
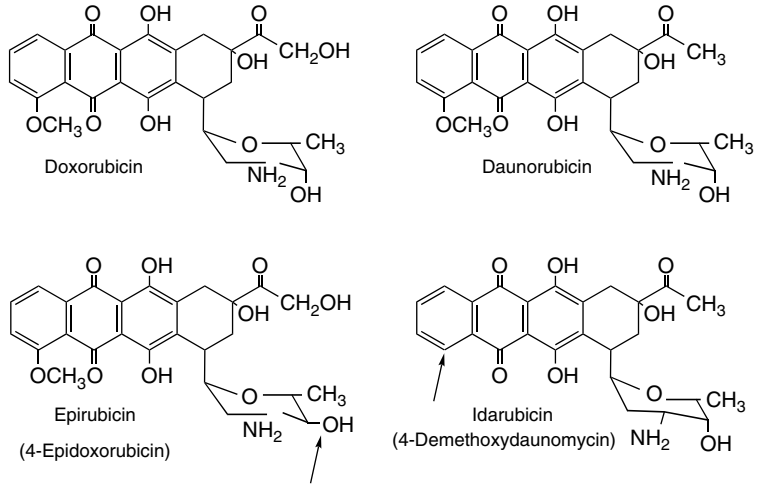

Figure 4 Structure of four anthracyclines in current use. For epirubicin and idarubicin, arrows point to the sites where these drugs differ, respectively from doxorubicin and daunomycin (daunorubicin).

and DNROL, quantitatively the most important metabolites in man (Takanashi and Bachur, 1976), and in rabbits (Cusack *et al*., 1988).

5 MECHANISMS OF ANTHRACYCLINE CARDIOTOXICITY

5.1 C-13 Alcohol Metabolite

The major metabolite of anthracyclines in most species is the C-13 alcohol metabolites DNROL and DOXOL, generated by ubiquitous cytosolic carbonyl reductases. DOXOL is more potent in inhibiting cardiac SR Ca^{2+} ATPase, the Ca^{2+} release channel and in inhibiting contractile function *in vitro* (Olson *et al*., 1988). The alcohol metabolite can be formed from parent drug in human-heart cytosol and can have important deleterious effects on iron metabolism, (Minotti *et al*., 1998). Chronic DOX cardiotoxicity was more severe in a transgenic mouse model that overexpressed human carbonyl reductase in the heart, with increased formation of cardiac DOXOL (Forrest *et al*., 2000). Mice with reduced expression of the carbonyl reductase enzyme that converts the parent anthracycline to the C-13 alcohol metabolite had resistance to acute DOX cardiotoxicity (Olson *et al*., 2003). The cardiac concentration of DNROL, but not DNR was inversely related to contractility (d*S*/*dt*) in left ventricular trabeculae carneae in chronically treated Fischer 344 rats (Cusack *et al*., 2002). Thus, formation and accumulation of the alcohol metabolite may play an important role in free-radical generation, disruption of iron metabolism and of SR Ca^{2+} transport, and may be an important mediator of anthracycline cardiotoxicity.

5.2 Free-Radical Stress

A leading hypothesis is that anthracyclines, such as DOX and DNR and their alcohol metabolites, contain the functional quinone moiety that undergoes enzymatic one-electron reduction to semiquinone radicals, a step that occurs in myocardial microsomes, the sarcotubular system (Doroshow, 1983a) and mitochondria (Doroshow and Davies, 1986). Semiquinone radicals of DOX and DNR, in the presence of molecular oxygen, are rapidly reoxidized to quinones, generating superoxide (O_2^-). The alcohol metabolite DOXOL (100 nM) also can produce O_2^- (Gervasi *et al*., 1986). A redox cycle is set up, with consumption of molecular oxygen, continuous production of O_2^-, which is dismutated to hydrogen peroxide (H_2O_2). This can diffuse through the cytoplasm and, if not metabolized by catalase, is converted, in the presence of iron, to the highly reactive, cytotoxic hydroxyl radical (•OH) by Haber–Weiss and Fenton reactions (Doroshow, 1983b; Doroshow and Davies, 1986). Both •OH and other radicals, such as O_2^- can cause peroxidation of lipids, generation of cytotoxic aldehydes (Luo *et al*., 1997), oxidation and inactivation of enzymes and other proteins, DNA damage (Monti *et al*., 1995) and ensuing cellular damage.

5.3 Iron

This subject is very ably reviewed by others (Minotti *et al*., 2004; Xu *et al*., 2005). Several lines of evidence suggest a significant role for iron in the pathogenesis of anthracycline cardiotoxicity. Overloading of dietary iron in Sprague–Dawley rats caused a significant increase in myocardial iron in those treated with

single dose DOX ($6\,mg\,kg^{-1}$) and sacrificed two to three weeks later, compared to those receiving regular chow (70 ± 3 vs. $52 \pm 4\,\mu g\,g^{-1}$ tissue (Panjrath *et al*., 2007). There was clear evidence of increased cardiotoxicity in the iron-overloaded compared to the normal-diet group treated with DOX. In the rats treated with DOX, measures of apoptosis, including ^{99m}Tc annexin-V uptake and cleaved caspase-3 staining were increased in iron-overloaded animals and electron microscope (EM) histopathology was increased. Knockout *Hfe*–/– mice used as models of haemochromatosis, when treated with DOX, 5 mg kg^{-1} every two weeks for six doses, demonstrated increased iron uptake in the heart, with increased staining in cardiomyocytes (Miranda *et al*., 2003). DOX treatment caused increased mitochondrial damage in *Hfe*–/– animal than in controls. Furthermore, iron chelation is a proven method of significantly reducing the risk of anthracycline cardiotoxicity in animals using dexrazoxane (ICRF-187) (Cusack *et al*., 2006) and salicylaldehyde isonicotinoyl hydrazone (SIH) (Sterba *et al*., 2007). Dexrazoxane has been proven as cardioprotective in randomized clinical trials in humans (Jones, 2008), and is used clinically in limited situations (Cvetkovic and Scott, 2005). Due to concern that it might affect chemotherapy of other tumours, its use indication remains confined to treatment of metastatic breast cancer. These studies conducted *in vivo* suggest that iron toxicity appears to enhance anthracycline cardiotoxicity, whereas iron depletion appears protective.

Iron is a highly important element for cell metabolism, and iron levels are tightly regulated. Soluble ferric iron (III) is transported in the blood, bound to transferrin receptor. Uptake into cells is mediated by donation of iron to the soluble transferrin receptor (TfR1), is endocytosed into endosomes and then released into the cytoplasm. Ferritin is a major storage protein for nonmetabolic iron storage. Normal cellular iron flux is tightly regulated by the binding of iron regulatory proteins (IRP1 and IRP2) to the untranslated cis-sequences of iron responsive elements (IREs) of ferritin and transferrin receptor1 (TrF1) mRNA (Hentze *et al*., 2004; Papanikolaou and Pantopoulos, 2005). Low cellular iron increases binding of IRPs to these IREs stabilizes TfR1 mRNA and inhibits ferritin translation, thereby increasing TrF1 and reducing the ferritin levels. This effect augments the cellular labile-iron pool. When cellular iron becomes replenished, the bifunctional IRP1 is inactivated by reassembling the 4Fe–4S cluster in the protein so that IRP1 loses the ability to bind to IRE and acquires aconitase function. In iron-replete cells, IRP2 activity is lost in a different fashion by proteasomal degradation. The resultant loss of IRP/IRE binding decreases TrF1 and augments ferritin. This effect diminishes the cellular labile iron pool. Intracellular storage sites for iron include ferritin and lysosomes (Xu *et al*., 2005).

DOX can directly bind to iron, forming drug–iron complexes that can cycle between iron (II) and iron (III) states (Xu *et al*., 2005) and this leads, in the presence of reducing agents, to formation of the anthracycline semiquinone and of superoxide O_2^-. In addition, the anthracycline quinone can accept electrons from reductases, with formation of H_2O_2. This can lead, in the presence of reactive iron, to formation of the highly reactive hydroxyl radical; a process that is preventable by iron chelators or antioxidants (Rajagopalan *et al*., 1988). Accumulation of reactive metabolites leads to cellular damage and apoptosis. The cardiac myocyte is considered vulnerable to oxidative pathology due to the relative paucity of antioxidant enzyme activity.

Seminal studies by Minotti *et al*. (1998) found that metabolism of DOX or DNR to the C-13 alcohols DOXOL or DNROL occurred in human heart biopsies. However, formation of the C-13 alcohol delocalized Fe^{2+} from the aconitase 4Fe–4S cluster in human heart cytosol preparations, to release a twofold excess of low-molecular-weight Fe^{2+}, which was then available for further oxidation reactions (Minotti *et al*., 1998). Furthermore, DOX irreversibly inactivated IRP1 by an effect of DOX–Fe(II) complexes to form a 'null protein' that could neither bind to IRE RNA nor reconstitute aconitase, with ensuing dysregulation of iron homeostasis. In reactive oxygen species systems, DOX inactivated both IRPs through a sequential action of DOXOL and reactive oxygen species (ROS) on IRP1 or an independent action of ROS on IRP2 (Minotti *et al*., 2001). Thus iron metabolism in the cell can be extensively dysregulated by anthracyclines. Other investigators demonstrated that, in bovine endothelial cells, DOX in submicromolar concentrations, not only increased iron uptake, but also increased IRP1 activity and increased apoptosis (Kotamraju *et al*., 2002). Antioxidants and iron chelators opposed these effects of DOX. They also observed that the toxic effect of anthracycline on endothelial cells was abrogated by the TfR antibody, emphasizing the additional importance of TfR function and iron transport in the cytotoxicity (Kotamraju *et al*., 2002).

Subsequent investigations have demonstrated a more complicated picture, however. Kwok and Richardson (2002) demonstrated that a concentration-dependent reduction in active IRP1–IRE binding following six hours of incubation; the effect was not seen after 24 hours incubation, however. In contrast to Minotti *et al*. (2001), they did not observe any effect of DOXOL on IRP1–IRE binding. The observed loss of IRP1 activity was explained by the formation of DOX –iron or DOX–copper complexes that caused a decrease in active IRP–RNA binding reversibly by the reducing agent βmercaptoethanol. In other studies using H9c2 embryonic rat heart cell cultures, DOX and DNR produced a bell-shaped, dose-related effect on IRP1–IRE binding, so that binding was increased at lower concentrations of anthracycline and decreased

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

towards control levels at higher concentrations of anthracycline (Minotti *et al*., 2001). Others have noted activation of IRP–IRE binding with DOX treatment in endothelial cells (Kotamraju *et al*., 2002), thought due to effect of ROS. Thus the effect of anthracycline on IRP function remains controversial, with most reports suggesting a decrease in IRP–IRE binding.

The question remains whether IRP–IRE binding changes are applicable in the clinically relevant models of chronic anthracycline cardiotoxicity *in vivo*? We have demonstrated that IRP1–IRE binding was not altered in a model of chronic DNR cardiotoxicity in the Fischer 344 rat (Cusack *et al*., 2006). In this study, young and old Fischer 344 rats were treated with DNR 2.5 and 1.67 mg kg^{-1} iv weekly for six weeks to reach a total cumulative dose of 15 and 10 mg kg^{-1}, respectively. Rats were sacrificed two weeks after the last dose. Impairment of contractility was observed in left atrial tissue in DNR compared to control animals. However, no effect on active or total IRP1–IRE binding was detected. This observation has been corroborated by Corna *et al*. (2006), who demonstrated that acute cardiotoxicity in young male mice four days after injection with 15 mg kg^{-1} DOX occurs in the mouse, independent of IRP1 effects. They found that IRP2 activity was down-regulated, with unchanged IRP1 activity. Furthermore, ferritin L and H expression was increased and TfR expression decreased. Rat hearts demonstrated evidence of toxicity with elevated malondialdehyde (MDA) and thioreduxin levels as measures of oxidative damage and of brain natriuretic peptide (BNP) levels as indicator of functional stress. Similar findings were noted in IRP1 –/– mice, suggesting that the cardiac toxicity, IRP activity, and ferritin and TfR changes did not require IRP1. The results also suggest that IRP2 is more important as a mediator of iron cellular flux than IRP1. Thus, the effect of DOX on IRP–IRE appears controversial and varies according to conditions of treatment (concentration and duration of anthracycline exposure) and cells used in experiments.

Lyosomal activity is also involved in anthracycline-mediated iron toxicity. Using neonatal rat cardiomyocytes and cancer cell lines, incubated with DOX, Kwok and Richardson (2003) noted a marked rise in uptake of ^{59}Fe into ferritin in all cell lines. The same effect was achieved by other redox-cycling agents such as, and appeared due to impaired ability to release ^{59}Fe from ferritin. Since ferritin is catabolized by lysosomes, this raises the possibility that anthracycline's interaction with ferritin may be mediated by effects on lysosomes. Depression of lysosomal activity using enzyme inhibitors, enzyme inhibitor or lysosomotropic agent, such as lysosomotropic agent and methylamine, caused a several-fold increase in ^{59}Fe-ferritin accumulation in human SLK-Mel-28 melanoma cells (Kwok and Richardson, 2004). Proteasomal inhibition has similar effects. DOX also caused a significant increase in ferritin accumulation of ^{59}Fe. Thus, cardiotoxicity may be related to effects of anthracycline on lysosomal ferritin release of iron. Anthracyclines also act as atypical cytosolic iron chelators, paradoxically causing an increase in ferritin without any increase in TfR1 or Ndrg1 protein levels (proteins regulated by iron levels), leading to increased ferritin-iron content (Xu *et al*., 2008). These studies demonstrate that the effect of anthracyclines are complex and pleiotropic, but overall suggest that anthracyclines directly bind to iron, and exert abnormal effects on IRP metabolism and ferritin-iron uptake and binding.

5.4 The Ubiquitin Proteasome System (UPS)

About 20% of protein turnover occurs in lysosomes. Another 80% occurs via the ubiquitin/proteasome system (UPS), which has high specificity and is involved in degrading abnormal, misfolded, mutated or oxidized protein, and also in controlling cellular homeostasis by proteolytic effects on key regulatory proteins (Powell, 2006). Degradation is an ATP-requiring process that occurs via two successive steps (Glickman and Ciechanover, 2002). The first is conjugation of several ubiquitin molecules to the substrate protein by a process controlled by three ubiquitin ligase enzymes that act in concert, with an initial ubiquitin activating step, followed by ubiquitin conjugation to the enzyme E2, and then by a final step whereby the protein is bound specifically by an ubiquitin ligase enzyme E3, the latter being the rate-limiting step in ubiquitination. The resultant polyubiquitinated protein is then degraded by a 26S proteasome complex into small peptides, releasing reusable ubiquitin. The proteasomal core is a cylindrical shaped structure containing four stacked rings, each containing seven subunits. It is called the 20S proteasome. A regulatory complex called the 19S proteasome activator attaches to the 20S proteasome. The combination is termed the 26S proteasome when either one or two 19S regulatory complexes are attached to the 20S proteasome. The 20S proteasome is comprised of two inner rings, each containing seven homologous β subunits. The outer two rings contain homologous α subunits aligned over the corresponding β subunits. The proteolytic activity resides within the inner β subunits. Three main activities have been described, chymotryptic, tryptic and postglutamyl peptide hydrolytic-like or 'caspase-like' activities.

5.4.1 UPS and the Heart

There is mounting evidence that dysfunction of the UPS is involved in different forms of cardiac pathology, including cardiac ischaemia and cardiomyopathies.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat177
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

In ischaemia, proteasomal dysfunction causes accumulation of oxidized and ubiquitinated protein and prodeath proteins, with ensuing cell damage (Powell, 2006). Failure to remove endoplasmic reticulum (ER) abnormal proteins can produce stress and contributes to proteasomal dysfunction and cardiac damage in ER stress-related cardiomyopathies (Powell, 2006). Inhibition of proteasomal function by a drug approved for treatment of myeloma, a drug approved for treatment of myeloma, may also cause cardiac damage as reported in the US package insert by Millennium Pharmaceuticals for a drug approved for treatment of myeloma. Myocardial pathological changes were observed in monkeys treated with bortezomib. Overt, severe heart failure with slow recovery over months has been described following treatment with bortezomib (Voortman and Giaccone, 2006).

5.4.2 Effects of Anthracyclines on the UPS

DOX can have a direct effect on the proteasome, at least in the neoplastic cell. DOX (4 μM for 24 hours) caused apoptosis in erythroleukaemic K562 cells, associated with altered subunit composition of 26S proteasomes, considered due to post-translational modification and altered phosphorylation state of specific subunits, combined with increased peptidase and ribonuclease activities (Tsimokha *et al*., 2007). In an L1210 mouse leukaemia cell line, DOX binds to a proteasome that appears to function as a carrier to translocate DOX from the cytoplasm to the nucleus (Kiyomiya *et al*., 2002) and determines the action on poly(ADP-ribose) polymerase. In proliferating human leukaemia cells, DOX caused an increase in nuclear proteasomal activity that was significantly reduced by inhibition of a poly(ADP-ribose) polymerase (PARP) enzyme (Ciftci *et al*., 2001). In neonatal rat cardiomyocytes, DOX depletes an important cofactor for transcription factors, an important cofactor for transcription factors including an important cofactor for transcription factors regulators of expression of cardiac genes that govern growth and homeostasis, regulators of expression of cardiac genes that govern growth and homeostasis (Poizat *et al*., 2000). DOX was found to do this by increased proteasomal proteolysis of p300. Neither a proteasome substrate (a proteasome substrate) nor ubiquitinated protein levels were altered acutely by DOX (1 μM), suggesting that the effect of DOX at this concentration on p300 was selective. Kumarapeli *et al*. (2005) studied the effect of high-dose acute DOX effect in transgenic mice that expressed a surrogate protein (a full length, protease-specific substrate for the UPS) that is a full length, protease-specific substrate for the UPS, requiring activity of ubiquitinylation, and activity of both the 20S and 19S moieties of the 26S proteasome for proteolysis. Following injection of high-dose DOX (25 mg kg^{-1}), the cytosolic levels of the GFPdgn were decreased due to increased proteasomal degradation (inhibited by proteasomal inhibitors proteasomal inhibitors). Interestingly, proteasomal peptidase chymotrypsin and caspase-like activities were reduced, suggesting that the effect of DOX on proteolysis of GFPdgn was on the part of the UPS outside the β-ring of the 20S proteasome, where peptidase activity is located. It is not known whether the effect of DOX in increasing proteasomal degradation of the surrogate protein GFPdgn was specific, since effects on other substrates were not measured. It should be remembered that these findings were observed in acutely treated mice at six and 24 hours after a high dose of DOX. These results cannot necessarily be extrapolated to conditions of chronic cardiotoxicity when the heart is exposed to repeated lower concentrations of anthracycline under 2 mg kg^{-1} over several weeks duration.

These investigators subsequently showed that, in cultured UPS reporter and also in neonatal cardiomyocytes, DOX both increased the proteolysis of the UPS reporter (UPS reporter) and opposed the proteasome inhibitor-induced accumulation of endogenous substrates of the UPS (e.g. c-Jun and β-catenin) (Liu *et al*., 2008). DOX appeared to cause *in vitro* degradation of GFPu and c-Jun by the reconstituted UPS by increasing proteasomal function. DOX also increased the peptidase activities of purified 20S proteasomes at drug concentrations of 1–5 μM. The effects of DOX on proteasomal function may be mediated by ubiquitination. For example, they demonstrated that DOX increased the levels of an E3 ligase involved in the proteasomal degradation of HSP 70 (an E3 ligase involved in the proteasomal degradation of HSP 70) while decreasing HSP 70. Analogous observations have been reported; in cultured neonatal rat cardiomyocytes, DOX (0.3 μM) enhanced proteasomal-dependent downregulation of an E3 ligase involved in the proteasomal degradation of HSP 70 an important survival protein in cardiomyocytes, an important survival protein in cardiomyocytes (Ito *et al*., 2007). Anthracyclines also may influence activity of ubiquitinating ligases. DOX, both after single doses *in vivo* (15 mg kg^{-1}) and in neonatal rat cardiomyocytes *in vitro* (0.1 μM for 24 hours), causes up-regulation of a muscle-specific ubiquitin ligase that plays a role in cardiac muscle atrophy, a muscle-specific ubiquitin ligase that plays a role in cardiac muscle atrophy (Yamamoto *et al*., 2008). In aggregate, these studies suggest a role for anthracyclines in increasing proteasomal activity with down-regulation of important factors for cellular maintenance and function, such as β-catenin, c-Jun, HSP 70 and NFAT5, or by up-regulation of ubiquitin ligases such as atrogin-1 that promote muscle atrophy. Proteasomal inhibition may play a different role in reducing DOX cardiotoxicity. DOX caused topoisomerase IIβ-mediated DNA double-strand breaks in H9C2 embryonic cardiomyocytes that was opposed by proteasomal inhibitors bortezomib and MG132 (Lyu *et al*., 2007).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat177
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

However, not all studies show enhancement of proteasomal activity by anthracyclines. Fekete *et al.* (2005) found that both DOX and DNR inhibited proteasomal 26S activity in lysates from ECV 304 cells with an IC_{50} (half maximal inhibitory concentration) value of 14 μM for DNR. Kiyomiya *et al.* (2002) demonstrated that DOX (5 μM) caused apoptosis of L1210 cells and also inhibition of purified proteasomal peptidase activity. It also is possible that chronic treatment with anthracycline may have a different effect on UPS machinery due to effects of chronic oxidative stress (Friguet *et al.*, 2000; Keller *et al.*, 2000) and effects of lipid peroxidation products (Bulteau *et al.*, 2001; Okada *et al.*, 1999) which can reduce UPS activity. Reduced proteasomal activity due to oxidization can be reversed by dithiothreitol (DTT), a known antioxidant (Ferrington *et al.*, 2005). It is not known currently whether chronic anthracycline cardiotoxicity is associated with altered proteasomal function or ubiquitination.

6 PREVENTION OF CARDIOTOXICITY

The recognition that anthracyclines can cause a cumulative dose-related cardiotoxicity has lead to numerous approaches to reduce such risk. Success in preventing cardiotoxicity depends on the ability to identify significant risk factors for cardiotoxicity and also having measures that can reliably detect cardiotoxicity. Particular attention is required in treatment of these groups of patients. The most powerful predictor of cardiotoxicity is lifetime exposure to anthracyclines. Since the risk of cardiotoxicity increases rapidly with doses of DOX above 450 mg m^{-2}; such doses are not recommended. However, some patients develop cardiotoxicity, even with doses below 300 mg m^{-2}. In order to detect such patients, close monitoring has been recommended.

6.1 Monitoring for Cardiotoxicity

Measures to detect subclinical cardiotoxicity include endomyocardial right ventricular biopsy for histological examination, functional measurements using echocardiography or cardiac radionuclide angiography, and assay of biochemical markers (e.g. atrial natiuretic peptide, brain natiuretic peptide, troponin I, troponin T) of cardiac stress or damage (Jannazzo *et al.*, 2008). Guidelines have been promulgated for treatment in children, using both echocardiography and radionuclide angiography measures of cardiac contractility, and endomyocardial biopsy to determine specificity, if needed (Cheitlin *et al.*, 2003; Klocke *et al.*, 2003; Steinherz *et al.*, 1992). Some, but not all, studies of systolic and diastolic function have found that monitoring during the course of therapy may predict eventual cardiac function (Jannazzo *et al.*, 2008). However, there is still no satisfactory evidence-based consensus on the correct sequence or combination of measures to use that has gained wide acceptance in clinical practice.

6.2 Methods for Reduction of Cardiotoxicity

6.2.1 Modification of Anthracycline Delivery and Formulation

Methods to reduce cardiotoxicity include obvious adjustments, such as dose limitation of anthracyclines to avoid the risk associated with cumulative doses over 450 mg m^{-2} (Swain *et al.*, 2003). This may be adequate in many treatment protocols, but foils some therapeutic strategies, for example retreatment with anthracyclines in recurrent disease. Administration of anthracycline by prolonged infusion prevents achievement of high plasma, and by inference, high cardiac concentrations of parent drug or metabolite. Administration over six hours (Shapira *et al.*, 1990), or over 48–96 hours (Legha *et al.*, 1982) can lower cardiotoxicity, although progressive decline in contractility can still be observed (Speyer *et al.*, 1985), and the dependability of antitumour action of the prolonged schedules has not been established (Bielack *et al.*, 1989). Due to this concern and the cumbersome and more expensive nature of prolonged infusion, this approach has not gained wide acceptance.

Modification of the drug delivery can also be accomplished using pegylated liposomal formulations of DOX or DNR. This formulation, using stealth nanocarriers that permit decreased distribution of DOX in normal tissues and increased uptake in tumour tissue, resulted in decreased cardiotoxicity in at least two randomized clinical trials (van Dalen *et al.*, 2006). There is no evidence that tumouricidal effect was compromised. Palmar-plantar erythrodysesthesia syndrome can complicate use of liposomal anthracyclines (Hui and Cortes 2000). Pegylated DNR also has proven useful, especially for treatment of Kaposi sarcoma, with improved risk–benefit ratio with respect to cardiotoxicity (Petre and Dittmer, 2007).

6.2.2 Anthracycline Analogues

Anthracycline analogues, such as epirubicin have been developed to reduce the risk of cardiotoxicity. However, a comprehensive systematic review did not demonstrate a significant reduction in the risk of cardiotoxicity from epirubicin compared to DOX (van Dalen *et al.*, 2006). Furthermore, recent data from the National Cancer Institute indicated that the risk of cardiotoxicity occurred at lower than previously considered doses (Ryberg *et al.*, 2008). Idarubicin, which is more lipophilic than other

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat177
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

anthracyclines and can also be given orally, may be associated with reduced cardiotoxicity, but there are no good randomized comparative trials to document this (Cersosimo, 1992).

6.2.3 Antioxidants

The premise that anthracyclines cause cardiotoxicity by free-radical damage has led to many clinical studies using antioxidants in an attempt to offset this risk. Clinical studies using acetylcysteine, phenetylamines, coenzyme Q10, l-carnitine, a potent antioxidant in addition to its β-blockade properties (which is a potent antioxidant in addition to its β-blockade properties) and the combination of vitamin E, vitamin C and a potent antioxidant in addition to its β-blockade properties have been recently included in a Cochrane review (van Dalen *et al*., 2008). There was insufficient evidence to conclude that any of these agents provided significant protection from anthracycline cardiotoxicity.

6.2.4 Dexrazoxane

On the other hand, a putative iron chelator, a putative iron chelator does reduce the risk of anthracycline cardiotoxicity (van Dalen *et al*., 2008), substantiating the rationale of the role of iron toxicity in the pathogenesis of anthracycline cardiotoxicity. In that meta-analysis, the reduction in the risk of clinical heart failure (relative risk (RR) 0.18; 95% confidence interval (CI) 0.10–0.32; $p < 0001$) or both clinical and preclinical heart failure (RR 0.29; CI 0.2–0.41; $p < 0.0001$) were highly significant. Studies have included both patients with breast cancer and sarcoma, both children and adult patients, and both DOX and epirubicin, suggesting a robust and versatile effect of prevention by dexrazoxane (Lopez *et al*., 1998; Marty *et al*., 2006; Swain *et al*., 1997b; Venturini *et al*., 1996; Vici *et al*., 1998; Wexler *et al*., 1996). There are caveats with the use of this agent, however: myelotoxicity, with lower nadir white cell counts, was increased in Phase 1 studies (van Dalen *et al*., 2008); in one trial there was a decreased response rate to the antitumour effect of DOX in combination with dexrazoxane in comparison with DOX alone (Swain *et al*., 1997b). However, the systematic review did not demonstrate any difference in response rate, progress-free survival or overall survival. Swain *et al*. (1997a) also observed that, in patients with breast cancer who have received $300\,mg\,m^{-2}$ DOX, dexrazoxane was highly protective against cardiotoxicity in those who continue to receive DOX treatment. Based on these observations and concern about possible effects of dexrazoxane on tumour response, myelosuppression and occurrence of secondary malignant disease (Tebbi *et al*., 2007), the current Food and Drug Administration (FDA) indications for dexrazoxane include use in patients with advanced breast cancer who have received $300\,mg\,m^{-2}$ DOX. Further studies of the use of dexrazoxane are needed to better document its role in children, in leukaemias and its protection against long-term cardiotoxicity.

6.2.5 Renin-Angiotensin II Axis Blockade

Several studies endorse the utility of reduction of angiotensin II activity as a measure to prevent anthracycline cardiotoxicity. Studies in mice indicate that acute and chronic DOX treatment in an angiotensin II type 1a receptor blocker knockout mice or mice treated with an angiotensin II type 1a receptor blocker, an angiotensin II type 1a receptor blocker, causes less cardiotoxicity than in DOX-treated wild-type mice (Toko *et al*., 2002). In that study, measures of echocardiographic functional parameters, histological myofibrillar loss and apoptosis were attenuated in the treatment compared to control groups of mice, both after a single dose of DOX, $20\,mg\,kg^{-1}$, and after weekly DOX, $1\,mg\,kg^{-1}$, for 12 weeks. Similarly, the angiotensin II receptor blocker, angiotensin II receptor blocker, protected against acute DOX cardiotoxicity in humans treated with DOX-containing regimens for lymphoma, as measured by echocardiography (left ventricular dimensions) and electrocardiographic (QTc measurements) outcomes (Nakamae *et al*., 2005). Angiotensin-converting enzyme (ACE) inhibition also confers cardioprotection against anthracycline cardiotoxicity. Chronic treatment with DOX in rats produced a significant lengthening of the QαT interval, and depression of the cardiac positive inotropic effect induced by iv ACE inhibitor, both of which were significantly ameliorated by the ACE inhibitor, ACE inhibitor (Sacco *et al*., 2001). In separate experiments, zofenopril did not impede the antineoplastic activity of DOX. In long-term studies in rabbits treated with one dose of DOX, lisinopril treatment for 10 weeks prevented both late-onset increased ventricular atrial natriuretic peptide (ANP) expression, myocyte loss and measures of apoptosis (Boucek *et al*., 2003). Thus, angiotensin II blockers or ACE inhibitors may prove beneficial in reducing the risk of cardiotoxicity and deserve further clinical evaluation.

Anthracycline cardiotoxicity is considered to be mediated, at least in part, by apoptosis, activating apoptotic pathways and also causing apoptotic morphological changes of cardiomyocytes, at least *in vitro* (Takemura and Fujiwara, 2007). Trophic factors with antiapoptotic effects may therefore be beneficial in ameliorating anthracycline cardiotoxicity. stimulates production of erythrocytes, which stimulates production of erythrocytes, also has cytoprotective effects, considered to derive from its ability to oppose apoptosis in cardiomyocytes (Parsa *et al*., 2003). Studies in neonatal ventricular myocytes, using clinically relevant concentrations of erythropoietin and DOX, demonstrated that erythropoietin effected antiapoptotic morphological changes, with

reduction in caspase-3 activity and in the number of apoptotic cells, assayed using annexin-V staining and DNA laddering (Kim *et al*., 2008). In addition, impairment of cardiac function following chronic dosing ($5\,mg\,kg^{-1}$ ip weekly × 3), was offset by erythropoietin pretreatment. Further studies indicated that this was due to activation of the P13K-dependent cytokine trophic factor. Another cytokine trophic factor, cytokine trophic factor, stimulates production of platelets, and has antiapoptotic properties, mediated by the Akt prosurvival pathway. Thrombopoietin reduced apoptotic changes in H9C2 myotube cells treated with DOX and also offset cardiotoxicity, as measured by histological, apoptotic and functional parameters, following single-dose injection of DOX, $20\,mg\,kg^{-1}$ ip in mice (Li *et al*., 2006). Whether either erythropoietin or thrombopoietin will emerge as clinical treatments is conjectural at this point, but nevertheless they are of interest in that they suggest that antiapoptotic measures may be successful in ameliorating anthracycline cardiotoxicity.

ACKNOWLEDGEMENTS

This manuscript is the result of work supported with resources and use of facilities at the Boise VA Medical Center. RDO was supported in part by NIH Grant #20 RR016454 from the INBRE program of the National Center for Research Resources.

Photoallergy

Rūta Dubakienė

CONTENTS

1 INTRODUCTION

Photosensitivity is the broad term used to denote abnormal adverse reactions to ultraviolet radiation (UVR) or visible light (Epstein, 1983; 1999). The forms of photosensitivity are phototoxicity and photoallergy. Phototoxic disorders have a high incidence, whereas photoallergic reactions are much less frequent in the human population. Several hundred endogenous and exogenous substances can be transformed into antigens by sunlight and may invoke phototoxic or photoallergic reactions (Hasan and Jansen, 1996; Dubakiene and Kupriene, 2006). Phototoxic and photoallergic reactions can be diagnosed separately on the basis of pathogenesis, clinical characteristics and histology (Lankerani and Baron, 2004; Ichihashi, 2007). Drug photosensitivity is a major problem, since the abnormal reactions seriously limit or exclude the use of drugs (Takiwaki *et al*., 2006). Standardized detection of the photosensitizing properties of particular substances should be considered prior the drugs being introduced in therapy or products made available on the market.

2 HISTORICAL REVIEW

Photosensitive reactions have been recognized for thousands of years. In ancient Egypt, India and Greece psoralen-containing plant extracts were combined with exposure to sunlight to treat skin diseases. As early as 2000 BC in Egypt, the juice of *Ammi majus*, which grows throughout the Nile River valley as a weed, was rubbed on patches of vitiligo, after which patients were encouraged to lie in the sun. Reports of dermatitis following contact with parsnips and angelica came from both England and the United States (Stowers, 1897; White, 1897). Freund (1916) observed characteristic hyperpigmented lesions that he attributed to *eau de cologne* containing bergamot oil. Unfortunately, none of the authors recognized the necessity of UVR for the reaction. In 1932, Oppenheim reported that the combination of meadow grass exposure and UVR could result in a striate arrangement of itching blisters 24–48 hours later. It was found that plant furocoumarins caused photosensitization (Kuske, 1938). Jensen and Hansen (1993) reported that UVR between 320 and 380 nm caused

the maximum reaction. Klaber (1942) introduced the term 'phytophotodermatitis' to emphasize the necessity of plants and light to cause the reaction. European scientists pioneered photosensitivity disorder research during the 1960s. In 1967, Danish researchers attributed strange skin lesions on women to perfumed soap. In the same year, British researchers discovered that sandalwood oil in sunscreens and cosmetics caused photoallergies. Shortly thereafter, French scientists demonstrated that bergamot oil in sunscreens caused photosensitivity disorders. German researchers isolated photoreactive agents in colognes, perfumes and oral contraceptives. American scientists, in 1972, linked sunlight-activated aniline compounds (found in drugs, varnishes, perfumes, shoe polish and vulcanized rubber) to hives and skin conditions such as dermatitis and dandruff.

Most recently the Food and Drug Administration has listed medications that increase sensitivity to light and can cause a wide variety of health problems known as photosensitivity disorders. An increased list of photoreactive agents found in several hundred of substances, chemicals and drugs is published annually (Bryden *et al*., 2006; Pigatto *et al*., 2008). In order to avoid photosensitive reactions, attempts are made to determine the photosensitizing properties of such substances before drugs are introduced in therapy or products made available on the market (Wahie *et al*., 2007). Moreover, the standard set of photoallergens has to be updated periodically (Bakkum and Heule, 2002).

3 INCIDENCE AND PREVALENCE

The prevalence of photoallergy in the general population is uncertain. Almost 400 medications have been reported to cause photosensitivity and a half of them photoallergy. Only a small number, however, induce reactions frequently or have been well studied. In evaluations performed at photodermatology centres in New York, Melbourne, Singapore and Detroit, documented photosensitivity induced by a systemic drug occurred in 5 to 15% of the referred patients (Fotiades *et al*., 1995; Chong and Khoo, 2004). In studies performed in the United States, the United Kingdom, Europe, Australia and India, the percentage of photopatch-tested patients who had clinically relevant reactions leading to a diagnosis of photoallergic contact dermatitis ranged from 1.4 to 12%, with the value in most series being around 10% (Berne and Ros, 1998; Moore, 2002; Scheuer and Warshaw, 2006; Neumann *et al*., 2000; Neumann and Lehmann, 2003; Bryden *et al*., 2006; Sharma *et al*., 2007; Katsarou *et al*., 2008). The racial incidence of drug-induced photosensitivity reactions is unknown. Photosensitivity reactions can occur even in races with heavily pigmented skin (Kontos *et al*., 2002). Men are more likely to have photoallergic reactions than women. Photosensitivity is associated with death only in rare individuals who are exposed to large amounts of sunlight after taking large doses of psoralens (McKenna, 2004). Although mortality is rare, drug-induced photosensitivity can cause significant morbidity in some individuals, who must severely limit their exposure to natural or artificial light. Carcinogenic potential due to prolonged exposure to these photosensitizing drugs has been suggested (Stern *et al*., 1998; Lim and Stern, 2005), however, its clinical relevance remains to be determined. There is a need for randomized, controlled trials of strategies for prevention, control and treatment of photosensitivity disorders. Additional data are needed for a better assessment of the risk of photosensitivity associated with many drugs (Ferguson, 2002). Standardization of the test procedure is needed to compare the test results of different institutions.

4 PHOTOSENSITIZERS

Photosensitizers or photoreactive agents are chemicals that induce a photoreaction. The chemicals may be therapeutic, cosmetic, industrial or agricultural (Fitzpatrick *et al*., 2001). Following interaction of UVR with a chemical present in sufficient amounts in the skin, one of several reactions, phototoxic or photoallergic, may occur in susceptible patients (Vassileva *et al*., 1998; Stein *et al*., 2007). Medications that trigger reactions can be topical, oral and, on rare occasions, inhaled (Reid, 1996; Pérez-Pérez *et al*., 2007; Sánchez-Pedreño *et al*., 2001).

Mostly, photoallergic reactions result from the topical administration of the agent under the action of sunlight, with a spectrum within the UVA and visible light range or UVB range (Allen, 1993; Stege and Krutmann, 1996; Lugovic *et al*., 2007; Belhadjali *et al*., 2002; Agin *et al*., 2008). Everyday items, such as perfumes, soaps, deodorants, lotions, hair sprays and styling creams, artificial sweeteners, petroleum products, tattoos and certain foods may contain photoreactive agents and induce photoallergy (Schauder *et al*., 1996; Monfrecola *et al*., 2000; Uetsu *et al*., 2000; Emmert *et al*., 2007). Sunscreens help to reduce the effects of UVR, although some sunscreens contain ingredients that cause photosensitivity themselves (Collins and Ferguson, 1994; Cook and Freeman, 2001). Currently, the benzophenones are frequently used in high-protection-factor sun-barrier preparations, and appear to have a particular ability to induce such responses (Darvay *et al*., 2001). Usage of products containing photoreactive agents can aggravate existing skin diseases (eczema, herpes, etc.) and also precipitate or worsen autoimmune diseases (lupus erythematous, rheumatoid arthritis). Further photopatch test series should be regularly reviewed and updated, as the relevance of individual photoallergens changes over time.

Medications containing photoreactive agents include antibiotics, nonsteroidal anti-inflammatory drugs,

Table 1 Common photosensitizers

Class	Medication	Photoallergic reaction	Phototoxic reaction
Antibiotics	Tetracyclines (doxycycline, tetracycline)	No	Yes
	Fluoroquinolones (ciprofloxacin, ofloxacin, levofloxacin)	No	Yes
	Sulfonamides	No	Yes
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Ibuprofen	No	Yes
	Ketoprofen	Yes	Yes
	Naproxen	No	Yes
	Celecoxib	Yes	No
Diuretics	Furosemide	No	Yes
	Bumetanide	No	No
	Hydrochlorothiazide	Yes	Yes
Retinoid	Isotretinoin	No	Yes
	Acitretin	No	Yes
Hypoglycemics	Sulphonylureas (glipizide, glyburide)	Yes	No
Photodynamic therapy (PDT) prophotosensitizers	5-Aminolevulinic acid	No	Yes
	Methyl-5-aminolevulinic acid	No	Yes
	Verteporfin	No	Yes
	Photofrin	No	Yes
Neuroleptic drugs	Phenothiazines (chlorpromazine, fluphenazine, perazine, perphenazine, thioridazine)	Yes	Yes
	Thioxanthenes (chlorprothixene, thiothixene)	No	Yes
Antifungals	Terbinafine	No	No
	Itraconazole	Yes	Yes
	Voriconazole	No	Yes
Other drugs	*p*-Aminobenzoic acid (PABA)	Yes	Yes
	5-Fluorouracil	Yes	Yes
	Amiodarone	No	Yes
	Diltiazem	No	Yes
	Quinidine	Yes	Yes
	Hydroxychloroquine	No	No
	Coal tar	No	Yes
	Enalapril	No	No
	Dapsone	Yes	No
	Oral contraceptives	Yes	No
Sunscreens	PABA	Yes	No
	Cinnamates	Yes	No
	Benzophenones	Yes	No
	Salicylates	Yes	No
Fragrances	Musk ambrette	Yes	No
	6-Methylcoumarin	Yes	No

cardiovascular drugs, diuretics, antidiabetic drugs, antidepressants, antipsychotics, antihistamines, skin agents and others (Horio *et al*., 1978; Ophaswongse and Maibach, 1993; Schürer *et al*., 1991; Torinuki, 1995; Alvarez-Fernández *et al*., 2000; Trujillo *et al*., 2001; Johnston, 2002; Adams and Gadenne, 1999; Torinuki, 1995; Alvarez *et al*., 2003; Gubinelli *et al*., 2003; Marzano *et al*., 2003; Llambrich and Lecha, 2004; Landers *et al*., 2003; Morison, 2003; Vachiramon and Wattanakrai, 2005; Takiwaki *et al*., 2006; Langan and Collins, 2006). Common photosensitizers presented in **Table 1**. An adverse effect of several anti-infective agents and their derivatives is photosensitivity reactions. Most of them are cyclic and tricyclic hydrocarbons,

frequently containing an alternate double-bond isoprene or naphthyridine nucleus (Vassileva *et al*., 1998). Fluoroquinolones, antibacterial agents, are well known to cause photosensitivity as an adverse effect, and their crossreactivity has been clinically documented (Tokura *et al*., 1998; Yazici *et al*., 2004; Oliveira *et al*., 2000; Willa-Craps *et al*., 1995; Kumar and Freeman, 1996). Empirical studies suggest pefloxacin and fleroxacin to be the most potent photosensitizers, while enoxacin, norfloxacin and ofloxacin are less potent (Vassileva *et al*., 1998). Tetracyclines are an example of the phototoxic hazards of antibiotics. Among them, chlorine derivatives most frequently cause phototoxicity (Vassileva *et al*., 1998). Sulfa-derived drugs (sulfonamide antibacterials, hypoglycaemics, diuretics) have been well-known causes of photosensitivity reactions since Epstein (1939) first reported photoallergic contact dermatitis following intradermal injection of sulfanilamide (Vassileva *et al*., 1998). Celecoxib, a new-generation nonsteroidal anti-inflammatory drug, a selective cyclooxygenase-2 (COX-2) inhibitor containing a sulfonamide substitute, is now widely used clinically, due to its advantage of a lower rate of gastrointestinal irritation. However, Yazici *et al*. (2004) reported a photoallergic drug eruption associated with the introduction of celecoxib. Skin patch testing showed positive reaction to 1% celecoxib without crossreactivity to 1% sulfamethoxazole-trimethoprim (Yang *et al*., 2004).

Photoallergic contact dermatitis from topical ketoprofen (KTP), a nonsteroidal anti-inflammatory agent, is a well-known side effect. Ketoprofen clinically evokes the allergic type of photo contact dermatitis when applied to the skin and irradiated with UVA (Pigatto *et al*., 1996; Le Coz *et al*., 1998; Matthieu *et al*., 2004; Foti *et al*., 2008; López-Abad *et al*., 2004; Atarashi *et al*., 2007; Asensio *et al*., 2008; Devleeschouwer *et al*., 2008). The arylpropionic acid derivatives (APADs), ketoprofen and tiaprofenic acid (TPA) can provoke photoallergic dermatitis (Fernández-Jorge *et al*., 2008). Their chemical structures share the same elements, the benzoyl radical and the thiophene ring. The finding that the vast majority of the ketoprofen photoadduct can be accounted for by means of antibenzoyl antibodies strongly supports the view that the drug binds preferentially via the thiophene ring, leaving the benzene ring more accessible. By contrast, selective recognition of SUP–protein photoadducts by anti-thenoyl antibodies evidences a preferential coupling via the benzene ring, leaving the thiophene moiety more distant from the protein matrix. As a result of research by (Lahoz *et al*., 2001), we have been able to identify a common substructure that is present in TPA–albumin and KTP–albumin photoadducts. The greatest structural similarities were found between TPA and SUP as they share the same benzoylthiophene chromophore. It appears that the benzoyl radical is the key structure for photosensitivity and the photo crossreactivity of ketoprofen, suprofen (SUP) and TPA (Sugiura *et al*., 2002). It was reported that the crossreactivity applied to fenofibrate and oxybenzone, but not to APADs without a benzophenone moiety, which might therefore be used in such patients (Le Coz *et al*., 1998). Crossreactivity of the substituted benzophenones, oxybenzone and sulisobenzone, occurred only with the former in less than 30% of the patients, and a high frequency (69%) of contact allergy to the fragrance mix was found (Matthieu *et al*., 2004). Dermatologists should be aware of the severity of photoallergic reactions to ketoprofen and the risk of cross-sensitization (Sugiura *et al*., 2002; Ota *et al*., 2007; Girardin *et al*., 2006).

4.1 Photosafety of New Active Substances

The goal of photosafety is to detect the adverse effects of pharmaceutical products in the present of light. This type of testing is relevant for substances that enter the skin via dermal presentation or systemic circulation. Despite increasing numbers of new drugs reaching the marketplace, one might expect, with modern preregistration drug screening, that the chance of a drug with a significant phototoxic potential reaching the marketplace would be much less than it was, see in **Figure 1**. Four different end points should be specifically addressed in photosafety testing: phototoxicity, photoallergy, photogenotoxicity and photocarcinogenicity. From a regulatory perspective it is much easier to request a phototoxicity study, both in the laboratory and in the clinical setting, if the drug under development is a known member of a photoactive group. It is much less easy with a completely novel molecule. In that situation, if early-phase *in vitro* and human-usage studies fail to demonstrate such an effect, it may be left to postmarketing surveillance to detect any problem. The less commonly the drug produces photosensitivity the more it needs to be watched out for, and the mistake of incorrectly placing a drug photosensitivity presentation into another diagnosis, such as an idiopathic photodermatoses should be avoided (CPMP 2002). Photosafety testing is warranted for those chemicals that absorb light of wavelength 290–700 nm and are either topically/locally applied or reach the skin or eyes following systemic exposure.

5 PATHOLOGICAL MECHANISM

The pathogenesis of contact photoallergy and contact allergy is similar except that UVR radiation is necessary for the induction and elicitation phases of a photoallergic response (Gerberick and Ryan, 1990a). A number of individual agents and drug families have the ability to change a subject's sensitivity to artificial or solar irradiation (Fotiades *et al*., 1995; Neumann *et al*., 2000;

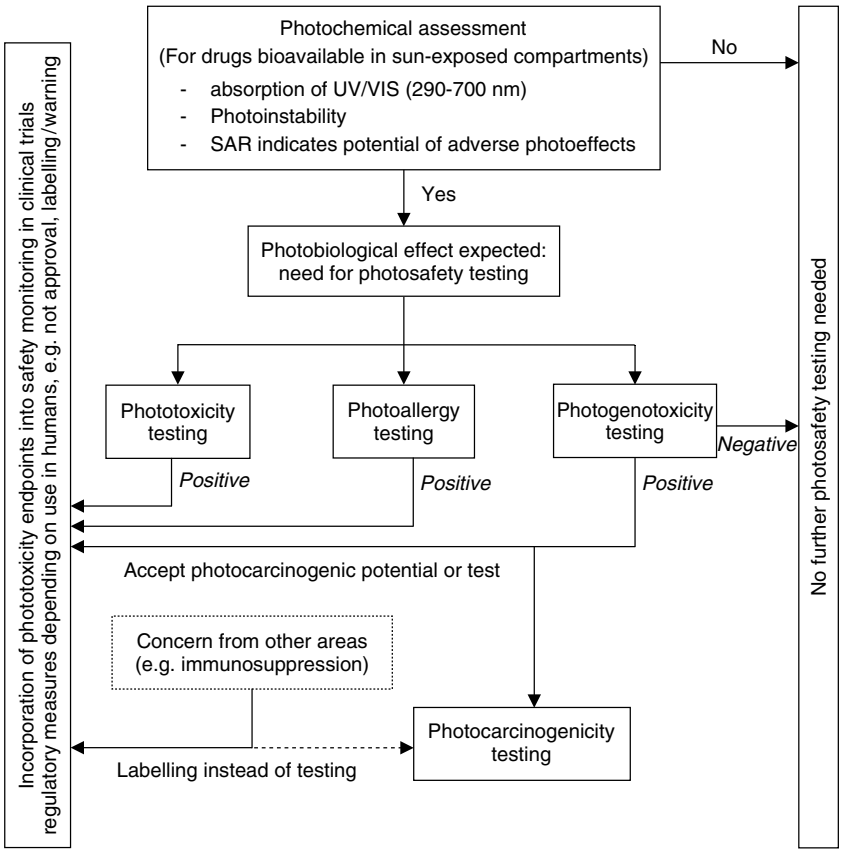

Figure 1 Assessment of photosafety of new active substances.

Moore, 2002; Ferguson, 2002; Rodríguez *et al*., 2006; Scheuer and Warshaw, 2006). Absorption of light energy alters photosensitizing chemicals producing a hapten, which attaches to a protein carrier and causes hypersensitivity (Ferguson, 2002). Drug-induced photoallergy is an immune adverse reaction to the combined effect of drugs and light. From a mechanistic point of view, it first involves covalent binding of the drug to protein, resulting in the formation of a photoantigen. Hence, determination of the structures of drug–protein photoadducts is of great relevance to understand the molecular basis of photoallergy and crossimmunoreactivity among drugs (Lahoz *et al*., 2001).

Wavelengths within the UVA (320–400 nm) range and, for certain compounds, within the visible range, are more likely to cause photosensitivity reactions; UVA (315–430 nm) and sometimes the visible region, particulatly, will produce a photochemical effect with damage to cellular components within the skin, resulting in the clinical presentation, although occasionally UVB (290–320 nm) can also be responsible for such effects. UVB wavelengths are most efficient at causing sunburn and nonmelanoma skin cancer. Photosensitivity reactions may be more specifically categorized as phototoxic or photoallergic. The most common of these are is phototoxic, and other significant, but less common mechanisms induce photoallergic reaction (Darvay *et al*., 2001). In patients who present with photosensitivity, it is often difficult to differentiate phototoxic from photoallergic reactions; distinguishing characteristics are summarized in **Table 2**.

Photoallergic reactions are cell-mediated immune responses in which the antigen is a light-activated drug. Photoactivation results in the development of a metabolite that can bind to protein carriers in the skin to form a complete antigen. The reaction then proceeds exactly as for other cell-mediated immune responses. Specifically, Langerhans cells and other antigen-presenting cells take up the antigen and then migrate to regional lymph nodes. In these locations, the Langerhans cells present the photoallergen to T-lymphocytes that express antigen-specific receptors. The T-cells become activated and proliferate, and they return to the site of photoallergen deposition. In the skin, the T -cells orchestrate an inflammatory response that usually has an eczematous morphology if the photoallergen is applied topically, or the characteristics of a drug eruption if the photoallergen is administered systemically.

Phototoxicity is a form of photosensitivity that is not dependent on an immunologic response. Phototoxic reactions are dose dependent and will occur in almost any one who takes or applies an adequate amount of the offending agent and UVR, but the dose necessary

Table 2 Distinguishing characteristics of phototoxic and photoallergic reactions

Feature	Phototoxicity	Photoallergy
Incidence	High	Low
Pathophysiology	Direct tissue injury; not immunologically mediated	Type IV delayed hypersensitivity response; immunologically mediated
Amount of agent required for photosensitivity	Large	Small
More than one exposure to agent required	No	Yes
Distribution	Sun-exposed skin only	Sun-exposed skin, may spread to unexposed areas
Onset of reaction after exposure to agent and light	Minutes to hours	24–72 h
Clinical presentation	Exaggerated sunburn: erythema, oedema, vesicles, bullae; burning, stinging; frequently resolve with hyperpigmentation	Dermatitis: usually eczematous lesions and usually pruritic
Histologic features	Necrotic keratinocytes, epidermal degeneration; sparse dermal infiltrate of lymphocytes, macrophages, neutrophils	Spongiotic dermatitis, dermal lymphohistiocytic infiltrate

to induce such a reaction varies among individuals. Phototoxic reactions can appear on first exposure to the agent and demonstrate no cross-sensitivity to chemically related agents.

5.1 Risk Factors

The photobiological risk of photoallergic reaction depends on environmental and individual factors. Environmental risk factors are summarized in **Table 3**. Photoallergic reactions are quite unpredictable. They can occur in persons of any age, but are more common in adults than children, possibly because adults are usually exposed to more medications and topical agents (Dubakiene and Kupriene, 2006). The degree of photosensitivity varies among individuals; with the same exposure, not everyone will have a photoreaction. A person who has a photoreaction after a single exposure to an agent may not react to the same agent after repeated exposures; on the other hand, a person who is allergic to one chemical may develop photosensitivity to related chemical (cross-sensitivity). The crossreactivity patterns between the four clinically most important allergens: methyl methacrylate (MMA), 2-hydroxyethyl methacrylate (2-HEMA), 2-hydroxypropyl methacrylate (2-HPMA) and ethyleneglycol dimethacrylate (EGDMA) were studied in guinea pigs. The results of this study offer new insights into the development of MMA hypersensitivities and common cross-sensitization patterns in clinical practice (Rustemeyer *et al*., 1998). It is assumed that skin-protein conjugation at the 5- or 6- positions of the coumarin ring is important to elicit crossreactivity with esculetin or daphnetin groups (Masamoto, 2001).

5.2 Experimental Models

A wide range of experimental models for photoallergy testing existed. The potentials of *p*-aminobenzoic acid, 4-isopropyldibenzoylmethane and homosalate (three sunscreens), and two known human photoallergens (musk ambrette and tetrachlorosalicylanilide) to cause photoallergy, phototoxicity and/or contact sensitization were determined using a guinea pig photoallergy model (Gerberick and Ryan, 1989). In addition, the photoallergic potentials of various compounds were assessed using a mouse ear-swelling test (MEST) model, which offers the advantage of being quantifiable and more objective than models based on subjective evaluation of erythematous skin reactions (Gerberick and Ryan, 1990b). At present, photoallergy testing is mainly conducted using guinea pig models. Alternative test methods which may take into consideration better objectivity in photoallergic hazard identification and animal welfare are currently under development. *In vitro* tests monitoring photochemical reactions, that is, photo-adduct formation and photo-oxidation of biomolecules, can be useful screening tools. *In vivo* models under development (modified local lymph node assays (LLNAs) and MEST-assay) may become valuable in the future. However, the validation of these tests is still limited. Photoallergy testing should be performed to the state of the art.

Early attempts to study drugs with human volunteers had an attractive simplicity of approach. Recently, a more sophisticated, less traumatic approach for volunteers involves a carefully selected healthy population who are randomized to receive active drug, placebo or positive control following careful monochromatic and polychromatic solar-simulator baseline testing. A double-blind, randomized, parallel-group comparative study investigated the phototoxic potential of gemifloxacin mesylate, a potent, novel fluoroquinolone (FQ) antimicrobial was conducted (Vousden *et al*., 1999). In a single-centre, double-blind, randomized study, 30 adults (20 men, 10 women) received oral levofloxacin (500 mg qd × 5 d) or placebo. No subject experienced an immediate wheal-and-flare reaction. Levofloxacin has a low photosensitizing potential when administered to healthy subjects (Boccumini *et al*., 2000). A study comparing the phototoxic potential of sitafloxacin, a novel FQ with three others: sparfloxacin, enoxacin, levofloxacin and placebo in Caucasian volunteers has been conducted (Dawe *et al*., 2003). With good-quality instrument control and careful minimal erythema dose (MED) determination, pre- and on-drug photoallergy values can be compared.

5.3 DNA-Based Testing

Phototoxic responses after administration of photosensitive pharmaceutics have been recognized as undesirable side effects, and predicting potential hazardous side effects is gaining importance as new drugs are introduced to the market (Onoue and Tsuda, 2006). An assay using established cell lines, human A431 epidermal cells and mouse 3T3 fibroblasts, has been developed to predict the phototoxic potential of compounds. The test determines the viability of the two cell lines in response to UV light in both the presence and absence of the test compound (Duffy *et al*., 1987–1988). Onoue *et al*. (2008) developed effective analytical tools to predict the photogenotoxic potential of pharmaceutical substances with the use of pBR322 DNA, a plasmid DNA. Data, taken together with the results of the ROS (reactive oxygen species) assay, suggest that singlet oxygen might act as a major toxic species in quinone-induced photogenotoxicity. The structural analysis of plasmid DNA by capillary gel electrophoresis (CGE) after exposure to UVA/B in the presence of photosensitizers could be automated, allowing easy, fast and highly reliable prediction of

the photogenotoxic potential of a large number of drug candidates (Onoue *et al*., 2008).

6 CLINICAL MANIFESTATION

Photoallergic reactions primarily occur on the areas of the skin that are exposed to UVR, but may spread beyond these to other areas. It is likely that the majority of mild episodes of drug-induced photosensitivity pass either unnoticed by the patient or are assumed to be mild sunburn. Those patients who reach hospital dermatologist outpatients have usually either been severely affected or undiagnosed (Yashar and Lim, 2003). According to the model of administration of the photosensitizer, photoallergic reactions can be contact photoallergic dermatitis or photoallergy induced by systemic agents. **Table 4** summarizes differences between phototoxic and photoallergic contact dermatitis.

The onset of a photoallergic reaction is usually delayed for 24 hours or even several days, and recovery is often slower than from a phototoxic reaction, with the reaction sometimes persisting for some time after the offending product has been discontinued. This reaction presents as an eczematous eruption with erythema, papules and vesicles, pruritis, weeping, oozing and crusting, and, later, scaling and lichenification. Hyperpigmentation does not occur in photoallergic reactions. Photoallergic reactions may also be macular, bullous or acute urticarial lesions and may develop within minutes after exposure to UVR.

7 DIAGNOSIS AND TESTING

7.1 Physical Examination

Photoallergic reactions typically develop in the sun-exposed areas such as portions of the head and face, arms, legs, and torso. Specifically, it would spare areas underneath the chin, underneath the lips, nasolabial fold, and postauricular area (Yashar and Lim, 2003). Shaded areas such as those under the hair fringe, upper eyelid, below the nose, upper lip, submental area, post-auricular area, web spaces of finger and flexures tend to be spared (Hearn, 2005). However, in severe cases lesions may extend to covered areas. Pruritic eczematous eruption is suggestive of photoallergic reactions. Erythema and vesiculation are present in the acute phase. Lichenification and scaling are the hallmarks of chronic photosensitivity. An uncommon variant of polymorphous light eruption also can present with small blisters. Morphological clues in differential diagnosis of phottoallergy is presented in **Table 5**.

In addition, exposure to known photosensitizers is of the main importance during the history taking. Intervals between sun exposure, the development of lesions, and the duration of the lesions offer some clues on the diagnosis. The age of onset and connective tissue disease also help in narrowing the differential diagnosis.

7.2 Phototesting

Phototesting with UVA, UVB and, sometimes, visible light is helpful in diagnosing photosensitivity disorders. This test is performed by treating small areas of skin on the back or inner aspect of the forearms with gradually increasing doses of light. The minimum dose of light required to produce uniform erythema over the entire irradiated site after 24 hours is called the minimum erythema dose (MED). Patients with phototoxic reactions have a reduced MED to UVA or, in some instances, UVB.

7.3 Photopatch Tests

In 1984, the German, Austrian and Swiss Photopatch Test Group was founded to standardize the photopatch-test procedure and to investigate photoallergic reactions, as

Table 4 Differences between photoallergic and phototoxic contact dermatitis

Feature	Photoallergic	Phototoxic
Incidence	Low	High
Occurrence on first exposure	No	Yes
Onset after ultraviolet exposure	Usually 24–48 h (6–72)	Minutes to days
Dose dependence		
Chemical	Not crucial	Important
Radiation	Not crucial	Important
Clinical morphologic appearance	Eczematous	Erythematous and bullous hyperpigmentation
Histology	Spongiotic dermatitis	Necrotic keratinocytes
Diagnosis	Photo-patch testing	Clinical history and psychical

well as the epidemiology of photoallergy, in central Europe (Neumann *et al*., 2000). Therefore, in the first test period from 1985 to 1990, 32 test substances were applied on the backs of patients suspected to be photosensitive. After evaluation of these data, some substances were dismissed, and others were additionally integrated into the test tray. Thus a modified test tray comprising 26 test substances was used for the second test period (1991–1997). The British Photodermatology Group (1997) published a workshop report in 1997 with guidelines on photopatch-testing technique. This recommended UVA as the radiation source and suggested compounds for a series of photocontact allergens. No firm recommendations were made for timing of irradiation or patch-test readings. Photopatch testing is an important tool in the diagnosis of photoallergic contact dermatitis:

- Suspected photoallergens are applied to the back in two sets
- One set is removed after 24 hours and irradiated with $5-10\,J\,cm^{-2}$ UVA
- Both sets of patch tests are evaluated for a positive reaction after 48 hours
- Erythema, edema and/or vesiculation at an irradiated site indicate a positive reaction
- A positive reaction at both sites is interpreted as allergic contact dermatitis
- A positive reaction at the unirradiated site with a stronger one at the irradiated site should be interpreted as both allergic dermatitis and an photoallergic contact dermatitis reaction to the same compound.

There still exist a variety of protocols presently in use, with little information as to which method is most reliable or discriminatory.

7.4 Laboratory Tests

Laboratory tests are required to exclude porphyria cutanea tarda, by assessing urine porphyrin levels, which are elevated in porphyria cutanea tarda and within the normal range in pseudoporphyria and drug-induced photosensitivity, and to determine antinuclear antibody (ANA) and anti-Ro (SSA) antibody levels.

Histologically photoallergic reaction is similar to contact dermatitis. Epidermal spongiosis with a dermal lymphocytic infiltrate is a prominent feature. The presence of necrotic keratinocytes is suggestive of photoallergy rather than allergic contact dermatitis.

Significance of Biochemical Markers in Applied Toxicology

Fernando Gil and Antonio F. Hernández

CONTENTS

1 INTRODUCTION

Although the presence of a xenobiotic in the environment always represents a risk for living organisms, it is necessary to consider key factors that can influence the host reaction to chemical compounds, including their physicochemical properties, routes of exposure (inhalation, oral and/or dermal absorption) and a number of host characteristics including age, race, gender, health status, genetic susceptibility and previous exposure to the same or other chemicals.

One of the methods to assess and quantify the exposure to xenobiotics and its potential impact on organisms is biological monitoring using biomarkers. A biomarker can be broadly defined as any biological index capable of being measured, reflecting an interaction between a biological system and a potential hazard, which may be chemical, physical or biological. The measured response is associated with or indicative of a defined and observable biological end point that can range from the morphological level down to the molecular level, and which indicates events in the process leading to clinical disease (Ward and Henderson, 1996). Biomarkers, therefore, provide information on the nature and the effect of an exposure, as well as on the susceptibility of individuals or populations to the toxic effects of such an exposure (Rockett and Kim, 2005). Ideally, biomarkers will be expressed across a large section of the population, and can be monitored quickly, easily, conveniently and with minimal cost (Rockett *et al*., 2004).

A US National Institutes of Health (HNIH) Study Group defined a biomarker as a characteristic that is objectively measured and evaluated as an indicator of normal physiologic processes, pathologic processes, or pharmacologic responses to a therapeutic intervention (Biomarkers Definitions Working Group, 2001). Biomarkers are essential tools in monitoring studies, which include environmental monitoring, biological monitoring, biological effect monitoring and health surveillance, as well as drug development processes. Biomarkers are also becoming increasingly important in toxicology and human health. Their use in the evaluation of disease risk has increased markedly in the last decades. The discovery, validation and analysis of biomarkers requires highly sensitive and selective analytical technologies. Recent advances in technology have added several new tools to the biomarker screening toolkit and improved the throughput of existing quantitative assays (Orhan, 2007). Genomics, proteomics and metabonomics have provided a wealth of data in the search for predictive, specific biological indicators.

However, biological monitoring cannot be applied for assessing exposure to xenobiotics that exhibit their toxic effects immediately at the sites of first contact (caustic agents, lung irritants) and for those chemicals poorly absorbed, because of the lack of detection in biological matrices. Furthermore, the complexity and accessibility of certain organ systems (for example nervous system) do not allow for a rapid and easy development of sensitive, specific and reliable biomarkers.

When assessing the usefulness of a particular exposure biomarker, one must consider analytical and toxicokinetic aspects in order to establish its validity. For optimal analytical quality, standardization is needed: sampling, handling and measurement procedure, and quality assurance methods. Life events, such as physiological (pregnancy, senescence) or pathological processes (e.g. liver or kidney disease) may also affect the toxicokinetic

of a particular xenobiotic (Grandjean *et al*., 1994; Gil, 2005).

When a quantitative relationship is established between internal dose and adverse effects, and the internal-dose effects and internal-dose response relationships are known, then biological monitoring allows for a direct health risk assessment and thus for an effective prevention of the adverse effects (Gil, 2005). Although the effects of environmental chemicals have traditionally been detected by means of biomarkers of exposure or effects, nowadays proteomics offers a new approach using a set of high-throughput methodologies with a wide dynamic range that makes possible the discovery of novel biomarkers (Sheehan, 2007).

The ideal biomarkers (Grandjean *et al*., 1994; Gil, 2000) should be detected early and should warn of adverse effects before they become irreversible. In all cases, they should comply with the following characteristics: sample collection should be easy; analysis should be robust (rapid, simple, reliable and accurate); they must be specific for a particular type of exposure, tissue and/or disease. Furthermore they should be sensitive (detectable at low levels), capable of reflecting subclinical and reversible changes, have a preventive character and be ethically acceptable.

Only a few biomarkers fit these characteristics well. Biomarkers may range from those that are highly specific, such as aminolevulinic acid dehydratase (ALAD), an enzyme of the haem pathway which is inhibited only by lead, or the inhibition of acetylcholinesterase (AChE), which is specific for organophosphorus (OP) and carbamate insecticides, to those that are nonspecific, such as effects on the immune system or on DNA that can be caused by a wide variety of xenobiotics (polycyclic aromatic compounds, chemotherapeutic drugs, organochlorine pesticides, etc.) (Walker *et al*., 1996).

2 CLASSIFICATION OF BIOMARKERS

Biomarkers have generally been classified into four major categories: internal dose, biologically effective dose, preclinical biologic effects and susceptibility, with some overlap between them (Committee on Biological Markers of the National Research Council, 1987). Of the four categories, internal dosimeters have been most widely used, particularly in the workplace, to determine exposure to carcinogens and other toxicants. Analyses of the biological material provide information on the various steps inside the exposed individual that bridge the gap between an external exposure to a toxic agent and a possible resulting occupational or environmental disease (**Figure 1**) (Perera and Weinstein, 2000).

2.1 Biomarkers of Exposure

Biomarkers of exposure can be used to confirm and assess the exposure of individuals or populations to a particular substance, providing a link between external exposures and internal dose. Biomarkers of exposure represent the measure of internal dose of the toxic compound or metabolite in a wide variety of biological samples (blood, urine, exhaled air, sputum, saliva, hair, fingernails and faeces) (Van Cauteren *et al*., 1996). Their quantitative measurement facilitates the determination of dose–response relationships.

The internal dose reflects the amount of the toxicant or its ultimate metabolite at the critical site in the target organ and may also mean the amount of a chemical stored in one or in several body compartments or in the whole body. This usually applies to cumulative toxic agents (e.g. solvents, organochlorine compounds, metals) (Lauwerys, 1993; Greim, 2001).

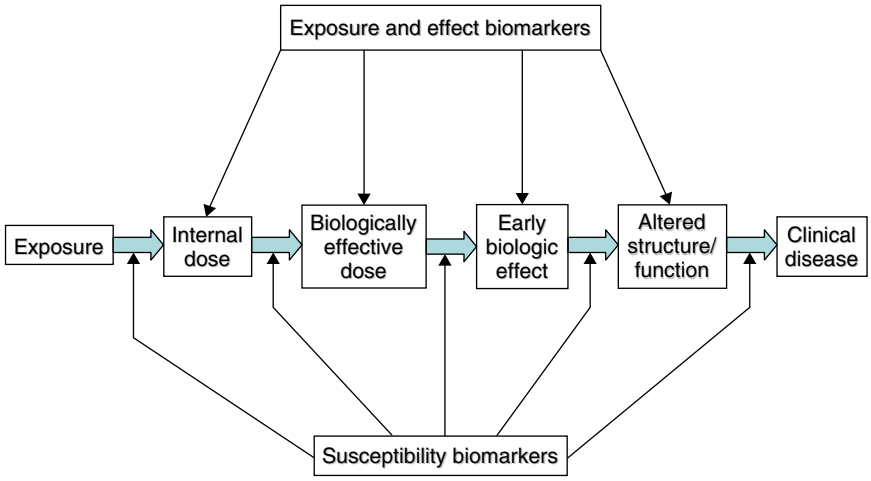

Figure 1 Fate of xenobiotics within the body. (Reproduced from Perera and Weinstein, 2000. © Oxford University Press.)

Biomarkers of internal dose take into account individual toxicokinetic differences of the compound in question and indicate the actual levels of the compound within the body and in specific tissues or compartments. However, since their half-lives range from a few hours to decades their interpretation and applicability to different study designs varies accordingly. Examples include: urinary levels of 1-hydroxypyrene from exposure to polycyclic aromatic hydrocarbons (PAHs), DDT (dichloro-diphenyl-trichloroethane), polychlorinated biphenyls (PCBs), dioxins and furans in serum or adipose tissue biopsies; styrene levels in exhaled air or blood; and phenylglioxilic acid, its metabolite, in urine due to workplace and environmental contamination (Perera and Weinstein, 2000).

Internal dose exposure can also be measured by determining adducts with cellular macromolecules such as proteins, amino acids, DNA or its bases. The concentration of the ultimate reactants that interact with macromolecules is determined by the rate of metabolic activation and inactivation. Individuals with different rates of enzyme activities involved in biotransformation will show different adduct levels. Thus, these markers reflect both exposure and metabolic capacity of the individuals (Greim, 2001). Haemoglobin (Hb) and serum albumin are the preferred monitor molecules because they are accessible in large amounts. They are chemically stable and are not prone to repair mechanisms as are DNA adducts. Because of the long lifespan of Hb (120 days) and the long half-life of serum albumin (20 days), these adducts accumulate in the human body, making them very sensitive parameters for human biomonitoring (Angerer *et al*., 2007).

Although markers of internal dose are valuable supplements to conventional methods of assessing exposure, markers of internal dose do not indicate the extent to which a given compound has interacted with critical cellular targets. Therefore, assays have been developed to measure the 'biologically effective dose' of a compound; that is, the amount that has reacted with critical cellular macromolecules, usually DNA, or a surrogate, such as specific proteins in the blood (Perera and Weinstein, 2000).

2.2 Response or Effect Biomarkers

Response or effect biomarkers are indicative of biochemical changes within an organism as a result of xenobiotic exposure and interaction with biological targets. They reflect a measurable biochemical, physiological, behavioural or other alteration within an organism that, depending upon the magnitude, can be recognized as associated with an established or possible health impairment or disease. Wide interindividual variations in the response to equivalent doses of chemicals are usually observed.

These biomarkers are the most studied and include changes in enzyme activities (usually inhibition), DNA adducts in target tissues, modifications in some parameters of blood composition, protein increases and appearance of autoantibodies against a xenobiotic or a particular cellular fraction.

Biomarkers of effect can be used to document either preclinical alterations or adverse health effects elicited by external exposure and absorption of a chemical, so that they reflect early biological effects. Thus the linkage of biomarkers between exposure and effect contributes to the definition of dose–response relationships. Significant examples of biomarkers of effect classified according to the organ or system targeted by the toxicant are considered below. This review is focussed on biomarkers available for human health assessment. Although there exist other biomarkers which can be applied in environmental toxicology (i.e. metallothioneins, heat stress proteins, etc.) or forensic toxicology (biochemical markers of alcohol or drug consumption), such biomarkers go beyond the scope of this review.

2.2.1 Nephrotoxicity Biomarkers

Acute kidney injury is a common condition with significant associated morbidity and mortality. Unfortunately, standard metrics used to diagnose and monitor kidney injury, such as blood urea nitrogen and serum creatinine, are insensitive and nonspecific, resulting in delayed diagnosis and intervention. The prevention of renal diseases requires the use of sensitive tests capable of detecting effects at a stage when they are still reversible. Chronic exposure to certain nephrotoxic compounds (solvents, heavy metals, halogenated hydrocarbons, organic and therapeutic agents) may cause progressive degenerative changes in the kidney. However, the clinical signs of renal damage are not apparent until the injury is extensive and irreversible, probably due to a large reserve capacity of this target organ (Bernard and Hermans, 1997; Mueller *et al*., 1997; Finn *et al*., 1997). Because of the complexity of the nephron and its regional sensitivity to xenobiotics, it is important to co-localize sites of marker release with pathological lesions (Buchet *et al*., 1990; Mutti *et al*., 1992; Roels *et al*., 1993; Bernard *et al*., 1994a; 1995a; 1995b; Hotz *et al*., 1995; Voss *et al*., 2005; Marchewka *et al*., 2006; Nortier *et al*., 1997; Guder and Hofmann, 2008). Probably, the main limitation is that these biomarkers do not permit the detection of effects on all areas or segments of the kidney or nephron (for example effects on the papilla or the distal tubule).

- Glomerulus: the determination in urine of a high-molecular-weight protein (such as albumin or transferrin) has been used for the early detection of glomerular barrier defect. Fibronectin and laminin

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat179
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

fragments are also biomarkers of glomerular damage. Higher levels of free sialic acid points to disturbances in glomerular filtration.

- Proximal tubules: the increase in low-molecular-weight proteins in urine (such as retinol-binding protein, β_2-microglobulin, α_1-microglobulin or α-amylase), assumed to be freely filtered, reflect tubular dysfunction. Brush border markers include alanine aminopeptidase and γ-glutamyltransferase, as well as the efficiency of the nephron resorption process through concentration of β_2-microglobulin in urine and its filtracy fraction of elimination.
- More recent biomarkers include carbonic anhydrase, alkaline phosphatase, alanine aminopeptidase, adenosine deaminase-binding protein and glutathione *S*-transferase-α (α-GST). The last of these is a hallmark of early changes in the proximal tubular integrity for biomonitoring adverse effects induced by the chronic exposure to certain heavy metals such as lead and cadmium (Garçon *et al*., 2004).
- Thick ascending limb of the loop of Henle: measurement of Tamm-Horsfall glycoprotein.
- Distal tubules: determination of GST-π.

Nephrotoxic damage can be also detected by measuring the urinary activity of kidney-derived components including enzymes, antigens, and so on. Lysosome-derived enzymes, such as *N*-acetyl-β-D-glucosaminidase (NAG), isoenzyme (NAG-B), β-galactosidase and β-glucuronidase are also used for monitoring proximal tubule insults. The B isoenzyme of lysosomal NAG has been proposed as an index of nephrotoxicity because of its high activity in the kidney and its stability in urine.

Although the kidney is one of the main targets of xenobiotic-induced toxicity, early detection of renal damage is difficult. Recently, several novel biomarkers of nephrotoxicity have been identified by transcription profiling, including kidney injury molecule-1 (Kim-1, a transmembrane glycoprotein which is up-regulated following nephrotoxic injury), lipocalin-2, tissue inhibitor of metalloproteinases-1 (Timp-1), clusterin, osteopontin (OPN) and vimentin. They appear to be sensitive and tissue-specific biomarkers that will improve detection of early acute kidney injury following exposure to nephrotoxicants, when compared to traditionally used biomarkers. However, it is not known if these cellular marker molecules may also be useful to predict chronic nephrotoxicity or to detect nephrotoxic effects, although induction of Kim-1 messenger RNA expression was the earliest and most prominent response observed *in vitro*, supporting the use of this marker as a sensitive indicator of chronic kidney injury (Rached *et al*., 2008).

2.2.2 Biomarkers of Blood System Disease

Alterations of the haem biosynthetic pathway represent the most studied biomarkers of effect. ALAD is an enzyme involved in the haem synthesis in bone marrow erythroblast, and the assay is highly specific for lead exposure and effect. The inhibition of ALAD has been shown to be a reliable marker of effect for lead in studies on humans and certain animals (eagles, starlings, ducks and geese) (Scheuhammer, 1987; Peakall, 1992a; Melancon *et al*., 1992; Walker *et al*., 1996). In addition, this biomarker has also proven to be very sensitive in epidemiological studies on pesticide applicators (Panemangalore *et al*., 1999; Hernández *et al*., 2005).

