The most recent (third) conference took place in Washington, DC, USA, 25–27 May, 2005.

2.1.2.3.2 Codex and the Joint Expert Committee on Food Additives (JECFA)

The Joint Expert Committee on Food Additives (JECFA) is an expert Committee jointly organized by the World Health Organization (WHO) and the Food and Agricultural Organization (FAO) of the United Nations. Some of JECFA's meetings are devoted to veterinary drugs and the Committee deals with residues and toxicology, producing both ADIs and MRLs. The Codex Alimentarius Commission (CAC) was created in 1963 by the FAO and WHO to develop food standards, and the MRLs and ADIs produced by JECFA are taken into the Codex Alimentarius system via the Codex Committee on Residues of Veterinary Drugs in Foods. The agreement on the application of sanitary and phytosanitary (SPS) measures (SPS agreement, WTO, 1994), achieved after tortuous negotiations in 1994, requires that, in most circumstances, CAC MRLs for *inter alia* veterinary residues be accepted for world trade purposes. This has inevitably raised the profile of the FAO/WHO expert committees such as the JECFA. Amongst the effects of the draft EU regulation to replace regulation EEC 2377/90, there would be an obligation to adapt Community legislation to include MRLs set by Codex with the support of the EU (European Commission, 2007). Thus Codex MRLs would generally be adopted by the EU.

2.1.3 Regulation of Pesticides and Biocides

2.1.3.1 In the European Union

The first European legislation to impinge on pesticides was Directive 79/117/EEC (Council of the European Communities, 1979), which forbade the marketing and use of plant protection products containing certain active substances. A comprehensive legal basis for regulation of agricultural and horticultural pesticides was commenced with Directive 91/414 (Council of the European Communities, 1991); under this directive such pesticides are referred to as plant protection products. The legal basis for regulation of nonagricultural pesticides (biocides) is Directive 98/8/EC (European Parliament and Council, 1998) (see below). Directive 91/414 is under review (European Commission, Health and Consumer Protection Directorate-General, 2004).

Before these directives came into force, the member states of the EU had their own national systems. In the UK, the first systematic controls were voluntary, through the notification of pesticides scheme, introduced in 1957, renamed the pesticides safety precautions scheme (PSPS) in 1964, following a review to ensure the scheme met the needs of the time (Miller, 1965; I. Rowland, 2008, personal communication, Pesticides Safety Directorate, York). The PSPS was a voluntary arrangement agreed between government departments and industrial associations. A major change was the introduction of the Control of Pesticides Regulations (1986) and Control of Pesticides Regulations (Northern Ireland) (1987), made under the Food and Environment Protection Act (1985), whereby the system was put on a statutory basis. The Pesticides Safety Division (later 'Pesticide Safety Directorate') of the Ministry of Agriculture, Fisheries and Food (PSD) was responsible for administering the system with regard to agricultural and horticultural pesticides and the Health and Safety Executive (HSE) was responsible for administering the system with regard to nonagricultural pesticides. In both cases, advice was given by the Advisory Committee on Pesticides (ACP), a committee of independent experts.

2.1.3.1.1 Marketing Authorizations

Directive 91/414 set out harmonized requirements for the authorization of plant protection products. The Directive provided for the compilation of three annexes.

Annex I: Active substances which may be incorporated into products intended for use.
Annex IIA: Requirements for the dossier to be submitted for the inclusion of an active substance in Annex I.
Annex IIIA: Requirements for the dossier to be submitted for the authorization of a plant protection product (Annexes IIB and IIIB deal with active substances and products consisting of micro-organisms, including viruses).

2.1.3.1.2 Data Requirements

Annex II, Part A, gives details of the toxicokinetic and toxicological data needed on the active substance (i.e. the ingredient(s) of the plant protection product with pesticidal activity); Annex II also covers environmental fate, ecotoxicology, physical and chemical properties and residues in treated crops. The toxicology data include studies of acute and repeated-dose toxicity, reproductive and developmental toxicity, genotoxicity and carcinogenicity. Any available human data as well as

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

proposed medical counter-measures need to be submitted. Additionally, studies of delayed polyneuropathy may be required. Studies on the toxicity of metabolites may be required as well. Annex III lists the required toxicological studies on the product (as opposed to the active substance). These include acute oral, percutaneous and inhalation toxicity, skin and eye irritancy and skin sensitization. Any toxicological data available on nonactive substances is also requested. From these data, ADIs, acute references doses (ARfDs) acceptable operator exposure levels (AOELs) and dermal absorption values are calculated (see below). Data on operator and bystander exposure are also generally required.

2.1.3.1.3 Field Trials and MRLs

Unlike MRLs for other food contaminants, for example veterinary drugs used in food-producing animals, MRLs for pesticides are not, in themselves, safety limits, although they should be consistent with food safety. They are generated from data from field trials where the pesticide is used according to good agricultural practice (GAP), that is, the pesticide being used in the correct amounts and using the appropriate preharvest interval. One role of MRLs is to ensure that pesticides are, indeed, used according to GAP. Numerous directives have been adopted with the aim of harmonizing MRLs within the EU: recently regulation 396/2005 (European Parliament and Council, 2005) has sought to further this process. This regulation has four draft annexes:

Annex I: This includes all products for which MRLs are set, as well as the other products for which it is appropriate to apply harmonized MRLs (see also Regulation (EC) No. 178/2006 European Commission, 2006b).
Annex II: This contains MRLs already established by Directive 86/362/EEC covering MRLs on cereals (Council of the European Communities, 1986a), Directive 86/363/EEC, covering MRLs for foodstuffs of animal origin (Council of the European Communities, 1986b) and Directive 90/642/EEC MRLs for foodstuffs of plant origin (Council of the European Communities, 1990b).
Annex III, Part A: This lists all draft temporary MRLs that are thus far not harmonized at EU level.
Annex III, Part B: This lists all draft temporary MRLs of active substances harmonized at EU level in and on new commodities.
Annex IV: This lists active substances for which no MRLs are needed.

2.1.3.1.4 Obtaining Marketing Authorizations

In order to obtain a marketing authorization in the EU, an applicant must submit a dossier in line with the requirements of Annexes II and III of Directive 91/414 data. The applicant chooses a Rapporteur Member State (RMS), which will confirm if the dossier is complete, and if other member states agree, the RMS produces a monograph (draft assessment report (DAR)). Originally this was reviewed by experts at European Community Coordination (ECCO) meetings. Before the establishment of the European Food Safety Authority (EFSA), the final decision on whether to include the active substance in Annex I of Directive 91/414 was made by the European Commission after obtaining an opinion from the Scientific Committee on Plant Health (SCPH). This opinion was delivered by member states in the SCPH following consideration in full working group meetings (attended by representatives from all the member states), and was reached by qualified majority voting. Since the establishment of the EFSA, the Standing Committee on the Food Chain and Animal Health (SCFCAH) has taken over the functions of the SCPH. The current peer review process involves the circulation of the completed DAR to the EFSA and all member states for a series of written commenting rounds. There is then a discussion at an expert peer review meeting organized by the EFSA (Pesticide Risk Assessment Peer Review Unit (PRAPeR)), which agrees the toxicological end points (see *www.efsa.europa.eu/EFSA/ScientificPanels/efsa_locale-1178620753812_PRAPER.htm*). The EFSA then produces a conclusion report (see *www.efsa.europa.eu/EFSA/ScientificPanels/PRAPER/efsa_locale-1178620753812_Conclusions494.htm*), which is used by the Commission and member states to determine, in the SCFCAH, if the active substance should be listed on Annex 1 of Directive 91/414. Independent expert advice can be sought from the EFSA Panel on Plant Protection Products and their Residues (PPR—see *www.efsa.europa.eu/EFSA/ScientificPanels/efsa_locale-1178620753812_PRAPER.htm*).

2.1.3.1.5 Surveillance

Under European legislation, member states must have in place programmes for the surveillance of residues in food (Council of the European Communities, 1990b; European Commission, 2000a). There is an obligation on member states to communicate the results to the European Commission. These programmes provide checks on whether MRLs are being exceeded (i.e. GAP is being followed), that pesticide residues are not posing a risk to public health and that residues of pesticides not authorized in particular crops are not present. In the UK, pesticide residues in food and drink are monitored under an official surveillance programme conducted by the Government's Chemicals Regulation Directorate of the HSE (formerly the Pesticides Safety Directorate) and overseen by the Pesticide Residues Committee (PRC), which comprises independent experts. The UK programme is mainly directed towards foods where residues are considered likely to be present, often on the basis of previous experience, so the finding cannot be taken

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

as representative of the whole UK food supply. Similar targeted approaches are used by other member states.

2.1.3.1.6 Consumer Risk Assessment

As with other food regulatory systems, the typical procedure is to use the most sensitive study in the most sensitive species (the critical study), incorporate a UF of (typically) 10 for extrapolation from animals to humans and a further UF of (typically) 10 for interindividual human variation. With all pesticides this procedure is used to generate ADIs and, with some, ARfDs. The former are used for chronic risk assessment and the latter where it is considered appropriate to undertake an acute risk assessment. Premarketing data from field trials are used for dietary risk assessment. A major difference from the USA is that nonthreshold carcinogens (genotoxic carcinogens) will not usually receive marketing authorizations.

2.1.3.1.7 Plant Metabolites

The main concern with plant metabolites is that they may represent a toxicological risk, in that, where risk assessment is based on animal studies, as it usually is, the animals may not have been exposed to such metabolites. If analysis indicates that residues in edible portions of the crop following treatment as proposed are $<0.01\,mg\,kg^{-1}$ for human food, or $<0.05\,mg\,kg^{-1}$ for animal feed, no characterization of terminal metabolites is usually required. If levels are above this, it is necessary to characterize and identify all single components of the residue which exceed $0.05\,mg\,kg^{-1}$ or 10% of the total radioactive residue and to characterize fractions or individual components of the residue which represent $0.01–0.05\,mg\,kg^{-1}$ (Directorate General for Agriculture, 1997; this document predates the establishment of the EFSA and it is likely that further guidance will be issued in the future).

2.1.3.1.8 Occupational Safety

Providing AOELs are not exceeded, it is expected that adverse effects will not be seen in those handling pesticides. In the UK, the Health and Safety Executive (HSE) is responsible for worker safety. Complaints involving pesticides are investigated by the Field Operations Directorate (FOD) of the HSE, and the Pesticide Incidents Appraisal Panel (PIAP), which comprises a mixture of government officials and nongovernment members, considers all incidents reported to FOD where there is any allegation that the use of a pesticide has caused ill health. PIAP is notified of these incidents only on completion of the inspector's investigation.

2.1.3.1.9 Review of Existing Substances

A review programme was established, under regulation 3600/92/EEC (Commission of the European Communities, 1992), for existing substances, that is, active substances on the market at the time Directive 91/414 came into force. The process for review was similar to the process for new active substances, with preparation of a DAR by a rapporteur member state (RMS), and peer review. There was considerable slippage in the first rounds of the review process. Subsequent changes to the procedures are aimed at completing the review of all existing active substances by the end of 2008.

2.1.3.1.10 Revision of Directive 91/414

This Directive is under review at the moment and important changes include the introduction of comparative assessment and (if necessary) substitution, and the removal of the option for the granting of national provisional authorizations for products containing new active substances pending Annex I inclusion. Furthermore, it is proposed that hazard triggers will take the place of much of the risk assessment presently used. The proposed revisions are subject to consultation, and industrial organizations and other interested parties have commented on the proposals (ECPA, 2005). The proposed alterations have been criticized as being not evidence based, and for having an adverse effect on food production (Trewavas, 2008; Buckenham, 2008; Titford, 2008). The effect is likely to be far ranging, with pesticides being regulated in a different way from other chemicals in the EU and from pesticides in other parts of the world (see also ADAS, 2008).

2.1.3.1.11 Pesticides in Water

The 1980 European Community Drinking Water Directive (80/778/EEC) (Council of the European Communities, 1980) set a standard for total pesticides in drinking water of $0.5\,\mu g\,l^{-1}$, and of $0.1\,\mu g\,l^{-1}$ for each individual pesticide. The latter concentration was equivalent to the detection limits of analytical methods available at the time and is not toxicologically based. These limits have been retained in subsequent EU legislation (Council of the European Union, 1998).

2.1.3.1.12 Biocides

The legal basis for the regulation of biocides in the EU is Directive 98/8/EC (European Parliament and Council, 1998). Biocides are defined so as to include disinfectants, chemicals used for preservation of products and materials (including wood), nonagricultural pesticides, products for controlling mice and rats and insects such as cockroaches and ants, and antifouling products used on hulls of boats. The Directive even covers embalming fluid!

From May 2000, new active substances have to be authorized as described below and there is provision for a 10-year review of products and active substances already on the market. There are a number of Annexes to the Directive. Of interest to the toxicologist are I, II, V and VI. Annex I is the list of permitted active substances; Annex IIA lists the core dataset required for active substances; Annex IIB lists the core dataset for products; Annex V lists the various types of biocides, and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Annex VI lists the common principles for the evaluation of dossiers (other annexes deal with microbiological biocides). The basic principles of Directive 98/8/EC are that active substances have to be assessed and the decision on their inclusion into Annex I of the Directive made at EU level. Toxicological data requirements are similar to those required for agricultural pesticides under Directive 91/414, however the principle of comparative assessment may be used under Directive 98/8/EC, that is, an active substance may be excluded from Annex I if there are less harmful, suitable substitutes available. Member states can only authorize products which contain active substances included in Annex I, and authorization of biocidal products has to done according to Annex VI of the Directive. There is also a provision for mutual recognition of product authorizations between member states.

As Directive 98/8/EC has caused a large number of products to be removed from the market, including many disinfectants, even disinfectant soaps, it remains to be seen, in these days of meticillin-resistant *Staphylococcus aureus, Clostridium difficile* and other hospital cross-infections, whether the impact on public health will be beneficial (see Booker, 2008).

2.1.3.2 *In the USA*

The first federal pesticide legislation predates most legislation in Europe and dates from 1910. This was the Insecticide Act (1910), which was enacted to prevent the manufacture, sale or transport of impure or improperly labelled insecticides and fungicides. In 1938, the Federal Food, Drug and Cosmetic Act *inter alia* established regulatory limits for pesticides (Food, Drug and Cosmetic Act, 1938). More extensive controls on pesticides were introduced with the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), in 1947 (Federal Insecticide, Fungicide and Rodenticide Act, 1947). This has been subject to extensive amendment, including the requirement that tolerances (maximum legal residue concentrations—equivalent to European MRLs) be established for pesticide residues on food. Up until 1970, the pesticide regulatory agency had been the United States Department of Agriculture, but after that time administration of FIFRA was transferred to the US EPA (Chaffey and Dobozy, 2004). Subsequent amendments further tightened the legislation, but a major change was made with the Food Quality Protection Act (FQPA) in 1996 (Food Quality Protection Act, 1996). The safety standard was revised from 'protect public health' to 'reasonable certainty of no harm'. The FQPA required that all existing tolerances be reviewed within 10 years to the new safety standard. For the purpose of establishing tolerances, the US EPA was required to provide for the protection of infants and children, and an extra safety factor of 10× was introduced with the young in mind. The FQPA introduced two new terms; the first was 'aggregate exposure' assessment; that is, consideration of all nonoccupational sources of exposure (i.e. food, drinking water and household uses). The other term introduced was 'cumulative exposure' assessment; that is, consideration of the impact of exposure to chemicals with a common mechanism of toxicological action. Aggregate exposure assessment presents no great scientific problems. Cumulative risk assessment, however, does. The default assumptions made are that (i) no interactions are likely at residue-type doses; (ii) pesticides with qualitatively the same toxicological action will act additively (i.e. exhibit dose additivity); (iii) pesticides with qualitatively different toxicological action will act independently. This means that pesticides have to be grouped into common mechanism groups (CMGs), which is relatively easy with some groups, for example organophosphate (OP) anticholinesterases, but more difficult with others, for example azole fungicides. Calculating the acceptability of exposure to more than one pesticide in a CMG can be done in several ways (see Wilkinson *et al*., 2000), but all the methods comprise adding exposure, allowing for the toxicological potency of the individual pesticides, and comparing the sum with some level of acceptability of total exposure. Another development in the USA is the requirement for developmental neurotoxicity tests (DNTs) to be done on some pesticides, and the US EPA has issued guidelines on doing such tests (US EPA, 1998a). DNTs have now been done on many pesticides, but a full analysis of the results has not been published, although an analysis of some studies was looked at by the Joint FAO/WHO Meeting on Pesticides Residues (JMPR) (FAO/WHO, 2003). Another development has been agreement with the other countries (Canada and Mexico) of NAFTA to share work on regulation and to harmonize data requirements (NAFTA, 2003).

2.1.3.2.1 Data Requirements

Data requirements are generally similar to those in the EU, with the exception of the additional requirements discussed above.

2.1.3.2.2 Field Trials and Tolerances

Initial calculations for risk assessment are based on residues observed in crop field trials conducted at maximum application rates with the minimum preharvest intervals (i.e. according to GAP) and with the assumption that 100% of the crop is treated. These trials are used to calculate tolerance values, which as in the EU are primarily to ensure compliance with GAP; thus tolerances are not in themselves safety limits. More refined exposure assessment can be carried out using factors to allow for percentage of crop treated and other factors that will reduce calculated exposure.

2.1.3.2.3 Residues Surveillance

The FDA collects residues data on particular commodity/pesticide combinations and carries out total

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

diet studies. The FDA is the agency which enforces tolerances in imported foods and in domestically produced foods shipped interstate. The US DA's Agricultural Marketing Service (AMS) conducts a residue testing programme directed primarily at raw agricultural products.

2.1.3.2.4 Consumer Risk Assessment

As in the EU, the typical procedure is to use the most sensitive study in the most sensitive species (the critical study), incorporate a UF of (typically) 10 for extrapolation from animals to humans and a further UF of (typically) 10 for interindividual human variation. With all pesticides this procedure is used to generate chronic RfDs and, with some, ARfDs. However, as discussed above, the FQPA makes a number of other demands that are not required in the EU, such as the requirement in some cases for an extra safety factor for protection of the young and for aggregate and cumulative risk assessment. Field trials are used as the source of consumption data for consumer risk assessment, and dietary surveys for food-item consumption. Where cumulative risk assessment is being undertaken, probabilistic exposure assessment is being studied as a way of avoiding compounded conservatism. Another major difference from the EU is in the treatment of nonthreshold carcinogens. Here, the cancer risk is calculated by multiplying cancer potency of the pesticide by food exposure. Dietary lifetime cancer risks of less than 10^{-6} are not generally considered to be of regulatory concern (see US EPA, 1998b; 2005; Chaffey and Dobozy, 2004).

2.1.3.2.5 Occupational Safety

Occupational safety is assured by quantifying exposure in studies undertaken during use of the pesticide. The exposure is then compared with the appropriate RfD.

2.1.3.2.6 Pesticides in Water

All sources of pesticide exposure, including exposure through drinking water, must be factored into decisions on establishing and reassessing tolerances. Intakes of pesticide via water are compared to a human health drinking water level of concern (DWLOC), which is the concentration in drinking water of a pesticide that would be an acceptable upper limit in light of exposure to that pesticide from other sources, that is, food and residential use.