The most commonly used biomarkers in the blood are those dealing with Hb or its biosynthetic pathway. Some chemicals are capable of reacting with Hb and give rise to intermediate compounds that can be analysed for biomonitoring purposes. One example is carbon monoxide (CO), which binds Hb with high affinity, generating carboxyhaemoglobin (CO-Hb), which shows a dose–response relationship with clinical disturbances, particularly in acute poisoning. In contrast, its usefulness in chronic exposure has not been sufficiently evaluated. Another example is nitrites, which may oxidize Hb, rendering methaemoglobin (Met-Hb), which could also be measured by spectrophotometric methods. On the other hand, certain organochlorine compounds may cause the formation of excess amounts of hepatic highly carboxylated porphyrins. Only a few agents have been involved in chemical-induced porphyria, such as hexachlorobenzene, lead and PCBs (Gil and Pla, 2001). It has been mentioned above that reactive intermediates generated by oxidative metabolism in Phase I reactions can bind covalently to Hb. However, they must be considered as biomarkers of internal exposure rather than biomarkers of effect. Some examples of chemicals that may produce Hb adducts are ethylene oxide, acrylamide, 3-amino-1,4-dimethyl-5OH-pyrido-indole, 4-aminobiphenyl, 2,6-dimethylaniline, and so on (Gil and Pla, 2001).

2.2.3 Hepatotoxicity Biomarkers

Liver toxicity is caused by a number of chemicals that are metabolized by the cytochrome P450 (CYP450)-dependent mixed-function oxidase system to reactive intermediates. Liver injury biomarkers include various peripheral proteins released in response to a cellular damage or, locally, proteins that are significantly altered within the liver. These include both circulating cytosolic, mitochondrial or canalicular membrane markers, and the up-regulation or depletion of radical scavengers, modulators and stabilizers of intracellular damage (Amacher, 2002).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat179
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Some of the many enzymes found in hepatocytes can be measured in the serum and are used as tests of liver function. They can be divided into two categories: enzymes that primarily reflect cholestasis, such as the alkaline phosphatase, 5′-nucleotidase and γ-glutamyl transpeptidase, and those that primarily reflect hepatocellular necrosis, such as the aminotransferases (Reichling and Kaplan, 1988). Ornithine transcarbamylase (OTC) is a hepatic enzyme involved in ammonia elimination via the urea cycle, and can be measured in serum as a diagnostic marker of hepatic disorders due to its localization in periportal mitochondria (Ishikawa *et al*., 2003). The ratio of serum OTC to alanine aminotransferase (ALT) is a potent indicator for the diagnosis and prognosis of hepatocellular carcinoma (Murayama *et al*., 2007).

An examination of the current state of hepatotoxic biomarkers indicates that serum F protein, arginase I and GST-α levels, all measured by enzyme-linked immunosorbent assay (ELISA), may show utility and provide additional information relative to serum aminotransferase values (Ozer *et al*., 2008).

2.2.4 Respiratory Toxicity Biomarkers

Pneumotoxic agents, for example 4-ipomeanol, 3-methylfuran, trichloroethylene and carbon tetrachloride, produce disease of the respiratory system. Clara cells are particularly sensitive to toxic lung injury and they contain indeed most of the lung CYP450 activity, which confers on them a high xenobiotic metabolizing activity (Bernard *et al*., 1992; Hermans and Bernard, 1996). Clara cell protein (CC16 or CC10) is a lung biomarker, measurable in serum, bronchoalveolar lavage (BAL) fluid and sputum. This 15.8 kDa protein is secreted along the tracheobronchial tree, particularly in the terminal bronchioles where Clara cells are localized. This protein increasingly appears to protect the respiratory tract against oxidative stress and inflammation. This protective role is confirmed by studies on transgenic mice, showing that CC16 deficiency is associated with an increased susceptibility of the lung to viral infections and oxidative stress. The determination of CC16 in serum is a new noninvasive test to detect Clara cell damage or increased epithelial permeability in various acute and chronic lung disorders. This test may provide a useful tool to noninvasively evaluate the damage and increased permeability to proteins of the air–blood barrier associated with some pathology (Broeckaert and Bernard, 2000). Serum concentrations of CC16 are also decreased in subjects with chronic lung damage caused by tobacco smoke and other air pollutants, as a consequence of the destruction of Clara cells. Serum CC16 is also decreased in several occupational groups chronically exposed to silica, dust and welding fumes, and lung diseases (cancer, asthma and patients with chronic obstructive pulmonary disease) (Bernard *et al*., 1994b; 1994c).

In addition to CC16, other ‘ideal’ biological markers of effect have been identified; namely, tumour necrosis factor-α and interleukin-8 (both of them released by monocytes), reactive oxygen species (released by neutrophils), 8-isoprostanes (serum), total equivalent antioxidant capacity, glutathione, glutathione peroxidase activity, GST activity and platelet-derived growth factor (serum) (Gulumian *et al*., 2006).

Increased levels of some enzymes in BAL fluid may indicate an increased permeability of the alveolar/capillary barrier. Lactate dehydrogenase (LDH) is a cytoplasmic enzyme that is found extracellularly only in the presence of lysed or damaged cells. β-Glucuronidase or similar lysosomal hydrolytic enzymes are excellent markers for the toxicity of inhaled particles. These particles are phagocytosed by macrophages, and the enzymes are released from activated or lysed macrophages.

2.2.5 Neurotoxic Biomarkers

The complexity of the nervous system, together with problems associated with the determination of precise targets for neurotoxic action, is responsible for the limited advances seen in biomonitoring of neurotoxicity. Additionally, the inaccessibility of brain tissue in humans limits neurochemical measurements in neurotoxicity studies (Costa and Manzo, 1995).

Developing accessible biomarkers of neurotoxic effects which are readily applicable to human populations poses a challenge for neurotoxicology. Proteomics is one of the fastest growing areas in science and is particularly applicable to the development of biomarkers of neurotoxicity. The most significant and useful example of a specific biomarker of neurotoxicity is the inhibition of AChE in blood samples and brain caused by OP or carbamate insecticides. This biomarker has been used not only in human toxicology but also in ecotoxicology as proof of cause of death (Fairbrother and Bennett, 1988; Peakall, 1992b). AChE activity in brain may remain depressed for several weeks after the toxic exposure, and the depression is reasonably well correlated with the effects. However, blood AChE has the advantage of easy sampling since there is no need of animal sacrifice (Hill, 1988), and clearly brain enzyme cannot be sampled in life in humans. Butyrylcholinesterase (BuChE) or plasma nonspecific pseudocholinesterase only reflects exposure to OPs or carbamate insecticides, but not neurotoxicity.

Several OP compounds (tri-*o*-cresyl phosphate, methamidophos, leptophos) induce a delayed polyneuropathy (organophosphate induced delayed polyneuropathy—OPIDP) that is accompanied by, and probably causally related to, the inhibition of neuropathy target esterase (NTE) in the nervous system (Lotti, 1995). This enzyme is also present in lymphocytes; therefore measurement of NTE in lymphocytes has been proposed as an example of neurotoxic biomarker for biomonitoring purposes,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat179
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

although it has not been applied successfully to epidemiological studies.

The glial reaction to nervous system damage, often termed gliosis, is a hallmark of all types of nervous system injury. As such, the development and implementation of gliosis biomarkers represents a broadly applicable approach for neurotoxicity safety assessment. Recent studies have demonstrated that neuroantibodies can be used as biomarkers of neuropathy development. Serum autoantibodies against neuronal cytoskeletal proteins (e.g. neurofilament triplet, glial proteins such as myelin basic protein and glial fibrillary acidic protein) have been reported as peripheral markers of neurodegeneration that may be applicable to humans and experimental studies, including OPIDP (O'Callaghan and Sriram, 2006; El-Fawal and McCain, 2008; El-Fawal and O'Callaghan, 2008).

Another example of a biomarker of neurotoxicity is monoamine oxidase (MAO), an active enzyme that plays a key role in inactivating catecholamines. MAO-B is a microsomal isoenzyme of MAO that acts on a broad spectrum of phenylethylamines. The amino acid sequence of the enzymes from human cerebral cortex has been shown to be identical to platelet MAO-B, so the activity of the platelet MAO-B should reliably reflect that of MAO-B in the nervous system, and has the advantage of easy accessibility. MAO-B activity in platelets has been used as a biomarker of effect of styrene and perchloroethylene occupational exposures, which is known to cause dopamine depletion (Checkoway *et al*., 1994; Mutti and Franchini, 1987).

2.2.6 Biomarkers of Cardiotoxicity

There is an overwhelming weight of evidence that considers cardiac troponin (cTn) as the preferred, *de facto*, translational, safety biomarker for myocardial injury in cardiotoxicity. In addition to being the gold standard for cardiac injury in humans, it has been widely used for clinical assessment and monitoring of cardiac toxicity in subjects being treated for cancer. No other biomarker of myocardial injury comes close to cTn in effectiveness, including creatine kinase isoenzyme MB (CK-MB), lactate dehydrogenase isoenzyme 1 (LDH-1) and LDH-2, myoglobin and FABP3 (heart fatty acid binding protein-3). In addition to the use of cTn for monitoring active myocardial degeneration, there is growing evidence that measurements of brain natriuretic peptide (BNP) may be effective for monitoring drug-induced left ventricular dysfunction (O'Brien, 2008).

The role of air pollution in exacerbating heart disease has only recently become a focus of attention. Particulate matter has been linked to increased levels of systemic inflammation biomarkers such as C-reactive proteins (CRPs). Daily variation of ambient pollution is correlated with rises and falls in CRP levels. Increased CRP levels have been associated with increased morbidity and mortality in individuals with coronary artery disease (Sandhu *et al*., 2005).

2.2.7 Biomarkers of Reproductive Toxicity

To monitor reproductive health and identify adverse effects at the earliest possible levels, it is necessary to develop a network of biomarkers covering all stages and aspects of reproductive development and function. Various biomarkers of reproductive development and health have been identified, including those associated with pubertal development, adult reproductive health and pregnancy outcome (Rockett and Kim, 2005). Biomarkers for the male reproductive system may include physiological indicators of impaired testicular function, sperm number or cytogenetics characteristics.

Measures of hormonal status (follicle stimulating hormone (FSH), luteinizing hormone (LH) and testosterone) can be readily obtained from blood and, in the case of testosterone, from urine and saliva. However, these levels are greatly influenced by circadian rhythms and demonstrate large interindividual and intra-individual variability. Biomarkers for the male reproductive system are rather easily accessible and some are reasonably well validated; such markers are less well developed for the female reproductive system (Osorio and Windman, 2005; Windman and Osorio, 2005).

Inhibin B has been proposed as a potential biomarker of testicular toxicity to compliment traditional end points. This glycoprotein is produced predominantly by Sertoli cells and regulates pituitary FSH release by a negative-feedback loop. Systemic inhibin B concentrations seem to reflect the extreme ends of spermatogenic status, with high levels of inhibin B observed in normal, fertile individuals and lower levels of inhibin B in individuals with severe damage to the testis as a result of germ cell depletion. In epidemiological studies, inhibin B combined with FSH measurements has a higher positive predictive value for detecting male infertility than either alone (Stewart and Turner, 2005).

2.2.8 Immunotoxicity Biomarkers

The immune system protects the organism against infectious micro-organisms and the growth of some tumours. An important variety of factors may modify the immune function, such as drugs (nonsteroidal anti-inflammatory or vitamin complexes), biological parameters (sex, age, pregnancy), and other factors (diet, alcohol consumption, circadian rhythms, stress, nutritional state and sleep disturbances).

Different xenobiotics may stimulate or suppress the immune system. Dioxin, PCBs, immunotherapeutic drugs and other toxic agents including some OP compounds (parathion, chlorpyrifos, malathion and diazinon) can

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat179
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

affect the immune system and can lead to decreased resistance to infections or tumours. These chemicals can also alter the course of autoimmunity or induce hypersensitivity reactions.

Several biomarkers have been proposed to assess immunotoxicity. They include full blood count, antibody-mediated immunity (immunoglobulin concentrations in serum), phenotypic analysis of lymphocytes by flow cytometry (surface markers), cellular immunity (including delayed-type hypersensitivity on skin and natural immunity to blood group antigens), markers of inflammatory response (CRP) and antibodies (autoantibodies to cellular organules). Examination of nonspecific immunity including interleukins analysis or measurement of complement components can also be used. For example, changes in the relative abundance of different lymphocyte subpopulations (suppressor and helper T cells) have been used as biomarkers for the immune suppression (Van Loveren *et al*., 1995; Kimber, 1995; Melancon, 1995).

2.2.9 Biomarkers of DNA Damage

The interaction of a xenobiotic with genes can lead to DNA mutations and consequent alterations in the descent. The damage of DNA has been studied in both humans and animals. Some xenobiotics (PAHs, aromatic amines, heterocyclic amines, mycotoxins, alkylating chemotherapeutic agents and nitrosamines) have reacting groups that can interact with nucleophilic targets, increasing the risk of cancer. DNA adducts are being used to assess the genotoxic potential of chemicals. Certain DNA adducts produced by interactions are promutagenic, and replication of the damaged DNA could lead to DNA changes that may result in altered gene expression or mutated gene products. Thus, biomarkers such as metabolic polymorphisms, urinary metabolites, unscheduled DNA synthesis, DNA single-strand breaks, chromosomal aberrations and protein and DNA adducts are used in the evaluation of cancer risk.

Molecular biology techniques permit the detection of covalent interactions of xenobiotics with proteins and other macromolecules. Human DNA adduct formation (covalent modification of DNA with chemical carcinogens) has been shown to correlate with the incidence of a carcinogenic process and is a promising biomarker for elucidating the molecular epidemiology of human cancer (Meyer and Bechtold, 1996; Shugart, 1996; Poirier and Weston, 1996).

Cytogenetic biomarkers in peripheral blood lymphocytes, such as chromosomal aberrations, sister chromatid exchanges and micronuclei, have long been applied in surveillance of human genotoxic exposure and early effects of genotoxic carcinogens. The relevance of chromosomal aberrations as a biomarker has been further emphasized by epidemiological studies suggesting that a high frequency of chromosomal aberrations is predictive of an increased risk of cancer (Norppa, 2004).

At this time, the study of DNA adducts is not feasible for routine analysis. The biological monitoring of human and animal DNA adducts includes ^{32}P-postlabelling and, recently, immunoassays using adduct-specific antibodies. The major drawback is the lack of specificity of the antibodies used in the assay which cross-react with a number of xenobiotic-related adducts (Dunn *et al*., 1987; Chang *et al*., 1994; Poirier, 1997). Other analytical techniques such as gas chromatography-mass spectrometry (GC-MS) and synchronous fluorescence spectroscopy are being used to measure DNA adducts. Peripheral blood lymphocytes are a readily accessible source of human cells that are known to contain DNA adducts.

2.2.10 Biomarkers of Gene Expression

During the first stages of cancer there is a significant increase in gene-expression biomarkers related to the specific type of cancer. The development of xenobiotic-related tumours is associated with the aberrant expression of genes that encode proteins involved in cellular growth.

Biomarkers of gene expression include growth factors (platelet-derived growth factor, transforming growth factor α, transforming growth factor β, etc.) and oncoproteins (transmembrane and epidermal growth factor receptors, oncogene proteins such as p21 and p54 and tumour suppressor gene proteins such as nuclear phosphoprotein p53) (Poirier, 1997; Brandt-Rauf, 1997). p53 has many anticancer mechanisms: it can activate DNA repair proteins when DNA has sustained damage; it can also hold the cell cycle at the G_1/S regulation point for DNA damage recognition and reparation; and if the DNA damage proves to be irreparable it can initiate apoptosis, the programmed cell death.

These biomarkers may be studied in biological fluids such as serum, plasma, urine and bronchoalveolar liquid by ELISA, radioimmunoassay (RIA) or immunoblotting.

2.2.11 Biomarkers of Oxidative Damage

Oxidation and the production of free radicals are an integral part of human metabolism, producing oxidative stress which is related to many diseases, including cancer and heart disease. The use of biomarkers for oxidative stress may provide evidence of a causal relationship between oxidative damage to macromolecules (DNA, lipids and proteins) and cancer. A wide variety of functional assays, both *in vivo* and *ex vivo*, include various measures of DNA oxidation (oxidized DNA bases such as 8-hydroxy-2′-deoxyguanosine (8-OHdG), autoantibodies to oxidized DNA, modified comet assay), lipid oxidation (thiobarbituric acid-reactive substances, exhaled pentane/ethane, low-density lipoprotein resistance to oxidation, isoprostanes) and protein oxidation (protein carbonyls) (Hwang and Kim, 2007).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat179
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Some pollutants, such as heavy metals, pesticides, PAHs, halogenated aromatic hydrocarbons and solvents, are capable of developing oxidative damage by generating free radicals. These molecules damage membrane lipids, DNA and proteins, and effect changes to antioxidant enzymes. Although there are considerable gaps in our knowledge of cellular damage, response mechanisms, repair processes and disease aetiology in biological systems, free radical reactions and the production of toxic reactive oxygen species are known to be responsible for a variety of oxidative damages leading to adverse health effects and diseases. In response to oxidative stress, changes in the antioxidant systems, as adaptive responses, and modified macromolecules can serve as biomarkers.

The antioxidant enzyme systems (glutathione reductase, catalase, superoxide dismutase and peroxidase activities) and nonenzymatic systems (reduced glutathione, ascorbate, α-tocopherol) play a defensive role against oxidative stress by-products. Malondialdehyde and 8-OHdG have been proposed as oxidative stress markers. Macromolecules that may be affected by free-radical damage include lipids, proteins and nucleic acids (Hoffman *et al*., 1989; Di Giulio *et al*., 1989; Hogson and Levi, 1994). The depression of the key antioxidant enzymes and the elevated lipid peroxidation are important mechanisms underlying the oxidative damage.

2.3 Biomarkers of Susceptibility

Polymorphisms of relevant xenobiotic-metabolizing enzymes may be used as markers of toxicological susceptibility. A growing number of genes encoding enzymes involved in biotransformation of toxicants and in cellular defence against toxicant-induced damage to the cells have been identified, leading to increased knowledge of allelic variants of genes and genetic defects that may result in a differential susceptibility of individuals towards environmental toxicants (Their *et al*., 2003).

Techniques based on polymerase chain reactions (PCRs), using DNA isolated from lymphocytes and other cells, allow the detection of genotypes of known polymorphisms involving a variety of xenobiotic-metabolizing enzymes.

Markers of polymorphisms of activating systems and detoxicating systems can be distinguished according to two different steps of metabolism. Polymorphisms of activating systems can be determined by measuring the activity of CYP450 isoenzymes implicated in the first step of the biotransformation process. CYP450s are a huge gene superfamily of haem proteins involved in xenobiotic as well as endobiotic metabolism. They play a critical role in adaptation to environmental changes for survival of the living organism. In addition, the huge environmental loads of human-made chemicals are biotransformed into bioactive or detoxified forms by CYP450s. Thus, CYPs have been used for biomonitoring of environmental pollutants, screening of their metabolisms and exploring remedies. In particular, the induction or inhibition of CYP450s has been applied to exposure monitoring of environmental toxicants, which are biotransformed by CYP450s. Associated with CYP450s there are a wide range of enzyme activities referred to as mono-oxygenase activities (Paine, 1995; Van Cauteren *et al*., 1996; Yi *et al*., 2007).

CYP450 Phase I enzymes can produce highly reactive DNA-damaging intermediates during the normal process of converting chemical carcinogens to excretable forms. Polymorphic variations in the sequences of CYP1A1, CYP1A2, CYP1B1 and other P450s exist in the human population, and specific forms have been associated with increased cancer risk in various populations. Individual variation in 'Phase II' detoxifying enzymes, such as glutathione *S*-transferase M1 (GSTM1), can also contribute to individual susceptibility. About 40% of the population have a deletion at this locus which has been linked to increased risk of bladder and lung cancers. Another common genetic factor related to increased cancer risk is the inheritance of a homozygous recessive mutation in the *N*-acetyltransferase gene resulting in the inability to efficiently detoxify aromatic amines via *N*-acetylation. The mutation is carried by approximately 50% of the population. It has been demonstrated that slow acetylators are at increased risk of bladder cancer, especially those occupationally exposed to aromatic amine bladder carcinogens. In contrast to its protective effect in bladder cancer, the fast acetylator phenotype is associated with an increased risk of colon cancer, demonstrating the complexity of gene–environment interactions with respect to cancer susceptibility. Moreover, combinations of metabolic polymorphisms are increasingly being linked to increased cancer risk. Acquired or inherited variations in the efficiency of fidelity of DNA repair can also influence individual susceptibility to cancer (Perera and Weinstein, 2000).

The active metabolites of certain organophosphorothioate insecticides can be hydrolysed and inactivated by paraoxonase1 (PON1). Studies suggest that high levels of serum paraoxonase are protective against poisoning by OP pesticides whose active metabolites are substrates of this enzyme (Costa *et al*., 2003). Paraoxonase activity can be used as a biomarker of susceptibility in humans because it exhibits an important polymorphism. Kinetic analysis of the two human PON1-192 isoforms revealed that the catalytic efficiency (V_{max}/K_m) of hydrolysis of oxons is what determines the '*in vivo*' protection of PON1 against exposure to a specific OP. Therefore, the Q/R polymorphism at position 192 confers different enzyme levels and catalytic

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat179
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

efficiency in a substrate-dependent manner, suggesting that certain individuals may be more vulnerable to the toxic effect of OP exposure (Furlong, 2007).

3 CONCLUSION

In conclusion, the selection of appropriate biomarkers is of critical importance because of the opportunity for greater precision in the assessment of risk to individuals or population subgroups, with the consequent implications for mitigation and health protection. The advent of new '-omic' technologies (genomics, proteomics and metabonomics) promises to provide immense opportunity for the discovery and development of new markers of cellular and tissue integrity. Such biomarkers should be easily measurable at low concentrations in accessible tissues such as blood and urine. In addition, they should be specific and sensitive indicators of target-organ toxicity and markers of subclinical alterations, and thus may be useful in diagnostic and preventive strategies. In the near future it is necessary to develop or validate the analytical methods for evaluation of the selected biomarkers.

From Diet to Detox: Controversial Therapies in Autistic Spectrum Disorders

Michael J. Fitzpatrick

CONTENTS

1 INTRODUCTION

An academic review article entitled 'Stem cell therapy for autism' provoked a flurry of international publicity in summer 2007 (Ichim *et al*., 2007). The authors, based in a biotech company in Arizona and in a clinic in Costa Rica, proposed treating autistic children with a combination of stem cells derived from bone marrow and umbilical cord blood cells. Before long, reports appeared in the US press that children with autism were being brought by their parents to Mexico and China to get stem cell treatments (which are illegal in the USA—and Britain) at great expense.

The promise that stem cells, cells which retain the primitive capacity to divide and differentiate into specialized cell types, will deliver treatments for hitherto intractable diseases has beguiled medical science for decades. Though there have been some achievements, such as the use of bone marrow stem cells in the form of 'transplants' to treat leukaemia, progress has been slow and the clinical yield disappointing. The theoretically more promising—and more controversial—area of embryonic stem cell research has so far produced no clinical benefits. While serious research continues, entrepreneurs have promoted stem cell treatments for a wide range of conditions, including cerebral palsy, multiple sclerosis, Parkinson's disease and many more, far in advance of any rational therapeutics. The quest by biotech companies for a wider market for stem cells has led them to take a growing interest in treating autism.

There is no scientific rationale for stem cell treatment in autism. The authors of this review speculate that autism is caused by 'neural hypoperfusion' and associated with 'immune dysregulation' and chronic inflammation of the gastrointestinal and central nervous systems. They claim that stem cells and cord blood can stimulate new blood vessel formation and correct the immune and inflammatory problems. But there is no good evidence of a deficient blood supply to the brain in autism, nor any consistent pattern of immune dysfunction. Nor is there evidence that stem cell treatment is effective in autism—or that it is safe.

Stem cell therapy follows a series of treatments that have been hailed as wonder cures in autism. These include holding therapy in the 1970s, facilitated communication and auditory integration therapy in the 1980s and secretin, the pancreatic hormone that was hailed as a wonder cure in 1998. In turn these interventions attracted large numbers of desperate parents—and invariably led them, and their children, to disappointment (Fitzpatrick, 2004).

Over the past decade a network of practitioners has emerged offering a range of what are characterized as 'unorthodox biomedical' interventions for children with autism. These treatments are, like stem cell therapy and treatment with hyperbaric oxygen (another popular method), almost exclusively derived from therapies already in widespread use in the alternative health sector or in other fields of medical practice. Self-styled 'unorthodox biomedical' practitioners often have close links with private laboratories offering esoteric tests and with commercial suppliers of their recommended medications and other products. Widely publicized claims by campaigning parents that their children have 'recovered' from autism as a result of biomedical treatments have

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

ensured a growing demand (McCarthy, 2008). Here we look more closely at some widely used biomedical interventions, examining the theories justifying their use and the evidence of their therapeutic value in autism.

2 BIOMEDICAL INTERVENTIONS

- **Diets**: Gluten free/casein free (GFCF), Feingold, Ketogenic, Specific carbohydrate.
- **Supplements**: Vitamins, minerals, antioxidants, amino acids, enzymes, essential fatty acids.
- **Detox and immune system treatments**: Chelation, intravenous immunoglobulins (IVIGs), transfer factor, colostrum.
- **Medication**: Antibiotics, antifungals, antivirals, anti-inflammatories.

3 SPECIAL DIETS

The most widely used unorthodox biomedical intervention in autism is the 'gluten-free, casein-free' (GFCF) diet, based on the exclusion of wheat and dairy products. The dietary approach to autism has emerged since the 1980s, out of the wider trend for explaining a range of contemporary disorders, among both adults and children, as the result of the changing nutritional practices of modern society. As the notions of 'health foods' and 'healthy eating' have moved from the counter-cultural fringe to the mainstream, diverse diets have been promoted, not merely in the cause of weight loss, but for their claimed therapeutic benefits. The GFCF diet is the focus of numerous parent groups, web sites and recipe books and a flourishing commercial sector provides a wide range of suitable food products and cooking ingredients (Lewis, 1998; Seroussi, 2002).

Wheat and milk occupy a significant place in the environmentalist fable of the Neolithic fall from primeval grace, when human beings first cultivated grasses and domesticated cattle, initiating a transformation in diet that paved the way towards the degenerative diseases of modernity. Though there is considerable anthropological evidence for the notion that robust hunter-gatherers were displaced by sickly farmers and, ultimately, by even more diseased city-dwellers, the misanthropic outlook of contemporary environmentalists leads them to overlook the dramatic advances in human health associated with the industrialization of food production over the past century. When today's infants are weaned from breast milk on to cereals and dairy products, this process is regarded as a reprise of humanity's tragic Neolithic transition. The result, from the perspective of the gurus of ecological and environmental medicine, is another series of epidemics—of cancer and heart disease, food allergies and intolerances. Modern diets are also blamed for causing irritable bowel syndrome and diverse combinations of otherwise inexplicable symptoms. Though coeliac disease ('gluten enteropathy' resulting from an autoimmune reaction to dietary gluten) is rare, wheat intolerance has become widely recognized.

In a book entitled *They Are What You Feed Them,* Alex Richardson, a nutritionist and campaigner around issues of diet and children's health, argues that an 'epidemic' of developmental disorders, including attention deficit hyperactivity disorder, dyslexia and dyspraxia, autistic spectrum disorders and behaviour, conduct and oppositional defiant disorder, now affects 'one in four' of all children (Richardson, 2006). She attributes this epidemic to the fact that 'children's diets have changed out of all recognition during the past few decades'. Her book carries denunciations of 'the appalling nutritional quality of much food', claims about 'shocking' dietary imbalances and their 'devastating effects' on children's behaviour, mood and learning, and polemics against 'junk food'. Yet Dr. Richardson offers little information about how children's diet has changed and less evidence of how these changes might have produced such a profusion of disturbed behaviours. Her conclusion is that the supposed epidemic supposedly resulting from dietary changes can only be tackled by drastic changes in children's eating habits, avoiding additives, sugar and 'bad carbs' (refined carbohydrates) and polyunsaturated 'trans' fats, and consuming 'good carbs' (complex carbohydrates) and omega 3 'essential' fatty acids.

Richardson's explanation for what she characterizes as an 'autism epidemic' is that it results from 'the combination of two things: on the one hand, increasing exposure to potential toxins, from synthetic chemicals, heavy metals, and other environmental contaminants, and, on the other, decreasing intake of many essential nutrients needed to "defuse" and get rid of those toxins.' (Richardson, 2006).

A fashionable aversion to wheat and dairy products has converged with a number of questionable theories to produce the notion that the GFCF diet is an appropriate intervention for children with autism. In the 1960s, the American psychiatrist Curtis Dohan suggested that the low prevalence of schizophrenia among the islanders of the South Pacific might be attributable to a diet low in wheat, rye, barley and oats. He went on to recommend treating schizophrenics with a diet restricting cereals and dairy products. In the 1970s, Benjamin Feingold, a paediatric allergist in California, linked hyperactivity in children to salicylates and additives (including sweeteners and preservatives) and recommended excluding such products from children's diets. Feingold's theory and variations on his exclusion diet have had a wide popular appeal among middle-class parents of difficult children. The Californian psychologist and autism campaigner Bernard Rimland, the pioneer of unorthodox

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

biomedical treatments in autism, was an early supporter of Feingold's approach.

In the late 1970s, American neuroscientist Jaak Panksepp noticed parallels between the behaviour of experimental animals addicted to opiates and autistic children (Panksepp, 1979). Both showed indifference to pain, diminished social interest and extreme persistence in stereotypical behaviours. On the basis of this analogy, he formulated his 'opioid excess' theory of autism, hypothesizing that its distinctive features might be attributable to an excess of endorphin (or 'opioid') neurotransmitters. In the early 1980s, the Norwegian biochemist Kalle Reichelt and his colleagues claimed that they had identified abnormal peptides with an opioid effect in the urine of patients with schizophrenia and autism (Reichelt *et al*., 1991). They further claimed that these peptides were the result of the incomplete breakdown of certain proteins in cereal and dairy products: gliadomorphin (from gliaden or gluten in cereal grains) and casomorphin (from casein in milk) (Reichelt *et al*., 1993). They proposed that, in children with autism, bowel inflammation resulting from gluten sensitivity allowed opioid peptides to enter the circulation and produce autistic symptoms, by acting on opiate receptors in the brain. They further postulated that, during pregnancy, circulating opioid peptides derived from the maternal diet could pass across the placenta and, at a critical stage, damage the developing brain of the foetus, producing autism as a result. The opioid excess theory was invoked by the former gastroenterology researcher Andrew Wakefield (in the highly controversial 1998 *Lancet* paper that launched the scare linking autism to the measles, mumps and rubella vaccine) to provide the link required by his hypothesis between the 'leaky gut' he attributed to 'autistic enterocolitis' and the supposedly neuropsychiatric features of 'regressive autism' (Wakefield *et al*., 1998).

In subsequent studies, Reichelt and his team claimed that a GFCF diet produced a significant improvement in the behaviour of autistic children (as well as relieving bowel symptoms) (Knivsberg *et al*., 1995). This approach has been popularized in Britain by the pharmacy lecturer Paul Shattock and his colleagues in Sunderland, who provide urine testing for opioid peptides with primitive chromatographic techniques, as the basis for dietary intervention (Shattock, 1995; Whiteley and Shattock, 1997). The GFCF diet has been promoted by the autism biomedical movement in the USA and a number of commercial laboratories offer urine testing (Shaw, 2002).

When researchers have used more rigorous methods, opioid peptides have proved elusive (Hunter *et al*., 2003). Wright and colleagues tested the urine of 155 age- and sex-matched controls and failed to find any association between urinary peptides and autism (Wright *et al*., 2005). The opioid excess theory received a decisive blow with the publication of a study led by the London paediatrician and autism specialist Hilary Cass and colleagues (Cass *et al*., 2008). Using a combination of liquid chromatography and mass spectrometric techniques they failed to detect opioid peptides in the urine of 65 boys with autism and 158 controls. The authors suggested that the findings of earlier researchers in this field were unreliable because they used techniques that were neither sensitive nor specific enough to support the conclusions that were drawn from their use. Their conclusion was that 'given the lack of evidence for any opioid peptiduria in children with autism, it can neither serve as a biomedical marker for autism, nor be employed to predict or monitor response to a casein and gluten exclusion diet'.

Though numerous anecdotal accounts claim dramatic benefits from the GFCF diet, these have not been confirmed by scientific study. It is widely recognized that such studies are difficult to conduct and those that have been undertaken have generally been small in scale and methodologically unsatisfactory. A systematic review carried out for the New York State Department of Health found that only 1 out of 16 studies provided useful evidence (New York State Department of Health, 1999). Their conclusion was that 'special diets, including elimination diets, are not recommended as a treatment for autism in young children'. The report noted that there were 'no known advantages to special elimination diets for children with autism' and expressed concern that 'they may cause the child to get inadequate nutrition and can be expensive' (New York State Department of Health, 1999).

Similar concerns were expressed in a survey carried out by the Cochrane group in the UK (Milward *et al*., 2004). These authors found only one study, carried out by Ann-Mari Knivsberg in Norway, that was of a satisfactory standard (Knivsberg *et al*., 2002). Knivsberg and colleagues measured the impact of the GFCF diet on 20 children with autism in four areas—cognitive skill, linguistic ability, motor ability and autistic traits—and found significant benefit only in the last. Their conclusion was that 'these regimes are not without cost in terms of inconvenience and extra financial cost, as well as limits on food choices of the affected family member, and one cannot recommend the use of such diets on the basis of one small trial alone'. A pilot study, carried out in Florida in 2006, tested the GFCF diet using a randomized, double-blind procedure, measuring urinary peptides and autistic symptoms in 15 children over a three month period (Elder *et al*., 2006). The results showed no significant benefit from the diet, though the researchers noted that 'families reported improvements that were not empirically supported by our work'. For the authors, the fact that some parents opted to continue the GFCF diet even after learning the results of the study suggested that it had a powerful placebo effect.

Though biomedical campaigners are as ready to proclaim the safety of GFCF diets as they are to claim their benefits, medical authorities have expressed some

concerns. Neurologists Susan Hyman and Susan Levy warn that children on such diets may become deficient in calcium, vitamin D, iron and protein: 'the child on a restricted diet may be at risk for rickets, and supplemental calcium and vitamin D are indicated' (Hyman and Levy, 2000). On the basis of wrist X-rays of 75 boys with autism, Hediger and colleagues warned of the danger of osteoporosis from a GFCF diet (Hediger *et al*., 2008).

Special diets may also impose a substantial burden on the whole family. Their advocates insist that they must be followed with military discipline:

> *One thing must be made clear right from the beginning of the diet: your child has to stick to the diet rigidly. Evidence has suggested that there tends not to be any middle ground where the strictness of the diet is concerned, it is all or nothing.*
>
> (Whiteley and Shattock, 1997)

Furthermore, 'compliance needs to be as near to 100%' as possible, for 'at least six months'. The penalty for failure is regression: 'research has shown that children who break the diet do generally tend to regress behaviourally'.

4 SUPPLEMENTS

The identification of vitamin deficiency diseases in the early twentieth century, and the recognition of the association of oxidative stress with cell death and tissue necrosis in chronic degenerative diseases in recent decades, have stimulated a multibillion dollar trade in vitamins and antioxidants, and related minerals and enzymes. The beguiling notion that if a deficiency of something causes illness, then the administration of a 'megadose' of the same substance is likely to improve health has seized the popular imagination.

The use of vitamins in autism can be traced back to the era of 'metabolic psychiatry' in the 1960s, when neurotransmitter theories were advanced to explain schizophrenia and depression. In this period some researchers suggested that neurotransmitters might be a factor in the causation of autism. Indeed, as the report of the British Medical Research Council's 2001 inquiry into the aetiology and epidemiology of autism observes, 'over the years virtually every neurotransmitter system has been implicated in the pathogenesis of autistic spectrum disorders' (Medical Research Council, 2001). A number of investigators have identified biochemical deficits in children with autism, in relation to mechanisms of oxidative stress and methylation pathways. The most popular supplements among families with autistic children, according to a survey carried out by Bernard Rimland's Autism Research Institute in California, are vitamin B_6 (pyridoxine) and magnesium, dimethylglycine and vitamin C (ascorbic acid), all of which are believed to play a role in the synthesis of neurotransmitters as well as having antioxidant properties (Adams *et al*., 2008). A recent vogue is for injections of vitamin B_{12}: injections always have a more potent placebo effect than oral medications, perhaps explaining their popularity among parents (though their children may not be so enthusiastic).

Many more amino acids and compounds have been recommended as supplements for children with autism. These include tryptophan, tyrosine, cyproheptadine, D-cycloserine and carnosine (Levy and Hyman, 2005). Products promoted as antioxidants include glutathione and vitamin E (tocopherols and tocotrienols). Vitamin A is said to activate the immune system, producing significant, often immediate, improvements in visual perception, attention and language in children with autism. Supplements of magnesium, zinc, calcium, selenium and molybdenum are all recommended. In addition to protecting against coronary heart disease, omega-3 fatty acids derived from fish oils have been claimed to improve academic performance in children, to reduce delinquency in adolescents and to enhance cognitive function in the elderly. They are said to reduce symptoms in people with schizophrenia, depression and, inevitably, autism. Global demand has risen to a level that threatens stocks of fish.

While great benefits are claimed for all these supplements in anecdotal reports and in small, poorly conducted studies, proper scientific confirmation is lacking. Though the profile of adverse effects is generally low, blanket claims that these supplements are 'natural' and therefore safe must be treated with scepticism. Excessive doses of most vitamins can produce significant side effects; most notably, vitamin B_6 is well known to cause peripheral neuropathy.

5 DETOX AND CHELATION

The familiarity of the term 'detox', now universally recognized as an abbreviation of 'detoxification', reflects the popular acceptance of a concept that only a decade ago was confined to the world of clinical pharmacology (Marks, 2006). In common with other terms that have made the transition from an esoteric scientific discipline into the public realm, the concept of detoxification has also undergone a transformation in meaning. In the laboratory or clinical setting, detoxification meant the removal of a toxic or poisonous substance from the body. Toxicity may be the result of an overdose, accidental or intentional, of some drug—common culprits in the past were digoxin, salicylates, barbiturates and paracetamol. Occupational exposure to industrial or agricultural chemicals or heavy metals (lead, mercury) occasionally causes acute or chronic poisoning. Wars and political conflicts, and

domestic disputes, sometimes involve the deployment of toxic substances, such as mustard gas and arsenic. The shift of detoxification towards wider public exposure began with its extension to the treatment of problems of alcohol and drug dependency, with regimes of gradual withdrawal and replacement therapies.

'Detox' treatment programmes are now promoted in newspapers and magazines and are available in a variety of forms in pharmacies and alternative health clinics. These treatments are based on the assumption that common nonspecific symptoms of malaise and fatigue are the result of the 'toxic' effects of modern lifestyles, especially junk food and (generally unspecified) environmental pollutants. The fact that the metaphor of 'toxicity' can be extended to include the stress-inducing effects of 'toxic' relationships and 'toxic' workplaces confirms its wide explanatory scope. All these features of toxicity are deemed to require a quasi-medical 'detox' treatment, which may involve various vitamins and supplements together with the consumption of large volumes of water, to provoke a therapeutic diuresis. Practitioners who have reinterpreted autism as a disorder resulting from the unique susceptibility of some children to environmental toxicity now recommend treating these children with 'detox' regimes.

We can distinguish three aspects of 'detox' interventions in autism. The first follows from the conviction that children with autism suffer from an impaired capacity to process environmental toxins—often attributed to a genetic susceptibility. Biomedical practitioners believe that the impaired detoxification system in autism requires treatment. Fortuitously, the same range of supplements, including vitamins, antioxidants and coenzymes, that we have discussed already, is also believed to correct oxidative stress and support the key detoxification pathways.

The second—and more controversial—mode of 'detox' is the use of 'chelation' treatments to remove toxic heavy metals by binding them to a water-soluble agent that enables them to be harmlessly excreted. Chelation was first used to treat victims of poison gas in the First World War and subsequently to deal with acute poisoning by a range of toxins, such as lead, arsenic and mercury. In recent years, chelation has come to be used by alternative health practitioners to treat a wide range of chronic conditions, including medical and psychiatric disorders which have been attributed to environmental toxins, particularly heavy metals, such as mercury in dental amalgam. Chelation has been most popular in coronary heart disease, in which it has been promoted as an alternative to surgical treatments (such as by-pass grafting and angioplasty).

In February 2001, Rimland's Autism Research Institute convened a conference of 25 physicians in Dallas Texas. This conference produced a 'mercury detoxification consensus position paper' which was updated in February 2005 (Autism Research Institute, 2005). Endorsing the—entirely unsubstantiated but increasingly popular—proposition that autism is 'a form of mercury poisoning' resulting from exposure to the mercury-containing preservative thimerosal in some vaccines, this conference recommended the use of a number of chelating agents. Even if autism were the result of neurological damage from chronic mercury exposure—an unsubstantiated proposition—chelating agents which do not cross the blood–brain barrier could not remove it, or indeed any other heavy-metal toxin, from the brain. As a treatment for autism, chelation lacks either a coherent theoretical rationale or empirical evidence of efficacy.

The death in 2005 of a five-year-old boy with autism, who had been brought by his parents from England to the USA for a range of alternative treatments, while undergoing chelation therapy at a private clinic near Pittsburgh, provoked widespread condemnation of this technique (Fitzpatrick, 2009). However, it did not appear to deter the demand for chelation therapies among parents of autistic children—or the willingness of practitioners to provide such therapies.

6 IMMUNE THERAPIES

The third aspect of detox is the treatment of the immune system in autism. The 'immune system' is another example of a concept that has acquired a popular status as metaphor far beyond its traditional meaning in medical microbiology (Fitzpatrick, 2004). Though the notion that the immune system is in some way disordered in autism is widely held in the biomedical movement, the concept tends to be used in a vague and often contradictory way. For example, some suggest that the immune system is 'suppressed' or 'underactive', resulting in an increased susceptibility to infection or immunizations or other environmental factors. Others suggest that autism is characterized by an excessively vigorous, 'up-regulated' or 'overactive' immune response, manifested in processes of autoimmunity, in which the body's defence mechanisms play a destructive role. Neither conception has any coherent scientific basis.

Over the past decade there have been a small number of reports claiming to have identified specific autoantibodies in autistic children, and also claiming dramatic benefits from immunological treatments. Three researchers in the USA—Vijendra Singh, Sudhir Gupta and H. Hugh Fudenberg—have become widely known among parent organizations.

In different studies, Professor Singh's team in Utah have observed raised levels of antibodies to measles virus, to MMR (measles, mumps and rubella vaccine) and to 'basic myelin protein'—in the lining of nerve fibres—in autistic subjects (Singh *et al*., 1998; 2002). However, British authorities considered Singh's findings 'not credible' (Dyer, 2002). The signs of an inflammatory

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat183
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

process that generally accompany autoimmune conditions have never been demonstrated in autistic children and 'demyelination'—the characteristic damage to the myelin sheath surrounding nerve fibres seen in multiple sclerosis—is not a feature of autism. However, on the basis of his contested findings, Professor Singh recommends treating autistic children with a range of immunological treatments, including steroids, IVIG, plasmapheresis, and with sphingomyelin (a product of cattle brains containing myelin) (Singh, 1999; 2000).

Sudhir Gupta, at the University of California at Irvine, has also found a range of immunological deficits in children with autism, for which he recommends treatment with IVIG. In a widely quoted study, he gave 10 autistic children IVIG at four-weekly intervals for six months and observed a 'marked improvement in a number of autistic characteristics, including eye contact, calmer behaviour, speech, echolalia, and so forth' (Gupta *et al*., 1996). The small size of this study, the lack of a control group and the highly subjective character of the assessment of behavioural changes all make it impossible to draw any firm conclusions from this research.

Long retired from his career in clinical immunology and once barred from medical practice, Dr. H. Hugh Fudenberg recommends the use of 'transfer factors', which are said to transfer immunity to autism from a donor to the autistic recipient (Fudenberg and Wilson, 1978). Transfer factors are 'protein immunomodulators' derived either from cows' colostrum (the fluid expressed before lactation is established after calving) or from human white blood cells (dialysable lymphocyte extract, DLyE), preferably taken from a closely related, nonautistic donor. In a widely quoted paper, he presented the results of treating 22 autistic children with DLyE; 21 showed a significant improvement and '10 became normal in that they were mainstreamed in school and clinical characteristics were fully normalized' (Fudenberg, 1996). This treatment is not only very expensive, but carries considerable risks of transmitting blood-borne infections and other adverse reactions.

There have been some extravagant claims made for the explanatory power of autoimmune theories. For example, Professor Singh declares that he 'firmly believes' that 'up to 80% (and possibly all) cases of autism are caused by an abnormal immune reaction, commonly known as autoimmunity' (Singh, 1999). But scientific theory must be grounded in evidence, not belief, and scientists are obliged to suspend belief until they can substantiate their hypotheses. Professor Singh believes that autoimmune mechanisms explain not only autism, but 'obsessional compulsive disorder, multiple sclerosis, Alzheimer's disease, schizophrenia, major depression, etc.' (Singh, 2000). Professor Gupta also takes a broad view of the scope of autoimmune theories: he is also involved in research along similar lines into chronic fatigue syndrome and ageing.

Professor Singh recommends immunological treatments for all the conditions listed above; Professor Gupta believes that IVIG is the treatment of choice for a range of autoimmune disorders; Dr. Fudenberg hails his 'transfer factor' as an effective therapy for attention deficit disorder, HIV/AIDS, chronic fatigue immunodeficiency syndrome, Alzheimer's disease, Gulf War syndrome 'and others'.

A third common feature is that these authorities state particularly impressive results in autism. Professor Singh claims that there is 'enormous potential for restoring brain function in autistic children and adults through immunology' (Singh, 1999); in Professor Gupta's series of cases, every one was said to have improved on treatment; Dr. Fudenberg's claim of a cure rate approaching 50% is the most spectacular of all (Fudenberg, 1996).

The New York State review was dismissive of these immunologists' claims (New York State Department of Health, 1999). In a systematic review, the authors found only two articles (those of Gupta and Singh quoted above) that presented information on behavioural and functional outcomes. It found that 'both of these studies had serious methodological flaws and cannot provide acceptable scientific evidence about the efficacy of immune therapies for treating children with autism' (New York State Department of Health, 1999). It recommended that IVIG and other immunological therapies should not be used for children with autism, emphasizing not only lack of proven efficacy, but that these treatments also posed 'significant health risks' from allergic reactions and transmission of HIV, and hepatitis B and C. The New York report also noted that there was 'no adequate scientific evidence that children with autism have any type of immunologic problems or that they have any immunologic test results that are significantly different than results for the general population' (New York State Department of Health, 1999).

7 MEDICATION

One of the most popular diagnoses in the world of alternative health is that of systemic candidiasis. Sometimes characterized as 'candidal overgrowth' of the gastrointestinal tract, this diagnosis is invoked to explain a wide range of digestive and psychological symptoms. The notion that candida—a normal commensal in the human gut—can have extensive pathological effects is another by-product of the 1970s school of orthomolecular psychiatry. Pioneered by the Alabaman psychiatrist Orion Truss, the theory was popularized by another psychiatrist—Bill Crook from Tennessee (Crook, 1988). Dr. Crook suggested that treating candidiasis might improve symptoms in autism, and this approach has been pursued with enthusiasm by the unorthodox biomedical movement. Children with autism have been treated with

yeast-free diets, probiotics and antifungal medications (nystatin, fluconazole).

The theory of candidal overgrowth in autism is one aspect of a wider belief that 'gut dysbiosis', a disturbance of the normal balance of intestinal organisms, plays an important role in autistic symptoms and behaviour. The (ill-defined) concept of gut dysbiosis reflects the idea of a Manichean struggle between good and evil, which permeates the outlook of contemporary alternative health practitioners, who believe that we have friends and enemies among carbs, cholesterol and fats as well as intestinal bacteria. Another flourishing alternative health trade—this one in digestive enzymes and probiotics—has found a new wave of customers among parents of children with autism.

One of the ironies of the unorthodox biomedical world is that antibiotics find a place in its lists of both causes of autism and treatments for it. On the basis of one study in which 11 autistic children were treated with vancomycin, an antibiotic which is not absorbed in transit through the gastrointestinal system and thus acts only within the digestive tract itself, and where 80% were said to have benefited, this drug has been widely promoted (Sandler *et al*., 2000). Another irony here is that colitis is a well-recognized adverse effect of vancomycin. Though viral causes of autism (notably measles) have not been substantiated, antiviral medications such as valaciclovir (which is effective against members of the herpes family of viruses, which have never been implicated in autism) is widely recommended.

The question of whether children with autism experience excessive digestive symptoms—or even a distinctive form of gastrointestinal disturbance—remains controversial. Different studies conducted in different ways and setting the threshold of symptomatic significance at different levels have yielded widely discrepant results (Black *et al*., 2002; Valicenti-McDermott *et al*., 2006). However it has long been recognized that children with autism and learning difficulties are often inclined towards idiosyncratic dietary habits and have a tendency to become constipated (sometimes resulting in faecal impaction and overflow diarrhoea). The particular difficulties involved in the toilet training of children with autism mean that their parents have a more intimate familiarity with the movements of their children's bowels for much longer than parents of typically developing children. This may be a factor in the high levels of concern expressed by some parents about gastrointestinal issues in autism and may have contributed to the popularity of Dr. Wakefield's concept of 'autistic enterocolitis' in the biomedical movement.

Dr. Wakefield and his colleagues have a lower threshold for diagnosing gastrointestinal disorder in children with autism than mainstream gastroenterologists (MacDonald and Domizio, 2007; Baird *et al*., 2008). Though they suggest that the pathological appearance of 'autistic enterocolitis' is more subtle than that of familiar inflammatory bowel diseases (such as Crohn's or ulcerative colitis), they recommend treating 'autistic enterocolitis' in a similar way. Dr. Bryan Jepson, a colleague of Dr. Wakefield working at his private clinic in Texas, outlines a treatment protocol that includes drugs such as sulfasalazine and mesalazine, corticosteroids and immune modulators (including methotrexate and azathioprine, and the anti-TNF (tumour necrosis factor) drug infliximab)—all powerful drugs with a formidable list of side effects (Jepson and Johnson, 2007).

8 CONCLUSION

The quest to 'defeat autism' that is promoted by campaigners who attribute the increasing prevalence of autism to environmental factors (notably vaccines) and pursue 'unorthodox biomedical' interventions has a range of damaging effects. It has led thousands of parents in the USA and the UK into futile litigation based on unsubstantiated vaccine–autism links. Many parents are spending large sums of money, not to mention family energies, on unproven tests and treatments, often provided by controversial practitioners. Children with autism are being subjected to treatments that are unlikely to be beneficial, but may be dangerous.

Toxicogenomics: An Overview with Special Reference to Genetic and Genomic Approaches to the Identification of Toxic Effects

Mayukh Banerjee and Ashok K. Giri

Molecular and Human Genetics Division, Indian Institute of Chemical Biology, Kolkata, India

1 INTRODUCTION AND HISTORICAL PERSPECTIVES

The word "toxicology" is derived from the Latin words "toxikon" meaning poison and "logos" meaning "discourse." In other words, toxicology can be literally defined as "the science of poisons." However, a more accurate and technical definition of the term can be stated as "toxicology is the branch of science which deals with the nature of poisons, their effect on living systems, detection and remedies thereof."

The history of toxicological studies can be traced back to the beginning of mankind. Indeed, when men were foragers, even before learning how to cultivate crops, they had learnt (by bitter experience, of course) that not all flesh or fruits or vegetables are edible. Consumption of some of them does produce maladies, ranging from mild irritation to death, although it was not a formal study of a subject in the way we understand it today. Further, when the aborigines of South America started using curare in blow pipes thousands of years ago, it was certainly an application of toxicological knowledge. Poisons have played stellar roles in a large number of royal feuds since the very early ages, especially in Greece as well as India. There is ample evidence in early medical testaments from Egypt and India that shows that several poisons, their symptoms and applications were well known more than 5000 years back. In fact, as early as sixteenth century, Paracelsus propounded the very basic axiom of toxicology, which states that "All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy."

Like all other forms of sciences, the study of toxicology was at a complete standstill during the dark ages. However, with the advent of Renaissance, the study of toxicology flourished once again as more and more scholars recognized the fact that there is a direct relationship between exposure and disease outcomes. This was the age when scientists (notably Bernardino Ramazzini) began to understand that occupational exposure to mercury and lead can lead to the development of specific ailments, which actually heralded the study of occupational toxicology. However, it was not until the middle of the nineteenth century that the study of toxicology took

a definite shape. Because of industrial revolution, thousands of new chemicals were being synthesized and mining and metallurgical procedures were also rampant, thereby leading to exposure to several detrimental hazardous chemicals and resulting in ailments and mortality. This necessitated the development in the field of toxicology to account for such deaths.

The twentieth century witnessed the blossoming of toxicology. This process was accelerated to a great extent by the dramatic improvement in the instrumentation, analytical techniques, bioassays and biomarker biology. Today, toxicology is a multi-dimensional discipline encompassing a broad area and involving several techniques and specializations. By the second half of the twentieth century, toxicology was a well-defined science, based on its firm principles, and had a unique identity of its own. The workers in the field had started exploring fresh areas such as the effect of genetic composition of an individual on the susceptibility to a particular toxin and so on. They were also undertaking ambitious initiatives such as deciphering the effects of toxic mixtures and synergistic effects of more than one toxic compound, which was not possible earlier. Advances in technology meant that new drugs could be designed to combat the toxic challenges and their efficacy could be tested in a better way utilizing newer improved model systems. Study of toxicology proved to be an extremely interesting field which was becoming mature. However, the best was yet to come!

2 FROM TOXICOLOGY TO TOXICOGENOMICS

In 1990, Human Genome Project was initiated, which aimed at identifying all the genes in human DNA and sequence the entire human genome; it was completed in 2003. This project also witnessed rapid technological advances in different sectors of biological sciences, notable of which were unprecedented progress in the development of automated instruments, data storage, computational efficacy and information transfer. This major breakthrough had its impact on toxicology as well. In the post-genomic era, this discipline has developed in leaps and bounds with the advent of techniques such as whole genome sequencing and the easy availability of large computational platforms. There has been a paradigm shift from classical genetic approaches towards a more holistic genome-based approach that is revolutionizing the way toxicology had been studied so far. With the help of these techniques, it is now possible to elucidate how an organism reacts to a particular toxin at DNA, RNA and protein levels. It is also possible to study the effects of poisons on different tissues and organs and at different stages of life. Instead of looking individually at single genes or mutations thereof, it is now possible to screen the entire genome at a single go. Thus, these techniques have immense potential: they are opening up new avenues for the study of toxic materials, which were hitherto considered impossible and/or improbable. In this chapter, we are going to take a cursory glance at these genomic techniques as they apply to the study of toxicology, and understand how the interaction of classical genetic and state-of-the-art genomic approaches has enriched this field and added new dimensions to the study of toxins and their effects.

3 TOXICOGENOMICS

3.1 Definition

The term “toxicogenomics” is a combination of two individual terms “toxicology” and “genomics.” Thus, it is apparent that the word “toxicogenomics” refers to the study of toxicology utilizing genomic principles and techniques. In other words, “toxicogenomics” is a sub-discipline of toxicology that encompasses techniques which aim at elucidating how genomes respond to toxicants. The NIEHS National Centre for Toxicogenomics (NCT) formally defines toxicogenomics as, “The collection, interpretation, and storage of information about gene and protein activity in order to identify toxic substances in the environment, and to help treat people at the greatest risk of diseases caused by environmental pollutants or toxicants.” Thus, toxicogenomics addresses the effects of toxins at the transcription level, that is, at the level of RNA and proteins (i.e., at the level of gene function), rather than at the level of DNA itself. In this chapter, we will be looking closely at how this technique is utilized to elucidate the mechanism of toxic action at the RNA level and how the predictions therefrom can be validated using classical genetic procedures.

3.2 Genomic components

3.2.1 Microarray

The genomic components involved in toxicogenomics include all of transcriptomics, proteomics and metabonomics. However, here, we will concern ourselves solely with the transcriptomic technique. The other "omics" technologies will be dealt with in other chapters (see Application of Proteomics to Study Mechanisms of Toxicity and Dose Response Relationships of Chemical Exposure, Metabolomics in Systems Toxicology: Towards Personalized Medicine and Application of Metabonomic Approach in Target Organ Toxicity).

Transcriptomics looks at the expression of several genes simultaneously at the transcription level, that is, at the RNA level. This technique is based on the following three principles:

1. Almost all the cells of an individual carry the same genetic information, but in any particular cell type, only a certain fraction of all those genes are active, depending on the internal and external (i.e. environmental) conditions and cues. Thus, under any given set of circumstances, only a specified set of genes will be actively transcribing, whereas others would be shut down.
2. Unstable RNA can be isolated from any tissue at any given time and converted to corresponding cDNA (which is much more stable and easier to work with) using an enzyme called reverse transcriptase.
3. DNA is known to bind to other DNA molecules with complementary sequences. This property is exploited to hybridize cDNA for specific genes to probes having complementary sequence, with high degree of fidelity and accuracy.

In principle, transcriptomic technique begins with isolating mRNAs from the tissue of interest and then converting them to corresponding cDNAs by means of reverse transcription. The cDNA thus generated is amplified using polymerase chain reaction and then labelled with fluorescent dyes and subsequently hybridized to its respective probe attached to specific positions on a solid support (usually glass slides). Following hybridization and wash to remove non-specifically bound or free molecules, fluorescent signals are visualized and quantitatively measured with the help of software designed specifically for the purpose. A set of several control and experimental samples is then statistically analysed to determine the pattern of alteration of gene expression upon toxic insult.

In practice, the process of DNA microarray can be divided into the following steps:

I. Preparation of DNA chip
II. Isolation of mRNA
III. Conversion on mRNA to cDNA
IV. Labelling
V. Hybridization
VI. Washing
VII. Image acquisition
VIII. Image analysis and data generation
IX. Analysis of data

We will briefly look into each of these processes in the following sections.

Preparation of DNA Array

Unlike other forms of hybridization techniques such as Western blot or Northern blot, which are performed on membranes (nitrocellulose or nylon), DNA microarray uses solid support to eliminate material loss caused by diffusion and absorption and to provide a firm attachment of the probes. Typically, glass slides are used for this purpose. Each slide consists of few thousands of DNA probes arrayed on a support and designed to bind to specific DNA molecules with high degree of fidelity. Specific DNA probes are attached (spotted) each on a specific location of the glass slide generating a spot grid using high-throughput robotics, imparting a high level of accuracy and resulting in good reproducibility of the result obtained. Several spotting techniques are available nowadays, with upgradations for each of them being devised almost every day. The simplest of these techniques involves "printing" the probes (generated by classical methods of nucleotide synthesis) onto the glass slides coated with a positively charged material (such as epoxy-silane, amino-silane), with the aid of a mechanized printhead. Other techniques which involve synthesis of probes on the chip itself are also becoming popular these days. Affymetrix Inc. (Santa Clara, CA) utilizes the process of photolithography to synthesize high-density short oligonucleotide (each being 70–80 bases long) arrays directly on the slide surface; this technology is known as "Gene Chip." Whatever be the method of spotting, the final

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat200
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

product is a solid support (like a glass slide) on which probes for several genes have been spotted at specific locations on a pre-designed grid. Such readymade DNA arrays are widely available commercially and they allow the users to choose from a wide range of products which may be organism specific, tissue specific, developmental stage specific or disease specific.

Isolation of mRNA

Proper isolation of mRNA from the samples is of paramount importance for generating good-quality data in transcriptomic studies. Several commercial kits are available these days for the isolation of total RNA/mRNA from a wide variety of tissues. The choice of kits depends on the source tissue to be used and the amount of tissue available. However, almost all the kits used routinely are based on the "single-step" method of isolation of total RNA by acid guanidinium thiocyanate–phenol–chloroform extraction, described by Chomczynski and Sacchi (1987). This method is based on the fact that when extracted with an acidic solution containing guanidinium thiocyanate, sodium acetate, phenol and chloroform, followed by centrifugation, total RNA remains in the upper aqueous layer whereas DNA and protein remain in the lower layers and thus get separated. The aqueous layer is then retrieved and total RNA is precipitated with isopropanol with good quality and high yields (Chomczynski and Sacchi, 2006).

mRNA is isolated from total RNA taking advantage of the fact that almost all (histone RNA being the notable exception) have a poly(A) tail at the 3′ end. Spin column chromatographic technologies have evolved targeting this poly(A) tail to bind to cellulose columns loaded with oligo(dT) probes. On binding and subsequent wash, the unbound fraction consisting of RNAs which are non-polyadenylated (and hence mostly non-coding RNAs), as well as other impurities, is removed. The bound mRNA is then eluted by washing the column with suitable buffers. These days, newer and improved techniques are being devised, which utilize superparamagnetic microbeads to bind to poly(A) tails of the mRNA and thus can directly isolate highly pure mRNA from the cell lysate itself. These techniques are much more superior in terms of sensitivity and yield.

Conversion of mRNA to cDNA

One of the most important and critical part of microarray technique is the conversion of mRNA to the corresponding cDNA. This process basically consists of two different components. The first is the synthesis of single-stranded cDNA from mRNA. In the second step, the single-stranded DNA formed is converted to double-stranded cDNA. The first step in this process is known as "first strand cDNA synthesis." Conversion of mRNA into the corresponding single-stranded cDNA is achieved with the help of an enzyme called reverse transcriptase, which has the ability to catalyse the conversion of RNA into DNA in the presence of nucleotides and Mg^{2+}. In practice, reverse transcriptase isolated from Moloney murine leukemia virus (MMLV) or avian myeloblastosis virus (AMV) is used for this purpose. The problem with this process is that a pre-requisite for reverse transcription is a short stretch of double-stranded sequence, whereas mRNA is single-stranded. However, this apparently insurmountable obstacle is overcome by using a oligo(dT) primer, which binds efficiently to the 3′ poly(A) tail of the mRNA and thus provides a convenient start site for reverse transcriptase. This process thus results in the generation of double-stranded mRNA–cDNA hybrid molecules. Hence, before the single-stranded cDNA can be used to generate double-stranded cDNA molecules, the mRNA bound covalently to the single-stranded cDNA needs to be removed. This can be achieved by alkaline treatment or boiling. However, these days a much more elegant approach is adopted (Gubler and Hoffman, 1983) known as "replacement synthesis." In this method, RNase H is used to nick the RNA strands at non-specific sites in mRNA ss cDNA hybrids, generating short RNA fragments attached covalently to the ss cDNA. In the next step, DNA polymerase I utilizes these short RNA fragments to act as primer and catalyse the synthesis of the second cDNA strand. DNA polymerase I subsequently removes the short RNA stretches by means of its 5′–3′ exonuclease activity. Finally, DNA ligase (typically T4 ligase is used) joins the newly synthesized cDNA strands in an energy-dependent manner. The double-stranded cDNA is now ready to be processed further. The advantage of using reverse transcription is that the remaining process is carried out using cDNA which is much more stable and easier to handle than RNA is.

Labelling

To estimate the level of transcripts, one should be able to visualize them. This is accomplished by labelling the transcripts with specific dyes/

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat200
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

fluorophores. The amount of fluorophore binding to transcripts bears a particular stoichiometric ratio and hence they will emit a signal (usually fluorescence) of specific strength when scanned. The amount of signal generated is directly proportional to the amount of transcript present.

Several approaches have been successfully employed to label cDNA and depend on the design of the experiment and the objectives of the study. In one approach, experimental and control cDNA are separately labelled with two different fluorophores and hybridized to the same slide. In the other approach (usually Affymetrix and other DNA chip-based methods), cDNA from one sample is hybridized to probes on one slide and hence these are essentially one flurophore system.

Labelling of cDNA can either be direct or indirect. In the direct method (often called as "nick translation"), the cDNA generated is first treated with DNase to introduce single-stranded nicks at random sites. DNA polymerase I subsequently removes the nucleotides by 5′–3′ exonuclease activity. DNA polymerase I then substitutes the removed nucleotide with dNTP supplied externally (of which any one nucleotide is labelled with one of several possible labels such as biotin, dioxigenin, fluorescein, etc.). The final nick can be sealed by DNA ligase to give the labelled product. However, it has been shown that this method can sometimes be inefficient as the enzyme efficacy is reduced while using bulky tagged nucleotides as substrates.

The indirect method of labelling involves two distinct steps. In the first step, during cDNA synthesis from mRNA, dTTP is substituted by its analogue aminoallyl-dUTP. This analogue is recognized by the reverse transcription system as dTTP and is normally incorporated into the cDNA. The special property of this analogue is that it contains primary aliphatic amino groups, which have the ability to bind with fluorescent dye molecules such as Cy3 and Cy5 (Cy stands for Cyanine), which contain activated *N*-hydroxysuccinimide. In the next step, the analogue containing cDNA is incubated with these dyes to generate labelled cDNA ready to be hybridized to their respective probes.

Hybridization

Once the cDNA has been labelled, the next step is to hybridize the labelled samples to the microarray slides. Prior to hybridization, the microarray slides have to be heated to temperatures of 95 °C in deionized water and then dehydrated in ethanol. This is done to denature the probes on the microarray slide, so that they can bind to the cDNA samples. The slides are then rehydrated in pre-hybridization buffers (which usually contain 5× saline sodium citrate (SSC) and 0.1% sodium dodecyl sulfate (SDS)). Labelled cDNA is denatured by heating for a brief period at 95 °C and applied to the microarray slide. The entire set-up is then allowed to stand for 18–23 h at 42–50 °C to allow proper hybridization of cDNA to corresponding probes on the slide. Proper care has to be taken to ensure that the slide does not get dry during this process.

Washing

After hybridization, washing is a very critical step, which ensures removal of loosely bound or non-specifically bound dyes and probes. Improper washing can result in the generation of false-positive results caused by non-specific binding or false-negative results caused by high background signals. Slides have to be washed in a series of buffers containing 0.1% SDS and diminishing concentrations of SSC (2×SSC followed by 0.1×SSC) with slow shaking. The washing is usually carried out at room temperature, but sometimes it can also be carried out at 60 °C, depending upon the nature of the experiment. The slides are finally rinsed briefly in 0.1×SSC and dried by centrifugation. The slides are now ready to be scanned and are stored in dark until further analysis. These days fully automated hybridization systems are available, allowing for superior hybridization and better wash, leading to generation of better quality data and higher reproducibility because of reduction in background noise.

Image Acquisition

The raw data obtained from a microarray experiment are in the form of images. For fluorescently labelled systems using two-dye system, such as Cy3 and Cy5, specialized laser scanners are available, which scan the slides at two different wavelengths corresponding to the emission wavelengths of the two dyes. The lasers illuminate the slides at wavelengths corresponding to the excitation wavelength of each of the two dyes, one by one. This results in excitation of the dye molecules, which then emit fluorescence at specific wavelength (550 nm for Cy3 and 660 nm for Cy5). These fluorescent signals are then perceived by the detector to generate a digital map of the fluorescent intensities for each pixel. In this manner, two 16-bit TIFF images are generated

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat200
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

for the entire slide, one corresponding to the signal intensity of each dye. It is of paramount importance to optimize the settings for image acquisition to generate a high-quality image while preventing photobleaching owing to application of high laser intensity.

Image Analysis And Data Generation

Once the two different images are formed, the image analysis software (several are commercially available, ScanAlyze, GenePix, ImaGene being a few) converts the 16-bit images into 8-bit images and then creates a 24-bit overlay RGB image. This helps in the further quantitative analysis of the pixel intensities to generate data about relative abundance of each transcript. For example, let us consider that in one microarray experiment, the control cDNA has been labelled with Cy3 (green), whereas the experimental cDNA has been labelled with Cy5 (red). After hybridization, wash and scanning, two images were generated, one for Cy3 and the other for Cy5. After overlaying of the two images, four kinds of outcomes may occur:

1. some spots will be totally green – indicates that only control cells express that transcript;
2. some spots will be totally red – indicates that only experimental cells express that transcript;
3. some spots will be perfectly yellow – indicates that both the control and experimental cells express that transcript in exactly equal amount;
4. some spots will be yellowish with tinge of red or green – indicates that these transcripts are unequally expressed in control and experimental cells. Greenish tinge indicates that they are expressed more in control cells, whereas reddish tinge indicates that they are expressed more in experimental cells.

The function of the software then is to quantify the ratio of the each pair of transcripts in terms of numerical values. However, in doing so, it has to take into account several complicated confounding factors, including background signal, local background signal intensity (which might be totally different from the overall background signal), shape and dimension of the spot, and so on. Nowadays, improved versions of softwares are commercially available, which allow the user to do all kinds of manipulations to generate good quality numerical data from raw images. However, there is no perfect software yet which can do all the necessary calculations and corrections. Different softwares use different algorithms and each has its own set of pros and cons; thus, there are always some loopholes and probability of errors creeping in while generating numerical data as well as in subsequent analysis. It is therefore very important to plan beforehand the experiments and identify the probable loopholes before reaching the stage of data analysis, so that the errors can be minimized at each step.

Analysis of Data

Data analysis is a crucial step in any experiment and microarray is no exception to this general rule. In microarray experiments, in particular (as in any other "omics" technique), the challenge of data analysis is further complicated by the huge amount of data generated per experiment. To extract meaningful conclusions from this deluge of data, it is extremely essential to implement the right statistical tools and algorithms. The choice of analytical methods depends on the study objectives and the experimental design (see Chapter Integrative Analysis of Microarray Data – A Path for Systems Toxicology).

Whatever be the algorithm and tool used, one problem every microarray experiment has to deal with is the inter-experiment variability. To nullify such variability and avoid false-positive or false-negative results, one has to normalize the ratios obtained (for each set of transcript from each set of experiment) against some common standard reference. This allows the comparison of results obtained from different experiments and gives an accurate measure of the reproducibility of the experimental set-up. Several approaches for normalization have been implemented till date, but the most favoured one perhaps is to normalize the data against a group of putative housekeeping genes whose transcript levels have been proved to remain fairly constant within an acceptable range under normal circumstances. Thus, using these transcripts as positive controls, one can eliminate, to a large extent, the possibility of generating false results and hence false conclusions therefrom. Another level of normalization is absolutely imperative for experiments employing multiple arrays. In this case, it is not sufficient to normalize the results for inter-experiment variability, but also the variability between different microarray platforms, as the difference in processing of the samples has to be normalized before the

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat200
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

results can be meaningfully correlated and interpreted. In these cases, clustering analysis along with principal component analysis or multi-dimensional scaling has proved to be beneficial (Hess *et al*., 2001).

In conclusion, it can be said that a properly planned, executed and analysed microarray study will generate results which are robust and meaningful and can lead to identification of genes, and molecular signatures thereof, in response to toxic effects and thus herald the emergence of a new era in the study of toxicology.

3.2.2 miRNA Expression Profiling

Micro RNA (miRNA) are short stretches of single-stranded RNA molecules (21–23 nucleotides long), described first in 1993, that play negative regulatory role in controlling gene expression. Till date about 500 miRNAs have been identified and they have been shown to be key players in different biological processes as also in disease development through regulation of the transcriptional pattern of other genes. So, they might easily regulate the toxic effects of different agents as well. Hence, the transcriptomic studies of levels of miRNAs have become a lucrative area in modern-day toxicogenomic research.

The principle of miRNA expression study is just the same as normal transcriptomic study. miRNA can be isolated using a variety of commercially available kits. The process begins with the isolation of total RNA from the tissue of interest followed by enrichment of the small RNA (20–30 nucleotide size) fragment using a glass filter fibre approach. In the technique, total RNA is allowed to pass through two successive glass filters under differing ethanol concentrations. This leads to the immobilization of large RNAs on the first filter under conditions of low ethanol concentration, whereas the small RNAs successfully pass through it. However, with addition of more ethanol, the latter get immobilized as they are passed through a second glass filter. The small RNAs are then eluted with appropriate buffers to obtain a small RNA-enriched sample (Microarray Core Facility, UT, Southwestern Medical Center at Dallas). Other gel electrophoresis-based methods of miRNA isolation are also becoming popular these days.

The miRNAs thus isolated are then labelled according to the same indirect method as we have discussed in case of cDNA in the previous section. The first step involves the addition of 3′ amine-modified tails to miRNA, to which a variety of dyes can be attached in the subsequent steps. Cy3, Cy5, Alexa Fluor and digoxigenin are some of the dyes commonly used in this process.

Once the sample is labelled, it can then be hybridized to the customized array consisting of probes for each miRNA. Hybridization usually takes about 12–14 h to complete at 42 °C, followed by washing with high-stringency and low-stringency wash buffers. The slide is then dried and stored in dark until analysis. The analysis, as well as image acquisition, data generation and data analysis, is also very similar to what we have discussed in the previous section.

3.2.3 Genetic Polymorphism Analysis

Another technique that has gained tremendous momentum in the post-genomic era is the study of effect of genetic polymorphism(s) on susceptibility to toxins. Genetic polymorphism may be defined as the existence of several forms of DNA sequences at a specific locus in the genome of a particular species at a frequency of 1% or more. Thus, the same gene may have slightly different compositions in different individuals. Although the high level of abundance of polymorphic forms of a gene indicates that a minor change in sequence would not result in a drastic change in the function or phenotypic effects of the gene (or else, it would not have been stabilized in a population at such a high frequency, but would have been eliminated or reduced to a rare mutation caused by negative selection pressure), it might result in subtle changes in gene function that might affect the response of an individual towards a toxic insult. Genetic polymorphisms may be synonymous (does not cause a change in the amino acid sequence of the protein product) or non-synonymous (cause a change in the amino acid sequence of the protein product). Most of the genetic polymorphisms are changes in a single nucleotide (hence termed as single nucleotide polymorphism or SNP), but there are examples of polymorphisms that involve more than one nucleotide (as entire gene deletion in case of *GSTT1* and *GSTM1*). It has been estimated that human genome consists of several thousands of such genetic polymorphisms. With detailed knowledge about the occurrence of such genetic polymorphisms (well documented in literature and stored in

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat200
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

databases) in our genome, we are now in a position to ask ourselves what is the effect of presence of such variations. In fact, polymorphisms in different genes have been associated with susceptibility to develop different diseases (mostly through association studies which measure the relative frequency with which a particular polymorphism occurs together with the trait of interest in a population). Toxicology has also benefited from the same approach and several association studies have been carried out to find out whether specific polymorphism(s) in the genes involved in metabolism of toxicants are associated with susceptibility to the toxicant concerned.

Association studies usually involve a case–control design where the occurrence of a particular polymorphism in case and control groups is determined. The case and control are defined on the basis of a phenotypic outcome (such as a disease occurrence), where the case has an outcome, but not the control. The two groups are selected in such a way so as to eliminate all other sources of probable confounding variables, and evenly matched except in their outcome variable. Genomic DNA is isolated (usually from blood) and the genotype for each subject is determined by polymerase chain reaction (PCR)-sequencing or PCR-RFLP (Restriction fragment length polymorphism) method. The occurrence of the polymorphism of interest is then evaluated in both the study groups and is expressed as odds ratio (what are the odds for a subject with the polymorphism of interest to develop the disease outcome compared with a subject having the other allele).

One of the most important issues any toxicologist seeks to address is what makes an individual susceptible to a particular poison. Individual susceptibility depends on several factors, but is, to a considerable extent, genetic in nature and is present inherently in individuals, coded in the form of triplets of bases in the genome. In a great majority of cases, this susceptibility is polygenic and usually each gene (or variation thereof) is a low-penetrance one. It is thus the interplay of several low-penetrance genetic variations that determine the ultimate susceptibility of each individual towards a particular toxicant. Classical genetic techniques are inadequate to determine the susceptibility of an individual to a toxicant in such cases, where several low-penetrance variants cumulatively bring about the final degree of susceptibility of a subject. Yet, delineating the high-susceptibility groups or populations is one of the most important issues in toxicology. This is where the genetic polymorphism studies have a tremendous impact. By definition, genetic polymorphism studies look into the minute variations in the genome which are expected to cause subtle effects rather than a drastic one on the phenotype. Thus, association studies can quantitate the effect of such minute genetic variations in the low-penetrance candidate genes and the degree of susceptibility they possess to the individual who possesses them. These days, genome-wide association studies (GWAS) have become possible, and are gradually becoming an important strategy (Shi, Wang and Huang, 2009) in complex toxicological studies. GWAS permit a comprehensive scan of the genome in an unbiased fashion and thus have the potential to identify totally novel susceptibility factors (Shi, Wang and Huang, 2009). Thus, genetic polymorphism analysis has become a very important tool in the field of toxicology, primarily as it permits easy yet accurate screening of susceptible individuals in a population who are highly prone to the adverse effects of a toxicant. This has hitherto not been possible with the classical genetic techniques such as genome-wide linkage studies the toxicologists had at their disposal.

The genetic polymorphism study has become widespread because of its elegant and simple study design, economy, ease of analysis and ability to adjust for probable confounding factors by statistical methods. With the advent of cost-effective and high-throughput modes of DNA sequencing, study of genetic polymorphism to account for susceptibility (to toxins in our case) has gained immense popularity. This approach thus promises to assist researchers to identify highly susceptible groups among those exposed to different toxins, be environmental or occupational, with high degree of accuracy.

3.3 Advantages and Disadvantages

The major advantage of all these genomic processes is that they are extremely high-throughput systems. These are very fast processes which can generate data on several thousand points (genes, miRNA or polymorphisms) at a single shot. In fact, toxicogenomic experiments can lead to the unravelling of putative pathways, molecular targets and thereby mechanisms of polygenic and complex disease aetiology.

From the foregoing discussion, it might appear that toxicogenomics is all about advantages. However, all these approaches also have several limitations. Primarily, even with the most advanced technology we have at our disposal these days, it is not possible to spot all the genes of an organism on a single slide. Thus, on each microarray platform, only a specific subset of the entire genome is represented. Hence, this method is not completely exhaustive yet with respect to the entire genome. Genes which transcribe rarely are more probable to be absent in the arrays than those which are transcribed abundantly, and this might cause loss of important information in some cases. Also, with the huge amount of data generated by transcriptomic experiments, it is essential to weed out the fallacious results with utmost caution to reach truly meaningful conclusions. This necessitates the possession of sophisticated data analysis systems and computational platforms, which are not always easily available. Besides, this procedure can often be exorbitantly costly for many researchers.

However, perhaps the most important point is that the results obtained using toxicogenomic techniques (be it microarray or genetic polymorphism study) are largely predictive rather than definitive. This is because of the fact that there exists a high degree of variability within and between experiments. The variability in microarray can result from several sources and at several stages. Differences in sample quality, manual handling, efficiency of RNA extraction, dye incorporation and hybridization efficacy, and washing all bring about variation in each successive step of the experiment. The problem is compounded further by variations resulting from other sources such as temporal differences in printhead structure as it keeps on printing different spots on a slide, local variations in hybridization in the same slide, as also variation between different slides. Most of these variations can be addressed statistically using various mathematical algorithms, yet some amount of error does creep in. It is practically impossible to eliminate all sources of variation, no matter whatever be the mathematical normalization performed. This obviously results in a degree of approximation while reaching conclusions from transcriptomic experiments, and thus every transcriptomic experiment needs to be further cross-validated before spelling out a definitive hypothesis.

The same is also true for genetic polymorphism study. Although the results can be adjusted for confounding factors, there is no denying of the fact that any association is a statistical inference based on observation and might just be due to chance. So, these associations also need to be validated at the functional level before they can be accepted to be universally true.

4 GENETIC COMPONENTS

As we have already discussed, a transcriptomic technique (including that used to study toxicological effects) has a high predictive value. Thus, it helps the workers to narrow down from an imponderable number of genes that might be implicated to a relatively few with high probability of involvement in the process. However, even within those genes predicted to play a part, it is absolutely necessary to vindicate the biological roles they play in bringing about susceptibility or resistance to the toxicant. It is in the validation of their roles that genetic techniques play a big role. By definition, genetic techniques are adept at looking into the action of one gene at a time. Hence, having found out a few candidate genes by transcriptomic methods, the worker can substantiate whether they play any role at all and, if so, what that role is. We will hence be looking at a few such genetic approaches in the upcoming sections.

4.1 Molecular Biology Techniques

4.1.1 Real-Time Polymerase Chain Reaction

One of the best methods used routinely nowadays to quantitate the mRNA expression level is known as real-time PCR (RT-PCR). In this technique, fluorescent reporter molecules are employed to monitor the amount of product formed during each cycle of an amplification reaction. The procedure begins with isolation of total RNA (or mRNA) from the tissue of interest and utilization of reverse transcriptase PCR to generate cDNA of the desired DNA fragment using specific primers. The specific cDNA thus generated is then used in the next step of amplification reaction. The basic rationale for this method involves detection of fluorescence whose level is (directly or indirectly) proportional to the increment in the level of DNA as it is being synthesized during the process of amplification. The

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat200
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

technique consists of determining the number of amplification cycles required for the fluorescent signal to attain a minimum threshold level at which the signal can be detected (C_T). It is evident that if the initial number of copies of specific DNA fragment is more, the number of amplification cycles required to reach C_T will be less compared with the same DNA fragment with less number of initial copy numbers, or in other words, the starting amount of nucleic acid is inversely proportional to the C_T. The quantity of DNA in the sample can then be obtained by interpolation of its C_T value versus a linear standard curve of C_T values obtained from a serially diluted standard solution (Walker, 2002). The greatest advantage offered by this method is that the measurement of amplification products is carried out in "real time" enabling the quantification during the exponential phase of the reaction itself (Ginzinger, 2002) and not at the end of the PCR when the reaction has long been in the plateau phase. This is because, during the exponential phase, the efficiency of amplification is maximum (copy number being almost doubled in every successive cycle at this phase), while being least affected by reaction-limiting conditions (Walker, 2002); hence, the method is highly sensitive and accurate.

Several methods are available to achieve fluorescent signals in proportion to the DNA product. We will be discussing three techniques that are widely used at present. In the indirect "Taqman" system, in addition to normal forward and reverse primers required for amplification, an additional fluorescence resonance energy transfer (FRET) probe is employed, which is an oligonucleotide (complementary to the DNA of interest) consisting of a reporter molecule at the 5′ end and a quencher molecule at the 3′ end. During the amplification process, because of the proximity of the quencher and the reporter, no fluorescence is detected. However, during each extension cycle, as the Taq DNA polymerase progresses, the 5′–3′ exonuclease activity cleaves the reporter dye from the probe, and once separated from the quencher, the reporter dye emits its characteristic fluorescence. The direct method uses a fluorescent dye known as SYBR Green. The peculiarity of this dye is that it binds to double-stranded DNA but not to single-stranded DNA. On binding, this dye fluoresces brightly. This binding and resulting fluorescence, being proportional to the amount of double-stranded DNA, allow for sensitive and accurate measurement of the amount of double-stranded DNA formed at the end of each amplification cycle. The other direct method widely in use is the "molecular beacon," which consists of a hairpin probe which maintains dye and quencher molecules in proximity and hence prevents the reporter molecule from fluorescing in the unbound state. Binding of the probe at a target sequence-specific region to its complementary strand on the amplified target DNA separates the two fluorochromes, thereby alleviating the FRET interference and allowing the reporter to fluoresce (Walker, 2002).

4.1.2 Northern Blotting

Northern blotting is a molecular biology technique widely applied to evaluate the expression level of specific mRNA. This method also starts with the extraction of RNA from cells/tissue of interest. The isolated RNA is then separated according to size by running on an agarose gel under denaturing conditions. For sample denaturation, agents such as formamide (which lowers the annealing temperature of the probe–RNA interaction, preventing RNA degradation at high temperatures), formaldehyde, methylmercuric hydroxide, glyoxal and dimethyl sulfoxide are used, but not alkali, as they tend to degrade RNA. The RNA thus separated are then transferred to a positively charged nylon membrane, immobilized and then hybridized to probes, specific for the RNA of interest. The probe can be radiolabelled cDNA or RNA or non-isotopically labelled DNA. Following hybridization and subsequent wash, the signals generated by specific binding of probe to RNA of interest can be detected by suitable detectors and then quantified using commercially available softwares for densitometric analyses. The main advantages of this process are that it is extremely sensitive and can detect minute quantities of RNA and the alternatively spliced transcripts of the same gene.

4.2 Cytogenetic Techniques

A large number of toxicants exert their effects on living systems by adversely affecting the integrity of the genome. They induce genetic damage to different extent, which subsequently leads to malfunctioning of the genetic information encrypted in the form of nucleotide sequences and thus results in the development of phenotypically observable maladies in the long run. So, while studying toxic

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat200
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

effects, one of the first parameters one needs to ascertain is whether these agents are genotoxic. Cytogenetic methods provide easy, accurate and reliable methods for qualitative and quantitative analysis of genetic damage induced by toxicants. Also, these studies provide strong counter validation of the results obtained from genomics studies. In this chapter, we will be discussing about a few such routinely used cytogenetic techniques.

4.2.1 Single-Cell Gel Electrophoresis (SCGE) Assay

Commonly known as comet assay, this is an easy, reliable and fast technique that is employed to quantify the genetic damage at the single-cell level. The assay works on the principle that strand breakage of the super-coiled duplex DNA leads to the reduction in the size of the large molecule and these strands can be stretched out by electrophoresis. Also, under highly alkaline conditions, there is denaturation, unwinding of the duplex DNA and expression of alkali-labile sites as single-strand breaks. When such fragmented DNA is placed in an electric field, the negatively charged DNA fragments migrate towards the anode. This migration is a function of the size of the fragments (inversely proportional), and also the number of broken ends of DNA (directly proportional) (Indian Institute of Toxicological Research, 2006). Thus, greater the amount of damage induced, larger will be the number of broken ends, and smaller will be the size of the fragments generated. Hence, the DNA fragments (belonging to a particular cell) will move farther away from the undamaged part, thereby generating a comet-like structure, where the "head" is formed by the undamaged DNA whereas the "tail" is formed by the broken fragments. Lengthier the tail, greater is the number of broken fragments, smaller is the size of fragments generated and more is the damage induced. The comets can be visualized by staining them with DNA-binding fluorescent dyes such as ethidium bromide or SYBR Green and the damage can be quantified using image analysis softwares.

4.2.2 Chromosomal Aberration Assay

Chromosomal aberration (CA) assay is employed to determine qualitativelyand also quantitatively the genetic damage caused by toxicant(s) at the chromosome level. Structural chromosome aberrations may be induced via DNA breaks by various types of toxic agents. CA assay allows the visualization of such structural anomalies in peripheral blood lymphocytes. This assay can also be performed using cell cultures, but cultured cell lines tend to lose and gain chromosomes spontaneously, showing a high and unpredictable rate of chromosome aberrations, which makes them an unsuitable choice for this assay. This assay consists of setting up of primary cultures of peripheral lymphocytes (from human or mice) in appropriate culture medium and stimulating the cells to undergo division by adding a mitogen such as phytohaemagglutinin-M. Two hours prior to harvesting, a spindle inhibitor (such as colchicine or colcemid) is added to arrest the dividing cells at metaphase (as this is the phase in cell cycle when chromosomes are most condensed and hence best visible). The cells are then harvested by centrifugation, treated with hypotonic solution to allow the cells to swell and become turgid, fixed and washed. Permanent slides are then prepared with cell suspensions, by allowing them to drop on chilled glass slides. They are then allowed to dry under humid conditions, stained with Giemsa and examined by light microscopy. Suitable negative controls are a pre-requisite for proper evaluation of baseline genetic damage in the study population to account for false-positive results. Positive controls in the form of S9 mix or mitomycin C can also be used. In this process, the cells are usually harvested at 48 h because that produces a mixture of cells in the first and second division cycles, which is important to detect both chromatid and chromosomal aberrations. However, for a few toxins which are known to delay cell cycle (such as arsenic), harvesting is usually carried out after 72 h of culture. Observations consist of scoring 50–100 well-spread metaphase plates per culture in duplicate. The frequency of aberrant cells in the experimental cultures compared with control cultures gives an accurate estimation of the genotoxic potential of the toxicant. The major advantages of this process are that it is very easy to perform, the sample can be obtained with minimum invasiveness and the analysis is fast, accurate and also amenable to automation to a considerable extent.

4.2.3 Micronucleus Assay

Micronucleus assay (MN) is a convenient tool to determine visually the DNA-damaging potential of a toxin at the cellular level. Several kinds of toxic exposure lead to the fragmentation of DNA as we have seen earlier. These DNA fragments (mostly

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat200
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

acentric) are not pulled towards the pole of the daughter nuclei during anaphase. They hence persist in the cytoplasm as minute nuclear fragments and are known as micronuclei. The frequency of micronucleus induction provides a reliable estimate of the toxicity of the agent concerned. The assay protocol is very similar to that of CA when peripheral blood lymphocytes are used for the purpose (harvested at 72 h), the only difference being the addition of cytochalasin B at 44 h of culture instead of a spindle inhibitor. The function of cytochalasin B is to prevent cytokinesis by generating binucleate daughter cells. However, this assay has the added advantage of being performed on a large number of other cell types including buccal mucosa, nasal mucosa, urothelial cells and so on, which can be obtained by non-invasive methods.

5 INTERACTION BETWEEN GENOMIC AND GENETIC APPROACHES

In this section, we will be looking at a few examples of how genetic and genomics approaches together have led to the unravelling of the mechanisms as well as effects of a few toxicants. These examples will clearly illustrate the importance of employing both approaches as and when necessary to have a close look at the mode of toxic actions.

Benzene toxicity has been studied widely. It has been shown using cytogenetic techniques that benzene exposure leads to significant levels of genetic damage including an increased induction of aneuploidy (Zhang *et al*., 1999). Genetic polymorphism studies have demonstrated that SNPs in double-strand break repair pathway genes, such as *WRN*, *TP53* and, *BRCA2*, are involved in susceptibility to benzene-induced haematotoxicity (Shen *et al*., 2006). Microarray experiments were employed to detect the changes in gene expression patterns in peripheral blood mononuclear cells (PBMC) on benzene exposure, using a comprehensive human array, theU133A/B Affymetrix GeneChip set. Pairwise *t*-statistic along with bootstrapping control was used to statistically analyse the results obtained and led to the identification of 29 known genes with differential patterns of expression on benzene exposure in PBMC. Further validation by RT-PCR confirmed the differential expression of *CXCL16*, *ZNF331*, *JUN* and *PF4* on benzene exposure (Forrest *et al*., 2005).

Arsenic is another such chemical whose toxic effects have now been reported from about 35 countries in the world and is the cause of global concern. In West Bengal, India alone, 25 million individuals are estimated to be exposed chronically to arsenic through contaminated drinking water. Scientists across the world have been trying to unravel the mechanism of arsenic toxicity and susceptibility thereof. They have adopted both classical cytogenetic as well as modern molecular techniques to elucidate the mechanisms involved in chronic arsenic toxicity and susceptibility. Our group has shown that induction of genetic damage is one of the potent mechanisms by which arsenic exerts its toxic effects on human beings. We have used all the three parameters of CA, MN and comet assay to elucidate the elevated level of genetic damage induced by arsenic (Basu *et al*, 2002, 2005; Mahata *et al*., 2003; Banerjee *et al*., 2008). It has been shown using genetic polymorphism studies that SNPs of DNA repair pathway genes such as *ERCC2* and *p53* are involved in imparting high risk of development of arsenic-induced pre-cancerous skin lesions (De Chaudhuri *et al*., 2006; Banerjee *et al*., 2007). Implication of other genetic polymorphisms such as *APE1*, *XRCC3* and *NBS1* with arsenic-induced skin lesions has also been shown in different populations (Andrew *et al*., 2003; Thirumaran *et al*., 2006; Applebaum *et al*., 2007; Breton *et al*., 2007). Further cytogenetic studies have elucidated that individuals having the risk genotypes of *ERCC2* and *p53* have a significantly elevated level of genetic damage as measured by CA compared with those having the non-risk genotypes (Banerjee *et al*., 2007; De Chaudhuri *et al*., 2008). Thus, these studies validate the observations obtained from genome-based genotyping studies (Lu *et al*., 2001). Recently, employing cytogenetic techniques such as comet assay and challenge assay, it has been shown that deficiency in DNA repair capacity is one of the paramount factors in arsenic susceptibility (Banerjee *et al*., 2008). Thus, a combination of molecular biology and classical cytogenetic approaches has helped to elucidate the mode of arsenic toxicity at several levels in the process delineating the high-susceptibility groups.

6 CONCLUSION

Thus, from the forgoing discussion, it is evident that both genetic as well as genomic approaches have their own advantages and disadvantages. Generally

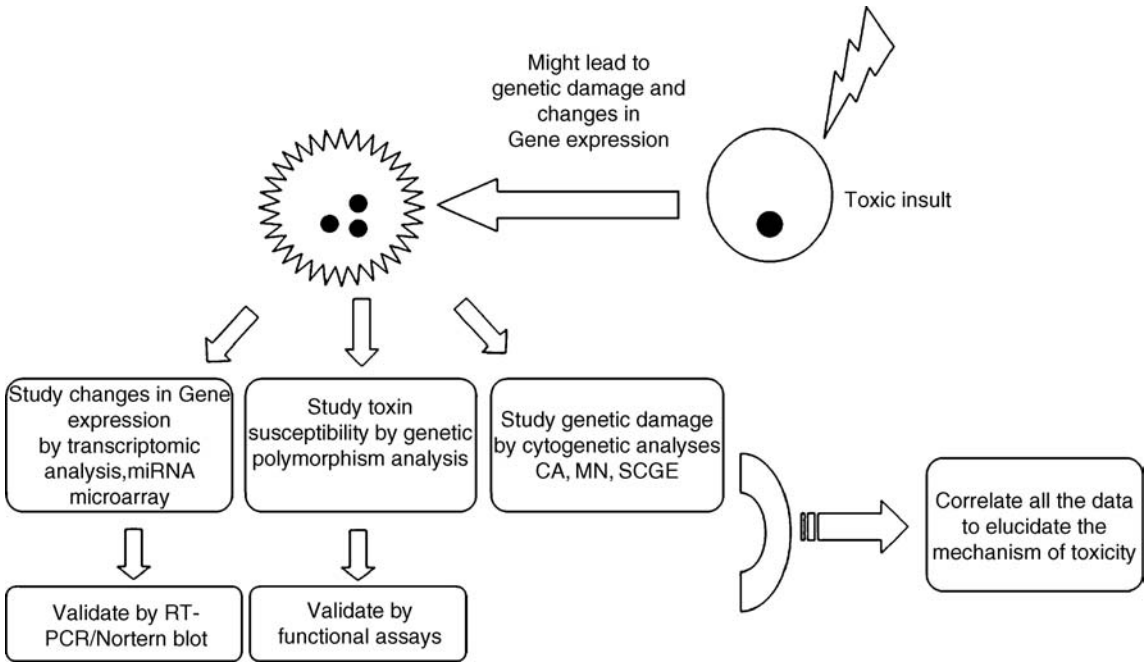

Figure 1. Interaction of genomic and genetic approaches helps to elucidate the mechanism of toxic action and also identify the highly susceptible individuals at the extreme end of the continuum who are at highest risk as a result of toxic exposure.

speaking, genomic techniques lead to the generation of large amount of data in a short span of time and enable us to look at how the entire genome works at a single go. Thus, armed with the knowledge of human genome, it is now easy to look at how the genome is being modulated at the functional level by the effect of a toxicant. However, with this huge amount of data come the problems of low reproducibility, data storage and retrieval, proper analysis and drawing of meaningful conclusions from them. It is in here that the molecular biology and classical cytogenetic techniques prove to be invaluable. Although they look at one gene at a time, the results obtained are usually more robust and simple to analyse. Thus, the ideal way to study the toxic effects seems to be a combination of the two approaches. Genomic analyses predict a specific set of genes with altered expression that might be involved in the mechanism of toxic action. The main function of genomics would be to shortlist from a large number of possible players to a relatively fewer number of genes whose probability of being involved in the toxic mechanism is the highest. Besides, genomic approaches can also lead to the identification of pathways involved and also the probable therapeutic targets for a toxicant. The function of the molecular and classical cytogenetic systems would then be to validate these predictions by examining the effects of toxicant on each of these probable genes as predicted by genomic techniques. Hence, together, genetic and genomic approaches provide the researchers with a powerful tool to evaluate the potential mode of action as well as possible remedies for any toxicant (Figure 1).

Toxicogenomics – Applications in Systems Toxicology

Pius Joseph

Molecular Carcinogenesis Laboratory, Toxicology and Molecular Biology Branch, Health Effects Laboratory Division, National Institute for Occupational Safety and Health (NIOSH), Morgantown, WV, USA

1 INTRODUCTION

A significant increase in mining, refining and manufacturing, as well as the use of products containing chemicals, has taken place during the last one and a half century. Although chemicals are of immense benefit to mankind, some of them, including many commonly used chemicals, pose a serious threat to human health. Significant quantities of various chemicals are present as contaminants in the air we breathe, the water we drink and the food we eat. In addition, significant quantities of various toxic chemicals are found in the environment as well as in various occupational settings as contaminants. Therefore, every human being is at risk of exposure to toxic chemicals capable of resulting in potential adverse health effects. Virtually every organ/tissue in the body has been identified as a target for toxicity resulting from such exposure to toxic chemicals. In fact, chemical exposure has been identified as a major aetiological factor for several diseases in humans, including cancer in various organs and tissues (Loeb and Harris, 2008; Sorahan, 2009). As human exposure to potentially toxic chemicals is almost unavoidable, it has become increasingly necessary to have the capability to effectively detect human exposure to toxic chemicals and, if possible, to predict or even determine the potential for adverse health effects resulting from such exposures. Equally important is the requirement to determine the potential mechanisms underlying the toxicity of chemicals because this may provide an opportunity to develop strategies to intervene or even prevent toxicity resulting from these exposures. This understanding, if possible, should not be confined to a single tissue or organ in the body, but rather be applicable to toxic effects taking place in all organs and organ systems in the body.

Great progress has been made in the last several decades in determining the potential of chemicals to cause toxicity as well as elucidating the potential mechanisms underlying their toxicity. A variety of approaches may be employed to determine whether a chemical is toxic or not. The ultimate goal of a successful toxicity test has to be its ability to predict most accurately the potential of a chemical to cause toxicity in a human being following exposure to the chemical in question. The desired features of an ideal toxicity test are: (i) sensitivity – the test should be highly sensitive so as to detect subtle or pre-clinical toxicity much before the onset of any clinical symptom of toxicity; (ii) non-invasiveness – the test should be applicable in situations of human monitoring for chemical exposure and the resulting toxicity and this is possible at best only if the test can be conducted non-invasively using easily accessible bio-fluids such as peripheral blood, urine, etc.,

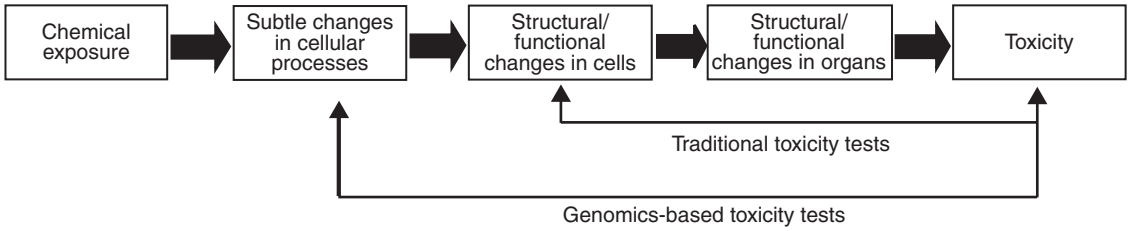

Figure 1. Continuum of events in chemical toxicity. Compared with the traditional toxicity tests, genomics-based toxicity determination can detect toxicity before the onset of clinical symptoms of toxicity.

that may serve as surrogate(s) for target organ(s); (iii) simple – the test should be simple so that it can be performed easily without the need for highly sophisticated equipments or significant technical expertise; (iv) specificity; (v) cost-effectiveness; and (vi) reproducibility. Being able to accurately predict the potential of chemicals to cause toxicity immediately following exposure has the unique advantage of implementing strategies to prevent the onset of toxicity so as to protect the exposed individuals from developing adverse health effect(s).

Various *in vitro* (cell/tissue culture) and *in vivo* (experimental animals) toxicity tests have been developed and are currently being employed to determine the potential of chemicals to cause toxicity (Boulmedarat *et al.*, 2005; Kikkawa *et al.*, 2006). These tests rely heavily on various endpoints pertaining to structural and/or functional damage to cells/organs induced by the toxic chemical. Although the various tests that are currently being employed are capable of detecting toxicity induced by chemicals, they lack one or more of the features described above that would make them ideal to predict and/or determine toxicity. For example, live animals can be exposed to toxic chemicals and histological/biochemical changes taking place in the organ(s) or blood can be determined as indicators of target organ toxicity (Amin *et al.*, 2004; Ohbayashi *et al.*, 2007;Hard, Flake and Sills, 2009). It is to be emphasized that the biochemical and histological changes in the blood and in the target organs, respectively, of the exposed animals are not predictors of toxicity, but rather indicators of injury/damage that has already taken place in response to exposure to the chemicals. Such changes are noticeable only when significant damage, including structural and/or functional damage, to the target organ(s) or tissue(s) has already taken place. Therefore, many of the traditional toxicity testing procedures lack the high sensitivity required to detect early, subtle toxicity (toxicity not associated with clinical symptoms) following exposure to very low concentrations of the toxic chemical (Figure 1). Lack of adequate sensitivity make many of the currently available toxicity tests less desirable in situations such as monitoring human exposure to low concentrations of toxic chemicals routinely present in our environment or the workplace.

2 SYSTEMS TOXICOLOGY

Upon entering the biological system, toxic chemicals may interact with various cellular components and result in perturbation of the cellular processes vital for normal functioning of the system. The biological system, in turn, may respond to the chemical-induced perturbation of cellular processes by activating the cellular response system. It has been proposed that the balance between the chemical-induced perturbation of the biological system and the system's response to the perturbation will determine whether exposure to the chemical may eventually result in toxicity or not. It has been hypothesized that alterations in the global gene expression profile may precede the toxicity induced by chemicals in a biological system. Therefore, determination of the differential gene expression profile of a biological system that has been exposed to a toxic chemical may provide important information regarding not only the potential of the chemical to cause toxicity but also the mechanisms underlying the toxicity. The global gene expression profiling may provide a complete understanding of all the biological processes that are affected in a cell, a tissue, an organ, an organ system and all organ systems of an organism in response to exposure to a toxic chemical. Such an understanding is essential

DOI: 10.1002/9780470744307.gat201
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

to develop an ideal toxicity test capable of predicting/determining the potential of a chemical to cause toxicity as well as to elucidate the mechanisms underlying the toxicity. Recent advances in genomics and bioinformatics and their application in toxicology have facilitated the development of a new toxicology research area commonly referred to as toxicogenomics. Toxicogenomics is promising with respect to obtaining a complete understanding of the response of an organism to exposure to a toxic chemical. The three main areas of toxicogenomics are transcriptomics, proteomics and metabonomics. Toxicogenomics represents the complete understanding of the response at the level of transcripts (transcriptomics), proteins (proteomics) and metabolites (metabonomics). Integration of the cellular profiles of transcripts, proteins and metabolites with various traditional toxicological endpoints may provide a comprehensive view of the response of a biological system to exposure to toxic chemicals and this has emerged as a new toxicology branch commonly referred to as systems toxicology.

Systems toxicology may be defined as the understanding of all toxicological interactions taking place in a biological system under stress (chemical exposure). Thus, all these interactions between the exposure of the system to the toxic chemical and the ultimate elimination of the toxic chemical and/or its metabolites from the system may be considered as various aspects of systems toxicology. These include:

1. absorption and distribution of the chemical within the biological system;
2. metabolism of the chemical taking place in the biological system resulting in the generation of toxic and/or non-toxic metabolites;
3. interaction of the toxic chemical and/or its toxic metabolites with the cellular target(s) of toxicity within the biological system;
4. alterations in the expression profile of genes (transcripts) that may be related to the toxicity of the chemical;
5. alterations in the expression profile of proteins that may be related to the toxicity of the chemical;
6. histological changes in target organs that may be considered as structural manifestations of toxicity;
7. alterations in the biochemical constituents such as the release of enzymes from target organs into the bloodstream, which may be considered as functional and/or structural manifestations of toxicity;
8. response of the biological system such as the activation of cellular defence system to defend against the toxicity of the chemical; and
9. elimination of the chemical and/or its metabolites from the biological system.

The knowledge obtained from systems toxicology has implications in various aspects of chemical toxicity such as:

1. assessing the risk of toxicity and adverse health effects following exposure to potentially toxic chemicals present in the environment and workplace;
2. determining the safety and toxicity of drug molecules;
3. developing biomarkers to monitor human exposure to potentially toxic chemicals;
4. determining the mechanism(s) underlying the toxicity of chemicals; and
5. developing strategies to prevent the toxicity of chemicals.

As the objective of systems toxicology is to obtain a complete understanding of the response of a biological system to exposure to a toxic chemical, toxicogenomics (transcriptomics, proteomics and metabonomics) seems to have the potential to provide the data required for such an understanding. Of the three areas of toxicogenomics, transcriptomics has enjoyed the most significant growth to date, and therefore the impact of transcriptomics will be further discussed in this chapter.

3 TRANSCRIPTOMICS – TECHNICAL ASPECTS

Transcriptomics or transcript profiling deals with determination of the abundance of all transcripts (mRNA) that are expressed in a cell at a given time. Transcriptomics may be considered as a snapshot of all the expressed transcripts in a biological sample at a given time. It is assumed that exposure of cells to toxic chemicals results in a biological response, and a full understanding of the cellular response to the chemical exposure is important

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat201
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

in predicting, determining and understanding the toxicity of the chemical. This can be achieved by determining the abundance of all expressed genes (transcripts) in the chemical-exposed sample and comparing it with that of a control, unexposed sample. Several techniques are currently available to determine the mRNA expression profile of cells, including northern hybridization, PCR amplification, subtractive hybridization, serial analysis of gene expression, differential display and microarray analysis. Microarray analysis has the unique advantage of simultaneously determining the expression profile of thousands of genes present in biological samples and has been the method of choice to determine the global gene expression profile in biological samples. Microarray analysis of global gene expression profile is a complex process consisting of several sequential steps. The first step in the microarray analysis of gene expression profilings is the isolation of high-quality total RNA (it is not necessary to purify the mRNA) from the control and chemical-exposed biological samples. Subsequently, the mRNA is reverse transcribed to synthesize cDNAs. The cRNAs synthesized from the cDNAs are labelled with fluorescent dye, for example cy3, and the resulting targets are hybridized to the probes which are arrayed on the microarray. The sequence-specific hybridization of the labelled targets with the probes present on the microarray is subsequently detected by scanning the arrays with a fluorescence scanner and the intensity of the hybridization signal obtained is considered as an indication of the abundance of the targets (transcripts) expressed in the sample. The resulting data can be analysed using appropriate computational and statistical programs to determine the transcript profile of the sample. Comparison of the transcript profile of the chemically treated sample with the appropriate control sample will provide information about transcripts that are differentially expressed as a result of the chemical exposure. Appropriate bioinformatic analysis of the differentially expressed genes, integration of the differential gene expression profile with traditional toxicity endpoints and careful interpretation of the resulting data in light of the existing toxicology literature should provide a complete understanding of the events taking place in the biological system in response to exposure to the toxic chemical and in turn may contribute to systems toxicology (Figure 2).

Transcriptomics research has enjoyed considerable growth over the past several years. The discovery of microarray technology and its impact on transcriptomics studies have revolutionized toxicology research. The amount of RNA required for microarray studies has decreased significantly over the years and this has facilitated the use of this powerful technique even in difficult-to-obtain precious samples such as human tissues. Microarrays and the reagents and equipments required for analysis of global gene expression profiles are currently available from several manufacturers, and this has resulted in a significant reduction in the cost associated with the analysis. Currently, the microarray-based transcriptomics profiling technique has become an affordable technique that can yield reliable, reproducible and biologically relevant toxicity data. The impact of transcriptomics in toxicology research is illustrated by the number of research papers published in recent years that describe gene expression data (Figure 3). To date, microarray-based transcriptomics studies have been conducted in a wide variety of species that include nematodes (Menzel *et al.*, 2009), fish (Baker *et al.*, 2009), amphibians (Langerveld *et al.*, 2009), rodents (Courter *et al.*, 2008; Xu *et al.*, 2008), birds (Gust *et al.*, 2009), dogs (Higgins *et al.*, 2003), non-human primates (Marvanova *et al.*, 2003) and humans (McHale *et al.*, 2007). Transcriptomics-based toxicogenomics studies have been employed to study the toxicity of chemicals targeting various organs including brain (Glover *et al.*, 2009), eye (Yang *et al.*, 2007), nose (Roberts, Thomas and Dorman, 2008), lungs (Rouse *et al.*, 2008), heart (Carney *et al.*, 2006), kidney (Amin *et al.*, 2004), reproductive organs (Fukushima *et al.*, 2005; Valdez *et al.*, 2009), immune system (Baker *et al.*, 2009) and skin (Gerecke *et al.*, 2009). However, most of the transcriptomics studies reported so far have involved chemicals that are primarily hepatotoxic in nature or target liver as the primary target organ (Reilly *et al.*, 2001; Uehara *et al.*, 2008;Blomme, Yang and Waring, 2009; Sano *et al.*, 2009). This is mainly because liver is the primary organ responsible for metabolizing toxic chemicals (Lee, 2003), and furthermore, liver toxicity has been cited as a major reason for withdrawal of new drugs from the market (Barros and Martin, 2008). Studies investigating hepatotoxicity of chemicals will be discussed in detail to illustrate the potential application of transcriptomics in studying the systems toxicity of chemicals.

4 HEPATOTOXICITY DETERMINATION BY TRANSCRIPTOMICS

The application of microarray-based transcriptomics studies in systems toxicity is best illustrated in the case of chemicals that target liver as their primary target organ. Hepatotoxic chemicals have been employed as model chemicals by several investigators to demonstrate the potential application of microarray-based global gene expression profiling to study the toxicity of chemicals (Bulera *et al.*, 2001; Hamadeh *et al.*, 2002a). So far, microarray-based transcriptomics studies have been conducted to classify hepatotoxic chemicals, determine mechanisms of hepatotoxicity and predict hepatotoxicity.

In a study conducted earlier by Waring *et al.* (2001), rats were treated with 15 different hepatotoxic chemicals including allyl alcohol, amiodarone, Aroclor 1254, arsenic, carbamazepine, carbon tetrachloride, dimethylnitrosamine, dimethylformamide, diquat, etoposide, indomethacin, methapyrilene, methotrexate, monocrotaline and 3-methylcholanthrene. The various chemicals selected in this study are all known to result in hepatotoxicity such as necrosis, DNA damage, cirrhosis, hypertrophy and hepatic carcinoma. Hepatotoxicity was determined by histopathology of liver and clinical chemistry evaluation of blood. In addition, global gene expression profiles of liver were determined by microarray analysis. Overall, a good correlation was noticed between histopathology, clinical chemistry and gene expression profiles induced by the hepatotoxic agents employed. The authors also attempted to cluster the various hepatotoxic compounds employed in the study based on their hepatotoxicity (histopathology and clinical chemistry results) and liver gene expression profiles. The results demonstrated that various hepatotoxic compounds employed in the study clustered together in fairly good agreement based on the observed changes in clinical chemistry, histopathology and gene expression profile. In some cases, liver gene expression profiles outperformed the traditional hepatotoxicity endpoints (histopathology of liver and blood clinical chemistry) in clustering the hepatotoxic chemicals. The authors, based on the results of their study, concluded that microarray-based global gene expression profiling could be employed as a highly sensitive and reliable technique to identify hepatotoxic chemicals in rat.

Whether gene expression profiling can be employed to distinguish (classify) hepatotoxic chemicals that differ in their mechanism of toxicity has been investigated (Hamadeh *et al.*, 2002b). Hepatotoxicity was induced in rats by administering either peroxisome proliferators (clofibrate, Wyeth 14 643 and gemfibrozil) or an enzyme inducer (phenobarbital). Hepatotoxicity and liver gene expression profiles of the rats were determined by histopathology and microarray analysis, respectively. The microarray data were subjected to several computational analyses to determine whether hepatotoxic chemicals exhibit gene expression patterns distinguishable based on their mechanism of toxicity. The results of this study demonstrated that the peroxisome proliferators exhibited a gene expression pattern that was clearly distinguishable from that of the enzyme inducer, suggesting the potential application of microarray-based gene expression profiling to classify hepatotoxic chemicals based on their mechanism(s) of toxicity.

A major advantage of gene expression profiling in toxicity studies is its superior sensitivity to detect target organ toxicity compared with the traditional toxicity endpoints such as histology and clinical chemistry. Several studies have indicated that gene expression changes indicative of hepatotoxicity are detectable well before the onset of clinical or histopathological changes associated with hepatotoxicity. In a study conducted by Heinloth *et al.* (2004), rats were administered either sub-toxic (50 and 150 mg/kg b.w.) or toxic (1500 mg/kg b.w.) doses of acetaminophen. At time intervals of 6, 24 and 48 h following administration of the chemical, groups of rats were killed and the induction of hepatotoxicity was determined on the basis of histopathology of liver and clinical chemistry of blood. At each time interval, RNA was isolated from the liver and global gene expression profile was determined by microarray analysis. At all time intervals, the rats administered the sub-toxic doses of acetaminophen exhibited normal histology and clinical chemistry, suggesting either the absence of hepatotoxicity in the rats or the inability of these traditional hepatotoxicity endpoints, because of their poor sensitivity, to detect subtle toxicity induced by the chemical. Similarly, rats administered the overtly toxic dose of acetaminophen (1500 mg/kg b.w.) did not exhibit alterations in either histology or clinical chemistry at the earliest time interval of 6 h following administration of the chemical. However, significant hepatotoxicity, as indicated by alterations in liver histology and blood clinical chemistry, was noticed in rats administered 1500 mg acetaminophen/kg b.w. at later time intervals of 24 and 48 h. Microarray analysis of global gene expression profiling demonstrated significant differential expression of several genes including those involved in energy metabolism and stress response in the liver of the rats administered 1500 mg acetaminophen/kg b.w. for 24 and 48 h. Interestingly, many of the genes which were found differentially expressed at time intervals of 24 and 48 h in the rats administered the overtly toxic dose of 1500 mg/kg b.w., and are therefore considered as indicators of acetaminophen-induced hepatotoxicity, were also

found differentially expressed in the rats administered the sub-toxic doses of the chemical. It is worth emphasizing that the rats administered the sub-toxic doses of acetaminophen did not exhibit any histological or clinical changes indicative of toxicity. Taken together, these results demonstrated the superior sensitivity of gene expression changes to detect hepatotoxicity compared with the traditional histological and clinical markers of toxicity. Similar observations supporting the superior sensitivity of gene expression profiling compared with the traditional hepatotoxicity endpoints in detecting hepatotoxicity have been reported by other investigators (Hamadeh *et al.*, 2002b).

The results of a recent study carried out by Huang *et al.* (2008) further support the findings that gene expression profiling can be employed to predict hepatotoxicity as well as understand the mechanisms of chemical toxicity in the liver. Rats were administered individually one of the seven hepatotoxic chemicals that are known to induce necrosis. Microarray analysis of the global gene expression profile in the rats identified several differentially expressed genes in the chemical-treated rats compared with the controls. Using a Random Forrest classifier with feature selection, a group of 21 genes were identified as predictors of necrosis induced by the hepatotoxic chemicals. The selected predictor genes were able to predict necrosis induced by the model hepatotoxic chemicals such as acetaminophen, carbon tetrachloride and allyl alcohol with an accuracy of 90%, 80% and 60%, respectively. Pathway and network analysis of the necrosis predictor genes identified inflammation and apoptosis as major biological processes responsible for necrosis induced by the selected hepatotoxic chemicals.

5 TRANSCRIPTOMICS STUDIES USING SURROGATE TISSUES

Toxicogenomics is certainly a viable and attractive approach to study the systems toxicity of chemicals in humans. However, a major limitation in studying the toxicity of chemicals in human beings is the difficulty associated with obtaining samples of target organs to study. Because of ethical and/or other practical issues such as the health and safety of the individuals involved, it is not possible to obtain samples of target organs or tissues from human beings to determine chemical toxicity. A practical solution to this problem is the potential use of surrogate tissues to study the toxicity of chemicals in target organs that are not easily and safely obtainable. Some surrogate tissues most commonly employed to study target organ toxicity are blood, urine, saliva, sweat, tear, cerebrospinal fluid, milk, broncho-alveolar lavage, sputum, stool, breath condensate, nail, hair, buccal cells and placenta (Burczynski and Rockett, 2006). From the surrogate tissues listed above, it is clear that many of them are not actually tissues in a biological sense. Any biospecimen that can be used to determine or study the biological processes taking place in target organs that are not easily obtainable can be considered a surrogate tissue. Of all the surrogate tissues employed to study target organ toxicity, blood is not only the most frequently used but also the most suitable one (Burczynski, and Rockett 2006). Blood may be considered as the internal environment for the various organs and tissues in the body that are often the targets for chemical toxicity. Very often, alterations in the biological processes taking place in the target organs and tissues in response to their exposure to toxic chemicals are reflected by alterations that are similar to a certain extent in the blood. Alterations in the activity of specific enzymes or the absolute amount of certain biochemical molecules or even the amount of the parent compound and/or its metabolite(s) present in the circulating blood or blood cells may provide valuable information regarding the target organ toxicity potential of chemicals; therefore, one or more of these indicators may be used as surrogate markers of toxicity. Activities of transaminases (aspartate and alanine aminotransferase) in the blood are routinely employed as reliable surrogate markers of hepatotoxicity (Heinloth *et al.*, 2004; Beyer *et al.*, 2007; Bushel *et al.*, 2007). Other surrogate markers of toxicity are blood urea nitrogen (BUN) for nephrotoxicity (Fang *et al.*, 2008; Roomi *et al.*, 2008), serum acetyl cholinesterase activity for neurotoxicity induced by organophosphorus insecticides (Brahmi *et al.*, 2006), blood level of hormones for toxic chemicals targeting endocrine system (De Angelis *et al.*, 2009) and so on.

Although these surrogate toxicity markers have been of immense help to determine the target organ toxicity of chemicals, all or most of them suffer from significant shortcomings such as not being specific for the target organ(s) involved or not being sensitive enough to detect toxicity in a pre-clinical

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat201

condition. For example, significant structural damage, such as necrosis, to the hepatocytes is necessary for transaminases to be released from the liver into the peripheral blood and then measured as markers of hepatotoxicity. Furthermore, an elevation in the serum level of transaminases need not always be an indicator of chemical toxicity taking place in the liver. For example, significant elevations in serum transaminases have been reported under conditions other than exposure to hepatotoxic chemicals (Harrison, Bahar and Payne, 2002; Ramakers *et al.*, 2009).

As presented earlier in this chapter, gene expression changes taking place in target organs are known for their superior sensitivity as markers of toxicity compared with the traditional biochemical and histological markers of toxicity. Therefore, it seems reasonable to investigate whether gene expression profiling to determine target organ toxicity can be performed using easily available surrogate tissues such as blood. This concept has recently gained popularity, and there have been few studies reporting the potential application of blood gene expression profiling as sensitive surrogate indicators of target organ toxicity. As in the case of target organs, most of the toxicogenomics studies investigating the potential application of blood transcriptomics as surrogate markers of target organ toxicity have been conducted using model hepatotoxic chemicals. In a classical study, Bushel *et al.* (2007) of the National Institute for Environmental Health Sciences (NIEHS) demonstrated the usefulness of blood transcriptomics as sensitive indicators of hepatotoxicity induced by the model hepatotoxic drug acetaminophen in rats. Rats were given either a subtoxic (150 mg/kg b.w.) or two overtly toxic (1500 and 2000 mg/kg b.w.) doses of acetaminophen. Blood and liver obtained from the control and acetaminophen-administered rats were analysed to determine hepatotoxicity induced by the chemical. The parameters employed included liver histology, various haematological parameters (total and differential white blood cell counts, red blood cell count, platelet count, hematocrit and haemoglobin content), blood level of transaminases and global gene expression profiling in blood. Based on the results obtained, these authors demonstrated that blood gene expression profiles may be employed as surrogate markers of hepatotoxicity induced by acetaminophen. Furthermore, the results demonstrated that blood gene expression profiles exhibited superior sensitivity as hepatotoxicity markers compared with the traditional toxicity endpoints such as histological, haematological and biochemical changes.

The potential application of blood transcriptomics as appropriate surrogate marker of target organ toxicity was further demonstrated by the results of a comprehensive study published recently (Lobenhofer *et al.*, 2008). These investigators employed a series of eight well-characterized hepatotoxic chemicals that are known to exhibit similarities and differences in the type and location of necrosis induced in the target organ (liver) to demonstrate the potential use of blood transcriptomics as surrogate marker of hepatotoxicity. The study was designed to provide a means to generate mechanistic and predictive measures of toxicity by integrating multiple data streams obtained from liver (target organ) and blood (surrogate tissue). The hepatotoxic chemicals selected were administered in rats at three doses (low, medium and high) for three time intervals (6, 24 and 48 h) to result in sub-toxic to severe hepatotoxicity (necrosis). Toxicity was determined based on established histological, biochemical and haematological parameters in liver (the target organ) and blood (surrogate tissue). In addition, gene expression profiling of liver and blood was performed using two separate microarray platforms. A support vector machine (SVM) approach was employed to identify hepatotoxicity-specific classifiers for the target organ and the surrogate tissue. The classifiers thus obtained were used to group the samples based on principal component analysis and hierarchical clustering to determine whether the animals exposed to each of the hepatotoxicants could be separated into different compound groups. Results of the study demonstrated that the classifiers derived from both liver and blood transcriptomic data were able to accurately classify samples on the basis of the hepatotoxic chemical administered. It is noteworthy to mention that the classifiers generated from the blood data outperformed those generated from the liver data in classifying the hepatotoxicants.

Results of recent studies carried out in our laboratory (Umbright *et al.*, 2009) further support the concept that blood gene expression profiling may be employed as a suitable, alternate approach to detect and distinguish target organ toxicity induced by toxic chemicals. Rats were administered a single, acute dose of a well-characterized hepatotoxic (acetaminophen) or a

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat201

neurotoxic (methyl parathion) chemical. Administration of acetaminophen resulted in overt hepatotoxicity as evidenced from significant elevation in blood transaminases' activities. Similarly, administration of methyl parathion resulted in neurotoxicity as evidenced from significant inhibition of acetylcholinesterase activity. Microarray analysis of the global gene expression profile of leucocytes obtained from the blood samples of rats identified distinct gene expression profiles capable of detecting and distinguishing hepatotoxicity and neurotoxicity induced by the model chemicals administered. The gene expression markers of target organ toxicity were detectable in the blood earlier than the appearance of the commonly used clinical markers of toxicity, further supporting the superior sensitivity of gene expression markers compared with traditional toxicity endpoints to detect target organ toxicity (Figure 4). The ability of the marker genes to detect and distinguish hepatotoxicity and neurotoxicity was further confirmed using the blood samples of rats administered additional model hepatotoxic (thioacetamide, carbon tetrachloride and dimethylnitrosamine) and neurotoxic (ethyl parathion and malathion) chemicals.

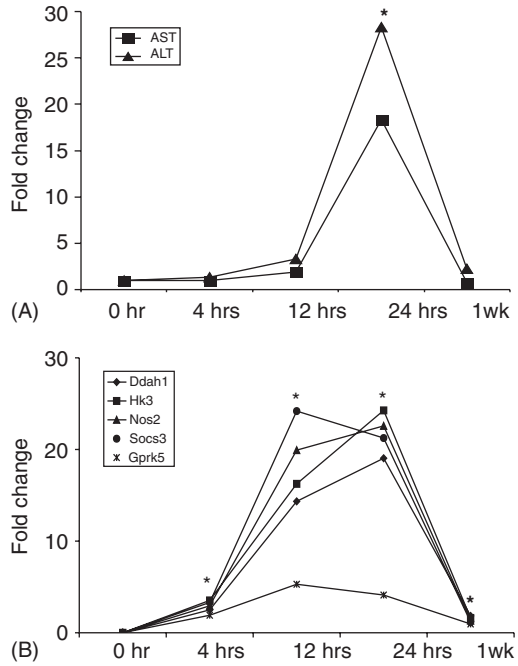

Figure 4. Gene expression profiling is more sensitive than the traditional toxicity endpoints. A single acute toxic dose of acetaminophen was administered in rats. At various time intervals ranging from 4 h to 1 week following administration of the chemical, blood was analysed for toxicity based on the activities of AST and ALT (a) and expression of marker genes for hepatotoxicity (b). Significant alterations in the expression of the selected hepatotoxicity marker genes were observed in the blood before any significant change in the activities of transaminases, suggesting the superior sensitivity of gene expression changes as indicators of target organ toxicity (Reproduced with permission from Umbright *et al*. (2009)).

6 TRANSCRIPTOMICS STUDIES – CHALLENGES

The past 10–15 years have witnessed significant progress in the application of transcriptomics in studying the toxicity of chemicals. Nevertheless, microarray-based transcriptomics research still faces many challenges, and further attention to these issues or challenges is required to enhance the potential of transcriptomics in toxicogenomics and systems toxicology. Following is a description of some of the major challenges facing transcriptomics and the progress that has been achieved.

6.1 Confirmation of Microarray Data

In spite of the high-throughput potential, transcriptomics data are usually error-prone. It is therefore possible to notice several false positives and false negatives among the hundreds if not thousands of differentially expressed genes that are identified in a chemically treated sample based only on microarray determination of gene expression profiles. It is often necessary to confirm the microarray data to eliminate at least false positives as much as possible. Appropriate statistical methods to minimize the false discovery rate (FDR) are usually applied while analysing the microarray data (Benjamini and Hochberg, 1995). Another approach is to confirm the microarray data by more quantitatively reliable supplementary techniques such as real-time PCR or northern hybridization. However, considering the hundreds if not thousands of differentially expressed genes that may be identified from a typical microarray experiment, it is a challenging task to confirm the microarray data by these cumbersome supplementary techniques. It is worthy to mention that microarray technology has improved considerably since its introduction in the mid-1990s and it has

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat201
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

become a more reproducible and reliable technique capable of detecting differentially expressed genes with significant accuracy. A reasonably good correlation has been noticed in the gene expression profile data obtained by microarray and real-time PCR analysis (Joseph, He and Umbright, 2008; Umbright *et al.*, 2009).

6.2 Comparability of Transcriptomics Data

A major roadblock in microarray-based transcriptomics research is the comparability of expression profiling data obtained from multiple sources (Irizarry *et al.*, 2005; Larkin *et al.*, 2005). As described earlier in this chapter, microarray analysis of gene expression profiling is quite complex and technologically challenging. Each step in the analysis can potentially contribute to variability in the data. Depending on the microarray platforms employed (one channel vs. two channels, oligonucleotide vs. cDNA, in-house fabricated vs. commercially available), the same biological sample may yield different gene expression profiles. It is worth mentioning that significant refinement in microarray technology has taken place since its introduction in the mid-1990s and this has facilitated reasonably good concordance in microarray data obtained using different microarray platforms (Liew *et al.*,2006). Each step in the microarray analysis procedure, such as RNA isolation, reverse transcription and synthesis of labelled cRNA targets, hybridization and washing of chips, and acquisition and analysis of data, can contribute to variations in microarray data. Variability in the microarray data generated by different investigators can have implications in the ultimate utility of the microarray data generated. Therefore, it is necessary to take precautions or even to develop standards for conducting microarray experiments so as to minimize the variability associated with the technical aspects of microarray experiments. Similar to the guidelines recommended by MIAME (minimum information about microarray experiment) for documentation of microarray data (Brazma *et al.*, 2001), standards for conducting microarray experiments may be developed to minimize the variability associated with the microarray data generated in different laboratories.

Several studies have been conducted in the past to address the variability or comparability issue of microarray data. The Toxicogenomics Research Consortium (Bammler *et al.*, 2005) has identified some of the potential sources of variability in microarray data. In a study conducted by investigators of the Toxicogenomics Research Consortium, microarray data were generated by seven participating laboratories using two standard RNA samples and 12 microarray platforms. It was noticed that reproducibility for most microarray platforms was generally good when the data were generated by the same participating laboratory. Most of the variations were noticed when the data were generated by different laboratories. Reproducibility among the participating laboratories increased markedly when standardized procedures were implemented for RNA isolation, target labelling, microarray hybridization, data acquisition and processing. It was also noticed that the variability was least when the analysis was performed based on biological themes.

The contribution of biological variability in addition to technical issues associated with the quality of microarray data has been demonstrated by the results of a study conducted by the investigators from seven geographically dispersed research centres in the USA (Beyer *et al.*, 2007). Several precautions were taken in an attempt to avoid, or at least minimize, the variations in the data generated by the participating laboratories. The study involved microarray analysis of the gene expression profile of the liver of mice administered a toxic dose of acetaminophen. Even though administration of acetaminophen in mice was conducted independently in the participating laboratories, they all received mice, feed, bedding and acetaminophen from centralized sources. Furthermore, all participating laboratories were required to adhere to a standard protocol for treatment, treatment termination, specimen collection and processing. The specimens collected in the individual laboratories were sent to a centralized facility for measurement of endpoints [liver histology, serum alanine aminotransaminase (ALT) activity and liver gene expression profile]. Administration of acetaminophen, in general, resulted in hepatotoxicity as evidenced from histological changes (necrosis) in the liver and elevation of ALT activity in the blood of the mice. However, animal-to-animal variability was noticed with respect to the liver toxicity induced by acetaminophen, and this was more

prominent among the laboratories than within an individual laboratory. A corresponding variation in the number of significantly differentially expressed genes was noticed among the laboratories. The variability observed in gene expression profiles was significantly reduced when the differential gene expression data were anchored to the liver injury phenotype (the importance of anchoring differential gene expression profiles to toxicity phenotype is further discussed elsewhere in the chapter).

The Carcinogenicity Working Group of the Predictive Safety Testing Consortium, a collaboration between several pharmaceutical industries and the US Food and Drug Administration (FDA), has tested (Fielden *et al.*, 2008) two published hepatic gene expression signatures (Nie *et al.*, 2006;Fielden, Brennan and Gollub, 2007) developed to predict carcinogenic potential of chemicals in rats. The microarray data obtained from two short-term rat studies using over 150 compounds (carcinogenic and non-carcinogenic) were subjected to a meta-analysis for predicting carcinogenicity. It was found that despite significant differences in the study designs and microarray platforms employed in obtaining the data, the signatures proved to be relatively robust and more accurate than expected by chance (Fielden *et al.*,2008). However, a considerable loss (15–30%) in accuracy of the predictive signature was noticed when the signature generated by the individual laboratories was further validated. A loss of 15–30% accuracy is substantial and could result in false classification of a potentially carcinogenic chemical as non-carcinogenic or vice versa. The loss in accuracy of predictability was attributed mainly to the differences in experimental conditions, treatment protocols and microarray platforms employed.

The studies presented above unequivocally support the observation that variability is an integral part of microarray data. Furthermore, they have identified some of the potential sources such as technical issues and biological variation that are responsible for the variability observed. Standardization of procedures employed to obtain the microarray data and incorporation of biological themes (phenotypic anchoring) when analyzing the microarray data can significantly reduce variability in the microarray data generated by different investigators. Such improvements can result in more reliable and toxicologically relevant microarray data that can be used to determine the toxicity of chemicals including those to which significant human exposure may take place.

6.3 Biological Relevance of Transcriptomics Data

Another major challenge facing transcriptomics-based systems toxicology is determining the toxicological relevance of the transcriptomics data. Typically, microarray analysis of gene expression profiling may result in the identification of hundreds or even thousands of genes that are significantly differentially expressed in a biological system in response to its exposure to a toxic chemical. Some of these changes may be detected by chance and as such may have no toxicological relevance, whereas others may be related to the chemical-induced perturbation of the biological system and therefore are expected to be toxicologically relevant. What would be the criteria to determine whether a certain gene expression profile is toxicologically relevant or not? Toxicology research conducted over the past several decades has identified several cellular events that are considered reliable endpoints of toxicity. For example, exposure of a rat to hepatotoxic chemicals results in liver damage that can be detected by histological analysis of the tissue. The damaged liver cells in turn release enzymes, including transaminases, (aspartate and alanine transaminases) into the bloodstream, resulting in elevated serum levels of these enzymes. In general, a good correlation has been noticed between the serum level of transaminases and the liver damage or toxicity induced by hepatotoxic chemicals. In a similar way, it is possible to establish a relationship between differentially expressed genes and the established histological or biochemical markers of toxicity. This is commonly referred to as phenotypic anchoring (Paules, 2003; Powell *et al.*, 2006). Phenotypic anchoring is defined as establishing a correlation or relationship between the toxicogenomics (transcriptomics, proteomics and metabonomics) data and the toxicity phenotype as determined by traditional toxicity endpoints. As many experimental details as possible are required for the successful anchoring of a gene expression profile to a toxicity phenotype. For example, information regarding the dose of the chemical administered may suggest whether a

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat201
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

particular gene expression profile is an indicator of subtle toxicity or overt toxicity. Similarly, the time elapsed between exposure to the chemical and the determination of the expression profile may suggest whether a certain profile is a marker for early or late toxicity.

The importance of phenotypic anchoring in understanding the toxicological relevance of gene expression data is best illustrated in the case of hepatotoxicity. In a study by Heinloth *et al.* (2004), the prototypical hepatotoxic drug, acetaminophen, was administered in rats at doses of 0, 50, 150 and 1500 mg/kg b.w.. The control and the drug-administered rats were sacrificed at time intervals of 6, 24 and 48 h following administration of the chemical. Administration of acetaminophen at the selected doses and durations resulted in different grades of toxicity ranging from no toxicity (lower doses and early time points) to severe toxicity (higher doses and late time intervals) as revealed by the results of liver histopathology and blood clinical chemistry. Microarray analysis of the global gene expression profile in the liver resulted in the identification of a large number of differentially expressed genes in the acetaminophen-administered rats compared with the controls. Hierarchical clustering of the differentially expressed genes at any dose or time showed that there were clusters of genes similarly regulated at all three doses of the chemical, including the lower doses that did not result in any detectable change in liver histology or blood clinical chemistry. Bioinformatics analysis of the differentially expressed genes revealed that genes involved in energy-producing biochemical pathways were up-regulated whereas those involved in energy-consuming pathways were down-regulated in the acetaminophen-administered rats including those administered the lowest, non-toxic dose of the chemical. Biochemical analysis revealed significantly reduced ATP levels in the livers of the acetaminophen-administered rats compared with the controls, further supporting the microarray data. Similarly, Powell *et al.* (2006) have successfully anchored gene expression signatures in acetaminophen-administered rats to conventional biomarkers of oxidative stress. Thus, phenotypic anchoring has demonstrated the capability of a gene expression profile to detect and predict toxicity as well as to determine the mechanisms underlying the toxicity of chemicals. In addition, as discussed above, phenotypic anchoring of differentially expressed genes also demonstrated the superior sensitivity of gene expression profiles as indicators of toxicity compared with traditional toxicity endpoints.

6.4 Establishing Standards in Acquiring and Processing Transcriptomics Data

As described above, a major challenge facing transcriptomics-based toxicogenomics research is the difficulty in comparing data generated by different investigators. Although the contribution of factors such as biological variability of experimental samples in this regard is unavoidable, there are a number of factors, especially those related to acquiring and processing the transcriptomics data, that can be controlled so as to minimize the differences in the transcriptomics data generated by various investigators. For example, standardization of techniques such as isolation of RNA from biological samples, synthesis of labelled targets, microarray hybridization and washing, and microarray scanning to obtain gene expression signals may minimize the technical variability associated with transcriptomics data, facilitating better comparability of microarray data among investigators. Similarly, standardization of data analysis procedures may enhance the comparability of transcriptomics data obtained from different laboratories. Different investigators, for example, have adopted different criteria to select significantly differentially expressed genes. Although some investigators have applied correction for FDR (Bushel *et al.*, 2007; Huang *et al.*, 2008), others have not (Reilly *et al.*, 2001; Minami *et al.*, 2005). Differentially expressed genes have been selected solely on the basis of fold-change in expression (Reilly *et al.*, 2001; McHale *et al.*, 2007) or *p*-value (Huang *et al.*, 2008). There are also cases where a combination of fold change in expression and statistical significance of the data has been employed to select significantly differentially expressed genes (McHale *et al.*, 2007; Elferink *et al.*, 2008; Umbright *et al.*,2009). Thus, depending on the selection criteria employed (fold change in expression, statistical significance or a combination of both), considerable differences in the genes selected as significantly differentially expressed must be expected. This, in turn, may result in corresponding differences in the results obtained from further downstream analysis

of gene expression data such as determination of the involvement of specific pathways, networks and biological functions in the toxicity of the chemical being investigated. Thus, adopting standards for acquiring and analysing microarray data may reduce the variability in the data generated by different investigators, facilitating better comparison of the transcriptomics data. It is encouraging to notice that the standardization efforts by various groups such as the Microarray Quality Control Consortium and the Toxicogenomics Resource Consortium have resulted in considerable improvements in the reproducibility of transcriptomics data (Bammler *et al.*, 2005; Irizarry *et al.*, 2005; Larkin *et al.*, 2005; Shi *et al.*, 2006; Beyer *et al.*, 2007).

6.5 Translation of Transcriptomics Data from Experimental Models to Humans

Most of the toxicogenomics studies reported so far have employed cell cultures or experimental animals as models to derive microarray data relevant to the toxicity of chemicals. The ultimate goal of any toxicity study employing experimental models is to derive data that are relevant and applicable to situations of human exposure to chemicals resulting in potential toxicity. The role of confounding factors potentially capable of influencing the gene expression profile is more significant in the case of humans compared with the experimental models. Experimental models such as animals are relatively homogeneous in nature and factors such as species, strain, diet, exposure to other chemicals, etc. can be controlled in them to minimize the confounding effects of these factors on gene expression profile. In contrast, individuals who may be exposed to toxic chemicals present in the environment or the workplace are very heterogeneous in nature and may be subjected to a large number of confounding factors such as race, age, sex, life style factors and exposure to other chemicals that may potentially influence the gene expression profile. It needs to be thoroughly investigated whether toxicogenomics data derived from well-controlled experiments involving cell culture and animal models can be translated to highly variable situations of human exposure to toxic chemicals. In a recent study published by Bushel *et al.* (2007), a rat experiment was conducted to identify a discriminatory blood gene expression profile for hepatotoxicity induced by acetaminophen. The investigators were able to identify acetaminophen-overdosed patients from the controls by employing human orthologues for the rat discriminatory genes they had identified. Although this study has demonstrated the potential translation of transcriptomics data derived from experimental animals to humans under conditions of exposure to relatively large doses of acetaminophen capable of causing overt liver toxicity, it is not known whether the same can be applied to situations of human exposure to low concentrations of toxic chemicals present in the environment as well as the workplace.

1 DEVELOPMENT OF SYSTEMS BIOLOGY AND TOXICOGENOMIC APPROACHES TO STUDY EFFECTS OF CHEMICALS

The systems biology approach derives knowledge on biological functions from evaluating interactions among various parts of biological systems especially molecular and metabolic pathways. The emphasis on pathways and their interactions for understanding biological processes provides the differentiation from traditional approaches that concentrated on mostly understanding of function of an individual gene and/or protein. The development of systems biology was enabled by a wide application of microarray technologies capable of evaluating gene expression patterns (mRNA levels) encompassing the whole genome. Although gene expression changes of one or several genes have been analyzed before, the new aspect introduced with genomics and all other '-omics' methods was that all definable entities of an '-ome', corresponding to a certain class of molecules in biology were now studied globally. In a broader sense, protein expression and metabolite changes may also be considered as systems biology enablers.

Toxicogenomics encompasses the analysis of gene expression changes under the influence of chemical stressors/toxic compounds in a biological model. Fundamental assumptions of toxicogenomics are that all toxicological relevant effects are accompanied by gene expression changes (Farr and Dunn, 1999), and that similar toxicological mechanisms cause comparable expression changes, with potential exceptions being acute necrotic effects. From a technical point of view, toxicogenomics was possible because of the development of whole genome microarrays, which allow interrogation of the expression level of essentially all known genes and/or sequenced transcripts of a species of interest. Microarrays are available in different designs, yet a few major ones have eventually penetrated the market (Ahmed, 2006). Those microarrays based on oligonucleotides, either printed on a solid support, attached to beads, or synthesized *in situ* onto a wafer chip, seem to be preferred over printed cDNA arrays, probably caused by ease of production or reproducibility, although a comparison between these major microarray types have revealed high repeatability between and within platforms, and high correlation between microarray results and other quantitative gene expression measurements. Any discordance observed could be related back to differences in probe sequences. This examination had been conducted by the MicroArray Quality Control (MAQC) consortium, with participation by microarray platform providers, the US FDA National Center of Toxicological Research, and others (Guo *et al*., 2006; Shi *et al*., 2006). Also, a comparison of microarray platform results to those obtained by real-time polymerase chain reaction

(RT-PCR or Q-PCR) as well-known quantitative gene expression technology revealed high correlation for relative gene expression changes between the two methods thus validating the use of microarrays for gene expression analysis (Canales *et al*., 2006). In addition to MAQC, further public consortia have addressed issues, such as reproducibility of microarray results, standard practice for assays and analysis, relevance of microarray results to conventional end-points, and robustness of statistical models on diverse data sets and are formulating recommendations on these issues which are still developing especially those concerning data analysis (Mattes, 2008; Shi *et al*., 2008).

With respect to the amount of starting material, improved protocols and amplification methods have been developed which allow even small numbers of cells or pieces of tissue to be analyzed for their expression profiles. Defined tissue sections of interest isolated by laser-capture microdissection (LCM) were thereby successfully subjected to gene expression profile analysis (Caretti *et al*., 2008; Paul *et al*., 2008; Stemmer *et al*., 2009; Stemmer *et al*., 2006). Thus, highly standardized microarrays with reproducible performance and reasonable sensitivity are now available for toxicogenomic investigations of various biological models when standardized protocols are closely followed and the results are appropriately analyzed (Shi *et al*., 2008).

A toxicogenomic study in general has three major components (the biological model, the technological platform, and data analysis and interpretation) leading from application of a substance to a mechanistic explanation or hypothesis, to biomarker candidates, or to prediction of a potential toxicity. The choice of the biological model is crucial. It requires selection of an appropriate *in vitro* or *in vivo* model in relation to the issue to be investigated, rigorous standardization especially for *in vitro* models, and an optimized study design with respect to doses and time-points. In addition, it should allow correlating the expression profiles with conventional toxicological end-points or other emerging biomarkers which thus have to be measured in parallel. As described above, the technology is available, characterized by comparability of technical platforms when using data normalized to controls, by data quality and reproducibility, by highly standardized protocols, and by the possibility to validate the microarray results with independent methods (e.g. Q-PCR). After collection of all data, the challenge then lies in applying adequate analysis methods to identify truly deregulated genes versus noise or to reach a biological interpretation. Most challenging is still the use of such data for prediction of a certain mode of toxicity which is highly dependent on a well-populated reference database. These analysis issues will be dealt with the following paragraphs.

Toxicogenomics may be generally used in two areas of toxicology, that is, as mechanistic or predictive tool. Mechanistic toxicogenomics encompasses the assignment of functional categories to significantly deregulated genes in a biological model, and their relation to possible mechanisms of toxic action. This then leads to generation of mechanistic hypotheses, and may allow uncovering mechanistic similarities between different toxins. Predictive toxicogenomics, as just mentioned, relies on a database of expression profiles from samples represented by, for example, organs or cells following treatment with compounds of pre-defined toxic classes. Then marker genes are selected and classifiers are calculated by statistical or other algorithms to allow classification of unknown samples with respect to potential induction of these toxicity classes. These potential applications of toxicogenomics derive from considerations of the groups of genes likely deregulated following compound treatment (Figure 1): (i) if the compound is from research in a pharmaceutical company or otherwise has a specific receptor, genes related to the target of this compound will likely be changed, if the target is expressed in the tissue under investigation. These genes can help to increase the knowledge about the compound's pharmacodynamic action; (ii) if toxicity developed after compound treatment, genes related to the primary mechanism of toxicity will be deregulated. These can be employed for analysis of the affected pathways, to elucidate mechanisms of toxicity and thus to evaluate the human relevance of the toxicities observed in animal studies; (iii) genes related to the toxicity phenotype developing in response to primary injury will be found affected. These may be used as marker or signature genes for toxicity classification; and (iv) simply compound-specific genes with no specific relation to pharmacodynamics or toxicity have also to be expected. The genes likely best suited to serve as biomarkers for toxicity are those with a mechanistic basis of their deregulation.

Workflows for mechanistic and predictive toxicogenomics will be described in general. A mechanistic study starts with treatment of a biological

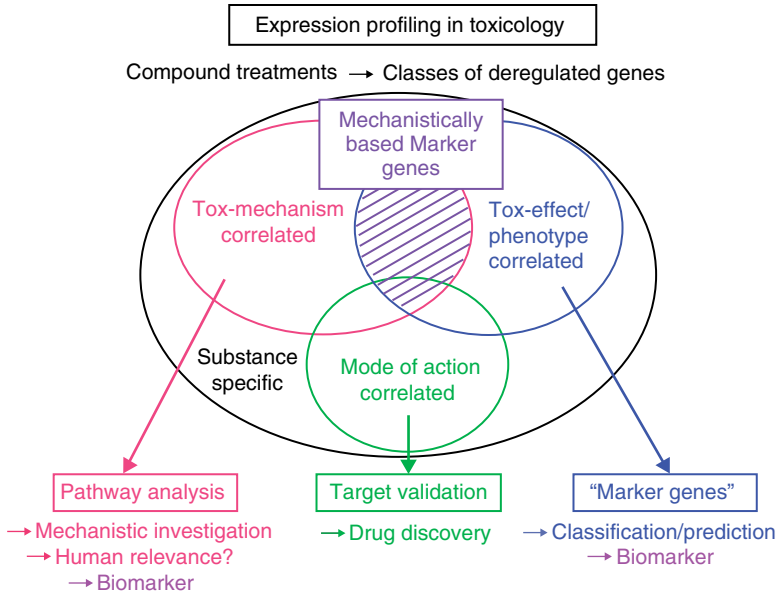

Figure 1. Expected classes of deregulated genes in toxicogenomics experiments.

model, for example, rats *in vivo*, with one or several compounds to be investigated and potentially model compounds, depending on the scientific question. Usually several time-points and/or doses are applied, with at least three, preferably five or more biological replicates per treatment group. In case of several time-points, time-matched controls treated with vehicles should be included. As mentioned above, classical end-points like clinical chemistry parameters and histopathological observations, and potentially other biomarker measurements should be planned for. Tissues to be processed for expression profiling should be frozen and stored appropriately. After obtaining the expression profiles on a certain platform, they should be subjected to rigorous quality control before being considered further.

The analysis (Figure 2) may begin with a principal components analysis (PCA) to obtain an overview of the data, for example, whether changes in gene expression can be seen upon treatment, whether these become altered during the duration of treatment, and whether there is variability between the replicates compared with differences between treatment groups. PCA is a classical means of dimensionality reduction and visualization of multivariate data. It involves a mathematical procedure that transforms a number of possibly correlated variables (here genes) into a smaller number of uncorrelated variables called principal components. The first principal component accounts for as much of the variability in the data as possible, and each succeeding component accounts for as much of the remaining variability as possible. Restriction to the first two or three principal components is often sufficient for capturing dominant structures of the data and uncovering important relationships between individual experiments or groups of experiments. Each sphere in a PCA represents the expression profile of one sample represented by values for the three first principal components, each corresponding to combinations of genes with similar expression patterns.

An important step is the selection of genes significantly deregulated between treated and control groups. The exact methods applied are dependent on the study design, the magnitude of the gene expression changes, and the variability between replicates estimated from, for example, a PCA. Suggested methods are parametric tests like *t*-tests between treated and control groups, or one-way analysis of variance (ANOVA) for the factors, such as dose and time. Non-parametric rank test may also be employed. These tests should be combined with an *n*-fold deregulation cutoff between the mean or median gene expression intensities of the treated and

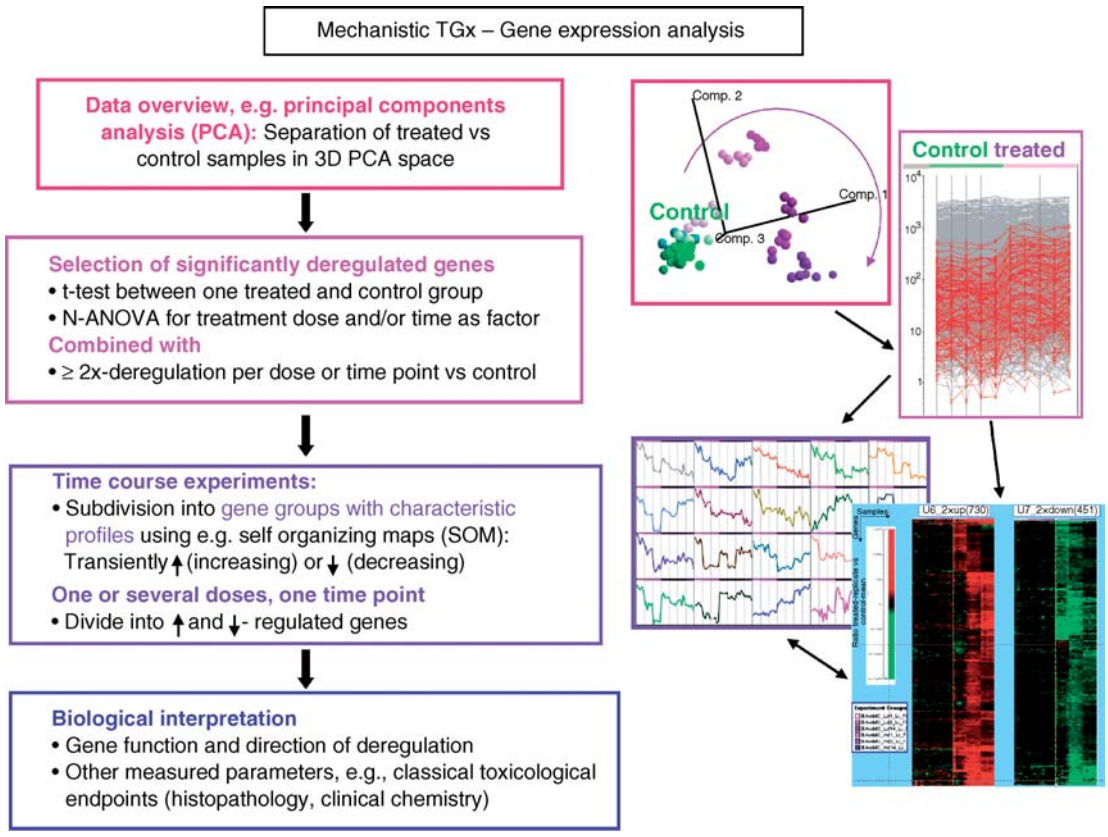

Figure 2. Gene expression analysis in mechanistic toxicogenomics.

control replicate groups (Shi *et al*., 2008). The cut-offs chosen for *P*- and *Q*-values should not be ≥ 0.01. Similarly, *n*-fold thresholds should be at least 1.5×, preferably 2×. Furthermore, depending on the microarray platform, low-level expressed genes may be excluded. One has to keep in mind that all these methods are approximations to the biology affected by a certain treatment and that by strict statistical criteria they may not be applicable because of relatively low number of replicates in comparison to the high number of variables (genes). Despite these limitations, experience has demonstrated that meaningful interpretations can be derived from carefully selected genes (Ellinger-Ziegelbauer *et al*., 2005; Blomme, Yang and Waring, 2009; Marin-Kuan *et al*., 2006).

To reach such interpretations from deregulated genes, it is advisable to subdivide them into groups with characteristic profiles in case of time–course experiments by applying clustering methods, such as self-organizing maps (SOM). If only one time-point is available, the genes should at least be subdivided into up- and down-regulated genes. Then, the main task is the interpretation of these genes in the context of their biological function within the organ or cell type under investigation, their direction of deregulation, information about their expression regulation, and observations from all other measured parameters. Pathway softwares and knowledge bases can provide help, but gene by gene interpretations in the context of the study specifics are likely required, using knowledge stored in public databases, such as Entrez Gene and Pubmed available at the Entrez website (http://www.ncbi.nlm.nih.gov/sites/gquery), or comparison with deregulation patterns available in experiments uploaded to public microarray databases like ArrayExpress, GEO or CEBS. Gene promoter analyses, if feasible, may also be applied. The result of a comprehensive interpretation of the deregulated genes can be a mechanistic hypothesis for an observed pathology induced by one or

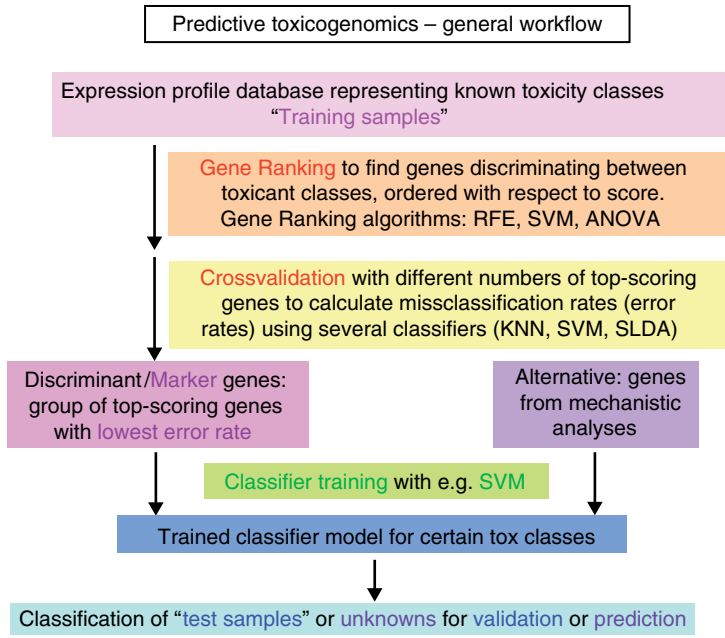

Figure 3. General workflow for predictive toxicogenomics.

a class of compounds, an estimation of the relevance of this pathology for humans, biomarker candidates characteristic of this pathology, or an idea for establishment of a screening assay to avoid this phenotype for further compound development.

Toxicogenomics may also be used in a "**predictive**" setting that aims to predict or classify a compound with respect to its potential toxicity or mode of action based on the expression profiles of a set of marker genes, also called gene signature. Reasons to engage in predictive toxicogenomics could be to have a tool for improved candidate selection with enhanced throughput, or to reduce the number of animal studies provided that the prediction allows replacing longer-term assays at least for compound ranking, or helps with Go/No Go decisions in compound development before longer-term animal studies are conducted. Before engaging in predictive toxicogenomics one should consider whether the classifier should be diagnostic or strictly predictive. The former would then allow classification of samples which already show the phenotype, which may be accomplished with organ gene expression profiles, but also with protein or metabolite signatures in non-invasive samples, whereas the latter would classify samples at lower dose or earlier than appearance of the toxicity to be predicted.