2.1.3.3 International Activities

2.1.3.3.1 OECD

The Organisation for European Economic Co-operation (OEEC) came into being in 1948; the OEEC emerged as part of the reconstruction of Europe after the Second World War, in connection with the Marshall Plan. In 1961 the Organisation for Economic Co-operation and Development (OECD) superseded the OEEC. The OECD is, unlike its predecessor, a worldwide body, with its headquarters in Paris, and amongst its many activities are the generation of guidelines for the testing of chemicals, a full list of which is available at *www.oecd.org/dataoecd/9/11/33663321.pdf* (OECD, 2007). These guidelines are widely accepted internationally and are used for regulatory studies on pesticides.

2.1.3.3.2 Joint FAO/WHO Meeting on Pesticide Residues (JMPR)

The JMPR is the pesticide counterpart of JECFA. Although not officially part of the CAC structure, the JMPR provides independent scientific expert advice to the CAC and its specialist Committee on Pesticide Residues. These meetings, which occur annually, are organized by the WHO and the FAO. Some active substances that are also used as veterinary drugs are dealt with by JECFA (see Section (2.1.2.3.1)). The CAC has been discussed above: the MRLs and ADIs produced by the JMPR enter the Codex Alimentarius system via the Codex Committee on Pesticide Residues and, in most circumstances, CAC MRLs for pesticides, *inter alia,* are accepted for world trade purposes (WTO, 1994).

2.1.4 Regulation of Food Additives, Flavourings and Food Contact Materials

Food additives are substances that are added to food as preservatives and stabilizers or colours. Flavourings are used to impart odour and/or taste. Packaging materials (often plastic) are used for convenience, to prevent contamination with micro-organisms and sometimes to prevent tampering; a consideration is the toxicity of any substance that might migrate into food. The aim of regulating these materials is to ensure that additives, flavouring agents and packaging do not present a risk to human health.

2.1.4.1 In Europe

2.1.4.1.1 Food Additives and Flavourings

The legislative underpinning of European regulation of food additives is Directive 89/107 (Council of the European Communities, 1989a), and this directive has been subsequently amended on many occasions. Annex I of the Directive lists the groups of substances to which the Directive applies and it specifically excludes processing aids, substances used in the protection of plants and plant products in conformity with Community rules relating to plant health, flavourings for use in foodstuffs, falling within the scope of Council Directive 88/388/EEC (Council of the European Communities, 1988), and substances added to foodstuffs as nutrients (for example minerals, trace elements or vitamins). Substances covered fall into a number of groups including colours, preservatives, antioxidants, emulsifiers, thickeners, gelling agents, stabilizers, flavour enhancers, acids and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

acidity regulators, anticaking agents, modified starch, sweeteners and enzymes. As noted above, flavourings were already controlled by Directive 88/388/EEC (Council of the European Communities, 1988), whose annexes set maximum limits for biologically active principles and for 3,4-benzopyrene. There have been numerous amendments to Directive 89/107; for example Directive 94/35 (European Parliament and Council, 1994), which concerned sweeteners used in food. Shortly afterwards, Directive 95/2 (European Parliament and Council, 1995) carried forward the harmonization of regulation of additives other than sweeteners and colours. This Directive specified the foods in which the additives were permitted and the MRLs allowed, furthermore each additive was given a unique E number; these are number codes for food additives and are found on food labels throughout the EU. The E numbers are grouped; thus E100–E199 are colours and E200–E299 are preservatives. Harmonization, insofar as flavourings is concerned, has been slower, but the intent has been similar. According to Regulation 2232/96 (European Parliament and Council, 1996), amended by Commission Regulation 1565/2000 (European Commission, 2000b), which established an evaluation programme for flavouring substances, new numbers, so-called 'FL numbers', are to be assigned to each flavouring substance. The establishment of the EFSA brought the establishment of its scientific panel on food additives, flavourings, processing aids and materials in contact with food (AFC panel). Directive 2006/52/EC (European Parliament and Council, 2006a) amended Directives 94/35 and 95/2, making changes largely on the basis of advice from the EFSA and/or the Scientific Committee on Food (SCF). One example was change to current authorizations in order to keep the level of nitrosamines as low as possible by bringing down the levels of nitrites and nitrates added to food whilst maintaining the microbiological safety of food. Scientific advice to the EFSA is supplied by the AFC panel (see above). The panel is currently conducting a comprehensive re-evaluation of all authorized food additives in the EU in order to give scientific support to the Commission. The panel delivers its views as opinions and has both *ad hoc* and permanent working groups.

In July 2006 the Commission published a set of proposals that constitute a comprehensive review of the existing EU legislation in the area. The proposals are at second reading stage in the European Parliament. They comprise:

- a framework regulation for the control of food additives;
- a framework regulation on flavourings used in food;
- a regulation to introduce EU-wide controls on the use of enzymes in food which introduces for the first time harmonized controls across the EU on the use of enzymes in food products;
- a regulatory regulation that sets out the approval processes common to the above three regulations.

They maintain or strengthen (e.g. for enzymes) consumer protection; they consolidate the existing EU legislation which has been amended several times, and they introduce comitology for community acceptance of new additives, enzymes and flavourings.

2.1.4.1.2 Food Contact Materials

The legislative underpinning for regulation of food contact materials is Regulation 1935/2004/EC (European Parliament and Council, 2004b); this replaced the earlier Council Directive 89/109/EEC (Council of the European Communities, 1989b). Article 5 of the Regulation provides for specific measures to be put in place for the particular materials listed in Annex I, and the list includes plastics, rubber, paper, wood and cork. Most attention has been given to plastics, in particular monomers and additives such as plasticizers. Initially the evaluations were undertaken by a working group of the SCF. Since the establishment of the EFSA, the role of the SCF has been taken over by the EFSA AFC panel which has a working group on food contact materials.

2.1.4.2 In the USA

The basis of the regulation of food additives in the USA is the Food, Drug and Cosmetic Act (1938), passed, as discussed above, in the wake of a therapeutic disaster. With the exception of meat, poultry and egg products the FDA is the relevant regulatory body, while the FDA shares responsibility with the Food Safety and Inspection Service of the US DA for the safety of food additives used in meat, poultry and egg products. Regulation of food additives formally started with the Food Additives Amendment (1958) (Food Additive Amendment to the Food, Drug and Cosmetic Act, 1958), which requires manufacturers of new food additives to establish safety.

Under the US legislation, additives to food are divided into three groups, the second of which can be subdivided. They are (1) substances that are generally recognized as safe (GRAS), (2) prior-sanctioned substances; these were assumed to be safe by either the FDA or the US DA before 1958, to be used in a specific food, (3) food additives, which are subdivided into (i) direct (deliberately added to food) and (ii) indirect (food contact materials), and (4) colours.

2.1.4.2.1 GRAS Substances

These are substances that were widely used before the enactment of the Food Additives Amendment, and whose use was generally recognized as safe by a panel of experts. In 1958, the FDA published in the Federal Register the first list of substances generally recognized as safe (GRAS). The list contained nearly 200 substances. Notification of the use of GRAS substances in food is not needed. GRAS status is, of course, generally based

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

upon prolonged safe usage, but if new data questions the safety of a GRAS substance, the FDA may take action to remove the substance from foods or require the manufacturer to conduct studies to meet any concerns. It is possible to get a substance affirmed as GRAS, but unless the substance was in use for a long period, this will involve submission of toxicological data.

2.1.4.2.2 Prior-Sanctioned Substances

These are similar to GRAS substances except that their use is restricted to certain foods.

2.1.4.2.3 Other Substances

Additives (including colours) other than GRAS and prior-sanctioned substances are tightly regulated and are subject to a premarketing regulatory system, based upon toxicological safety. The toxicological requirements for direct food additives and for colour additives are available in the Red Book (FDA, 2007a). A tiered approach is used whereby the minimum dataset required is determined by the level of concern assigned to the compound. The level of concern is based upon the molecular structure of the compound, and substances are assigned to categories A, B or C. Within these categories, estimated human exposure will determine the initial concern level, I being those of least concern and concern level III being those of highest concern. As concern level increases the duration of toxicological studies required also increases. The Red Book also contains guidelines for the conduct of the studies required.

2.1.4.2.4 Indirect Food Additives

These are substances that come into contact with food as part of packaging or processing. They are not intended to be added directly to, become a component of, or have a technical effect in or on the food. They include substances in food-contact articles, adhesives and components of coatings, paper and paperboard components, polymers, and adjuvants and production aids. New indirect food additives are authorized through the food contact notification programme (FDA, 2007b).

2.1.4.3 Codex and the Joint Expert Committee on Food Additives (JECFA)

JECFA, already discussed above (Section (2.1.2.3.2)), is an expert Committee jointly organized by the WHO and the FAO of the United Nations. Some of JECFA's meetings are devoted to food additives and contaminants, and the Committee deals with residues and toxicology, producing both ADIs and MRLs. ADIs and MRLs established by JECFA are taken into the Codex system via the Codex Committees. The relevant committee was the Codex Committee on Food Additives and Contaminants, but in 2006, this was split into the Codex Committee on Contaminants in Food and the Codex Committee on Food Additives. The terms of reference of the latter, which meets in China, are '(i) to establish or endorse permitted maximum levels for individual food additives; (ii) to prepare priority lists of food additives for risk assessment by the Joint FAO/WHO Expert Committee on Food Additives; (iii) to assign functional classes to individual food additives; (iv) to recommend specifications of identity and purity for food additives for adoption by the Commission; (v) to consider methods of analysis for the determination of additives in food; and (vi) to consider and elaborate standards or codes for related subjects such as the labelling of food additives when sold as such.'

2.2 Reserve Schemes for Chemicals

Reserve schemes for chemicals can be divided into 'supply-side' schemes and 'user-side' risk assessment/risk management schemes. Supply-side schemes are those requiring information, assessment and possibly further testing. Their aim is to provide information for the supply chain. The supplier classifies the substance or preparation on the basis of the toxicity found and standard criteria, and labels the packaging for the substance/preparation appropriately. The major methods for transfer of this information through the supply chain involve labelling and the preparation of safety data sheets. The headings in the safety data sheet are common internationally, although the content tends to differ slightly to accord with EU, national and state legislation. This information being transferred includes, in effect, a hazard characterization, intended to enable the user to examine the risks for their particular exposure circumstances. It also includes suggestions concerning handling and storage and the use of personal protective equipment when handling the substance/preparation. Management of the supply is achieved through different legislation.

2.2.1 Supply Side

2.2.1.1 New Chemicals — USA

The USA adopted an approach based on premanufacturing notification contained in the Toxic Substances Control Act of 1976. The new substance provisions of the Toxic Substances Control Act require that available information be sent to the EPA for evaluation prior to manufacture or import. A list of existing chemicals was drawn up. There is no legal requirement for routine testing of new substances. The decision as to whether a testing programme is required and what tests should be undertaken has to be based on available information (and any structure–activity information available concerning the new substance) and justified by the regulator, the EPA.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat114
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2.2.1.2 New Chemicals—Excluding USA

'Supply-side' schemes for new chemicals originated in an OECD-derived approach, aimed initially at providing a minimum dataset (the minimum premarketing set of data (MPD)) for new substances, and stepped testing based on tonnages placed on the market. Most OECD adherents, including the EU, implemented this. The first step was to produce lists of existing substances—in principle substances not on these lists are 'new'. The EU scheme is typical and was originally implemented as the sixth amendment of Council Directive 67/548/EEC (Council of the European Economic Community, 1967), and reimplemented as the seventh amendment, Council Directive 92/32/EEC (Council of the European Communities, 1992). Testing is staged, based largely on tonnages placed on the market, but with some scope for varying the higher-level testing on grounds of toxicity seen in earlier studies, possible structure–activity relationships, and numbers exposed and levels of exposure seen.

2.2.1.3 Existing Chemicals/Substances

The OECD has run a risk assessment programme for high-production-volume chemicals since the late 1980s, and refocussed the programme in 1998. The chemicals chosen were those believed to be on the market at high tonnage and for which it was believed few data were available. One central requirement is a 'Screening Information Dataset'. Essentially this dataset is similar to that required under REACH Annexes VII and VIII for existing chemicals (see below), but with the omission of skin and eye irritation tests.

In general the principle has been that industry generates the data and the individual national regulator sponsors the chemical and moderates the information provided. The information is collated into a standardized format, a Screening Information Data Set (SIDS), Screening Initial Assessment Report (SIAR), and profile (summary). The moderated data is then reviewed by the OECD at a Screening Information Assessment Meeting (SIAM) and published on the IPCS web site. In the USA, the process has been conducted by the US EPA under the High Production Volume challenge, in the EU sponsorship has been by individual member states. The International Council of Chemical Associations launched a global initiative in 1998 aimed at providing data on approximately 1000 high-production-volume substances, nominally by the end of 2004, with the costs of information gathering and any testing required being borne by industry.

Within the EU evaluation of existing chemicals has been conducted using the information in an EU regulation setting out the principles for assessment (Commission Regulation (EC) No 1488/94; European Commission, 1994) and several EU regulations providing priority lists of chemicals. The drafts of the risk assessments are written by individual Member State Competent Authorities (as rapporteurs, usually in cooperation with industry), and the evaluation (including proposals for classification and labelling and areas where further work is required) is peer reviewed by the EU Scientific Committee on Toxicology, Ecotoxicology and the Environment (CSTEE). When the substance has been subject to an EU risk assessment (properly evaluation), the EU risk assessment information is accessible through the European Chemicals Bureau web site. Effectively, this programme is being subsumed into REACH.

2.2.1.4 Safety Data Sheets

Safety data sheets are required for dangerous substances and preparations. Existing substances are classified on the basis of available information. The classification of preparations may involve a calculation method for amalgamating the toxicities of the individual components given in Directive 1999/45/EEC (European Parliament and Council, 1999), or testing of the preparation. The headings and content of safety data sheets are specified in an ISO (International Organization for Standardization) standard and EU Commission Directive 2001/58/EEC (European Commission, 2001) (**Table 3**). They include the requirement to state the classification and labelling identified by toxicity testing or, in the case of a preparation, as a consequence of the application of the procedures given in Directive 1999/45/EEC.

2.2.1.5 Marketing-and-Use Directives

Unlike schemes for specified use, where the onus is on those wishing to market the chemical for that use to demonstrate safety to the regulator, here the onus is on the regulator to demonstrate that there is a need for the

regulatory action proposed. This applies both in the USA (Toxic Substances Control Act) and in the EU, through the Marketing and Use Directive (Directive 76/769/EEC, Council of the European Communities, 1976). By 2008 there have been some 30 amendments to the Marketing and Use Directive seeking regulatory action on specific chemicals or groups of chemicals.

2.2.1.6 REACH and GHS

Within the European Economic Area all of these EU Directives are being replaced by the EU REACH Regulation (European Parliament and Council, 2006b), and by the introduction of the relevant parts of the United Nations Economic Commission for Europe (UN ECE) Globally Harmonised System (GHS) for Classification and Labelling of Chemicals (UN ECE, 2007). The latter is periodically updated.

The REACH regulation is being implemented over a prolonged period (2007–2022). It includes the essentials of the new substances scheme—that is, a tiered testing system based on tonnages (**Table 4**). It also includes a procedure for registering existing chemicals and ensuring that appropriate toxicity information is available, with certain high-hazard (including proven human or animal carcinogens, mutagens or reproductive toxins) and high-tonnage existing chemicals being dealt with first. The data required for the first two levels of testing must be supplied with the registration (although grouping of similar chemicals and application of structure–activity relationships and 'read across' are provided for—see **Table 4**), with proposals for appropriate further testing.

REACH requires safety data sheets and, for substances placed on the market in quantities of 10 tonnes or more, detailed chemical safety assessments for the various intended uses. Finally there is an authorization process for chemicals exhibiting specific hazardous properties. The GHS is a classification system largely intended as a means of providing harmonized hazard characterizations.

3 SCHEMES FOR AIR/WATER

3.1 Air and Water Quality

The WHO publishes air and drinking-water quality guidelines. Essentially they are drawn up and reviewed by experts after evaluating existing toxicity data, and published. National and regional governments can use these guidelines to set their own standards or develop standards themselves.

The WHO air quality guidelines global update in 2005 (WHO, 2006a) covered particulates, ozone, and nitrogen and sulfur dioxides. National or regional authorities can implement these guidelines or derive their own. In the UK, air quality objectives and standards have been set using advice from expert committees. Air quality objectives set time limits for achieving

Table 4 REACH testing proposals

Annex no.	Tonnage level	Tests proposed
VII	1 tonne or more	Skin irritation/skin corrosion (*in vitro*), eye irritation (*in vitro*), skin sensitization (mouse local lymph node assay), *in vitro* gene mutation in bacteria (Ames test), acute toxicity (oral).
VIII	10 tonnes or more	Skin irritation (*in vivo*), eye irritation (*in vivo*), *in vitro* gene mutation in mammalian cells, second acute toxicity test (dermal or inhalation, as appropriate), repeated-dose toxicity (min: 28 days), reproductive toxicity screen (OECD 421 or 422), assessment of toxicokinetics.
IX	100 tonnes or more	Additional *in vivo* genotoxicity studies, repeated-dose toxicity studies and reproductive toxicity studies, depending on the results of the earlier studies.
X	1000 tonnes or more	Additional (second) *in vivo* genotoxicity study, long-term repeated-dose toxicity study, carcinogenicity bioassay, additional repeated-dose toxicity studies.
XI	General rules for the adaptation of the standard test regime	Testing does not appear scientifically necessary: use of existing data, weight of evidence, qualitative or quantitative structure–activity relationships, *in vitro* methods, grouping of substances and read across. Testing is technically not possible (e.g. substance too volatile, too highly reactive or too unstable, or mixing substance with water causes danger of fire or explosion, or, if radiolabelling is required, the radiolabelling is unfeasible). Substance-tailored exposure-driven testing (exposure scenarios indicate that testing is unnecessary).

Note: Only the toxicity tests are included in the table. Physical chemistry and ecotoxicity tests have been omitted. Also omitted are the conditions that have to be fulfilled before conducting the tests.
(European Parliament and Council, 2004a)

specified levels of the substance in air on the way to achieving a standard. Although the objective is an acceptable risk, the time required to achieve it is set using the technical feasibility criterion. Air quality standards are 'broadly acceptable' risks based on equity. Air quality objectives exist for benzene, 1,3-butadiene, carbon monoxide, lead and polycyclic aromatic hydrocarbons as well as particulates, ozone, and nitrogen and sulfur dioxide.

Drinking-water quality standards in the UK are derived from the WHO guidelines (WHO, 2006b) via the EU. They cover microbiological and radiation hazards as well as chemical hazards. Levels of pesticide, nitrate, lead and iron are particularly monitored. The actual standards are set out in regulations.

3.2 Occupational Exposure

3.2.1 Occupational Exposure Levels/Workplace Exposure Limits and Biological Exposure Measurements

There are two main types of standards for workplace exposure—ones based on uptake (biological exposure indices/biological monitoring guidance values) and ones based on intake (occupational exposure levels/workplace exposure limits).

These measurements and standards are intended to play a part in controlling the exposure of workers to airborne substances. Some are legally enforceable, others are for guidance. Some are influenced by what level of control is achievable with current technology without exorbitant cost, others are idealistic targets. Thus a direct comparison of numerical lists of occupational exposure limits or biological measurement values is very difficult to undertake and may not reflect the relative standards of occupational health protection in different countries. Without appropriate control regimes and means to ensure that these regimes are adhered to, these limits will be ineffective.

3.2.2 Sources of Occupational Exposure Limits

The two principal sources of occupational exposure limits in the USA are the American Association of Governmental Industrial Hygienists' 'Threshold Limit Values' and 'Biological Exposure Indices' Committee and list (revised annually), and the US Occupational Safety and Health Administration's list of Permissible Exposure Limits. The EU, through the Chemical Agents and Carcinogens Directives and the Scientific Committee on Occupational Exposure Limits, has set some exposure limits, but most limits in EU member states remain national limits. Perhaps the two most relevant airborne limits are those of the German authorities in their Technical Rules for Hazardous Substances, TRGS 900 (2006): the *Maximal Arbeitskonzentrationen* (MAK—the maximum acceptable concentration for a chemical in the workplace) and *Technisch Richtkonzentration* (TRK—technical guidance concentrations based on best available technology for carcinogens) and *Biologische Arbeitsstofftoleranzwerte* (BAT—biological tolerance value); and those in the UK, the Workplace Exposure Limits and Biological Monitoring Guidance Values (HSE, 2005). Workplace Exposure Limits are further divided into two groups, those for which adherence to the limit is adequate control and those classified in certain categories associated with carcinogenesis, heritable genetic damage and sensitization by inhalation (asthma), for which there is a duty to control exposure to as low a level below that limit as is reasonably practicable.

Biological monitoring can act as guidance or as legal limits. The chief example for biological monitoring values being used as legal limits in the EU (including the UK) is for blood lead values following exposure to inorganic lead. There are both action levels (when control measures must be reviewed) and suspension levels (where workers must be transferred away from working with lead until their levels have adequately fallen), and these levels vary according to whether the person is an adult, a woman of child-bearing age or a young person.

3.2.3 The Place of Occupational Exposure Standards in Workplace Risk Assessment/Evaluation

Occupational exposure limits are a part of any strategy concerning control of risks from chemical exposure in the workplace. They are an indication of what is an acceptable, or, at least, a tolerable risk in the workplace. Together with classification and labelling data communicated through the materials safety data sheet, occupational exposure limits should provide the underlying information for conducting risk assessments within organizations and for individual workstations. Control of the risks should be by engineering means where possible—preferably in intrinsic design of the equipment, but also by use of appropriate ventilation. If engineering means are not possible or not adequate, personal protective equipment can be used to prevent exposure. All of this has to be within management systems that encourage proper attention to worker safety and health if it is to be effective. This is the realm of the professional occupational hygienist and safety specialist and will not be examined further here.

4 MAJOR HAZARDS

Approaches to major accident hazards toxicity are described in **Toxicology and Disasters** and will not be repeated here. The toxicology associated with these risk assessments is a very specialized area specifically concerned with predicting toxic effects following rare events. These approaches apply equally to industrial accidents, natural disasters involving chemicals and terrorist attacks involving chemical warfare agents.

5 AFTERWORD

Regulatory schemes are society's response to particular problems. They are intended to ensure that the hazards and risks associated with the chemicals to which we are exposed are adequately characterized, evaluated and controlled.

Toxicology is a major contributor to risk characterizations and evaluations, with other important contributions coming from specialists in exposure, intended effects (where relevant), structure–activity relationships, epidemiology, psychology, sociology and law, and administrators. A team effort is required if society is to be adequately satisfied with the outcomes.

Toxicological Considerations for Pharmaceutical Products

Lynnda Reid

CONTENTS

The contents and views expressed in this overview are my own and do not necessarily represent the views of the Food and Drug Administration (FDA), the Center for Drug Evaluation and Research (CDER) or individual divisions within CDER, or any other international regulatory body. Any questions regarding the development or safety of an investigational or marked pharmaceutical product should be directed to the relevant CDER review division or governing international agency.

1 INTRODUCTION: HISTORICAL BASES FOR NONCLINICAL REQUIREMENTS TO SUPPORT NEW PHARMACEUTICAL PRODUCTS

Early drug development was unregulated and characterized by marketplace trial and error. Therapeutic agents were often derived from poisons given in doses large

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat115

enough to kill pathogenic organisms without ostensibly harming the host. In this sense, toxicology has always been an integral partner in the development of therapeutic agents. The systematic evaluation of the safety of medicines did not become common practice until the early 1900s. Until that time, the regulation of 'medications' was accomplished on a local/regional level, and demonstration of safety or efficacy was not required. One of the first laws regulating the marketing of drugs was the 1906 Pure Food and Drug Act which gave government authorities in the USA the power to remove drugs from sale only if they were found to be mislabelled, contaminated or adulterated. This law required that the presence and amount of selected dangerous or addictive substances, such as arsenic, alcohol and opiates, had to be labelled, and it identified the United States Pharmacopoeia and the National Formulary as official standards for drugs. However, it fell short of requiring demonstration of either safety or efficacy.

Implementation of standards requiring demonstration of safety and efficacy prior to marketing was driven primarily by two pharmaceutical disasters. In the USA, ingestion of Elixir Sulfanilamide, a cough syrup using the untested solvent diethylene glycol, was responsible for the deaths of over 100 patients, including children. In response, the 1938 Food, Drug, and Cosmetic Act was implemented, and formed the basis for regulation of modern pharmaceutical development. This act required firms to provide proof of safety prior to marketing in the USA. In Japan, government regulations requiring demonstration of safety prior to marketing were implemented in the 1950s, while in Europe, the trigger was the thalidomide tragedy of the 1960s. In the USA, the thalidomide disaster also triggered the Drug Amendments Act of 1962, which required drug firms to satisfy the Food and Drug Administration (FDA) as to both the safety and efficacy of a new drug for its intended use.

By the early 1960s and 1970s most countries had initiated some form of regional product registration controls requiring premarketing demonstration of safety and efficacy. With the globalization of markets and large multinational pharmaceutical companies it became imperative to try to harmonize requirements related to the type of data needed to demonstrate safety and efficacy. In the late 1980s, harmonization of regulatory requirements was pioneered by the European Community (now the European Union), and bilateral discussions with Japan and the USA were initiated. The joint regulatory–industry initiative on international harmonization was conceived at the World Health Organization (WHO) Conference of Drug Regulatory Authorities, in Paris, 1989. Representatives of the regulatory agencies and industry associations of Europe, Japan and the USA met in Brussels in 1990 to form the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH). The ICH Steering Committee was formed to harmonize regulations regarding safety, quality and efficacy, which are the basis for approving and authorizing new medicinal products. The WHO remains active in disseminating information and providing input beyond the ICH member countries. **Table 1** contains an annotated listing of all currently available ICH guidance documents related to nonclinical testing of pharmaceutical products. **Table 2** contains an annotated listing of guidance documents generated by the US FDA and European regulatory agencies.

There are still many areas involving safety which have not been harmonized. In these instances, companies seeking marketing approval in multiple countries must meet the requirements set forth by each regulatory body as to the type, timing and duration of studies needed to support clinical development and registration.

2 CONSIDERATIONS IN THE OVERALL DESIGN OF A NONCLINICAL DEVELOPMENT PROGRAMME

The scope of nonclinical studies needed to support clinical development and approval of new pharmaceutical agents is generally dictated by the stage of development and the proposed therapeutic use of the product. Factors determining the type and duration of nonclinical studies necessary to support new drugs include the following:

- targeted population
- duration of treatment
- timing of studies in relationship to clinical development
- route of administration
- pharmaceutical class
- relevance of animal models.

2.1 Targeted Population

Initial clinical studies are performed primarily to determine a safe human dose and to collect pharmacokinetic data. Except for extremely toxic products, for example cytotoxic, genotoxic and/or chemotherapeutic products, initial clinical studies are performed in normal, healthy human volunteers who will not derive any benefit from treatment. In these cases, the medical mantra of 'do no harm' is especially important. Animal studies are usually the only basis for dose selection for 'first-in-human' studies. The minimal requirements for nonclinical studies needed to support initiation of clinical studies usually include the following:

- acute safety pharmacology studies
- *in vitro* genotoxicity studies

Table 1 ICH guidance for industry

E8 (1997)	General Considerations for Clinical Trials	This ICH document describes the internationally accepted principles and practices both in the conduct of individual clinical trials and in overall development strategies for new medicinal products.
M3 (1997)	Nonclinical Safety Studies for the Conduct of Human Clinical Trials for Pharmaceuticals	The nonclinical safety study recommendations for the marketing approval of a pharmaceutical usually include single- and repeated-dose toxicity studies, reproduction toxicity studies, genotoxicity studies, local tolerance studies and, for drugs that have special cause for concern or are intended for a long duration of use, an assessment of carcinogenic potential. Other nonclinical studies include pharmacology studies for safety assessment (safety pharmacology) and pharmacokinetic (absorption, distribution, metabolism and excretion (ADME)) studies. These types of studies and their relation to the conduct of human clinical trials are presented in this guidance.
M3 (R1) (2000)	Maintenance of the ICH Guideline on Nonclinical Safety Studies for the Conduct of Human Clinical Trails for Pharmaceuticals	
S1A (1996)	The Need for Long-Term Rodent Carcinogenicity Studies of Pharmaceuticals	The objective of this guideline is to define the conditions under which carcinogenicity studies should be conducted, to avoid the unnecessary use of animals in testing, and to provide consistency in worldwide regulatory assessments of applications. It is expected that these studies will be performed in a manner that reflects currently accepted scientific standards. The fundamental considerations in assessing the need for carcinogenicity studies are the maximum duration of patient treatment and any perceived cause for concern arising from other investigations. Other factors may also be considered, such as the intended patient population, prior assessment of carcinogenic potential, the extent of systemic exposure, the (dis)similarity to endogenous substances, the appropriate study design, or the timing of study performance relative to clinical development.
S1B (1997)	Testing for Carcinogenicity of Pharmaceuticals	This document provides guidance on approaches for evaluating the carcinogenic potential of pharmaceuticals. These include: choice of species for a long-term carcinogenicity study and additional *in vivo* tests for carcinogenicity. Also discussed are: appropriate mechanistic studies that can be useful for the interpretation of tumour findings and their relevance to human risk assessment; general considerations in the choice of appropriate species for long-term carcinogenicity testing; and evaluation of carcinogenic potential.
S1C (1995)	Dose Selection for Carcinogenicity Studies of Pharmaceuticals	This guidance outlines four generally acceptable criteria for selection of the high dose for carcinogenicity studies of therapeutics: maximum tolerated dose, 25-fold AUC ratio (rodent : human), dose-limiting pharmacodynamic effects, saturation of absorption and maximum feasible dose. The use of other pharmacodynamic–pharmacokinetic- or toxicity-based end points in study design is considered based on scientific rationale and individual merits.
S1C(R) (1997)	Dose Selection for Carcinogenicity Studies of Pharmaceuticals: Addition of a Limit Dose and Related Notes	This guidance outlines the approaches used in determining the high dose for carcinogenicity studies. In using these approaches, it may not be necessary to exceed a dose of 1500 mg kg^{-1} day^{-1}. This limit dose applies only in cases where there is no evidence of genotoxicity and where the maximum recommended human dose does not exceed 500 mg day^{-1}.
S2A (1996)	Specific Aspects of Regulatory Genotoxicity Tests for Pharmaceuticals	This guidance discusses recommendations for genotoxicity testing of pharmaceuticals. Specific guidance is given for: *in vitro* tests (base set of strains used in bacterial mutation assays, and definition of the top concentration for *in vitro* tests); *in vivo* tests (acceptable bone marrow tests for the detection of clastogens *in vivo*, and use of male/female rodents in bone marrow micronucleus tests); and evaluation of *in vitro* and *in vivo* test results.

Table 1 (*continued*)

S2B (1997)	A Standard Battery for Genotoxicity Testing of Pharmaceuticals	Registration of pharmaceuticals requires a comprehensive assessment of their genotoxic potential. It is clear that no single test is capable of detecting all relevant genotoxic agents. Therefore, the usual approach should be to carry out a battery of *in vitro* and *in vivo* tests for genotoxicity. Such tests are complementary rather than representing different levels of hierarchy. This guidance recommends the following standard test battery: (i) a test for gene mutation in bacteria; (ii) an *in vitro* test with cytogenetic evaluation of chromosomal damage with mammalian cells, or an *in vitro* mouse lymphoma thymidine kinase (tk) assay; and (iii) an *in vivo* test for chromosomal damage using rodent haematopoietic cells.
S2(R1) (2008)	Genotoxicity Testing and Data Interpretation for Pharmaceuticals Intended for Human Use	This draft guidance is intended to replace and combine the ICH S2A and S2B guidelines. The purpose of the revision is to optimize the standard genetic toxicology battery for prediction of potential human risks, and to provide guidance on interpretation of results, with the ultimate goal of improving risk characterization for carcinogenic effects that have their basis in changes in the genetic material. The revised guidance describes internationally agreed-upon standards for follow-up testing and interpretation of positive results *in vitro* and *in vivo* in the standard genetic toxicology battery, including assessment of nonrelevant findings.
S3A (1995)	Toxicokinetics: The Assessment of Systemic Exposure in Toxicity Studies	Toxicokinetics is defined as the generation of pharmacokinetic data, either as an integral component in the conduct of nonclinical toxicity studies or in specially designed supportive studies, in order to assess systemic exposure. The guidance highlights the need to integrate pharmacokinetics into toxicity testing, which should aid in the interpretation of the toxicology findings and promote rational study design development.
S3B (1995)	Pharmacokinetics: Guidance for Repeated Dose Tissue Distribution Studies	Tissue distribution studies are essential in providing information on distribution and accumulation of the compound and/or metabolites, especially in relation to potential sites of action. This paper provides guidance on circumstances when repeated-dose tissue-distribution studies should be considered, and on the conduct of such studies.
S4A (1999)	Duration of Chronic Toxicity Testing in Animals (Rodent and Nonrodent Toxicity Testing)	This guidance represents the current thinking on the duration of chronic toxicity testing in animals (rodent and nonrodent toxicity testing). The ICH guidance recommends nine-month chronic toxicity studies in nonrodents, although shorter studies may be equally acceptable in some circumstances, and longer studies may be more appropriate in others, as discussed in the guidance.
S5A (1994)	Detection of Toxicity to Reproduction for Medicinal Products	The aim of reproduction toxicity studies is to reveal any effect of one or more active substance(s) on mammalian reproduction. This guideline addresses the design of studies that allow exposure of mature adult animals and all other stages of development from conception to sexual maturity. These include: premating to conception; conception to implantation; implantation to closure of the hard palate; closure of the hard palate to the end of pregnancy; birth to weaning; and weaning to sexual maturity.
S5B (1996)	Detection of Toxicity to Reproduction for Medicinal Products: Addendum on Toxicity to Male Fertility	This text is an addendum to the above Guideline on Detection of Toxicity to Reproduction for Medicinal Products, and it provides amendments to the published text. The amendments are intended to provide a better description of the testing concept and recommendations, especially those addressing flexibility, premating treatment duration and observations.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.
This article is © 2009 John Wiley & Sons, Ltd.
DOI: 10.1002/9780470744307.gat115
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

S5B(M) (2000)	Toxicity to Male Fertility, an Addendum to the ICH Tripartite Guideline on Detection of Toxicity to Reproduction for Medicinal Products	The amendments provide a better description of the testing concept and recommendations for male fertility studies, especially those addressing flexibility, premating treatment duration, and observations.
S6 (1997)	Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals	This guideline recommends a basic framework for the preclinical safety testing of biotechnology-derived pharmaceutical products. It applies to products derived from characterized cells through the use of a variety of expression systems including bacteria, yeast, insect, plant and mammalian cells.
S7A (2001)	Safety Pharmacology Studies for Human Pharmaceuticals	This guidance was developed to help protect clinical trial participants and patients receiving marketed products from potential adverse reactions to pharmaceuticals, while avoiding unnecessary use of animals and other resources. This guidance defines safety pharmacology and describes general principles and recommendations for its evaluation.
S7B (2005)	Non-clinical Evaluation of the Potential for Delayed Ventricular Repolarization (QT Interval Prolongation) by Human Pharmaceuticals	This guideline describes a nonclinical testing strategy for assessing the potential of a test substance to delay ventricular repolarization. This guideline includes information concerning nonclinical assays and an integrated risk assessment.
S8 (2006)	Immunotoxicity Studies for Human Pharmaceuticals	This ICH guidance provides: (i) recommendations on nonclinical testing approaches to identify compounds which have the potential to be immunosuppressive, and (ii) guidance on a weight-of-evidence decision-making approach for immunotoxicity testing.
Q3A (2003)	Impurities in New Drug Substances	This revised document is intended to provide guidance for registration applications on the content and qualification of impurities in new drug substances produced by chemical syntheses and not previously registered in a region or member state. It is not intended to apply to the regulation of new drug substances used during the clinical research stage of development. Biological/biotechnological, peptide, oligonucleotide, radiopharmaceutical, fermentation and semisynthetic products derived therefrom, herbal products, and crude products of animal or plant origin are not covered.
Q3B(R) (2006)	Impurities in New Drug Products	This revised document provides guidance recommendations for registration or marketing applications on the content and qualification of impurities in new drug products produced from chemically synthesized new drug substances not previously registered or approved for marketing in a region or member state. This guideline addresses only those impurities in drug products classified as degradation products of the active ingredient or reaction products of the active ingredient with an excipient and/or immediate container/closure system (collectively referred to in this guideline as degradation products). Impurities arising from excipients present in the drug product are not covered in this document.
Q3C (1997)	Residual Solvents	This guidance recommends acceptable amounts of residual solvents in pharmaceuticals for the safety of the patient, and recommends the use of less-toxic solvents in the manufacture of drug substances and dosage forms. This guidance does not apply to potential new drug substances, excipients or drug products used during the clinical research stages of development, nor does it apply to existing marketed drug products.
Q3C (2003)	Tables and Lists	This is the companion document for the ICH guidance for industry Q3C Impurities: Residual Solvents (1997), which makes recommendations as to what amounts of residual solvents are considered safe in pharmaceuticals.