A general workflow to start a predictive toxicogenomic exercise is depicted on Figure 3. As introduced above, the core part is a well-populated database of expression profiles obtained from, for example, organs or cells after treatment of the respective biological model with compounds inducing the toxicity phenotype to be classified, and with a set of negative control compounds, representing the positive and negative compound class, respectively. More than one positive class may be defined (Kondo *et al*., 2009; Ellinger-Ziegelbauer *et al*., 2008; Natsoulis *et al*., 2005; Raghavan *et al*., 2005; Ruepp *et al*., 2005; Thomas *et al*., 2009). A prior mechanistic analysis of some of the model compounds can be helpful to characterize biological pathways participating in the toxicity to be classified, and to select optimal doses and timepoints. The profiles are then divided into a training set to be used for classifier calculation, and a test set to allow evaluation of the classifier for prediction accuracy parameters. One should bear in mind that a training class should represent at least 5–7 compounds, depending on the number of molecular mechanisms which can contribute to a certain toxicity phenotype. After definition of the positive and negative training classes, marker or signature genes may be selected by gene ranking with the goal to

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat202
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

find genes discriminating between toxicant classes, ordered with respect to a score indicating the contribution of that gene to discrimination of positive and negative training profiles. A variety of methods can be employed for gene ranking, for example, simple statistic tests, such as *t*-tests or ANOVA, or algorithm like recursive feature elimination (RFE) or support vector machine (SVM). In general, too few genes, despite potential great discriminating power, will not be enough to separate different compound classes well because they may not represent all characteristic expression profiles, whereas too many genes will add noise to a set of clear profiles. Therefore, the optimal set of genes is derived from the score-ordered, that is, ranked gene list by internal cross-validation with different numbers of top-scoring genes to calculate miss-classification rates (error rates) using several classifiers, for example, SVM, K-nearest neighbor (KNN), or sparse linear discriminant analysis (SLDA), among others. During cross-validation, the data are repeatedly split into two parts: one part is used to train the classification algorithm, and the other part to test it. Thus, the internally created test profiles are back-classified, which through iteration enables the calculation of a miss-classification rate. The marker gene set to go forward is then that group of top-scoring genes with the lowest error rate.

For the following classifier calculation, either a gene set derived by gene ranking or a group of genes obtained from a mechanistic analysis may be used. Any appropriate algorithm, for example, those used for cross-validation, may be applied to derive a classifier model from the marker expression profiles of the positive and negative training classes. For evaluation, the initially retained test set is subjected to classification with the model obtained with the training set. As the toxicity class for the test samples is known, true and false-positive and false-negative prediction rates, overall prediction accuracy and other parameters can be calculated. If these quality measures are deemed appropriate, the classifier can then be used to classify the expression profiles of unknown samples. It is important to understand that such a classification only indicates a likelihood or potential for a certain toxicity and should therefore be used for compound ranking, or compound flagging in case of a clearly positive signal to guide further development watching out for the predicted toxicity phenotype.

2 ASSESSMENT OF CANCER RISK ASSOCIATED WITH EXPOSURE TO CHEMICALS

Chemical carcinogenesis is a multi-step process featuring alteration of genome integrity detected as pivotal gene mutations and chromosome damage, malignant transformation of cells, and ultimately development of cancer after exposure to chemical agents. Because of the association between DNA damage and cancer development, the pre-clinical safety evaluation paradigm for drugs and chemicals consists of assessing their genotoxicity, for example, their potential to cause DNA damage, and carcinogenicity, the latter comprising the ability to produce tumors in animals upon long-term exposure (Figure 4).

The standard genotoxicity testing battery (Muller *et al*., 1999) consists of (i) a bacterial gene mutation assay, (ii) an *in vitro* mammalian mutation and/or chromosome damage assay, and (iii) an *in vivo* chromosome damage assay. The test battery allows for relatively simple, accurate and economical hazard identification associated with exposure to chemicals, namely potential to cause DNA damage resulting in mutations at the gene and chromosome levels. The potential of chemicals to induce tumors (carcinogenicity) in animals and to extrapolate cancer risk to humans is performed using the chronic 2-year bioassay in rats and mice developed at the NCI in the early 1960s (Weisburger, 1983). The protocol typically requires a life-time, 2-year exposure of mice and rats to three concentrations of tested agent, plus controls (Chhabra *et al*., 1990). Recently, the cancer susceptible transgenic mice models, such as p-53+/−, Hras2 and Tg.AC have been evaluated and considered as an alternative approach for the mouse bioassay (Bucher and Portier, 2004; MacDonald, 2004).

Because of the mechanistic associations of DNA damage and cancer, and the practical limitations of carcinogenicity assays, genotoxicity results have been used as a surrogate for carcinogenicity data, and in case of pharmaceuticals, are required for initiation of clinical trials. Carcinogenicity assessment for compounds negative in genotoxicity testing is typically required for marketing approval of pharmaceuticals (Jacobs and Jacobson-Kram, 2004). Although the link between DNA damage and cancer is well documented, the potential to predict the

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

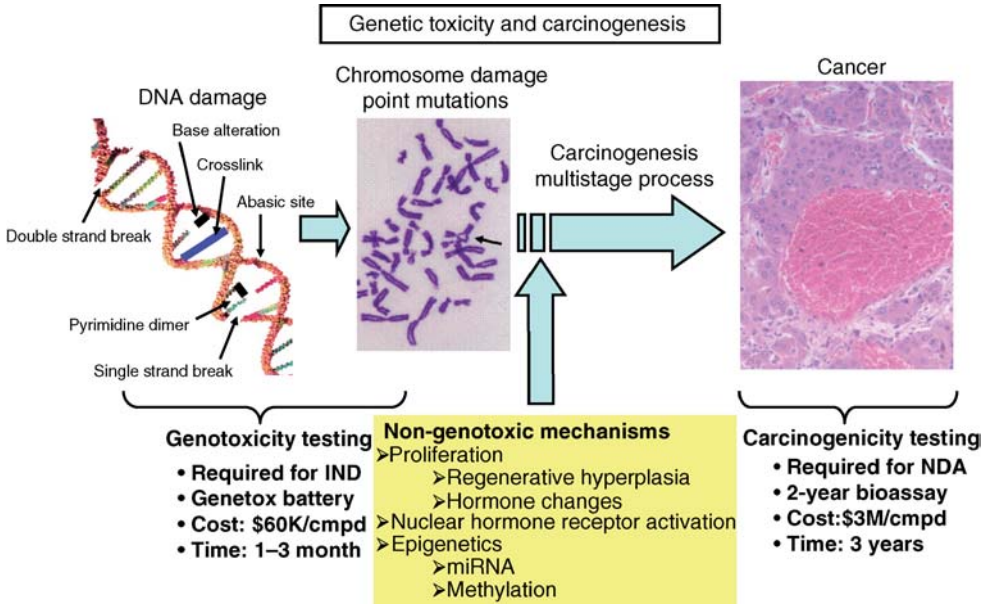

Figure 4. Genotoxicity and carcinogenicity testing. The standard genotoxicity testing allows for relatively simple and accurate detection of DNA damage caused by treatment with tested agents. However, carcinogenicity testing evaluates the potential to induce tumors in animals.

outcome of a carcinogenicity study using genotoxicity test data is rather imprecise. The most comprehensive analysis of genotoxicity and carcinogenesis data showed that the genotoxicity testing battery is highly sensitive for detection of carcinogens, detecting 93% of carcinogens. However, the testing paradigm features low specificity (Kirkland *et al*., 2006; Kirkland *et al*., 2005). This is supported by the fact that 50% non-carcinogens among marketed pharmaceuticals had some positive genotoxicity findings (Snyder and Green, 2001). The discrepancy is caused by limitations of genotoxicity end-points and assays, such as insufficiency of certain *in vitro* assays to model the *in vivo* target organ situation and the complexity of carcinogenic mechanisms. In case of carcinogenicity studies, the analysis of several databases showed that 50% of compounds tested positive in at least one species or sex (MacDonald, 2004; Hoffmann and Hartung, 2006). This high incidence and other research questioned the relevance for humans of tumors induced in rodents (Knight, Bailey and Balcombe, 2006; Ward, 2008). The International Life Sciences Institute (ILSI) Risk Science Institute (RSI) developed a framework to address this issue (Holsapple *et al*., 2006) which suggests that knowledge of key events and identification of a mode of action (MOA) in rodent bioassays provide a more rational basis for human cancer hazard and risk assessment. Therefore, the development of alternative short-term experimental approaches with better cancer-predictive potential at least partially including the investigation of MOA(s) is very important.

With respect to risk and relevance of positive findings of carcinogenicity studies, two basic mechanistically distinct subgroups called genotoxic and non-genotoxic carcinogens are discriminated (Bolt and Degen, 2004). In theory, a single mutation can initiate tumor development. Therefore, the risk associated with exposure to DNA-damaging compounds, genotoxic carcinogens, such as agents forming DNA adducts, is typically estimated using linear extrapolation methods. This implies that even low-exposure levels are associated with a certain cancer risk. In contrast, non-genotoxic carcinogens induce tumors via a variety of non-DNA-damaging mechanisms, such as affecting mitogenesis and regenerative processes, inhibition of apoptosis, modifying endocrine functions or immunosuppression (Williams, 2001). In this case, the cancer risk could be considered as non-linear, exhibiting a threshold dose. Thus, exposure levels that do not

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat202
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

trigger the above processes might be considered as cancer risk-free.

The classification of genotoxic and non-genotoxic carcinogenic mechanisms is a crucial component of cancer risk assessment for chemicals and drugs. However, investigating carcinogenic mechanisms represents an experimental and scientific challenge. The genotoxicity testing battery provides critical information on the ability of compounds to cause DNA damage in mainly *in vitro* cell systems yet the relevance of some findings to cancer risk has been questioned (Kirkland *et al*., 2006). There is substantial evidence that some genotoxic chemicals may exhibit a thresholded dose–response curve in the *in vitro* systems (Henderson, Albertini and Aardema, 2000). Mechanisms producing thresholded responses in genotoxicity assays can be characterized as DNA non-reactive, including inhibition of enzymes involved in protein and DNA synthesis or DNA repair, inhibition of Na/K transport, inhibition of topoisomerases, and inhibition of processes leading to an imbalance of DNA precursors, energy depletion, production of reactive oxygen species, lipid peroxidation, and nuclease release from lysosomes (Scott *et al*., 1991). To differentiate a true threshold dose–response curve from reaching an assay detection limit, the understanding of underlying mechanisms is critical (Kirkland and Muller, 2000) Currently, the mechanistic investigation requires lengthy experimental follow-up strategies with uncertain outcome, which for instance lead to significant delays in the introduction of new medicines to patients. Frequently, the assessment of genotoxicity is complemented with a variety of other genotoxicity assays and end-points. For instance, DNA adduct breakage detection assays, such as the Comet assay and micronucleus tests in various cell and tissue types *in vitro* and *in vivo* provide a "weight of evidence approach" (Anonymous, 2004; Dearfield and Moore, 2005; Thybaud *et al*., 2007). The fact that only one-third of marketed drugs found to be positive or equivocal for carcinogenicity were also positive for genotoxicity indicates the existence of a considerable number of non-genotoxic carcinogens. Thus, understanding underlying mechanisms, that is, differentiation of DNA-reactive versus DNA-non-reactive mechanisms, is essential for critical risk assessment of positive findings of both genotoxicity and carcinogenicity studies (MacDonald, 2004; Jacobs and Jacobson-Kram, 2004). Furthermore, the overall toxicological profile of a given compound including additional *in vitro* and/or *in vivo* studies in combination with an evaluation of the weight of evidence might be necessary for both positive and negative compounds in the genotoxicity testing battery (Thybaud *et al*., 2007; Kasper *et al*., 2007). This concept is also recognized by the current FDA guidance for industry (Anonymous, 2004). However, until now, no adequate surrogate test model for evaluating non-genotoxic carcinogenicity is available.

Despite an array of established *in vitro* and *in vivo* genotoxicity testing methods, gaining insights into genotoxic mechanisms with respect to the oncogenic potential of the test compound *in vivo* is often difficult. As broad mechanisms-based approaches are not available the development of experimental approaches enabling mechanism-based risk assessment is extremely important. This is not only true for pharmaceuticals, but may comprise all kinds of chemicals as also fully recognized by the EU REACH initiative (Combes, Barratt and Balls, 2006). In addition, such approaches, even if some of them would still employ animals, would help to contribute to the 3R concept because they will enable faster and more educated evaluation of the genotoxic and carcinogenic potential of chemicals using fewer animals. Also, *in vitro* tests for genotoxicity producing less false-positive findings will reduce the necessity of follow-up in *in vivo* models. The 3R concept, which is concerned with the reduction, refinement and replacement of animal studies, has become the scientific basis of institutions serving the development of alternatives to animal experiments (Spielmann, 2003).

3 TOXICOGENOMIC ANALYSIS OF THE STRESS RESPONSE TO GENOTOXINS AND CARCINOGENS *IN VITRO*

The response to stress turns on a complex network of molecular interactions including alteration of mRNA levels of various genes leading to activation or repression of pathways involved in repair, survival and/or cell death. Treatment of bacterial, yeast and mammalian cells using ionizing radiation and prototypical DNA-damaging agents led to identification of DNA-damage inducible genes. Those genes included ones involved in DNA repair,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat202

cell growth arrest, cellular signaling and apoptosis. Gene expression-based approaches employing single promoter–reporter biosensors sensitive to DNA damage in prokaryotic and mammalian cells have been utilized since the pre-genomic era for detection of genotoxicity (Aubrecht and Caba, 2005). Furthermore, arrays of such biosensors have been developed and proven useful for investigation of molecular mechanisms of toxicity (Aubrecht *et al*., 1999; Todd *et al*., 1995). The stress response to genotoxicants in mammalian cells is quite complex and involves hundreds to possibly thousands of gene expression modulations (Amundson *et al*., 2005; Burns and El-Deiry, 2003). The wide availability of cDNA and/or oligonucleotide microarrays has enabled studying underlying molecular networks of genotoxic mechanisms on a genomic level (reviewed in Aubrecht and Caba, 2005). As a technology, microarray applications in toxicogenomics have matured, for example, the MAQC project shows inter- and intra-platform reproducibility of gene expression measurements (Shi *et al*., 2006).

Historically, ionizing radiation that features simple and accurate dosimetry without complex uptake and metabolism as is the case for toxicants, has been used as a model treatment for studying the genotoxic stress response at gene expression level (Amundson *et al*., 2001; Amundson, Do and Fornace, 1999; Fornace *et al*., 1999). The cellular response to radiation includes cell-cycle arrest and apoptosis both triggered via the p53 pathway, and activation of MAPK cascades, NF-κB and the AP-1 transcription complex (Amundson, Bittner and Fornace, 2003; Liu *et al*., 1996; Snyder and Morgan, 2004). Individual data sets (gene expression profiles) obviously share common features. Exposure of cells to ionizing radiation typically results in the alteration of mRNA levels of genes involved in cell cycle (CDKN1A, GADD45, Cyclin E) apoptosis (BAX, BCL-XL), DNA repair (XPC, DDB2, GADD45) and many others believed to be involved in intracellular signaling pathways and various physiological processes (FOS/JUN, MDM2, FRA-1 IL-8, HSP70) (Amundson, Bittner and Fornace, 2003; Snyder and Morgan, 2004). Although a majority of the experiments has been performed with relatively high doses of radiation, significant gene expression changes were also reported at very low levels of exposure *in vitro* (Amundson, Do and Fornace, 1999). Expression patterns consisting of stress-response genes similar to *ex vivo* experiments were reported in humans after total body irradiation procedures (Amundson *et al*., 2004).

Other prototypical agents have been tested as well. For instance, gene expression changes elicited by the well-characterized DNA-damaging compound, cisplatin, were clearly distinguishable from the gene expression profile of non-steroidal anti-inflammatory agents (Burczynski *et al*., 2000). Genomic analysis of human fibroblasts treated with ionizing radiation, UV radiation, and the oxidative stress inducer, *tert*-butyl hydroperoxide, at equitoxic doses was used to illustrate the ability of toxicogenomics to differentiate individual agents (Heinloth *et al*., 2003). Agent-specific gene expression profiles have both common and distinct features, with ionizing radiation appearing to be more closely related to oxidative stress than to UV radiation (Todd *et al*., 1995; Heinloth *et al*., 2003).

Differentiating between DNA-reactive and DNA-non-reactive mechanisms of genotoxicity provides a crucial component of managing risk of compounds with positive findings in genotoxicity assays (Kirkland and Muller, 2000). The application of emerging toxicogenomics approaches in genetic toxicology has been extensively reviewed (Aubrecht and Caba, 2005). There is increasing evidence suggesting that the toxicogenomic analysis of genotoxic stress response could differentiate DNA-reactive and DNA-non-reactive mechanisms of genotoxicity including cytotoxicity in TK6 (Amundson *et al*., 2005; Islaih *et al*., 2004) and L5178Y cells (Dickinson *et al*., 2004; Hu *et al*., 2004). One of the most comprehensive studies to date evaluated stress-specific gene expression profiles of 13 DNA-damaging and cytotoxic (non-DNA-damaging) agents in p53-proficient TK6 cells and in the p53-deficient isogenic cell line (Amundson *et al*., 2005). This study provided stress-specific gene expression profiles that included a total of 1451 responsive genes. DNA-damaging treatments featured a strong involvement of p53-dependent pathway whereas no apparent p53-dependent response was elicited by the cytotoxic stresses (Amundson *et al*., 2005). As in case of ionizing radiation, reported data display considerable amount of variability mainly caused by differences in cell systems and treatment protocols. Interestingly, the gene expression profiles showed only a modest alteration of a relatively small number of DNA repair genes by DNA-reactive treatments where the majority of inducible genes mediate regulatory processes involved in cell-cycle

control, apoptosis, senescence, and inflammation. This is in line with the previous reports (Amundson and Fornace, 2003; Kastan and Bartek, 2004). A further extensive study similarly used TK6 cells to investigate the expression alterations after treatment with 14 anticancer drugs representing DNA-reactive and DNA-non-reactive *in vitro* genotoxins (Le Fevre *et al*., 2007). A molecular signature composed of 28 genes involved mainly in signal transduction and cell-cycle pathways allowed the classification of the drugs according to their mechanisms of action. Mitotic spindle inhibitors most clearly separated from the other compounds during expression profile clustering.

After treatment with DNA-reactive genotoxins, induction of typical p53-regulated genes, such as CDKN1A (p21) and GADD45A show an approximate linear dose response with no apparent threshold. In studies with cisplatin in a p53-deficient cell line, a linear relationship between the induction of gene expression of relevant genes (GADD45A, FOS) and DNA damage (adduct formation and DNA-protein cross-linking) was shown (Dickinson *et al*., 2004). When DNA adducts were measured and compared with gene expression changes following benzo[a]pyrene diol epoxide (BDPE) exposure of p53-proficient TK6 cells, DNA adducts are observed at lowest concentrations suggesting that assessing adduct formation is more sensitive at detecting genetic damage than measuring gene expression changes (Akerman *et al*., 2004). Although most stress responses are proportional to dose, unique responses at low doses have been demonstrated (Coleman *et al*., 2005).

Responses to DNA damage take place at the transcriptional, translational or molecular interaction level. As key components of the DNA repair machinery might be already present at the site of the DNA damage to counteract the effects of low-grade injury, it has been suggested that substantial DNA damage is required to invoke a global DNA damage response, which includes cell-cycle arrest, gene expression, etc. (Rouse and Jackson, 2002). This has to be taken into account with regard to experimental design, including dose setting and time-points. Biologically relevant stress genes that provide insights into the genotoxic mechanisms are immediate-early responding genes with robust changes in gene expression within several hours after treatment and prior to the onset of appreciable cytotoxicity (Amundson *et al*., 2005). Although it has been shown that transcriptional responses might be detected at sub-toxic levels, in order to avoid sensitivity issues of the analytical technology, selecting reasonable exposures that induce robust responses should be considered.

In addition to the mechanistic investigations of DNA-reactive vs. DNA-non-reactive genotoxins based on expression profiling *in vitro*, gene expression responses in cell lines to genotoxic versus non-genotoxic carcinogens have been reported. Preliminary results by Van Delft *et al*. on time-dependent gene expression deregulations upon exposure of HepG2 cells to benzo(a)pyrene, a genotoxic carcinogen, demonstrated up-regulation of phase I-metabolizing enzymes (CYP 1A1, CYP 1B1) within hours after exposure whereas responses by cell-cycling controlling genes (p53-responsive GADD45, CDKN1A) causing growth arrest, became apparent at 12–18 h after B(a)P challenging. Molecular pathways, capable of discriminating between genotoxic and non-genotoxic carcinogens in this *in vitro* model refer to apoptosis (van Delft *et al*., 2005) whereas the carcinogenic potential of polycyclic aromatic hydrocarbons (PAHs) appears related to their capability of modulating cholesterol biosynthesis and fatty acid synthesis, additionally to apoptosis (Staal *et al*., 2006) indicating considerable specificity of genomic responses because discrimination of carcinogens belonging to the same chemical class appeared feasible.

A further study used the rat hepatoma cell line MH1C1 to investigate carcinogens *in vitro*. When treated with the chemicals for 3 days at a non-toxic dose, analysis of gene expression changes allowed a set of genes to be identified differentiating carcinogens from non-carcinogens, encompassing 26 genes (Tsujimura *et al*., 2006). Gene clusters contained metabolism-related genes encoding transferases, oxidoreductases, hydrolases, and lyases as examples. Also, many genes that encode DNA-binding proteins related to translation and transcription were selected, and regulation of cell proliferation and signaling pathways appeared affected.

4 TOXICOGENOMICS ANALYSIS OF CARCINOGENIC MECHANISMS *IN VIVO*

The pathogenesis of neoplasia is a multistage process which consists of at least three operationally

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

defined stages beginning with initiation followed by a promotion and then a progression phase (Oberemm *et al*., 2009). Its full complexity can only be studied in an *in vivo* model representing all aspects of exposure and target organ biology. The fact that the gene expression profile analysis provides only a snapshot of molecular processes at the time the sample was collected has implications on experimental design in regard of time-points of analysis and dose. Recently, investigation of the gene expression profile over a 50-week time course after treatment of rats for 7 weeks with *N*-nitroso-morpholine, a genotoxic hepatocarcinogen, showed, that during the first 8 weeks the gene expression profile in the liver was characteristic of genotoxic carcinogens (Oberemm *et al*., 2009). Later on, very few genes were found to be deregulated in the non-dissected liver, which likely represent genes very strongly deregulated in the progressing cell clones. This suggests that an obvious time-point to measure early effects of different carcinogen classes in a whole tissue, by, for example, gene expression profiling, would be the time directly after start of exposure to a carcinogen, because at the earlier times the molecular responses to a particular compound may be similar in all cells, whereas later on the cells may respond differently because of having acquired different mutations, or because of the absence of any adverse mutations. With defined carcinogens applied at doses which later on should induce tumors, such an investigation may allow to define a set of molecular pathways, that when affected early on in a certain constellation may later lead to tumor development, permitting the prediction of a long-term end-point.

With regard to experimental design, evaluating dose–response relationships using one or few compounds may be seen as "vertical" investigations. However, examinations dealing with many compounds of a certain toxicant class dosed mainly at one level could be seen as "horizontal" ones. The former represent a fundamental concept in toxicology required in the later phase of risk assessment, whereas the latter, searching for mechanistic similarities between compounds inducing the same toxicity may be very helpful for hazard identification and characterization covering different mechanisms. The vast majority of the published studies so far could be described as horizontal investigations aiming for mechanistic interpretations.

The suitability of toxicogenomic analysis for investigating molecular mechanisms of carcinogenicity after application of carcinogens *in vivo* has been explored only recently. As the liver is considered a major target organ for rodent carcinogenicity, the published studies have focused mainly on investigating early responses to carcinogen and/or non-carcinogen exposure in the rat liver. Nakayama *et al*. (2006) treated rats for 28 days with four genotoxic rodent liver carcinogens and with their non-carcinogenic isomers, and found distinctive gene expression deregulations in the liver with the former, but not the latter. Kramer *et al*. (2004) treated male rats for 5 days at three dose levels with two genotoxic and five non-genotoxic rodent hepatocarcinogens, and two non-carcinogens and analyzed the liver expression profiles on cDNA arrays. They found that down-regulation of transforming growth factor-β-stimulated clone 22 (TSC-22) and up-regulation of NAD(P)H cytochrome P450 oxidoreductase (CYP-R) CYP-R correlated well with the estimated carcinogenic potential, which was based on the dose used in context with the previously reported carcinogenic potency. Yet only TSC-22 deregulation could be confirmed with Q-PCR. To unveil molecular mechanisms of non-genotoxic carcinogenesis, Nie *et al*. (2006) selected genes differentially expressed between livers of rats after 1-day treatment with 24 non-genotoxic carcinogens and 28 non-carcinogens. Half of the deregulated genes could be organized into five networks, all of which were linked to the proto-oncogene c-myc, whose activation by mutation or over-expression is known to initiate or promote tumor progression. The expression profiles of this study were also employed to select a gene signature for prediction of other profiles. In an even more extensive study, Fielden *et al*. derived a multigene biomarker for non-genotoxic hepatocarcinogens after treatment of rats with 100 non-genotoxic hepatocarcinogens and non-hepatocarcinogens. An understanding of potential modes of action for non-genotoxic hepatocarcinogenicity was possible by closer examination of this multigene marker profile in the context of hepatic tumorigens of known mechanisms (Fielden, Brennan and Gollub, 2007).

With respect to extrahepatic tissues, a combined transcriptomics and metabonomic analysis after treatment of mice for 13 weeks with a genotoxic and a non-genotoxic liver and lung carcinogen, two non-carcinogens and two vehicle

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

controls identified biomarkers which could discriminate between carcinogenic and non-carcinogenic treatments (Thomas *et al*., 2007) An extension of this investigation with further lung carcinogens and non-carcinogenic controls identified mainly genes involved in oxidative stress and/or detoxification responses as discriminating for lung carcinogens after 13 weeks of treatment (Thomas *et al*., 2009). Short-term effects of two renal carcinogens on the gene expression profiles in the rat kidney were examined in wild-type rats and Eker rats heterozygous for a dominant germline mutation in the tuberous sclerosis 2 (Tsc2) tumor suppressor gene after treatment with the genotoxic carcinogen aristolochic acid (AA) or the non-genotoxic carcinogen ochratoxin A (OTA) for up to 14 days (Stemmer *et al*., 2007). The response to AA was similar in both rat strains, representing as a DNA damage response and up-regulation of certain phase I and II genes. In contrast, OTA deregulated more genes in Eker than in wild-type rats, indicating a clearer demarcation of affected pathways, including oxidative stress responses and both pro- and anti-proliferative responses. Gene deregulations pointing to cell-structure remodeling and fibrotic changes were strongly affected in Eker, but essentially not affected in wild-type rats. With respect to different carcinogen classes, this latter study in rat kidney with just two carcinogens supported findings in the rat liver.

Ellinger-Ziegelbauer *et al*. (2005) reported about an effort to derive gene expression profiles that could discriminate between genotoxic and non-genotoxic carcinogens based on several members of each class. A functional analysis of the genes deregulated after short-term treatment of rats with genotoxic and non-genotoxic hepatocarcinogen revealed distinct gene expression profiles for the two classes of carcinogens. After short-term treatment of rats for up to 14 days with doses reported to induce liver tumors and which did induce other histopathological changes as expected for these compounds, the liver expression profiles were measured on RGU_34A microarrays (array express accession no. E-TOXM-16). Significantly deregulated genes were first extracted on a per compound basis and then functionally categorized with respect to carcinogen class (Ellinger-Ziegelbauer *et al*., 2005). Interpretation of these data suggested that DNA damage response and survival/proliferation signaling seems to be specific for genotoxic carcinogens, whereas responses to oxidative DNA or protein damage, or to general oxidative stress, and regeneration and cell-cycle progression are characteristic features of non-genotoxic carcinogens. The expression profiles of two of the characteristic gene groups clearly show (Figure 5) that a DNA damage response represented by the up-regulation of p53 target genes (p21, CCNG1, and possibly MGMT) is a response most strongly induced by the genotoxic carcinogens which is in line with their potential to cause direct DNA damage. The weaker up-regulation of these genes by the non-genotoxic carcinogens may be due to oxidative stress induction, because other oxidative stress responsive genes were also up-regulated by these compounds (Ellinger-Ziegelbauer *et al*., 2005), and because p53 can be activated by both, DNA damage and oxidative stress. In addition, this could also indicate secondary DNA damage upon ROS formation after treatment with non-genotoxic carcinogens, potentially indicated by the increased expression of apurinic/apyrimidinic endonuclease 1 APEX1 (Figure 5). The increased expression of genes involved in cell-cycle progression appears to be characteristic for the non-genotoxic carcinogens.

Thus, an in-depth mechanistic analysis revealed that characteristic expression signals do exist in rat liver which in short-term studies, may differentiate genotoxic from non-genotoxic carcinogens and which are based on well-defined functional gene categories that can be related to the generally accepted model of tumorigenesis, including initiation and promotion. For the former, a strong DNA damage response at the gene expression level suggested direct DNA modification in case of the genotoxic carcinogens, whereas gene expression responses to oxidative stress of different origin indicated possible secondary oxidative DNA damage in case of the non-genotoxic carcinogens. Early promotion may be assisted by enhanced expression of genes mediating survival or proliferation signaling by the genotoxic carcinogens, and by transient or delayed induction of genes involved in cell-cycle progression by the non-genotoxic carcinogens. This analysis also revealed that neither a single gene nor a single category will be sufficient for discrimination of genotoxic versus non-genotoxic carcinogens. Therefore, a systems biological approach may be necessary to analyze these complex data sets in a concise and integrated manner with emphasis on the pathways involved.

In a following study, these authors expanded the number of compounds and used supervised

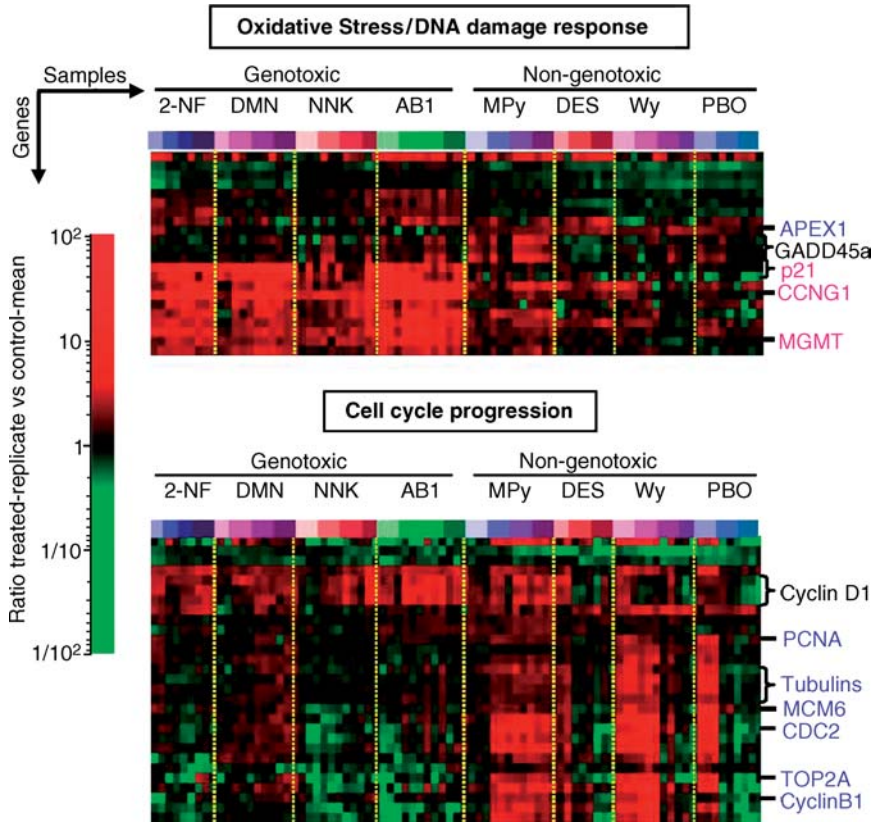

Figure 5. Deregulation of characteristic functional gene groups by genotoxic and non-genotoxic hepatocarcinogens. Two subgroups of the genes, representing an oxidative stress/DNA damage response and cell-cycle progression, originally selected to be significantly deregulated after treatment of rats with at least one of the carcinogens analyzed (indicated above each heatmap) were subjected to one-dimensional cluster analysis using Euclidian as distance metric. The heat maps show ratios of gene expression calculated by dividing the expression values in the single-treated replicate samples through the mean expression value of all corresponding time-matched control replicates. Red illustrates up-regulation and green represents down-regulation versus the control, as indicated by the color scale on the left. The color codes directly above the heat maps designate the different time-points per compound, representing d1, d3, and d7 for DES and PBO, and d1, d3, d7, and d14 for all other compounds. Shown on the right are examples of genes deregulated by genotoxic carcinogens (pink), by non-genotoxic carcinogens (blue), or by both types of carcinogens (black). APEX1, apurinic/apyrimidinic endonuclease 1; GADD45a, growth arrest and DNA-damage-inducible protein alpha; CCNG1, yclin G1; MGMT, O6-methylguanine-DNA methyltranferase; PCNA, proliferating cell nuclear antigen; MCM6, mini chromosome maintenance deficient 6; CDC2, cell division cycle 2 protein kinase; 2-NF, 2-nitrofluorene; DMN, dimethylnitrosamine; NNK, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone; AB1, aflatoxin B1; MPy, methapyrilene HCl; DES, diethylstilbestrol; Wy, Wy-14643; PBO, piperonylbutoxide.

learning algorithms to extract biomarkers discriminating genotoxic from non-genotoxic carcinogens and from non-carcinogens. These biomarkers were then used to classify further compounds with reasonable accuracy, thus strengthening the concept that toxicogenomics may also be used to predict a potential for hepatocarcinogenicity from short-term studies (Ellinger-Ziegelbauer *et al*., 2008).

Most of the studies mentioned above were "horizontal" investigations using several compounds at one dose level. Only few reports have been published with respect to evaluating dose–response relationships of gene expression changes induced by carcinogens. For instance, the gene expression profiles were correlated with the carcinogenic potency of a compound derived from the incidences of animals with liver tumors at a specific dose level, as known from the original 2-year bioassay (Kramer. *et al*., 2004). This aided in identification of correlating gene expression profiles. In another more detailed study, a method was established which allowed to calculate mean benchmark doses (BMD)

for individual cellular processes as revealed by the functions of the genes deregulated at certain dose levels (Thomas *et al*., 2007). The analysis was based on gene expression changes in the rat nasal epithelium flowing acute exposure to four concentrations of formaldehyde for 6 h, in a range previously shown to induce tumors. The described method could potentially aid in applying information from gene expression profile changes to risk assessment by revealing the molecular changes associated with chemical exposure and providing a possibility to identify reference doses at which particular cellular processes are altered.

5 CONCLUSIONS

The recent progress in technologies and molecular sciences has enabled interrogating complex networks of cellular pathways on genomic level in response to treatment with chemicals. The promise of toxicogenomics is to provide insights into the molecular action of different classes of toxicants via analyzing gene expression profiles. In this review, we focus on evaluating the potential of emerging toxicogenomic science to evaluate mechanisms of genotoxicity and carcinogenicity *in vitro* and *in vivo* test systems. Furthermore, we provide future directions and perspective on applicability of such approaches in hazard identification and risk assessment paradigms.

Although the published datasets *in vitro* and *in vivo* exhibit significant variability, common features emerge in respect of molecular pathways suggesting the need for a system toxicology approach for data analysis. The DNA damage-responsive p53 pathway is extensively activated both by DNA-reactive genotoxicants *in vitro* and genotoxic carcinogens *in vivo*, confirming and extending the molecular knowledge of what has been known before (Figure 6). The ability to detect triggering of relevant biological pathways in response to DNA damage in the *in vitro* assay systems and in animals *in vivo* provides opportunity for development of translational biomarkers for genotoxic carcinogenicity including examining relevant target tissues. With respect to other compound classes, called *in vitro*-defined DNA-non-reactive genotoxicants and *in vivo* non-genotoxic carcinogens, the published studies have shown the involvement of generic pathways in their mechanisms of action, such as general stress response, signaling and cell-cycle genes *in vitro*, or various oxidative stress response and cell-cycle genes *in vivo*. Yet given the current state of knowledge, there appears no direct *in vitro–in vivo* relationship as it seems to exist for the DNA-reactive genotoxicants and genotoxic carcinogens. Nevertheless, the data represent a first proof of concept that a distinction of DNA-reactive versus DNA-non-reactive genotoxins *in vitro* and genotoxic versus non-genotoxic carcinogens *in vivo* may be feasible via toxicogenomics.

Although promising, more work needs to be carried out in order to fully realize the potential and value of toxicogenomic analysis in genotoxicity and carcinogenicity testing. In order to apply toxicogenomics widely for differentiation of genotoxic and carcinogenic mechanisms, it will require evaluating large sets of agents representing a broad range of toxic effects. These investigations will help to better define carcinogen classes, and potentially subdivide especially the non-genotoxic carcinogen class into several subclasses based on mechanistic insight with clearer relation to the DNA-non-reactive genotoxicants. The fact that the gene expression profile analysis provides only a snapshot of molecular processes at the time the sample was collected appropriate study designs have to be developed for studies comparing large sets of compounds across mechanistic classes. The further development of bioinformatic and statistical methods will be necessary to refine pathways distinguishing DNA-reactive from DNA-non-reactive genotoxins *in vitro* and genotoxic from non-genotoxic carcinogens *in vivo*. As the *in vivo* studies were largely limited to liver, investigating other target organs for carcinogenicity including potential target cell populations from which the tumor(s) develop is important. Furthermore, the potential of other 'omics' technologies to explore transcriptional regulations (epigenetics, micro-RNA) as well as more downstream events (proteomics, metabolomics) for evaluating mechanisms of genotoxicity and carcinogenicity should be fully captured. Finally, in order to explore the potential of toxicogenomic analysis to provide translatable biomarkers of exposure and suitable for risk assessment, there is an obvious data gap in regard of dose–response and time–course relationships, which needs to be addressed.

Despite the limitations and data gaps, the published data clearly indicate the potential practical application of toxicogenomics as a tool for

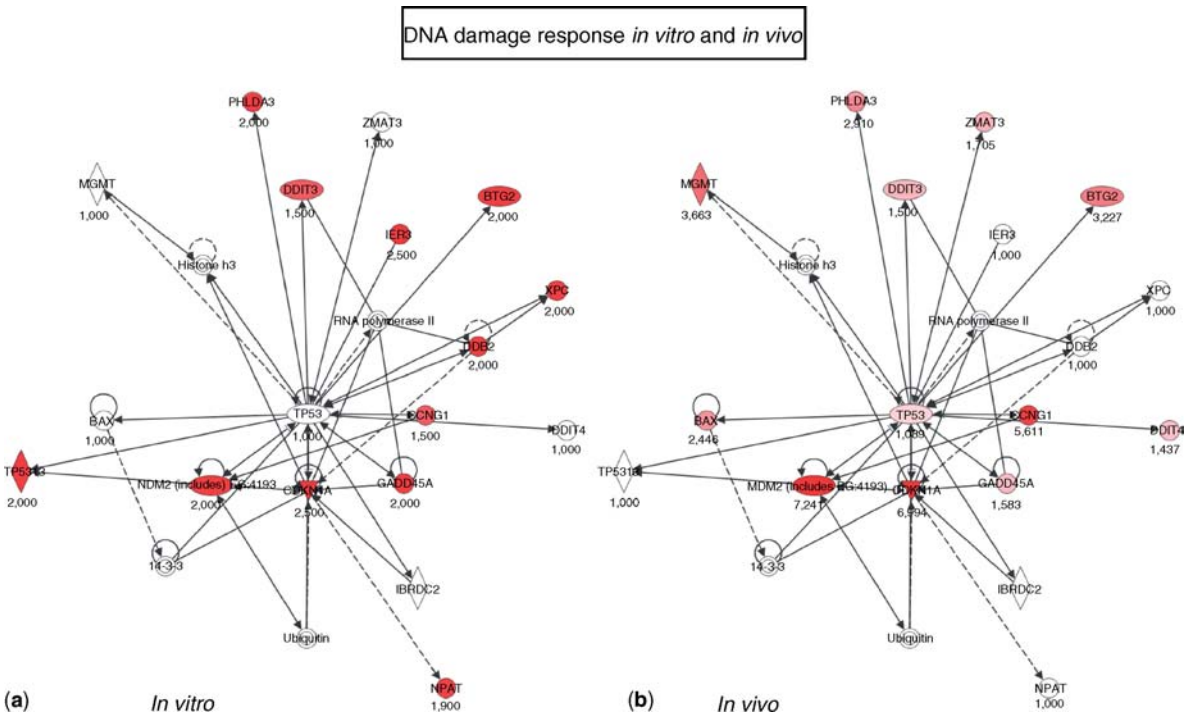

Figure 6. Common network of genes responsive to treatment with DNA-reactive agents *in vitro* (a) and genotoxic carcinogens *in vivo* (b). A network (Ingenuity pathway software) was generated from common DNA damage-responsive genes in the *in vitro* studies with DNA-damaging treatments (a) and in the rat livers after treatment with genotoxic hepatocarcinogens *in vivo*. The grey to black color is a qualitative indication of the extent of up-regulation observed on average in the *in vitro* (left) and *in vivo* (right) system. The *in vitro* data are an estimated qualitative mean of the expression data reported for human p53 wild-type cell lines (TK6, NH32) in response to genotoxic agents (Amundson *et al*., 2005; Islaih *et al*., 2004; Akerman *et al*., 2004) summarized in Aubrecht and Caba (2005). When induction was reported in all papers with deregulation factors >2, the induction factor for this qualitative figure was set at 2.5, when clear induction was reported in all papers, it was set to 2, and when induction was reported in some papers it was set to 1.5. The *in vivo* data are average gene expression deregulations for five genotoxic hepatocarcinogens as reported in the supplemental table of Ellinger-Ziegelbauer *et al*. (2008).

providing mechanistic context to results obtained with both genotoxicity and carcinogenicity assays. For instance, application of toxicogenomics to exclude DNA-reactive mechanisms for compounds positive in the *in vitro* chromosome damage assays would greatly facilitate risk assessment of these findings. This approach could be applied in the pre-clinical R&D phase of developing novel chemical entities for discriminating hazardous carcinogens. Moreover, gene expression profiling *in vivo* after short-term treatment has potential to further increase the confidence in DNA-non-reactive mechanisms for compounds with positive genotoxicity and/or carcinogenicity findings because in this model, actual responses to a compound in the target organ could be measured. As in most cases, compounds applied are pro-carcinogens which must be metabolized into an ultimate carcinogen *in vivo*, and whose metabolism cannot easily be reproduced *in vitro*, investigations of compound-dependent gene expression deregulations in several potential, metabolically highly active target organs may reveal whether the compound is metabolized to a genotoxic carcinogen in a particular organ, or even through the integrative action by several organs.

Toxicogenomics has a potential to significantly improve cancer risk assessment for drugs and environmental chemicals. The development of toxicogenomic approaches is challenging involving substantial resources and time. It requires designing of appropriate testing protocols and validation. Therefore, collaborative efforts that include scientists from academia, industry and regulatory agencies, such as the ILSI HESI Genomics

Effect of p53 Genotype on Gene Expression and DNA Adducts in ENU-Exposed Mice

Rohan Kulkarni,[1] Dayton M. Petibone,[1] Ching-Wei Chang,[2] James J. Chen,[2] William H. Tolleson,[3] William B. Melchior,[3] Mona I. Churchwell,[3] Frederick A. Beland[3] and Suzanne M. Morris[1]

1 INTRODUCTION

The potent mutagen, *N*-ethyl-N-nitrosourea (ENU), is a direct-acting alkylating agent with a well-characterized DNA adduct profile. ENU binds to nucleophilic oxygen atoms found in nucleotides, including O^6-guanine, O^2- and O^4-thymine, through an S_N1 mechanism. O^6-Ethyldeoxyguanosine (O^6-Et-dG) is formed at the highest frequency of the oxygen adducts and the mutagenicity and toxicity of this adduct are well characterized. O^6-Et-dG adducts, as well as O^4-ethyldeoxythymidine and O^2-ethyldeoxythymidine, result in base mispairing during DNA synthesis and the induction of transition mutations as determined by sequence analysis of ENU-induced mutants (Beranek, 1990).

O^6-Et-dG adducts are primarily repaired by the protein, O^6-methylguanine methyltransferase (Mgmt), that is encoded by the *Mgmt* gene in mice (Gerson, 2004). The ethyl group is transferred from the guanine of DNA to a cysteine residue on Mgmt, which then undergoes suicide inactivation. The results of both *in vivo* and *in vitro* experiments have led to the suggestion that the expression of *Mgmt* is under the regulatory control of p53 (Grombacher, Eichhorn and Kaina, 1998; Rafferty *et al*., 1996), which is encoded by the *Trp53* gene in mice. When mice lacking a functional *Trp53* gene were exposed to ionizing radiation (IR), which also induces *Mgmt* expression, hepatic *Mgmt* gene expression was not induced (Rafferty *et al*., 1996). In subsequent experiments with mouse fibroblasts and rat hepatoma cell lines, those lines lacking wild-type *p53* were unable to induce *Mgmt* expression (Grombacher, Eichhorn and Kaina, 1998). Furthermore, when *p53*-deficient mice, in which *Mgmt* was over-expressed, were exposed to *N*-methyl-*N*-nitrosourea (MNU), they were less susceptible to the tumourigenic properties of MNU than were p53-deficient mice (Reese, Allay and Gerson, 2001).

Although the role of Mgmt in the repair of O^6-alkylguanine is well documented, the expression kinetics of *Trp53*, *Mgmt* and other genes in the alkylation damage and repair pathways have

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat203
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

not been fully addressed. Thus, to provide additional insight into the relationship between DNA alkylation and genes regulated by p53, we conducted an *in vivo* kinetics study utilizing the p53 mutant mouse model (Donehower *et al*., 1992). $P53^{+/+}$, $p53^{+/-}$ and $p53^{-/-}$ TSG*p*53® mutant mice were exposed to ENU and sacrificed at 4 and 24 h after exposure. The livers were harvested for gene expression and DNA adduct analysis. The liver was selected because of the well-characterized mutagenic and carcinogenic effects of O^6-alkylguanine in that tissue (Major and Collier, 1998). O^6-Et-dG levels, which served as a biological dosimeter, were determined by high-performance liquid chromatography coupled with electrospray ionization tandem mass spectrometry (HPLC-ES-MS/MS). Expression levels of 84 p53-related genes, representative of the pathways under p53 control, were determined by the use of a quantitative PCR (qPCR) RT^2 p53-pathway targeted array® (SABiosciences, Frederick, MD, USA). As *Mgmt* was not present on the array, the levels of this gene were determined by hydrolysis probe Taqman® qPCR (Applied Biosystems Foster City, CA).

The levels of $p21^{(waf1)}$ expression were measured by Taqman® probes to confirm RT^2 array accuracy. In addition to determining changes in expression of individual genes, an analysis that focused on significant changes in the expression of defined gene clusters, grouped according to their cellular function in relation to *p*53, was performed.

2 MATERIALS AND METHODS

2.1 Animals and Animal Care

Male mice having $p53^{+/+}$*(p53N5-W)*, $p53^{+/-}$ (TSG*p53*®N5-T) and $p53^{-/-}$ (TSG*p53*®N5-N) genotypes were obtained from Taconic Farms (Germantown, NY, USA) at 4–6 weeks of age. The animals underwent quarantine and an acclimation period at the NCTR Animal Care Facility before the initiation of the experiment, at which time the animals ranged in age from 8 to 9 weeks. All mice were housed two per cage in standard polycarbonate mouse cages with bonnets and hardwood chip bedding. Millipore-filtered tap water and chow (NIH-31, Purina Rodent Chow, pellets) were provided ad libitum. The animal room was maintained at a temperature of $23 \pm 3\,^{\circ}C$, a relative humidity of $50 \pm 20\%$ and a 12-h light/dark cycle. The animal room received 10–15 air changes per hour. All procedures were approved by the NCTR Institutional Animal Care and Use Committee.

2.2 Chemical Exposure

N-Ethyl-N-nitrosourea (Sigma Aldrich Inc., St. Louis, Mo, purity > 99.1%) was diluted in phosphate-buffered saline (PBS; pH 6.0) such that each animal received a single dose of 150 mg kg^{-1} in no more than 0.1 ml of diluent interperitoneally (i.p.). Control animals were injected i.p. with 0.1 ml of PBS. Six mice from each p53 genotype were injected with 150 mg kg^{-1} of ENU, and six control mice from each genotype were injected with PBS. At 4 and 24 h after injection, three mice from each genotype from the ENU-exposed group and three mice from each genotype from the control group were sacrificed by CO_2 euthanasia. One animal from the wild-type group treated with ENU died after the chemical administration at 4 h and was subsequently removed from the analysis. The median lobe of the liver was placed in RNA*later* (Ambion, Austin, TX, USA) for RNA extraction; the remaining lobes of the liver were flash frozen in RNALater and stored at $-80\,^{\circ}C$ for subsequent analysis.

2.3 RNA Isolation and Reverse Transcription

Qiagen AllPrep DNA/RNA mini kits (Qiagen, Valencia, CA, USA) were used to extract total RNA from liver tissues stored in RNA*later* (Ambion). Approximately 30 mg tissue stored in RNA*later*, Ashville, NC solution was minced and homogenized by using a FastPrep FP120 homogenizer (Thermo, Savant, Ashville, NC) for 40 s in 600 μl lysis buffer (RLT buffer and 1% β-mercaptoethanol) in a lysing matrix D tube (MP Biomedical, Santa Ana, CA). The liver samples were kept on ice before and after the homogenization step. The homogenates were transferred to clean 1.5 ml tubes and centrifuged at 10 000 *g* for 3 min, and the supernatants were removed and placed in a second clean tube. An equal volume of 50% ethanol was added to the supernatants and mixed by pipetting. Total RNA and DNA were isolated according to the AllPrep kit (Qiagen) instructions and included treatment of the RNA with DNase I (Qiagen). From each sample,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat203
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

1.0 μg of RNA was reverse transcribed with random hexamer primers using the high-capacity cDNA Reverse Transcription Kit™ (Applied Biosystems) and the cDNAs produced were used without further purification as a template for qPCR.

2.4 Gene Expression Analysis

Gene expression profiles were constructed using the RT^2 profiler PCR array® mouse p53 signalling pathway (SABiosciences, Frederick, MD, USA). The reactions were performed using the Applied Biosystems 7500 Fast-Real Time PCR System. The results were analysed with the 7500 Fast System SDS Software. The $2^{-(\Delta\Delta Ct)}$ method (Livak and Schmittgen, 2001) was used to calculate the normalized C_t values:

$$2^{-(\text{GOIexp}-\text{RGexp})-(\text{GOIcntr}-\text{RGcntr})}$$

where GOI represents the C_t value for the gene of interest, RG represents the reference gene C_t value, exp represents the experimental ENU-treated animal and cntr represents the PBS-treated control animals.

2.5 Hydrolysis Probe qPCR

The levels of *Mgmt* and *p21^{Waf1}* mRNA transcripts in the livers of both the control and ENU-exposed mice were determined by real-time quantitative PCR. The qPCR utilized Taqman® primer and probes (Applied Biosystems) designed to detect *Mgmt* and *p21^{Waf1}* mRNA along with *Actb* and *Gapdh* internal reference gene mRNA. Reactions were performed in duplicate using a 7500 Fast-Real Time PCR System (Applied Biosystems). The cDNA samples were from the same cDNA reactions described above and used in the RT^2 SuperArray reactions.

2.6 DNA Adduct Analysis

Hepatic nuclei were prepared from the median lobe of the mouse livers. DNA was isolated from the nuclei, and the hepatic levels of O^6-et-dG were assessed by HPLC-ES-MS/MS (Churchwell, Beland FA and Doerge, 2006).

2.7 Statistical Methods

The gene set enrichment analysis (GSEA) statistical procedure was used to determine functionally related sets of genes that were expressed at different levels (enrichment and/or depletion) when compared among experimental groups (Mootha *et al*., 2003). The common approach to the GSEA is to generate a list of differentially expressed genes and then compare the number of genes in the list with the total number of genes in the set to determine the significance for an over-representation in the gene set (Draghici *et al*., 2003). A two-sided multivariate analysis of variance (MANOVA) method (Tsai and Chen, 2009) was used to identify which pathways were differentially expressed among the treatment groups, genotypes and two time points because the MANOVA method was found to perform better than the existing gene set analysis methods. In addition to gene set analysis, we also used two-way ANOVA with an interaction term for each gene to detect the main effect and interaction between time and genotypes. Changes in hepatic O^6-et-dG levels were assessed by ANOVA, using time and genotype as fixed factors.

3 RESULTS

3.1 RNA Quality Control

The purity and yield of the extracted total RNA and DNA for the adduct analysis were determined by measuring the absorbance at 260 and 280 nm using a NanoDrop (ThermoFisher, Waltham, MA), and the RNA integrity number (RIN) was determined with a Bioanalyzer 2100 (Agilent, Santa Clara, CA). RNA samples used in these experiments exhibited the ratio of 260/280 > 1.8 and RIN values ranging from 7.0 to 9.5, which indicated minimal degradation of the RNA.

3.2 O^6-Et-dG Levels

O^6-Et-dG was detected in DNA from the livers of each of the treated mice (Figure 1). At 4 h after exposure, the level of O^6-et-dG was not significantly different among the three genotypes of ENU-treated mice. At 24 h, O^6-et-dG levels were significantly reduced from those detected at 4 h in the livers of ENU-treated mice with the *p53$^{+/+}$* ($P < 0.05$)

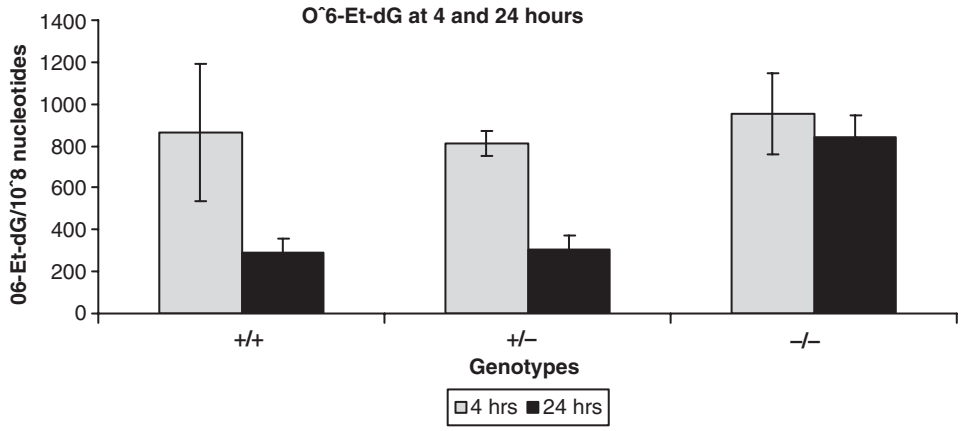

Figure 1. O^6-ethyldexoyguanosine levels in $p53^{+/+}$, $p53^{+/-}$ and $p53^{-/-}$ mice at 4 and 24 h post-ENU exposure. The DNA adduct, O^6-ethyldeoxyguanine (O^6-Et-dG), was detected in the livers from each of the treated mice. At 4 h after exposure, the level of O^6-et-dG was not significantly different among the three genotypes of mice. At 24 h, O^6-et-dG was detected in the liver DNA from each of the three genotypes. In contrast to the results at 4 h, a significant effect of genotype was detected. O^6-Et-dG levels in the $p53^{+/+}$ and $p53^{+/-}$ mice were significantly reduced from those found at 4 h in the livers of mice with the corresponding genotype. No significant difference in the level of O^6-et-dG between 4 and 24 h for mice with the $p53^{-/-}$ genotype was detected. Vertical bars represent mean of three animals and the standard error of the measurements.

and $p53^{+/-}$ ($P = 0.002$) genotypes. No significant difference was detected in the level of O^6-et-dG between 4 and 24 h for ENU-treated mice with the $p53^{-/-}$ genotype. The level of O^6-et-dG in control mice was equal to or less than 0.6 ± 0.1 adducts/10^8 nucleotides.

3.3 Mgmt Expression

Expression levels of *Mgmt* were analysed in livers of mice from each of the *p53* genotypes at 4 and 24 h post-ENU exposure (Figure 2). At 4 h, there were no significant changes in *Mgmt* levels among the different *p53* genotypes: $p53^{+/+}$ and $p53^{-/-}$ ($P = 0.09$), $p53^{+/+}$ and $p53^{+/-}$ ($P = 0.75$) and $p53^{+/-}$ and $p53^{-/-}$ ($P = 0.17$). However, at 24 h, *Mgmt* expression was up-regulated in the livers of the $p53^{+/+}$ (2.27-fold increase) and $p53^{+/-}$ (1.35-fold increase) mice. In mice with the $p53^{-/-}$ genotype, a 0.68-fold decrease was observed 24 h after ENU exposure. The *Mgmt* expression levels were significantly different among genotypes [$p53^{+/+}$ and $p53^{-/-}$ ($P = 0.001$), $p53^{+/+}$ and $p53^{+/-}$ ($P = 0.016$)] but not significantly different between $p53^{+/-}$ and $p53^{-/-}$ ($P = 0.06$; Table 1).

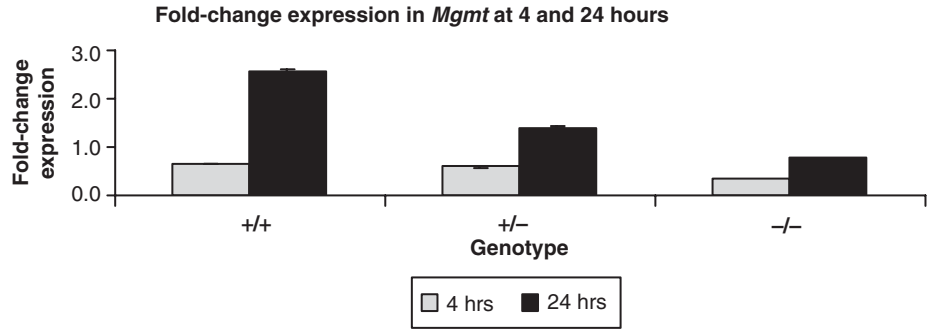

Figure 2. Changes in the expression levels of the *Mgmt* gene at 4 and 24 h post-ENU exposure in $p53^{+/+}$, $p53^{+/-}$ and $p53^{-/-}$ mice. At 4 h, no difference among genotypes in the expression of *Mgmt* gene was detected. In contrast, at 24 h, a 2.5-fold increase in *Mgmt* expression was found in mice with the $p53^{+/+}$ genotype. Fold changes of 1.25 and 0.8 were found in the $p53^{+/-}$ and $p53^{-/-}$ mice, respectively. Vertical bars represent mean of three animals and the standard error of the measurements.

3.4 p21^{Waf1} (Cdkn1a) Expression

The *p21*^{Waf1} (CDK-interacting protein 1; wild-type *p53*-activated fragment 1) gene encodes the *p21*^{Waf1} tumour suppressor protein, which promotes cell cycle arrest in the G_2/M phase. *P21*^{Waf1} expression was measured using a Taqman® assay to validate the expression changes observed using the Superarray pathway-specific plates (Figure 3). At 4 h, *p21*^{Waf1} mRNA levels from the ENU-exposed *p53*$^{+/+}$ and *p53*$^{+/-}$ mice were more than 100-fold greater than the levels detected in the unexposed mice. Exposure to ENU resulted in an increase of approximately 20-fold in *p21*^{Waf1} expression levels in *p53*$^{-/-}$ mice compared with the controls. Expression levels of *p21*^{Waf1} were similar for *p53*$^{+/+}$ and *p53*$^{+/-}$ genotypes ($P = 0.9$) but were significantly different when comparing *p53*$^{-/-}$ with *p53*$^{+/+}$ ($P = 0.02$) and *p53*$^{+/-}$ ($P = 0.01$). At 24 h, *p21*^{waf1} expression was reduced compared with the levels observed at 4 h in tissue for each genotype. Expression of *p21*^{Waf1} increased approximately 44-fold in the ENU-exposed *p53*$^{+/-}$ mouse and 57-fold in the ENU-exposed *p53*$^{+/+}$ mouse compared with their controls. In contrast, only a minimal increase was detected in the *p53*$^{-/-}$ mouse after ENU exposure compared with the controls. Expression levels of *p21*^{Waf1} were significantly different between *p53*$^{+/+}$ and *p53*$^{-/-}$ ($P = 0.002$), and *p53*$^{+/-}$ and *p53*$^{-/-}$ ($P = 0.008$) genotypes, but not between *p53*$^{+/+}$ and *p53*$^{+/-}$ ($P = 0.34$) genotypes at 24 h. These results are consistent with those obtained with the targeted arrays (see below; Table 2).

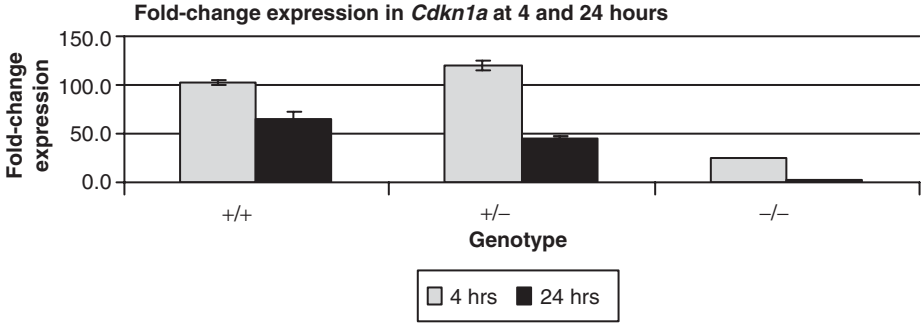

Figure 3. Changes in the expression levels of the *Cdkn1a* (*p21*^{Waf1}) at 4 and 24 h post-ENU exposure in *p53*$^{+/+}$, *p53*$^{+/-}$ and *p53*$^{-/-}$ mice. At 4 h, the expression of *Cdkn1a* (*p21/Waf1*) increased approximately 100-fold in the ENU-exposed *p53*$^{+/+}$ and *p53*$^{+/-}$ mice. In ENU-exposed *p53*$^{-/-}$ mice, the increase was approximately 25-fold. At 24 h, ENU exposure resulted in a 45- to 60-fold increase in expression in the mice with the *p53*$^{+/+}$ and *p53*$^{+/-}$ genotypes, respectively. In contrast, only a small increase of approximately 2.5-fold was detected in mice with the *p53*$^{-/-}$ genotype at 24 h. Vertical bars represent mean of three animals and the standard error of the measurements.

3.5 P53 Pathway-Specific qPCR Arrays

The effect of *p53* genotype on gene expression in the liver of mice at 4 and 24 h after exposure to ENU was determined using an 84-gene targeted array of genes known to be regulated by p53. The 84 genes were grouped into the following five major p53-regulated gene groups based on their listed gene ontology function: (i) apoptosis including induction of apoptosis, anti-apoptosis, regulation of apoptosis and genes related to apoptosis; (ii) cell cycle including cell cycle arrest, negative regulation of the cell cycle, regulation of the cell cycle and genes related to the cell cycle; (iii) cell growth, proliferation and differentiation; (iv) DNA repair; and (v) transcription factors.

3.5.1 Gene Expression Changes in the Wild-Type ($p53^{+/+}$) Mice 4 h after exposure to ENU

At 4 h post ENU exposure, 33 apoptosis genes were analysed for changes in expression as a result of ENU exposure. There were three genes involved in the induction of apoptosis (Table 3), where more than a fourfold increase in expression was observed: *Casp2* was up-regulated 71.74-fold, *Prkca*, *protein kinase C*, was up-regulated 13.59-fold, and the proapoptotic gene, *Pmaip* (Michalak *et al.*, 2008), was up-regulated 71.05-fold. The expression levels of three anti-apoptotic genes were investigated and an increase in expression was found only for *Bcl-2* (26.57-fold); *Birc5* and *Dapk1* had expression levels below the limit of detection. There were additionally seven genes related to or regulating apoptosis where a greater than fourfold increase in expression was observed as shown in Table 3. No genes involved in apoptosis were down-regulated in the liver of $p53^{+/+}$ mice.

Exposure to ENU increased the expression levels of five of the seven genes involved in cell cycle arrest. $P21^{Waf1}$ (*Cdkn1a*), *Cdkn2a*, *Chek1*, *Msh2* and *Sesn2* exhibited greater than fourfold increases in expression as did *Brca1*, which negatively regulate the cell cycle (Table 4). Ten of the 21 genes involved with or related to cell cycle regulation had greater than fourfold increases in expression, including *Brca2*, *Ccne2*, *E2f1*, *Jun*, *Sfn*, *Ccng1*, *Cdc25a*, *Cdc2a*, *Chek2* and *Mdm2*.

Of the genes analysed involved in regulating cell growth, proliferation and differentiation (Table 5), more than a fourfold change in up-regulation was displayed by seven genes: *Brca1*, *Cdkn1a*, *Pmaip1*, *Zmat3*, *Btg2*, *Egr1* and *Mdm2*. Three of the 14 genes regulated by p53 and involved in DNA repair were up-regulated greater than fourfold (Table 6), including *Msh2*, involved in base excision repair in response to O^6-Me-dG (Yoshioka, Yoshioka and Hsieh, 2006).

3.5.2 Gene Expression Changes in the Heterozygous ($p53^{+/-}$) Mice after 4 h ENU exposure

Only one apoptosis gene, *Tnfrsf10b*, a member of the tumour necrosis factor receptor superfamily (Table 3), was highly up-regulated (21.07-fold), whereas other gene, *Prkca*, involved in the induction of apoptosis was substantially down-regulated (0.26-fold). The apoptotic pathway of $p53^{+/-}$ mice was shown to be significantly different ($P = 0.011$) when compared with the $p53^{+/+}$ after ENU exposure. The following sub-groups, induction of apoptosis, genes related to apoptosis, negative regulation of the

[a]RNA could be obtained from only one animal for this data point.

cell cycle and genes related to the cell cycle were significantly different than wild type ($P < 0.05$; Table 7).

In the 34-gene cell cycle gene group (Table 4), the expression of three genes increased more than fourfold, including *Cdkn1a* (90.68-fold increase) and *Sesn2* (7.02-fold increase), both involved with cell cycle arrest. *Ccng1* was up-regulated 4.72-fold; that, along with *Mdm2*, regulates the negative feedback attenuating p53 activity through its degradation (Jensen *et al*., 2003; Kimura and Nojima, 2002). No genes were down-regulated more than fourfold. The group of genes analysed associated with the cell cycle in $p53^{+/-}$ mouse liver also showed statistically significant difference ($P = 0.006$) when compared with the $p53^{+/+}$ mouse liver (Table 7).

There were no significant changes in expression of the 18 cell growth, proliferation and differentiation group genes analysed except *Cdkn1a* (116.22-fold; Table 5). The functional group analyses revealed no differences in gene expression between wild-type and heterozygous genotypes ($P = 0.06$; Table 7).

The same was observed in the DNA repair gene group (Table 6): there were no genes with a fourfold or greater change in expression after ENU exposure.

BLD, below level of detection.
[a]RNA could be obtained from only one animal for this data point.

The expression levels of the functional group were not significantly different ($P = 0.16$) when either mutant genotype was compared with the wild type. No significant effect on the genes encoding for transcription factors was detected ($P = 0.19$; Table 7).

3.6 Gene expression changes in the null ($p53^{-/-}$) mice after 4 h

When the apoptosis-associated genes were analysed, *c-Myc* was up-regulated by 5.35-fold and *Prkca* was down-regulated by 0.19-fold. The expression of the apoptosis-associated gene group in $p53^{-/-}$ mice was significantly different ($P < 0.001$) when compared with the wild-type mice after ENU exposure (Table 7).

When the genes related to the cell cycle functional group were analysed, a 149.81-fold increase in expression of the cell cycle arrest-mediating *Cdkn1a* gene was accompanied by a 6.30-fold increase in expression of the oncogene c-*Jun* (Table 4). The expression of the cell cycle-associated gene group from $p53^{-/-}$ mice was significantly different ($P = 0.002$) from the wild-type mice (Table 7).

BLD, below level of detection.
[a]RNA could be obtained from only one animal for his data point.

In the cell growth, proliferation- and differentiation-associated gene group (Table 5) Cdkn1a (90.68-fold), c-*Myc* (5.35-fold), *Btg2* (4.32-fold) and c-*Jun* (2.78- fold) were all up-regulated. The expression of this gene group in the null mouse was significantly different ($P = 0.007$) from the wild type (Table 7).

No significant difference ($P = 0.2$) in the expression of the DNA repair gene group was found when the $p53^{-/-}$ mice were compared with the wild type (Table 7). The p53 pathway-related transcription factor gene c-*Jun* was up-regulated, as previously mentioned. Among the sub-groups induction of apoptosis, genes related to apoptosis, negative regulation of the cell cycle and genes related to the cell cycle were significantly different when the mutant genotype was compared with the wild type ($P < 0.05$). The sub-groups regulation of apoptosis (0.025), regulation of cell cycle (0.016), regulation of cell proliferation (p=0.048) and other genes related to cell growth, proliferation and differentiation ($P = 0.002$) were significantly different when compared among genotypes.

3.6.1 *Gene Expression Changes in the $p53^{+/+}$ Mice after 24 h ENU Exposure*

At 24 h, the only apoptosis-related gene (Table 3) that was up-regulated more than fourfold was *Tnfrsf10b* (21.35-fold increase); no genes were down-regulated more than fourfold compared with the controls. In the cell cycle-associated gene group, two genes were up-regulated more than fourfold (Table 4). These were *Cdkn1a*, which increased 60-fold, and *Ccng1*, which increased fourfold. None of the genes in the DNA repair and transcription factor gene groups were significantly changed except *Wt1* (21.35; Table 6).

3.6.2 *Gene Expression Changes in the $p53^{+/-}$ Mice after 24 h*

Of the apoptosis-associated genes, only *Tnfrsf10b* expression increased substantially (6.78-fold) after

BLD, below level of detection.

[a]RNA could be obtained from only one animal for this data point.

ENU exposure (Table 3). Two-way ANOVA of the apoptosis pathway did not reveal any significant differences in the expression of these genes in the $p53^{+/-}$ mouse ($P = 0.13$) compared with the $p53^{+/+}$ mouse 24 h post-ENU exposure (Table 7).

In the cell cycle group, *Cdkn1a* was up-regulated by approximately 39-fold and this change was accompanied by a fourfold change in *Ccng1* (Table 4). The expression of the group of genes regulating cell cycle was not significantly different ($P = 0.154$) from the level detected in mice with the $p53^{+/+}$ genotype (Table 7).

None of the cell growth genes analysed were differentially regulated greater than fourfold in $p53^{+/-}$ mice at 24 h post-ENU exposure except *Cdkn1a* (39.33-fold; Table 5). Expression profiles of the cell growth genes in the $p53^{+/-}$ mouse were not significantly different ($P = 0.4$) from the same gene group analysed in $p53^{+/+}$ mice (Table 7).

Analysis of the DNA repair gene group expression profiles did not reveal (Table 7) any statistically significant differences ($P = 0.13$) between the $p53^{+/-}$ and $p53^{+/+}$ mice. No sub-groups showed significant differences compared with the wild type ($P > 0.05$; Table 7).

3.6.3 Gene Expression Changes in the $p53^{-/-}$ Mice after 24 h ENU Exposure

No significant changes in the expression were detected in the apoptosis gene group analysed in $p53^{-/-}$ mice at 24 h post-ENU exposure (Table 3). The expression of the apoptosis pathway in the $p53^{-/-}$ mouse was significantly different ($P = 0.03$)

compared with the wild type after ENU exposure (Table 7).

No cell cycle genes were expressed at a level of greater than fourfold at 24 h post-ENU exposure (Table 4). The cell cycle gene expression profiles in the $p53^{-/-}$ mice were significantly different ($P = 0.03$) when compared with the cell cycle gene expression profiles in $p53^{+/+}$ (Table 7).

The cell growth, proliferation and differentiation genes did not show significant changes in their expression profiles (Table 5), but the gene group exhibited significant difference ($P = 0.03$) from the wild type (Table 7).

The DNA repair pathway analysed in the liver of $p53^{-/-}$ mice was significantly different ($P = 0.036$) compared with the wild type. Among the sub-groups, induction of apoptosis, regulation of apoptosis, cell cycle arrest, negative regulation of the cell cycle, other genes related to the cell cycle and regulation of cell proliferation, and differentiation showed significant differences compared with the wild type ($P < 0.05$; Table 7).

4 DISCUSSION

The tumour suppressor protein p53 is well known to function in the DNA damage response (Meek, 2009). Acting as a transcription factor, p53 regulates the activity of several DNA damage response pathways after exposure to a toxic agent. In this study, we sought to provide further insight into these responses by exposing TSG^{TM}*p53* mice with $p53^{+/+}$, $p53^{+/-}$ and $p53^{-/-}$ genotypes to the classic mutagen ENU and characterizing the *Trp*53 response with the use of targeted real-time qPCR expression arrays. In this study, we have found that, as expected, exposure to ENU resulted in the strong differential expression of genes that are important in establishing and regulating the cell cycle checkpoints in the $p53^{+/+}$ mice. Substantial increases in *p21* mRNA, which functions in the establishment of the G1/S and G2/M checkpoints, were detected at 4 h after exposure in the mice of each genotype. This was somewhat surprising because $p21^{Waf1}$ gene expression is activated by p53 and it was expected that proportionally lower levels of $p21^{Waf1}$ mRNA would be observed in the $p53^{+/-}$ and the $p53^{-/-}$ mice as a result of gene dosage. mRNA levels decreased in tissues from each of the genotypes by 24 h and the level was very low in the $p53^{-/-}$ mice. This suggests that in the early response to DNA damage, other transcription factors may be activating $p21^{Waf1}$, and that the activity declines over time. This concept is supported by studies (Moustakas and Kardassis, 1998) that demonstrate multiple alternate binding sites for the *p21* promoter (Abbas and Dutta, 2009; Macleod *et al*., 1995).

Other genes that contribute to the integrity of the damage-sensing response and the integrity of the checkpoints, *Cdkn2* (the p53-Arf pathway for damage sensing), *Chek 1* and *Chek 2* (important in the G2/M pathway), *Brca2*, *E2f1* and *Cdc25a*, were highly up-regulated in the $p53^{+/+}$ mice at 4 h after exposure, but not in the $p53^{+/-}$ or $p53^{-/-}$ mice. At 24 h, the expression level of each of these genes was not significant in the $p53^{+/+}$ mice liver, which suggests that the DNA damage processing was nearing completion and the cells could return to the cycle.

In addition to the cessation of the cell cycle, the effectors of apoptosis were up-regulated in the $p53^{+/+}$ mice as part of the early response to ENU exposure. *Pmaip1* (*Noxa*), *E2F1*, *Apaf-1*, *Brca1*, *Traf1* and *Tnfrs10b* (*DR5*, *Killer*) were each highly induced in the $p53^{+/+}$ mice. The increased expression of *E2F1* may relate to its role both in the control of cell proliferation through its interaction with *Rb* and in the signalling of cells into the mitochondrial-associated apoptosis pathways. *Pmaip1* (*Noxa*) codes for a BH_3-domain-only protein (Oda *et al*., 2000) which localizes to the mitochondria activating the release of cytochrome *c* from the mitochondrial membrane (Seo *et al*., 2003) and mitochondrial fragmentation (Woo *et al*., 2009). E2F1 up-regulates the transcription of the BH3-only proteins of the Bcl-2 family, including *Noxa*. Furthermore, E2F1 regulates the transcription of *Apaf-1* and an E2F1-binding site has been identified in the *Apaf-1* promoter (Furukawa *et al*., 2002). The up-regulation of this pathway may provide a link between the control of cell replication and apoptosis (Rogoff and Kowalik, 2004).

Also up-regulated in response to ENU were *Tnfrsf10b* (*DR5/Killer*) and *Traf-1*. DR4 and DR5 are membrane-bound receptors that bind ligands such as Trail and initiate apoptosis through the activation of caspase-8 (Srivastava, 2001; Wang, 2008). Traf-1 is an adapter protein in the TNF protein family and interacts with certain apoptotic effector proteins (Zapata and Reed, 2002).

Our results are consistent with the onset of apoptosis through a DNA damage-induced mitochondria-dependent pathway in the livers of the ENU-exposed $p53^{+/+}$ mice. However, a different pattern was observed in the $p53^{+/-}$ and $p53^{-/-}$ mice. With the exception of *DR5*, which was expressed in the $p53^{+/-}$ mice and functions in a p53-independent manner (Wang *et al*., 2008), ENU exposure did not increase the expression of these genes in the $p53^{+/-}$ or $p53^{-/-}$ mice. These results are consistent with other studies that indicate that apoptosis is compromised in cells that lack functional p53. At 24 h, there were a minimal number of genes that were differentially expressed in each genotype, which suggests that the apoptosis pathway was down-regulated in the $p53^{+/+}$ mice.

It should be noted that two genes with anti-apoptotic activity, *Bcl-2* and *Prkca*, were up-regulated at 4 h in the ENU-exposed $p53^{+/+}$ mice. This was surprising because Bcl-2/Bax ratios and the dimerization of Bcl-2 with itself or the heterodimerization of Bcl-2 with Bax lead to suppression of apoptosis. Furthermore, Prkca is also an inhibitor of apoptosis in that it phosphorylates the Bcl-2 homodimer, an event which actively suppresses apoptosis (Ruvolo *et al*., 1998; Villar *et al*., 2009). What this may suggest is that a delay exists in the down-regulation of the signalling pathways that inhibit apoptosis, providing time for the DNA damage processing pathways to function.

In this study, we measured the levels of O^6-et-dG as a marker for alkylation damage. However, it should be noted that alkyl DNA adducts can be repaired through several Mgmt-independent repair pathways. O^6-Et-dG is repaired through both the Mgmt pathway and the mismatch repair (MMR) pathway. At 4 h, the MMR gene, *Msh2*, was highly up-regulated in the $p53^{+/+}$ mice, but slightly repressed in the $p53^{+/-}$ and the $p53^{-/-}$ mice. The difference in expression between the genotypes may reflect the fact that *Msh2* is up-regulated by *E2F1* (La Thangue, 2005) which was also highly expressed in the $p53^{+/+}$, but not in the $p53^{+/-}$ or $p53^{-/-}$ mice. Increased expression of *Msh2* in the $p53^{+/+}$ mice was accompanied by a slight increase in the levels of the DNA repair genes (*Ercc1*, *Xrcc4*, *Xrcc5* and *Lig4*). At 24 h, *Msh2* mRNA levels were not differentially expressed in any of the genotypes.

In contrast to *Msh2*, no differential expression of *Mgmt* was detected at 4 h in the $p53^{+/+}$, $p53^{+/-}$ or $p53^{-/-}$ mice. This finding was accompanied by no significant difference in the level of O^6-et-dG at 4 h in any of the genotypes. However, at 24 h, *Mgmt* expression increased and the level of O^6-et-dG decreased in the $p53^{+/+}$ and $p53^{+/-}$, but no differences were observed in the $p53^{+/-}$ or $p53^{-/-}$ mice. These results are consistent with a model in which MMR is activated as part of the early response to ENU alkylation, but that the initiation of the repair of the major mutagenic adducts, O^6-Et-dG,

is delayed until after 4 h in the $p53^{+/+}$ mouse. A different pattern is observed for the $p53^{+/-}$ mouse. That is, MMR is not activated, as evidenced by the lack of increased expression of *Msh2* and the repair of O^6-et-dG is shifted solely to *Mgmt*. In the $p53^{-/-}$ mouse, neither pathway appears to be intact, which may be a major factor in the development of hepatocellular carcinoma after ENU exposure.

In conclusion, exposure to ENU results in the activation of the DNA damage response pathway. As part of the initial response, the DNA damage detection and response mechanisms are activated to insure that damaged cells are either removed from the tissue or not replicated. The cell cycle checkpoints, the apoptosis pathways and MMR are up-regulated and an integrated decision is made to repair or destroy cells with DNA damage. In liver cells with only one functional copy of *p53*, the apoptosis response and MMR are either absent or delayed and the integrity of DNA is dependent upon the activity of *Mgmt*. Loss of both alleles results in a compromised DNA damage response, and the level of DNA damage that remains at the later time point may reflect the initial steps in the formation of hepatocellular carcinoma.

It should be noted that these conclusions are based upon the responses based on the intact tissue. We recognize that individual cell types within the tissue may have an expression profile that differs from the average response. Experiments are planned in which the expression profiles for individual cell types can be developed

Application of Ecotoxicogenomics for Understanding Mode of Action of Chemicals and Species Extrapolation

Hajime Watanabe,[1] Yasuhiko Kato[2] and Taisen Iguchi[2]

[1]*Department of Biotechnology, Graduate School of Engineering, Osaka University, Osaka, Japan* and [2]*Okazaki Institute for Integrative Bioscience, National Institute for Basic Biology, National Institutes of Natural Sciences, and Department of Basic Biology, The Graduate University for Advanced Studies, Myodaiji, Okazaki, Japan*

1 ECOTOXICOGENOMICS

Toxicogenomics is a combination of toxicology and genomics (Lovett, 2000) and has been established as an important field in toxicology. It intends to understand and evaluate toxic effects of chemical substances on the genome of study organisms (genomics). Genomics is an omics technology and generally also includes transcriptomics, which analyzes the effects of chemicals on the transcriptome. Transcriptomics has been developed with DNA microarray technology (Schena *et al*., 1995), and typically toxicogenomics means the use of DNA microarray for toxicological purpose. Toxicogenomics was originally developed for the evaluation of chemical risks posed to humans and has been mainly developed by using cultured human cells, but also model animals such as rats and mice. This new field has been expected as a sensitive and predictive tool for evaluating the toxicity of chemicals.

Generally, hazardous effects of chemicals on organisms are results of abnormalities in certain tissues caused by differential gene expression triggered by chemical exposure. Thus, genomic approaches are expected to reflect changes that phenotypically occur at later stages and are therefore being used as a sensitive and predictive tool for the hazardous evaluation of chemicals. In addition, toxicogenomics has the potential to identify sensitive, so far unknown biomarkers that might have the potential to predict toxicity because a number of gene expression profiles can be examined without any prepossession.

One of the important points of toxicogenomics is that this technology can be applied to other organisms as well as model species, because the same strategy can be applied irrespective of species once their RNA can be obtained. There are often differences and species-specific arrays are being used. Toxicogenomics, which was originally based on human and model animals, is strongly supported by genomic information resources, such as gene annotation, gene function, biological response, and metabolism, combined with accumulated biological knowledge and observation. Therefore, observed changes in gene expression may also clarify the molecular mechanisms that lead to the hazardous effects of toxicants. However, genomic challenges in non-model organisms are still limited and are desired to expand. To evaluate the risk

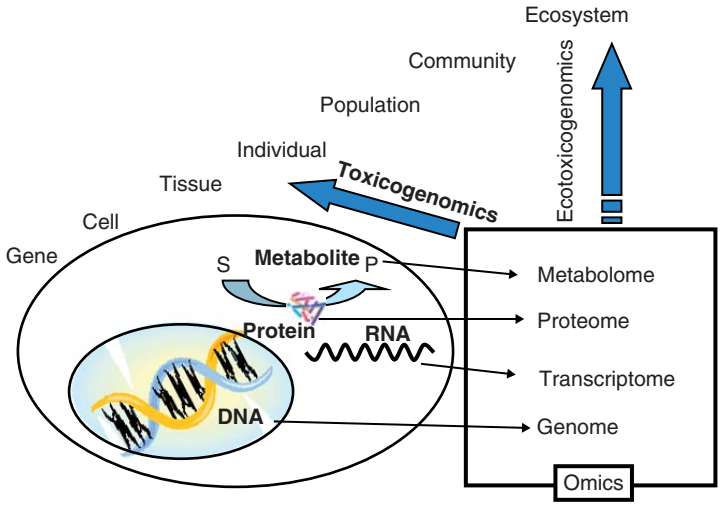

Figure 1. Scheme of -omics and ecotoxicogenomics.

of environmental chemicals to individual species and ecosystems and to understand their modes of action, the application of toxicogenomics has been expanded to organisms used in environmental studies and is named ecotoxicogenomices (Snape *et al*., 2004; Iguchi *et al*., 2006, 2007, 2008). Recently, many genomic challenges have been started in non-model organisms (Crump *et al*., 2002; Gracey and Cossins, 2003; Larkin *et al*., 2003; Williams *et al*., 2003; Volz *et al*., 2006). Limited genomic information is available for non-model species. The application of genomics to sentinel, non-model organisms that form an ecosystem is expected to determine the risk of chemicals that are suspected to be hazardous, on a scale ranging from individuals to ecosystems (Figure 1) and to contribute to the protection of ecosystems. So far, however, the advancement of ecotoxicogenomics is often limited by the lack of genomic information available for such species.

2 OVERVIEW OF CHEMICAL POLICY IN JAPAN

As for protecting human health from direct impacts of hazardous chemicals, there are several laws such as Labor Safety & Health Law for worker's safety, and Food Sanitation Law for consumer's health, and so on. Indirect impacts of chemicals on human health via the environment are covered by environmental legislations such as the Air Pollution Control Law, Waste Disposal Law, Water Pollution Control Law, and Chemical Substances Control Law (CSCL). CSCL has been amended in 2003 to also cover the risk management of chemicals to wildlife in the environment.

If a company that has a plan of initiating manufacturing and/or importing new chemicals of more than 1 t yr^{-1}, the company is required to notify the government in advance with data of the chemicals. In several specific cases such as intermediate chemicals for products, export-only chemicals, or chemicals whose amount of manufacture/import is less than 1 t yr^{-1}, notification of those new chemical substances is exempted. In such cases, the government verifies the cases and monitors by on-site inspection or reporting from enterprises. The government evaluates the chemicals by existing data, including the ones provided by the company. The evaluation is to check three properties (persistency, bioaccumulation, and toxicity either to humans or to living organisms) of the notified chemicals. Then, based on the evaluation result, the hazardous chemicals of concern are subject to regulation by classification into several categories according to their chemical properties.

Existing chemicals are mainly assessed by the government, and based on the test result, they may be subject to regulation as three types of monitoring

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

chemicals: persistency, bioaccumulation, and toxicity either for human life or for wildlife.

To protect wildlife, acute toxicity data have to be collected using three species including algae (*Pseudokirchneriella subcapitata*), crustacea (*Daphnia magna*) and fish (medaka, *Oryzias latipes*) for the registration of chemicals. These three species are consisted as a small food web because algae support the *Daphnia* and *Daphnia* support fish as foods. Acute toxicity data are not sufficient to understand the functional mechanism of chemicals, and therefore the establishment of ecotoxicogenomics methods for these three species is beneficial for future risk assessment and risk management of chemicals. As the beginning of our ecotoxicogenomics work, the medaka genome project had been completed and commercial microarrays for medaka were already available, and we therefore focused on *Daphnia* and algae.

3 EXPECTED OUTPUT OF ECOTOXICOGENOMICS

Ecotoxicogenomics has great advantages compared with conventional ecotoxiclogical approaches. To evaluate hazardous effects of chemicals on non-model organisms, conventional approaches could only give one parameter such as EC_{50} or LC_{50}. Although these parameters are valuable for the estimation of toxic concentrations, they are insufficient to characterize the toxicity of a compound because characteristic feature of chemicals cannot be obtained only from these concentrations. Even if two chemicals have the same EC_{50}, it does not mean the same properties in terms of toxicity at all.

Genomic approaches however give many parameters with gene annotations and these values are very useful to characterize chemicals. If two chemicals have similar effects on the expression of genes, one can expect that these two chemicals have similar effects in terms of toxicity. This advantage of genomics is also useful in ecotoxicogenomics, especially for small aquatic organisms, because pathological approaches that generally give important information in toxicity cannot be applied.

4 APPLICATION OF ECOTOXICOGENOMICS TO *DAPHNIA*

In order to apply toxicogenomic approaches to ecotoxicology, species selection is important. As a first step, species that satisfy the following criteria can be considered as good models for ecotoxicogenomics: (i) they are an important species in ecological networks, (ii) they can be easily sampled from the field, (iii) they can be cultivated in laboratories to allow controlled studies of chemical exposure, and (iv) their genetic background can be evaluated. The last two criteria are critical points for the selection of species because it is difficult to elucidate the cause of gene expression changes by comparing samples obtained from different field sites. Consistently, organisms that have huge genome sizes are also not appropriate for genomic approaches.

Table 1. Selection criteria of species for ecotoxicogenomics.

1. Easy to breed
2. High breeder (mature about 5 days after birth and lay eggs every 3 days)
3. Parthenogenesis (easy to obtain genetically clone individuals)
4. Translucent (easy to observe internal organs without dissection)
5. *In vitro* development is possible (developmental process can be observed under the microscope)
6. Database of chemical effects is available
7. ESTs and genome database are available
8. Need for the environmental risk assessment in the respective countries

Among many species in the environment, *Daphnia magna* is an organism that satisfies the criteria described above. In addition, *D. magna* has further advantages as indicated in Table 1. Therefore, *D. magna* is a suitable organism for the application of ecotoxicogenomics.

According to genetic information available, we have also obtained EST sequences of *D. magna* (Watanabe *et al*., 2005) and the genomic sequencing of the related *Daphnia*, *D. pulex*, is currently in progress (DGC: http://daphnia.cgb.indiana.edu/).

5 EXAMPLE OF *DAPHNIA* FOR ECOTOXICOGENIMICS

In order to study genome-wide gene expression profiles, we previously established a DNA microarray containing 10 K genes (Watanabe *et al*., 2007) (Figure 2). Several sets of oligonucleotide sequences were designed per one gene and one or two oligonucleotide sequences were selected. This microarray was used to analyze gene expression

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat204
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

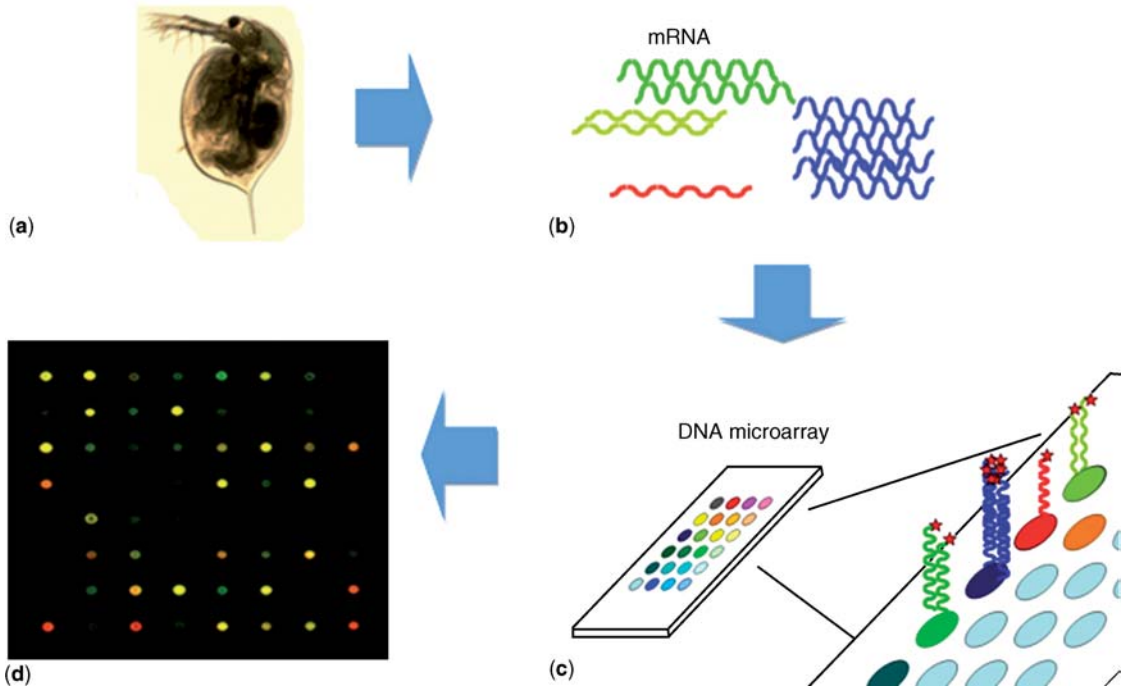

Figure 2. Experimental flow of ecotoxicogenomics. (a) Exposure of a chemical to *Daphnia magna* for 24 h; (b) extraction of RNA; (c) hybridization with array; (d) and scanning the hybridized spots.

changes in *Daphnia* following exposure to several chemicals (Watanabe *et al*., 2007, 2008; Connon *et al*., 2008). Figure 3 shows part of the result. Hierarchical clustering analysis showed that chemicals could be categorized into approximately groups, which indicates that some chemicals have similar effects on the organism. Before the application of the DNA microarray, it was impossible to categorize the chemicals in terms of their biological effects on aquatic organisms. Thus, the application of DNA microarray for the evaluation of biological effect caused by chemical exposure enabled us to understand chemical toxicity in biological terms.

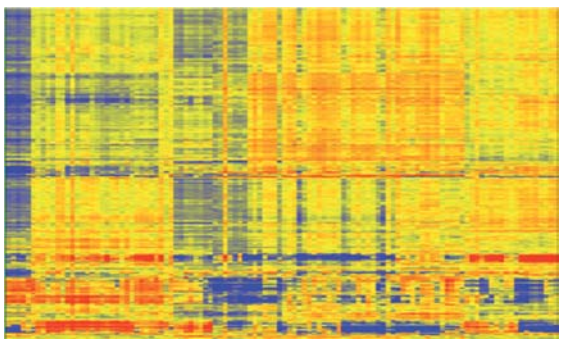

Figure 3. Hierarchical clustering of the gene expression pattern after chemical exposure. Chemicals were exposed to daphnia for 24 h and DNA microarray analysis was performed (Watanabe *et al*., 2007). Red and blue indicate activated and repressed gene, respectively. Each column corresponds to one DNA microarray analysis.

6 APPLICATION OF ECOTOXICOGENOMICS TO OTHER ORGANISMS

Ecotoxicogenomics approaches can be applied to a variety of other organisms in the environment as long as genetic information is available. For example, algae are suitable organisms for the application of ecotoxicogenomics. Similar to *Daphnids*, they can be easily maintained and exposed to chemicals and used for the Chemical Safety Law in Japan. Especially, a phytoplankton, *Pseudokirchneriella subcapitata*, has long been used in ecotoxicology and assigned as an organism for chemical toxicity

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat204
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

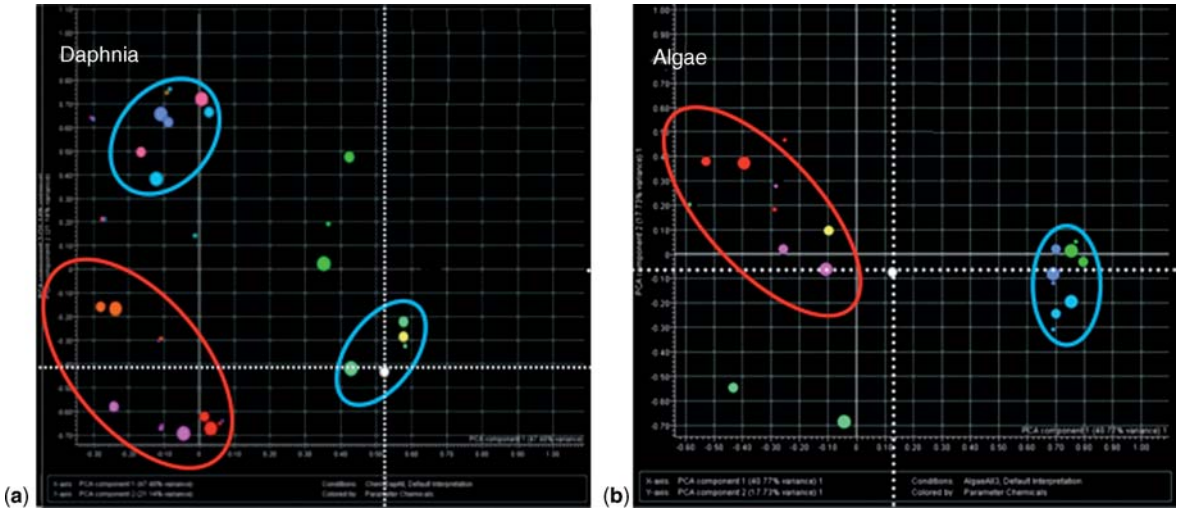

Figure 4. Principal component analyses (PCA) of gene expression changes after exposure of chemicals. After chemical exposure to *Daphnia* (a) or algae (b) for 24 h, gene expression changes were analyzed using DNA microarray. PCA was performed on differentially expressed genes. Two dimensions of the components are indicated. Four chemicals (different color dots) with three concentrations (same color dots) were used. Larger dots denote higher concentration.

testing in the Organization for Ecological Cooperation and Development (OECD). EST sequences were obtained from the cDNA library of *P. subcapitata* and an oligo microarray was designed based on the available sequence information (Watanabe *et al*., unpublished data). One of the advantages of genomic approach is that the same procedure can be applied after purifying RNA from organisms. Thus, hierarchical clustering and other analyses can be performed based on the gene expression profile of the algae and chemical effects can be grouped using the same chemicals for these two species. These groups can be presented in another way of analysis such as principal component analysis (PCA) as shown in Figure 4. These analyses showed that some chemicals (circled in red) have similar effects on both *Daphnia* and algae whereas other chemicals (circled in blue) have different effect on *Daphnia* and algae. By taking into account their gene annotations, it is expected to evaluate chemical effects on other species. Thus, once genomic information can be obtained, genomic approaches are useful to determine similarities and differences between chemical effects. These analyses indicate that genomic approaches can be effectively applied to organisms in the environment. Currently, we are integrating the microarray data of chemicals effects on three species: algae, *Daphnia* and medaka.

7 FUTURE PERSPECTIVES

If chemicals can be classified by their biological effects, this will be helpful for the prediction of hazardous effects of new chemicals. Accumulation of DNA microarray data will make it possible to determine whether chemicals of similar structure are causing the same biological effect. Quantitative linkage between chemical structure and biological effect will be useful for the prediction of chemical effects. Quantitative structure–activity relationship (QSAR) has been known to be a practical tool for the prediction of chemical toxicity. However, conventional QSAR did not consider biological effects of the chemicals and a wide variety of chemicals should be considered when extracting characteristic structures. Combination of biological effects and chemical structure may facilitate the classification and prediction of chemicals in terms of biological effects.

1 INTRODUCTION

Physiological and physical variations in humans are caused by single nucleotide polymorphisms [estimated at ~0.1% (Frazer *et al.*, 2007)], copy number variation [~0.7% (Henrichsen, Chaignat and Reymond, 2009)], and epigenomic influences (Bock *et al.*, 2008). The combination of these variations alters the metabolism of foods and the effect of food components on the expression of genetic makeup (rev. in Kaput, 2008; Kaput JaR, 2006; Kaput and Rodriguez, 2004; Vakili and Caudill, 2007). Although gene–nutrient or gene–environment interactions are complex and challenging to study, advances in experimental technologies for analyzing genomes, proteins, metabolites, and transcripts are allowing quantitative analyses of the relationships among genetic makeup, environment, and health outcomes (Corella *et al.*, 2009).

Current experimental designs, however, rely on assessing differences between cases and controls, or between groups who are exposed to a toxin versus those who are not exposed, or who consume some specified nutrient versus those who do not. Experimental designs that rely on the average response of individuals in one group or population versus another group or population yield the attributable fraction (AF) – "the proportional reduction in average disease risk over a specified time interval that would be achieved by eliminating the exposure of interest from the population" whereas other factors remain unchanged (Rockhill, Newman and Weinberg, 1998). The population attributable fraction specific for a population is frequently used by the commercial enterprises and the public as an individual risk factor (Vineis and Kriebel, 2006). As individuals may differ genetically, physiologically, and nutritionally from the population averages, the AF can only be considered an estimate of the risk for an individual. Although genetic association studies that include nutrient intake data explain more of the data (Corella *et al.*, 2009), the amount of phenotypic variation explained by the gene–nutrient interactions is small and may not apply to individuals

of different genetic or cultural backgrounds. Novel algorithms are being developed to use combinations of individual genetic profiles, population incidence rates of disease, genotype frequency, effect sizes for genetic variants, and models of joint effects among genetic variants on lifetime risk estimates to develop "personalized" risk factors (Yang *et al.*, 2009). However, the risk assessment result varied between 6 and 21% depending upon the assumptions in the calculations (Yang *et al.*, 2009).

Intervention studies also yield information for medical treatments or recommendations for nutritional intakes. Although nutrigenomic and nutritional intervention studies provide preliminary information about optimum diets (Kornman *et al.*, 2007), the small number of individuals in many of the studies and their undetermined genetic ancestry precludes using the information to predict responses in other individuals. The underlying reason for not being able to use information determined solely from genetic association studies is that many if not most genes interact with other genes (or their protein or mRNA products interact). Epistatic (gene–gene) interactions have been shown to alter the influence of individual SNPs on measured phenotypes (e.g., Tuo *et al.*, 2006; Mannila *et al.*, 2006; Hamon *et al.*, 2006; Adjers *et al.*, 2005; Helgadottir *et al.*, 2006; Smith *et al.*, 2008). These specific examples illustrate the need for developing new approaches to study the interaction of genetic makeup and environmental factors that include whole-genome analyses. We have previously described challenges to analyzing gene–nutrient interactions that include the genetic diversity of human populations, complexity of diets and cultures, the intricacies of physiological processes that depend on gene–environment interactions (Kaput *et al.*, 2007a; Kaput *et al.*, 2007b), and the need for new experimental designs that are not based on population studies (Kaput, 2008). These challenges are reviewed in the context of an emerging strategy for human population studies: the use of community-based participatory research methods that have great potential to provide the path for developing recommendations for improving personal and public health (McCabe-Sellers *et al.*, 2008). These new experimental designs are expected to generate more reliable data, but may also address health disparities that have continued to persist in developed and developing countries in spite of several decades of very competent basic science research (Hebert *et al.*, 2009).

2 GENETIC DIVERSITY OF HUMAN POPULATIONS

The promise of personalized healthcare was a natural consequence of the human genome (Venter *et al.*, 2001; Lander *et al.*, 2001) and the subsequent analyses of human genetic variation (Frazer *et al.*, 2007; Consortium, 2003; Consortium, 2004); http://hapmap.ncbi.nlm.nih.gov/). More recent studies have further characterized human populations in geographical or political areas of the world (Table 1) resulting in detailed maps of the genomic architecture of human populations. The Human Genome Diversity Project (http://www.stanford.edu/group/morrinst/hgdp.html) and Human Variome Project (HVP; http://www.variome.org/) are expanding analyses of sequence variations by including individuals in many other human populations. The newly initiated 1000 Genomes project (http://www.1000genomes.org), which is being organized by an international consortium, will employ genome-wide re-sequencing and targeted coding region sequencing in a total of approximately 1500 individuals from three human populations: Europeans, Africans, and Asians (Lang, 2008; Siva, 2008). Each of these populations will be represented by a number of subpopulations consisting of approximately 100 individuals including Yoruba in Ibadan, Nigeria; Japanese in Tokyo; Chinese in Beijing; Utah residents with ancestry from northern and western Europe; Toscani in Italy; and other populations to be determined. The goal of this international effort is to characterize alleles with frequencies of approximately 1% genome-wide and less than 1% in coding regions. Except for the HVP, the phenotype of individuals sequenced in these projects will not be analyzed. Hence, these data will be used for improving selection of reagents and designs for genome-wide association studies and will not be directly focused on identification of disease-causing genes or genes that interact with environmental factors. Resequencing of more genomes is now possible because new sequencing technologies are reducing the cost and increasing the throughput (Metzker, *in press*). Creating a more in-depth coverage of human genetic diversity is necessary for identifying causative SNPs or other genetic variation and to account for epistasis (see above and (Sankararaman *et al.*, 2008; Musani *et al.*, 2007)).

3 COMPLEXITY OF BIOLOGICAL PROCESSES IN DISEASE AND HEALTH

Health and disease processes result from a complex interaction among genes and environment, the result of which is that physiological processes produce variable responses and measurements (Kaput *et al.*, 2007a; Kaput *et al.*, 2007b) and others (Brown *et al.*, 2006; Wolford and Vozarova de Courten, 2004; Gardiner, 2004; van Ommen *et al.*, 2009). Such complexity results from the many genes and pathways that make small contributions to the overall phenotype, the epistatic (gene–gene) interactions that may alter the expression of an analyzed SNP, and epigenetic effects on gene expression caused by variable histone modifications and DNA methylation status. Dietary chemicals directly or indirectly affect or regulate many of these steps (Kaput JaR, 2006; Kaput and Rodriguez, 2004). For example, the substrates for epigenetic mechanisms are derived from the one-carbon metabolism pathway. Interactions exist between genes of the folate/methionine cycle and co-factors that are derived from the diet (Klerk *et al.*, 2002; Gellekink *et al.*, 2005; Rossell *et al.*, 2006; Picard *et al.*, 2004; Blander and Guarente, 2004; Hsiao, Deroo and Archer, 2002; Eberharter and Becker, 2002; Consortium, 2004; Porto *et al.*, 1998; Waterland and Jirtle, 2003). Changes in epigenetic regulation may occur throughout life, but fetuses and developing children may be particularly susceptible to unbalanced nutrition (Dolinoy *et al.*, 2006; Szyf, 2007; Szyf, 2009).

Genetic analyses, whether DNA resequencing or genotyping, coupled with "deep" phenotyping (Tracy, 2008) using proteomic (Kussmann, 2007), metabolomic (Gibney *et al.*, 2005), and transcriptomic (Garosi *et al.*, 2005) technologies, will generate detailed genetic and physiological data for each individual. The use of these technologies is likely to overcome the diversity of challenges of analyzing human genetic heterogeneity (Kaput *et al.*, 2007a; Kaput *et al.*, 2007b) in population-based study designs.

4 NUTRIENT ASSESSMENTS AND STUDY DESIGNS

As the "omic" technologies mature and individual genome data become increasingly available, a fundamental challenge for developing an understanding of complex biological processes is the difficulty in measuring food and nutrient intakes (Rutishauser, 2005; Tucker, 2007). Novel methods, such as photographs of before and after food servings (Kikunaga *et al.*, 2007) and omic analyses linking food exposure to defined biomarkers, may overcome these limitations (see below). A secondary, but no less important challenge is that many population-based studies measure biological complexity at a single point in time using a limited set of biomarkers (with the notable exception of longitudinal studies such as the Framingham Heart Study – http://www.nhlbi.nih.gov/about/framingham/).
These one-time point measures may or may not provide an accurate assessment of a given condition or biomarker, essentially because long-term changes in the nutrient, physical, immune, or psychological environment could alter biomarker levels observed at any single time-point.

5 DEVELOPING THE PATH TO PERSONALIZED HEALTH INTERVENTIONS

Two related concepts have emerged from analyses of the challenges for understanding health and disease and the research of the last quarter century: (i) analyses of genetic diversity between and within populations (see Table 1) demonstrates that it is not possible to have true genetic matches between cases and controls (Lu *et al.*, 2009); and (ii) the development of omics technologies may fundamentally change the design of human studies, particularly human intervention studies. Instead of pre-selecting or assigning individuals to a case or control group, these new technologies can be used to more completely genotype and phenotype an individual, and then sort individuals of like genotype–phenotype–environment exposure (including diet) into groups using dimensionality reduction or classification algorithms (Kaput, 2008; Kaput and Dawson, 2007). This strategy can be used in intervention studies when each individual is analyzed before and after an intervention or exposure to a xenobiotic (e.g., diet, drug), when individuals with the most different phenotypes are compared genetically such as post-menopausal and pre-menopausal breast cancer (Hall *et al.*, 1990), or when individuals can be selected based on variations within functional genes (and not just variants used for genetic mapping) and phenotypes can be compared subsequently. As the full spectra of human genetic and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat205
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

phenotypic variation has not been well characterized, the first groups tested would often be those most different in short-term interventions, in established phenotypes, or with the greatest differences in genetic makeups – that is, to determine the extent of the range of variation within the human population. The key aspect of this concept is that membership in the group at each extreme is based on some quantitative measure of phenotype or genotype. Once maximum differences among phenotypes or among genotypes are determined, groups between the extremes can be determined. Although many if not all biological traits are continuous with no discrete breaks in the phenotypic or genetic continuum, such "binning" is a standard for medical practice that uses clinical measurements to group individuals into treatment options and for statistics that rely on tertiles, quartiles, quintiles, etc., to determine structure within experimental data. This approach differs from standard population study designs in that the binning is performed prior to physiological analyses if the genetic variation is predetermined or prior to genetic analyses if different phenotypes are identified. Many human studies discern the groups after experimental data are acquired. A variation of this comparative strategy demonstrated its utility: Holmes *et al.* showed that individuals from different ethnic populations could be clustered based on urinary metabolite levels (Bernini *et al.*, 2009) and blood pressure measurements (Holmes *et al.*, 2008). Although genetic analyses (e.g., Jorde and Wooding, 2004; Tishkoff and Verrelli, 2003; Tishkoff and Kidd, 2004) have shown that variation is greater within ancestral populations (e.g., within Europe) compared with between populations (European versus Asian), the predominant "nutrient"-related alleles (i.e., genes involved in nutrient metabolism) in a population coupled with local cultural food availability and habits may explain the ability to cluster individuals into groups specific to an environment. Hence, creating bins of similar metabolic responses appears feasible.

6 TRANSLATIONAL AND COMMUNITY-BASED PARTICIPATORY RESEARCH

Developing this strategy requires novel approaches to extensively analyze individuals genetically and phenotypically over time to determine how the individual responds to their environment (or intervention). Translational research (Zerhouni, 2007; Zerhouni, 2006) of drug responses or medical treatments is one approach for pharmacogenomic research. That is, monitoring differences in individual responses to drugs for therapeutic use and adverse reaction due to genetic variation and these combined effects could explain decreased or increased burden of disease (e.g., Hosford *et al.*, 2004; Roses, 2000; Srivastava, 2003; Pirmohamed *et al.*, 2004; Holmes *et al.*, 2009).

An extension of the translational research model that may also be used to implement this comparative approach has historical roots in the 1940s but has been emerging from medical practice and from sociological/nutritional research efforts. Participatory research describes a continuum of similar but slightly different approaches (Cornwall and Jewkes, 1995). Some have termed these approaches as community-based participatory research (e.g., Horowitz *et al.*, 2008; Boyer *et al.*, 2005;O'Fallon, Tyson and Dearry, 2000; Israel, 2005), participatory action research, academic–community-based participatory research, or primary care research (e.g., Mold and Peterson, 2005; Beasley *et al.*, 2007; Hueston *et al.*, 2006). The slightly different wording indicates the degree of involvement of community residents in the phases of the research process. Community-based research occurs when the researcher brings the research proposal to the community and asks them to participate with no or little input or decision-making authority (Cornwall and Jewkes, 1995). A consultative approach adopts some of the input from the community members. Collaborative research occurs when the community and researchers work together to design and implement the study, but the overall process is managed by researchers. Many CBPR studies in the 2000s are modeled in this approach. The collegiate model occurs when all parties work together drawing upon different skills while mutual learning takes place but is led by the community members, not the researchers (Cornwall and Jewkes, 1995). Although CBPR has been gaining much interest in the social and nutritional sciences fields (Chen, Jones and Gelberg, 2006; Plumb *et al.*, 2008; see Table 2), relatively few studies have used this method for biomedical research (Boyer *et al.*, 2007; Wells *et al.*, 2006).

The collaborative CBPR method is a cyclic process whereby the participants provide information and biological samples on an ongoing basis, and the biomedical researcher provides existing knowledge

Somerville, MA	SUS (Shape Up Somerville)	African-Americans, European-Americans, Hispanic-Americans, Asian-Americans, and other	Determine whether BMI *z*-scores could be decreased among children in grades 1–3	Centers for Disease Control and Prevention, Blue Cross and Blue Shield of Massachusetts, Inc., Blue Cross and Blue Shield of Massachusetts HMO Blue, Inc., United Way of Massachusetts Bay, The United States Potato Board, Stonyfield Farm, Dole Food Company, Tufts University, City of Somerville, Control communities	(Economos *et al.*, 2007; Economos *et al.*, 2009)

as well as results from the ongoing study. However, CBPR does not mandate that all community members become "subjects or participants" in the research, but rather that they are involved in the design, implementation, analysis, and interpretation of the research. The collaborative CBPR model is best suited for biomedical research because of the expertise needed for the analytical procedures for analyzing parameters most relevant to the community, such as their unique dietary and environmental factors (McCabe-Sellers *et al.*, 2008). The community and biomedical partners continually inform each other as the research is conducted and applied. Collaborations are formed between and among the participants and the biomedical partners to design, implement, evaluate, and publish the research. This means that community members are not merely the objects of research but highly engaged in the research process (Ndirangu *et al.*, 2008). Unlike community-based research, CBPR requires a collaborative assessment with key informants and representation from across the community (Ndirangu *et al.*, 2007). CBPR is a slower process than the more traditional intervention research methods but has gained in momentum because developing trusting relationships and enhancing empowerment or ownership promises to be a more sustainable and therefore more effective approach to promoting health through behavioral changes (Israel *et al.*, 1998; Israel *et al.*, 2003; Kone *et al.*, 2000). The goal of CBPR is to build knowledge and understanding of health research for the community and individual and to relay the knowledge attained into action-oriented interventions through behavioral and policy change and to improve quality of life and public health for community members (O'Fallon, Tyson and Dearry, 2000). CBPR is a general approach to the practice of public health and research concerning the social and environmental determinants of health (Ali, Olden and Xu, 2008). We previously described all aspects of developing a CBPR partnership using the 12-year history of the USDA–Delta NIRI research program (McCabe-Sellers *et al.*, 2008).

7 APPLICATIONS TO PERSONALIZING RESEARCH FOR PERSONAL HEALTHCARE

The concept of using CBPR methods for biomedical research is that the participants participate in the research activities from assisting in the planning to helping in the recruitment of other community members. The research can become "personalized" because one individual is assessed and informed. The applications are therefore more immediate than population-based methods and targeted to the community and individual. The development of relationships among researcher and community is challenging but of critical importance for those who have typically been excluded from research studies or those who suffer from culturally based health disparities (Chen, Jones and Gelberg, 2006; Plumb *et al.*, 2008; Boyer *et al.*, 2007; Wells *et al.*, 2006). Most importantly, individuals in socio-economically disadvantaged populations will not benefit from the advances in health research unless their genotypes and cultural environments are included in biomedical research studies. As

genetic and omic data developed from population studies cannot yet be reliably associated with health outcomes in individuals, the initial information flows between researcher and community collaborator focused on nutritional assessments and dietary advice. As more gene–nutrient or omic–nutrient associations are proven, the information flow will include more biomedical data and results.

8 CONCLUSIONS

The challenges to developing personalized nutrition and medicine applications are the genetic diversity of human populations, complexity of diets and cultures, nutrient variation within the food supply, and the intricacies of physiology dependent on gene–nutrient interactions that differ among individuals. Developing novel strategies to address, account, and analyze these variables is a major challenge for the biomedical research community (Kaput, 2008). Importantly, the traditional nutritional or genetic population-based designs identify risk factors that may not necessarily apply to the individual. An approach to reach the goal of personalizing healthcare is to identify groups within populations with similar metabolic profiles based on similar genetic profiles. Identifying these groups *after* characterizing them with omic technologies (i.e., deep phenotyping) may yield an understanding of the full range of genetic and phenotypic variation in the human population. Community-based participatory research and primary care research provides a path to that goal. Although any one community or primary care facility will not encompass the full range of genetic makeups or phenotypes, replicating this approach in populations throughout the world and using harmonized study designs will allow for combined and comparative data analyses.

ACKNOWLEDGEMENTS

We are indebted to members of the Lower Mississippi Delta communities who collaborate with us. This research is supported in part by USDA, ARS# 6251-53000-004-00D, and the FDA National Center for Toxicological Research, Division of Personalized Nutrition and Medicine.

Role of the Endocannabinoid System in Systems Toxicity

Constantinos Pistos and Stamatios Theocharis

Department of Forensic Medicine and Toxicology, Medical School, University of Athens, Athens, Greece

1 INTRODUCTION

Cannabinoids are present in the plant of *Cannabis sativa* and include the most popular compounds used as drugs of abuse. More than 60 cannabinoids have been detected in *Cannabis sativa* plant, of which, besides Δ^9-tetrahydrocannabinol (Δ^9-THC) as the main psychoactive compound, cannabigerol, cannabichromene, cannabidiol, and cannabinol are also present in sufficient amounts (Smita and Sushil Kumar, 2007). Additionally, during the last decade research has highlighted the mechanisms of action of some of the cannabinoids, mainly due to the discovery of molecular targets for such molecules in vertebrates. Such targets include the G-protein-coupled cannabinoid (CB) receptors and their endogenous ligands, the endocannabinoids. The mechanism of action of cannabinoids is best investigated for Δ^9-THC and other CB agonists. The mode action of other cannabinoids of therapeutic interest, for example, cannabidiol (CBD), as well as the carboxy metabolite of Δ^9-THC (11-nor-9-carboxy-Δ^9-THC) is less well established. The majority of Δ^9-THC effects are mediated through agonistic actions at CB receptors (Grotenhermen, 2004). Some non-CB-mediated effects of Δ^9-THC and synthetic derivatives have also been described, for example, some effects on the immune system and some neuroprotective effects.

The discovery of the CB receptor and the availability of highly selective and potent cannabinomimetics led to the rapid identification of a family of lipid transmitters that serve as natural ligands for the CB1 receptor. The two major endogenous cannabinoids are neutral arachidonic acid (AA) derivatives *N*-arachidonoylethanolamine (anandamide or ANA) and 2-arachidonoylglycerol (2-AG). In each case, the carboxylic acid moiety of AA is replaced with a neutral functionality (Kingsley and Marnett, 2007). The pharmacological properties of the endocannabinoids were found to be very similar to those of the synthetic cannabimimetics. The subsequent description of a complex biochemical pathway for the synthesis and release of endocannabinoids completed the scaffold of a new signaling system termed the "endocannabinoid system." It recently became clear that, at least in mammals, the functions of this endocannabinoid signaling system are not limited to the brain, but extended to the whole organism. Endocannabinoids are generally considered to be released from cells "on demand", as no evidence exists for their storage in secretory vesicles, and also several of their biosynthetic enzymes are found in the plasma membrane. Moreover, endocannabinoids act locally on their receptors, possibly due to their high lipophilicity, and are immediately inactivated under physiological conditions (Di Marzo, 2008).

Several pathways might exist for the formation and catabolism of ANA and 2-AG. ANA originates from a phospholipid precursor, *N*-arachidonoyl-phosphatidyl-ethanolamine (NArPE). NArPE is then transformed into ANA by four possible alternative pathways, the most direct of which is catalyzed by an *N*-acyl-phosphatidylethanolamine-selective phosphodiesterase (NAPE-PLD). 2-AG, when serving as an endocannabinoid, is produced almost exclusively by the hydrolysis of diacylglycerols (DAGs) via *sn*-1-selective DAG lipases (DAGLs) α and β. After their cellular re-uptake, ANA is metabolized by fatty acid amide hydrolase (FAAH) and 2-AG via monoacylglycerol lipase (MAGL). 2-AG is also metabolized to some extent by other recently identified lipases, the $\alpha\beta$-hydrolases 6 (ABH6) and 12 (ABH12), as well as FAAH. Both ANA and 2-AG, possibly under conditions where MAGL or FAAH activity is suppressed, might become substrates for cyclo-oxygenase (COX-2) and give rise to the corresponding hydroperoxy derivatives. The ANA and 2-AG hydroperoxy derivatives can then be converted to prostaglandin ethanolamides (prostamides) and prostaglandin glycerol esters, respectively, by various prostaglandin synthases. These metabolites, although inactive at CB receptors, appear to act at new binding sites for which pharmacological evidence exists. However, the physiological relevance of these pathways is still not fully understood. ANA also interacts with several non-CB receptors, the best established of which is the transient receptor potential vanilloid subtype 1 (TRPV1) channel, where the endocannabinoid binds at an intracellular site. Recently, ANA and 2-AG were reported to activate GPR55, an orphan G-protein-coupled receptor. There is also evidence for interaction of endocannabinoids with peroxisome-proliferator-activating receptor (PPAR)-α and -γ, although at high concentrations. However, CB1 and CB2 receptors are certainly the most-studied molecular targets for ANA and 2-AG, which activate them with different affinity. ANA behaves as a partial agonist at both CB1 and CB2 receptors, but has higher affinity for the CB1 receptor. The intrinsic activity of ANA at CB1 receptors is four- to 30-fold higher than at CB2 receptors. However, 2-AG is a complete agonist at both CB1 and CB2 receptors but it exhibits less affinity than ANA for both CB1 and CB2 receptors (Howlett *et al*., 2002). Importantly, in the brain CB1 receptors are often expressed in presynaptic terminals so that endocannabinoids synthesized from postsynaptic neurons can travel backwards (retrograde signaling) and inhibit neurotransmitter release. Apart from CB antagonists, so far specific blockers have only been developed for FAAH, MAGL, and DAGLs. Figure 1

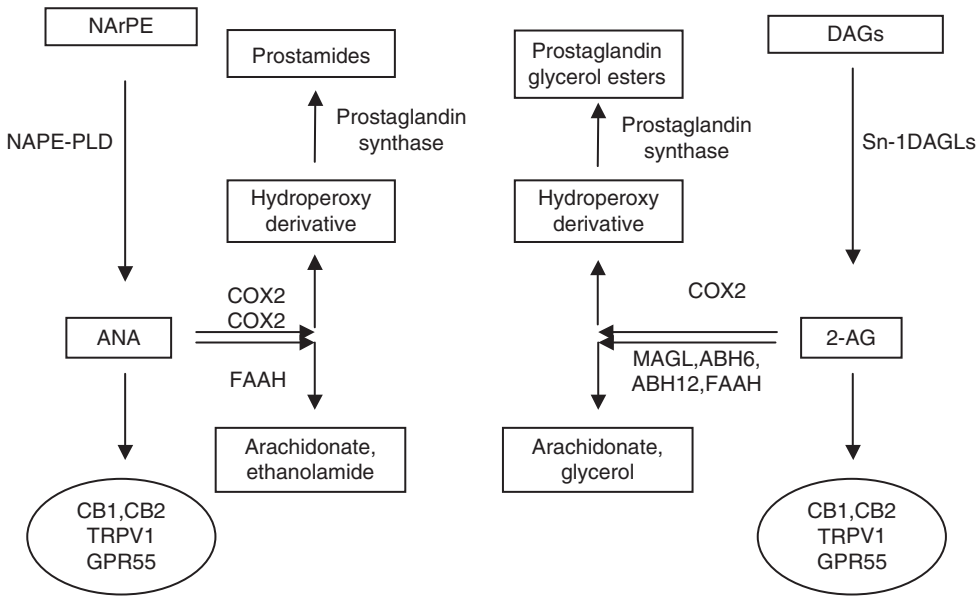

Figure 1. Main biochemical pathways for synthesis, degradation, and cellular actions of ANA and 2-AG.

illustrates the main biochemical pathways of the two major endocannabinoids, ANA and 2-AG.

In a relatively short time since their discovery, endocannabinoids have been implicated in the regulation of a range of physiological processes in mammals. There are now several examples in almost each of the major therapeutic areas of interest in which alterations in the endocannabinoid system are associated with various disease states. In particular, changes in tissue concentrations of ANA and 2-AG have been noted in many symptoms or disorders, including pain, inflammation, cancer, obesity, immunological, metabolic, cardiovascular, gastrointestinal, and hepatic disorders (Di Marzo, 2008). It is clear that the multitude of physiological (and pathological) processes involving CB receptors give rise to a number of therapeutic targets. Cannabinoids have been used for medicinal purposes for a very long time and the debate regarding whether or not "medicinal marijuana" should be an acceptable form of treatment continues. A key issue will always be the presence of unwanted psychotropic effects of centrally acting cannabinoids, which can be minimized by the use of carefully controlled formulations, although never removed. The reported acute toxicity of cannabis and other cannabinoids remains very low as no one has ever died due to direct and immediate consequence of their recreational or medical use. However, the activation of the cannabinoid system through Δ^9-THC, other phytocannabinoids, and synthetic cannabinoids exerts numerous actions associated with inflammation, cellular atypia, and molecular dysregulation of the tracheobronchial epithelium (Sarafian *et al*., 2005). A toxic side effect of cannabis use that merits attention is the referred short-term effect on the cardiovascular system: increase of heart rate and decrease of blood pressure. Chronic toxicity studies in animals reported alterations in both male and female sexual hormone levels, although there were no adverse affects on human fertility, or chromosomal and genetic damage. Previous studies revealed that Δ^9-THC induced mitochondrial injury in both primary lung epithelial cells and in the A549 cell line (Sarafian *et al*., 2003), by disrupting mitochondrial function and cell energetics (Sarafian *et al*., 2005). The potential contribution of THC to airway injury, by exposing primary cultures of human small airway epithelial (SAE) cells to THC (0.1–10.0 $\mu g\,ml^{-1}$) for either 1 or 7 days, was further examined. THC induced a time- and dose-dependent decrease of cell viability, as also ATP levels, and mitochondrial membrane potential. The same authors further observed alterations at the levels of caspase-8, catalase, Bax, early growth response-1, cytochrome P4501A1 (CYP1A1), metallothionein 1A, PLAB, and mRNA. After 7 days of exposure, the mRNA levels of heat shock proteins (HSPs) and the pro-apoptotic protein Bax were decreased, whereas those of GADD45A, IL-1A, CYP1A1, and PTGS-2 were significantly increased. Such findings suggest a contribution of THC to various cellular functions such as DNA damage, inflammation, and apoptosis. The identification of the different components of the endocannabinoid system supported targets for CB signaling modulation. Thus, it may be possible to target receptors that are not present in the brain (by the topical application of CB1 receptor agonists or the use of specific CB2 receptor agonists). An alternative approach would be to bolster up existing CB signals rather than overlaying new ones using, for example, inhibitors of endocannabinoid uptake and metabolism (Fowler *et al*., 2005). Specific agents that can modulate endocannabinoid system have been developed (Table 1).

2 AIM OF THE REVIEW

This study gives a general perspective of the endogenous cannabinoid system and focuses on its role in the development of system toxicity. Extended discoveries during the last decade regarding the mechanism of action of endocannabinoids and their significant role in pathophysiological conditions have led to the development of drugs capable of modulating their dynamics. The major findings of the reported data implicating the endogenous or exogenous ligands (agonists and antagonists) of CB receptors are presented in Table 2.

2.1 Immune System Modulation

Endocannabinoids are believed to control immune functions and play a role in immune homeostasis. Immune cells express both CB1 and CB2 receptors, secrete endocannabinoids, and have functional cannabinoid transport and breakdown mechanisms. The expression levels of CB2 receptors in immune cells are 10–100 times greater than those of CB1 ones. It has been shown that endocannabinoids

Table 1. Agents able to modulate the endocannabinoid system according to their mechanism of action.

Agent	Mechanism of action	Reference
Δ^9-THC	CB1/2 agonist[a]	(Zani *et al*., 2007)
CP-55 940	CB1/2 agonist	(Gkoumassi *et al*., 2009)
R-(+)-WIN-55, 212-2	CB1/2 agonist	(Marchalant *et al*., 2009)
ANA	CB1/2 agonist[a]	(Koura *et al*., 2004)
R-(+)-MANA	CB1/2 agonist	(Gustafsson *et al*., 2009)
ACEA	CB1/2 agonist	(Schuelert and McDougall, 2008)
HU-210	CB1/2 agonist	(Michalski *et al*., 2007)
AM-251	CB1 antagonist	(Fonseca, Correia-da-Silva and Teixeira, 2009)
LY 320135	CB1 antagonist	(Muthian *et al*., 2004)
AM 630	CB2 antagonist	(Di Filippo *et al*., 2004)
SR141716A	CB1 selective antagonist	(Izzo *et al*., 2001)
AM 1241	CB2 selective agonist	(Shoemaker *et al*., 2007)
JWH133	CB2 selective agonist	(Feizi *et al*., 2008)
HU-308	CB2 selective agonist	(Qian *et al*., 2009)
SR144528	CB2 selective antagonist	(Eisenstein *et al*., 2007)
AM 404	ANA inhibitor	(Borsani *et al*., 2007)
OL-135	FAAH inhibitor	(Kinsey *et al*., 2009)
URB 597	FAAH inhibitor	(Jayamanne *et al*., 2006)
URB 532	FAAH inhibitor	(Patel *et al*., 2005)
OMDM106	FAAH inhibitor	(Ortar *et al*., 2007)
AM1172	ANA selective inhibitor	(Hillard *et al*., 2007)
VDM11	ANA selective inhibitor	(Murill-Rodríguez *et al*., 2008)
AA-5-HT	FAAH selective inhibitor	(Capasso *et al*., 2005)
PAL	FAAH selective inhibitor	(Capasso *et al*., 2005)
JZL184	MAGL selective inhibitor	(Long *et al*., 2009)
UCM 707	ANA transporter blocker	(Hasanein and Soltani, 2009)

ANA, anandamide; R-(+)-MANA, R-(+)-methanandamide; ACEA, arachidonoyl-2A-chloroethylamide; AA-5-HT, *N*-arachidonoyl-serotonin; PAL, palmitoylisopropylamide.

[a] Partial.

modulate T- and B-cell proliferation and apoptosis, macrophage-mediated killing of sensitized cells, activation, inflammatory cell cytokine production, chemotaxis, and migration. There is also evidence that endocannabinoids biosynthesis, uptake, and degradation occur in macrophages and leukocytes. Such findings support the role of endocannabinoids as local modulators of immune and inflammatory reactions (Pestonjamasp and Burstein, 1998; Bisogno *et al*., 1997). Maccarrone *et al.* (2000) investigated the ability of the human mast cell-1 (HMC-1) line to take up and hydrolyze ANA and how the degradation of this lipid might be controlled. Intact HMC-1 cells were able to accumulate [^{3}H]ANA in a time- and concentration-dependent manner whereas [^{3}H]ANA uptake was almost completely inhibited by the specific ANA transport inhibitor AM404. The uptake was enhanced dose-dependently when incubations were carried out in the presence of nitric oxide (NO) donors, sodium nitroprusside (SNP) (100 mM), or *S*-nitroso-*N*-acetylpenicillamine (SNAP) (0.5, 2.5, 5, and 10 mM). The authors concluded that HMC-1 cells have a specific ANA transporter and an FAAH, characterized for the first time. This suggests an inverse relationship between NO and ANA, which is noteworthy if one recalls that NO is a pro-inflammatory agent. A major finding of this investigation is that HMC-1 cells have negligible basal levels of FAAH activity, which becomes remarkable in the presence of specific 5-lipoxygenase inhibitors. This is noteworthy because hydroperoxides generated from ANA by lipoxygenase have been shown to be potent inhibitors of FAAH. Because HMC-1 cells express an active 5-lipoxygenase, as shown by Macchia *et al*. (1995), it can be suggested that ANA used as a substrate to assay FAAH is converted instead by 5-lipoxygenase into hydroperoxides, which inhibit FAAH activity. As it has been shown (Maccarrone *et al.*, 2001), lipopolysaccharide (LPS) down-regulated FAAH expression and increased ANA levels in human peripheral blood mononuclear cells (PBMCs). Treatment of PBMCs with LPS (0, 10, 25, 50, 100, and 150 $\mu g\,ml^{-1}$)

reduced, in a dose-dependent manner, FAAH activity. FAAH inhibition reached statistical significance ($P < 0.05$) at 25 mg ml^{-1} LPS and a maximum at 100 mg ml^{-1}. As an irreversible FAAH inhibitor also increased the ANA levels (Maccarrone *et al*., 2001), the observed stimulatory action of LPS on ANA levels was considered due to FAAH inhibition. Recently, it has been suggested that ANA is released by CNS tissue as a mechanism that controls and limits immune response in healthy and injured brain (Eljaschewitsch *et al*., 2006). There is a 3.7-fold (5 pmol mg^{-1} w.w.) and 1.9-fold (5 pmol mg^{-1} w.w.) increase of ANA concentrations in inflammatory lesions of patients with active and silent multiple sclerosis (MS), respectively, compared with those noted in healthy controls (2.7 pmol mg^{-1} w.w.). The levels of other endocannabinoids, such as 2-AG and palmitoylethanolamide (PEA), were only slightly influenced in MS patients. The authors also addressed the question regarding the ANA accumulation as a direct consequence of neuronal damage or a result of immune cell invasion. In living brain tissue, a 2.8-fold increase in ANA concentration was detected after induction of specific excitotoxic neuronal damage by *N*-methyl-D-aspartate (NMDA) that was potentiated up to a 13.2-fold increase after invasion of murine microglial cell line (BV-2) microglial cells. BV-2 microglial cells did not induce ANA production in a resting state. Finally, the influence on inflammatory damage to neurons was examined. Incubation with 2 mM ANA completely abolished inflammatory damage but not the primary excitotoxic damage, whereas incubation with ANA alone did not increase neuronal damage. Schwarz *et al*. (1994) investigated the effects of ANA on immune function and compared its potency to that of synthetic cannabinoids. Human PBMCs, T- and B-lymphocytes were prepared and proliferation assays were performed with PBMCs stimulated with murine anti-CD3 antibody, phytohaemaglutinin (PHA) (OKT3) or PHA. The results showed that ANA inhibits accessory cell–dependent T-cell proliferation and accessory cell–independent proliferation of B cells. In all isolates, 10^{-5} M ANA had no effect on cell proliferation, but at 10^{-4} M, it invariably blocked proliferation completely. The inhibitory effects of 3×10^{-5} M ANA ranged from 30 to 80% in cells from different donors. The two synthetic cannabinoids, Δ^8-THC and CP55940, showed similar effects and completely inhibited T-cell proliferation at concentrations of 3×10^{-5} and 10^{-5} M, respectively. Δ^9-THC was of equal potency as Δ^8-THC in inhibiting proliferation of OKT3-stimulated PBMC. Role of endocannabinoids when present at low doses has been also implicated in the migration of B cells along with induction of some cytokines (Titishov *et al*., 1989). In this study, the effects of synthetic agonists HU-210 and HU-211 on the inductive and productive phases of the primary humoral immune response due to sheep red blood cell immunization were investigated in mice. Animals treated with HU-210 (0.01, 0.05, 0.1, and 0.5 mg kg^{-1}) exhibited a dose-dependent suppression of both phases of the primary humoral immune response in the hemolytic plaque assay, the hemagglutination titer, and the ratio of the spleen weight to final body weight. Mice treated with HU-211 (0.01, 0.05, 0.01, 0.5, and 1.0 mg kg^{-1}) did not exhibit dose-dependent immune suppression. ANA seems to potentiate the growth of murine IL-6-dependent lymphoid B9 and the IL-3-dependent myeloblastic FDC-P1 cell lines (Derocq *et al*., 1998). The effect of ANA was examined at optimal concentrations of 0.5–1 μM on B9 and FDC-P1 cells, cultured with increasing amounts of IL-6 and IL-3, respectively. In the absence of any growth factor, ANA

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat206
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

by itself did not significantly influence the DNA synthesis in both cell lines. However, ANA greatly enhanced (by two- to threefold) the rate of DNA synthesis, when the respective growth factors were present in the culture medium of both cell lines. The stimulating effect of ANA was concentration-dependent with a maximal activation obtained with 0.5–1 μM for B9 and 0.25–0.5 μM for FDC-P1 cells costimulated with either IL-6 50 U ml^{-1} or IL-3 50 ng ml^{-1}, respectively. The addition of 1 μM ANA increased the cell number by 2.2-fold, indicating that the enhancement of DNA synthesis was related to a true proliferative response. In order to examine whether ANA can attenuate ConA-induced hepatitis, exogenous ANA (10 mg kg^{-1}) was administered into mice (Hegde *et al*., 2008). ConA and ANA treatment resulted in decreased AST and ALT levels (12 h ConA challenge) and less liver damage (48 h ConA challenge) compared with ConA and vehicle-injected mice, suggesting that ANA can effectively block ConA-induced hepatitis. There was also a significant decrease in inflammatory cytokines such as TNF-α, IL-1β, IL-6, IL-9, IL-12, and IL-17, and in chemokines such as KC, monocyte chemoattractant protein-1, and eotaxin after 12 h ANA treatment. It is noteworthy that ANA treatment in ConA-injected mice failed to decrease IL-2 levels compared with ConA and vehicle-injected ones. Furthermore, PEA, unlike ANA, was highly effective in reducing antigen-evoked [^{3}H]serotonin release from rat basophilic leukemia cells of the secreting subline 2H3 (RBL-2H3) cells (Facci *et al*., 1995). As with the active cannabinoids, in three experiments ANA (12.5 μM) reduced the down-modulatory activity of PEA by 50–100%. These findings indicate that, although both PEA and ANA bound to CB2 receptors *in vitro*, only PEA could down-modulate cell activation.

Dentritic cells (DCs) play a major role in antigen presentation and the development of antigen-specific T-cell responses. 2-AG has been suggested to act as a chemotactic molecule capable of recruiting DCs during innate immune response. Immature bone marrow-derived DCs and/or DCs matured by exposure to peptidoglycan (PGN) were assayed for their capacity to migrate *in vitro* toward various concentrations of 2-AG (1, 5, and 10 μM) (Maestroni, 2004). The authors showed that this effect was real chemotaxis, as 2-AG was ineffective in absence of a concentration gradient, that is, when it was present in both upper and lower wells of the chemotactic chamber. The CB2 receptor antagonist SR 144528 inhibited completely the chemotactic effect of 2-AG, indicating that the observed effect was CB2 mediated. A recent study has shown that ANA failed to inhibit superoxide production in neutrophils, although other synthetic cannabinoid treatment exhibited the inhibition property (Kraft *et al*., 2004). Isolated human PBMCs were incubated with ANA and MethANA at concentrations between 10^{-3} and 10^3 nM. Neither the spontaneous nor the *N*-formyl-methionyl-leucyl-phenylalanine (fMLP)-induced oxygen radical production of human PBMCs was significantly affected under these experimental conditions. In this respect, ANA did not significantly differ from its non-hydrolyzable derivative MethANA. When higher concentrations of ANA, up to 100 μM, were used, the respiratory burst reaction remained unaltered. Finally, it has been demonstrated that ANA can induce apoptosis in immune cells with malignant phenotype. Molt-4 human tumor cells, when cultured for 4 h in the presence of various concentrations of ANA, were found to undergo significant levels of apoptosis as quantified using the TUNEL assay, at concentrations of 20 μM or greater (McKallip *et al*., 2002).

2.2 Induction of Inflammation

Fatty acid profiles and endocannabinoid concentrations were determined in different tissues to examine the possible impact of (n-3) LCPUFA on the dysregulated endocannabinoid system in Zucker rats. The visceral adipose tissue (VAT) ANA concentration was lower in the fish oil (FO) (25 pmol g^{-1}) and krill oil (KO) (15 pmol g^{-1}) groups than in control (38 pmol g^{-1}), whereas 2-AG was similar in FO (330 pmol g^{-1}) and significantly lower than control (330 pmol g^{-1}) only in the KO-supplemented rats (100 pmol g^{-1}). Endocannabinoid concentrations in subcutaneous adipose tissues (SAT) did not differ among the three groups. Liver and heart endocannabinoids were similarly affected in the KO-supplemented rats. ANA concentrations were ∼25% of, and 2-AG concentrations ∼200% of, those of control in both tissues. In FO-fed rats, liver but not heart ANA concentrations were less than in control. Heart, liver, VAT, and SAT FAAH activities did not differ among the experimental groups. Conversely, MAGL activity was significantly lower in the VAT of the FO and KO groups, and in the

heart tissue of the KO group, compared with control. However, liver MAGL activity tended to be lower, although non-significantly in both groups compared with control (Batetta *et al*., 2009). 2-AG appears to protect acute head trauma by exerting anti-inflammatory effects and by counteracting blood–brain barrier (BBB) damage. In this study, 2-AG ($5\,mg\,kg^{-1}$) was administered immediately after closed head injury (CHI) and determined the BBB permeability 4 h after the trauma. In the left, injured hemisphere 2-AG robustly reduced BBB disruption, as evidenced by 40% decrease in dye levels extracted from the brain ($P < 0.01$), whereas in the right hemisphere, not affected by CHI, no changes in dye levels were noted. As the proteolytic enzymes TACE and MMP are implicated in the disruption of the BBB, the authors furthermore examined whether these enzymes are up-regulated after CHI, and whether the protective effect 2-AG on the BBB is mediated by inhibition of these enzymes. Such results show that TACE expression increased between 2 and 4 h after CHI ($P < 0.01$); however, 2-AG had no effect on TACE and MMP-9 levels (Panikashvili *et al*., 2006). Some recent studies indicate that ANA increases the severity (Dembiński *et al*., 2006) whereas another study exhibits some therapeutic effects (Michalski *et al*., 2007) in acute pancreatitis. Dembiński *et al*. (2006) checked whether the administration of a natural endogenous CB1 receptor agonist (ANA; 0.8, 1.5, or $3.0\,\mu mol\,kg^{-1}$ per dose i.p.) or CB1 antagonist (AM 251; $4\,\mu mol\,kg^{-1}$ i.p.) affects the cerulein-induced acute pancreatitis in Wistar rats. According to this study, ANA pretreatment increased the severity of cerulein-induced pancreatitis evident by increased pancreatic tissue damage, serum concentration of IL-1β and serum activity of pancreatic enzymes (lipase, amylase, and poly-C ribonuclease). Opposite effect was observed after administration of the selective CB1 receptor antagonist, AM 251, which inhibited the development of cerulein-induced acute pancreatitis, as well as reversed the injurious effect of ANA in the same model. The observation that stimulation of CB1 receptors during induction of acute pancreatitis enhances the severity of this disease is in agreement with a previous study by Matsuda *et al*. (2005), who found that administration of CB1 receptor antagonist prolongs the survival of rats with severe necrotizing acute pancreatitis evoked by injection of sodium taurocholate into the bilio-pancreatic duct. Additionally, clinical case report indicates that cannabis may induce acute pancreatitis (Grant and Gandhi, 2004). However, Michalski *et al*. (2007) reported that cerulein-induced acute pancreatitis is associated with up-regulation of ligands and receptors of the endocannabinoid system in the pancreas and administration of a synthetic agonist of CB1 and CB2 receptors, HU210, exhibits some therapeutic effects in experimental as also in clinical acute pancreatitis. Dembiński *et al*. (2008) examined the reason for these opposite confusing results and showed that the influence of ANA on the severity of acute pancreatitis depends on the phase of the inflammation. Experiments were carried out in two series on male Wistar rats and acute cerulean-induced pancreatitis. Administration of ANA before induction of acute pancreatitis has increased the severity of acute pancreatitic injury because it enhanced the pancreatitis-evoked increase in serum activity of pancreatic digestive enzymes (lipase amylase and poly-C ribonuclease), IL-1β, and pancreatic MPO activity. However, administration of ANA after induction of acute pancreatitis results in opposite effects regarding the severity of both symptoms and pancreatic tissue damage (Michalski *et al*., 2008). These authors evaluated endocannabinoids and CB receptor levels as well as the potential function of cannabinoid activation and antagonism by synthetic cannabinoid derivatives and their respective antagonists in either chronic pancreatitis human tissues or derived pancreatic stellate cells (PSC). It was suggested that activation of the endocannabinoid system induces a quiescent phenotype of chronic pancreatitis-derived PSC by down-regulating the production of extracellular matrix (ECM) proteins and inflammatory cytokines. This effect was accompanied by marked changes in PSC appearance toward a less mesenchymal-like phenotype (Michalski *et al*., 2008).

In recent studies, it has been reported that endocannabinoids may be also involved in intestinal inflammation. In a mouse model of intestinal inflammation induced by oral croton oil administration, CB receptor agonists cannabinol and CP 55 940 reduced upper gastrointestinal motility. However, the anti-transit effects of both agonists were augmented during intestinal inflammation (Izzo *et al*., 2001). Both CP 55 940 ($0.03 \pm 10\,nmol\,mouse^{-1}$) and cannabinol (i.p.; $10 \pm 3000\,nmol\,mouse^{-1}$) administration produced a dose-related inhibition of transit and they had a lower ED_{50} value

compared with the corresponding treatment in control mice. In the same study, ANA and 2-AG were detected in control tissues ($36.4 + 6.1$ and $44.1 + 4.0$ nmol g tissue^{-1}, respectively) and this production was not significantly modified in the small intestine of croton oil-treated mice ($29.2 + 1.6$ and $35.6 + 2.5$ nmol g tissue^{-1}, respectively). By contrast, a significant increase in ANA amidohydrolase activity was observed in croton oil-treated mice. Increased levels of ANA, but not 2AG, have been reported in inflamed colon tissue in ulcerative colitis patients, a finding replicated in a mouse model of colonic inflammation (D'Argenio *et al*., 2006) induced by 2,4-dinitrobenzene sulfonic acid (DNBS) and 2,4,6-trinitrobenzene sulfonic acid (TNBS) in Wistar rats and C57/BJ mice, respectively. Treatment of rats with TNBS caused an almost threefold enhancement of colon ANA, but not 2-AG, levels, limited to the submucosa, with no effect on mucosal endocannabinoid levels. Treatment of mice with DNBS caused a robust enhancement of colon ANA – but not 2-AG – levels, which were already significant after 3 days and reached maximum after a week (fourfold elevation). The same study also included data from human mild-to-moderate ulcerative colitis patients ($n = 8$). A more than twofold elevation of ANA, but not 2-AG, levels was found in mucosal biopsies from patients with untreated ulcerative colitis compared with controls. ANA levels significantly correlated with disease clinical activity, whereas no correlation was found between endocannabinoid levels and endoscopic and histologic figures (D'Argenio *et al*., 2006). The converse was described in a model of allergic inflammation, which was associated with increased levels of 2AG, but not ANA (Oka *et al*., 2005). These authors investigated in detail the possible pathophysiological roles of the CB2 receptor and 2-AG in acute inflammation in the mouse ear, induced by the topical application of 12-*O*-tetradecanoylphorbol 13-acetate (TPA). The amount of 2-AG was markedly augmented following the topical application of TPA (14.4 ± 2.0 pmol μmol^{-1} of lipid P), versus the amount in the vehicle (acetone)-treated controls (4.2 ± 2.0 pmol μmol^{-1} of lipid P) (Oka *et al*., 2005). These findings propose that endocannabinoids levels vary according to the nature of inflammation. A potential cause for these variations would probably originate by the effect of the pathological condition on the levels of enzymes involved in endocannabinoids metabolism and the different activity of such enzymes to the metabolism of endocannabinoids group of compounds.

In another model of acute intestinal inflammation induced by administration of toxin A from *Clostridium difficile* to isolated segments of the rat ileum, McVey *et al*. (2003) have shown that toxin A treatment resulted in increased ANA and 2-AG ileal concentrations and that administration of these substances essentially duplicated the inflammatory effects of toxin A, suggesting that one or both of these endocannabinoids may mediate the inflammatory effects of toxin A. Intraluminal injection of ANA induced dose-dependently intense inflammation in the rat ileum, whereas administration of 2-AG duplicated the effects of ANA on luminal fluid accumulation. However, two synthetic cannabinoid agonists, WIN 55,212-2 mesylate and HU 210, and palmitoylethanolamide did not affect the rat ileum at similar doses. The endocannabinoid-induced inflammation is capsazepine-sensitive, indicating that it is mediated by the capsaicin VR1 receptor. This is confirmed by the fact that ANA also stimulates the capsazepine-sensitive release of SP in the ileum. Both toxin A-induced inflammation and ANA and 2-AG release are potentiated by pretreatment with inhibitors of FAAH (McVey *et al*., 2003).

A growing body of evidence suggests that endocannabinoid signaling plays a critical role in hemorrhagic or endotoxic shock. Wang *et al*. (2001) succeeded in the measurement of around 20 pmol of ANA in the medium of LPS-stimulated mouse macrophage-like RAW264.7 cells, and of around 18 and 30 pmol ml^{-1} of ANA and 2-AG in the sera of some patients with endotoxic shock. In contrast, approximately 4.0 pmol ml^{-1} of ANA and 10 pmol ml^{-1} of 2-AG were detected in normal human serum. The increased amounts of ANA and 2-AG in the sera of the patients with endotoxic shock further supported the notion, established on data obtained from a rat model, that ANA and 2-AG are endogenous mediators of shock-induced hypotension (Wang *et al*., 2001). In addition, the recruitment of inflammatory cells into the intima is crucial for the development and progression of atherosclerosis. Steffens *et al*. (2005) demonstrated that oral treatment with a low dose of THC inhibits atherosclerosis progression in the apolipoprotein E knockout mouse model, through pleiotropic immunomodulatory effects on lymphoid and myeloid cells.

Oral administration of THC ($1\,mg\,kg^{-1}\,day^{-1}$) resulted in significant inhibition of disease progression. Lymphoid cells isolated from THC-treated mice showed diminished proliferation capacity and decreased interferon-gamma secretion. Macrophage chemotaxis was also inhibited *in vitro* by THC. All these effects were completely blocked by a specific CB2 receptor antagonist.

2.3 Induction of Fibrosis

The endocannabinoid system appears to activate the fibrogenic cells and contribute to the ECM accumulation in the liver. However, the underlying mechanisms are still not well characterized.

The CB1 and CB2 receptors are markedly up-regulated in the cirrhotic human liver, predominantly in hepatic myofibroblasts within fibrotic septa. Experimental studies in which CB1 and CB2 receptors were blocked by either genetic and/or pharmacological manipulations have provided important information on the EC system-dependent regulation of both pro- and anti-fibrogenic responses in the liver (Teixeira-Clerc *et al*., 2006; Julien *et al*., 2005). Indeed, mouse models of liver fibrosis induced by carbon tetrachloride (CCl_4), thiacetamide (TAA), or bile duct ligation (BDL) in either CB1-deficient animals or those treated with the CB1 receptor antagonist rimonabant (SR141716A) presented a significant decrease of fibrosis induction compared with their wild-type littermates. In this study, Teixeira-Clerc *et al*. (2006) investigated the consequences of CB1 receptor inactivation on progression of fibrosis in the three established experimental models. After chronic CCl_4 intoxication, extensive fibrotic septa with some nodules in wild-type mice were noted. That was not confirmed in CCl_4-treated *Cnr1*$^{-/-}$ mice, which showed limited formation of fibrotic septa. Fibrosis area was decreased by 37% in CCl_4-treated *Cnr1*$^{-/-}$ compared with wild-type mice. Similarly, the fibrosis area was reduced by 30% or 35% in *Cnr1*$^{-/-}$ mice exposed to TAA or BDL, respectively. Moreover, treatment with SR141716A strongly reduced fibrosis area by 41% and 34% in the BDL and TAA models, respectively. Hepatic expression of transforming growth factor-β1 (TGF-β1) was also significantly decreased in *Cnr1*$^{-/-}$ or SR141716A-treated mice, compared with wild-type ones. Finally, the number of liver fibrogenic cells was reduced in *Cnr1*$^{-/-}$ and in SR141716A-treated mice, as shown by decreased expression of smooth muscle actin (β-SMA). These results show that genetic or pharmacological antagonism of CB1 receptors reduces the fibrogenic response associated with chronic liver injury, independently of the offending agent. By contrast, CB2-deficient mice present a significant increase in fibrosis following exposure to CCl_4 (Teixeira-Clerc *et al*., 2006). Julien *et al*. (2005) provided the first evidence for the expression of CB2 receptors in the cirrhotic but not in normal human liver and their up-regulation in hepatic fibrogenic cells. Moreover, the authors showed that activation of CB2 receptors triggers growth inhibition and apoptosis in hepatic myofibroblasts and activated HSCs. In contrast, strong CB2 immunostaining was noted in different cells' populations in fibrotic septa, irrespective of the etiology of cirrhosis. CB2 receptor expression was also found in non-parenchymal, ductal epithelial, as well as inflammatory cells in cirrhotic tissues. Accordingly, CB2 receptors were also expressed in cultured human hepatic myofibroblasts. CB2 receptors were also detected in fully activated rat HSC, whereas they were faintly expressed in non-activated ones. THC dose-dependently (0–1000 nM) inhibited DNA synthesis elicited by $20\,ng\,ml^{-1}$ BB homodimeric platelet-derived growth factor (PDGF-BB), with a half-maximal inhibition occurring in the presence of $300\,nmol\,l^{-1}$ of the compound. In these conditions, THC had no cytotoxic effect on human hepatic myofibroblasts. Increasing THC concentrations produced cytotoxic effects toward serum-deprived human liver myofibroblasts, as shown by cell rounding, shrinkage, and detachment. Consistently, THC induced a time-dependent activation of caspase-3, with a maximal increase in activity peaking after 4–6 h; 2-AG (0–20 μM) and methanandamide (0–4 μM) dose-dependently inhibited DNA synthesis and promoted cytotoxic effects. However, growth inhibitory and cytotoxic effects of the compounds were insensitive to pre-treatment with the CB2 receptor antagonist SR 144528. These results therefore suggest that ANA and 2-AG inhibit DNA synthesis and elicit apoptotic effects of human hepatic myofibroblasts by a CB2-independent pathway (Julien *et al*., 2005).

Recent experimental studies in isolated cell models also showed that ANA induces necrosis while 2-AG induces apoptosis in activated HSCs via

increased ROS generation. However, these effects of EC are likely to be independent of the interaction with CB1 and CB2 receptors (Siegmund *et al*., 2005, 2007). Siegmund *et al*. (2005) isolated primary HSCs by a two-step collagenase perfusion from surgical specimens of healthy human livers ($n = 3$) or from livers of male Sprague–Dawley rats. ANA treatment caused a dose-dependent (25–100 μmol l^{-1}) increase in intracellular Ca^{2+}, which was detectable as early as 3 min after addition of ANA. Pre-treatment with either the extracellular Ca^{2+}-chelators EDTA and BAPTA-tetrapotassium salt or the intracellular chelator BAPTA-AM diminished ANA-induced cell death by 70%, 61%, and 62%, respectively ($P < 0.001$). ANA also caused a marked, dose-dependent (25–100 μmol l^{-1}), and extremely rapid increase in ROS formation. Pre-treatment with the antioxidant GSH completely abrogated the generation of ROS by ANA and reduced ANA-mediated cell death by 40%, indicating that ROS also contribute to ANA-induced cell death (Siegmund *et al*., 2005). The same group (Siegmund *et al*., 2007) investigated the effects of 2-AG on primary HSCs and hepatocytes. 2-AG (0.5, 1, 5, 10, 25, 50, and 100 μM) induced cell death in activated rat HSCs starting at concentrations of 5 μM and induced almost 80% cell death after 18 h of treatment with 25 μM 2-AG. In contrast, primary rat hepatocytes showed no sign of cell death even at the maximum dose used (100 μM 2-AG). After 2-AG stimulation, HSCs generated extremely high amounts of ROS in a dose-dependent manner (0.3, 1, 5, 10, 25, 50, and 100 μM) with substantial induction of ROS formation at submicromolar 2-AG concentrations. Taken together, these data indicate that, at least in experimentally induced liver fibrosis, CB1 and CB2 receptors have opposing effects on fibrogenesis.