Table 2 Regional guidance documents

FDA (2005)	Estimating the Maximum Safe Starting Dose in Initial Clinical Trials for Therapeutics in Adult Healthy Volunteers	This guidance outlines a common process (algorithm) and vocabulary for deriving the maximum recommended starting dose for 'first in human' clinical trials of new molecular entities in normal, healthy volunteers. The goals are to: (i) establish a consistent terminology for discussion of the starting dose, (ii) provide common conversion factors for deriving a human equivalent dose, and (iii) delineate a strategy for selecting the highest recommended starting dose for normal volunteers, regardless of the projected clinical use.
FDA (1995)	Content and Format of Investigational New Drug Applications (INDs) for Phase 1 Studies of Drugs, Including Well-Characterized, Therapeutic, Biotechnology-Derived Products	This guidance clarifies requirements for data and data presentation related to the initial entry into human studies of an investigational drug, including well-characterized, therapeutic, biotechnology-derived products. The most significant clarifications are: (i) the explicit willingness to accept an integrated summary report of toxicology findings based upon the unaudited draft toxicologic reports of completed animal studies as initial support for human studies, and (ii) specific manufacturing data appropriate for a Phase 1 investigation.
FDA (1996)	Single Dose Acute Toxicity Testing for Pharmaceuticals	Acute toxicity studies in animals are usually necessary for any pharmaceutical intended for human use. The information obtained from these studies is useful in choosing doses for repeat-dose studies, providing preliminary identification of target organs of toxicity, and, occasionally, revealing delayed toxicity. Acute toxicity studies may also aid in the selection of starting doses for Phase 1 human studies, and provide information relevant to acute overdosing in humans.
CPMP (2004)	Position Paper on Non-Clinical Safety Studies to Support Clinical Trials with a Single Microdose	This position paper from the Committee for Proprietary Medicinal Products (CPMP) of the European Medicines Agency (EMEA) defines common standards of nonclinical studies needed to support human clinical trials of a single dose of a pharmacologically active compound using microdose techniques.
FAMHP (2007)	Guidance to the Conduct of Exploratory Trials in Belgium	This working document from the Belgian Federal Agency for Medicines and Health Products (FAMHP) offers a temporary framework for preparing and evaluating exploratory clinical trial applications that are outside the scope of the microdosing approach and to be conducted in Belgium. Discussed are various aspects of drug development, including types of preclinical studies needed to support exploratory clinical trials.
FDA (2004)	Botanical Drug Products (2004)	This guidance explains the circumstances in which a botanical drug may be marketed under an over-the-counter (OTC) drug monograph, and when FDA approval of a new drug application (NDA) is required for marketing. In addition, this document provides regulatory and scientific guidance to sponsors on conducting initial and expanded clinical investigations of botanical drug products, including those botanical products currently lawfully marketed as foods and dietary supplements in the USA.
CPMP (1997)	Points to Consider: The Assessment of the Potential for QT Interval Prolongation by Non-Cardiovascular Medicinal Products	This document from the European CPMP discusses considerations for assessing risk of drug-induced QT interval prolongation. Included is a discussion of the various *in vitro* and *in vivo* assays, methodological issues and their regulatory implications.
FDA (1997)	Points to Consider in the Manufacture and Testing of Monoclonal Antibody Products for Human Use (1997)	This document was developed for manufacturers of monoclonal antibody products and represents the FDA Center for Biologics Evaluation and Research (CBER)'s current (i.e. 1997) thinking on the subject. Discussed are issues relating to product manufacture, quality control, and safety testing in animals and humans, among others.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.
This article is © 2009 John Wiley & Sons, Ltd.
DOI: 10.1002/9780470744307.gat115
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

FDA (2002)	Carcinogenicity Study Protocol Submissions	This guidance is intended to inform sponsors of the types of information the FDA Center for Drug Evaluation and Research (CDER) relies on when evaluating protocols for animal carcinogenicity studies. These include: general toxicity information, animal and human metabolic profiles, toxicokinetic data and genotoxicity.
FDA (2006)	Nonclinical Safety Evaluation of Drug or Biologic Combinations	This guidance provides recommendations on nonclinical approaches to support the clinical study and approval of fixed-dose combination (FDC) products, co-packaged products, and adjunctive therapies. The nonclinical studies that the FDA recommends sponsors use to characterize the combination will depend on the toxicologic and pharmacokinetic profiles of the individual drugs, the treatment indication or indications, and the intended population.
FDA (2002)	Drug and Biologic Drug Products: Evidence Needed to Demonstrate Effectiveness of New Drugs When Human Efficacy Studies are Not Ethical or Feasible	This final rule provides for approval of certain new drugs and biological products based on animal data when adequate and well-controlled efficacy studies in humans cannot be ethically conducted, because the studies would involve administering a potentially lethal or permanently disabling toxic substance or organism to healthy human volunteers. Although human data can be taken into account, animal studies alone can be used to demonstrate effectiveness when: (i) the pathophysiological mechanism for the indication (i.e. effects of bioterrorism) is well understood, as well as its treatment by the product; (ii) the drug effect is demonstrated in two animal species, unless one species has been well characterized; (iii) the end point in animal studies is clearly related to the human end point (e.g. survival); and (iv) PK/PD data is available to allow selection of an effective human dose.
FDA (2005)	Nonclinical Studies for the Safety Evaluation of Pharmaceutical Excipients	This document provides guidance concerning development of safety profiles to support use of new excipients as components of drug or biological products. In this document, the phrase 'new excipients' is defined to mean any ingredients that are intentionally added to therapeutic and diagnostic products but which: (i) do not directly exert therapeutic effects at the intended dosage (although they may act to improve product delivery, for example enhancing absorption or controlling release of the drug substance); and (ii) are not fully qualified by existing safety data with respect to the currently proposed level of exposure, duration of exposure or route of administration.
FDA (2006)	Exploratory IND Studies	This draft guidance describes what approaches should be considered when planning a clinical trial for a drug or biologic that occurs early in Phase 1, involves limited human exposure, and has no therapeutic intent. Such clinical studies can be helpful to: (i) gain an understanding of the product's mechanism of action, (ii) provide PK information, (iii) select a lead candidate for further development, or (iv) explore a drug's biodistribution using imaging techniques. Since such studies use a limited number of subjects with a limited dose range for a limited period of time, the preclinical requirements to support such clinical studies can be flexible, because the potential risks to human subjects are thought to be less than traditional Phase 1 studies. Examples of preclinical studies that can be used to support exploratory IND studies in humans are provided.
FDA (2006)	Recommended Approaches to Integration of Genetic Toxicology Study Results	This guidance is intended to inform industry on how CDER views positive findings in genetic toxicology assays during drug development. It provides recommendations on how to proceed with clinical studies while ensuring the safety of study participants when results in genotoxicity studies suggest a potential cancer or genetic hazard. The decision of whether to begin a clinical trial when there are positive genetic toxicity study results is based on a weight-of-evidence approach that includes consideration of the results of all genetic toxicology tests, the genotoxic mechanism of action, and the nature of the proposed clinical trial.

Table 2 (*continued*)

CPMP (2006)	Guideline on Detection of Early Signals of Drug-Induced Hepatotoxicity in Non-Clinical Studies	This *draft* guideline provides guidance on how to identify, collect and report early nonclinical signs of medicinal product-induced hepatotoxicity in order to decrease the risk of clinical adverse liver reactions. This guideline applies mainly to new active substances. However, the principles as introduced in the present guideline would also help to identify mechanisms underlying adverse liver reactions of a medicinal product already on the market.
FDA (2002)	Immunotoxicology Evaluation of Investigational New Drugs	This guidance makes recommendations to sponsors of INDs on (i) the parameters that should be routinely assessed in toxicology studies to determine effects of a drug on immune function, (ii) when additional immunotoxicity studies should be conducted, and (iii) when additional mechanistic information could help characterize the significance of a given drug's effect on the immune system. This guidance is intended for drug products and does not apply to biological products.
FDA (1999)	ANDAs: Impurities in Drug Substances	This guidance provides recommendations for including information in abbreviated new drug applications (ANDAs) and supporting drug master files (DMFs) on the identification and qualification of impurities in drug substances. Although this guidance is similar, but not identical to ICH-Q3A, many of the recommendations found in ICH-Q3A are applicable to drug substances used in generic drug products.
FDA (1997)	FDA's Policy Statement for the Development of New Stereoisomeric Drugs	Stereoisomers are molecules that are identical in atomic constitution and bonding, but differ in the three-dimensional arrangement of the atoms. This document focusses on issues relating to the study and pharmaceutical development of individual enantiomers (individual stereoisomers) and racemates (50 : 50 proportion of enantiomers). Circumstances for additional pharmacology, ADME and/or toxicity testing of individual enantiomers are discussed.
CPMP (2002)	Note for Guidance on Specification Limits for Residues of Metal Catalysts	This draft guidance from the European CPMP recommends maximum acceptable limits on specific metal residues arising from the use of catalysts in the synthesis of pharmaceuticals. The toxicological literature was used to define the maximum safe intake limits for individual elements, or permitted daily exposure (PDE), in $\mu g\,kg^{-1}\,day^{-1}$. Included are monographs of individual metal elements.
CPMP (2006)	Position Paper on the Limits of Genotoxic Impurities	This position paper describes a general framework and practical approaches on how to deal with genotoxic impurities in new drug substances.
FDA (2008)	Safety Testing of Drug Metabolites	This guidance discusses when additional animal testing may be required for metabolites formed in humans that were not formed in the animal species used during original safety assessment studies.
FDA (1997)	Drug Metabolism/Drug Interaction Studies in the Drug Development Process: Studies *In Vitro*	This FDA guidance provides suggestions on current approaches to studies *in vitro* of drug metabolism and interactions. It describes techniques and approaches for studies conducted *in vitro* of drug metabolism and drug interactions, correlation between *in vitro* and *in vivo* studies, the timing of metabolism studies in relation to drug development, and metabolic and exposure comparisons between animals and humans.
FDA (2006)	Nonclinical Safety Evaluation of Pediatric Drug Products	This document provides guidance on the nonclinical safety evaluation of therapeutics intended for paediatric patients. Some conditions under which juvenile animals are considered meaningful predictors of toxicity in paediatric patients are discussed and recommendations on nonclinical testing are provided. It also provides guidance on the role and timing of animal studies in the safety evaluation of therapeutics intended for the treatment of paediatric patients.

DOI: 10.1002/9780470744307.gat115
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

FDA (2005)	Pharmacogenomic Data Submissions	This guidance is intended to facilitate scientific progress in the field of pharmacogenomics and to facilitate the use of pharmacogenomic data in informing regulatory decisions. It discusses when pharmacogenomic data is to be submitted, the format of that data, and how the data will be used. Pharmacogenomic data must be submitted to an IND if any of the following apply: (i) the test results will be used for decision making in any clinical trial, or in an animal trial used to support safety; (ii) the sponsor is using the test results to support scientific arguments pertaining to, for example, the safety, effectiveness, dosing and pharmacology of the drug; or (iii) the test results constitute a known valid biomarker for physiologic, pathophysiologic, pharmacologic, toxicologic or clinical states or outcomes in humans, or a known valid biomarker for a safety outcome in animal studies. Data submission for NDAs is required if it is used to support scientific/clinical arguments or for labelling purposes. Otherwise, data submission is voluntary.
FDA (2007)	Pharmacogenomic Data Submissions: Companion Guidance	The recommendations made in this draft document apply to development of microarray data that might be submitted in support of INDs, NDAs and biologics licence applications (BLA)s. It covers issues relating to generation of gene expression data, genomic data and formats for data submission.
FDA (2008)	Nonclinical Safety Evaluation of Reformulated Drug Products and Products Intended for Administration by an Alternate Route	This draft guidance provides recommendations regarding the nonclinical evaluation of a new formulation containing a previously approved drug substance, and of a product proposed for use by an alternate route of administration for which the product was not previously approved.
FDA (2003)	Photosafety Testing	This guidance is intended to help applicants decide whether they should test for photosensitivity and assess potential human risk for photochemical carcinogenesis (cancer) of their drug products during the clinical development process. The guidance describes a consistent, science-based approach for testing for topically and systematically administered drug products. Basic concepts of photobiology and phototesting are described.
CPMP (2002)	Note on Guidance on Photosafety Testing	This guidance from the European CPMP defines the conditions under which photosafety evaluation of pharmaceuticals should be conducted. Also included are various test procedures, strategies and approaches to photosafety testing.
FDA (1993)	Guideline for the Study and Evaluation of Gender Differences in the Clinical Evaluation of Drugs	This guideline addresses the concern that the drug development process does not produce adequate information about the effects of drugs in women. It discusses the FDA's expectations regarding inclusion of patients of both genders in drug development, analyses of clinical data by gender, assessment of potential pharmacokinetic differences between genders and, where appropriate, assessment of pharmacodynamic differences and the conduct of specific additional studies in women. It also withdraws previous (1977) restrictions on the participation of women of childbearing potential in early clinical trials, including clinical pharmacology studies (e.g. dose tolerance, bioavailability and mechanism-of-action studies) and early therapeutic studies.
FDA (2001)	Integration of Study Results to Assess Concerns about Human Reproductive and Developmental Toxicities	This draft guidance describes a process for estimating the increase in human developmental and reproductive risks as a result of drug exposure when definitive human data are unavailable. The integration process focusses on the likelihood a drug will increase the risk of adverse human developmental or reproductive effects.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat115
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- appropriate toxicology studies which define a no observable adverse effect level (NOAEL) as well as defining the dose-limiting toxicity and potential major toxicity targets.

For products that will first be studied in patient volunteers with serious or life-threatening conditions, in addition to the above-mentioned studies, it is also imperative that nonclinical proof of concept and/or mechanistic studies demonstrating a reasonable chance of efficacy be submitted. For most clinical studies, it is necessary to take patients off current medications; therefore, for ethical reasons, there should be some evidence that the drug will not only be safe, but may also have some benefit.

The timing of reproductive and developmental studies differs between regulatory agencies. Teratogenicity studies are generally required prior to initial studies in humans. However, some agencies may waive this requirement if initial clinical studies can be performed using reliable methods of birth control, for example physical barriers (condoms) in men and either double-barrier protection or single-barrier combined with reliable birth control methods in women, or enrolment of nonfertile female volunteers. Prior to any exposures to pregnant or potentially pregnant women, most regulatory agencies require that the entire battery of reproductive and developmental studies be completed.

2.2 Duration of Treatment

The general rule is that the nonclinical studies should be of equal or greater duration than the proposed clinical study. For registration purposes, the nonclinical studies should be at least twice the duration of the proposed labelled clinical dosing regimen up to 6 months in rodents and 6, 9 or 12 months in nonrodents. The duration of chronic treatment in nonrodents depends on regional recommendations which take into consideration the safety profile of the drug and the patient population; for example, some regulatory agencies may recommend 12-month nonrodent studies for paediatric drugs.

2.3 Timing of Studies in Relationship to Clinical Development

In recent years, the term preclinical has given away to nonclinical to better reflect the ongoing development programmes designed to keep pace with clinical development. Clinical trials are conducted in phases grouped by their purpose and objectives. ICH E8 clinical guidance has defined the phases of clinical development as follows:

Phase 1: first-in-human exposure studies generally single dose, followed by dose escalation and short-term studies to evaluate safety and determine pharmacokinetic profiles.
Phase 2: exploratory safety and efficacy studies in patients.
Phase 3: confirmatory safety and efficacy studies in patients designed to support registration and labelling.

As mentioned above, the required duration of the nonclinical studies to support clinical development is dependent on the proposed clinical duration of treatment. The timing for particular studies may be dependent on the intended patient population. For example, fertility studies need only be done in one sex if the product is intended for only male or female use, although teratogenicity studies should be done regardless of sex, since effects may be mediated by either sex. Generally prenatal and postnatal developmental studies need only be submitted to support treatment in reproductively competent female patients.

As mentioned above, *in vitro* genotoxicity studies are required prior to first time in humans, whereas the *in vivo* genotoxicity study should be submitted prior to initiation of Phase 2 of clinical development. Carcinogenicity studies for nongenotoxic products are required at the time of registration. However, for products for which the weight of evidence suggests they are genotoxic, carcinogenicity studies may be required to support chronic clinical exposures during development.

2.4 Route of Administration

Pharmacodynamics (PD) can differ significantly between species. If adequate systemic exposures cannot be achieved in animal models compared with human exposures via the clinically relevant route of exposure, it may be necessary to conduct both local and systemic toxicity studies. Local studies would be performed using the clinically relevant route of exposure, for example dermal, intrathecal, intravaginal, and so on, whereas the systemic and reproductive toxicity studies may need to be performed using an alternative route such as oral, intramuscular or subcutaneous.

2.5 Relevance of Animal Models (Species Selection)

In general, toxicology studies are required in two species, one being nonrodent. However, there are exceptions to this rule based on the relevance of the available animal models. If it can be demonstrated that only one animal model has any relevance to humans, it may be possible to justify the use of a single species. This is the case for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat115
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

many biological products which may have targets that are only expressed in primates.

Metabolic profiles are also important in determining the relevance of animal models. Metabolism is important since toxicity may be dependent on a species' ability to clear and detoxify the parent molecule or conversely to form or eliminate a toxic metabolite. If an animal model cannot be found which has a similar metabolic profile to humans, then it may be necessary to produce and test any major, uniquely human metabolites along with the parent compound.

Caution should be exercised when planning a nonclinical development plan that it does not proceed far in advance of clinical development. Human pharmacologic data are vital in determining the adequacy of the nonclinical models and studies.

3 NONCLINICAL PHARMACOLOGY

For many therapeutic products, the exact mechanism of action is difficult to determine. Most drug developers have a working hypothesis of how the drug may work prior to dedicating costly resources to development. However, proof-of-concept studies in animals are just that, and are not considered evidence of efficacy. Nonclinical proof-of-concept studies are required only for products where the risk : benefit ratio is extremely high or where ethical considerations for serious and life-threatening conditions make it unethical to remove patients from a potentially beneficial approved treatment to enroll them in a clinical trial. Another scenario which requires animal efficacy studies is for indications where it would be unethical to test products under conditions of use, such as products to prevent or treat effects resulting from exposure to chemical or biological warfare agents.

Secondary pharmacologic targets should also be explored. This should include *in vitro* receptor and/or tissue-binding profiles. Secondary pharmacologic effects may be important in explaining off-target or species-specific toxicity, or lack of efficacy.

4 SAFETY PHARMACOLOGY STUDIES

Safety pharmacology studies are usually acute studies performed at the highest tolerated doses to evaluate potential acute effects on vital functions including the cardiovascular, renal, respiratory and central nervous systems. These studies should be performed prior to first time exposure in humans. Other safety pharmacology studies include evaluation of effects on gastrointestinal (GI) motility and abuse liability, which generally should be completed to support repeat-dose clinical studies.

5 TOXICOKINETIC AND PHARMACOKINETIC STUDIES

Exposure data in nonclinical models are important not only for comparing exposures in animals to humans, but also in determining the appropriateness of the selected animal model(s). Prior to 'first-time-in-human' clinical studies, *in vitro* metabolism data should be generated using liver microsomes, comparing nonclinical species and humans to ensure qualitatively comparable metabolic profiles prior to the first exposures to humans. These data also are necessary prior to selecting the animal species for studies conducted to support clinical trials. *In vivo* data should be generated early in development to qualitatively and quantitatively compare animal and human exposures and support selection of nonclinical models for pivotal toxicology, reproductive and carcinogenicity studies.

C_{max}, T_{max}, AUC, half-life and bioavailability are important parameters in determining safe doses in humans (see **Toxicokinetics of Xenobiotic and Metabolite Distribution and Excretion**). Additionally, ADME parameters, that is, absorption, distribution, metabolism and excretion, can vary widely between species and can significantly affect the toxicokinetic profile. Bioavailability may vary widely between species and even large doses in animals may result in only limited exposures compared with humans due to differences in absorption. Differences in metabolism and elimination can also significantly affect overall exposure to either the parent or an active or toxic metabolite. Acute toxicologic effects often correlate with C_{max} and are usually associated with central nervous system (CNS), respiratory, or cardiovascular toxicity, While most chronic and tissue-related effects are related to overall exposures, that is, AUC, and drug distribution.