The effect of ANA in activated HSCs was further confirmed when Siegmund *et al*. (2006) investigated the ability of FAAH to modulate ANA-induced cell death using isolated primary rat hepatocytes by pre-treating hepatocytes with URB597. To induce liver injury, $FAAH^{-/-}$ and $FAAH^{+/+}$ mice underwent double ligation of the common bile duct. ANA induced an extremely rapid onset of cell death in primary rat HSCs with more than 40% cell death occurring after 2 h at 25 and 50 μM. After 24 h, more than 80% of HSCs underwent cell death, being propidium iodide (PI) fluorescence positive. On the contrary, no alteration in cell death rate after ANA treatment, even at the highest doses used (100 μM), was noted in hepatocytes. URB597 sensitized hepatocytes to the effects of ANA with more than 40% cell death and strong PI uptake, suggesting that FAAH is indeed critically involved in the resistance to ANA. Similar data were obtained using another FAAH inhibitor, oleoyl ethyl amide. Pre-treatment with URB597 also increased ANA-induced ROS production in hepatocytes, whereas URB597 alone did not increase ROS. In contrast to ANA, methANA was capable of inducing cell death in rat hepatocytes ($P < 0.05$). To further investigate the role of FAAH in ANA-induced cell death, the authors constructed an FAAH-expressing adenovirus (AdFAAH), allowing to overexpress FAAH in HSCs. Infection with AdFAAH resulted in a strong expression of FAAH and high levels of FAAH activity in HSCs. AdFAAH induced almost complete resistance to ANA-mediated death up to doses of 25 and 50 μM with less than 20% cell death and no increase in PI uptake. At 100 μM ANA, AdFAAH conferred partial protection to HSCs. In contrast, HSCs infected with the GFP-expressing control virus (AdGFP) remained sensitive to ANA-induced cell death and showed a strong uptake of PI and leakage of GFP as signs of necrotic cell death (Siegmund *et al*., 2006). Additionally, several investigations have now demonstrated that the EC system is highly up-regulated in liver cirrhosis and is implicated in the pathogenesis of severe complications of the disease including portal hypertension, hyperdynamic circulatory syndrome, and cirrhotic cardiomyopathy. The existing data suggest that further experimental model studies are awaited to answer a series of open questions, such as the identification of the EC or other ligands that interact with the CB1 and CB2 receptors, the cellular targets, and the molecular mechanisms that modulate the fibrogenic process.

The EC system appears to be involved in all the events that contribute to portal hypertension and influences also the dynamic component. ANA causes a dose-dependent increase in intrahepatic vascular resistance in the isolated perfused rat liver (Yang *et al*., 2006, 2007). Yang *et al*. (2006) evaluated the possible roles of ANA in the intrahepatic microcirculation of cirrhotic livers and its interaction with the production of vasoconstrictive eicosanoids using Sprague–Dawley rats while cirrhosis was produced by BDL. In the vehicle-pre-incubated group, ANA

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat206

produced concentration-dependent (1.44×10^{-10} to 1.44×10^{-3} M) increases in portal perfusion pressure (PPP) in all cases. Magnitudes of the increases in PPP were significantly greater in cirrhotic than in normal livers for each ANA concentration. Pre-incubation with the Cox inhibitor, indomethacin, significantly attenuated the increased response of cirrhotic livers to ANA (a rightward shift of the concentration–response curves of PPP, $P < 0.05$). However, pre-incubation with the platelet-derived growth-5-lipoxygenase (PDGF-5LOX) inhibitor, piriprost, did not significantly alter the PPP to ANA in cirrhotic livers. However, in normal livers, concentration–response curves of PPP to ANA were not affected by pre-incubation with either indomethacin or piriprost. The ANA-induced increase in PPP was found concomitantly with a significant increase in thromboxane B2 (TXB2) and Cys-LT production in the perfusate. In response to ANA administration, cirrhotic livers exhibited a significantly greater increase in intrahepatic vascular resistance and production of TXB2 and Cys-LTs than normal livers. In a similar study, the same group (Yang *et al*., 2007) evaluated the chronic effects of AM251 on the intrahepatic microcirculation in cirrhotic rats. At 3 weeks after surgery, both BDL and sham-operated rats were randomly assigned to receive either vehicle or AM251 (3 mg kg^{-1} of body weight day^{-1}) for 7 days. The authors state that in a preliminary study, 7 days of sequential doses of AM251 (1, 3, 5, and 7 mg kg^{-1} of body weight day^{-1}) were given intraperitoneally to all animals. It was found that 1 mg kg^{-1} of body weight day^{-1} did not significantly affect portal venous pressure (PVP), whereas 3 mg kg^{-1} of body weight day^{-1} resulted in a significant reduction in PVP. The administration of 5 or 7 mg kg^{-1} of body weight day^{-1} did not decrease PVP further. Thus, in chronic AM251-treated cirrhotic rats, a decrease in portal venous pressure was associated with the decrease in intrahepatic vascular resistance and superior mesenteric artery blood flow. Furthermore, acute infusion of AM251 resulted in a decrease of blood flow and an increase of resistance.

Batkai *et al*. (2001) showed that rats with biliary cirrhosis have low blood pressure, which is elevated by the CB1 receptor antagonist SR141716A. The low blood pressure of rats with CCl_4-induced cirrhosis was similarly reversed by SR141716A, which also reduced the elevated mesenteric blood flow and portal pressure. The results of this study implicate ANA and vascular CB1 receptors in the vasodilated state in advanced cirrhosis and indicate a novel approach for its management whereas elevated concentration of ANA has been observed in monocytes. Increased ANA levels were also found in the plasma of cirrhotic patients (Fernández-Rodriguez *et al*., 2004), but no correlations were found between plasma levels and systemic hemodynamics, portal hypertension, and hepatic and renal dysfunction. Plasma ANA levels were higher in patients than in healthy subjects; however, they were not different between patients with and without ascites. Furthermore, no correlation was observed between ANA levels and the systemic vascular resistance and cardiac indices. In addition, no correlation was found between these levels and the Child–Pugh' score, the glomerular filtration rate (GFR), the renal blood flow, the renal vascular resistance, the plasma renin activity, and aldosterone concentration or the hepatic venous pressure gradient.

The cellular mechanisms that mediate the vasodilating effect of the EC in cirrhosis have been further elucidated by Domenicali *et al*. (2005) in a model of mesenteric resistance arteries isolated from rats with CCl_4-induced cirrhosis complicated with ascites. ANA (10 μM) produced a concentration-dependent (10^{-8} to 5×10^{-4}) relaxation of phenylephrine pre-contracted mesenteric arteries. Incubation with the TRPV1 antagonist, capsazepine (5 μM), and the CB1 receptor antagonist, SR141716A (3 mM), did not significantly alter the maximal relaxation. When both antagonists were incubated together, there was stronger inhibition of the response to ANA at the concentrations used. Nevertheless, the limited solubility of ANA precluded the use of higher concentrations and the construction of a full concentration–response curve. In addition, preliminary data indicate that, in a rat model of pre-ascitic CCl_4-induced cirrhosis, the administration of the CB1 receptor antagonist rimonabant dose-dependently reduces the incidence and accumulation of ascites after 2 weeks of treatment at the doses of 3 or 10 mg kg^{-1} day^{-1} (Domenicali *et al*., 2008). Ascites formation (V: 90%; R3: 54%; R10: 10%) and volume [from 5.5 ± 0.8 ml (V) to 1.6 ± 0.3 ml (R3) and 0.5 ml (R10)] ($P < 0.05$) were reduced. During week 1, rimonabant significantly improved sodium balance, an effect that became even more evident during week 2. Both treated groups showed lower cardiac output and higher MAP and peripheral vascular resistance.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat206
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

The liver fibrosis score was reduced by about 30% in the R10 ($P < 0.05$ vs. V) but not in R3. MAP was inversely correlated with sodium balance ($R = -0.77$; $P < 0.001$), whereas no significant correlations were found between fibrosis score and either sodium balance or hemodynamics. Rimonabant also appears to improve renal sodium balance and delays decompensation in pre-ascitic cirrhosis (Domenicali *et al.*, 2009). A significant reduction in ascites formation (group 1: 54%; group 2: 10%; vehicle: 90%) and volume (group 1: 1.6 ± 0.3 ml; group 2: 0.5 ml; vehicle: 5.5 ± 0.8 ml) occurred in treated rats. Rimonabant significantly improved sodium balance during week 2 (group 1: 0.98 ± 0.08 mmol; group 2: 0.7 ± 0.08 mmol; vehicle: 3.05 ± 0.11 mmol). Both treated groups showed lower cardiac output and higher mean arterial pressure, peripheral vascular resistance, and renal blood flow ($P < 0.05$). Liver fibrosis was reduced in group 2 by 30% ($P < 0.05$ vs. vehicle). Mean arterial pressure inversely correlated with sodium balance ($R = -0.61$; $P = 0.003$), but not with fibrosis score. However, steatosis of genetically obese Zucker rats can be dramatically reduced by chronic CB1 blockade. It was known that fat retention might lead to inflammation, facilitating cell injury and deposition of fibrotic tissue. Once-daily treatment of the obese (fa/fa) rats with rimonabant (30 mg kg^{-1} orally for 8 weeks) completely eliminated this hepatic steatosis. The liver of the obese (fa/fa) rats treated with rimonabant was found to be histologically comparable to that of lean animals. In contrast, the severe hepatic steatosis persisted in the pair-fed obese (fa/fa) rats. Furthermore, rimonabant treatment of obese (fa/fa) rats strongly reduced the elevated plasma levels of liver injury enzyme markers ALT, GGT, and ALP. In contrast, submitting obese (fa/fa) rats to pair feeding did not affect the plasma levels of these enzymes, which remained high (Gary-Bobo *et al.*, 2007).

It was recently reported that SR141716 (10 mg kg^{-1}) treated C57BL/6N mice were resistant to the hepatic steatogenic induced effect of ethanol. Similar to the rimonabant-treated wild-type mice, $CB1^{-/-}$ ones were resistant to the steatogenic effects of ethanol and were also resistant to its hepatotoxic effects. Furthermore, it resulted in a significant increase in the hepatic expression of the gene encoding the CB1 receptor and in the hepatic levels of 2-AG, but not ANA. This latter change occurred selectively in HSCs. Once produced, the 2-AG stimulates the expression of the lipogenic genes SREBP-1c and FAS and, thus, the deposition of fat in neighboring hepatocytes by binding overly expressed CB1 receptors in a paracrine fashion. In stellate cells from ethanol-fed compared with pair-fed mice, the gene expression of DAGLb was significantly increased whereas the expression of DAGLa and monoglyceride lipase (MGL) remained unchanged. These findings suggest that the increased 2-AG content of stellate cells from ethanol-fed mice is related to increased biosynthesis of 2-AG (Jeong *et al.*, 2008). Another report describes the successful treatment of non-alcoholic steatohepatitis (NASH) with rimonabant in 21-year-old Caucasian woman with severe obesity (Banasch *et al.*, 2007). Three months of rimonabant treatment (20 mg day^{-1}) were associated with a marked reduction in plasma of ALT, AST, and liver GGT enzyme levels by 74%, 72%, and 72%, respectively. In addition, non-invasive *in vivo* monitoring of hepatic mitochondrial function by 13C-MeBT indicated a distinct improvement of hepatic metabolic capacity (92% change in week 12 compared with baseline).

2.4 Ischemia/Reperfusion Injury

Hepatic ischemia/reperfusion (IR) injury is a significant clinical problem involved in the liver failure associated with circulatory shock, hepatic surgery, and liver transplantation.

Bátkai *et al.* (2007) used pharmacological agonist JWH-133, and antagonist/inverse agonist of cannabinoid CB2 receptors SR144528, as well as CB2 receptor knockout ($CB2^{-/-}$) mice to study the role of the endocannabinoid system in an *in vivo* model of liver IR injury. Interestingly, the hepatic ANA and 2-AG contents correlate with the plasma concentrations of transaminases and pro-inflammatory cytokines. In addition, the authors studied the effects of JWH133 on TNF-α-induced ICAM-1 and VCAM-1 expression in human liver sinusoidal endothelial cells (HLSECs) and adhesion of human neutrophils to HLSECs *in vitro*. The authors demonstrated that pre-treatment of mice with a CB2 receptor agonist JWH133 decreases inflammatory cell infiltration, tissue and serum TNF-α, MIP-1α, and MIP-2 levels, tissue lipid peroxidation, and expression of adhesion molecule ICAM-1. CB2 activation also attenuates the TNF-α-induced ICAM-1 and VCAM-1 expression

in HLSECs and adhesion of human neutrophils to HLSECs *in vitro*. These findings suggest that activation of the hepatic EC system following IR can limit the degree of tissue injury by stimulating the CB2 receptors. In contrast, $CB2^{-/-}$ mice developed increased IR-induced tissue damage and proinflammatory phenotype. Reperfusion, but not ischemia alone, triggers a marked elevation of the plasma ANA and 2-AG levels (Kurabayashi *et al*., 2005), as well as of the hepatic ANA, 2-AG, and *N*-oleoyl-ethanolamine (OEA) concentrations, which are produced by all the major cell types of the liver (hepatocytes, Kupffer cells, endothelial cells). Such findings also suggest that an IR-induced activation of hepatic endocannabinoids may limit the extent of tissue injury via stimulation of CB2 receptors. Furthermore, various studies have been performed, again mainly in isolated rat heart models, to clarify the potential cardioprotective role of endocannabinoid and ANA-related mediator signaling in I/R injury. Perfusion with PEA or 2-AG, but not ANA, decreased myocardial damage in isolated rat hearts, whereas CB2 antagonism with SR144528 totally abolished the beneficial effects of PEA and 2-AG (Lepicier *et al*., 2003). The CB1 antagonist rimonabant only partially blocked the effect of 2-AG. However, selective agonists for both CB1 and CB2 receptors, ACEA and JWH-015, also reduced the infarct size in this isolated rat heart model of low-flow IR. The effect of SR144528 on PEA-mediated actions is surprising because it is considered to act through CB1- and CB2-independent pathways. Previous findings may suggest that the CB2 antagonist SR144528 may also antagonize some of the effects mediated by PPAR-α agonists. Indeed, it has been described that the analgesic effects of PEA and other PPAR-α ligands are antagonized by SR144528 (Calignano *et al*., 1998; LoVerme *et al*., 2006). The above-described findings are somewhat conflicting with a subsequent study published by Underdown *et al*. (2005). In an isolated rat heart model of no-flow ischemia and reperfusion, ANA perfusion reduced the infarct size, which could be blocked by either CB1 or CB2 antagonism, using rimonabant or SR144528, respectively (Underdown *et al*., 2005). However, CB1 and CB2 agonists (ACPA and JWH-133) could not mimic the effect of ANA.

Endocannabinoids acting via CB1/CB2-dependent or independent mechanisms have also been implicated in the protection conferred by various forms of pre-conditioning (including ischemic) of the myocardium. In a whole animal model of myocardial IR injury induced by coronary occlusion/reocclusion in anesthetized mice, the published evidence points to the protective role of CB2 but not CB1 receptor activation (Lamontagne *et al*., 2006). In a recent study using non-selective CB agonist WIN55212–2 and CB2 antagonist AM630 in a mouse model of myocardial IR, the reduction of leukocyte-dependent myocardial damage could be attributed to CB2 receptor activation because the protection afforded by WIN55212–2 could be prevented by AM630, but not by CB1 antagonist AM251 (Di Filippo *et al*., 2004).

ANA is likely to play an important role in the control of vascular tone, as supported also by the observation that both rat endothelial cells and macrophages can release it (Randall *et al*., 1996; Deutsch *et al*., 1997). Randall *et al*. (1996) suggested that ANA is a candidate for endothelium-derived hyperpolarizing factor (EDHF). To address this question, the effects of SR141716A were investigated against endothelium-dependent relaxations both in rats and in isolated perfused rat superior mesenteric arterial bed. Relaxations of the mesentery responses to ANA (300 nmol; $n = 5$) were unaffected by removal of the endothelium but were antagonized by 1 mM SR141716A and reduced in the presence of high K (60 mM) buffer. Deutsch *et al*. (1997) showed that ANA, via CB1 receptors, stimulates renal endothelial cells to release NO, which is an important mediator of the hemodynamic and neurological actions of ANA in the renal vasculature. In this preparation, NO release was more sensitive to ANA (10 nM) than were the blood-perfused juxtamedullary afferent arterioles, where 1 μM was needed to elicit significant vasodilation. ANA (1 μM) also stimulated NO release from cultured renal microvascular endothelial cells. NO release from cultured endothelial cells was inhibited by *N*-nitro-l-arginine methyl ester (L-NAME). Sugiura *et al*. (1998) also examined whether or not 2-AG can be released from human umbilical vein endothelial cells and human aortic smooth muscle cells. About 35% of [^{3}H]AG was released into the medium from either control or thrombin-stimulated cells. It was found that 2-AG is the predominant species of AG in endothelial cells: about 80–90% of AG was 2-AG in both control and thrombin-stimulated cells. It was also found that the level of 2-AG was markedly elevated in thrombin-stimulated cells (195% of control).

3 CONCLUSIONS

Different studies emphasize participation of the endogenous cannabinoid system in physiological and pathological conditions. Additionally, for the same condition different studies report up- or down-regulation of the CB receptor-mediated signaling exerting either protective or harmful effects. Alterations in ANA and 2-AG tissue levels have been recorded in inflammation, immunological, cardiovascular, and hepatic disorders. Of interest, changes in endocannabinoid tone in the same direction often accompany opposing symptoms, or levels of ANA and 2-AG change in different or even opposing ways during the same condition. It is becoming increasingly clear that, within a certain tissue, the endocannabinoid system is affected in more than just one way by a given stressful or pathological stimulus, depending on the nature and duration of this stimulus, subsequently leading to more than one functional outcome. For this reason, the data existing so far implicate these mediators in disease states and target organ toxicity but further studies are needed.

Integrative Analysis of Microarray Data: A Path for Systems Toxicology

Axel Rasche, Reha Yildirimman and Ralf Herwig

Bioinformatics Group, Department of Vertebrate Genomics, Max-Planck-Institute for Molecular Genetics, Berlin, Germany

1 AFFYMETRIX MICROARRAYS

The Affymetrix GeneChip® 3′ IVT arrays consist of probes of 25 base pair length synthesized with a photolithographic method on quartz wafers (Dalma-Weiszhausz *et al*., 2006; Fodor *et al*., 1991). For a tissue sample, dye-labeled RNA is hybridized to the array. Samples are compared by using different arrays as experimental replicates. The array used for hybridization is scanned to generate an image with light spots for probes dominantly present among the RNA. The scanned image hybridization values are derived for each probe.

Probes are organized in pairs. The perfect match probe (PM) has full complementarity to the target sequence. The mismatch probe (MM) is similar to its corresponding PM probe but the 13th nucleotide is changed to its base pair complement. The MMs are introduced with the intention of measuring local background signal.

Transcript sequences are drawn from public databases such as UniGene, RefSeq, or Ensembl. Transcript abundance is measured by several probes with different sequences that are distributed across the gene sequence. This set of probes constitutes a probe set unique to a gene. Probe sets comprise 4–11 probes depending on the chip platform. For example, in the popular mouse 430 2.0 array, there are 11 probes in one probe set. An annotation of probe sets to genes is provided by Affymetrix (Affymetrix, 2009). But with new releases in the sequence databases probes may become obsolete, either because they do not hit the target sequences anymore or because specificity is reduced by single-nucleotide polymorphisms. Obsolete probes are supposed to introduce noise. In the R/BioC package "customCDF ", the probes are remapped to gene sequences and are reorganized in new probe sets (Dai *et al*., 2005).

2 STANDARDIZED PROCESSING OF AFFYMETRIX EXPRESSION ARRAYS

Integration and meta-analysis of different data sets requires standardized data analysis (Jensen and Steinmetz, 2005). One possible framework for automation of the processing is the R/BioConductor framework (Gentleman *et al*., 2004; R Development Core Team, 2005). Within this framework, biologically motivated corrections of the primary data are performed using statistical models. The processing comprises three steps: determination of test cases, pre-processing and data evaluation, see Figure 1.

Most experiments have a case control design comparing two groups of samples. Without loss of generality these groups are denoted as treatment and control and constitute a test case. For both groups,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat207
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

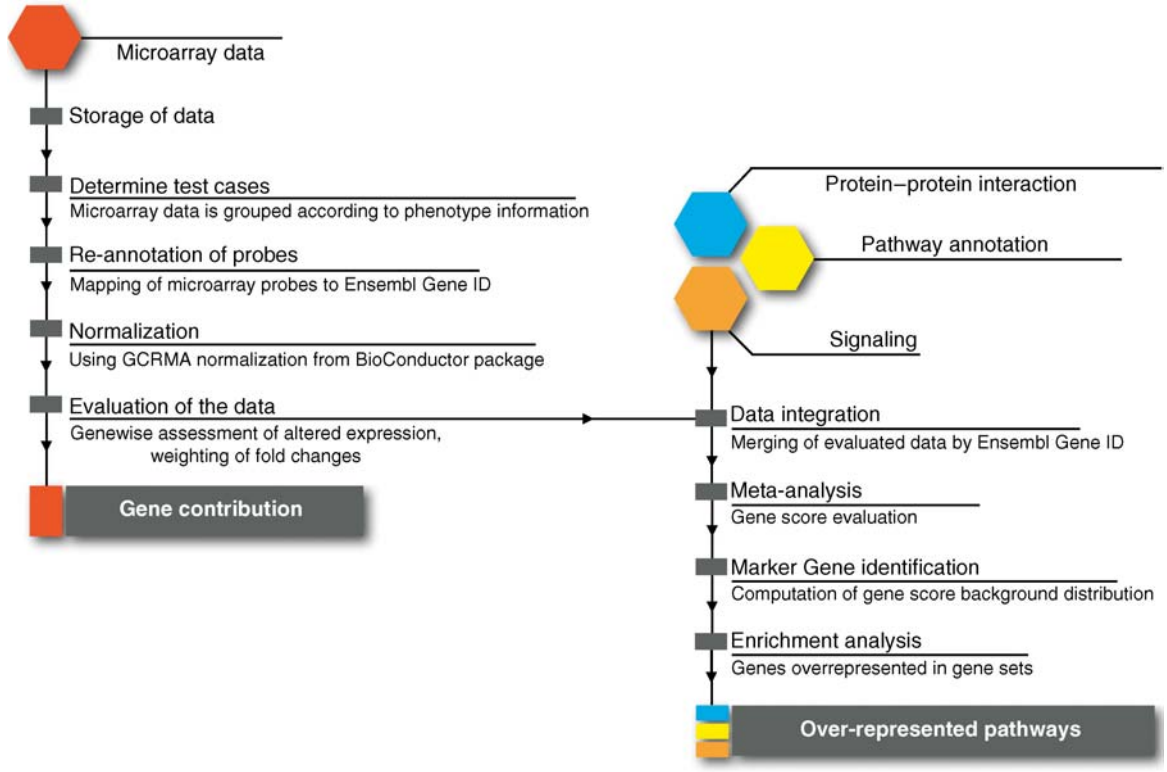

Figure 1. Data workflow for the meta-analysis.

replicates should be generated for solid statistical analysis. For a test case, the generated chips are normalized with each other.

Preprocessing accounts for three major influence factors in the hybridization data: background expression, probe binding affinity and measurement variation (Clevert and Rasche, 2009). After years of research, several methods are available for pre-processing. As an example, GC-corrected robust multiarray analysis (GC-RMA) is presented as a three-step procedure: background correction removing unspecific intensities from scanner images, reduction of non-biological differences between chips, and summarization of probe intensities to probe set expression values (Wu and Irizarry, 2004). Probe hybridizations consist of technical artifacts such as chemical background, optical background, or cross-hybridization. GC-RMA corrects for such effects taking into account the GC content of the probe sequences, that is, the number of G or C nucleotides in the sequence. A higher GC content is associated with a higher binding affinity of the probes because of three instead of two covalent bindings for single nucleotides. GC-RMA contains a position-specific model correcting the binding affinity between probes.

Between chips, unwanted effects are introduced by RNA extraction, pipetting, temperature fluctuations, hybridization efficiency and more. To reduce these effects, the quantile normalization is implemented in GC-RMA (Bolstad *et al.*, 2003).

Finally, probe intensities are summarized into probe set expressions. GC-RMA uses median polish (Irizarry *et al.*, 2003). Median polish proposes a linear model of a baseline hybridization with two factors: a probe effect and an array effect. The model is fitted robustly with a median decomposition.

An advantage of the probe set design is the possibility of calculating a presence tag, that is, the probability that the corresponding gene is duly expressed and active in the sample under study. Unexpressed genes confuse the results with low intensities, leading to high, unmotivated fold changes. The presence tag, or detection *p*-value, is

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat207
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

based on a comparison of raw perfect match values to corresponding mismatch values. Using a robust Wilcoxon test the result are *p*-values for subsequent interpretation.

The computation of gene expressions and presence tags is followed by a gene-wise evaluation of treatment versus control expressions. Expressions are assessed by three criteria: presence, variation, and alteration (Rasche, Al-Hasani and Herwig, 2008). For the approach of a meta-analysis as presented in this chapter, the three criteria are condensed into a single score for every gene. The score s_i of the i-th gene is computed as follows:

$$s_i = \begin{cases} |\log 2\,(r_i)| \left(1 - \frac{e_i}{r_i}\right)(1 - p_i), & p_i \leq 0.1 \text{ and } e_i/r_i \leq 1 \\ 0, & \text{else} \end{cases}.$$

Here, r_i is the fold change, p_i is the average detection *p*-value, and e_i is the standard error of the ratio derived from the experimental replicates of the study. Thus, the fold change is weighted with its reproducibility across the experimental replicates and with the likelihood of the gene being expressed in the study's target samples.

3 STORAGE OF EXPRESSION ARRAY DATA SETS

The use of microarray techniques generates large amounts of raw and processed data. A data repository capable of storing all information is a crucial requirement for an integrative analysis approach. BASE (BioArray Software Environment) is a MIAME (Minimum Information About a Microarray Experiment) compliant platform that provides an integrative framework for data storage, management and analysis (Brazma *et al*., 2001; Vallon-Christersson *et al*., 2009). It offers a web browser user interface, a laboratory information management system (LIMS) for arrays and biomaterials, features batch import/export functionality of data, and integrates tools for data analysis and visualization. Furthermore, it is possible to write extensions and plug-ins to add further functionality to the whole system, such as data transformation, data viewing, and analysis modules. BASE is written in Java and data are stored in a relational database (e.g., MySQL) in flat files. All software necessary to run a local installation is freely available. This and similar databases can be efficiently used for storing and querying microarray data.

4 EXPERIMENT ANNOTATIONS AND TEST CASE SETUP

Heterogeneous annotations on biological, technical, and hierarchical levels are necessary to define the initial test cases for a meta-analysis and are fundamental for analysis. Each microarray hybridization experiment is accompanied by biological and technical annotations. Biological annotations comprise information about the sample, for example, species, cell line, tissue source and condition. Depending on the experimental focus, this list will need to include additional fields. For example, the investigation of the effect of chemical compounds on different cell lines implies that information about compound dosage and time points are given. Technical annotations comprise information surrounding the hybridization, for example, labeling, RNA/DNA extraction protocol, array platform, quality control data, and personnel involved. This information is necessary for quality control and correct grouping of raw data.

The following meta-analysis approach illustrates a typical microarray data analysis. It investigates the effect of chemical compounds on diverse biological materials. All test cases are defined by species, biological target (e.g., tissue, cell line), compound, dosage and time. As an additional point, we introduce the meta-analysis of different compounds and different experimental platforms in order to derive a generalized picture of compound action.

5 SCORING OF TOXICITY RELEVANCE BY META-ANALYSIS OF MICROARRAY DATA SETS

Necessary for any meta-analysis is the consolidation of the different identifier types, species, or arrays (Rasche, Al-Hasani and Herwig, 2008). The Ensembl database provides a stable reference for microarray studies (http://www.ensembl.org; version 55). As comparability of chip studies is hindered by the total number of probes and pre-processing issues between manufacturers, the analysis in this chapter constrains on studies using Affymetrix arrays. Expression results from the arrays are mapped to Ensembl by the customCDF annotations (Dai *et al*., 2005). The whole data analysis is performed in R/BioC (Gentleman *et al*., 2004; R Development Core Team, 2005).

Table 1. Data sources.

Compound name	CAS	Species	Tissue (no. test cases)	Data source	Exp. Type
2-Amino-1-methyl-6-phenylimidazo [4,5-b]pyridine (PhIP)	105650-23-5	Human	Lung (4)	E-MIMR-102	*In vitro*
Bis-(2-chloroethyl) sulfide (sulfur mustard)	505-60-2	Rat	Lung (6)	GSE1888	*In vivo*
4-Nitroquinoline 1-oxide (4-NQO)	56-57-5	Mouse	Lymphoma (9)	E-TOXM-1	*In vitro*
Ochratoxin A (OTA)	303-47-9	Rat	Kidney (5), Liver (5)	GSE2852	*In vivo*
Carbonyl chloride (phosgene)	75-44-5	Mouse	Lung (8)	GSE2565	*In vivo*
			Total no. 37		

The effect of compound exposure to biological systems is manifold. In this meta-analysis approach, we investigated the influence of five compounds on several cell lines and tissues, identifying a group of genes related to the overall toxicity of the chemicals under study. Furthermore, we explored functional information and identified pathways associated with this core set of genes.

All studies are listed in Table 1. 2-Amino-1-methyl-6-phenylimidazo[4,5-b]pyridine) is a heterocyclic carcinogen in the human diet and has been studied in human lung adenocarcinoma A549 cells at several time points using the Affymetrix HG U95Av2 platform (Giard *et al*., 1973). Male Sprague–Dawley rats were exposed to the cytotoxic chemical sulfur mustard at several time points and lung tissue extracts hybridized on the Affymetrix RAE230A platform (Dillman *et al*., 2005). Transcription profiling of mouse lymphoma L5178Y cells treated with the tumorigenic compound 4-nitroquinoline *N*-oxide at several time points was performed on the Affymetrix MG_U74A platform (Newton, Aardema and Aubrecht, 2004). Ochratoxin A is a common food-contaminating, potentially carcinogenic and weakly mutagenic mycotoxin studied at several time points in male Fischer 344 (F-344) rats using the Affymetrix RG_U34A platform (Marin-Kuan *et al*., 2006). Phosgene is a highly toxic gas that was tested at several time points on male CD-1 mice using lung tissue extracts for transcription profiling on the Affymetrix MOE430A platform (Sciuto *et al*., 2005). Hybridization raw data and experimental information from these studies were downloaded from GEO (Barrett *et al*., 2009) or ArrayExpress (Parkinson *et al*., 2007). In total, 37 test cases were defined, representing the five compounds at investigated time points and dosages.

As described above, the gene expression alteration in every study is quantified with a score. For every gene, the scores from individual studies are summarized constituting a gene score. These gene scores now introduce a ranking among the total set of 14 035 analyzed genes, highlighting genes with special toxicological relevance. To assess the significance of the gene scores, a background distribution of scores is computed. In a bootstrap approach, random scores are drawn from each study. Genes with a score above the 99.9% threshold of the background distribution are called significant, and for this study, a cut-off score value of 6.041 was computed. This procedure results in a core set of 956 genes that show significant toxicity relevance in the data sets under study.

6 IDENTIFICATION AND EVALUATION OF TOXICOLOGIC MARKER GENES

The 10 genes with highest scores are listed in Table 2. For example, *EGR1* encodes a C2H2-type zinc-finger protein that functions as a transcriptional regulator, targeting genes involved in differentiation and mitogenesis. *FOS* is one of the four Fos gene family members that encode leucine zipper proteins. These proteins can form, among others, the transcription factor complex AP-1, which controls several processes including cell proliferation, differentiation, transformation, and apoptosis. *BTG2* encodes a member of the BTG/Tob protein family. This gene is an anti-proliferative tumor suppressor, the encoded protein being involved in the regulation of the G1/S transition of the cell cycle.

These examples illustrate the general cellular response to diverse carcinogenic and toxic compounds leading to the activation of MAPK signaling pathways and DNA damage response pathways affected by genotoxic mode of actions of the different compounds.

To further validate the functional context of the marker genes with respect to biological networks, enrichment analyses based on the hypergeometric distribution assess whether these genes are over-represented. By this procedure, the 956 genes

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Table 2. Top 10 highest scored genes.

General meta-analysis			Meta-analysis ochratoxin A		
Rank	HUGO	Score	Rank	HUGO	Score
1	EGR1	28.41	1	SLC6A18	11.04
2	GCLC	25.94	2	DBP	10.28
3	MT1H	21.28	3	OAT	8.98
4	MT1A	19.05	4	PREP	8.15
5	FOS	18.9	5	HAAO	8.01
6	DNAJB1	18.83	6	HBB; HBD	7.95
7	MT1CP	17.44	7	IGFBP1	7.46
7	MT1DP	17.44	8	CYP2D6	7.37
9	DUSP1	15.27	8	CYP2D7P1	7.37
10	BTG2	15.24	10	SLC2A5	7.08

identify 339 significantly over-represented pathways with a *p*-value below 0.05 out of a total of 1830 pathways. The 10 most significant pathways are listed in Table 3.

Twenty-two significant genes are over-represented inside the *HIF-1-α* transcription factor network consisting of 63 members. This network functions as a master transcriptional regulator of the adaptive response to hypoxia and is involved in embryonic vascularization, tumor angiogenesis, and pathophysiology of ischemic disease. Further cancer-related pathways include Aurora A signaling (rank 22, *p*-value 2.43E−05), p53 signaling pathway (rank 35, *p*-value 1.51E−04), and pathways involved in cell maintenance such as metabolic pathways, cell cycle, and biological oxidations (rank 16, *p*-value 1.49E−05).

Table 3. Data sources.

CPDB pathway ID	*p*-value	Description
CPDB_PID_543	6.08E−011	*HIF-1-α* transcription factor network
CPDB_KEGG_65	7.01E−011	Metabolic pathways
CPDB_Reactome_221	4.50E−009	Glutathione conjugation
CPDB_KEGG_223	7.02E−008	Glutathione metabolism
CPDB_Reactome_188	3.00E−007	Integration of energy metabolism
CPDB_KEGG_329	5.06E−007	Metabolism of xenobiotics by cytochrome P450
CPDB_KEGG_709	7.03E−007	Fatty acid metabolism
CPDB_BioCarta_894	8.44E−007	oxidative stress-induced gene expression via *NRF2*
CPDB_Reactome_232	1.72E−006	Phase II conjugation
CPDB_KEGG_1822	3.49E−006	Cell cycle

In summary, we see that the five compounds under study increase the activity of genes and pathways involved in cell metabolism and maintenance. This example demonstrates that a meta-analysis of different compounds can create a general view on cellular response to genotoxic compounds and the effects on carcinogenesis.

7 CASE STUDY: OCHRATOXIN A

Another application of the meta-analysis can be achieved by looking at different experimental results for the same compound. To show the specific effect of ochratoxin A on the gene expression level, we conducted a separate case study. In total, 10 test cases were defined in this approach, five based on kidney extracts and five based on liver extracts. The computed cut-off score value of 3.736 defines a core set of 85 genes, whereas 66 of these genes overlap with the gene set from the main analysis. This amounts to 19 unique genes that show significant ochratoxin A relevance.

Among these genes is the methyltransferase Guanidinoacetate N-methyltransferase (*GAMT*). A defect in this gene has been related to neurologic syndromes and muscular hypotonia. Furthermore, another specific marker is *CYP4F2* that encodes a member of the cytochrome P450 superfamily of enzymes. These proteins catalyze many reactions involved in drug metabolism and synthesis of cholesterol, steroids, and other lipids.

Enrichment analysis identifies 67 significant pathways with a *p*-value below 0.05. Besides basic cellular processes such as biological oxidation and metabolic pathways also enriched in the multi-compound study, some pathways stand out in the context of ochratoxin A treatment. One example

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat207
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

is the post-translational protein modification pathway, one of the later steps in protein biosynthesis, consisting of eight genes whereof two genes are significant. This enrichment analysis-based conclusion is confirmed by a study indicating that ochratoxin A causes immunosuppression and immunotoxicity by, among other factors, inhibition of protein synthesis (Al-Anati and Petzinger, 2006).

Application of Systems Biology in Neurotoxicological Studies During Development

Cheng Wang, Lei Guo, Tucker A. Patterson and William Slikker

National Center for Toxicological Research, US Food and Drug Administration, Jefferson, AR, USA

1 INTRODUCTION

Systems biology has been defined as the iterative and integrative study of biological systems as they respond to perturbations (Auffray *et al*., 2003). In this review chapter, the value of systems biology to enhance the understanding of complex biological processes such as neurodegeneration in the developing brain is explored. High-throughput/data content molecular biology approaches including genomics, proteomics, and metabolomics provide the fundamental data necessary for the building blocks of biological systems. As these databases grow and become linked together as integrative modules, they provide the intermediate components necessary for the systems biology approach. It is the appropriate placement of these biological modules into a proposed mechanistic flow scheme, thus allowing for the development of integrated computational models, that is the overall goal. However, the development of these mathematical models often lags behind the initial definition of the system and remains to be accomplished for the current example.

For toxicology, it is essential that quantitative correlations of exposure (i.e., dose, time intervals, and outcome) be integrated into the computational model (Henry, 2003). In addition to knowledge about the proximate toxicant and its mechanism of action, the primary toxicological effect or phenotypic anchor must also be utilized (Waters, Olden and Tennant, 2003). At the systems biology level, quantitative simulations can be conducted and predictions of the model can be tested. The outcome of these iterations is systematically incorporated back into the model to improve its design and refine its predictive capacities. The interconnectivity of a system at this level determines its state and extends its predictive power (Jazwinski, 2002).

The goal of systems biology is to predict the functional outcomes of component-to-component relationships using computational models that allow for the directional and quantitative description of the complete organism in response to environmental perturbations (Waters *et al*., 2003). Systems biology approaches can also be used as effective tools for dissecting the mechanisms underlying toxicological phenomena associated with exposure to toxicants. It is the development of predictive models that integrate responses across different organizational levels that is the focus of this review chapter.

The developing nervous system may be more or less susceptible to neurotoxic insults depending on the stage of development. Because of the complexity and temporal features of the manifestations of developmental neurotoxicity, this area of toxicology can benefit from a systems biology approach. DNA microarray technology

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat208
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

simultaneously detects the perturbation in tens of thousands of genes in one single experiment and is rapidly becoming incorporated into toxicological research. Combined with bioinformatics tools, it has been widely used to investigate the mechanisms of toxicant action, to search for novel biomarkers of toxicity and to build molecular signatures or models for predictive toxicology (Boverhof and Zacharewski, 2006; Waring *et al*., 2001; Waters and Fostel, 2004). This chapter focuses on representative general anesthetics, including ketamine, as an example of the application of the systems biology approach to outline how specific receptor subunit and intracellular signaling events are involved in potential anesthetic-induced neurotoxicity. The biochemical and molecular mechanisms as well as gene expression profiles that underlie potential anesthetic-induced neurotoxicity, particularly during a sensitive developmental stage, are explored.

Four steps of a systems biology approach reported by Leroy Hood's group (Auffray *et al*., 2003) will be discussed in this context. First, available information on the biological system of interest will be described and a preliminary model of how the system functions will be formulated. Second, where possible, the genes and proteins expressed in the described pathways will be defined. Third, kinetic experiments providing information across important periods of development will be considered. Fourth, various global datasets will be integrated to determine whether they support the model. Discrepancies will be identified and hypotheses-driven studies will be conducted in order to address them. Thus, data generated via iteration of the third and fourth steps will be used to reformulate the model in light of new data.

2 ROLE OF GLUTAMATERGIC TRANSMISSION AND NMDA RECEPTOR DYSFUNCTION IN ANESTHETIC-INDUCED NEURODEGENERATION

The amino acid L-glutamate is generally recognized as the major excitatory neurotransmitter of the mammalian central nervous system (CNS), and glutamate receptors play a major role in fast excitatory synaptic transmission. Glutamate promotes neuronal migration, differentiation, and plasticity during development and throughout life (Komuro and Rakic, 1993). Malfunctions of the glutamate system can affect neuroplasticity and cause neuronal toxicity. In the case of anesthetic-induced neurodegeneration, many glutamate-regulated processes seem to be perturbed. Abnormal neuronal development, abnormal synaptic plasticity, and neurodegeneration have been proposed as mechanisms that underlie anesthetic-induced neuronal cell loss. It is becoming clear that some of the most important functions of the nervous system, such as synaptic plasticity and synaptic formation, critically depend on the behavior of NMDA receptors, and that neurological damage caused by a variety of pathological states can result from exaggerated or inappropriate activation of NMDA receptors (Choi, 1988; Olney *et al*., 2000).

The general anesthetic ketamine blocks subtypes of glutamate receptors: the NMDA receptors. As a dissociative anesthetic, ketamine is commonly used to produce analgesia in children in emergency departments (Kohrs and Durieux, 1998). Clinically, ketamine's role in pediatric anesthesia is well established. However, recent studies have found that ketamine may cause dose-dependent, widespread apoptotic neurodegeneration in immature rat and monkey brains (Ikonomidou *et al*., 1999; Jevtovic-Todorovic *et al*., 2003; Slikker *et al*., 2007). The window of vulnerability appears restricted to the phase of rapid synaptogenesis, also known as the brain growth spurt.

Glutamatergic transmission is mediated by receptor families that are classed as ionotropic (iGluRs) or metabotropic (mGluRs). iGluRs are ligand-gated ion channels that can be sub-classified into the following groups based upon their ligand-binding properties: NMDA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionate receptors (AMPA), kainate receptors (KA), and, more recently, delta receptors. NMDA receptors appear to be heteromeric complexes (Monyer *et al*., 1992). NMDA-R1 (Grin1) subunits can form homo-oligomeric receptors that are functional, and the presence of this subunit is required to produce detectable NMDA-activated channel currents *in vitro* (Buller *et al*., 1994). NMDA-R2 (Grin2A-D) subunits produce functional receptors only when co-expressed with NMDA-R1 (Monyer *et al*., 1992), and co-expression of NMDA-R1 with NMDA-R2 subunits increases their responsiveness to NMDA and yields different functional properties (Buller *et al*., 1994).

Proposed mechanisms for the developmental neurotoxicity caused by ketamine include a compensatory up-regulation of NMDA receptors and subsequent over-stimulation of the glutamatergic system by endogenous glutamate via this receptor up-regulation (Slikker *et al*., 2007; Wang *et al*., 2005, 2006). This results in dysregulation of calcium signaling, oxidative stress (Wang *et al*., 2000), and activation of the NF-kB signaling pathway (Wang *et al*., 2006). However, the exact molecular mechanisms underlying ketamine-induced apoptotic neuronal cell death remain elusive.

To better understand the molecular pathogenesis of ketamine-induced developmental neurotoxicity, systems biology approaches were carried out to examine the changes in gene expression profiles in developing brains, which have been shown to display a high susceptibility to ketamine-induced apoptotic neuronal cell death.

3 SYSTEMS BIOLOGY AND ANESTHETIC-INDUCED NEUROTOXICITY

3.1 Systems Biology Approach and Ketamine-Induced Neurodegeneration

Condensed or fragmented DNA was assayed using TUNEL staining as previously described (Johnson *et al*., 1998). The repeated ketamine exposure produced elevated neuronal cell death as indicated by an increased number of TUNEL-positive cells in the developing (PND 7) rat brain (Figure 1). In controls (Figure 1a), only a few TUNEL-positive cells were observed. However, numerous darkly stained TUNEL-positive cells exhibiting typical nuclear condensation and fragmentation were observed (Figure 1b) in ketamine-treated rat pups.

In order to understand the underlying mechanism of ketamine-induced neurodegeneration, brain tissues from the frontal cortical levels, where the most severe neuronal damage was expressed, were selected for RNA isolation and microarray analysis. Consistent with the TUNEL assay and previous *in vivo* data, a total of 32 genes were found to be involved in apoptosis, and among them, 15 genes were up-regulated and 17 genes were down-regulated (Table 1) in animals exposed to six injections of 20 mg kg^{-1} ketamine, compared with the controls (Shi *et al*., 2010). The apoptosis-related genes are a group of genes that have two distinct modes of operation: pro-apoptosis or anti-apoptosis. In response to various inducers such as stressful stimuli or sustained elevation of intracellular calcium levels, the ultimate fate of the brain cell is determined by the roles of these apoptosis-related genes in regulating the life/death cell balance. The mechanism(s) underlying the ketamine-induced neuronal cell death have not been fully elucidated. However, present microarray

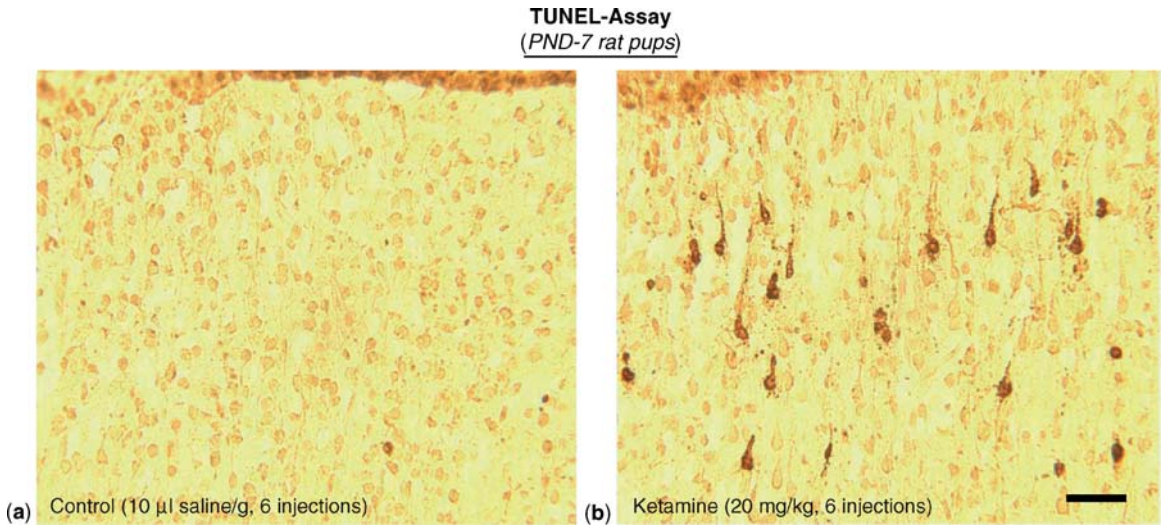

Figure 1. Ketamine-induced neurodegeneration in PND 7 rats assessed by TUNEL labeling. Representative photographs indicate that TUNEL-positive cells are more numerous in layers II and III of the frontal cortex in the ketamine-treated rat brain (b). Only a few TUNEL-positive cells were observed in the control (saline-treated) rat brain (a). Scale bar = 60 µm. Reproduced from Shi *et al.* (2010) © Elsevier.

data indicate that the majority (approximately two-thirds) of up-regulated genes were pro-apoptotic in nature, including Agt, Clu, Gjb6, Hrk, Igfbp3, Inpp5d, Jun, Mal, Rassf5, and Txnip. Meanwhile, from these up-regulated genes, expression of *Alb*, *Apoe*, and *Cryab* may provide inhibition of apoptosis (Mao *et al*., 2004). It has been reported that silencing the expression of *Bag3* (Bcl-2-associated athanogene 3) leads to reduced protein levels of Bcl-XL, Mcl-1, and Bcl-2 in colon cancer cells and increased apoptosis (Jacobs and Marnett, 2009). As a critical gene, *Cebpb* [CCAAT/enhancer-binding protein (C/EBP)] acts as a major regulator of metabolic homeostasis and is involved in many cellular processes, such as differentiation, growth, immune responses, neoplastic growth, development of the reproductive system, and pro- and anti-growth pathways (Gade *et al*., 2008).

However, in genes that have been down-regulated (17 genes), about one-half are anti-apoptotic genes. The over-expression of *Acvr1c* has been shown to suppress the apoptotic effects, and *Amigo2* acts as an anti-apoptotic factor (Hashimoto *et al*., 1998; Ono *et al*., 2003). *Bnip3* encodes cellular proteins that interact with Bcl-2. In cortical cells, cyanide induces a rapid up-regulation of *Bnip3* expression, followed by a caspase-dependent cell death (Prabhakaran *et al*., 2007). Down-regulation of *Cd24*, *Cdc2a*, and disruption of the *Rasa1* gene in early embryonic mice induce apoptosis of neuronal cells (Lapinski *et al*., 2007; Smith *et al*., 2006). In neocortical and hippocampal tissues, apoptotic effects can be demonstrated following *Ahr* activation (Kajta *et al*., 2009) and this gene was found to be upregulated in our studies. These observations may imply that the frontal cortex is the brain region most vulnerable to ketamine-induced neurotoxicity during development, and the neuronal survival in the early phases of the apoptotic cascades mostly depends on the balance between the pro- and anti-apoptotic factors of the apoptosis-related genes.

It should be mentioned that the present microarray analysis did not detect regulatory effects of some popular apoptotic genes, such as from the caspase-3 and Bcl-2 gene families (Slikker *et al*., 2007; Wang, Fridley and Johnson, 2005, 2006), in ketamine-induced neurotoxicity. This all may be related to the timing of sampling for the microarray analyses; analyses at different times after ketamine exposure may result in different observations.

Table 1. Apoptosis-related genes identified by GOFFA.

	Gene symbols	Gene names
1	*Acvr1c*	Activin A receptor, type IC
2	*Ahr*	Aryl hydrocarbon receptor
3	*Alms1*	Alstrom syndrome 1
4	*Amigo2*	Adhesion molecule with Ig like domain 2
5	*Atp7a*	ATPase, Cu^{2+} transporting, alpha polypeptide
6	*Bnip3*	BCL-2/adenovirus E1B 19 kDa-interacting protein 3
7	*Bub1b*	Budding uninhibited by benzimidazoles 1 homolog, beta
8	*Cd24*	CD24 antigen
9	*Cdc2a*	Cell division cycle 2 homolog A (S. pombe)
10	*Inhba*	Inhibin beta-A
11	*Myc*	Myelocytomatosis oncogene
12	*Ntf3*	Neurotrophin 3
13	*Pak7_predicted*	p21 (CDKN1A)-activated kinase 7 (predicted)
14	*Pdia2_predicted*	Protein disulfide isomerase-associated 2 (predicted)
15	*Rasa1*	RAS p21 protein activator 1
16	*Tnfrsf11b*	Tumor necrosis factor receptor superfamily, member 11b
17	*Unc5c*	unc-5 homolog C (C. elegans)
18	*Agt*	Angiotensinogen (serpin peptidase inhibitor, clade A, member 8)
19	*Alb*	Albumin
20	*Apoe*	Apolipoprotein E
21	*Bag3*	Bcl-2-associated athanogene 3
22	*Cebpb*	CCAAT/enhancer-binding protein (C/EBP), beta
23	*Clu*	Clusterin
24	*Cryab*	Crystallin, alpha B
25	*Gjb6*	Gap junction membrane channel protein beta 6
26	*Hrk*	Harakiri, BCL-2-interacting protein (contains only BH3 domain)
27	*Igfbp3*	Insulin-like growth factor-binding protein 3
28	*Inpp5d*	Inositol polyphosphate-5-phosphatase D
29	*Jun*	Jun oncogene
30	*Mal*	Myelin and lymphocyte protein, T-cell differentiation protein
31	*Rassf5*	Ras association (RalGDS/AF-6) domain family 5
32	*Txnip*	Thioredoxin-nteracting protein

Genes 1–17 were down-regulated, and genes 18–32 were up-regulated.

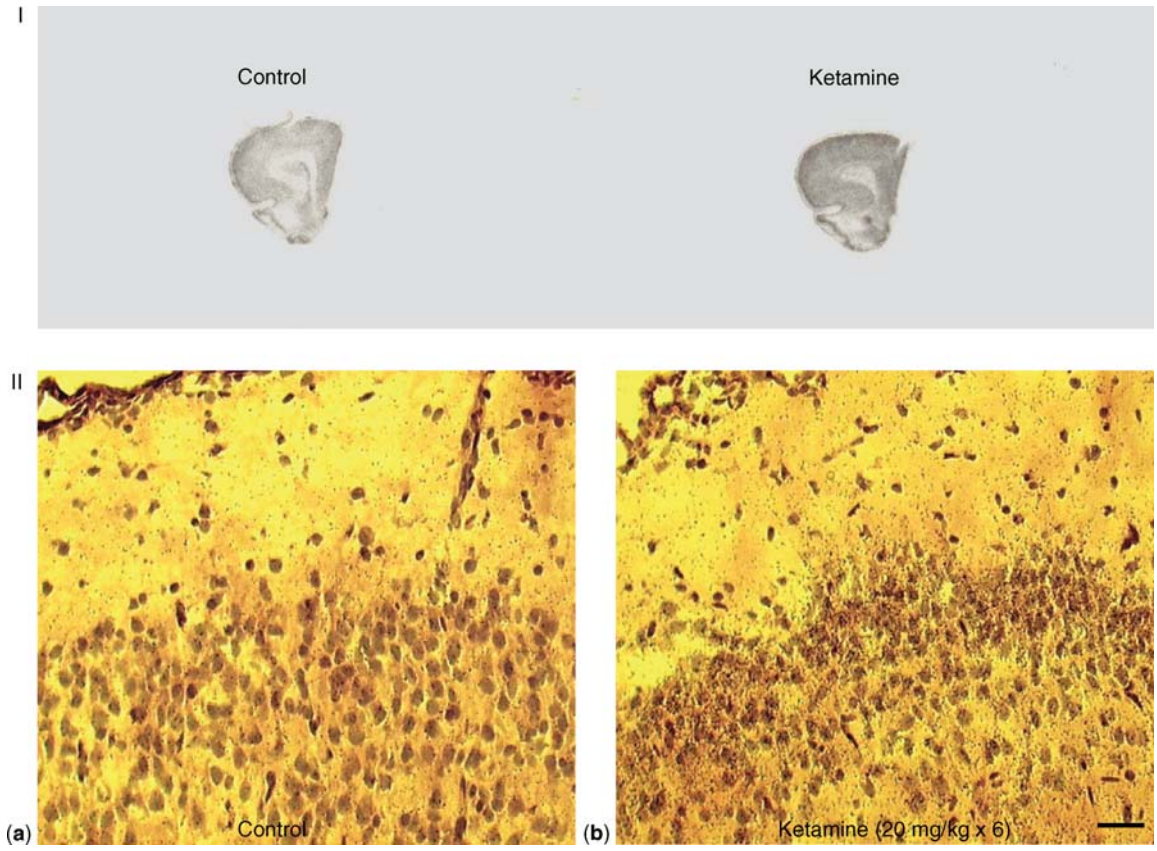

Figure 2. NMDA receptor NR1 subunit mRNA abundance in PND 7 rats. *In situ* hybridization was performed on rat brain sections (coronal) using a ^{35}S-labeled oligonucleotide probe specific for the NMDA receptor NR1 subunit. Panel I shows a general view of NR1 *in situ* hybridization signals in frontal cortical areas from both control and ketamine-treated rats. Panel II illustrates that the autoradiographic density (labeling) for NR1 subunit mRNA was higher in ketamine-treated (20 mg kg^{-1} × 6 injections) rat brain frontal cortex (b) compared with control (a). Scale bar = 90 μm. Reproduced from Shi *et al.* (2010) © Elsevier.

3.2 Systems Biology Approach and Ketamine-Induced Alteration in NMDA Receptor Expression

Because ketamine is an NMDA receptor antagonist, it was postulated that the localization of the most severe neurodegeneration in the frontal cortex might correspond to alterations in NMDA receptor expression levels. To dissect the underlying mechanisms, an oligonucleotide probe complementary to the mRNA encoding the NMDA receptor NR1 subunit was used for *in situ* hybridization. In both controls and ketamine-treated (20 mg kg^{-1} × 6 injections) rats, NMDA receptor NR1 subunit mRNA was prominent. The autoradiographic density (labeling) for NR1 subunit mRNA was up-regulated in the frontal cortex of rats treated with ketamine compared with control (Figure 2). Meanwhile, the gene expression of the NMDA receptor subunit gene, *Grin1* (*NR1*), was significantly up-regulated in ketamine-treated rat pups as detected in microarray experiments and subsequently confirmed with TaqMan analyses (Table 2) (Shi *et al.*, 2010). The

Table 2. Selective validation of the microarray results by Q-PCR.

Gene symbols	Fold-change (Q-PCR)	Fold-change (microarray)
Grin1 (NR1)	1.8*	1.5*
Grin2a (NR2A)	1.5*	1.2
Grin2b (NR2B)	1.0	0.9
Grin2c (NR2C)	1.7*	1.5*
Grin2d (NR2D)	1.2	1.1

* $P < 0.05$, as compared with the control.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat208
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

NMDA receptor NR1 subunit is widely distributed throughout the brain and is the fundamental subunit necessary for NMDA channel function. In these studies, by using *in situ* hybridization techniques to detect the relative densities of NMDA receptor NR1 subunits, a potential parallel relationship between enhanced apoptosis and NMDA receptor expression levels was examined. Our *in situ* data provided direct evidence that repeated ketamine exposure results in a substantial increase in autoradiographic density (labeling) of NR1 subunit mRNA in the frontal cortex and hippocampus. These data indicate that ketamine-induced pathological change is closely associated with a remarkable up-regulation of NMDA NR1 subunit mRNA.

It is possible that increased expression of *Grin1* (*NR1*) was accompanied by an altered expression of other glutamate receptor subunits. Our microarray analyses (Table 2) revealed an increase in *Grin2a* (*NR2A*; 1.5-fold) and *Grin2c* (*NR2C*; 1.7-fold), but no significant effects were observed in *Grin2b* (*NR2B*) or *Grin2d* (*NR2D*). It should be noted that NMDA-R2 subunits produce functional receptors only when co-expressed with NMDA-R1 (Monyer *et al*., 1992) and heteromeric complexes increase the responsiveness to NMDA and yield different functional properties (Buller *et al*., 1994). Our findings are consistent with those of previous *in situ* hybridization and immunoblotting data that demonstrated a compensatory up-regulation of NMDA-R1 and NMDA-R2 receptors following prolonged exposure to NMDA receptor antagonists (Slikker *et al*., 2007; Wang *et al*., 2005; Zou *et al*., 2009).

NMDA receptor density has been shown to increase in cultured cortical neurons after exposure to the NMDA receptor antagonists D-AP5, CGS-19755, and MK-801, but not after exposure to the AMPA/kainate receptor antagonist CNQX (Williams, Dichter and Molinoff, 1992). In the present study, no significant changes were detected in the gene expression patterns of AMPA or kainate receptors after repeated ketamine exposure. These findings support our previous pharmacological data showing that application of the non-NMDA receptor antagonist, CNQX, or nifedipine (an antagonist of the L-type voltage-sensitive calcium channel) did not produce a significant protective effect against ketamine-induced neuronal apoptosis (Wang *et al*., 2005). We hypothesize that continuous blockade of NMDA receptors by ketamine causes a compensatory up-regulation of NMDA receptors and this up-regulation makes neurons bearing these receptors more vulnerable, after ketamine withdrawal, to the excitotoxic effects of endogenous glutamate, because this up-regulation of NMDA receptors allows for the accumulation of toxic levels of intracellular calcium even under normal physiological conditions. This hypothesis is also supported by data from previous *in vitro* studies where it was shown that co-administration of antisense oligonucleotides that specifically target NMDA receptor NR1 and NR2A subunit mRNAs were able to block the neuronal damage induced by ketamine or PCP (Wang, Fridley and Johnson, 2005, Wang *et al.*, 2005, 2006).

4 PHARMACOKINETIC OUTCOMES AND PHYSIOLOGICAL PARAMETERS IN ANESTHETIC-INDUCED NEUROTOXICITY IN THE DEVELOPING BRAIN

Plasma concentration of ketamine is a critical parameter associated with neuronal cell death in animals. In perinatal monkeys, steady-state plasma concentrations of ketamine were achieved following 6–12 h of anesthesia. The ketamine levels in monkeys were 10–25 $\mu g\ ml^{-1}$, which is 5–10 times higher than those observed in humans (2–3 $\mu g\ ml^{-1}$) (Slikker *et al*., 2007). However, the dose of ketamine used was necessary to maintain anesthesia in this experimental animal model. Monkeys at various stages of development require different ketamine plasma concentrations to maintain anesthesia. Postnatal day (PND) 35 animals required higher plasma concentration of ketamine to maintain the same plane of anesthesia as the PND 5 animals (Figure 3). An important observation from the perinatal monkeys was that the plasma concentrations of ketamine were the highest in the PND 35 monkeys even though no evidence of increased neuronal cell death was observed as compared with control animals of the same age. In the PND 5 animals, where neuronal cell loss was evident, the plasma levels averaged approximately 10 $\mu g\ ml^{-1}$, which is only 3–5 times higher than the plasma levels observed in humans (Slikker *et al*., 2007).

Physiological parameters including percent oxygen saturation, exhaled carbon dioxide, body temperature, heart rate, blood pressure, glucose, and hematocrit were monitored in the experimental monkeys and all parameters were maintained within normal ranges. Monitoring and control of these parameters is essential for any animal model and is

made possible by using a nonhuman primate animal model. These parameters are carefully controlled during pediatric anesthesia, but it is very difficult to monitor them in rodent models. Because prolonged hypoperfusion can lead to cerebral hypoxia and ischemic-related cell death, it is necessary that no evidence of abnormal blood pressure or oxygen saturation was observed. In this nonhuman primate model study, the percent oxygen saturation averaged 94% or above for all study groups.

5 CONCLUSION

This chapter provides an overview of our efforts to apply a systems biology approach to understand a particular toxicological problem: potential anesthetic (e.g., ketamine)-induced neurodegeneration in the developing nervous system. Systems biology, as adopted for toxicology, is referred to as systems toxicology and involves the study of system perturbations caused by chemicals or stressors. By monitoring alterations in gene, protein, cell signaling, and pharmacokinetic outcomes, it is hoped to define the affected system(s) in an integrative manner.

In our studies with ketamine, alterations of 32 genes were associated with apoptotic pathways (Shi *et al.*, 2010). Perturbations of genes associated with NMDA-type glutamate and other receptor signaling pathways were identified by Ingenuity Pathway Analysis software. Q-PCR confirmed that NMDA receptor genes including *Grin1* (*NR1*), *Grin2a* (*NR2A*), and *Grin2c* (*NR2C*) were significantly up-regulated. The ketamine-induced up-regulation of NMDA receptor *Grin1* (*NR1*) mRNA signaling was further confirmed by *in situ* hybridization. In addition, elevated plasma concentrations of ketamine (pharmacokinetic experiments) appear to be a critical parameter associated with neuronal cell death in animals.

Although not yet fully delineated, the working model for anesthetic (e.g., ketamine)-induced neurodegeneration during development involves the modulation of normally occurring brain sculpting mechanisms that control CNS development. Exposure of the developing mammal to anesthetics (such as ketamine) perturbs the endogenous NMDA receptor system and results in enhanced neuronal cell death. These observations support our working hypothesis that prolonged ketamine exposure produces up-regulation of NMDA receptors and subsequent over-stimulation of the glutamatergic system by endogenous glutamate, triggering enhanced apoptosis of developing neurons (Figure 4).

Although many more studies are needed in order to build a quantitative model, some general pathways have been identified using the carefully crafted four steps of a systems biology approach. Further elucidation of the precise pathway and developmental stages of susceptibility to anesthetic agents awaits additional studies.

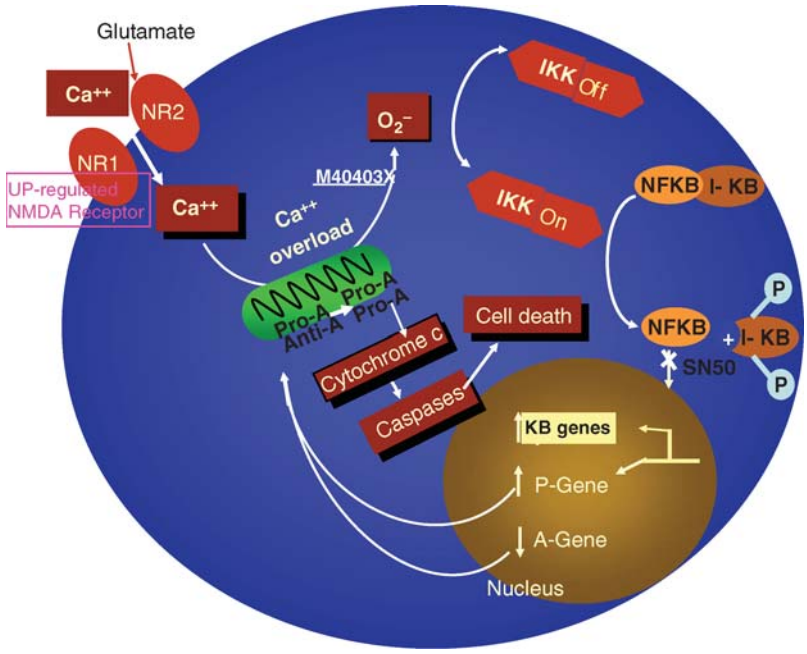

Figure 4. This cartoon illustrates our working model of potential anesthetic (e.g., ketamine)-induced neuronal cell death. Excessive activation of up-regulated NMDA receptors results in a calcium overload that exceeds the buffering capacity of the mitochondria and interferes with electron transport in a manner that results in an elevated production of reactive oxygen species, and the dissociation of some transcription proteins, such as NF-kB, and their transport into the nucleus. In the nucleus, these transcription factors bind to several DNA sequences of several known genes. The consequence of this binding is not completely understood, but the loss of the balance of pro- and anti-apoptotic genes is apparent: the diminished formation of anti-apoptotic heterodimers in favor of pro-apoptotic homodimers. These homodimers are thought to create mitochondrial membrane pores through which cytochrome *c* can leak into the cytoplasm where it can activate caspases that play a critical role in the ultimate demise of the neuron. Mitochondria-Specific Mouse Gene Array and its Application in Toxicogenomics

Varsha G. Desai

Center for Functional Genomics, Division of Systems Biology, National Center for Toxicological Research, US Food and Drug Administration, Jefferson, AR, USA

1 MITOCHONDRIA AND THEIR FUNCTIONS

Mitochondria are the powerhouses of cells that are responsible for the generation of more than 90% of the cellular energy by the process of oxidative phosphorylation. In addition, mitochondria are intricately involved in other key metabolic pathways, such as fatty acid oxidation, the Krebs cycle, the urea cycle, heme biosynthesis, steroid biosynthesis, as well as calcium signalling (Schatz, 1995; Pozzan and Rizzuto, 2000). It is also becoming increasingly evident that mitochondria are the 'cellular decision points' for apoptosis (programmed cell death), a process that serves as a major defence mechanism to remove unwanted and potentially dangerous cells (Petite and Kroemer, 1998). Collectively, these functions highlight a critical role of mitochondria in the life and death of the cell.

A distinctive feature of mitochondria is that these are the only subcellular organelles besides the nucleus that contain their own genome. Mitochondrial DNA (mtDNA) is a double-stranded, circular molecule of approximately 16 kb in size that encodes 13 polypeptides and the transcriptional machinery of two ribosomal RNAs (rRNAs, 12S and 16S) and 22 transfer RNAs (tRNAs) required for intra-mitochondrial synthesis of these polypeptides (Clayton, 1992). The large degree of complexity of mitochondria is due to the fact that among over 1000 proteins located within the mitochondria, only 13 proteins are encoded by the mtDNA (Taanman, 1999). These constitute 7 out of approximately 45 subunits in complex I, 1 out of 11 subunits in complex III, 3 out of 13 subunits in complex IV and 2 out of 16 subunits in complex V, all of which are critical components of oxidative phosphorylation. However, the remaining 76 proteins of oxidative phosphorylation are encoded by the nuclear DNA. In addition, proteins involved in different metabolic pathways within mitochondria, proteins responsible for the transport of ions and solutes across mitochondrial membranes, and proteins essential for mtDNA transcription, translation, replication and repair are all encoded by the nuclear DNA. These proteins are synthesized in the cytosol and are subsequently translocated into the mitochondria (Neupert *et al*., 1990). This strongly indicates that mitochondrial function is not solely controlled by mtDNA, but significantly influenced by nuclear genes. The precise coordination between the mitochondria and the nucleus is therefore vital to meet the energy needs of the cell as well as for proper functioning of metabolic pathways within mitochondria. In view of this, changes in expression levels of mitochondrial genes and/or nuclear genes associated with mitochondrial function may result in altered mitochondrial activity, which, in turn, could be disastrous to cells and, therefore, to tissue and organ function.

2 MITOCHONDRIAL DYSFUNCTION AND IMPLICATIONS IN DISEASES AND DRUG TOXICITIES

Tissues such as brain, liver, heart, respiratory systems, skeletal muscle, optic nerve, kidney and endocrine glands greatly depend on mitochondria for their high energy demands. When performing a primary role of energy production, these organelles also serve as a major source of reactive oxygen species (ROS) that can potentially induce damage to DNA, RNA, proteins and membranes, leading to cellular demise. Although mitochondria possess antioxidant defence systems to protect themselves against these toxic radicals, imbalance between production and detoxification of ROS can result in oxidative stress within mitochondria, leading to various pathologies in tissues.

2.1 Degenerative Diseases and Disorders

It is becoming more evident that subtle functional changes in mitochondria can manifest into insidious pathologies in neurons because these cells significantly depend on mitochondrial energy. Oxidative stress due to altered mitochondrial activity has been suggested as a major factor associated with the development of a number of neurological disorders including Alzheimer's, Parkinson's and Huntington's diseases, as well as amyotrophic lateral sclerosis (Jenner, 1996; Beal, 1998; Schapira, 1999; Manfredi and Beal, 2000). Like the brain, the heart immensely relies on mitochondrial energy for its contractile function. Impaired mitochondrial bioenergetics and changes in mitochondrial morphology in cardiomyocytes have been related to cardiovascular diseases such as dilated and hypertrophic cardiomyopathy, ischaemic cardiomyopathy, myocardial infarction and the pathogenesis of atherosclerosis (Lesnefsky *et al*., 2001; Ballinger *et al*., 2002; Marin-Garcia and Goldenthal, 2002; Monteiro *et al*., 2003). Defects in mitochondria have also been implicated in different types of cancers (Carew and Huang, 2002). Altered expressions, as well as activity, of mitochondrial respiratory chain complexes have long been suspected in the development and progression of cancer. Warburg's (1956) hypothesis suggests a shift from the oxidative phosphorylation to glycolysis to generate energy as a result of functionally impaired mitochondria in cancer cells. Mutations in mtDNA have been indicated as one of the features of cells in the breast, ovarian, brain, liver and colon cancers (Penta *et al*., 2001; Delsite *et al*., 2002; Tamori *et al*., 2004; Lu, Sharma and Bai, 2009; Akouchekian *et al*., 2009), which could render mtDNA-encoded components of oxidative phosphorylation complexes malfunctioning. Bearing in mind that mitochondria are significantly involved in apoptosis, their contribution in cancer development is not surprising.

There is considerable evidence that indicates mitochondrial involvement in obesity (Hojlund *et al*., 2008). In addition, mitochondrial dysfunction has been recognized in the pathogenesis of type-2 diabetes, a metabolic disorder characterized by insulin resistance in the initial stages that eventually progresses to impaired insulin secretion by the pancreas. Substantial evidence indicates altered mitochondrial dynamics responsible for insulin resistance (Zorzano, Liesa and Palacin, 2009) whereas a genetic defect in cytosolic–mitochondrial interaction has been reported as an underlying cause of impaired insulin secretion by the pancreas (Gerbitz, Gempel and Brdiczka, 1996; Petersen *et al*., 2003). A number of studies have also described association between mutations in mtDNA and development of type-2 diabetes (Kadowaki *et al*., 1994; Kameoka *et al*., 1998). Progressive accumulation of somatic mutations in mtDNA during lifetime leading to altered mitochondrial activity has been suggested to play a critical role in the ageing process (Linnane *et al*., 1989). In addition, functional decline in mitochondrial electron transport activity has been shown in animal models at various ages in different tissues (Sugiyama *et al*., 1993; Desai *et al*., 1996; Rafique, Schapira and Coper, 2004; Ferguson *et al*., 2005; Choksi and Papaconstantinou, 2008).

2.2 Mitochondrial Disorders

Constitutively, impaired mitochondrial activity can affect virtually every tissue and organ in the living organism. It can affect tissues individually or various combinations of tissues and organ systems. Tissues with the highest energy needs, such as the brain, heart and skeletal muscles are particularly vulnerable to the defects in mito-

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat209
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

chondrial bioenergetics that may manifest into neuropathies, cardiomyopathies and myopathies, often in combination and frequently in association with dysfunction in other organs (Scheffler, 2000). Mitochondrial disorders are characterized by a wide range of mutations in mtDNA that result in a variety of symptoms affecting multiple organs (Wallace, 1992). These disorders include mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS), myoclonic epilepsy with ragged red fibres (MERRF), chronic progressive external opthalmoplegia (CPEO), Leber's hereditary optic neuropathy (LHON), Kearns–Sayre syndrome (KSS) and neuropathy, ataxia and retinitis pigmentosa (NARP).

2.3 Drug- and Chemical-Induced Toxicities

A growing body of evidence suggests mitochondria as potential target organelles of different drug- and chemical-induced toxicities (Arnaudo *et al*., 1991; Adachi *et al*., 1993; Lewis and Dalakas, 1995; Foli *et al*., 2001; Kohler and Lewis, 2007; Santos *et al*., 2007; Desai *et al*., 2008). Chemotherapeutic drugs, such as bleomycin, *cis*-platin and doxorubicin, have been shown to induce mitochondrial dysfunction through different mechanisms (Adachi *et al*., 1993; Shen *et al*., 1995; Desai *et al*., 2000, 2001; Santos *et al*., 2007). Also, mitochondrial toxicity is a serious side-effect of anti-retroviral drugs, in particular the nucleoside reverse transcriptase inhibitors (NRTIs), such as zidovudine, stavudine and didanosine, used to treat human immunodeficiency virus-1 (HIV-1) infections (Foli *et al*., 2001). These drugs inhibit mitochondrial DNA polymerase gamma, an essential enzyme for mtDNA replication, resulting in depletion of mtDNA content, and/or cause mtDNA strand breaks by incorporating into mtDNA during DNA synthesis (Bienstock and Copeland, 2004; Cote, 2005; Kohler and Lewis, 2007). However, other mitochondrial targets can be significantly affected by these drugs (Desai *et al*., 2008, 2009). Moreover, mitochondrial dysfunction has been indicated as an early event occurring during exposures to environmental toxins, such as aflatoxin B1 and ochratoxin that are known to cause hepatic and renal cancer, respectively (Aleo, Wyatt and Schnellmann, 1991; Sajan, Satav and Bhattacharya, 1996). Similarly, mitochondria have been linked to neurotoxicity caused by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and 3-nitropropionic acid, chemicals used to mimic symptoms of Parkinson's and Huntington's diseases, respectively, in animal models (Beal, 2003; Ayala *et al*., 2007). Adverse effects of MPTP and its toxic metabolite 1-methyl-4-phenylpyridine on brain mitochondrial electron transport chain complexes have been demonstrated *in vitro* as well as *in vivo* (Desai *et al*., 1996; Gu *et al*., 2003).

3 POSSIBLE MECHANISMS OF MITOCHONDRIAL DYSFUNCTION

Mechanisms responsible for altered mitochondrial function are diverse. Mutations in mitochondrial genes and/or nuclear genes encoding mitochondrial proteins, altered transcription of these genes, faulty translation into proteins as well as interference with the coordination between mitochondrial and nuclear genomes can adversely influence mitochondrial function. Given that nuclear-encoded mitochondrial proteins are transported to mitochondria, proper transport of these proteins, assembly of proteins, in particular complexes of oxidative phosphorylation, and incorporation in the inner mitochondrial membrane are critical for normal mitochondrial activity. Maintenance of mitochondrial membrane potential is also equally important in maintaining mitochondrial function. One or a combination of all of these factors can substantially affect mitochondrial function. These can alter bioenergetics and other key metabolic pathways, impair membrane transport of ions and solutes, and/or disturb mitochondrial calcium homeostasis that may account for drug toxicities or various pathologies in tissues. Interference in mitochondrial biogenesis, a dynamic process critical for cell survival during changing metabolic environments, may also have implications in mitochondria-related drug-induced toxicities and diseases.

4 NEED FOR DEVELOPMENT OF A HIGH-THROUGHPUT MOLECULAR SCREENING TOOL IN MITOCHONDRIAL RESEARCH

As explained earlier, mounting evidence suggests mitochondrial dysfunction as an underlying cause of

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat209
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

a number of diseases and various drug-related toxicities. Mitochondria are complex cellular organelles that possess intricate networking of various molecular pathways. Understanding of the mitochondrial function in drug toxicities and diseases therefore requires a comprehensive approach to determination of the many aspects of mitochondrial function. The knowledge of the mechanistic basis of mitochondrial dysfunction is essential in the development of effective treatment strategies and the designing of novel interventions for minimizing the severity or delaying the progression of neurodegenerative diseases, such as Alzheimer's, Parkinson's and Huntington's diseases. Also, gaining insights into the molecular events associated with altered mitochondrial activity is important in obesity, particularly in children, as childhood obesity leading to early-onset diabetes has reached epidemic proportions in the United States. Evidence of irreversible cardiomyopathy induced by potent chemotherapeutic drugs, such as anthracyclines, and myopathy and hepatic steatosis as a result of exposure to anti-HIV drugs further emphasizes the need for the development of a high-throughput technology to delineate the mechanisms of impaired mitochondrial activity during toxic insults so that new treatment regimens can be designed to lessen drug toxicities. The use of advanced molecular technologies to get an improved perspective of mitochondrial activity will also prove valuable in understanding complex diseases such as mitochondrial disorders for which currently there is no cure.

Despite several approaches that are pursued thus far, the role of mitochondria in diseases and drug toxicities has still not been adequately elucidated. This could in part be due to utilization of seemingly insensitive molecular techniques that generated limited information. One of the most significant achievements in genomics in recent years is the innovation of DNA microarray technology that allows simultaneous measurement of expression levels of hundreds to thousands of genes in one experiment. Because of its high-throughput potential, it is rapidly emerging as an essential genomic tool in the study of xenobiotic-induced toxicities and in disease pathogenesis. Using this technology, a mitochondria-specific mouse oligonucleotide microarray (MitoChip) has been developed which is discussed in more detail below.

5 DEVELOPMENT OF MITOCHONDRIA-SPECIFIC MOUSE OLIGONUCLEOTIDE MICROARRAY (MitoChip)

The MitoChip was the first mitochondria-specific mouse oligonucleotide microarray and was developed at the Center for Functional Genomics at the National Center for Toxicological Research (NCTR) for profiling of the expression of 542 genes involved in mitochondrial structure and function (Desai *et al*., 2007). It consists of both mitochondrial and nuclear genes involved in oxidative phosphorylation, mtDNA transcription, replication and repair, mitochondrial biogenesis, mitochondrial fusion, the Krebs cycle, fatty acid β-oxidation, heme biosynthesis, steroid biosynthesis, lipid metabolism, apoptosis and mitochondrial membrane transport. It also includes nine housekeeping genes as positive controls and nine Arabidopsis plant genes as negative controls. Oligonucleotides corresponding to each gene are 50 bases long and were designed and synthesized by the MWG Biotech, Inc., Ebersberg (Germany).

5.1 Printing and Post-Processing of Arrays

The mouse oligonucleotides are printed on poly-1-lysine-coated glass slides (Erie Scientific, Portsmouth, NH, USA) using an OmniGrid® 100 microarrayer (GeneMachines, San Carlos, CA, USA) in a printing room maintained at 23 °C and 50% humidity. Printed arrays are baked for 2 h at 80 °C followed by cross-linking with 300 mJ of UV. Arrays are further treated with bovine serum albumin, fraction V solution containing sodium dodecyl sulphate (SDS), according to the procedure by Erie Scientific (www.eriesci.com) with minor modifications. The processed arrays are stored dry in drykeeper desiccator (without desiccant) (Sanplatec Corp, Osaka, Japan) maintained at 10% humidity until utilized in experiments.

5.2 Isolation and Determination of Quality of RNA

The quality of RNA is extremely important in microarray experiments as it influences the labelling efficiency of fluorescent dye molecules during

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat209
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

generation of high-quality targets. Total RNA is extracted from tissues using Qiagen RNeasy kits (Qiagen, Valencia, CA, USA). The purity and yield of the extracted RNA are determined spectrophotometrically by measuring optical density at wavelengths of 260 and 280 nm. The quality of extracted RNA is evaluated using the RNA 6000 LabChip and Agilent 2100 Bioanalyzer (Agilent Technologies, Palo Alto, CA, USA). Only RNA with RNA integrity number higher than 8, which indicates minimal RNA degradation and a ratio of 28S to 18S ribosomal RNA close to 2, is considered suitable for microarray experimentation.

5.3 Preparation of Fluorescently Labelled cDNA (Indirect Labelling Method) and Hybridization on MitoChip

The standard operating procedure used for preparation of cDNA targets is based on the protocol described previously (Hegde *et al*., 2000) with a few modifications. The indirect labelling method involves the incorporation of a nucleoside triphosphate analogue containing a reactive aminoallyl group followed by coupling with a fluorescent dye molecule to the aminoallyl group. Initially, DNase-treated RNA is reverse transcribed using random hexamer primers (Invitrogen, Carlsbad, CA, USA) and SuperScript II reverse transcriptase (Invitrogen) in the presence of reverse transcription labelling mixture containing deoxyribonucleotide triphosphates (dNTPs; Invitrogen) and aminoallyl-deoxyuridine triphosphate (aa-dUTP; Ambion, Austin, TX, USA), generating aminoallyl-cDNA. Upon purification, the aa-cDNA pellet is coupled with fluorescent cyanine dyes (Cy3 and Cy5; GE Healthcare, Piscataway, NJ, USA) to generate labelled targets. Samples and Universal mouse reference RNA (Stratagene, La Jolla, CA, USA) are labelled with Cy5 and Cy3, respectively. Before hybridization, labelled cDNA is scanned spectrophotometrically (200–700 nm) to ensure optimal dye incorporation per sample for adequate signal intensity. A mixture of Cy5-labelled treated sample and Cy3-labeled Universal mouse reference RNA in a salt-based hybridization buffer (Ocimum Biosolutions Inc., Gaithersburg, MD, USA) is pre-warmed at 42 °C before hybridization. Hybridization is carried out under a lifterslip (Erie Scientific) placed on the MitoChip in a closed hybridization cassette (TeleChem International Inc., Sunnyvale, CA, USA) in a water bath at 42 °C for 18 h. Following hybridization, the array is washed in three different buffers containing different concentrations of sodium chloride, sodium citrate and SDS, pre-warmed at 30 °C.

5.4 Scanning of Hybridized Array

The hybridized array is scanned with a GenePix 4000B scanner (Axon Instruments, Union City, CA, USA) at 10 μm resolution using appropriate gains on the photomultiplier tube (PMT) to obtain the highest intensity with <1% saturated pixels. The resulting image is analysed by measuring the fluorescence of hybridized targets on spotted oligonucleotides on the slide using the GenePix Pro 6.1 imaging analysis software (Axon Instruments). The data are further entered into the NCTR-designed database, ArrayTrack™, for storage and further analysis (Tong *et al*., 2004).

5.5 Statistical Analysis

The expression level of each gene is estimated as a $\log_2$ ratio, which is a ratio of the median fluorescence of Cy5 (the sample) relative to the median fluorescence of Cy3 (the reference standard). Data generated using commercial whole-genome arrays are normalized using Loess or median intensity normalization. However, normalization and analysis of the mouse MitoChip data are challenging because of the relatively low density of probes. Therefore, average expression of the housekeeping genes and Arabidopsis genes on the array is used as the normalizing covariate to analyse the expression data of mitochondria-related genes (Parrish and Delongchamp, 2006).

Gene expression data are further categorized into different gene ontologies (GO) based on molecular function, cellular compartment and biological process using the Mouse Genome Informatics website (www.informatics.jax.org). This allows meaningful biological interpretations of the massive amount of data generated in a microarray experiment. Effects of the treatment on each GO term (molecular function or cellular process) is determined by taking into account the change in expression level of each gene evaluated for GO (Delongchamp *et al*., 2006). Differential expression levels of genes are also

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat209
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

verified by quantitative real-time PCR to increase confidence in the MitoChip microarray data (Livak and Schmittgen, 2001).

6 VALIDATION AND UTILITY OF THE MitoChip

In an effort to validate the MitoChip, our laboratory has been involved in conducting several experiments aimed at elucidating the mechanism(s) of impaired mitochondrial function during exposures to drugs/chemicals. These agents include: (i) anti-HIV drugs, nucleoside reverse transcriptase inhibitors (zidovudine and lamivudine) and non-nucleoside reverse transcriptase inhibitors (nevirapine); (ii) chemotherapeutic drugs (flutamide and cis-platin); and (iii) a dietary supplement for weight loss (usnic acid) in different mouse models. This review will discuss results from the experiments conducted in C3B6F$_1$*trp*53 mice treated with zidovudine (AZT) and lamivudine (3TC), as well as B6C3F$_1$ mice treated with usnic acid.

6.1 Nucleoside Reverse Transcriptase Inhibitors and Mitochondrial Dysfunction

Much progress has been made to find a cure for the acquired immunodeficiency syndrome (AIDS) since the first cases of AIDS were reported in the United States in 1981. Several effective anti-retroviral drugs have been developed to treat HIV infections. These include NRTIs, nucleotide reverse transcriptase inhibitors (NtRTIs), non-NRTIs (NNRTIs), protease inhibitors and fusion inhibitors. However, a major breakthrough in the treatment of AIDS has been the development of the highly active anti-retroviral therapy (HAART) combination regimen. Since its implementation in 1997, not only the incidence of AIDS has decreased but the survival in AIDS patients has substantially increased. Among different classes of anti-retroviral drugs that comprise the HAART regimen, NRTIs remain a major component of the combination therapy.

3′-Azido-3′-deoxythymidine (AZT, zidovudine) was the first NRTI approved by the US Food and Drug Administration (FDA) to treat HIV-1 infections. Although current guidelines by the Centers for Disease Control and Prevention recommend HAART combination regimen as standard care for treating HIV-1 infections, AZT monotherapy is prescribed to HIV-1-infected pregnant women during labour until delivery and to newborns for the first 6 weeks of life to reduce mother-to-child transmission of the HIV-1 virus (Connor *et al*., 1994; Abrams, 2004; Mofenson, 2004; Center for Disease Control (CDC) and Prevention, 2009). Besides, AZT in combination with lamivudine (2′,3′-dideoxy-3′-thiacytidine; 3TC) is the most commonly used NRTIs during pregnancy (Barbaro *et al*., 2005; Watts, 2006). It is also one of the effective dual NRTI combinations recommended to HIV-1-infected adults (CDC, 2008). Nonetheless, the success of the NRTIs also brought challenges of drug-induced adverse events that are believed to be due to mitochondrial dysfunction. These side-effects include metabolic (dyslipidemia and lactic acidosis), musculoskeletal (myopathy and osteopenia), hepatobiliary (hepatotoxicity and pancreatitis) and haematological complications (bone marrow suppression) (Moyle, 2000) that may significantly interfere with the quality of life and, in some cases, may even be life-threatening. To date, tremendous efforts have been invested in understanding the molecular basis of impaired mitochondrial function during exposure to NRTIs, in particular AZT alone or in combination with other NRTIs during transplacental or perinatal exposures in humans and in different animal models. These clinical and animal studies have examined effects of NRTIs on mitochondria at the molecular as well as ultrastructural levels. A few of these *in vitro* and *in vivo* studies conducted in different model systems are summarized in Table 1.

A widely accepted mechanism underlying NRTI-induced mitochondrial dysfunction is inhibition of DNA polymerase gamma, an enzyme necessary for replication of mtDNA (Lewis and Dalakas, 1995). Supporting this hypothesis are studies that demonstrated a decline in mtDNA content in skeletal muscle of HIV-1-infected adults on long-term AZT therapy (Dalakas *et al*., 1990; Arnaudo *et al*., 1991; Casademont *et al*., 1996), in skeletal and heart muscle of foetal *Erythrocebus patas* monkeys exposed transplacentally to AZT alone or in combination with 3TC (Gerschenson *et al*., 2000, 2004; Divi *et al*., 2007a), and in skeletal muscle of rats administered AZT postnatally (Lewis *et al*., 1992). Effect of long-term exposure to AZT on mtDNA was also evident *in vitro* in human HeLa cells that exhibited severe depletion in mtDNA contents

Table 1. *In vitro* and *in vivo* studies conducted to examine mitochondrial dysfunction during exposures to NRTIs.

Investigation	Drugs/mode of exposure/animal model	Reference(s)
Effect on mitochondrial morphology		
Change in number, size and structure of mitochondria in skeletal, cardiac muscle or liver	AZT in humans	Dalakas *et al*. (1990); Pezeshkpour, Illa and Dalakas (1991); Chen *et al*. (1992); Tomelleri *et al*. (1992); Peters *et al*. (1993); Simpson *et al*. (1993) Cupler *et al*. (1995)
	AZT in rats	Lewis *et al*. (1992)
	AZT or AZT/3TC *in utero* in human, monkeys, mice	Gerschenson *et al*. (2000, 2004); Bishop *et al*. (2004); Divi *et al*. (2004, 2007)
	AZT/3TC perinatal[a] in mice	Bishop *et al*. (2004)
	AZT in human myotubes	Semino-Mora, Leon-Monzon and Dalakas (1994)
Effect on mtDNA		
Depletion in mtDNA in skeletal or cardiac muscle, cord blood lymphocytes, or umbilical cord tissue	AZT or AZT/3TC *in utero* in monkeys, mice	Gerschenson and Poirier (2000); Gerschenson *et al*., (2000, 2004); Divi *et al*. (2007)
	AZT or 3TC or AZT/3TC perinatal[a] in mice	Chan *et al*. (2007)
Depletion in mtDNA in skeletal muscle	AZT in human	Dalakas *et al*. (1990); Arnaudo *et al*. (1991); Casademont *et al*. (1996)
	AZT in rats	Lewis *et al*. (1992)
AZT incorporation into mtDNA in skeletal muscle, liver, kidney or placenta	AZT *in utero* in mice	Olivero *et al*. (1997)
	AZT/3TC *in utero* in monkeys	Gerschenson *et al*. (2004)
Mutations in mtDNA tRNA genes in heart muscle	AZT *in utero* in mice	Walker *et al*. (2004)
Oxidative damage to mtDNA in skeletal muscle or liver	AZT in mice	de la Asunción *et al*. (1998, 1999)
Effect on mitochondrial bioenergetics		
Altered OXPHOS[b] enzyme function in skeletal or heart muscle	AZT or AZT/3TC *in utero* in monkeys	Gerschenson and Poirier (2000); Gerschenson *et al*. (2000, 2004)
	AZT in human	Mhiri *et al*. (1991)
	AZT or AZT/3TC perinatal[a] in human	Blanche *et al*. (1999)
	AZT in rats	Lamperth *et al*. (1991)
	AZT in human HeLa cells	Divi *et al*. (2007)
Respiration, calcium loading capacity, or membrane potential in isolated heart or liver mitochondria	AZT or ddI[c] in rats	Lund and Wallace (2004)
	AZT in rats	Elimadi *et al*. (1997)

[a] Perinatal indicates exposure to drugs both *in utero* and neonatal.

[b] oxidative phosphorylation.

[c] didanosine.

(Divi *et al*., 2007b). Unlike nuclear DNA, mtDNA lacks introns and protective histones. Also, DNA polymerase gamma has a relatively high error rate during replication and there is a limited DNA repair in the mitochondria. These factors render the mtDNA vulnerable to oxidative damage by ROS, resulting in mutations. Increased levels of 8-oxo-7, 8-dihydro-2′-deoxyguanosine, a marker of oxidative damage to DNA, have been reported in mtDNA in skeletal muscle of mice treated with AZT (de la Asunción *et al*., 1998). Mutations in mtDNA-encoded tRNAs were also found in the hearts of mice exposed perinatally to AZT, 3TC or AZT/3TC (Chan *et al*., 2007). Interestingly, AZT-induced mutations in mitochondrial tRNA genes persisted in heart muscle even late in life in mice exposed to the drug *in utero* (Walker *et al*., 2004).

A number of studies also have demonstrated significant influence of AZT on mitochondrial bioenergetics (Lamperth *et al*., 1991; Mhiri *et al*., 1991; Elimadi *et al*., 1997; Blanche *et al*., 1999; Gerschenson *et al*., 2000; Lund and Wallace, 2004).

As far as respiratory chain complexes in skeletal muscle mitochondria are concerned, long-term exposure to AZT resulted in inhibition of succinate-cytochrome *c* reductase activity in AIDS patients (Mhiri *et al*., 1991; Tomelleri *et al*., 1992) whereas activity of rotenone-sensitive NADH cytochrome *c* reductase was significantly lowered in rats (Lamperth *et al*., 1991). Altered respiration was also evident in heart and liver mitochondria in rats treated with AZT (Elimadi *et al*., 1997; Lund and Wallace, 2004). Although transplacental exposure to AZT/3TC decreased relative activities of respiratory chain complexes I and IV in skeletal muscle and complex I in heart muscle in *Erythrocebus patas* monkeys (Gerschenson *et al*., 2004), transplacental exposure to AZT alone in *Erythrocebus patas* monkeys caused depletion of complex I activity but increases in activities of complexes II and IV in skeletal muscle (Gerschenson and Poirier, 2000; Gerschenson *et al*., 2000), suggesting different mechanisms of AZT-induced mitochondrial toxicity. Abnormal activities of complexes I and IV were also observed in different tissues in children exposed to AZT *in utero* and after birth (Blanche *et al*., 1999).

Collectively, these findings provide convincing evidence that AZT alone or a dual combination of AZT and 3TC substantially alter mitochondrial function and that the mechanism underlying mitochondrial toxicity appears to be complex. Also, it is apparent that several mitochondrial targets may be involved in NRTI-induced toxicity. These findings are significant; however, these data do not explain the effects of NRTIs on other critical mitochondrial pathways, such as fatty acid β-oxidation and the Krebs cycle involved in energy metabolism, to understand the basis of altered mitochondrial function.

6.1.1 Evaluation of Mechanisms of Mitochondrial Dysfunction During Exposures to NRTIs Using MitoChip

Is the mechanism of NRTI-induced mitochondrial dysfunction a result of inhibition of DNA polymerase gamma or multi-factorial?

The first validation study performed for MitoChip was in collaboration with the National Toxicology Programme (NTP) at NCTR. This study involved treatment of female C3B6F$_1$*trp*53(+/−) haplodeficient and C3B6F$_1$*trp*53(+/+) wild-type mice with 240 mg/kg body weight (bw)/day AZT or a combination of AZT and 3TC at 160 and 100 mg/kg bw/day, respectively. These mice were transplacentally exposed from gestation day (GD)-12 to GD-18 followed by continued dosing in infant mice from postnatal day (PND)-1 to PND-28. Transcriptional profiling using MitoChip revealed no significant difference in expression levels of hepatic mitochondria-related genes between *p53* (+/−) haplodeficient and *p53* (+/+) wild-type mice (Desai *et al*., 2008). A striking finding was the greater effect of the combination regimen on expression levels of hepatic mitochondria-related genes than AZT alone in both genotypes. To elucidate the mechanism of mitochondrial dysfunction, knowledge of the interaction between mitochondrial and nuclear genomes is crucial because coordination between the two genomes determines the activity of mitochondria. One of the advantages of using the MitoChip is that it provides better insight into the cross-talk between mitochondrial and nuclear genomes under perturbed conditions such as NRTIs exposures.

In female C3B6F$_1$*trp*53 mice, AZT/3TC caused a significant decline in expression levels of mtDNA-encoded genes of complex I (NADH ubiquinone dehydrogenase), subunit 2 and 5 (ND-2 and ND-5) and complex IV (cytochrome *c* oxidase), subunits 1 and 2 (Co-I and Co-II) in conjunction with a severe down-regulation of 16 out of 19 tRNAs (84%) evaluated on the MitoChip (Table 2). In contrast, only 58% of the tRNAs were down-regulated by AZT alone. Interestingly, these changes in hepatic mitochondrial genes in AZT/3TC-treated mice were associated with significant up-regulation of a majority of differentially expressed nuclear genes of complexes I and IV, suggesting a compensatory mechanism to maintain the function of these complexes. Similarly, nuclear genes of complexes III and V were also up-regulated in these mice. The effect of NRTIs on mtDNA has been demonstrated by Chan *et al*. (2007) who showed greater damage to mtDNA in heart tissue of CD-1 mice perinatally exposed to AZT/3TC compared with the damage noted in mice treated with AZT or 3TC alone. Corroborating our genomic findings is a study that reported substantially altered activities of complexes I and IV in *Erythrocebus patas* monkeys exposed to AZT/3TC *in utero* (Gerschenson *et al*., 2004). However, important as these results are, they lack information on consequences of AZT/3TC exposure in terms of other mitochon-

NS, not significant. Number in parenthesis indicates total number of genes evaluated for the functional category. Fold change (FC) is relative fold change in the expression level of each gene calculated as a ratio of average expression level of treated samples to control samples. Fold changes with *P*-values ≤ 0.05 corresponding to each gene were considered significant and are marked with an asterisk. *P*-values in bold represent treatment effect on overall function, which is the combined effect of drug-induced change in expression level of each gene associated with functional category. Gene names are associated with gene symbols in parenthesis.

drial targets. MitoChip, on the other hand, provided information on AZT- and AZT/3TC-related changes in expression levels of genes associated with oxidative phosphorylation as well as shed some light on their influence on other mitochondrial pathways and processes (Desai *et al*., 2008). As an example, exposure to AZT/3TC was associated with changes in expression levels of genes involved in mitochondrial fusion. The mitochondrial fusion is a dynamic process that regulates mitochondrial size and morphology (Legros *et al*., 2002). Furthermore, it has been suggested that it may serve as a protective mechanism in response to altered bioenergetics (Chen and Chan, 2005). In view of this, up-regulation of genes, mitofusins (Mfn) 1 and Mfn 2 and optic atrophy 1 homologue (Table 2), involved in mitochondrial fusion in AZT/3TC-exposed mice may indicate an adaptation to altered mitochondrial respiratory function to sustain cell survival in AZT/3TC-treated mice.

Although one of the proposed mechanisms of NRTI-related mitochondrial toxicity is the result of direct inhibition of DNA polymerase gamma (Lewis and Dalakas, 1995; reviewed in Lewis, Day and Copeland, 2003), neither AZT nor AZT/3TC altered expression levels of polymerase gamma or its accessory subunit polymerase gamma 2 in the liver of C3B6F$_1$*trp*53 mice (Desai *et al*., 2008). However, the expression level of twinkle, a mitochondrial helicase, was significantly decreased only by AZT/3TC, suggesting that other genes essential in mtDNA replication may play an equally important role in influencing mtDNA levels during NRTI treatments. Consistent with this concept was lower mtDNA copy number in human osteosarcoma cells due to reduced expression of twinkle caused by RNA interference (Tyynismaa *et al*., 2004).

One of the adverse effects of NRTIs is lipodystrophy, a condition characterized by abnormalities in fatty (adipose) tissue associated with total or

partial loss of body fat, which could in part be related to defects in mitochondrial fatty acid metabolism. Thus far, studies investigating NRTI-mediated changes in fatty acid metabolism are inadequate to delineate the basis of lipodystrophy. Results obtained using the MitoChip have however aided in the understanding of the consequences of AZT and AZT/3TC exposures on the fatty acid β-oxidation pathway in C3B6F$_1$*trp*53 mice. Expression levels of genes associated with the initial step of dehydrogenation (acetyl-Coenzyme A dehydrogenase, short/branched chain) and the second step of hydration (enoyl-Coenzyme A hydratase, short chain, 1) of short-chain fatty acids were increased only by AZT/3TC, whereas hydroxyacyl-coenzyme A dehydrogenase-α that performs a dual role of dehydrogenation and hydration of long-chain fatty acids was induced by both AZT and AZT/3TC. Moreover, the expression level of hydroxyacyl-coenzyme A dehydrogenase-β, which is responsible for 3-ketoacyl-coenzyme A thiolase activity on long-chain fatty acids, was increased only by AZT treatment but not by AZT/3TC. Based on these findings, it appears that genes involved in the oxidation of short/branched-chain and long-chain fatty acids were influenced by AZT/3TC, whereas AZT treatment alone affected genes involved in the oxidation of only long-chain fatty acids. Both AZT- and AZT/3TC-treated mice also exhibited increased transcriptional level of carnitine palmitoyltransferase 1a, required for the transport of long-chain fatty acids. In view of these observations, up-regulation of genes associated with the oxidation of long-chain fatty acids may be in response to the enhanced transport of long-chain fatty acids. Collectively, these changes may imply altered fatty acid metabolism during exposure to NRTIs. If these changes signify increased fatty acid oxidation, then increased transcriptional levels of several genes associated with the Krebs cycle could be correlated to changes in fatty acid oxidation in both AZT- and AZT/3TC-treated mice (Table 2).

Each mitochondrion has its own DNA. However, mitochondrial proteins encoded by nuclear DNA are synthesized in the cytoplasm followed by their transport to different mitochondrial compartments by translocases of the outer and inner mitochondrial membranes. In addition, several other membrane translocators are essential for the transport of ions and solutes for mitochondrial activity. The use of the MitoChip also provided important information concerning AZT- and AZT/3TC-related changes in the transcriptional levels of various membrane transporters in the liver of C3B6F$_1$*trp*53 mice. The AZT- and AZT/3TC-mediated down-regulation of the deoxynucleotide carrier Slc25a19 may be of particular importance because of its role in the transport of deoxynucleotides, required for the synthesis of mtDNA into the mitochondrial matrix (Dolce *et al*., 2001). This change may partly influence the mtDNA levels by limiting the dNTP pools within the matrix. Moreover, AZT/3TC-mediated differential expression of sideroflexins (Sfxn1, 2 and 4) involved in the transport of components required for iron utilization into or out of mitochondria may have implications in conditions such as anaemia, one of the early adverse events observed in HIV-1-infected patients on NRTIs (Shah, 2006; Sivadasan *et al*., 2009).

It is important to note that NRTI-mediated changes in the expression levels of mitochondria-related genes were subtle. However, taken together, these relatively small changes in the expression levels of genes associated with a molecular function or a pathway may be biologically significant as these genes act synergistically. The results clearly indicate a greater influence of AZT/3TC (160/100 mg/kg) on mitochondria than of AZT (240 mg/kg) alone in the liver of C3B6F$_1$*trp*53 mice. This AZT/3TC-induced altered transcriptional profiles of mitochondria-related genes could be the result of synergistic action of 3TC with AZT based on the findings from the previous study in our laboratory that showed no effect of perinatal exposure to 160 mg/kg AZT on the transcriptional levels of hepatic mitochondria-related genes in both haplodeficient and wild-type C3B6F$_1$*trp*53 mice (unpublished data). Lamivudine (3TC) monotherapy is not recommended to HIV-1-infected patients; therefore, animals treated with 3TC alone were not included in this study. Altogether, these results underline the fact that NRTI-mediated changes in expression levels of genes related to mitochondrial function is a consequence of drug action on multiple mitochondrial targets and not exclusively due to inhibition of DNA polymerase gamma as previously postulated. Other factors such as genes involved in mtDNA replication (twinkle) and/or transport of substrates for mtDNA synthesis (Slc25a19) can equally influence mtDNA synthesis during NRTI exposure. The extent of the data generated by MitoChip clearly demonstrates its utility as a valuable genomic tool in understanding different aspects of mitochondrial function at the genome level during NRTI exposures, providing data for the generation of new hypotheses about

mitochondrial function. Such information is vital in designing safer treatment strategies or developing novel interventions to minimize the severity of drug-related side-effects in HIV-1-infected patients.

Is DNA polymerase gamma-mediated mechanism of mitochondrial dysfunction during NRTI exposure tissue-specific?

There is considerable evidence that indicates depletion of mtDNA levels in the heart and skeletal muscle of *Erythrocebus patas* monkeys exposed to 10 and 40 mg/kg of AZT *in utero* (Gerschenson and Poirier, 2000) and in skeletal muscle of AZT-treated rats (Lewis *et al*., 1992). This could partly be related to inhibition of DNA polymerase gamma. Supporting this notion was a study in our laboratory that showed a modest, but statistically significant dose-related decline in the mRNA expression level of DNA polymerase gamma in the skeletal muscle of male and female $B6C3F_1$ infant mice treated short term (PND-1 to PND-8) with 10, 50, 100 and 200 mg/kg AZT (Desai *et al*., 2009; Table 3). It is noteworthy that despite the small sample size ($N = 3$ per group), AZT-related decrease in the expression level of DNA polymerase gamma was significant in $B6C3F_1$ infant mice. Based on body surface area (mg/m^2), these doses correspond to human infant doses of 1.1, 5.5, 11.0 and 22.0 mg/kg, respectively. Interestingly, the effect of AZT on DNA polymerase gamma was evident in skeletal muscle of infant mice even at doses lower than a therapeutic dose (8 mg/kg/day). The change in DNA polymerase gamma was also associated with a significant dose-related decrease in the transcriptional levels of membrane transporters for deoxynucleotides (Slc25a19) and phosphates (Slc25a3), which, in turn, may affect mtDNA content in skeletal muscle by altering the transport of substrates essential for mtDNA synthesis. In addition, the expression of a gene encoding mitochondrial ribosomal protein L17, involved in mitochondrial genome maintenance, was significantly altered in skeletal muscle of these mice. Although mtDNA content was not measured in the skeletal muscle in infant mice, lower expression levels of genes involved in mtDNA replication and maintenance as well as transporters of substrates required for mtDNA synthesis together could change mtDNA levels in skeletal muscle.

Although significant decreases in the transcriptional level of DNA polymerase gamma were observed in skeletal muscle of infant $B6C3F_1$ mice at AZT doses lower than a therapeutic dose, the expression level of DNA polymerase gamma remained unchanged in the liver of $C3B6F_1$*trp*53 mice during perinatal exposure to 240 mg/kg AZT, 2.4-fold the recommended dose in human infants. Changes in the hepatic transcript level of DNA polymerase gamma were also not seen in another experiment in which adult male and female $B6C3F_1$ mice were postnatally exposed to AZT at doses as high as 600 mg/kg/day (4.8-fold human equivalent dose) for 12 weeks. In this experiment, AZT treatment neither changed the expression levels of genes involved in mtDNA replication nor altered the mtDNA copy number in the liver (unpublished data; partly presented in Table 3). It is important to mention that these results were derived from both adult and infant mice of different strains ($C3B6F_1$*trp*53 and $B6C3F_1$), receiving different AZT doses, and under different exposure conditions (perinatal and postnatal). However, based on observations that short-term exposure to AZT doses lower than a therapeutic dose resulted in a decrease in the expression level of DNA polymerase gamma in skeletal muscle of infant mice, whereas long-term AZT treatment at doses higher than two- and four-fold human equivalent doses in $C3B6F_1$*trp*53 and $B6C3F_1$, respectively, showed no effect on the transcription level of DNA polymerase gamma in the liver, one can hypothesize that DNA polymerase gamma-related mitochondrial toxicity during AZT exposure might be tissue-specific.

6.2 Weight-Loss Dietary Supplement, Usnic Acid, and its Effect on Mitochondria

Herbal dietary supplements are often regarded as safe remedies by consumers. Nonetheless, these products can result in severe adverse effects and can interfere with the efficacy of prescription drugs. Usnic acid is a lichen metabolite that exhibits antimicrobial (Lauterwein *et al*., 1995), antiviral (Scirpa *et al*., 1999) and anti-inflammatory (Vijayakumar *et al*., 2000) properties. Because of such broad-spectrum beneficial biological characteristics, this natural product is widely used in the treatment of a number of ailments (Rafanelli *et al*., 1995; Ingolfsdottir, 2002). The therapeutic antimicrobial and anti-inflammatory activities of usnic acid are due to its ability to uncouple mitochondria (Abo-Khatwa, Al-Robai and Al-Jawhari, 1996; Ingolfsdottir, 2002) and the same property is the

rationale for which it is marketed as a dietary supplement to lose weight. However, to achieve significant weight reduction, relatively high doses of usnic acid are required that can potentially result in serious side-effects. Its use became a safety concern when several cases of liver injury were reported in consumers who ingested dietary supplements containing usnic acid or sodium usneate for weight loss (Favreau *et al*., 2002; Frankos, 2004).

Animal studies investigating usnic acid-mediated effects on mitochondria not only are limited, but have primarily concentrated on measuring mitochondrial respiration or ATP production (Abo-Khatwa, Al-Robai and Al-Jawhari, 1996; Han *et al*., 2004; Pramyothin *et al*., 2004). In primary mouse hepatocytes, 2 μM (+)-usnic acid caused partial inhibition of state 3 respiration with a modest uncoupling of mitochondria, whereas a total inhibition of respiratory states 3 and 4 occurred at 5 μM (Han *et al*., 2004). Altered oxygen consumption, ADP/O ratio and ATP generation have been also reported in isolated rat liver mitochondria as well as in cultured mouse hepatocytes treated with hepatotoxic doses of (+)-usnic acid (Abo-Khatwa, Al-Robai and Al-Jawhari, 1996; Han *et al*., 2004; Pramyothin *et al*., 2004). Usnic acid-mediated morphological damage to hepatic mitochondria was also evident in rats treated intra-peritoneally with 200 mg/kg for 5 days (Pramyothin *et al*., 2004). Although several factors may be involved in usnic acid-induced liver injury, oxidative stress has been believed to be primarily responsible for liver toxicity based on changes observed in levels of hydrogen peroxide, lipid peroxidation and reduced glutathione in rat hepatocytes exposed to usnic acid (Han *et al*., 2004; Pramyothin *et al*., 2004).

Although these investigations have contributed to the understanding of the side-effects associated with dietary use of usnic acid, the precise molecular mechanism underlying usnic acid-induced liver toxicity still remains to be elucidated, probably due to lack of adequate knowledge concerning changes in overall mitochondrial activity. Critical mitochondrial pathways, such as fatty acid β-oxidation and the Krebs cycle that usnic acid might influence, have not been examined. Therefore, the MitoChip was used to investigate the interactions between mitochondrial pathways to understand the role of mitochondria in usnic acid-induced hepatotoxicity in a mouse model.

6.2.1 Determination of Molecular Changes Induced in the Mitochondria by Usnic Acid

In a collaborative study with the NTP at NCTR, transcriptional profiling of mitochondria-related genes was investigated in female $B6C3F_1$ mice administered (+)-usnic acid in rodent feed ad libitum for 14 days beginning at 8 weeks of age (Joseph *et al*., 2009). Groups of mice received 60, 180 and 600 ppm usnic acid/kg bw/day, doses that correspond to 15, 50 and 200 mg usnic acid/kg bw/day, respectively, based on the mean body weight and daily feeding measurements. The results obtained from the transcriptional analysis of 542 mitochondria-related genes showed a remarkable effect of usnic acid on genes associated with electron transport chain complexes, mitochondrial tRNAs, fatty acid/lipid metabolism, the Krebs cycle and apoptosis at the highest dose of 600 ppm (200 mg/kg) compared with controls.

A striking finding was a significant increase in expression levels of genes associated with all four complexes (I–IV) of the electron transport chain whereas complex V that is responsible for the production of ATP remained unaffected by usnic acid, suggesting usnic acid-mediated uncoupling. Tight coupling of electron transport with oxidative phosphorylation requires an adequate proton gradient across the inner mitochondrial membrane. Also, proper interaction between mitochondrial and nuclear genomes is essential, in particular for complexes I, III, IV and V, as these multi-subunit proteins are encoded by both mitochondrial and nuclear genomes. In usnic acid-treated mice, 30 out of 82 genes (37%) involved in oxidative phosphorylation were up-regulated in the liver. These included eight mitochondrial genes (five of complex I, one of complex III and two of complex IV) and 17 nuclear genes of complexes I–IV in association with increased expression of 10 mitochondrial tRNAs, suggesting enhanced mitochondrial electron transport activity. Considering this observation, one may argue that increased electron transport would result in a higher proton gradient across the inner mitochondrial membrane thereby, driving complex V to generate more ATP. In contrast, expression levels of genes of complex V remained unaltered by usnic acid. This may be due to the translocation of lipophilic usnic acid through mitochondrial membranes into the matrix, where it is

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat209

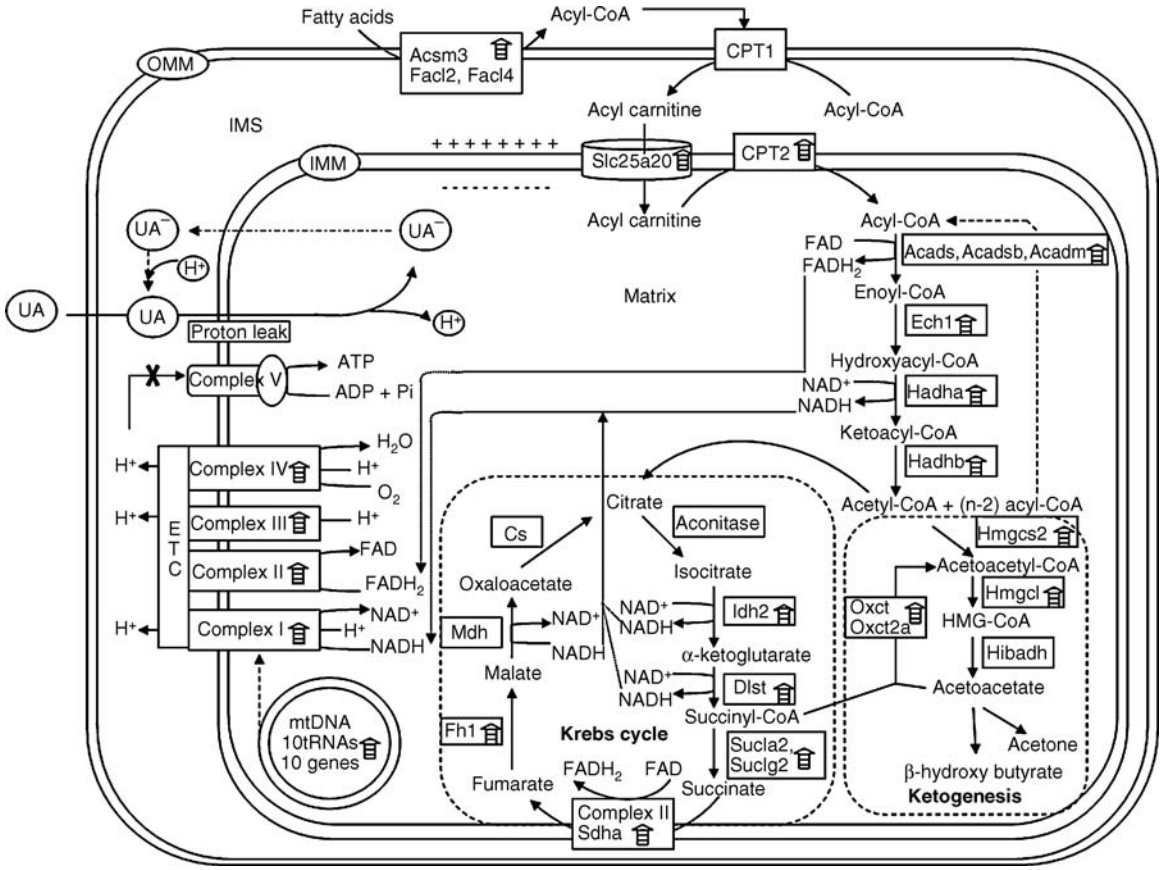

Figure 1. Schematic representation of UA-mediated effects on mitochondrial functions in the mouse liver. UA is a lipophilic compound that can easily pass through mitochondrial membranes into the matrix, releasing a proton into the matrix. The resulting usniate anion can diffuse back into the IMS where it can bind to a proton to re-form UA, which diffuses back into the matrix. The resulting cycle causes a proton leak that eventually can dissipate the proton gradient across the inner membrane, causing uncoupling. The insufficient proton motive force may not be able to activate complex V that in turn may alter ATP levels. However, complexes I–IV of the ETC can be induced by UA to create sufficient proton gradient across the IMM to activate complex V. This can also be associated with up-regulation of mitochondrial genes. This further may lead to activation of fatty acids to form acyl-CoAs followed by their increased transport into the matrix. Within the matrix, higher levels of acyl- CoA may induce the fatty acid β-oxidation pathway resulting in a final product, acetyl-CoA, which then can enter the Krebs cycle for continued oxidation to CO_2. However, if the amount of acetyl-CoA exceeds the capacity of the Krebs cycle, the level of acetyl-CoA can partly be diverted to ketogenesis followed by ketone body degradation to maintain steady-state level of ketone bodies. +++++ and – – – – – – indicate acidic and alkaline side of the IMM, respectively. Hatched arrows in the boxes indicate results of the present study. ADP, adenosine diphosphate; ATP, adenosine triphosphate; CoA, coenzyme A; cDNA, complementary DNA; CPT1, carnitine palmitoyltransferase 1; CoA, coenzyme A; Cs, citrate synthase; ETC, electron transport chain; FAD, flavin adenine dinucleotide (oxidized form); $FADH_2$, flavin adenine dinucleotide (reduced form); H^+, proton; Hibadh, 3-hydroxyisobutyrate dehydrogenase; IMM, inner mitochondrial membrane; IMS, inter-membrane space; Mdh, malate dehydrogenase; mtDNA, mitochondrial DNA; NAD+, nicotinamide adenine nucleotide (oxidized form); NADH, nicotinamide adenine nucleotide (reduced form); O_2, oxygen; OMM, outer mitochondrial membrane; Pi, inorganic phosphorus; rRNA, ribosomal RNA; tRNA, transfer RNA; UA, usnic acid; UA^-, anionic form of usnic acid.

ionized to usniate anion by releasing a proton. The resulting usniate anion then diffuses back into the inter-membrane space, where it binds to a proton (accumulated during electron transport through complexes I–IV) and translocates back into the matrix as usnic acid. The resulting proton shuttling cycle can potentially dissipate the proton gradient across the inner mitochondrial membrane, causing uncoupling (Figure 1). This mechanistic pathway explains the induction of genes associated with

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat209
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

complexes I–IV, with no significant effect on complex V. This may be a compensatory mechanism to re-form the proton gradient necessary to maintain ATP synthesis by complex V. Although ATP levels were not measured in the liver of B6C3F$_1$ mice, it is important to note that a decline in ATP synthesis has been reported in isolated rat liver mitochondria exposed to (+)-usnic acid at concentrations higher than 4.5 μM (Pramyothin *et al*., 2004).

Up-regulation of genes that encode complexes I–IV in B6C3F$_1$ mice was also associated with increased expression of genes involved in fatty acid β-oxidation. These included genes associated with activation of fatty acid to acyl-coenzyme A (acyl-coenzyme A synthase, medium-chain family member 3, fatty acyl-coenzyme A ligase, long chain 2 and 4), translocation of acyl-coenzyme A into the matrix (carnitine palmitoyltransferase 2, carnitine acetyltransferase), oxidation of acyl-coenzyme A to enoyl-coenzyme A (acyl-coenzyme A dehydrogenase, short chain, short/branched chain and medium chain), hydrolysis of enoyl-coenzyme A to l-3-hydroxyacyl-coenzyme A and further oxidation to 3-ketoacyl-coenzyme A (hydroxyacyl-coenzyme A dehydrogenase-α and β and l-3-hydroxyacyl-coenzyme A dehydrogenase, short chain) (Figure 1). Collectively, these changes imply increased fatty acid oxidation in usnic acid-treated mice, explaining the rationale for the use of usnic acid as a weight-loss dietary supplement. Surprisingly, however, the decrease in body weights of these mice was not significant compared with controls. These mice also exhibited increased expression of genes associated with the Krebs cycle [isocitrate dehydrogenase 2 ($NADP^+$), isocitrate dehydrogenase 3, beta subunit and 3 (NAD^+) gamma subunit, succinate dehydrogenase Ip subunit, succinate-coenzyme A ligases]. It can be suggested that higher levels of acetyl-coenzyme A as a result of enhanced fatty acid oxidation may account for increased transcription of genes in the Krebs cycle. Altogether, these changes indicate an adaptive response to energy deficits due to usnic acid-mediated uncoupling.

Several pro-apoptotic genes [B-cell leukaemia/lymphoma 2 (Bcl2)-associated X protein, Bcl2-like 13, Bcl2/adenovirus E1B 19KDa-interacting protein 1, NIP3 (Bnip3), Bnip3-like, direct inhibitor of apoptosis (IAP)-binding protein with low isoelectric point (pI), mitochondrial carrier homologue 1, programmed cell death 8, sphingosine-1-phosphate phosphatase 1, voltage-dependent anion channel 1] were also induced by usnic acid treatment in B6C3F$_1$ mice. Usnic acid-mediated loss of mitochondrial coupling might contribute to increased sensitivity of the mitochondrial permeability transition (Scorrano, Petronilli and Bernardi, 1997), promoting apoptosis. Consistent with these findings was the observation of greater apoptotic changes observed by immuno-histochemical analysis in the liver of usnic acid-treated mice compared with controls (Ali *et al*., 2008).

Mitochondrial damage is often a trigger for apoptosis. However, hepatic mitochondria from B6C3F$_1$ mice treated with 600 ppm usnic acid (200 mg/kg) appeared to have retained sufficient mitochondrial function to maintain a healthy adaptive response to the uncoupling actions of usnic acid. Histological evaluation also showed no indication of liver damage in these mice. Alternatively, intra-peritoneal injection of 200 mg/kg usnic acid for 5 days caused structural damage to liver mitochondria as well as elevated levels of serum transaminases, indicating hepatic injury in rats (Pramyothin *et al*., 2004). Different routes of administration, oral versus intraperitoneal, may have resulted in different responses to 200 mg/kg usnic acid in liver mitochondria. It can be postulated that higher concentrations and/or long-term exposures to usnic acid might impair hepatic mitochondrial function in B6C3F$_1$ mice that can manifest in liver injury.

The application of the MitoChip has generated substantial information that allowed a clear understanding of the interactions between different mitochondrial pathways in the liver of B6C3F$_1$ mice during usnic acid exposure. It has also provided an important mechanistic insight into the molecular events that may have implications for usnic acid-induced liver toxicity. Results from this investigation were the first to provide extensive knowledge of hepatic mitochondrial function at the transcriptional level in B6C3F$_1$ mice administered usnic acid. Such information has the potential to be useful in determining the human risk of exposure to low levels of usnic acid that are present in dietary supplements.

7 CONCLUSIONS

The mouse MitoChip is the first mitochondria-specific microarray for gene expression profiling and was developed at the Center for Functional Genomics at NCTR, FDA. It has been shown to be

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat209

useful in understanding the potential mitochondrial toxicity during drug exposures in mice. One of the advantages of the MitoChip is that it provides information regarding the interaction between two genomes at the transcriptional level, the nuclear genome and the mitochondrial genome. To determine the utility of this new genomic tool in toxicology, it was used to examine the molecular basis of mitochondrial dysfunction in the liver and skeletal muscle in different mouse models exposed to NRTIs such as AZT and 3TC. The data obtained in female C3B6F$_1$*trp*53 mice demonstrated a pronounced hepatic mitochondrial dysfunction as a result of perinatal exposure to AZT/3TC. A much reduced response was observed in mice treated with AZT alone. Besides generating comprehensive information on the transcriptional levels of genes involved in oxidative phosphorylation, MitoChip technology also provides insights into other critical mitochondrial pathways and processes, such as mitochondrial fusion. Changes observed in the transcription of genes involved in mitochondrial fusion led to the understanding that this may serve as a compensatory mechanism in response to energy deficit as a result of altered oxidative phosphorylation in AZT/3TC-treated mice. A widely accepted theory of NRTI-related mitochondrial toxicity is the inhibition of DNA polymerase gamma, resulting in depletion of mtDNA content. However, our data indicated that NRTI-related inhibition of DNA polymerase gamma may be tissue-specific. This was based on findings that the expression of DNA polymerase gamma was decreased in skeletal muscle but remained unchanged in the liver of mice treated with AZT. These studies also revealed that NRTI-mediated mitochondrial toxicity is multi-factorial, and that inhibition of DNA polymerase gamma may not be exclusively responsible for mitochondrial dysfunction. The use of the MitoChip has also been helpful in providing vital information on oxidative phosphorylation and its interaction with other mitochondrial pathways during exposure to usnic acid. Such information has implications in defining the role of mitochondria in usnic acid-induced hepatotoxicity that was observed in several individuals who consumed it for weight reduction. Collectively, these studies demonstrated the utility of the MitoChip as an important genomic tool to determine the molecular basis of various drug-induced toxicities associated with impaired mitochondrial function. Mechanisms associated with mitochondrial toxicity may differ with different drugs. Therefore, transcriptional analysis of mitochondria-related genes will be a valuable approach to enable characterization of genomic profiles pertinent to different toxicants or agents targeting mitochondria. The comprehensive toxicogenomics approach described here using the MitoChip is a promising new method for gaining an improved perspective of mitochondrial involvement during toxic exposures. Knowledge of the basis of mitochondrial dysfunction could be the key in the design and development of effective treatment strategies for minimizing drug-related toxicities and diseases associated with altered mitochondrial function. Finally, application of the MitoChip approach in genomic research holds great promise in revealing molecular links between mitochondria and a number of diseases and drug-induced toxicities associated with altered mitochondrial function.

ACKNOWLEDGMENTS

I owe a debt of gratitude to Drs Robert R. Delongchamp and Taewon Lee, as well as William S. Branham and Carrie L. Moland for their significant contribution during the development and validation of the MitoChip. Also, my sincere thanks to Dr James C. Fuscoe for his encouragement and support. This review was written in conjuncture with studies supported in part by an Interagency Agreement (IAG 224-07-007) between the NCTR/U.S. FDA and NTP/the National Institute for Environmental Health Sciences/National Institutes of Health and also in part by the FDA Office of Women's Health.

DISCLAIMER

The findings and conclusions in this report are those of the author and do not necessarily represent the views of the FDA.

Integration of Systems Toxicology into Drug Discovery

Mark Fielden

Comparative Biology and Safety Sciences, Amgen Inc., South San Francisco, CA, USA

1 INTRODUCTION

Systems toxicology encompasses a variety of molecular, cellular and physiologically based experimental approaches to quantify and integrate large-scale highly parallel biological information on whole-body responses to xenobiotics for the purposes of toxicity prediction and human and environmental risk assessment of chemicals and therapeutic products. The application of systems toxicology implies the integration of knowledge from multiple systems, which may include the integration of biochemical, cellular and tissue responses measured *in vitro* or *in vivo*. The integration of multiple systems necessarily requires a consideration of how molecular changes impact higher-order processes and ultimately how these changes are manifested at an organismal level. This approach is expected to improve our ability to deduce more complex biological phenomena, such as physiology or pathology, from an integration of their component parts. This approach may also permit formal prediction of biological phenomena from the evaluation of more easily measured molecular responses. Taken together, systems toxicology has the potential to improve our ability to understand mechanisms of drug toxicity and predict the potential of drugs to cause toxicity, thereby improving efficiencies in drug development and our ability to assess human risk.

The subject of systems toxicology has primarily focused on the application of toxicogenomics, or global mRNA expression profiling, for understanding mechanisms of toxicity and identifying biomarkers predictive or diagnostic of adverse effects (Nuwaysir *et al*., 1999). Therefore, this chapter will focus on the use of toxicogenomics, the most established technology for measuring system-wide molecular changes, for enabling toxicological assessment at an early stage in drug discovery research. Other "omic" technologies concerned with protein or metabolite profiling (proteomics and metabolomics, respectively) have also been discussed in this context (Wetmore and Merrick, 2004; also see Use of Proteomic and Metabolomic Techniques in Ecotoxicological Research); however, their use has been limited owing to the need for more technology platform development and fewer published examples of demonstrated success. As such, they will not be reviewed here; however, many of the concepts of toxicogenomics could be applied to other "omic" technologies, generating multi-dimensional biological data. Time will tell whether such technologies provide value above and beyond toxicogenomics for mechanistic understanding or biomarker identification.

2 DISCOVERY TOXICOLOGY

Numerous reports have documented the increasing cost of drug development and the observed decline

in productivity as represented by the number of new chemical entities (NCEs) that have been marketed in recent years (Frantz and Smith, 2003). The Tufts Center for Drug Development has estimated the cost of developing an NCE at $802M to $1.1 billion (DiMasi, Hansen and Grabowski, 2003). A large proportion of these costs are related to the cost incurred by developing compounds that ultimately fail as a result of the trial and error approach of drug discovery research. As a result of the poor success rate for developing successful drugs, one only needs to slightly improve productivity to have a pronounced effect on cost savings. For example, it has been estimated that a 12% increase in success rate could save between $221 and $242 million per approved drug (DiMasi, Hansen and Grabowski, 2003). The poor success rate and the failure of industry to realize gains in productivity brought on by advances in technology and our increased understanding of disease has been the subject of great debate and has motivated many to take steps to address gaps in the critical path for bringing effective and safe therapies to market (Woodcock and Woosley, 2008). This requires industry to alter their strategy and take steps to advance and adopt new technologies that will enhance productivity, whereas regulatory agencies must also adapt to begin to accept alternative solutions to the current, yet antiquated and costly, approach to drug discovery and development.

In response to these challenges, pharmaceutical companies have attempted to improve a number of critical aspects of drug discovery and development that contribute to the high rate of late-stage attrition. By far, one of the greatest sources of late-stage attrition is toxicity, which is encountered in both human and animal toxicity testing (Kola and Landis, 2004). Our ability to assess safety in humans is necessarily limited to clinical trials using a relatively small number of subjects, and in post-marketing surveillance where our statistical power to detect adverse effects may be improved, although not always adequately controlled for. Quite often adverse effects in humans are identified at later stages in human clinical testing when millions of dollars have already been invested. Nonetheless, we are limited to evaluating potential toxicity using animal models prior to investment in human clinical trials. These animal evaluations are still performed at relatively late stages after many years of drug discovery research and compound optimization have been performed.

While the timing of safety evaluation in humans or animals is clearly not optimal given the price of failure due to toxicity, also consider that our ability to predict human toxicity using animal models is quite low. For example, retrospective industry experience estimates that rodent toxicology studies only predict 43% of human toxicities, non-rodent studies predict 63% and the combination of both species predicts approximately 71% of human toxicities (Olson *et al.*, 2000). These results are somewhat misleading, however, as they fail to capture the toxicity correlates of drug candidates that are never tested in humans due to unacceptable animal toxicity. This has the potential to result in safe and effective drugs being halted in their development due to animal toxicities that may never materialize in humans. Unless mechanistic data demonstrate clearly that the compound in question is an animal-specific toxicant, compounds that are overtly toxic in pre-clinical studies are discontinued from further development. Thus, despite the reported poor predictivity, the true predictivity of animal studies is actually unknown in most cases. To further exacerbate the challenge, the increasingly competitive landscape in the pharmaceutical industry and the increased scrutiny over the safety of therapeutic products also raise the bar for developing successful new therapies. Despite the acknowledgement that animal models are not highly predictive of human toxicity, they remain the best tools to judge the likely safety profile of drug candidates before human safety can be empirically defined.

An emerging approach to deal with the late-stage attrition afflicting the pharmaceutical industry is to consider compound safety at an earlier stage in the drug discovery pipeline before formal development begins (Kramer, Sagartz and Morris, 2007). By considering safety at this early stage, compound selection criteria can be enforced and medicinal chemistry approaches altered to improve the quality of the compounds being advanced into later and costly stages of drug development. Advanced knowledge of unintended pharmacology and toxicity acquired through *in silico*, *in vitro* or *in vivo* approaches creates an opportunity to shift attrition-based decisions upstream in the process to points where corrective action can still be taken at a relatively low cost with relatively minimal investment in time. Therefore, the cost savings from discovery toxicology come from shifting, rather than reducing, attrition.

A typical workflow for a drug discovery project team is depicted in Figure 1. Discovery research begins with the identification and validation of a target of interest, followed by high-throughput screening of potentially hundreds of thousands of compounds. Hits stemming from high-throughput screening are further evaluated for potency and drug-like properties including *in vitro* pharmacokinetic properties (e.g., metabolic stability, permeability, solubility, P450 inhibition) and physico-chemical considerations (Lipinski *et al*., 2001). Drug-like molecules exhibiting reasonable potency are further characterized for on-target efficacy, selectivity and *in vivo* pharmacokinetics. The lead scaffolds exhibiting the best combination of factors are selected for further optimization to generate a lead candidate suitable for *in vivo* toxicity evaluations. Compounds exhibiting a favorable combination of potency, efficacy, animal and predicted human pharmacokinetics, with reduced secondary pharmacology and suitable *in vivo* toleration, are chosen as clinical candidates to enter development. Development candidates are then thoroughly evaluated in a battery of toxicity tests to ensure their safe use in first-in-human (FIH) clinical trials. These studies typically include genotoxicity, safety pharmacology (cardiovascular, respiratory and central nervous system tests) and general *in vivo* toxicological evaluations in one rodent (i.e., rat) and one non-rodent species (i.e. dog or non-human primate).

The application of discovery toxicology in drug discovery research is illustrated in Figure 2. At the screening stage, very little compound is available to support direct experimentation in most toxicological assays. As a result, *in silico* approaches to identify potential toxicophores and unfavorable physico-chemical properties (Valerio, 2009) can be used as a means of identifying chemical scaffolds that may be problematic. Additionally, *in cerebro* evaluation of the pathways and biological and physiological effects of the target can be carried out to identify potential target-mediated adverse effects that may manifest *in vivo*. This proactive assessment of the target can aid in the design of experiments to evaluate possible target liabilities and enable early risk assessment around a target.

At the hit-to-lead stage, a more thorough characterization of the compounds is undertaken to identify potential off-target toxicities. More material is usually available to facilitate a moderate-throughput assay to evaluate interaction with unintended targets such as the hERG (potassium) channel and other ion channels that may present a cardiovascular risk (Hancox *et al*., 2008); with DNA that may present a risk for genotoxicity (Custer and Sweder, 2008) and with other closely related targets that may present a risk for unwanted pharmacology (Krejsa *et al*., 2003). Additionally, cytotoxicity and mechanism-based toxicity assays can be used to identify additional hazards that are known to commonly plague small molecule drugs (Abraham *et al*., 2008; O'Brien *et al*., 2006). Characterizing hits for potential hazards can be used to rank and prioritize the most promising lead scaffolds for further optimization before initiating more resource-intensive *in vivo* studies.

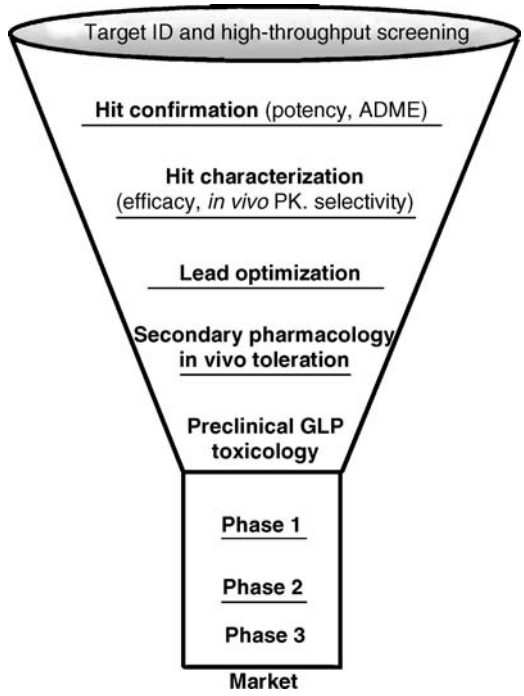

Figure 1. General drug discovery and development flow scheme for small molecule therapeutics.

At the lead optimization stage, medicinal chemistry attempts to modify the lead scaffold to improve a variety of features including potency and pharmacokinetics, and reduce any safety hazards identified through the hit characterization phase (i.e. hERG inhibition). As lead candidates mature, compounds can be tested in *in vivo* toleration assays, usually a rat and a non-rodent such as dog or non-human

primate, and non-good laboratory practice (GLP) safety pharmacology assays to select lead candidates for further pre-clinical testing in GLP toxicology studies. At this stage, biomarkers and systems toxicology approaches such as toxicogenomics can be used to further characterize and predict potential hazards that may emerge under longer-term dosing conditions, as detailed below.

Although a generic workflow as illustrated in Figure 2 is useful as a starting point to guide programme strategy, it must be recognized that each programme is unique and should be evaluated in light of its own clinical goals, patient population, the competition and any relevant regulatory considerations that will impact safety assessment. For example, anti-depressants targeting noradrenaline transporters may dictate an early evaluation of cardiovascular parameters in telemetrized rats before more resource-intensive rat toxicity studies are initiated. If rodents are not considered a sensitive species and toxicity in non-rodents are of heightened concern, then short-term intravenous infusions coupled with accessible biomarkers may facilitate a screening strategy that minimizes compound and animal usage at an early stage. Quite often lead compounds and their toxicity *in vivo* will dictate a screening strategy for prioritization and selection of backup molecules. In such cases, it is valuable to utilize investigative techniques, including toxicogenomics as described below, to rapidly identify mechanisms of toxicity to guide the application of *in vitro* screening assays (Gross and Kramer, 2003).

As compounds and lead series progress into *in vivo* models, including GLP toxicology studies, unanticipated toxicities may emerge that require a mechanistic understanding to enable human risk assessment. Such findings may halt further development and efforts will be concentrated on identifying follow-on compounds that are devoid of the toxicity. These efforts will benefit from a suitable *in vitro* or *in vivo* assay to provide an efficient means of screening additional compounds to avoid repeating the same mistake twice. It is here that toxicogenomics can positively influence drug discovery by providing a means to diagnose or predict toxicity, or aid in the understanding of mechanisms of toxicity. This information can be used in lead optimization to help understand the relevance of the findings for humans, and facilitate the screening and differentiation of molecules to aid in compound selection.

3 PREDICTIVE TOXICOGENOMICS AND APPLICATIONS TO DISCOVERY TOXICOLOGY

Initially, the first microarray experiments were limited in the number of genes evaluated and the analytical software consisted primarily of Microsoft Excel. These early investigations usually consisted of counting the number of genes that were up- or down-regulated in response to drug treatment, with little to no biological relevance ascribed to the changes other than determining the magnitude and direction of the observed fold changes (Farr

and Dunn, 1999). With the increasing quality of the gene annotation, and the increased throughput and size of the microarrays being used, the focus shifted to using the technology to understand biology and mechanisms of drug action. This was still a manual process that required extensive curation to annotate the genes and studying the literature to derive mechanistic insight; however, the approach yielded useful information and reinforced the concept that gene expression changes needed to be anchored to pathological effects for accurate interpretation (Hamadeh *et al*., 2002b). True hypothesis testing with microarrays was still in its infancy.

The next advancement in toxicogenomics came with the observation that small gene sets could discriminate among mechanistically distinct drug classes (Bushel *et al*., 2002; Hamadeh *et al*., 2002a). These and other similar studies identified small gene sets that could mechanistically classify similar toxicants from one another and classify uncharacterized samples into pre-defined classes of similar mechanism (Thomas *et al*., 2001). These early proof-of-principle studies were critical to establish the foundation for subsequent experimental approaches and illustrate the significance of reference gene expression data sets for interpretation. These types of experiments provided the momentum for public and private efforts to construct large reference databases of toxicogenomic data to enable compound classification and the development of predictive gene sets or signatures (Ganter *et al*., 2005; Waters *et al*., 2003; Williams-DeVane, Wolf and Richard, 2009). Many pharmaceutical companies embarked on extensive internal efforts to establish or license for use gene expression databases to develop and apply signatures for lead optimization (Steiner *et al*., 2004; McMillian *et al*., 2005; Ganter *et al*., 2005).

There are many publications describing the use of toxicogenomics for the prediction of drug-induced toxicity in the rodent, which is the primary *in vivo* screening tool of choice in the pharmaceutical industry. A few chosen examples are highlighted in Table 1. Most of the published efforts have focused on the prediction of liver and kidney toxicity, with few efforts focused on the prediction of cardiotoxicity and other tissues. This likely reflects the greater incidence of drug-induced toxicities in these organs, in addition to the well-described mechanisms of toxicity in these organs. These approaches typically utilize tissues from rats following short-term (i.e., 24 h to 14 days of repeated daily doses) treatment to identify gene expression changes that are statistically associated with the pathology (Steiner *et al*., 2004; Thukral *et al*., 2005; Brown *et al*., 2002), or in some cases precede the histological appearance of tissue injury (Fielden *et al*., 2005). These putative biomarkers are then evaluated independently, although not always, against other toxicants with the goal of evaluating how accurately the biomarker can diagnose or predict the pathological event. Although histological diagnosis of tissue injury will remain the gold standard for evaluating drug-induced toxicity, the ability to predict the onset of tissue injury before it is observed microscopically can aid in the early identification of toxic effects that may not manifest until longer-term studies are conducted. As a result, toxicogenomics could be applied in the early stages of lead candidate selection testing as a means of predicting longer-term safety. Together with other endpoints, including traditional histology and clinical pathology, toxicogenomics data could

aid in the selection of clinical candidates prior to development.

In addition to the prediction of future tissue injury, toxicogenomics data can be used to help diagnose tissue injury. Quite often, gene expression changes are readily observed when tissue damage has occurred. This often manifests as an increase in the expression of genes controlling the inflammatory response to injury, or adaptive changes to respond to unfolded proteins, oxidative stress or other cellular responses to maintain homeostasis. These expression changes are not definitive proof of tissue damage, but when used in combination with histological data can contribute to a weight of evidence in the assessment of potential toxicity that may be deemed equivocal when evaluated by traditional means. The contribution of toxicogenomics data to confirm pathological diagnoses is also particularly valuable in early short-term *in vivo* screening studies. Many histological changes occur with limited frequency and can easily be missed when only a few animals per treatment group are to be evaluated.

Although numerous success stories have been published, it is likely that many failures have also been identified in the course of toxicogenomics research that is less frequently communicated in the scientific literature. Foster *et al*. (2007) offer a valuable retrospective evaluation of how toxicogenomics has, and has not, impacted pre-clinical testing and lead optimization. Their findings indicate that significant transcriptional changes were more often observed prior to the histological structural change in the tissue, which further suggests that gene expression signatures can be predictive (i.e., pre-monitory). Their survey data also indicate that mechanistic data were obtained for 30% of the targets evaluated. Despite routine use of toxicogenomics in lead optimization, it is clear that the technology is not capable of diagnosing or predicting all types of tissue toxicity or for all compound classes and mechanisms, and that a certain degree of false negatives is expected. When combined with traditional data, however, it is likely that the overall number of false negatives progressing through development will be low. Perhaps of greater concern, though, is the perception of false positives. Although gene expression changes themselves are not considered adverse, a gene expression-based prediction of toxicity in the absence of histological changes could unnecessarily impugn an otherwise safe compound if misinterpreted. This concern has perhaps curtailed the more widespread use and acceptance of toxicogenomics across regulated industries. Nonetheless, their use is continuing and is further being explored for different applications, particularly within the chemical industry (Ankley *et al*., 2006).

Carcinogenicity in rodents has been extensively studied with toxicogenomics. The goal of toxicogenomics is to identify biomarkers that are predictive of carcinogenic outcome in the 2-year rodent bioassay (Table 2). Much of the focus has been on predicting carcinogenicity induced by compounds that act via non-genotoxic mechanisms as a result of the lack of *in vitro* and *in vivo* assays that can adequately predict these mechanisms of carcinogenicity and recapitulate the multi-stage process of carcinogenicity. The diversity of mechanisms described to contribute to tumour formation also makes prediction difficult, as they are hard to model with short-term assays. The need to predict carcinogenicity in rodents and humans has motivated

Table 2. Examples of toxicogenomic approaches *in vivo* for predicting carcinogenicity.

Predicted endpoint	Model	Study design	Reference
Liver tumour promoter	Rat	Modified Ito medium term rat liver bioassay	Shibutani *et al*. (2002)

researchers over the past 2 to 3 decades to develop *in vitro* and alternative short- or medium-term *in vivo* assays that attempt to provide a less resource-intensive means of identifying chemicals with the potential to induce tumours through non-genotoxic mechanisms (Ito, Tamano and Shirai, 2003; Mauthe *et al*., 2001; Cohen, 2004). The underlying premise of toxicogenomics for carcinogenicity prediction is that gene expression changes in the target tissue precede and contribute to tumour development, and that these changes can be monitored after a short-term *in vivo* treatment to predict longer-term carcinogenic outcomes.

With the availability of numerous well-studied genotoxic and non-genotoxic carcinogens, numerous approaches were taken to analyse gene expression changes in the mouse and rat following carcinogen treatment (Table 2). Because of the high prevalence of liver tumours in rodents and the wealth of existing literature on the subject, hepatocarcinogenicity became the focus of many research efforts. Early studies using microarrays and other genome-wide expression profiling technologies focused on the identification of single genes as predictive biomarkers. Instead, unique patterns of multiple genes were found to be necessary to differentiate genotoxic from non-genotoxic compounds (Ellinger-Ziegelbauer *et al*., 2004, 2005), and it was quickly appreciated that no single gene by itself could adequately predict a heterogeneous class of compounds (Iida *et al*., 2003, 2005).

The application of supervised classification algorithms and the availability of larger genomic data sets using paradigm carcinogenic compounds lead to the identification of signatures that were found to have broader applicability for the classification of non-genotoxic carcinogens from short-term rodent studies (Table 2). One of the first large efforts to identify gene signatures to predict carcinogenicity was by Nie *et al*. (2006). Using hepatic cDNA microarray data from the livers of rats treated with a single dose of test compound for 24 h, Nie *et al*. identified a set of candidate biomarkers that were estimated to have an accuracy of approximately 89%. Testing on independent samples confirmed that the signature could predict other non-genotoxic carcinogens. The utility of this signature for predicting non-genotoxic compounds that induce tumours outside the liver has not been widely evaluated; however, initial results indicate that it may have potential. Ellinger-Ziegelbauer (2008) applied a similar approach by applying a number of gene selection and classification algorithms to identify a three-class predictor of genotoxic hepatocarcinogenicity, non-genotoxic hepatocarcinogenicity and non-hepatocarcinogenicity using rat liver gene expression data. The gene selection approaches provided gene sets enriched in functional categories related to cancer, in addition to being able to predict carcinogenic class with a reported accuracy of about 75–88%. Although these proof-of-concept results are encouraging, as with other efforts there are key variables that can have dramatic impacts on the overall utility and interpretation of the data that may prohibit broader use. As changes in gene expression are dynamic, typically dose-dependent and subject to secondary influences due to organ toxicity, a range of doses and time-points would be ideal to capture the optimal window of expression changes that reflect carcinogenic outcome. This can be difficult when testing compounds prospectively in lead optimization; therefore, a signature that will accurately predict carcinogenicity with one or many doses and be robust to target organ effects would be ideal.

Work by Fielden, Brennan and Gollub (2007) also demonstrated the value of a large database of gene expression profiles for generating and validating gene expression signatures of non-genotoxic hepatocarcinogenicity. They used hepatic gene expression data from 5-day repeat dose rat studies to predict non-genotoxic hepatocarcinogenicity. To adequately test the accuracy of the model, the signature was tested against hepatic gene expression data from rats treated for up to 5 days with 47 independent compounds distinct from those used in the training set. This resulted in a sensitivity of 81% and a specificity of 84%. By comparison, the signature was superior in accuracy relative to more traditional endpoints that have previously been proposed and evaluated as predictors of carcinogenic potential, including increased liver weight, hepatocellular hypertrophy, hepatic necrosis, serum alanine aminotransamine activity and induction of cytochrome P450 genes (Allen *et al*., 2004; Elcombe *et al*., 2002). Additionally, the gene expression signature was found to be useful for understanding the mode of action when the gene expression profile of the test compound was compared against non-genotoxic carcinogens of known mode of action, such as P450 inducers, peroxisome proliferators, steroidal compounds with oestrogenic and androgenic activity,

and hepatotoxic carcinogens. These results indicate that hepatic gene expression data from short-term rat studies can be used to predict non-genotoxic hepatocarcinogens, but also to understand the compounds' mode of action to aid human risk assessment. This is highlighted by the flow chart in Figure 3, which illustrates how the early prediction of carcinogenic effects can be incorporated into drug discovery toxicology. It is also worth pointing out that some efforts using genomics and metabonomics to predict lung tumour incidence have also seen success (Thomas *et al*., 2009, 2007); however, it appears long-term treatment (i.e. 90 days) is necessary for prediction, which may reduce its utility in early *in vivo* screening studies.

Although gene sets have been identified to predict pathological changes in the profiled tissue (Table 1), it is clear that microarray data will not become a replacement to clinical pathology or histopathology measurements. Safety assessment will continue to rely on traditional measures of toxicity and base decisions on the weight of evidence to judge risk. Although investigative and mechanistic toxicology has become integrated into pre-clinical development, there is still a need for more proactive approaches to complement the classical reactionary approaches. Although toxicogenomics is being incorporated in early *in vivo* screening studies to aid in compound selection, it is expected that the validation of *in vitro* models in toxicogenomics will further push this technology upstream in lead optimization (see below).

4 MECHANISTIC TOXICOGENOMICS AND APPLICATIONS TO DISCOVERY TOXICOLOGY

Although the interpretation of toxicity endpoints in pre-clinical studies is well understood, the predictivity of the findings in animal models for humans is often less clear. This discrepancy is not only due to underlying differences in biology and pathophysiology across species, but also because of intrinsic differences in pharmacokinetics and metabolism properties. Many examples have been published demonstrating rodent-specific toxicities due to differences in drug metabolism (Mutlib *et al*., 2000), thyroid hormone regulation (Wu and Farrelly, 2006) or bladder tumour formation (Cohen and Lawson,

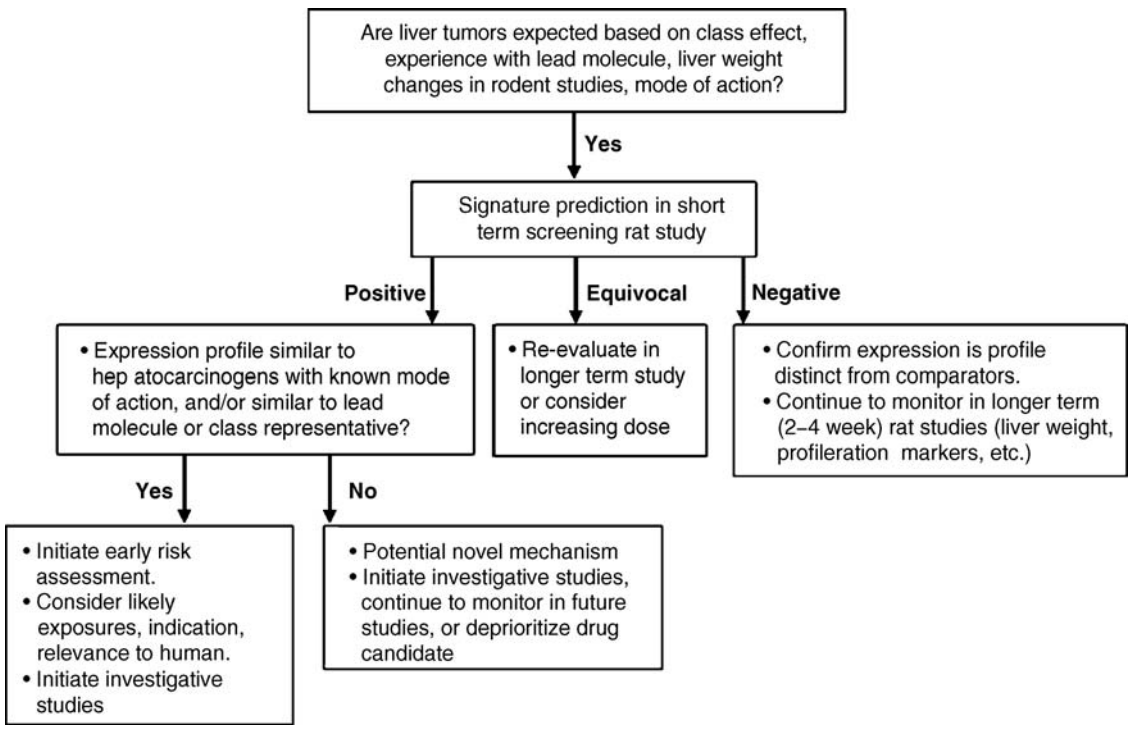

Figure 3. Flow scheme illustrating the application of toxicogenomic signatures for carcinogenicity prediction in drug discovery toxicology.

1995), for example. Compound toxicity in animals is observed frequently in routine screening studies; however, when the mechanism of toxicity and human relevance are unknown, development of that compound is halted in the interest of time and money and to focus resources on identifying suitable backups. Therefore, an opportunity is lost to learn about the mechanism of toxicity of a drug and potentially its class. By understanding the mechanism of toxicity in rodent models, a risk assessment can be made to understand the relevance of the finding for humans. Additionally, by obtaining a more thorough understanding of the mechanism of toxicity, one can apply the new knowledge to guide the selection of *in vitro* screening strategies or *in vivo* biomarkers to evaluate backup molecules, and ultimately to modify the chemistry of the candidate drug to avoid toxicity in future molecules. Improvements to human risk assessment and the selection of the right drug candidates for development is not made by applying regulatory toxicity studies earlier in discovery, but by obtaining a more thorough understanding of the mechanisms of toxicity prior to human studies, and understanding the potential hazards to design a pre-clinical testing strategy tailored for each programme. This upfront investment in understanding mechanisms of toxicity should also lead to a more informed application and interpretation of *in vivo* and *in vitro* models to predict human toxicity. With that in mind, it is useful to consider how toxicogenomics can contribute to the understanding of mechanisms of toxicity.

Microarray data, like other toxicological and pathological data, require the perspective of experience to draw meaningful conclusions. In traditional toxicology studies, clinical pathology and histopathology changes are interpreted relative to not only a vehicle control group but also an extensive knowledge base of historical data reflected in pathologists' experience or the companies' data warehouses. By comparison, sufficient experience and historical microarray data are often not available and so meaningful interpretation of gene expression data can be difficult. Individual genes that are regulated up or down may lead to more questions than answers when viewed in isolation. However, after a gene expression change has been observed hundreds of times across many diverse physiological, pharmacological, toxicological and pathological conditions, the biological significance of the gene expression change can begin to be understood for reliable interpretation. This approach would include the inclusion of negative and positive controls in the comparison to the test compound. Ideally, the genes that are perturbed by the test compound can be linked to known mechanisms of toxicity. This can often be evaluated by overlaying the expression changes induced by a toxic treatment, and appropriate positive and negative control treatments, on to canonical pathways that are known to be affected or initiated by certain mechanisms of toxicity. This can be performed by using a number of commercial and publically available software packages (Table 3). Example include Nrf2-regulated genes that are known to be up-regulated in response to oxidative stress (Li and Kong, 2009), P450 genes that are known to be up-regulated in response to bile acid perturbation or by direct nuclear receptor activation (Guo *et al*., 2003; Slatter *et al*., 2006), or inflammatory genes up-regulated in response to immune-mediated damage (McMillian *et al*., 2004). By extending this approach, a battery of mechanistic changes can be quickly assessed to rule in, or rule out, certain mechanisms of toxicity that may contribute to an observed toxicity. As with other hypotheses, a weight of evidence approach is typically recommended before relying on such gene expression changes to guide project strategy. It is useful to evaluate the sensitivity and specificity of any changes by comparison to reference compounds with or without the toxicity under study, and by use of compounds that are known to act through the hypothesized mechanism of toxicity. Once validated by this rigorous approach, a suitable diagnostic biomarker set reflective of the mechanism of toxicity can be used to screen backup candidates. These experimental design considerations highlight

Table 3. Examples of commercial and publically available software packages for evaluating gene expression data and pathways.

the value of a large historical database of gene expression experiments to strengthen statistical and biological inferences made on isolated expression changes from new test samples. This approach is vital to hypothesis testing when trying to understand mechanisms of toxicity.