In order to evaluate the potential risk of products with significant adverse effects, it is necessary to compare exposures. When comparing exposures between nonclinical species and between animals and humans, the optimal parameter is either C_{max} and/or AUC, based on the type of toxicity observed. In the absence of adequate pharmacokinetic (PK) data, doses should be compared based on body surface area ($mg\,m^{-2}$), which is a more conservative estimate than using body weight ($mg\,kg^{-1}$). Conversion factors used by the FDA to convert doses to $mg\ m^{-2}$ are presented in **Table 3** (FDA Guidance for Industry: Estimating the Maximum Safe Starting Dose in Initial Clinical Trials for Therapeutics in Adult Healthy Volunteers).

It is also important to evaluate the effect of gender and food consumption on ADME and pharmacokinetic parameters. If the product is to be used in both paediatric and adult populations, then age-related changes in ADME and pharmacokinetic parameters should also be evaluated.

Minipig	40	25–64	1.14	35	1.1	0.946

[a]For animal weights within the specified ranges, the HED for a 60 kg human calculated using the standard *km* value will not vary more than ±20% from the HED calculated using a *km* based on the exact animal weight.
[b]Assumes 60 kg human. For species not listed or for weights outside the standard ranges, human equivalent dose can be calculated from the formula: HED = animal dose in mg kg^{-1} × (animal weight in kg/human weight in kg)$^{0.33}$.
[c]The *km* is provided for reference only since healthy children will rarely be volunteers for Phase 1 trials.
[d]For example, cynomolgus, rhesus, stumptail, and so on.

6 NONCLINICAL TOXICOLOGY

In the development of pharmaceuticals, toxicology studies are used to support clinical development and to evaluate the potential risk to clinical volunteers and patients. Anyone performing toxicology studies to support submissions to regulatory agencies should consult all pertinent guidance documents. One of the most helpful and important guidances to consult when designing a nonclinical programme is ICH M3 Guidance for Industry: Nonclinical Safety Studies for the Conduct of Human Clinical Trials for Pharmaceuticals. This guidance discusses the extent and timing of nonclinical studies needed to support various stages of clinical development and an eventual submission for marketing approval.

Toxicology studies should be designed to define potential target organ toxicity, define a NOAEL and identify biomarkers that can be used to safely monitor potential toxicity in clinical trials. For new molecular entities, the toxicology studies are used to establish a safe starting dose and can influence inclusion and exclusion criteria for enrolment into clinical trials. In addition, the toxicology studies determine the scope of the initial clinical studies; for example, duration, doses, volunteer population, and so on.

6.1 Species Selection

Toxicology studies are generally conducted in two species, one rodent and one nonrodent. Although the rat and dog are the two most commonly used species, the choice of species should be based on its relevance to humans. If only one relevant animal model exits, then studies should only be conducted in that species. Whenever an alternative study design or a single or nontraditional species is used, investigators should contact the appropriate regulatory authority for concurrence.

6.2 Dose Selection

Toxicology studies are generally conducted at a minimum of three dose levels. Selection of the highest dose should

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat115
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be based on one of the following:

- Maximum tolerated dose (MTD)—the MTD is defined as the highest dose which does not result in intolerable or overt toxicity (e.g. convulsions, excessive body weight loss, necrosis, pain, paralysis, etc.) or death.
- Maximum feasible dose (MFD)—the MFD may be defined by such parameters as solubility, administration volume, dosing frequency, and so on.
- Dose-limiting pharmacodynamic effects.
- Saturation of absorption or exposure.
- Limit dose of $1000\,mg\,kg^{-1}\,day^{-1}$ (applicable for pharmaceuticals with human exposures of less than $1\,g\,day^{-1}$).

When a MTD, MFD or limit dose has been used in repeat-dose toxicology studies and the toxicity profile has been well characterized, then it may be possible in subsequent studies to use a large exposure multiple of the human exposure for the highest dose tested.

The low dose should be close to, or a low multiple of, the projected clinical dose, and ideally should identify the NOAEL. The median dose should induce mild toxicity and is used to establish the dose–response curve and help identify toxicity that may not have been evident at the high dose due to extreme toxicity or morbidity. The mid dose may also be important in establishing reversibility of findings that are lethal at higher doses. Ideally, the use of at least three dose levels allows investigators to identify target organ toxicity, potential dose-limiting effects, generate dose–response curves and identify the NOAEL. These parameters are essential for assessing risk at clinical doses and designing future nonclinical and clinical studies.

6.3 Duration

As stated earlier, the duration of the toxicology studies is dictated by the clinical development program. During development, nonclinical studies should be of equal or greater duration that the proposed clinical trial(s) that they are intended to support. For registration of a new product, the duration of the toxicology studies should be twice the duration of the proposed clinical dosing regimen up to a duration of three months. For indications that require chronic treatment greater than three months, toxicology studies should be conducted for up to six months in rodents and nine months in nonrodents (see ICH S4A Guidance for Industry: Duration of Chronic Toxicity Testing in Animals (Rodent and Nonrodent Toxicity Testing)). There are exceptions to the maximum duration of the nonrodent studies which can justify study durations of 6 or 12 months. Justifications for shorter durations may include intermittent dosing schedules, well-characterized drug classes, and/or low toxicity potential. On the other hand, 12-month studies may be requested based on use in paediatric populations, compounds with a unique mechanism of action, or late onset toxicity. For questions regarding the optimal duration for chronic nonrodent toxicology studies, one should consult the regional regulatory agency.

Use of a staged nonclinical development programme allows investigators to begin preliminary clinical investigations prior to investing large amounts of time or capital in lead compounds. Although a single-dose study in humans can be supported by single-dose studies in two animal species (one being nonrodent), two-week repeat-dose studies are preferred for a new molecular entity. Early clinical pharmacokinetic studies provide exposure data and metabolic data important for assessing risk and validating the appropriateness of the selected animal models.

All toxicology studies submitted to support clinical development or approval should be conducted in compliance with Good Laboratory Practice (GLP).

7 GENOTOXICITY

The standard battery for genotoxicity testing consists of two *in vitro* assays and one *in vivo* genotoxicity study (See ICH S2A and S2B). The *in vitro* assays should be conducted not only on the active drug substance, but also for any new excipients or impurities in the drug product. The *in vitro* genotoxicity assays should be completed and submitted to regulatory authorities to support first-time exposures in humans. The *in vivo* study should be conducted using the clinical product whenever possible and should be completed to support Phase 2 clinical studies or to support Phase 1 studies when there are positive or equivocal findings observed in the *in vitro* assays.

In general, genotoxicity is unacceptable except for drugs intended to treat life-threatening indications. Follow-up genotoxicity studies should also be performed according to the draft ICH S2(R1) Guidance for Industry: Genotoxicity Testing and Data Interpretation for Pharmaceuticals Intended for Human Use. If the drug substance is determined to be genotoxic, the carcinogenicity potential of the product should be evaluated using either *in vitro* or *in vivo* carcinogenicity models prior to repeat-dose clinical studies. Single-dose pharmacokinetic studies in patients are allowed to evaluate the adequacy of the selected animal species. Interpretation of the genotoxicity risk associated with drug products should be based on a weight-of-evidence assessment and the risk/benefit profile for the particular drug and intended population.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat115
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

8 CARCINOGENICITY

Carcinogenicity studies are designed to assess tumorigenic risk associated with use of pharmaceutical products. In general, carcinogenicity studies are required for products that will be administered continuously for six months or longer, or for products that are administered intermittently with a cumulative exposure period of six months over a 10-year period (ICH S1A). For nongenotoxic products, carcinogenicity studies are generally performed during Phase 3 of clinical development, and should be filed with the supporting documents for product registration. All studies should be conducted in compliance with GLP.

Most studies are performed with food available *ad libitum*. Use of dietary restriction has been shown to decrease the number of spontaneous tumours in control animals; therefore, if this type of protocol is selected, the incidence of tumours should be compared only across historical controls from dietary-restricted studies.

For most products needing carcinogenicity assessment, two-year studies in mice and rats of both sexes are required, regardless of the intended population (i.e. male-only or female-only drugs). Six-month studies in transgenic mice may be used as an alternative for the traditional two-year mouse study. The P53 transgenic mouse model is appropriate only for genotoxic compounds, whereas the Tg.AC transgenic mouse model is appropriate only for topically applied products. Regardless of the model selected, particular attention should be made to ensure that all major human drug metabolites are represented in one or the other of the species selected. If metabolism is not qualitatively or quantitatively similar, it may be necessary to either test the metabolite alone, or spike dosing preparations with the metabolite to ensure proper assessment of carcinogenic potential.

Vehicle controls and three dose groups should generally be evaluated. Dose selection for two-year studies is most often based on 13-week toxicology studies using the same strain of animals, and studies in transgenic carcinogenicity models on one-month toxicology studies. The wild-type background strain can be used for dose selection. The high dose should be selected with care to ensure that it will not have an effect on overall survival. ICH S1C outlines five generally acceptable criteria for selection of the high dose: (i) MTD established in 13-week (or longer) toxicology studies, (ii) 25-fold rodent : human AUC ratio, (iii) dose-limiting pharmacodynamic effects, (iv) saturation of absorption or exposure, and (v) MFD. The low dose should be similar to the proposed clinical dose, and the mid dose should fall between the low and high doses, with optimally at least a three-fold difference between doses or exposures. The frequency of dosing is usually once per day, but can be varied depending on the PK parameters of the product. In general, the route of administration should be similar to the intended clinical route. An alternative route of administration may be acceptable if it can be shown to have a similar kinetic profile to the clinically relevant route. For orally administered drugs, mixing the product in the feed is acceptable as long as comparable systemic exposure levels can be achieved. In the USA, results from dose-range finding studies and carcinogenicity study protocols should be submitted prior to initiation of the studies, for concurrence on species and dose selection by the Executive Carcinogenicity Assessment Committee (see FDA Guidance for Industry: Carcinogenicity Study Protocol Submissions).

Exceptions to the requirement of carcinogenicity studies in two species are made on a case-by-case basis, and there are cases where carcinogenicity studies might we waived completely, for example an active metabolite of an already approved product, chronic tolerability issues, traditional medicines or dietary components with a long history of use, and so on. Waiver requests should be submitted to each regional authority where marketing applications will be filed.

9 REPRODUCTIVE AND DEVELOPMENTAL TOXICOLOGY STUDIES

Reproductive and developmental toxicology studies are performed to assess any effects pharmaceutical products may have on: male and female fertility; early embryo/foetal development including implantation; embryonic development through organogenesis; parturition and maternal behaviour, lactation and weaning; and postnatal development (i.e. behaviour, cognition, growth and reproductive competence). Studies can be combined into one study design or into segments: (i) fertility and early embryonic development, (ii) embryo-foetal development, and (iii) prenatal and postnatal development. Dose range-finding studies should be performed in pregnant animals to determine a MTD or MFD, and species selection should be based on applicability to humans and similar metabolic profiles. Whenever possible, the clinical route of exposure should be used; however, if this route does not provide adequate systemic exposure, an alternative route may be used. Definitive studies should be performed in accordance with GLP guidelines.

The timing of reproductive and developmental studies should coincide with the clinical development plan. Even when using reliable forms of birth control, pregnancies do occur during clinical trials. Therefore, the embryo-foetal developmental (teratogenicity) studies are generally needed to support repeat-dose clinical studies in reproductively competent women. Regional differences exist on the timing for fertility studies, but they are generally recommended prior to performing repeat-dose

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat115
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

studies in reproductively competent men and women. The prenatal and postnatal reproductive and developmental studies are generally conducted during Phase 3 of development and submitted with the marketing application. For investigational products which are designed for use during pregnancy, all stages of reproduction and development, including fertility and postnatal studies, must be completed prior to dosing in pregnant women.

9.1 Fertility and Early Embryonic Development

Fertility and early embryonic development studies are generally assessed in a single species, usually the rat. Males are dosed prior to, and through, mating, while females are dosed prior to mating through implantation, that is, gestation day 6–7 of presumed pregnancy. Doses can be selected based on toxicology studies of at least two to four weeks duration. If treated animals are mated, it should be done on a 1 : 1 ratio; however, the more conservative approach is to mate treated animals with untreated animals to assess male and female parameters independently. Parameters evaluated include mating behaviour, fertility, preimplantation stages of the embryonic development, and implantation. Reversibility of any effects on fertility should be assessed.

9.2 Embryo-Foetal Development

Embryo-foetal developmental studies are assessed in two species: one rodent (generally rat) and one nonrodent (generally rabbit). Pregnant females are exposed from implantation through the period of major organogenesis and closure of the hard palate. Doses should be selected based on dose range-finding studies in pregnant animals using the same criteria used for general toxicology studies. Potential changes in pharmacokinetic parameters between pregnant and nonpregnant animals should also be assessed in the dose range-finding studies rather than in the pivotal studies since maternal stress can significantly affect reproductive outcomes.

Potential product-related effects that should be assessed include enhanced maternal toxicity relative to that in nonpregnant animals, embryo-foetal death, altered growth and teratogenicity.

Exceptions to the requirement for embryo-foetal developmental studies in two species are made on a case-by-case basis. Whenever an alternative study design or a nontraditional species is used, investigators should contact the appropriate regulatory authority for concurrence.

9.3 Prenatal and Postnatal Development

Prenatal and postnatal development studies are generally assessed in a single species, usually the rat. These studies are designed to assess effects on parturition, lactation, maternal behaviour and postnatal development. Postnatal parameters which are evaluated include survival, altered growth and development, including behaviour, learning and memory, and reproductive maturation and function. Pregnant females (F0 generation) are exposed from implantation through the end of lactation. If the active pharmaceutical substance and major metabolites are not excreted in maternal milk, it may be necessary to directly dose the first generation (F1) offspring. Following birth, litters are generally culled to allow for litter-to-litter comparisons to be made on developmental and maternal parameters. Following puberty, one male and one female from each litter are selected for assessment of reproductive function. These animals are mated to either untreated animals or to treated animals in the same dosing group to assess potential effects on fertility and early embryonic development in the next generation (F2).

10 PRODUCT-SPECIFIC CONSIDERATIONS

Certain classes of pharmaceutical products may not be amenable to the standard paradigms for toxicologic assessment, for example, two species, chronic studies including two-year carcinogenicity studies, and so on, or might not require all recommended studies. Examples of products which might fall into this category include recombinant human proteins which may elicit an immune response in all nonhuman species, botanical products which are found in either traditional medicines or in commonly consumed foods, and active metabolites of previously approved pharmaceutical substances. Consultations with the appropriate regulatory authorities are recommended when planning an alternative nonclinical development programme.

Assessment of immunogenic effects is important for all biological products (See ICH S6). The nature and extent to which antiproduct antibodies are formed in nonclinical species is important in data interpretation and study design. Antiproduct antibody can neutralize activity and affect clearance, limiting the duration of dosing and species selection. It is also important to select a species in which the biologic is active in order to assess potential exaggerated and secondary pharmacodynamic effects. If an appropriate animal model cannot be found it may be necessary to use a surrogate analogue in an appropriate species in which the analogue has similar biological function.

For many botanical products, depending on the past history of use, an abbreviated nonclinical programme

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat115
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

may be recommended. If there is a long history of safe use in traditional medicine or the agent is commonly consumed at similar levels in the diet, then many of the standard studies may be waived. However, it should be noted that if the use of the product consists of purified individual components, or is administered via a route of administration different from its traditional use, then the standard recommendations for toxicology, genotoxicity, carcinogenicity, and reproductive and developmental studies will commonly be required for registration.

For pharmaceutical products that are an active metabolite, a new salt form, or a new formulation of an already approved product, then it may be possible that bridging studies can be used to bridge the safety of the new product with the already approved product. Typically, bridging studies consist of a three-month standard toxicology study. If no significant difference is observed in the toxicology profiles of the two products, no further nonclinical studies are generally required as long as the proposed clinical exposures and patient populations are similar. For sponsors with products seeking a new indication in a different patient population, for example paediatrics, opposite gender, immune deficient, and so on, specific studies may be needed to ensure the safe use in that population.

11 ROLE OF NONCLINICAL TOXICOLOGICAL SUPPORT FOR CLINICAL STUDIES AND MARKETING

Nonclinical studies play an important role in the development of pharmaceutical products. They are used as the bases for setting dosing limits and inclusion/exclusion criteria for first-time exposures in human clinical studies, to provide valuable data regarding clinical monitoring and identify relevant biomarkers, and to assess reversibility of adverse effects. Nonclinical studies, because they are done at considerably higher doses than used in clinical studies, can also be used to assess potential toxicity resulting from a medication overdose. Two areas where it is difficult if not impossible to establish safety during clinical investigation are in potential risks during pregnancy and long-term carcinogenicity potential, making these studies pivotal to evaluating the overall safety of drugs prior to marketing.

12 CLINICAL TOXICOLOGY

Monitoring for adverse effects associated with pharmaceuticals products is a continuous process. It begins in the nonclinical studies and continues in clinical trials and postapproval.

During the investigatory process and postapproval, investigators must submit annual reports detailing all reported adverse effects. The FDA requires that all product-related deaths, and unexpected life threatening adverse events requiring hospitalization, or reports of congenital malformations, must be reported to the agency within 15 days. This also applies to effects observed in animals and includes carcinogenic findings in routine toxicology studies.

In the USA, patients, investigators and physicians are informed of potential risks associated with pharmaceutical products by various means, including:

- investigator's brochures
- patient informed-consent forms
- FDA alerts
- Dear Dr. letters
- MedGuide
- Drug Safety Newsletter.

ACKNOWLEDGEMENTS

I would like to acknowledge and thank Dr. David Jacobson-Gram and Dr. Amy C. Nostrandt for their editorial comments, and Dr. Thomas Papoian for compiling and annotating the guidance documents and recommended reading. I would also like to thank the countless unnamed authors of the ICH and regional guidance documents for their dedication and commitment to providing guidance for nonclinical development programmes for pharmaceutical products.

FURTHER READING

Baillie, T. A., Cayen, M. N., Fouda, H., Gerson, R. J., Green, J. D., Grossman, S. J., Klunk, L. J., LeBanc, B., Perkins, D. G. and Shipley, L. A. (2002). Drug metabolites in safety testing (PhRMA Position Paper). *Toxicology and Applied Pharmacology*, **182**, 188–196.
This publication is the result of a joint PhRMA (Pharmaceutical Research and Manufacturers of America)/FDA workshop held in November 2000. It proposes to define practical and scientific-based approaches to the use of metabolite data in the safety evaluation of drug candidates in both humans and animals. Metabolites are distinguished by: major vs. minor; pharmacologically active vs. inactive; Phase 1 (oxidative metabolites) vs. Phase II (conjugates); formation via a reactive intermediate; and possession of any structural alerts.

The article provides a general overview of excipients as components of drug products. Discussed are historical uses and specific toxicities of excipients, and issues relating to safety testing of potential excipients.

Roth, A., Kadyszewski, E., Geffray, B., Paulissen, J. and Weaver, R. J. (2007). Excess mortality in two-year rodent carcinogenicity studies. *Toxicological Pathology*, **35**, 1040–1043.
This paper considers the impacts of various patterns of differential or excess mortality on the biological and statistical interpretation of two-year rodent carcinogenicity studies. It provides suggestions on experimental design that are intended to maximize the value of such studies for carcinogenic risk assessment. Specifically, it recommends dose reduction, possibly to the level of dose cessation, when biologically feasible, and considers the merits of termination of the entire study as alternatives to the commonly employed strategy of terminating particular dose groups. It then recommends statistical analysis modifications that are appropriate when these suggestions on experimental design are adopted.

Sakai, T., Takahashi, M., Mitsumori, K., Yasuhara, K., Kawashima, K., Mayahara, H. and Ohno, Y. (2000). Collaborative work to evaluate toxicity on male reproductive organs by repeated dose studies in rats—overview of the studies. *The Journal of Toxicological Sciences*, **25**, 1–21.
This study was performed to examine whether or not lesions in the male reproductive organs noted in four-week treatment studies can also be detected after two-week treatment. The data supported the conclusion that in most cases adverse effects on male reproductive organs could be detected with two-week treatments.

Combustion Toxicology and Implications for Adverse Human Health Effects

Bryan Ballantyne

CONTENTS

1 INTRODUCTION AND BACKGROUND

Combustion toxicology is essentially concerned with the nature and potential adverse health effects of products resulting from the heating or burning of materials; effects include local irritation, incapacitation, systemic toxicity and lethality. In the USA there are around 6000 deaths annually due to fires, with a very much larger number of nonfatal injuries (Alexeeff and Packham, 1984; Gad, 1990a). Annual fire- and flame-related deaths in the USA are apparently responsible for more than all natural disasters combined, and account for one of the highest fire-death rates per capita in the industrialized world (Beljan *et al*., 1987). About one-fifth of fire-related deaths occur in the workplace. Thus, the National Traumatic Occupational Fatalities (NTOF) surveillance system of the National Institute for Occupational Safety and Health (NIOSH) recorded 1518 fire- and flame-related occupational fatalities among the civilian workforce in the USA between 1980 and 1994 (Biddle and Hartley, 2000). Fires associated with tobacco use are the leading cause of residential fire deaths in the USA (Hall *et al*., 2006). Casualties that occur during or as a consequence of exposure to a fire do so for various

reasons, of which the following are the principal causes:

1. **Direct physical trauma:** for example, resulting from structural collapse of buildings.
2. **Flame and heat:** direct thermal injuries to the skin and/or respiratory tract, or as a result of secondary complications from primary thermal injuries.
3. **Oxygen depletion:** this may be a primary factor for adverse effects and/or enhance the toxicity of respirable chemicals in the fire atmosphere (see also Section 3.2.2).
4. **Factors hindering escape:** these may increase the likelihood for further exposure to flame, heat, oxygen depletion and toxic materials in the atmosphere. Escape may be impeded by physical injury, obscuring smoke, prior use of alcoholic drinks or narcotic drugs, panic, the presence of peripheral chemosensory irritants (PCSI) or depression of central nervous system (CNS) function from specific materials in the fire atmosphere. It has been shown that alcoholic intoxication has been a significant impairing factor in some fires, and may have impeded escape. Thus, in a study of fire deaths in Maryland, USA, blood ethanol concentrations $>150\,\mathrm{mg\,ml^{-1}}$ were found in 35% of victims (Radford *et al*., 1976). In an study of 178 deaths in fires in Victoria, Australia, 53 victims had ethanol detected in blood (average concentration 0.07%), of which 42 had blood ethanol $\geq 0.01\%$ (legally intoxicated); the mean carboxyhaemoglobin (COHb) concentration was higher in those who were intoxicated (Yeoh and Braithberg, 2004). Marshall *et al*. (1998), in a series of 190 burn victims, measured ethanol in 130 adults that was found to be $\geq 0.01\%$ in 69 cases (53%). In a series reported from Scotland, Squires and Busuttil (1997) reported that in 1064 adult cases, blood ethanol could be detected in 694 cases; a mean concentration of 0.14% was reported, with a concentration of $\geq 0.01\%$ in 393 cases. The incapacitating effects of several chemicals found in fire atmospheres are appreciated, because of their effects on CNS and/or muscle function. For example, it is well known that hydrogen cyanide (HCN) and carbon monoxide (CO) can rapidly produce incapacitating effects (see Sections 5.2 and 5.3). Behavioural impairment in smoke environments has been reviewed by Purser (1996).
5. **Toxic substances in the fire atmosphere:** these may be in gaseous, vapour or particulate form, being produced by the heating or burning of materials, or released from chemical storage sites as a result of container damage. These materials may produce local (eye, skin, respiratory tract) toxicity and/or cause systemic toxicity if absorbed. Also, as, for example, with fire-fighters, in addition to paying attention to acute effects there should also be consideration of repeated exposures and the potential for cumulative and long-term effects. Immediate and long-term adverse health effects also need to be taken into consideration in developing protection factors for respiratory protective equipment (Burgess and Crutchfield, 1995).

According to the US Consumer Product Safety Committee, between 1970 and 1985 the total numbers of deaths from structural fires decreased from 5000 to 4000 per year, but the number of fatalities attributable to smoke inhalation remained constant at around 3000 per year (USCPSC, 1988). Other estimates have indicated that about 30% of major burns victims have smoke-inhalation injury, and, for fatalities, up to 80% may have had smoke inhalation (Bowes, 1976; Heimbach and Waeckerle, 1988; Haponik, 1993).

The site, structure(s) affected and related geography of fires may be major determinants of the severity and potential complications. For example, fires involving industrial complexes may present physical and toxic hazards because of the possible presence of warehouse stores of flammable and explosive materials, and of large amounts of toxic chemicals and mixtures, hence increasing the likelihood of hazards from potential physical, thermal and toxic injuries. Wildfires, which generate significant quantities of known health-damaging pollutants, including carcinogens (Naeher *et al*., 2007), present a multiplicity of problems, including the following: may affect very large areas; produce considerable heat and smoke; result in destruction of involved properties; cause the evacuation of local populations; dependent on meteorological conditions be difficult to contain and control; be a source of smoke exposure to fire-fighters and to surrounding populations, again dependant on meteorological conditions; may require sustained days of intense work by fire-fighters who are thus at increased physiological and psychological stress and result in considerable economic losses. For example, over the period 21–26 October 2007, wildfires consumed hundreds of thousands of acres and forced the evacuation of more than 300 000 people in San Diego County, California, USA. The health effects resulting from this disaster were monitored using the BioSense system of the US Centers for Disease Control (CDC), which is a national system that enables receipt, analysis and visualization of electronic health care data from emergency departments (EDs) and hospitals (CDC, 2004). For six hospitals in San Diego County, analysis of combined data for respiratory disease indicated that, compared with the previous 20 weekdays, ED visits during the five-day fire period increased from 48.6 to 72.6 $\mathrm{day^{-1}}$ for dyspnoea and from 21.7 to 40.4 $\mathrm{day^{-1}}$ for asthma (CDC, 2008).

2 GENERATION OF FIRE ATMOSPHERES RELATED TO MORTALITY AND MORBIDITY

Smoke is a complex mixture of airborne solid and liquid particulates, vapours and gases, which are evolved when materials undergo vapourization and thermal decomposition. Thermal decomposition may conveniently be described under the following considerations:

1. **Anaerobic pyrolysis:** thermal breakdown and chemical conversion of materials in a low-oxygen environment.
2. **Oxidative pyrolysis:** thermal breakdown and chemical conversion of materials in a normal oxygen environment, but in the absence of flaming ('shouldering').
3. **Flaming combustion:** thermal breakdown and chemical conversion of materials in a normal oxygen environment in the presence of flaming.

All the above processes may be operating at the same time and at different geographical locations in a fire, and one or another may predominate. *Pyrolysis* is usually defined as the thermal degradation of a material at a temperature below the autoignition temperature. *Flaming* is the highly efficient burning of a material above the autoignition temperature in the presence of sufficient oxygen. *Thermolysis* is a generic term covering flaming, pyrolysis and shouldering.

The atmosphere from a fire is usually of extremely complex chemical composition and, because of the constantly changing conditions during the progress of a fire, the chemical composition (both the nature and the concentration of materials) varies markedly at different stages of the fire. Also, the characteristics and hazards of one fire may be entirely different to that of another. The chemical composition of the fire atmosphere and the concentrations of individual constituents depend on a large number of variable factors, of which the most important are:

1. The nature of the materials available for heating or burning
2. Phase of the combustion process
3. The potential for chemical and/or physical interactions between materials present in the fire atmosphere
4. The potential for additive or synergistic toxic effects
5. Temperature
6. Airflow and oxygen availability.

A review of European and North American literature indicates that some 50–75% of deaths that occur within a few hours of a person being involved in a fire are due to toxic effects of chemicals in the fire atmosphere. After about 12 hours, the contribution of toxic effects to mortality is considerably less. Over the past few decades the contribution of chemical toxicity to mortalities and nonfatal injuries has increased. For example, in the UK, during the period 1955–1974, the total number of fire fatalities increased by 70%; whilst those due to burns and scalds fluctuated around 400–600 annually, those attributed to the effects of smoke and gases showed a steady increase. The increasing hazard from exposure to toxic materials was also been demonstrated by consideration of the total incidence of fatal and nonfatal smoke casualties; there was a 600% increase over the 19-year period (Ballantyne, 1981). In the USA there are approximately 6000 deaths annually related to fires, with smoke inhalation being responsible for about 80% of fatalities (Alexeeff and Packham, 1984; Kaplan, 1988; Gad, 1990a). Also, there is an increased probability of death for fire victims having smoke-inhalation injury and burns (Zawacki *et al*., 1977; 1979; Shirani *et al*., 1988). There are very reasonable grounds to believe that the marked increase in smoke and gas casualties is due to the introduction of man-made materials for construction and furnishing. Thus, combustion processes involving polymers result in the generation of a variety of low-molecular-weight materials that may have significant irritant effects and acute and/or long-term systemic toxicity. The nature and relative proportions of toxic substances generated from the combustion of polymeric materials varies with both the nature of the polymer and the conditions of burning. The possible range of toxicity resulting from exposure to an atmosphere generated by combustion is reflected in the following list of products typically produced from combustion of different types of polymers: acetaldehyde, acrolein, phosgene, HCN, CO, hydrogen chloride and vinyl chloride. Mortalities resulting from the inhalation of chemicals in a fire atmosphere may be due to local chemical injury of the respiratory tract and/or systemic toxicity following absorption of inhaled materials. The latter may include disturbances of biochemical mechanisms or transport processes, or tissue injury. Nonlethal adverse health effects may be due to more restricted or less severe local respiratory-tract injury or systemic toxicity.

It should also be appreciated that inhaled smoke and fumes may contain the products of incomplete combustion, which continue to release heat following inhalation, resulting in thermal injury to the laryngotracheobronchial mucosa and, with sufficient penetration, to the alveolar epithelium. These thermal injuries will complement any chemically induced respiratory-tract injury (Zachria, 1972). Smoke inhalation may cause pulmonary oedema, in which there is increased permeability of the pulmonary microvasculature (Niemann *et al*., 1989). Studies of experimentally produced smoke injury in sheep showed that the primary, and dose-responsive, injury was acute cell-membrane damage in the trachea and bronchi leading to oedema, progressive necrotic tracheobronchitis with

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat116
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

pseudomembrane formation and obstruction of airways (Hubbard *et al*., 1991). Morphological alterations occurring in the alveolar epithelium included intracellular oedema (Type II cells) and interstitial oedema. Hales *et al*. (1988; 1992) postulated that acrolein might be a major component of smoke causing pulmonary oedema. In work with anaesthetized sheep, and using smoke from burning cotton, they found an acute increase in pulmonary vascular permeability, an increase in airways resistance and decreased P_aO_2. A combined cyclo- and lipo-oxygenase inhibitor, BW-755 C, prevented all these changes, whereas indomethacin, a cyclo-oxygenase inhibitor, prevented the increase in airways resistance, but not the increase in microvascular permeability. They regarded their studies as indicating that leukotrienes may have a role in producing cotton-smoke-induced noncardiogenic pulmonary oedema.

Respiratory-tract injuries in humans resulting from smoke inhalation and causing local thermal and chemical injury may be severe and result in multiple complications, such as tracheobronchitis, pneumonia, pulmonary oedema and low ventilation/perfusion ratio. Blood creatine kinase (CK) activities are raised, possibly due to induced rhabdomyolysis, and may be prognostic of the overall severity of injury (Irrazabal *et al*., 2008). Fibre optic bronchoscopy can be useful for identifying the severity of airway injury and for performing bronchial toilet and bronchoalveolar lavage culture to permit early diagnosis of pulmonary infections. Although the role of corticosteroids in the acute management of smoke-inhalation injury is subject to controversy (Micak *et al*., 1997), others regard them as being effective for the treatment of noninfectious pulmonary complications, such a persistent acute respiratory distress syndrome (ARDS), interstitial pneumonia or bronchiolitis obliterans (Irrazabal *et al*., 2008).

Although most emphasis is usually devoted to the acute toxic effects of fire atmospheres, there is also the potential for long-term adverse health effects, particularly when exposures are prolonged and, especially, when repeated. This is a notable consideration for assessing the hazards of fire-fighting; see Section 7. The general management of casualties from fires has been discussed with reference to toxicology by Harrigan and Winograd (1994), Irrazabal *et al*. (2008) and Latenser and Iteld (2001).

Whilst most discussions on the toxicology of combustion products is of the harmful products liberated during fire situations, adverse effects also result from exposure to products resulting from the heating or burning of materials in defined occupational and domestic conditions. Two typical examples of illnesses resulting from inhalation exposure to the products resulting from heating of polymers are meat wrappers' 'allergy' and polyfume fever. Meat wrappers' allergy affects some workers exposed to fumes whilst wrapping meat in polyvinyl chloride (PVC) film. The origin of fumes comes from several sources, including cutting rolls of PVC with a hot wire (about 105°C), from heat sealing of the film ends, and from thermal fixing of an adhesive label to the wrapped product. The heating element temperature is around 200°C (Levy, 1988). The major products from hot-wire cutting of PVC film include di-2-ethylhexyl phthalate and hydrogen chloride, and those from the thermal attachment of labels include dicyclohexyl phthalate, phthalic anhydride, dicyclohexyl ether and cyclohexylbenzoate (Levy *et al*., 1978; Vandevort and Brooks, 1979). Affected meat wrappers complain of cough, wheezing, shortness of breath and chest tightness, together with symptoms and signs due to irritation of the throat and eyes. The spectrum of the illness should be interpreted as a complex response to emissions from all phases of the wrapping process (Andrasch *et al*., 1975). It is generally considered that exposure to the products resulting from the heating of PVC in the meat-wrapping environment produce effects compatible with irritation of the eyes and respiratory tract. In those with pre-existing asthma or chronic obstructive airways disease there may be an exacerbation of these conditions. The effects produced accord with respiratory-tract irritation and hyper-reactivity; the role of an immune process is debatable (Brooks, 1983). The clinical presentation is similar to that of the reactive airways dysfunction syndrome (RADS) described by Brooks *et al*. (1984). Polyfume fever is the result of exposure to the pyrolysis products of polytetrafluoroethylene (PTFE) after contamination of cigarettes with the polymer in an occupational environment. Workers who smoke PTFE-contaminated cigarettes subsequently develop an 'influenza-like syndrome', characterized by cough, chest tightness, a choking sensation and chills. There is, characteristically, a latent period of several hours between exposure and the development of symptoms; recovery is usually complete within 12–48 hours (Gantz, 1988). Long-term sequelae are unusual. The principal thermal decomposition product of PTFE up to 500°C is the tetrafluoroethylene (TFE) monomer, but also perfluoropropene and other perfluoro compounds containing four or five carbon atoms. In the temperature range 500–800°C, the major pyrolysis product is carbonyl fluoride (Hathaway *et al*., 1991).

It is relevant to note that flame retardants themselves may exert toxicity and adverse human health effects, and also lead to the release of toxic products on their combustion. Polybrominated diphenyl ether (PBDE) and polybrominated biphenyl (PBB) flame retardants are widely used in consumer products, including electronic equipments, fabrics and carpet linings (Alaee *et al*., 2003; Saito *et al*., 2007). Of the 209 PBDE congeners (Darnerud *et al*., 2001), penta-, octa- and deca-BDE have been most used commercially. PBDEs are reported to be thyroid-hormone antagonists and endocrine disrupters (Gillner and Jakobsson, 1996; Hallgren and Darnerud, 2002; Legler *et al*., 2002; Meerts

et al., 2001; 2002; Rahman *et al*., 2001), and to be associated with neurobehavioural, reproductive and developmental toxicity (Branchi *et al*., 2003; Viberg *et al*., 2004), and possibly immunotoxic effects (Reistad *et al*., 2005). Blood levels and temporal trends of PBDEs have been reported by Schecter *et al*. (2005). The combustion products from phosphorus-based fire retardants, and their toxicological effects has been discussed in detail by Purser (1992).

3 NATURE AND TOXICITY OF FIRE ATMOSPHERES

3.1 General Considerations

The thermal decomposition of a material may produce a wide range of lower-molecular-weight species of differing irritancies and toxicities. In the atmosphere, the number, nature and relative proportions of the individual products from a fire depend on the chemical and physical nature of the material burned and the conditions of the combustion process. This may be illustrated by considering the simple burning of wood in an enclosed space (**Table 1**). Carbon, hydrogen and sulphur are available as the common combustion elements. During the early phase of burning, sulphur dioxide, carbon dioxide, CO and water are formed. As oxygen becomes depleted and burning becomes slower, more CO and sulphur dioxide are formed. With further decrease in oxygen availability, incomplete combustion occurs and hydrogen, methane, CO and free carbon are produced. In the smouldering phase, hydrogen, methane, sulphur dioxide, carbon dioxide, CO, free carbon and smoke are all generated. This simple example indicates that as a fire progresses and the temperature increases, the available oxygen decreases (especially in enclosed spaces), and toxic, irritant and flammable gases are produced, and an obscuring smoke is formed. Additionally, and also with combustion of wood, other irritant and systemically toxic materials may be produced; for example, formaldehyde, methanol, acetic acid and other organic irritants (DeKorver, 1976). Even with the apparently simple example of wood, a multiplicity of differing chemicals may be produced; for example, combustion of Douglas fir produced in excess of 75 discrete chemicals in the smoke (Packham and Hartzell, 1981). Smoke is often defined as a complex mixture of airborne solid and liquid particulates and gases produced when a material undergoes thermal decomposition (Kaplan, 1988). Smoke may be obscuring, contain smouldering particles that can produce thermal injury to the respiratory tract, and contain irritant and toxic substances in gas or vapour form, or absorbed onto the surface of particulates. As noted above in Section 2, the ubiquitous introduction of man-made polymeric materials into domestic, industrial, business and public buildings and furnishings has been associated with a wider spectrum of toxicity than that produced from natural polymers (Alarie, 1985; Ballantyne, 1981; Gad, 1990a). Products released by the combustion of synthetic polymers may have a significant contribution in morbidity and mortality in fires (Ballantyne, 1981).

Examples of the different highly toxic and irritant chemical species produced by the combustion of synthetic polymers are shown in **Table 2**. It can be seen that the nature and number of chemical species depends on the conditions of combustion for the particular specific polymer. For example, PVC yields hydrogen chloride as a principal combustion product, but, additionally, another 75 chemicals may be produced (Dyer and Esch, 1976; Wooley, 1971). Combustion of polyethylene yields 55 compounds, and polypropylene yields 56 compounds (Mitera and Michael, 1985). With polypropylene, the main thermal degradation products are formaldehyde, acetaldehyde, 2-methylacrolein, acetic aid and acetone (Frostling *et al*., 1984). N-containing polymers may yield HCN and various cyanogens.

Inhaled products of combustion consist of solid and liquid particulates, mists, vapours and gases. In general,

Table 1 Products from the burning of wood in an enclosed space, and the influence of the stage of burning

	Burning stage[a]			
Factor	Free	Slowed	Incomplete combustion	Smouldering
Oxygen (%)	20	17	15	<13
Temperature (°C)	40	205	370	550
Products	SO_2+	SO_2+	SO_2++	SO_2++
	H_2O++	H_2O++	H_2O++	H_2O++
	CO+	CO+	CO++	CO++
			H_2+	H_2+
			CH_4+	CH_4+
			Free C+	Free C+++
			Smoke+	Smoke+++

[a]The + designation shows the relative proportion of the product present.

Table 2 Examples of toxic and irritant chemicals that may be generated by combustion of commonly occurring polymeric materials

Material	Combustion products[a]	Reference
Poly(vinyl chloride)	Hydrogen chloride Carbon monoxide	Dyer and Esch (1976). Michal (1976)
Polyethylene	Formaldehyde Acrolein	Morikawa (1976)
Polyacrylonitrile	Hydrogen cyanide	Morikawa (1978)
Polyurethane foams	Toluene di-isocyanate	Wooley (1974)
	Hydrogen cyanide Carbon monoxide	Bowes (1974)
Polytetrafluoroethylene	Hydrogen fluoride	Young *et al*. (1976)

[a]These are not necessarily the only low-molecular-weight products generated on combustion of the polymer, but are given to illustrate the more toxic materials produced. The relative proportion of the materials generated depends on the conditions of the combustion process.

the local injury from inhaled combustion products is of greater concern than thermal injury from inhaled hot smoke. The upper airways dissipate heat, and most thermal injury is limited to the supraglottic airway (Bizovi and Leikin, 1995). The site and extent of injury is determined by the nature and relative amounts of inhaled irritants and particulates. Head (1980) and Haponik *et al*. (1988) have documented the histopathology of smoke inhalation. This includes pulmonary hyperexpansion, atelectasis and congestion. Features such as focal intra-alveolar haemorrhages and pulmonary oedema may be followed by infective changes (Hill, 1996).

3.2 Factors Affecting the Generation of Combustion Products

The specific chemical species generated during combustion, and their relative proportions, are dependent on various environmental factors (**Table 3**). Additionally, these factors may quantitatively modify toxic response. Particularly relevant factors are as follows.

3.2.1 Oxygen Availability

The availability of oxygen in the in the burning area may significantly affect the generation of combustion products. For example, at a temperature in the range of 500–600°C and with low atmospheric oxygen content, polyethylene combustion gives a high acrolein yield, but with the same temperature range and a high atmospheric oxygen content the acrolein yield is low (Morikawa, 1976). As an example of the influence of atmospheric oxygen availability on toxicity, **Figure 1** shows that for any given atmospheric CO concentration, lethal toxicity increases at that concentration with decreasing oxygen content of the atmosphere. This is due, at least in part, to a proportionately lower oxygen availability to maintain vital processes where oxygen transport is already compromised by CO toxicity. This consideration is clearly highly relevant to practical fire situations, in which CO presence is ubiquitous and oxygen depletion common.

3.2.2 Temperature

The temperature in a zone of burning or smouldering may significantly influence the products released into

Table 3 Examples of the influence of various factors on the generation of thermolysis products from specific materials

Material	Variable	Observation	Reference
Polyurethane foam	Time	In the early stages, both hydrogen cyanide and carbon monoxide are produced; in the latter stages only carbon monoxide	Bowes (1974)
Polyurethane foam	Temperature	Pyrolysis at 300°C yields a polymeric smoke. At 800°C smoke decomposition to N-containing materials, notably hydrogen cyanide, acetonitrile, acrylonitrile, pyridine and benzonitrile.	Wooley (1972)
Polyethylene	Oxygen availability	Low-oxygen atmosphere (500–600°C) gives high acrolein yield high oxygen atmosphere (500–600°C) gives low acrolein yield.	Morikawa (1976)

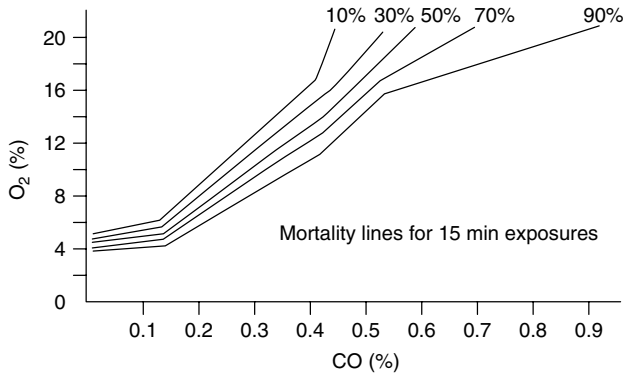

Figure 1 Mortality of male rats exposed for 15 minutes to atmospheres containing various proportions of oxygen and carbon monoxide. For any given carbon-monoxide concentration, mortality increases with decreasing oxygen content of the atmosphere. (Reproduced from Ballantyne, 1981. © Taylor & Francis Group.)

the atmosphere. For example, pyrolysis of polyurethane at 300°C yields a polymeric smoke, but at 800°C the smoke decomposes to N-containing materials such as HCN, acetonitrile, pyridine and benzonitrile (Wooley, 1972). Several investigations have demonstrated that environmental temperature may influence toxicity. For example, Nomiyama *et al*. (1980) showed an increase in acute toxicity for various organic solvents, heavy metals and agrochemicals at elevated environmental temperatures. Sanders and Endecott (1991) showed, in laboratory studies with rats, that incapacitation occurred earlier when exposure to CO was combined with elevated temperature, compared with the effects of CO or temperature alone.

4 INCAPACITATING FACTORS IN FIRES

4.1 General Considerations

In the context of a fire, incapacitating factors are those that hinder escape from the fire as a consequence of an impairment of physical and/or mental functions. Clearly, obstacles, physical injury and dense smoke are physical factors that may impair mobility and thus escape. Hypoxia (discussed in Section 4.2) may impair mental functions as a result of a wide range of effects varying from impairment of judgement to loss of consciousness. Some chemicals that may be encountered in a fire atmosphere may be absorbed from the respiratory tract and affect CNS functions, producing to a wide range of potentially incapacitating effects, including disturbance of consciousness, disturbances of coordination, weakness and decreased reaction-responsiveness times. Examples of materials that may produce such effects include volatile organic solvents, CO (Section 5.2) and HCN (Section 5.3). The above considerations of the effects of hypoxia and absorbed chemicals from the fire atmosphere on behaviour and judgement clearly apply, not only to impairment of escape from the fire environment, but also are relevant to safe and effective performance of those occupationally involved in fire-fighting operations. Impairment of behavioural reactions in smoke environments has been reviewed by Purser (1996). The growing interest and recognition of the relevance of performance deficits has lead to the introduction of neurobehavioural toxicity testing as a component of some combustion toxicology procedures (Rossi *et al*., 1996).

Several materials that are released into a fire atmosphere produce PCSI effects, and are thus capable of producing eye discomfort, excess lacrimation and blepharospasm. Such ocular effects will clearly result in a disturbance of vision and have a distracting influence, and thus cause impairment of vision, interfere with the performance of coordinated tasks and hinder escape from the area of a fire. These aspects of the PCSI response are discussed in more detail in **Peripheral Chemosensory Irritation: Fundamentals, Investigation and Applied Considerations**.

4.2 Hypoxia

4.2.1 General Considerations

Hypoxia is a broad term covering conditions in which there is a physiologically inadequate supply of oxygen to tissues or an impairment of the cellular utilization of oxygen. Hypoxaemia is a more restricted word used to describe decreased carriage of oxygen in arterial blood, as in anaemic and hypoxic hypoxia. Although tissue oxygen supply is decreased in hypoxaemia, significant damage does not occur until arterial oxygen saturation falls to about 50% and P_aO_2 falls to around 30 mmHg (Campbell *et al*., 1984). If of a sufficient degree, hypoxia may result in death. However, lesser degrees of hypoxia are also significant in fires because of the following possibilities:

1. The development, sometimes insidious, of neurological (CNS) abnormalities. These may include impaired coordination, impaired judgement, disturbance of consciousness, ranging from drowsiness to disorientation and coma (Autian, 1976; Ganong, 1977). All these clearly can produce variable degrees of mental and/or physical incapacitation.
2. Hypoxia may increase chemoreceptor activity, leading to an increase in both the rate and depth of breathing. This can result in increased minute volume and enhanced exposure to toxic materials in inspired air.

3. Hypoxia *per se* may enhance the toxicity of some inhaled materials.

In the context of a fire, all or a combination of the following types of hypoxia may occur.

4.2.2 Hypoxic Hypoxia

This is present when there is a decrease in the arterial blood PO_2 resulting from inadequate availability of oxygen to blood in the pulmonary alveolar capillaries. There is a reduced amount of oxygen in the arterial blood, but no reduction in P_aO_2. This may be a result of depletion of atmospheric oxygen in inspired air, airways obstruction, lung injury sufficient to reduce diffusing capacity, low tidal volume and increased dead space.

4.2.3 Anaemic Hypoxia

This is present when there is a decreased oxygen transporting capacity of the blood, as, for example, with a reduced circulating erythrocytes mass. In a fire, anaemic hypoxia may occur from reduced haemoglobin oxygen-binding sites; this is often the result of the formation of COHb or of methaemoglobin (metHb).

4.2.4 Cytotoxic Hypoxia

This is an intracellular effect where there is an interference with the utilization of oxygen by cells. A common cause of this is the inhibition of cytochrome c oxidase by cyanide (see Section 5.3)

5 MATERIALS COMMONLY PRESENT IN FIRE ATMOSPHERES

5.1 General Considerations

Different fires vary with respect to the nature of materials generated and resultant hazards, mainly as a consequence of the materials available for burning, the conditions of burning, and multiple environmental factors. In these respects, each fire is unique with respect to the spectrum of toxic and irritant materials generated and the potential health problems that may ensue. A multiplicity of differing chemicals may be generated by the processes of combustion, and many are of differing chemical classes. However, a few substances are common to nearly all fire atmospheres, of which CO and HCN are examples.

5.2 Carbon Monoxide

CO is a major and ubiquitous component of fire atmospheres, and often present at potentially lethal concentrations (Jankovic *et al.*, 1991). Barnard (1979) measured concentrations of CO in 25 Los Angeles fires and found that in 12% the peak CO concentration was <100 ppm, in 40% the peak values ranged 100–500 ppm, in 25% the peak range was 501–1000 ppm, and in 23% >1000 ppm; the highest CO concentration measured was 3000 ppm. The presence of toxicologically significant amounts of CO in fire atmospheres also comes from measurements with occupationally exposed fire-fighters; see Section 7.1

A major factor in the systemic toxicity of CO is related to the high affinity of CO for haeme proteins, with haemoglobin (Hb) being most affected. Binding with Hb results in the formation of COHb; this affinity is about 200 times that for O_2 (Weaver *et al.*, 2000). A sufficient inhalation exposure to CO causes an anaemic hypoxia. An additional factor influencing the toxicity of CO is the fact that the presence of COHb causes a shift to the left in the of the O_2–Hb dissociation curve due to a modification of the Hb molecule configuration. As a consequence there is an increased affinity of Hb for O_2, and hence that at any given PO_2 the release of O_2 will be reduced compared with conditions where COHb is not present (Ayres *et al.*, 1973). Also, CO inhibits cytochrome a_3, as a function of plasma CO (Goldbaum, 1977; Goldbaum *et al.*, 1976), but binding only occurs if cytochrome c oxidase is in a reduced form and when significant hypoxia is present. Therefore tissues at greatest risk are those with the steeper intracellular O_2 gradient, including the brain and myocardium. Cytochrome c oxidase inhibition has been shown to persist for several days, and may be responsible for persistent metabolic derangements (Miro *et al.*, 1998). A further toxic mechanism of action is by brain lipid peroxidation (Thom, 1990). By competing with nitric oxide (NO) for ligand biding, CO increases the concentrations of NO in tissues, which undergoes a reaction with superoxide anion to produce peroxynitrite, which injures endothelium. There then follows adhesion of neutrophils to the injured endothelium via B_2 integrin. The proteases and reactive species released from the activated neutrophils subsequently convert endothelial xanthine dehydrogenase to xanthine oxidase (Thom, 1992; Thom and Ischiropoulos, 1999), leading to lipid peroxidation. Damage to the endothelium results in production of cerebral oedema, a common accompaniment to CO poisoning.

Interpretation of COHb values in the context of fire mortality and morbidity, particularly at low concentrations, requires to be undertaken with caution because of the influence of rural and/or urban environmental factors, and of cigarette smoking, on COHb concentrations (Ballantyne, 1981). Also, if dichloromethane is present, this may be endogenously converted to CO

(Hathaway *et al*., 1991). Additionally, if analyses for COHb are not carried out promptly, from blood stored appropriately in containers, analytical artefacts due to losses may occur (Chance *et al*., 1986; Levin *et al*., 1990). The majority of individuals who are exposed to a fire atmosphere will have elevated concentrations of COHb, the magnitude of which depends on depends on the time of exposure and the atmospheric CO concentration. Low concentrations of COHb may be an indication that death has occurred rapidly from trauma or severe burns, and there has been insufficient time for high COHb concentrations to develop (Levin *et al*., 1990; Mayes, 1991; 1992). Thus, in fires or accidents involving fires, COHb measurements may be of value in assessing the time between physical injury and death. For example, with aircraft accidents, if there is severe impact with subsequent fire then those dying at impact will have relatively low COHb concentrations. With less severe impact situations, or if fires develop before a crash, the COHb concentration may be higher in those who survive for a period. Clearly, in such situations, the value of the COHb concentration needs to be interpreted against other forensic information; for example, inhaled smoke, pulmonary fat and bone-marrow emboli (Blackmore, 1974). However, it should be noted that even though breathing continues after exposure to a fire, tracheal debris might not be present (Rodgt and Olving, 1996). Similar considerations apply to automobile crashes when fire may be present. For example, Wirthwein and Pless (1996) reviewed 28 fatalities involving fires in automobiles, and found that COHb concentrations ranged from <10 to 92%. In 16 cases with COHb $<10\%$ a collision occurred, and in 12 of these blunt trauma was sufficient to have caused death. In seven cases with no collision, six had COHb $\geq 47\%$. From a detailed review of individual cases, the authors concluded that a COHb $>30\%$ strongly suggests that inhalation of combustion products is the main cause of death, but if COHb is $<20\%$, a search for other causes of death should be undertaken. In cases of death due solely to CO poisoning, as, for example, from coal-gas poisoning, the COHb concentration range stated to be compatible with death from acute CO is in the range 50–60%. In fire victims the COHb concentrations may show a wide range of values, some compatible with death due to CO poisoning, and others substantially lower. For example, in 90 fire deaths, Harland and Wooley (1979) found COHb concentrations $>50\%$ in half of the cases; those cases above 50% had a mean value of 67% and those below a mean value of 18%. When interpreting lower concentrations of COHb in fatal cases, it requires to be remembered that hypoxia may enhance the toxicity of CO, and that CO toxicity may be an interactive factor in the presence of other toxic substances and with physical and thermal trauma.

Maeda *et al*. (1996), in a review of cases and an evaluation of post-mortem cases with a CO-oximeter system, noted that with a COHb concentration $\geq 70\%$, acute fire deaths may be explained on the basis of the immediate effects of CO poisoning; in the range of COHb 30–70%, there is CO poisoning combined with other factor(s); below 30% COHb, other effects are the major cause of death. They noted that other oximetric findings, such as oxyHb and reduced Hb might assist in determining the final balance of blood gases in fire victims. Patterns of COHb found in differing fires may reflect the circumstances of an individual specific fire. For example, in the MGM Grand Hotel fire, 51.3% of victims had COHb $>50\%$; in this fire most of the victims were found in areas remote from the conflagration (Birky *et al*., 1985). In contrast, in the DuPont Plaza Hotel fire in Puerto Rica, 80–85% of victims had COHb $<50\%$; in this fire the majority of victims were burned and found in the area of the fire (Levin *et al*., 1990).

Exposure to sublethal concentrations of CO can result in a variety of potentially adverse health effects. Of particular practical importance are neurological and behavioural effects, which can hinder the performance of skilled tasks, or the recognition and escape from critical situations. These effects include headache, dizziness, disturbance of vision, confusion, difficulties in coordination, decreased reaction times, drowsiness, convulsions, impairment of consciousness and coma (Stewart, 1974; Zarem *et al*., 1973). Later neurological sequelae include memory loss and cognitive deficits that appear after a lucid interval of between two and 40 days (Ginsberg, 1985). Additionally, acute exposure to CO may produce cardiac arrhythmias, myocardial damage and circulatory failure (Stewart, 1974). Also, there may be aggravation of exercise-induced angina, decreased exercise tolerance, S-T segment depression in the electrocardiogram (ECG) and increased vulnerability to ventricular fibrillation (Anderson *et al*., 1973; Aronow, 1976; DeBias *et al*., 1976).

The human foetus is particularly sensitive to CO because of several differences from the adult. Thus, under steady-state conditions, foetal COHb is around 10–15% greater than the corresponding maternal blood COHb. Additionally, the partial pressure of O_2 in foetal blood is lower, at 20–30 mmHg, compared with the adult value of 100 mmHg (Longo, 1976; 1977; McDiarmid *et al*., 1991). Furthermore, the foetal oxygen–Hb dissociation curve lies to the left of the adult curve, resulting in a greater degree of hypoxia at equivalent COHb concentrations. It is also considered that the foetal half-life of elimination of CO is longer than in the mother (Margulies, 1986). Acute exposures to CO concentrations that are nonlethal to the mother have been associated with foetal loss (Goldstein, 1965; Muller and Graham, 1955), or to permanent neurological sequelae in the foetus (Cramer, 1982). These factors need to be taken into consideration if pregnant women are exposed to fire atmospheres, and also to the employment of women of child-bearing age in the fire services.

DOI: 10.1002/9780470744307.gat116
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Since CO is ubiquitous in various types of fires, all accident victims from fires should have blood COHb concentrations determined on hospital admission. Expired alveolar gas CO measurements can be undertaken to ascertain COHb concentrations, but this approach requires patient cooperation in sustained apnoea for a prolonged period (Fife *et al*., 2001). CO-oximetry measures the relative concentrations of oxygenated and deoxygenated Hb, as well as COHb and metHb, and this can be done noninvasively with sensitivity, and can identify occult CO toxicity (Suner *et al*., 2008). A portable noninvasive CO-oximeter that performs rapid COHb measurements using a fingertip probe is available for clinical use. When CO poisoning is suspected or chemically proven there should be immediate administration of 100% O_2. When available at the facility or a nearby facility, hyperbaric oxygen (HBO) therapy may be considered a therapeutic alternative, in which the patient breathes 100% O_2 at a pressure usually between 2 and 3 atm. This causes in an increase the amount of dissolved O_2 in blood plasma, according to Henry's law, which states that the amount of gas that will dissolve in a liquid at a give temperature is directly proportional to the partial pressure of the gas and the solubility factor of the gas in the liquid. HBO therapy enhances the elimination of CO; for example, a $t_{1/2}$ of 23 minutes at 3 atm compared with 60–90 minutes with 100% O_2 at 1 atm, and 240–320 minutes with room air (Reisdorff and Shah, 1993). HBO reduces tissue hypoxia by several mechanisms, which include (Domachevsky *et al*., 2005):

1. Increased pO_2 accelerates CO dissociation from Hb.
2. HBO increases the dissolved fraction of O_2 in plasma, and hence improves delivery of O_2 to injured tissues.
3. Prevention of leukocyte-mediated inflammatory changes and resultant lipid peroxidation by an inhibition of leukocyte adherence mediated by B_2 integrin, (Thom, 1993; Zamboni *et al*., 1993).
4. HBO causes vasoconstriction and reduces cerebral oedema (Nylander *et al*., 1985).

Details of the HBO management of CO intoxication have been discussed by Buckley *et al*. (2005) and Domachevsky *et al*. (2005).

There is still variable discussion on the absolute value of HBO in the management of CO poisoning, and criteria for its use (Buckley *et al*., 2005; Brent, 2005). Although coma is an undisputed indication for HBO, other circumstances suggested for the use of HBO are more debatable, and, as a result, the criteria for the use of HBO in CO poisoning have varied between different authorities (Kao and Nañagsa, 2004; Tibbles and Perrotta, 1994). Careful patient selection for HBO treatment is necessary, and involves consideration for those who have loss of consciousness, pregnancy and possibly cardiovascular (CV) dysfunction or neurological impairment (Brent, 2005). Representative examples of criteria for HBO are given in **Table 4**.

Table 4 Examples of criteria listed for the use of hyperbaric oxygen (HBO) in cases of acute CO poisoning

1. Criteria listed by Harrigan and Winograd (1994)
COHb > 25%
COHb > 15% if cardiac disease present
COHb > 10% in a child
ECG changes present
Metabolic acidosis present
P_aO_2 < 60 mmHg
Pregnancy (COHb > 15%)
2. Criteria by Myers and Thom (1994) and Ernst and Zibrak, (1998)
Coma
Any period of unconsciousness
COHb > 40%
Pregnancy with COHb > 15%
COHb > 20% with history of ischaemic cardiac disease
Current indications of cardiac arrhythmia or ischaemia
Symptoms unresolved after 4–6 h with normobaric O_2
3. Criteria by Undersea and Hyperbaric Oxygen Medical Society (Hyperbaric Oxygen Therapy, 1999)
Transient or prolonged unconsciousness
Neurological signs
Cardiovascular dysfunction
Severe metabolic acidosis
COHb > 25% (in pregnant women COHb > 10%)
4. Criteria by Bentur (2005)
Transient or prolonged unconsciousness
Neurological signs
Cardiovascular dysfunction
Severe metabolic acidosis
COHb > 25% (>10% in pregnant women)
Start treatment within 24 h of exposure
Breathing 100% O_2 at 2.8 absolute technical atmosphere (ATA) for 90 min, two sessions of 45 min each with a 5 min break in between (to achieve maximal inhibition of leukocyte adherence without oxygen toxicity)
Acute exposure (<12 h) is treated with one HBO session
Continue 'trailing treatments' as long as further improvement is noted
Discontinue treatment after two consecutive sessions if no improvement is noted
Chronic exposure (>12 h) is treated with three HBO sessions at 6–12 h intervals
If HBO is required but a contraindication for its use exists, administer normobaric O_2 for 72 h
If HBO is not indicated, administer normobaric O_2 for 24 h

5.3 Hydrogen Cyanide

Any material that contains carbon and nitrogen will liberate HCN under appropriate combustion conditions.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat116
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

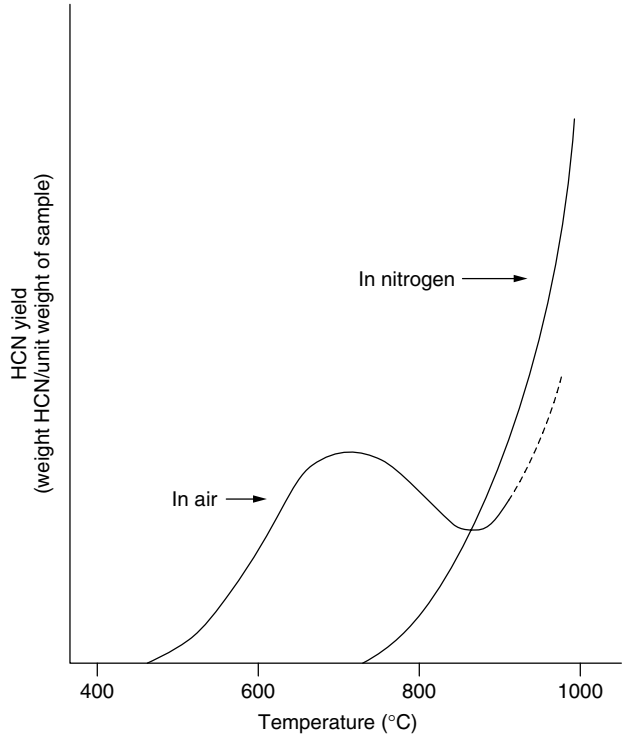

Figure 2 Graphical representation of the yields of HCN from N-containing polymers as a function of thermolysis temperature in oxidative and inert atmospheres. In air there is an initial increase in HCN yield followed by a decrease; a secondary increase in HCN yield may occur at higher temperatures.

In addition, various cyanogenic materials may be thermally generated, such as acrylonitrile, acetonitrile, adiponitrile, benzonitrile and propionitrile (Stark, 1974; Wooley, 1982). Cyanogens have also been detected in the blood of fire victims (Anderson *et al*., 1979). Polymeric materials are a particularly notable source of HCN; for example, nylon (Purser and Woolley, 1983), polyacrylonitrile (PAN) (Bertol *et al*., 1983), polyurethanes (Jellinek and Takada, 1977), urea-formaldehyde (Paabo *et al*., 1979) and melamine (Moss *et al*., 1951). Although some studies have shown that the evolution of HCN from polymers is proportional to their elemental N content (Morikawa, 1978), this is not a consistent finding. For example, Bertol *et al*. (1983) found that proportionately more HCN (1500 ppm) was evolved from PAN (19% elemental N) than from wool (200 ppm; 14.3% elemental N). Also, Urhas and Kullik (1977) found that with pyrolysis temperatures in the range 625–925°C, the yield of HCN was inversely related to the N content of three fibres. Both temperature and O_2 availability influence the yield of HCN from N-containing materials. The general effect of temperature on HCN yield from N-containing polymers in oxidative and inert atmospheres is illustrated in **Figure 2**. In oxidative atmospheres, HCN is evolved at lower temperatures, and as temperature increases so does HCN liberation, up to a maximum, and then decreases with further increase in temperature; a secondary rise in HCN liberation may occur at even higher temperatures. Polyester and polyether flexible urethane foams decompose at relatively low temperatures (200–300°C) in inert atmospheres to produce yellow smoke which is stable up to 800°C; however, over the range 800–1000°C there is decomposition yielding HCN, acetonitrile, benzonitrile and pyridine as the major N-containing products (Wooley, 1972). These and other studies indicate that the evolution of HCN varies with temperature, O_2 availability, the chemical nature of the N-containing material and burning time. Although these variables will differ at any give time, practical estimates for HCN generation have been determined. For example, Morikawa (1978) calculated that if nylon is burned at 950°C under restricted air conditions, then only 1.5 g is necessary to raise the HCN concentration to around 135 ppm in a 1 m^3 space. Bertol *et al*. (1983) calculated that a toxic concentration of HCN could be generated in an average-sized room by the burning of 2 kg of PAN.

Several laboratory-animal studies have shown that when animals are exposed to combustion products, particularly from N-containing polymers, then HCN may be generated in amounts sufficient to produce physical incapacitation or lethality. Thus, Yamamoto (1975) studied the acute inhalation toxicity of combustion products from various fibres and found that in rats exposed for up to 30 minutes, signs of incapacitation developed most rapidly (<10 minutes) following exposure to PAN. Blood removed after the development of signs showed COHb concentrations were ~10% with PAN and wool, and in the range 20–40% for silk; blood cyanide concentrations ranged from 1.5–3.0 $\mu g\,ml^{-1}$ for silk, 1.5–2.0 $\mu g\,ml^{-1}$ for PAN and ~0.5 $\mu g\,ml^{-1}$ for wool. Thus, under these conditions of exposure to the combustion products from silk and PAN, HCN was the major cause of incapacitation and blood cyanide concentrations of potentially lethal significance were measured. Purser *et al*. (1984) exposed primates to the combustion products from PAN, and a comparable group to HCN vapour. The pathophysiological effects were similar for the two groups; hyperventilation, loss of consciousness, bradycardia and cardiac arrhythmias. Following these signs, breathing was slowed and respiratory minute volume was markedly decreased. For both groups there was a relationship between chamber HCN concentration and time to incapacitation. Blood cyanide concentrations in the PAN-combustion group were similar to those in the HCN-alone group. Purser and Grimshaw (1984) exposed primates for 30 minutes to the products of pyrolysis of flexible polyurethane foam generated at 900°C or oxidative thermal decomposition of rigid polyurethane foam at 600°C. Signs included hyperventilation, followed by loss of muscle tone and limb reflexes, and then loss

of consciousness. Venous blood COHb at the end of the exposure period ranged 17–28%, and whole blood cyanide ranged 1.9–2.3 $\mu g\,ml^{-1}$. They noted that the CNS effects could be extreme because of the cytotoxic hypoxia, circulatory failure and hyperventilation that may produce cerebral arterial constriction due to the induced hypocapnia. Thomas and O'Flaherty (1979) demonstrated that the products of pyrolysis of polyurethane foam inhibited brain and heart cytochrome oxidase activity, which was positively correlated with blood cyanide concentrations. These and other studies involving the inhalation exposure of laboratory animals to the products of combustions from various N-containing polymers have shown that significant inhalation dosage may be received, resulting in physical incapacitation, coma or lethality.

As with animal studies, there is a considerable information base suggesting that humans exposed to combustion products have absorbed cyanide, and indeed smoke inhalation is probably the major cause of acute cyanide poisoning (Eckstein and Maniscalco, 2006). Thus, the first detailed description of cyanide in the blood of fire victims was presented by Wetherell (1966), who found cyanide in the blood of 39 of 53 individuals dying in fires; the average concentration was 0.65 $\mu g\,ml^{-1}$ (range 0.17–2.20 $\mu g\,ml^{-1}$). Other representative studies include the following. Hart *et al.* (1985) described five subjects with smoke-inhalation injury who were comatose on admission to hospital; blood cyanide ranged 0.35–3.9 $\mu g\,ml^{-1}$ (avenge 1.62 $\mu g\,ml^{-1}$). The subject with the highest blood cyanide died four days after admission. In postcrash airplane fires, Mohler (1975) reported blood cyanide in victims having a range 0.01–3.9 $\mu g\,ml^{-1}$. In some cases, increased cyanide concentrations indicated death from acute cyanide poisoning. For example, Tscuhiya (1977) described two persons found dead after a fire involving a polyurethane mattress; the blood cyanide concentrations were 7.2 and 23.0 $\mu g\,ml^{-1}$. In a more extensive study, in which there were 35 deaths of convicts resulting from exposure to smoke from burning polyurethane mattresses in an insurrection in a Buenos Aires prison, Ferrari *et al.* (2001) found the average blood HCN concentration to be 3.5 $mg\,l^{-1}$ (range 2.0–7.2 $mg\,l^{-1}$); these values are compatible with death from acute cyanide poisoning. In a study of fire victims in Victoria, Australia, blood cyanide concentration measurements were conducted in 138 cases, cyanide was not detected in 52 cases, and the remaining 86 had a mean blood cyanide concentration of 1.65 $mg\,l^{-1}$, with 11 cases having a concentration $>3.0\,mg\,l^{-1}$.

Exposure to HCN released into a fire atmosphere can lead to muscle weakness, difficulty in coordination, physical incapacitation, a confusional state and partial or complete loss of consciousness. This clearly will impede escape from the area of a fire. The high concentration of cyanide measured in some fire victims has lead to suggestions for the routine use of cyanide antidotes in cases of severe smoke inhalation, either prehospital, at the scene of the fire, or on hospital admission. Clearly, for prehospital use, the chosen antidote should not cause adverse side effects and have a high benefit: risk ratio. Early suggestions included the use of stroma-free Hb solutions, but more recently evidence points to the use of hydroxocobalamin as a safe and effective antidote. Few adverse effects from hydroxocobalamin *per se* have been record, although a limited transient increase in mean arterial blood pressure has been described. For example, Uhl *et al.* (2006), in a randomized, placebo-controlled, single-dose (2.5–10.0 g) trial in healthy volunteers subjects ($n = 136$), found that mean blood-pressure changes from baseline ranged 22.6–27.0 mmHg for systolic blood pressure (SBP) and 14.3–25.4 mmHg for diastolic blood pressure (DBP), compared with placebo-group control values of 0.2–6.7 mmHg SBP and 3.0–3.8 mmHg DBP. In a pharmacokinetic study, Uhl *et al.* (2008) demonstrated that the transient increase in mean arterial pressure is closely linked to initial exposure to total and free cobalamins (III). It has been pointed out that acute cyanide poisoning is often associated with hypotension, and the hydroxocobalamin associated increase in blood pressure may be of value in improving haemodynamic stability (Baud and Borron, 2006; Fortin *et al.*, 2006). The effect of hydroxocobalamin on blood pressure is suggested, but not proven, to be due to its action as an NO scavenger, which is a free radical and an endogenous vasodilator (Gerth *et al.*, 2006). Based on eight years of experience of the Paris Fire Brigade with the prehospital use of hydroxocobalamin, Fortin *et al.* (2006) concluded that hydroxocobalamin had a risk:benefit ratio which indicated it suitable for prehospital use in the management of acute cyanide poisoning caused by smoke inhalation. It should be noted that the antidotal use of hydroxocobalamin may interfere with co-oximetry measurements (Denninghoff *et al.*, 2008; Lee *et al.*, 2007).

HCN as a product of combustion and its significance has been reviewed by Ballantyne (1987).

5.4 Interactions Between Fire Atmosphere Components

5.4.1 General Comments

The atmosphere of a fire is a continuously varying complex mixture of a multitude of materials having differing chemical structures and differing toxicities. The potential for short- and long-term adverse health effects is known for several of the individual components, but is incomplete to variable extents for many other fire-atmosphere components. Also, the likelihood for

chemical and toxicological interactions in the changing conditions of a fire is, in general, poorly understood. This includes the formation of new compounds having differing toxicity by chemical interactive factors, and the possibility for one maternal having an influence on the quantitative toxicological expression of toxicity by another, or the potential for additional interactive toxicity between individual chemical components in an atmosphere. The potential for toxic interactive factors between a few fire-atmosphere components, particularly with binary systems, has been investigated for some materials, and estimates made of the variability in hazard according to the relative proportions of the components. Some illustrative examples are given below for three common fire-atmosphere materials, HCN, CO and carbon dioxide.

5.4.2 Binary Atmosphere of Hydrogen Cyanide and Carbon Monoxide

The investigational approaches to determining the toxic modifying interactivity between HCN and CO, a common practical combination in fires, have been variable, and include mortality studies, measurements of blood cyanide and COHb and assessment of physiological functions. Moss *et al*. (1951) found that simultaneous exposure to CO (2000 ppm) and HCN (10–20 ppm), both at individually sublethal concentrations, caused death. Smith *et al*. (1976) found that the times to death for rats exposed to an atmosphere containing 450 ppm HCN and 13 500 ppm CO (3.7 ± 0.4 SD minutes) was slightly longer than for a corresponding concentration of HCN alone (10.9 ± 2.0 SD minutes) or CO alone (5.8 ± 1.2 SD minutes). Norris *et al*. (1986) investigated the effect of a three minute inhalation exposure of mice to CO (0.3–0.66%) on the lethal toxicity of intraperitoneal (ip) potassium cyanide (KCN). A significantly lower LD_{50} for KCN was found in CO-pretreated mice (6.51 (6.04–7.00) mg kg^{-1}) than for air-alone controls (7.90 (7.36–8.45) mg kg^{-1}). In further studies they found evidence for a synergism between CO and HCN, and suggested that this may have been the result of augmentation of the inhibition of cytochrome oxidases in the CNS.

Pitt *et al*. (1979) investigated the effects of CO and HCN on cerebral circulation in the dog. When given together, CO and HCN increased cerebral blood flow in an additive manner; however, a significant decrease in cerebral oxygen consumption occurred with combined exposure to HCN and CO, neither of which alone had an effect. Ballantyne (1984; 1987) investigated the effects of differing proportions of HCN and CO in the atmosphere on lethal toxicity, and blood cyanide and COHb concentrations, and determined that the contribution of either substance to toxicity depends on their absolute and relative atmospheric concentration. Thus, when there was a marked excess of CO, the presence of HCN lowered the lethal inhalation dosage for CO by a less than additive toxicity; that is, HCN physiologically potentiated (by hyperventilation) the toxicity of CO. When there was an excess of CO with respect to HCN, but not sufficient to produce a clear biochemical evidence of death due to CO, then the blood picture indicated death not primarily due to CO or HCN. In these circumstances, because of less than additive toxicity, it is likely that both are acting at a common target site, probably cytochrome oxidase. When CO and HCN were present in equal mass proportions, biochemical evidence indicated that death was due to acute cyanide poisoning.

5.4.3 Binary Atmosphere of Carbon Monoxide and Carbon Dioxide

Nelson *et al*. (1978) found that the 30 minute lethal concentration of CO to rats was 6000 ppm, and was decreased to 2560 ppm in the presence of 1.44% CO_2. Redkey and Collison (1979) found more rapid times to death in rats exposed to 6000 ppm CO with 4.5% CO_2 (16.8 ± 0.6 minutes) compared to 6000 ppm alone. Levin *et al*. (1989), in detailed studies, found that above a certain concentration of CO (4100 ppm) some rats died, and adding CO_2 had no influence. Below 2500 ppm CO, the addition of CO_2 (up to 17.7%) was not sufficient to produce mortality. However, with a CO concentration in the range 2500–4100 ppm CO_2 (>1.5%) (which produced few mortalities *per se*) produced a high level of mortality. They noted that CO and CO_2 act together by: (i) increasing the rate of COHb formation, (ii) producing a severe acidosis which is greater than the metabolic acidosis from CO alone or respiratory acidosis, from CO_2 alone and (iii) prolonging the recovery period from acidosis.

6 INVESTIGATION OF THE TOXICOLOGICAL HAZARDS OF FIRES

6.1 General Considerations

Investigations into the toxicology of fire atmospheres and the assessment of potential adverse health effects from the products of combustion are complex and difficult because of the multiplicity of thermolysis products and the variability of factors which affect the quantitative and qualitative of the biological response to them. Therefore, from a practical point of view it is possible only to give an overview of the combustion products likely to be present under the conditions of thermolysis, and a qualitative assessment of hazards. Although detailed studies have been conducted on some binary systems, permitting quantitative assessments of interactions to be undertaken, the majority of studies have been conducted

on combustion products. A overview of the various approaches to investigating toxicological hazards from fire is presented below. Details can be found in Gad (1990b) and Kaplan (1988).

6.2 Physiochemical Studies on Thermolysis Products