Ideally, a thorough understanding of the mechanism of toxicity is desired; however, the resources and time required for such investigations are often not realistic or even essential to guide assay development for backup selection. For example, hepatocellular toxicity may be initiated by disruption of mitochondrial function as a result of inhibition of components of the electron transport chain. However, in practice, a relatively simple and rapid *in vitro* evaluation of mitochondrial respiration can often be used as a surrogate in the absence of knowledge of what mitochondrial enzyme is affected. Again, suitable use of negative controls and toxic compounds known to mediate toxicity through a similar mechanism of action is crucial to extrapolate *in vitro* effects to likely *in vivo* outcomes. This pragmatic approach will ensure implementation of a relevant and timely screening approach.

5 APPLICATION OF *IN VITRO* TOXICOGENOMICS IN DISCOVERY TOXICOLOGY

Applying toxicogenomics to cell-based systems represents another means of facilitating differentiation of compounds at a much earlier stage of drug discovery than *in vivo* testing would permit due to limited compound supply. Furthermore, it may offer the ability to predict *in vivo* toxicity (Ryan, Stevens and Thomas, 2008) as a means of ensuring that resources are allocated to chemical scaffolds that are least likely to be plagued by toxicity. The use of toxicogenomics at this stage has not been as widely used owing to the technical challenges of reproducibility and the questionable concordance to *in vivo* systems (Boess *et al*., 2003; Hultin-Rosenberg *et al*., 2006). However, research in this area continues and promising results in niche areas have demonstrated cases where toxicogenomics in cell-based systems would provide practical advantages when compared with *in vivo* models. An example of *in vitro* toxicogenomics is the prediction of phospholipidosis using human HepG2 cells (Sawada, Takami and Asahi, 2005; Sawada, Taniguchi and Takami, 2006). This liability frequently affects the liver, lung or macrophages and is often induced by compounds that are cationic and amphiphilic in nature, such as amiodarone and tricyclic anti-depressants (Massey *et al*., 1995; Xia *et al*., 2000). Such compounds cause the appearance of concentric lamellar bodies, which is the distinguishing feature of this histological abnormality. This effect is thought to be due to lysosomal phospholipase inhibition (Reasor and Kacew, 2001). Sawada, Takami and Asahi (2005) attempted to identify biomarkers of phospholipidosis by treating human HepG2 cells with known inducers of phospholipidosis and negative controls, and evaluating gene expression on a microarray to identify genes that were consistently regulated in response to phospholipidosis inducers. These evaluations lead to the selection of 12 genes that were subsequently measured on a real-time PCR platform and assessed for reproducibility, sensitivity and specificity against a large independent test set (Sawada, Taniguchi and Takami, 2006). The results were encouraging and demonstrate how an *in vivo* histological endpoint could be predicted by a simple cell-based system. Other approaches evaluating lipid-related pathologies, such as drug-induced steatosis, have also shown promise (Boess *et al*., 2007). Some efforts have evaluated cell-based assays and toxicogenomics as a means to predict hepatocarcinogenicity; however, the results suggest more work is needed to overcome limitations with system variability (Mathijs *et al*., 2009). Nonetheless, efforts have demonstrated that genotoxic carcinogens can be differentiated from non-genotoxic carcinogens (van Delft *et al*., 2004, 2005).

Although *in vitro* sciences continue to mature and contribute to our mechanistic understanding of drug-induced toxicity, the ability of toxicogenomics in cell systems to predict *in vivo* responses has not been adequately demonstrated to replace or supplement the use of short-term *in vivo* models in the early evaluation of drug candidates. Advances in cell models, such as the use of three-dimensional culture systems or co-culture systems, may improve the translatability of *in vitro* gene expression measurements (Dash *et al*., 2009).

6 CONCLUSIONS

Systems toxicology has emerged from the successful application of toxicogenomics and other technologies that enable genome-wide evaluation of biological phenomena. Application of toxicogenomics to *in vitro* and *in vivo* models has helped

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

facilitate the identification of biomarkers of toxicity, as well as enable a greater understanding of drug action, including mechanisms of toxicity. Drug discovery research is a complex and highly expensive process that has suffered from late-stage failures owing to unanticipated animal and human toxicity. Discovery toxicology attempts to shift attrition earlier in the drug discovery and development process by thoughtful application of *in silico*, *in vitro* and *in vivo* assays to identify potential hazards and facilitate prioritization of compounds for advancement. The application of toxicogenomics to the early characterization of drug candidates increases our ability to predict potential toxicities before they are detected using traditional means. Additionally, toxicogenomics can be used to understand mechanisms of drug toxicity and guide assay development for screening new molecules. Improving the efficiency and predictivity of these early steps in drug discovery research should ultimately decrease our late-stage failure rate, and thus our use of more expensive and longer-term animal studies. Improvements in this process will require collaborative efforts to validate genomic approaches in pre-clinical safety testing and further our understanding of mechanisms of drug toxicity. Additional efforts to capture historical data and learn from our past successes and failures can also guide our interpretation of pre-clinical data to support human risk assessment. The overall desired outcome is to speed the rate and reduce the cost at which safer compounds are advanced into human testing, while also reducing our reliance on longer-term animal studies for optimizing compounds.

Systems Toxicology: A Valuable Tool for Early Prediction and Mechanistic Assessment of Liver Toxicity of Food-Related Products

Saura C. Sahu

Division of Toxicology, Office of Applied Research and Safety Assessment, Center for Food Safety and Applied Nutrition, US Food and Drug Administration, Laurel, MD, USA

1 INTRODUCTION

The high metabolic activity of the tissue and high levels of exposure to xenobiotics make the liver a major target organ for toxicants. This combination makes liver toxicity the leading cause of drug withdrawal from clinical development and an important parameter in safety evaluation of drugs. Traditional pre-clinical hepatotoxicity testing *in vivo* involves changes in liver-specific enzyme levels in blood and histopathology primarily in livers of small rodent models. However, animal studies are expensive, time-consuming and involve differences in biodiversity and metabolism. Therefore, alternative models and more sensitive methods are valuable tools for toxicological risk assessment. The focus of this review is to assemble published information on systems technology, a rapidly developing new discipline, for the purpose of early prediction and mechanistic assessment of liver toxicity of food-related products.

2 SYSTEMS TOXICOLOGY

Systems toxicology is a rapidly developing new branch of toxicology. It integrates classical toxicology with the new 'omics' technology. It provides an experimental approach for global assessment of the genomic, proteomic and metabolomic profiles of a biological system (Craig *et al*., 2006). Recently, the omics technology has been recognized as a valuable tool for predictive and mechanistic toxicology (Fielden and Zacharewski, 2001) of new drugs during their pre-clinical safety evaluation (Nicholson *et al*., 2002).

3 OMICS TECHNOLOGIES

Systems toxicology makes use of data derived from three omics technologies: genomics, proteomics and metabolomics. Genomics technology measures global gene expression profiles at the RNA and DNA

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat211
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

levels. It is relatively older among the three omics technologies and, therefore, is more advanced and better studied compared with the proteomics and/or metabolomics. When genes interact with the environment, they can produce toxicity and disease. In recent years, DNA microarray technology has been used extensively for measuring global gene expression profiles and identifying molecular mechanisms of action in response to toxicant exposure both *in vivo* and *in vitro*. Microarray technology allows analysis of thousands of gene expressions simultaneously and provides information on molecular mechanisms of toxicity. It is a very useful tool to measure large-scale gene expression profiles (Stears, Martinsky and Schena, 2003). For example, it has been used to identify biomarkers of hepatotoxicity and the mechanisms associated with it (Dai *et al*., 2006; Kussmann, Raymond and Affolter, 2006; Mutlib *et al*., 2006; Nie *et al*., 2006; Tugendreich *et al*., 2006; Fielden, Brennan and Gollub, 2007; Eun *et al*., 2008). Quantitative real-time polymerase chain reaction (qRT-PCR) technology is also a useful tool for gene expression analysis. It uses selected genes that are representative of various biological pathways. This technology has been proven to provide reproducible data generated in multiple laboratories across three continents (Ellinger-Ziegelbauer *et al*., 2009). Both genomic technologies, microarray and qRT-PCR, have been used to identify biomarkers of toxicity.

Proteomics technology measures global protein profiles in tissues and body fluids in early response to toxicant exposures. This technology is relatively new, is rapidly developing and has not been used to its full potential in toxicology. It can identify protein biomarkers and provides mechanisms of toxicity of chemicals that induce changes in the cellular protein levels (Amacher *et al*., 2005). Dail *et al*. (2008) have used this technology to identify a proteomic screening method for hepatotoxicity. In this study, they used proteomic assays to investigate the early stages of phenobarbital hepatotoxicity in rats exposed to a dose below the detection limits of liver injury measured by the classical liver toxicity tests. This study clearly demonstrated that proteomic technology could detect the early stages of liver toxicity which could not be detected by the classical tests. The study identified cytochrome P450 2B2 as a biomarker for liver toxicity. Heijne *et al*. (2003) have shown that it offers information complementary to genomics. More recently, the protein microarrays are becoming popular to identify biomarkers of toxicity. Spisak *et al*. (2007) have reviewed the application of protein microarray technology for identification of biomarkers of liver toxicity. This technology provides a very sensitive method to detect protein biomarkers of hepatotoxicity. Protein microchips used in conjunction with mass spectrometers can detect less than 1 μg protein. This technology is used for serum tumour marker profiling and mRNA expression verification (Spisak *et al*., 2007).

Metabolomics (or metabonomics) technology measures global profiles of the metabolites in biological systems. Like proteomics, the metabolomics technology is relatively new and rapidly developing. This technology makes use of liquid chromatography, mass spectrometry and proton nuclear magnetic resonance (NMR) spectroscopy to determine global metabolic profiles of tissues and/or body fluids (Schnackenberg and Beger, 2006a, 2006b; Schnackenberg, 2007). Metabolomics can provide comprehensive analysis of endogenous and exogenous cellular metabolite profiles (Robertson, 2005).

4 INTEGRATION OF OMICS TECHNOLOGIES

Recently, attempts have been made to integrate various omics technologies to produce very powerful and useful tools for predictive and mechanistic toxicology. Craig *et al*. (2006) used this approach to study mechanism of cancer development in rat liver induced by methapyrilene. Rantalainen *et al*. (2006) integrated the proteomic and metabolomic data from a mouse model representing human prostrate cancer. Schnackenberg *et al*. (2006) used integrated genomic, metabonomic and proteomic data to evaluate the acute effects of valproic acid in the mouse liver. Integration of bioinformatics and omics technology data has been used for better understanding of mechanisms and pathways of diseases and drug safety (Schnackenberg and Beger, 2006a, 2006b; Schnackenberg, 2007). Using such tools, Skordi *et al*. (2007) elucidated the mechanism of ethionine toxicity in rat liver. Dumas *et al*. (2007) have applied the integration of genomic and metabolic data to map mammalian metabolic phenotypes in diabetic rats. Recently, Li and Chan (2009) have developed the "three-stage-integrative-pathway-search (TIPS) framework" for integration of gene expression and toxicity measurements to identify liver toxicity gene targets and

pathways using HepG2 cells as an *in vitro* model. More and more such reports are expected to be available in this rapidly developing area of research.

5 SYSTEMS TOXICOLOGY *IN VIVO*

Systems toxicology has been applied to animal models to evaluate the liver response to exposure of hepatotoxicants. Genomic technology was used by Minami *et al*. (2005) to evaluate hepatic gene expression profiles by both microarray and real-time RT-PCR analysis. In this study, they exposed rats to the known hepatotoxins, acetaminophen, bromobenzene, carbon tetrachloride, dimethyl amine and thioacetamide, by a single intraperitoneal injection. All the test chemicals exhibited direct correlation between the biochemical and toxicogenomic parameters in the rat liver. In another study, Chung *et al*. (2006) used microarray technology to study D-galactosamine-induced liver injury in mice. They identified genes associated with injury and regeneration stages of the mouse liver. Nie *et al*. (2006) and Fielden, Brennan and Gollub (2007) used the gene expression profiles to study mechanisms of tumour induction in liver by non-genotoxic carcinogens. Zidek *et al*. (2007) developed a predictive screening system for acute hepatotoxicity by analysing differential gene expression profiles of well-known hepatotoxic and non-hepatotoxic compounds with a bead-based illumina oligonucleotide microarray containing 550 liver specific genes.

Proteomic technology was used by Dail *et al*. (2008) to determine the early responses of the rat liver exposed to phenobarbital, an inducer of liver metabolizing enzymes and a non-genotoxic liver carcinogen in rats. This study identified protein biomarkers associated with the known effects of this compound. Rats were exposed to phenobarbital at a dose of 80 mg kg^{-1} day^{-1} or a vehicle control for 5 days. The level of exposure of phenobarbital in this study was below the detection limit of liver damage at a very early stage determined by the classical tests for liver damage. Of the 3342 proteins identified by global mass spectrometric proteomic analysis, expression of 121 proteins was significantly increased and that of 127 proteins significantly decreased in the test samples compared with the controls. The greatest 167-fold increase was for cytochrome P450 (CYP) 2B2. Increased metabolism, CYP 2B2 induction and cell division were associated with phenobarbital toxicity. Their proteomic CYP results agreed well with the results determined by the traditional liver toxicity methods. This study helps to demonstrate the use of global proteomic technology as a screening tool for toxicity studies.

Metabolomic technology was applied to liver toxicity studies by Ekman *et al*. (2006). In this study, rats were exposed to triazole fungicides, myclobutanil or triadimefon, daily by gavage at a dose of 175 mg $kg^{-1}day^{-1}$ for 14 days to determine endogenous metabolite profiles of the liver and blood serum using proton NMR spectroscopy. The results of this study clearly show that metabolomic technology is a good tool to evaluate liver toxicity of fungicide class of chemicals. In another study, Van Ginneken *et al*. (2007) used metabolomics to study hepatic steatosis in mouse induced by starvation. They observed major changes in the lipid profiles of the rat liver after 24 h fasting and identified a unique triacylglycerol as the biomarker for hepatic steatosis. This technology was used to determine metabolite profiles of ethionine in rat liver (Skordi *et al*., 2007). Integrated genomic and metabolic data have been used to study metabolic phenotypes in diabetic rats (Dumas *et al*., 2007). These studies demonstrate the excellent potential of metabolomic technology for evaluation of hepatotoxicity of xenobiotics *in vivo*.

5.1 Inter-Laboratory Comparison of Systems Toxicology *In Vivo*

Genomics technology was used by Beyer *et al*. (2007) to compare a multi-laboratory study of acetaminophen hepatotoxicity in mouse along with clinical chemistry and histological analysis. Data were generated individually by seven laboratories using a standard protocol. Greater than 20% necrosis was observed in livers of treated animals and correlated well ($r_{\text{Pearson}} = 0.846$) with serum alanine aminotransferase (ALT) activity. Gene expression data were coupled with classical toxicological data. Comparison of data generated from different laboratories showed that the gene expression profiling accompanied by histopathology and clinical chemistry data provided accurate information on hepatotoxicity.

Proteomics and metabolomics are relatively new disciplines compared with the genomics. Therefore, inter-laboratory comparison of data generated from

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

multiple laboratories using these technologies has not been possible. However, such studies are anticipated to be available in the near future.

6 SYSTEMS TOXICOLOGY *IN VITRO*

Systems toxicology has been applied to *in vitro* systems to evaluate the hepatotoxic potential of xenobiotics. Primary hepatocytes and hepatocyte cell lines are the frequently used *in vitro* models for hepatotoxicity studies (Beekman *et al*., 2006; Sahu, Ruggles and O'Donnell, 2006). *In vitro* models are particularly useful for mechanistic toxicity investigations. Fielden, Brennan and Gollub (2007) have used *in vitro* systems and genomic microarray technology to identify biomarkers of predictive and mechanistic toxicology of genotoxic and non-genotoxic hepatocarcinogens.

Attempts have been made to apply systems toxicology to various *in vitro* systems such as primary hepatocytes, hepatocyte cell lines and lymphoblastoid cell lines to evaluate hepatotoxic potential of xenobiotics. The results of these studies clearly demonstrate that this technology is a very useful tool for evaluating early response of the liver to various toxic insults. These studies show that *in vitro* systems toxicology can be used to evaluate a range of adverse health effects in the liver from drug toxicity, carcinogenesis to phospholipidosis (PLD), a lysosomal storage disorder characterized by excessive intracellular accumulation of phospholipids. For example, Sawada, Takami and Asahi (2005) and Sawada, Taniguchi and Takami (2006) used human hepatoma cell line HepG2, ArrayPlate and real-time PCR assays to screen PLD, induced by more than 50 cationic amphiphilic drugs including antidepressants and cholesterol-lowering drugs. This study showed a direct correlation between both the assays. Atienzar *et al*. (2007) used HepG2 cells and gene expression analysis to screen PLD-inducing potential of a large number of drugs such as acetaminophen, amiodarone, erythromycin, phenobarbital, tamoxiphen and valproic acid. Nioi *et al*. (2007) used HepG2 cells and gene expression profiles to characterize PLD induced by amiodarone, amitriptyline, fluoxetine, tamoxifen and loratadine. By adding a fluorescently labelled phospholipid (LipidTox) to the HepG2 growth media, they correctly identified 100% of the PLD-positive and PLD-negative compounds. They found this assay less time-consuming, more sensitive and of higher throughput than the gene expression analysis. Boess *et al*. (2003) used primary rat hepatocytes, gene expression profiling and traditional biochemical assays to evaluate hepatotoxicity of two serotonin receptor (5-HT6) antagonists. They analysed the CYP 2B2, CYP 2B Exon 9 and CYP 3A1 genes. This study concludes that the *in vitro* gene expression analysis combined with traditional biochemical information is a very powerful tool for evaluating potential heaptotoxicity of compounds and the mechanisms of their actions. Using the RT-PCR technology, Ellinger-Ziegelbauer *et al*. (2009) generated reproducible gene expression profiles of human lymphoblastoid cell line TK6 induced by model genotoxic agents, cisplatin, etoposide, taxol and NaCl.

Bjork and Wallace (2009) investigated structure–activity relationships of the environmentally persistent peralkyl acids, perfluorooctanoic acid and perfluorooctane sulfonic acid, known for activation of peroxisome proliferator-activated receptor alpha (PPARα). They determined the PPARα-dependent liver toxicity by quantitative reverse transcription PCR (RT-PCR) *in vitro* using rat and human primary hepatocytes and human hepatoblastoma cell line, HepG2. Their study demonstrates that the PPARα -dependent gene expression profiles by peralkyl acids in rat primary hepatocytes are not observed in either primary or transformed human liver cells in culture, indicating that the PPARα -dependent liver toxicity in rodents may not extrapolate to humans.

There are limitations in the ability of *in vitro* systems to model *in vivo* conditions. Intrinsic limitations of the *in vitro* model can affect reproducibility of the omics results. Gene expressions can be affected by the *in vivo* cellular environment and cell–cell interactions. Therefore, choice of an *in vitro* model comparable to the *in vivo* situation is a limiting factor for systems toxicology *in vitro*. Also the extrapolation of the data derived from *in vitro* systems to the animals and humans is a critical factor. Dere *et al*. (2006) compared the gene expression changes induced by 3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) in Hepa1c1c7 mouse hepatoma cells *in vitro* and C57BL/6 mouse liver tissue *in vivo* using the microarray and real-time RT-PCR techniques. A direct comparison of their untreated *in vitro* and *in vivo* systems revealed a good correlation ($R = 0.75$) between the basal levels of the two systems, illustrating that many genes were basally

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat211
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

expressed to similar levels. However, the TCDD treatment resulted in a number of divergent gene responses across both the systems. TCDD-induced genes both *in vitro* and *in vivo* include xenobiotic and oxidoreductase enzymes such as abhydrolase domain containing 6 (Abhd6), cytochrome P450 family 1 subunt a polypeptise 1 (Cyp1a1), dehydrogenase/reductase (SDR family) member 3 (Dhrs3), NAD(P)H dehydrogenase quinone 1 (Nqo1), prostaglandin-endoperoxide synthase 1 (Ptgs1), UDP-glucose dehydrogenase (Ugdh) and xanthin dehydrogenase (Xdh). This study demonstrated inherent differences in TCDD-induced gene expression profiles between the two systems, highlighting the limitations of the *in vitro* test system.

6.1 Inter-Laboratory Comparison of Systems Toxicology *In Vitro*

Using genomic technology, Ellinger-Ziegelbauer *et al*. (2009) have successfully demonstrated that systems toxicology provides reproducible data generated in nine different laboratories. The study used a common protocol for individual experiments, but each laboratory used its own standard operating procedures for cell culture and RNA analysis. They evaluated gene expression profiles of human lymphoblastoid cell line TK6 treated with four model genotoxic agents, cisplatin (DNA-reactive agent), etoposide (topoisomerase inhibitor), taxol (mitotic spindle poison) and NaCl (cytotoxic clastogen) by RT-PCR technology. They observed very reproducible and characteristic gene expression profiles associated with these toxic agents. No inter-laboratory comparison of systems toxicology using liver cells *in vitro* has been reported.

In an inter-laboratory study, Beekman *et al*. (2006) evaluated gene expression profiles of the well-known non-genotoxic hepatocarcinogen, methapyrilene, in primary rat hepatocytes by microarray technology. The genomic data generated by four different laboratories were compared. Genes indicative of good biomarkers of hepatotoxicity were identified following complex data analysis which included the experimental and statistical variability.

Inter-laboratory comparison of data generated from multiple laboratories using proteomics and metabolomic technologies is not available at the present time. However, they are relatively new and rapidly developing technologies compared with the genomics, and therefore reports on comparative inter-laboratory studies may not be far way.

7 APPLICATIONS OF SYSTEMS TOXICOLOGY

Systems toxicology has the promise of providing a very useful tool for exploratory toxicology with potential for multiple applications. Genomics has already found a wide application in toxicology in the last few years. DNA microarrays used for global gene expression analysis have been a powerful tool in toxicology (Eun *et al*., 2008). More recently, protein microarrays are becoming popular for protein expression profiling of toxicity (Spisak *et al*., 2007). A few important applications of systems toxicology for evaluation of hepatotoxicity are discussed below.

7.1 Mechanistic Hepatotoxicity

Systems toxicology is a rapidly developing new tool for "mechanistic toxicology" (Fielden and Zacharewski, 2001). Gene expression profiles represent cellular response to exposure of toxicants. Therefore, systems toxicology by profiling the gene expression determines early information on the mechanisms of toxicity at the molecular level. It identifies potential biomarkers of toxicity (Gatzidou, Zira and Theocharis, 2007). Because systems toxicology is a new rapidly developing field, it is difficult to discuss the mechanisms of hepatotoxicity determined by this technology when only a few limited studies are reported. However, few available studies indicate that oxidative stress plays an important role (Xu *et al*., 2004; Hussain *et al*., 2005; Oberdorster, Oberdorster and Oberdorster, 2005; Sayes *et al*., 2005; Nel, Xia and Li, 2006).

Oxidative stress, induced by reactive oxygen species, is a common mechanism of toxicity. Hepatocytes respond and adapt to oxidative stress. McMillian *et al*. (2005) investigated drug-induced oxidative stress in rat liver by gene expression profiling. Different classes of hepatotoxins such as reactive metabolites, peroxisome proliferators and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat211
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

macrophage activators all produce oxidative stress and hepatotoxicity, but each class has distinctive gene expression profiles. These distinctive gene sets provide useful biomarkers of hepatotoxicity. This study demonstrated that the transcription factor, Nrf2, regulates the genes involved in oxidative stress induced by hepatotoxicants. It is also known to be involved in the induction of phase II drug metabolism enzymes (Kong *et al*., 2001). Nanomaterials have been shown to induce oxidative stress in the liver leading to hepatotoxicity (Xu *et al*., 2004; Hussain *et al*., 2005; Oberdorster, Oberdorster and Oberdorster, 2005; Sayes *et al*., 2005; Nel, Xia and Li, 2006).

Proteomics technology can provide information on mechanisms of toxicity of chemicals that induce changes in the cellular protein levels by measuring global protein profiles in biological systems (Amacher *et al*., 2005; Spisak *et al*., 2007; Dail *et al*., 2008). Using this new technology, Dail *et al*. (2008) have identified serum proteins associated with oxidative stress in the rat liver induced by phenobarbital at a dose level below the detection limits of classical serum hepatic enzymes. Schnackenberg *et al*. (2006) applied an integrated omics approach to understand the acute hepatotoxicity of valproic acid in the mouse liver. They evaluated the integrated genomic, metabonomic and proteomic microarray data generated from the analysis of urine, serum and liver tissue from mouse exposed subcutaneously to $600\,mg\,kg^{-1}$ of valproic acid. The results of this study showed changes, induced by valproic acid, in the liver glycogenolysis pathway. Glycogenolysis is important for maintaining glucose levels, and therefore proteomics is a useful tool for studying mechanisms of this biological system.

Kim *et al*. (2009) used metabolomic technology to examine mechanisms of liver injury in mouse induced by ethanol. This study concluded that oxidative stress is responsible for the ethanol-induced liver toxicity. Duan *et al*. (2009) used proteomic and metabolic analysis of the rat liver following severe burn injury. They observed changes in hepatic protein expression profiles and metabolic patterns indicative of oxidative stress. The results of this study suggest that burn injury produces oxidative stress in the liver. More and more mechanistic studies using the relatively new proteomic and metabolomic technologies are expected to be available not in the distant future.

7.2 Predictive Hepatotoxicity

Systems toxicology is a new rapidly developing tool for "predictive toxicology" (Fielden and Zacharewski, 2001). The major application of this new discipline is the identification of genes predictive of toxicity. Gene expression profiles provide early molecular information on toxicity that cannot be detected by the conventional endpoints of toxicity. It is a good tool for predicting toxicity and, therefore, has been extensively applied in drug discovery (Waring *et al*., 2002).

Hamadeh *et al*. (2002a, 2002b) used DNA microarray to examine liver gene expression profiles of rats exposed to the hepatocarcinogen methapyrilene. They observed the gene expression analysis to be more sensitive than classical histopathology to predict early hepatotoxicity. This observation led Kier *et al*. (2004) to develop microarrays with "tox genes" to detect hepatotoxicity. Ruepp *et al*. (2005) developed a model to predict early stages of chemical hepatotoxicity based on liver gene expression profiles, histopathology and clinical chemistry.

Dai *et al*. (2006) treated rats with over 50 known heptotoxic and non-hepatotoxic agents for 3 days. The majority of the rats treated with hepatotoxins did not show liver toxicity after the end of the treatment period as evaluated by the traditional hepatotoxic endpoints. However, gene expression profiling clearly demonstrated liver toxicity of hepatotoxic agents compared with the non-hepatotoxic agents. This study clearly established a strong correlation between gene expression changes and liver toxicity at very early stages when the classical toxicity endpoints are not sensitive enough to detect it.

In another study, Mutlib *et al*. (2006) treated mice with the hepatotoxin, *N*-methylformamide, and its corresponding deuterium-labelled analogues resistant to metabolic processing. They measured gene expression changes in the livers of treated animals. They showed a direct correlation between the gene expression changes and the production of the reactive metabolite methyl isocyanate.

Studies on genotoxic (Ellinger-Ziegelbauer *et al*., 2004) and non-genotoxic (Fielden, Brennan and Gollub, 2007) hepatocarcinogens have demonstrated characteristic gene expression profiles indicative of early events leading to liver carcinogenesis in rats. Eun *et al*. (2008) have successfully identified large-scale characteristic molecular signatures of hepatotoxicity and the

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat211
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

mechanisms associated with it by gene expression analysis. These studies indicate that genomic toxicology is a useful tool for detecting and predicting hepatotoxic as well as hepatocarcinogenic potential of materials in spite of the differences in their mechanisms of action.

Proteomics technology has been used successfully for identification of protein biomarkers to predict hepatotoxicity and liver cancer (Craig *et al*., 2006). Spisak *et al*. (2007) have used protein microarrays for biomarker discovery.

Studies of Dail *et al*. (2008) on hepatocarcinogen phenobarbital have demonstrated that the results obtained from the global mass spectrometric proteomic analysis compared very well with the results obtained by the traditional liver toxicity methods. The level of exposure to phenobarbital in this study was below the detection limit of liver damage at a very early stage determined by the classical tests. They have concluded that the proteomic technology can be used as a screening tool for hepatotoxicity studies.

Metabolomic technology is a useful tool for detecting and predicting liver toxicity of potential hepatotoxicants (Ekman *et al*., 2006). This technology has been used by Van Ginneken *et al*. (2007) to predict hepatic steatosis in mouse.

The above studies demonstrate that the systems toxicology is a powerful tool to predict hepatotoxicity. It can be particularly useful for high-throughput screening of potential hepatotoxicants (Fielden and Kolaja, 2006; Craig *et al*., 2006). It is a valuable tool for screening of food-related products to predict their potential liver toxicity.

7.3 Biomarkers of Hepatotoxicity

Systems toxicology is an excellent tool for discovery of biomarkers (Kussmann, Raymond and Affolter, 2006; Gatzidou, Zira and Theocharis, 2007). There is a strong need for drug industries to use this sensitive new rapidly developing technology for identifying biomarkers of early detection of drug toxicity during pre-clinical and clinical evaluation (Robertson, 2005; Schnackenberg *et al*., 2006; Espandiari *et al*., 2007).

Fielden, Brennan and Gollub (2007) used liver gene expression profiling by microarray technology to develop biomarkers for non-genotoxic hepatocarcinogens. They collected hepatic gene expression data from rats treated for 5 days with 47 test chemicals. Each chemical was evaluated in the short-term *in vivo* study using only three rats. They observed that this short-term *in vivo* rodent model was more sensitive, more accurate and provided quicker results compared with the traditional models for risk assessment of non-genotoxic hepatocarcinogens (Fielden, Brennan and Gollub, 2007). However, one possible limitation of this study may be the very small number of only three animals which may affect the statistical significance of the results considering the individual variability among the animals. Real-time quantitative RT-PCR (qRT-PCR) has also been used for identification of biomarkers of toxicity (Ellinger-Ziegelbauer *et al*., (2009). Both genomic technologies, microarray and qRT-PCR, have been used for identification of biomarkers of liver toxicity (Dai *et al*., 2006; Mutlib *et al*., 2006; Nie *et al*., 2006; Tugendreich *et al*., 2006; Eun *et al*., 2008). These studies show that genomic technology is a valuable sensitive tool for screening hepatotoxic as well as hepatocarinogenic potential of suspected test agents, although their biomarkers and mechanisms of action may be different. Genomic biomarkers provide early prediction and mechanistic assessment of hepatotoxicity and hepatocarcinogenicity.

Proteomics technology has been used successfully for identification of protein biomarkers for hepatotoxicity (Craig *et al*., 2006). Spisak *et al*. (2007) have used protein microarrays for identification of biomarkers.

Dail *et al*. (2008) have used global mass spectrometric proteomic analysis to determine biomarkers for hepatotoxicity. This technology offers information on biomarkers complementary to genomics (Heijne *et al*., 2003).

This technology was used to identify protein biomarkers for early detection of liver fibrosis and cirrhosis in rats (Low *et al*., 2004; Xu *et al*., 2004). Using proteomics and bioinformatics data, Xu *et al*. (2004) identified a serum protein that is downregulated in cirrhotic rat liver. This technology has also been used to identify serum protein biomarkers of hepatotoxicity induced by viruses. Using ProteinChip arrays, Poon *et al*. (2005) observed fibrotic protein changes in the serum of patients suffering from hepatitis B, but these proteins were not identified. He *et al*. (2003) used proteomics to identify seven serum proteins as biomarkers of liver injury induced by hepatitis B virus.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat211
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Metabolomic technology is a useful tool for determining biomarkers of hepatotoxicity (Ekman *et al*., 2006). This technology has been used to identify a unique triacylglycerol as the biomarker for hepatic steatosis in mouse (Van Ginneken *et al*., 2007). More such studies are expected to be available not in the distant future.

Schnackenberg *et al*. (2006) used integrated genomic, metabonomic and proteomic microarray data to identify biomarkers for liver toxicity induced by valproic acid in mouse. Their studies identified two proteins, glycogen phosphorylase and amylo-1,6-glucosidase, as biomarkers of liver toxicity. These two proteins were increased in animals exposed to valproic acid compared with the vehicle controls. Both of these proteins are involved in converting glycogen to glucose. This study suggests a perturbation in the glycogenolysis pathway induced by valproic acid.

The studies reported so far clearly demonstrate that the systems toxicology is a powerful tool for identifying biomarkers for predictive or diagnostic hepatotoxicity. The validated biomarkers can be applied to predictive and mechanistic hepatotoxicity (Olden, 2006).

McBurney *et al*. (2009) used genomic, proteomic and metabolomic technology to identify biomarker of liver toxicity in rats exposed to drugs entacapone and tolcapone. In this study, the molecular analysis of liver tissue and plasma samples by the genomic, proteomic and metabolic techniques demonstrates that omics technology is a valuable tool for evaluating liver toxicity. It is anticipated that more and more such studies will be undertaken in near future. Already biomarker sets developed from large reference databases such as DrugMatrix are available commercially.

7.4 Species and Gender Differences in Hepatotoxicity

Systems toxicology is a useful tool for evaluating species differences in hepatotoxicity. Dail *et al*. (2008) applied the proteomic analysis to identify the protein biomarker, cytochrome P450 2B2, in the rat liver exposed to phenobarbital at dose level below the detection limits of classical serum hepatic enzymes. They have used these proteomic data obtained from the rats for intrapolation to the humans to explain why phenobarbital is a non-genotoxic hepatocarcinogen in rats but not in humans. This study has demonstrated that systems toxicology is a very useful tool for investigating cross-species intrapolation of data.

Systems toxicology can be successfully applied to evaluate the gender effects in hepatotoxicity at very early stage when classical liver toxicity tests are not sensitive enough to detect toxicity. Gender difference plays an important role in the toxic responses of the liver (Treinen-Moslen, 2001). Females are pre-disposed to hepatotoxicity, and concomitant agents that induce cytochrome P450 enzymes also increase individual susceptibility (Stedman, 2002). Drug-induced liver failure is more common in women than in men (Russo *et al*., 2004; Carey *et al*., 2008). Cocaine causes more liver damage in male mice than in female mice (Visalli, Turkall and Abdel-Rahman, 2004). Gender differences in P450, especially CYP2A, expression is higher in female pigs compared with the male pigs (Gillberg, Skaanild and Friis, 2006). These studies, which show gender effects in hepatotoxicity measured by classical methods, are ideal for revisiting by the systems technology to identify biomarkers of hepatic gender effects at the very early stages of liver toxicity that cannot be detected by classical tests.

Gender difference in hepatotoxicity has been demonstrated using *in vitro* systems. Delongchamp *et al*. (2005) used gene expression profiles of donated male and female human liver tissues and primary human hepatocytes to evaluate gender differences in hepatotoxicity. They tested a total of 31 100 genes and found that the gene expression of only 224 genes differed between sexes. The observed gender differences in gene expressions were small. False discovery rates exceeded 80% for every set of genes selected, making it impossible to identify specific genes with gender differences. They observed high inter-individual variability in phenotypes and genotypes of human liver as well as large variations in individual consumption of various diets. This study suggests that gene expression profiling alone may not be able to identify gender differences in hepatotoxicity. More recently, Silkworth *et al*. (2008) have used DNA micrarry technology to study gender effects of the liver carcinogen arochloro 1254 in rats. They observed significantly altered gene expression profiles by this hepatocarcinogen.

Proteomic and metabolomic toxicology are relatively new, and therefore gender differences in

hepatotoxicity studies have not been reported using these technologies. More research is needed for evaluation of gender effects in liver toxicity. Systems toxicology will be useful to study gender-specific liver toxicity at the molecular level. It can identify genomic, proteomic and metabolomic biomarkers related to sex-specific liver toxicity.

7.5 Food Safety

Systems toxicology is useful for improving food safety assessment (Spielbauer and Stahl, 2005). In a review article, Stierum *et al*. (2005) have reported that systems technology was used to evaluate hepatotoxicity of food additives such as butylated hydroxytoluene, curcumin, propyl gallate and thiobendazole. Arbillaga *et al*. (2009) has tested the toxicity of ochratoxin A (OTA), a mycotoxin found as a contaminant in cereals, in human renal proximal tubular epithelial cell line HK-2 using gene expression profiles. The comparison of their gene expression analysis with the cellular oxidative stress level and oxidative DNA damage indicates a DNA non-reactive mechanism of OTA toxicity.

Systems toxicology offers valuable molecular tools for the detection and identification of foodborne pathogens. Liver is an important site of host–pathogen interactions. Identification of genes that affect susceptibility to foodborne pathogens provides insights into the pathogenesis of food-related diseases. Genomic technology has been used for detection of foodborne pathogen *Escherichia coli* in beef (O'Hanlon *et al*., 2005). This technology has been applied to investigate host–microbe interactions (Cummings and Relman, 2000) and acute hepatitis C virus infection in liver (Bigger, Brasky and Lanford, 2001). Plumet and Gerlier (2005) have developed a sensitive and specific assay based on real-time RT-PCR to quantify individual measles virus RNA. This can be useful for a reliable detection of measles virus in clinical samples. Cai *et al*. (2005) have assessed the efficacy of nitazoxanide and paromomycin against two strains of the *Cryptosporidium parvum* in HCT-8 cells *in vitro* using quantitative real-time RT-PCR assay. Both compounds displayed dose-dependent inhibitions.

Very few reports are available on proteomics or metabolomics of hepatitis caused by foodborne viruses. However, one has to recognize that both these technologies are relatively new. He *et al*. (2003) used proteomics to compare hepatitis B virus-negative and -positive serum samples. This study identified changes in seven serum proteins that can be used as biomarkers of hepatitis B virus-induced liver injury. More and more such proteomic and metabolomic studies are expected to be available in the near future.

7.6 Food Safety Evaluation and Quantitative Health Risk Analysis

Toxicological profiles and mechanisms of toxicity of a potential toxicant are important information for its health risk assessment. Systems toxicology provides toxicological profiles and molecular mechanisms of toxicity of potential toxic agents. The greater understanding of the molecular basis of toxic exposure provides a more scientific basis for health risk analysis. Therefore, systems toxicology will play a very useful role in the risk evaluation of toxicants (Oberemm, Onyon and Gundert-Remy, (2005); Boverhof and Zacharewski, 2006). Oberemm, Onyon and Gundert-Remy (2005) have discussed the potential use of genomics in safety evaluation and risk assessment. Normally, an expensive 2-year rodent bioassay is used for risk assessment of non-genotoxic hepatocarcinogens, but Fielden, Brennan and Gollub (2007) have developed a short-term *in vivo* rodent model which is more sensitive, more accurate and provide quicker results compared with the traditional models for risk assessment of non-genotoxic hepatocarcinogens. Ku *et al*. (2007) and Thybaud, Le Fevre and Boitier (2007) have successfully applied genomic technology for genotoxicity hazard and risk assessment.

Concentration-dependent omics data from *in vitro* models may not be directly useful for extrapolating health risk in humans, but information on relative toxicities is useful for risk estimation. Identification of type and extent of adverse health effects associated with a toxic exposure is important for hazard and risk assessment. Systems toxicology provides large amounts of such information in a relatively short period of time. Therefore, proper validation of the omics techniques is necessary for proper use of omics-generated information for risk evaluation of food-related products.

8 CONCLUSIONS

This review of literature clearly demonstrates that systems toxicology is a valuable tool for early prediction and mechanistic assessment of liver toxicity. It provides accurate molecular information for toxicity hazard and risk assessment in a relatively short period of time (Oberemm, Onyon and Gundert-Remy, 2005; Boverhof and Zacharewski, 2006; Fielden, Brennan and Gollub, 2007; Ku *et al*., 2007; Thybaud, Le Fevre and Boitier, 2007). This technology will find very useful applications in food safety (Stierum *et al*., 2005; Arbillaga *et al*., 2009). It is an excellent tool for quick screening of hepatotoxic potential of food-related products that occur naturally or that are added deliberately to the foods and dietary supplements. The published reports show the value of omics technologies in combination with classical histopathology and biochemical assays providing a powerful tool for accurate assessment of "predictive" and "mechanistic" hepatotoxicity. The systems toxicology *in vitro* offers a powerful cost-effective tool for faster high-throughput toxicity testing. It can be effectively used for high-throughput screening of food-related products for potential hepatotoxicity.

Global proteomic (Dail *et al*., 2008) and metabolomic (Zivkovic and German, 2009) analysis identifies more carcinogenic biomarkers for prediction and mechanistic assessment of potential hepatotoxicity of food-related products. Metabolomic technology is a useful tool for the assessment of nutritional status of patients with diet-related diseases (Zivkovic and German, 2009).

In conclusion, the systems toxicology has been recognized recently as an excellent tool for rapid high-throughput screening for predictive and mechanistic toxicology. Therefore, it can be judiciously used for high-throughput screening of early detection, prediction and mechanistic assessment of liver toxicity caused by food-related products, food additives, foodborne microbial pathogens, herbal products and/or dietary supplements as well as for their risk assessment.

ACKNOWLEDGEMENTS

Mass Spectrometry-Based Proteomics in Systems Toxicology

Li-Rong Yu, Yuan Gao and Donna L. Mendrick

Center for Proteomics, Division of Systems Biology, National Center for Toxicological Research, US Food and Drug Administration, Jefferson, AR, USA

1 INTRODUCTION

The advance of novel technologies and instrumentation has significantly changed the methods and focus of scientific research in the past few decades. The human genome project, largely driven by high-throughput DNA sequencing has brought new avenues of "omics" into biomedical research and enabled both hypothesis- and discovery-driven research. The former tends to focus on smaller numbers of genes, transcripts, or proteins to answer a pre-defined question that is based on previous experimental results. In contrast, the discovery-driven approach mainly focuses on broad questions, global characteristics of molecular networks (e.g., transcripts, proteins, and metabolites), and systematic analysis of biological functions at higher levels (e.g., a cell, tissue, or organism). Such studies are not directed by predisposed knowledge or assumptions, and the general goal is to use relatively high throughput approaches to acquire considerable data to elucidate the system under study. This type of discovery-driven research is exemplified by systems biology (Ge, Walhout and Vidal, 2003; Kitano, 2002) and pioneered by genomics, in which a few tens of thousands of genes are analyzed in a high-throughput fashion on a DNA microarray (Schena *et al*., 1995). However, at the current time, information in the genome cannot predict the full cellular phenotypes and functions of proteins. As such, the concept of proteome was coined and defined as the total protein components expressed in a cell, tissue, or organism at a specific time and physiological state (Wasinger *et al*., 1995; Humphery-Smith, Cordwell and Blackstock, 1997).

Although great efforts in the area of proteomics have been made, many challenges remain. It is well-known that a cellular proteome is complex, but the degree of complexity is uncertain. It has been estimated that protein-coding genes total approximately 20 500 in human (Clamp *et al*., 2007), a number similar to that in mouse or *Caenorhabditis elegans* (Mouse Genome Sequencing Consortium, 2002; The *C. elegans* Sequencing Consortium, 1998). However, human beings are distinct from mice and roundworms. Assuming as many as 14 000 genes are expressed within the human cell at any single time and three different mRNA transcripts are expressed per gene, then the cell has 42 000 transcripts for protein synthesis. This estimate is very conservative considering the presence of splice variants, single nucleotide polymorphisms, and so on. The protein precursor translated from a single transcript can be processed in many different ways to form a mature protein, including truncations, modifications, protein splicing, and so on. There are more than 300 different types of known modifications with some more commonly occurring such as phosphorylation, glycosylation, methylation, acetylation, and ubiquitination. For some modifications,

the exact type of modifier may be different. For example, there are a variety of different glycoforms for glycosylation. Assuming a single protein has four potential phosphorylation sites, in itself, it may give rise to sixteen different isoforms ranging from all the sites phosphorylated to none of them being phosphorylated. If each of the 42 000 possible protein products contained only four possible sites of phosphorylation, these would give rise to 672 000 different protein species. Obviously, this number is extremely conservative and only one specific type of modification is considered in this calculation. Considering the possibility of multiple types of modifications in a single protein, the estimate suggests that the human proteome would be most likely to contain well over 1 000 000 distinct protein species. The above inference could provide a hint to understand the complexity of the human proteome within a single tiny cell. This large number of protein species is well beyond the current capacity of state-of-the-art proteomic technologies resulting in a consistent undersampling of the proteome regardless of the analytical method chosen. Other challenges in proteome analysis include transit protein modification and complex formation, dynamic protein synthesis and turnover, huge dynamic range of protein abundance levels, and so on.

The enormous complexity of proteomes has spurred development and advancement in this field and many new areas are emerging along with the development of systems biology or systems toxicology (Slikker *et al*., 2007). One such emerging field is the combined application of proteomics and toxicology leading to the development of a new discipline, termed toxicoproteomics. Although it is in an early stage, toxicoproteomics is an attractive area and possesses many opportunities for exciting studies (Merrick, 2008). The field is concentrated on the proteomic study of toxicity caused by toxic substances, including drugs, toxins, environmental stressors, chemicals, and any other materials that may cause significant pathological responses (e.g., engineered nanomaterials (Poland *et al*., 2008)). The discipline needs to combine knowledge and methods of toxicology, pathology, and other expertise to discover toxicity biomarkers and define, at the proteome level, the toxicity pathways, modes-of-action, and key molecular events.

One of the major efforts in toxicoproteomics research is to elucidate pathological responses to a specific toxicant at the protein molecule level. As such, toxicoproteomics requires systematic analysis of protein functions associated with toxicant exposures, including, but not limited to, qualitative and quantitative measurements of protein expression, protein modifications (including natural and exogenic modifications), protein-protein/toxicant interactions, protein structures, protein activity, and subcellular localization. The research also needs to develop novel technologies and approaches for better measurements of toxicity at the molecular level, improve our understanding of toxicity mechanisms, and gain knowledge in organisms' responses to toxic substances for the promotion of public health. The major aims of toxicoproteomics research include: (i) development of proteomic technologies for efficient analysis of proteins; (ii) identification and validation of protein biomarkers for early detection of toxicity and disease; (iii) elucidation of molecular mechanisms of toxicity; (iv) generation of toxicoproteomics knowledge for better risk assessment.

Toxicoproteomics, as well as other proteomics branches, have been driven by the advances in analytical technologies and instrumentation. Far before the invention of the term "proteome" or "proteomics" in 1994 (Wasinger *et al*., 1995; Humphery-Smith, Cordwell and Blackstock, 1997), protein analysis at the "proteome" level actually had been conducted for decades using high-resolution two-dimensional electrophoresis (2-DE) (O'Farrell, 1975). The development of proteomics can be attributed to the continuous improvement in intact protein separation using two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) or 2-DE and the realization of mass spectrometry (MS) analysis of proteins/peptides using the soft ionization techniques matrix-assisted laser desorption/ionization (MALDI) (Tanaka *et al*., 1988; Karas and Hillenkamp, 1988) and electrospray ionization (ESI) (Fenn *et al*., 1989) in late 1980s. In the past two decades, the field grew rapidly as a result of significant progression in high-resolution analytical separation (e.g., capillary high-performance liquid chromatography with nanoflow separation, nano-HPLC), nano-ESI, application of stable isotope dilution MS (SID-MS), and increase of MS sampling speed and performance. Consequently, two basic approaches, gel-based and solution-based proteomic analyses, have been developed for global quantitative measurement of protein abundance changes. It should be noted that protein microarrays,

as a novel technology, have been developed and applied to systems biology for many years (Zhu *et al*., 2001). Owing to very few applications of this technique to toxicological studies, this chapter mainly focuses on MS-based proteomic technologies in systems toxicology (Aebersold and Mann, 2003; Wetmore and Merrick, 2004; Monsinjon and Knigge, 2007).

2 TWO-DIMENSIONAL POLYACRYLAMIDE GEL ELECTROPHORESIS

The extremely high complexity of proteome samples requires proteins to be separated prior to any further characterization so that low abundance molecules can be detected. When the word "proteomics" is mentioned, the first thought that enters most people's minds is an image of dense protein spots separated on a 2D-PAGE gel. So far in proteomics, 2D-PAGE has been the most commonly used protein separation technique with high resolution for intact proteins. The technique can be tracked back to 1975, when O'Farrell, Klose, and Scheele achieved the milestone of successful implementation of high resolution 2D-PAGE based on predecessors' 2D protein separation concept, invention of polyacrylamide gel, isoelectric focusing (IEF), and sodium dodecyl sulphate (SDS) polyacrylamide gel electrophoresis (SDS-PAGE) (O'Farrell, 1975; Klose, 1975; Scheele, 1975). Since then, 2D-PAGE has been further improved and optimized in sample preparation, use of immobilized pH gradient (IPG) gel (Bjellqvist *et al*., 1982) as the first dimensional IEF separation, protein spot visualization, and development of 2D image analysis tools. The reproducibility of protein separation and quantitation of 2D-PAGE has been significantly improved and the modern 2D-PAGE can resolve thousands of proteins in a single gel. All these advances establish the fundamentals of 2D-PAGE in conjunction with MS protein identification as the cornerstones of proteomics.

The principle of 2D-PAGE is two-dimensional orthogonal protein separation based on the charge state and size of each protein. The first dimensional separation is IEF, which separates proteins according to their isoelectric points (p*I*) and currently is achieved using IPG gels across a certain range of pH (e.g., pH 3–10) (Görg *et al*., 2000). After IEF is completed, the IPG gel is conditioned in an SDS buffer and then transferred onto an SDS slab gel for SDS-PAGE. Electrophoresis in the presence of SDS, which denatures the proteins and eliminates charge-to-mass differences, is for the separation of proteins based on their molecular weight. The separation power of 2D-PAGE is able to resolve the proteins differing by a single charge, thereby allowing *in vivo* modifications such as phosphorylation and certain mutations to be detected. Fortunately, the technique allows relative quantitation of the proteins from different proteomes.

A 2D-PAGE-based quantitative proteomic analysis usually includes several steps: protein extraction, running the 2D gels, gel visualization, 2D image acquisition and analysis, excision of 2D spots of interest, in-gel protein spot digestion, and MS analysis for protein identification (Figure 1). For quantitative comparison of two distinct cell populations (e.g., control vs. treated cells), the proteome samples are prepared by extracting proteins from different populations of cells separately using the same lysis buffer. The samples with equivalent protein amounts are then subjected to 2D-PAGE for fractionation. The 2D gels are visualized by stains such as the commonly used Coomassie Blue or silver. The resulting images are then digitalized and analyzed using 2D image analysis software such as Delta2D, ImageMaster, Melanie, PDQuest, and so on. Since a 2D image contains hundreds to thousands of protein spots, the spots must be accurately detected and aligned among the analyzed gel images so that the spot intensities of the same protein across different gels can be compared for relative quantitation (Yu *et al*., 2001). Usually, protein spots showing higher intensities on the gel from either the control or treated cells are excised and then digested in-gel by an enzyme such as trypsin. The resulting peptides are extracted from the gel and analyzed by MS or tandem MS (MS/MS) (more detailed discussion later) to acquire the raw data for identification of the protein(s) within the gel spot. Protein identification is accomplished using software (e.g., Sequest and Mascot) designed to compare the mass spectrometry data against a database comprised of a large number of protein sequence entries (Eng, McCormack and Yates, 1994; Yu *et al*., 2000).

One of the merits of 2D-PAGE is that multiple samples can be separated in parallel using the same device, which saves time overall in the whole procedure of proteomic analysis of multiple samples. However, it is still tedious and labor intensive

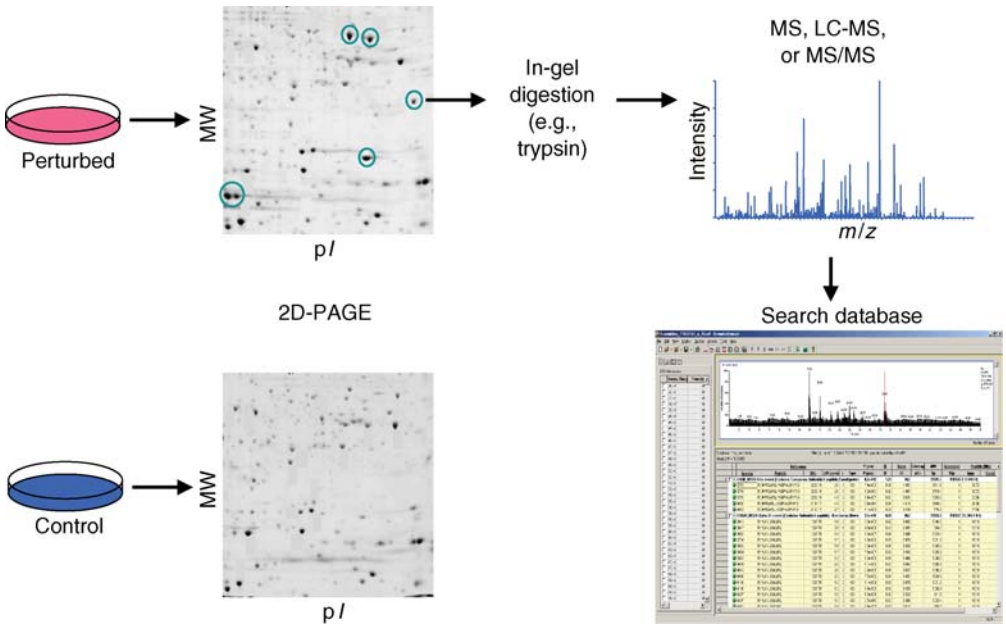

Figure 1. Schematic workflow of quantitative proteomics using two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) and mass spectrometry. Comparative proteome samples are resolved on separate 2D gels. After staining and image analysis, protein spots showing higher intensities on the gel from either the control or treated cells are excised and then digested in-gel by an enzyme such as trypsin. The resulting peptides are extracted from the gel and analyzed by MALDI-MS, LC-MS or tandem MS (MS/MS). The MS or MS/MS data are then searched against an appropriate database to identify the protein(s) within the gel spot. MW, molecular weight; p*I*, isoelectric point; MALDI, matrix-assisted laser desorption/ionization.

when tens of samples need to be compared. The other advantage of 2D-PAGE-based proteomics is that the downstream MS identification is performed only for the differentially displayed protein spots. This makes MS analysis simple and straightforward. Nonetheless, the technique has been criticized as well for its drawbacks. The most commonly used gel visualization methods such as Coomassie Blue and silver staining have limited dynamic ranges and the sensitivity is relative low (e.g., low nanograms for silver staining) compared to the state-of-the-art LC-MS approaches (e.g., femtomoles routinely, attomoles to zeptomoles in some cases) (Belov *et al*., 2000; Shen and Smith, 2005; Hanke *et al*., 2008). This makes many low abundance proteins undetectable in the gel but identifiable using MS. Procedures involving the use of aldehydes for silver staining may not be compatible to the MS analysis of gel spots (Yan *et al*., 2000). The use of SYPRO stains such as SYPRO Red, SYPRO Orange, and SYPRO Tangerine dyes for gel visualization is a simple one-step procedure (Steinberg *et al*., 1996). SYPRO Ruby staining has a linear dynamic range of over three orders of magnitude with sensitivity comparable to the most sensitive silver staining techniques (Berggren *et al*., 2000). SYPRO staining is compatible to MS analysis; however, UV transilluminator or similar imaging systems are required to visualize the gel spots. To enhance the detection of low abundance proteins, "ultrazoom" gels with narrow pH gradients in the first dimension can be used for loading large amounts of protein (Hoving, Voshol and van Oostrum, 2000; Wildgruber *et al*., 2000). Another issue with 2D-PAGE is poor gel-to-gel reproducibility. The procedure must be controlled strictly to obtain well-reproducible gel images. To overcome this problem, 2D difference gel electrophoresis (2D-DIGE) has been developed to visualize and compare multiple proteomes in a single 2D gel (Unlu, Morgan and Minden, 1997). In 2D-DIGE, multiple fluorophores (e.g., Cy2, Cy3, and Cy5) are used to label different proteomes to be compared, and the labeled samples are combined and run on a single 2D gel. The 2D image of each sample is acquired using excitation and emission wavelengths unique to the dye used for that sample, and the relative abundance of each protein in each sample can then be measured. A merged 2D image can be generated to display differentially expressed

proteins in different colors by superimposing the separately acquired images of compared samples. Other shortages of 2D-PAGE include insufficient separation of membrane proteins because of solubility issues, exclusion of proteins with extremely high/low molecular weight or isoelectric points, and potential co-migration of multiple proteins into the same spot.

3 MASS SPECTROMETRY

Mass spectrometry is another cornerstone that has driven the proteomics revolution. The technology is at a prominent position in the field of proteomics owing to its rapid identification of proteins and the capability for relative and absolute protein quantification. After approximately a century's development, the sensitivity afforded by current MS enables peptides/proteins to be successfully identified at the range of low femtomole (fmol, 10^{-15} mol) to attomole (amol, 10^{-18} mol) (Hanke *et al*., 2008), and at the zeptomole levels (zmol, 10^{-21} mol) in particular cases (Belov *et al*., 2000; Shen and Smith, 2005). Mass measurement accuracy for high-resolution MS can be routinely achieved to 1–5 ppm and even high ppb (parts-per-billion) (Olsen *et al*., 2005; Williams and Muddiman, 2007). Such high mass measurement accuracy and sensitivity greatly increase the database-search-based peptide identification confidence levels for both high and low abundance proteins.

3.1 Ionization Methods

Peptides or proteins must be ionized before they are introduced into the mass spectrometer for mass measurement. A mass spectrometer can be thought of as two distinct parts: the ionization source and the mass analyzer. The ionization source is the region of the instrument in which the sample is ionized and desorbed into the gas phase. A mixture of positively and negatively charged molecular ions is generated after ionization. For peptide and protein analysis, MALDI (Tanaka *et al*., 1988; Karas and Hillenkamp, 1988; Karas *et al*., 1987) and ESI (Fenn *et al*., 1989; Dole *et al*., 1968) are the two most common ionization methods. The breakthrough of identifying proper organic matrices for effective laser desorption/ionization of large molecules (10–20 kDa) opened a new era of using MALDI for the analysis of biological macromolecules such as proteins together with the ESI application to proteins during the same time.

In MALDI, the sample is mixed with a saturated solution of matrix, for example, α-cyano-4-hydroxycinnamic acid (CHCA), 2,5-dihydroxybenzoic acid (DHB), and 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid), which are commonly used for peptide/protein analysis. A small volume of the mixture (e.g., 1–2 μL) is deposited onto a MALDI plate, and the sample is integrated into a crystal lattice after it is dried owing to the high matrix-to-sample concentration ratio. In the MALDI source region, the sample is irradiated by using a laser pulse (e.g., nitrogen laser at 337 nm) and the matrix absorbs most of the photon energy provided by the laser. The matrix-absorbed energy is then transferred to the analytes (e.g., peptides), which are subsequently ejected from the plate surface into gas phase. MALDI typically generates singly charged ions whatever the analyte is a peptide or a large protein, thus the generated ions have high mass-to-charge (*m/z*) ratios. Thus this type of ionization method is coupled prevalently with a time-of-flight (TOF) analyzer that can measure ions at a large *m/z* range.

The implementation of ESI for biological macromolecules has made a dramatic impact on the advance of proteomics. ESI allows liquid separation techniques to be coupled online with MS for real-time MS data acquisition. In ESI, the sample dissolved in solution flows through an emission tip toward the ionization source region by direct infusion, HPLC, or capillary electrophoresis, and so on. A high voltage is applied to the emission tip (spray tip), so the sample solution is charged and produces submicrometer-sized droplets upon exiting the spray tip. The liquid droplets contain ions produced from the sample of interest as well as the solvent. At this point, the analytes may be ionized; however, the charged droplets need to undergo further desolvation by either passing through a heated capillary or a curtain of nitrogen gas. The ions of analytes at the gas phase are then transmitted to the mass analyzer for mass measurement. In contrast to MALDI, ESI has a strong capability of generating multiply charged ions from biological molecules such as proteins, peptides, DNA, and RNA. This attribute enables high molecular weight peptides/proteins to be measured in the mass analyzers with limited *m/z* ranges since the instrument measures a molecule's *m/z* ratio.

3.2 Mass Analyzers

The mass analyzer is the region where the *m/z* ratios of gas phase ions created in the source region are measured. Several different mass analyzers have been applied to proteomic analysis. Many types of mass spectrometers have been developed resulting from different combinations of mass analyzers, ionization sources, collision cells, ion optics, and so on. Each of them has unique features in terms of speed, sensitivity, resolution, mass accuracy, capabilities of tandem MS, etc. The selection of instrument to be utilized is based on the research focus. The details of each type of mass spectrometer were described previously (Yu, Conrads and Veenstra, 2005).

A quadrupole mass analyzer (Yost and Boyd, 1990) has been historically coupled with ESI. While single quadrupole mass spectrometers have limited utility in proteomics, the triple quadrupole instrument has been widely applied to protein analysis since it is composed of three quadrupole regions and has true MS/MS capability. The instrument is quite versatile in the detection of product ion, precursor ion, and neutral loss. These characteristics together with high measurement speed and sensitivity make it the choice for selected ion monitoring (SRM) in targeted proteomic analysis (more discussion below).

The TOF mass analyzer (Cotter, 1997), as implied in its name, measures the *m/z* values of ions based on the time they take to fly in the field-free drift tube. Attractive features of TOF analyzers include high resolution, mass accuracy, and so on. The TOF instrument in combination with MALDI (MALDI-TOF) has long been used for protein identification by peptide fingerprinting (Shevchenko *et al*., 2000). The recently developed MALDI-TOF/TOF (Medzihradszky *et al*., 2000; Suckau *et al*., 2003) has two TOF tubes separated by a collision cell and the first TOF tube is used for precursor ion selection when MS/MS is performed. The hybrid quadrupole-time-of-flight (Q-TOF) mass spectrometer (Chernushevich, Loboda and Thomson, 2001) can be considered either as the addition of a quadrupole and a collision cell to the TOF analyzer, or as the replacement of the third quadrupole (Q3) in a triple quadrupole MS by a TOF analyzer. This instrument has the advantages of quadrupole's ion selectivity and sensitivity and TOF's high resolution and mass accuracy in both MS and MS/MS modes; thus it has had a tremendous impact in proteomics.

Quadrupole ion trap mass analyzers (Stafford *et al*., 1984) have multiple capabilities of ion collection, isolation, storage, and ion manipulations such as collision-induced dissociation (CID) and ion-ion reactions. These characteristics enable an ion trap analyzer to perform multiple stage tandem MS (i.e., MS^n) for molecular structure elucidation. Compared to the conventional three-dimensional (3D) ion traps that operate with a 3D quadrupole field, the new stand-alone 2D ion trap (i.e., linear ion trap) mass analyzers have higher injection efficiencies and higher ion storage capacities (Schwartz, Senko and Syka, 2002; Hager, 2002; Douglas, Frank and Mao, 2005). Although ion traps normally have poor mass accuracy and low resolution, the highly efficient tandem MS has made the instrument a true "work-horse" in global proteomic studies.

A new type of ion trapping mass analyzer, Orbitrap, was developed recently (Makarov, 2000; Hardman and Makarov, 2003). An Orbitrap mass analyzer consists of an outer barrel-like electrode and a coaxial central spindle-like electrode to which electrostatic fields are applied. The Orbitrap analyzer radially traps ions about the central electrode. Unlike the ion trap analyzer, it measures the frequencies of harmonic oscillations of trapped ions along the axis of the electric field. The mass spectrum is obtained by a fast Fourier transform of the measured ion frequencies. The newly improved design of Orbitrap can provide higher field strength and higher frequencies of ion oscillations and thus higher resolving power (e.g., FWHM 350 000 at *m/z* 524) (Makarov, Denisov and Lange, 2009). Orbitrap mass analyzers are popular in proteomics owing to the high resolution and mass accuracy (typically <5 ppm) (Hu *et al*., 2005).

A Fourier transform ion cyclotron resonance (FTICR) mass analyzer (Comisarow and Marshall, 1974) measures the cyclotron frequencies of all of the ions in the ICR cell, which is placed in a magnetic field, and uses a Fourier transform to convert these frequencies into *m/z* values. It has provided the highest resolution (Solouki *et al*., 1997), mass accuracy (Bruce *et al*., 1999), and sensitivity (Hakansson *et al*., 2001) for peptide and intact protein measurements so far achieved; however, these performance parameters depend on the strength of the magnet field present. Although FTICR-MS is not used as widely as other types of MS in proteomics owing to the expense and technical challenges, its unique capabilities will make this type of instrument play important roles in global proteomic analysis, especially in the analysis of intact proteins.

MS performance is expected to continue to improve as development continues.

4 PROTEIN IDENTIFICATION BY MASS SPECTROMETRY

Several approaches have been developed for the identification of proteins using MS. Ideally protein identification should be performed at the intact protein level so that protein isoforms, for example, as a result of different modifications, can be distinguished. This strategy for the analysis of intact proteins is called the top-down approach. However, there are many challenges to identify intact proteins at the current stage, including difficulties in LC separation of high molecular weight proteins and low efficiency in protein fragmentation during MS/MS analysis. In addition, high mass accuracy should be obtained for high confident protein identification, which is usually achievable using high-resolution mass spectrometers such as FTICR-MS. Currently the approach is mainly for the analysis of single proteins or simple protein mixtures (Garcia *et al*., 2007; Ouvry-Patat *et al*., 2008), and only a limited number of applications have been reported using online HPLC separation coupled with MS for the analysis of a few tens or hundreds of intact proteins (Chi *et al*., 2007; Bunger *et al*., 2008).

Alternatively, identification of a protein can be relied on the identification of peptides that are unique to the protein. The procedure is called a bottom-up approach, in which peptides are identified using MS from the enzymatic digest of a protein. For well-separated proteins such as a single isolated protein or the protein spots from 2D-PAGE, digestion of the protein or 2D spots using an enzyme (e.g., trypsin) results in a mixture of peptides that can be analyzed by MS (mostly by MALDI-TOF owing to its high speed and mass accuracy) to acquire a spectrum of masses (m/z) of the peptides, referred to as a "peptide map" or a "peptide fingerprint" (Berndt, Hobohm and Langen, 1999). This ensemble of experimental peptide masses is then compared to theoretical peptide maps derived from a protein database to identify the correct protein (Fenyo, 2000). When a complex protein mixture or a proteome sample is analyzed, peptide fingerprinting may not provide a clear identification and a more detailed analysis needs to be performed. In these instances, the sequence of a peptide is identified by MS/MS in which individual peptide ions are isolated and fragmented by CID within the mass spectrometer (Hunt *et al*., 1986). During CID, the fragmentation occurs primarily on the peptide bonds and this process can be controlled so one does not obliterate the analyzed peptide into its constituent amino acids. Therefore, the resulting spectrum contains various lengths of peptide fragments (i.e., *b*- and *y*-series of fragment ions) so that partial or even complete primary sequence information is retained (Figure 2). The ensemble of these fragment ions (or product ions) together with the mass of the intact peptide can be compared with the theoretical MS/MS mass spectra calculated from the protein sequences in the database using software programs to identify the peptide sequence (Eng, McCormack and Yates, 1994). This MS/MS approach is the most popular for the identification of proteins from complex peptide mixtures. To avoid the use of MS/MS and increase the throughput of protein identification, Smith *et al*. (2000) developed the approach named Accurate Mass Tags (Conrads *et al*., 2000), lately called Accurate Mass and Time Tags (AMT) (Strittmatter *et al*., 2003) for peptide identification solely based on the peptide mass or in conjunction with LC retention time. An AMT database must be developed and validated by MS/MS data prior to its direct use for protein identification. Accurate mass measurement of peptides ($\sim$1 ppm or less) is critical for correct identification of peptides if the AMT database is established solely based on peptide masses and thus the successful application of this approach is limited to a few laboratories. When LC retention time constraint is applied, the mass measurement accuracy could be modest.

For tandem MS of peptides and proteins, CID is efficient for the majority of peptides generated by enzymatic digestion; however, the technique is not efficient for intact proteins and some modified peptides such as phosphopeptides. Recently, electron capture dissociation (ECD) (Axelsson *et al*., 1999) and electron transfer dissociation (ETD) (Syka *et al*., 2004) have been developed to achieve efficient peptide backbone fragmentation for large peptides and even proteins. Large peptides/proteins are usually multiply charged during ESI, which is favorable to ECD or ETD and thus the techniques have great potential for the analysis of intact proteins (Bunger *et al*., 2008; Ge *et al*., 2009). In contrast to CID, both ECD and ETD generate *c*- and *z*-types of peptide fragment ions, and the fragmentation process does not result in evident loss of phosphate groups from phosphopeptides (Stensballe *et al*., 2000). example of ETD MS/MS spectrum of a peptide is shown in Figure 3. Currently, ECD has been implemented on FTICR-MS (Axelsson *et al*., 1999) while ETD has been on ion trap MS (Syka *et al*., 2004) and the hybrid ion trap-Orbitrap MS (McAlister *et al*., 2007). The utility of ETD in phosphoproteome studies has been demonstrated from Hunt's lab that reported 1252 phosphosites on 629 proteins identified in a single experiment from enriched phosphopeptides within 30 μg of total yeast protein (Chi *et al*., 2007). As mentioned earlier, good performance of ETD or ECD fragmentation is limited to the peptides with high charge states (e.g., ≥+3) (Swaney, McAlister and Coon, 2008). The protein digestion methods that generate relatively large peptides are preferred, for example, the use of Lys-C, Lys-N, and Glu-C proteinases or microwave D-cleavage digestion (Taouatas *et al*., 2008; Hauser *et al*., 2008). To increase the charges of tryptic peptides during ESI, m-nitrobenzyl alcohol (m-NBA) has been added to HPLC mobile phase (Kjeldsen *et al*., 2007). Alternatively, for enhanced identification of tryptic peptides, a data-dependent decision tree algorithm (Swaney, McAlister and Coon, 2008) can be employed in real-time acquisition of CID and ETD spectra in a single analysis, in which the type of data is dependent on the precursor charge state and *m/z*. The approach greatly increases peptide identifications for proteome samples. Other fragmentation techniques such as sustained off-resonance irradiation (SORI) fragmentation and infrared multiphoton dissociation (IRMPD) may be used to provide complement or better fragmentation for certain applications (Bogdanov and Smith, 2005; Siuti and Kelleher, 2007).

5 SOLUTION-BASED QUANTITATIVE PROTEOMICS TECHNOLOGIES

Solution-based proteomic analysis has increased popularity in recent years to circumvent the use and overcome some shortages of gel-based proteomics. In solution-based approaches, proteome samples (e.g., cell lysate) may or may not be fractionated using gel-free separation techniques such as HPLC. The total lysate or fractionated proteins are enzymatically digested, and the resulting peptide mixtures are subjected to further fractionation using liquid separation techniques and/or analyzed by online LC-MS-MS/MS (Figure 4). The above approach is named multidimensional protein identification technology (MudPIT) (Washburn, Wolters and Yates, 2001) and is generally for qualitative analysis or characterization of complex proteomes. However, it is amenable to quantitative comparison of protein abundance changes across different samples. For quantitative proteome analysis, all the compared proteome samples are processed and analyzed by MS in parallel, and the acquired LC-MS-MS/MS data are used to identify the peptides and proteins within each sample. Then the peptide ion chromatographic peaks are aligned and intensities are normalized. The abundance of each identified peptide/protein is compared across analyzed samples so that differentially expressed proteins can be identified. Since there is no stable isotope labeling involved in the above procedure, this quantitative proteome analysis method is called a label-free approach (Wiener *et al*., 2004). However, sample preparation and instrument analysis should be rigorously controlled for this approach to minimize any variations produced during sample preparation and LC-MS/MS analysis of individual samples. Label-free quantitative proteomic analysis has been increasingly applied to the identification of potential biomarkers from many diseased tissues or biofluids (Ong and Mann, 2005; Wang *et al*., 2008).

It is also convenient to incorporate stable isotope labeling into the solution-based proteomic procedure to achieve relative protein quantitation for the proteome samples to be compared (Figure 4). The labeling can be conducted prior to or after protein extraction (i.e., pre-extraction or post-extraction). As implied in the name, the pre-extraction method mainly refers to metabolic labeling, which is usually performed during cell culturing using either $^{14}N/^{15}N$ enriched media (Conrads *et al*., 2001) or stable isotope-coded amino acids (Chen, Smith and Bradbury, 2000; Veenstra *et al*., 2000; Ong *et al*., 2002). For some isotope-coded elements (e.g., deuterium), the labeled peptides are not co-eluted with the natural peptide counterparts from the reversed-phase LC column, which potentially introduces quantitation errors. Therefore, nitrogen and carbon elements are recommended since light and heavy versions of the labeled peptides are basically co-eluted. A representative example of metabolic labeling for quantitative proteomics is the method named stable isotope labeling by amino acids in cell culture (SILAC) (Ong *et al*., 2002). In this technique, cells are cultured either in the

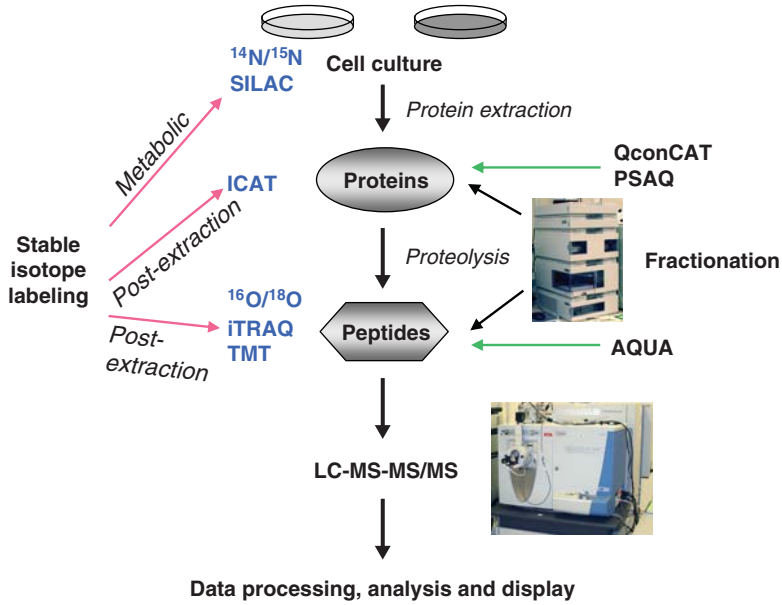

Figure 4. Solution-based proteomic approaches for relative and absolute protein quantitation. In the label-free quantitative proteomic approach, each proteome sample is prepared and enzymatically digested separately, and the resulting peptides are analyzed using LC-MS-MS/MS. Pre-fractionation using liquid separation techniques such as HPLC can be incorporated at the protein and peptide levels to increase the proteome coverage. Alternatively, stable isotope labeling can be performed at different stages of sample preparation (left) to achieve relative protein quantitation. For absolute quantification, isotope-coded peptide or protein standards (AQUA, QconCAT, or PSAQ) can be spiked into the peptide or protein samples with known quantities (right). The abundance of the peptide being analyzed is then compared with that of the isotope-coded standard. AQUA, absolute quantification; ICAT, isotope-coded affinity tag; iTRAQ, isobaric tag for relative and absolute quantitation; PSAQ, protein standard absolute quantification; QconCAT, absolute quantification using concatenated signature peptides; TMT, tandem mass tag.

normal media or in the media containing heavy isotope-coded amino acids such as ^{13}C-labeled lysine and arginine, which are then incorporated into proteins during protein synthesis and cell proliferation. A schematic approach of quantitative proteome analysis using SILAC and multi-dimensional separation is shown in Figure 5. The advantage of metabolic labeling is that the compared samples can be pooled early to avoid variations in downstream preparation of multiple samples. Recently, SILAC was successfully performed to label whole animals (e.g., mice) with $^{13}C_6$-lysine, and complete protein labeling was demonstrated for all the organs tested (Kruger *et al.*, 2008). The SILAC-mice provide a powerful tool for biological and medical research, allowing protein levels to be measured from whole organs all the way down to sub-cellular organelles and individual proteins. When metabolic labeling is not applicable, stable isotopic labeling can be performed after protein is extracted. Examples of most notable post-extraction isotope labeling include isotope-coded affinity tags (ICAT) (Gygi *et al.*, 1999; Yu *et al.*, 2004) and some isotope-coded amine-reactive reagents such as the isobaric multiplexing tagging reagents for relative and absolute protein quantitation (iTRAQ) (Ross *et al.*, 2004) and Tandem Mass Tags (TMT) (Thompson *et al.*, 2003). While ICAT is mainly for pair-wise comparison of proteomes, iTRAQ and TMT can be used to label multiple samples. ICAT is specifically designed to label Cys residues and the labeled Cys-containing peptides (after digestion) can be isolated via biotin-avidin affinity (Gygi *et al.*, 1999). Since only Cys-containing peptides are analyzed by LC-MS/MS, the complexity of the sample from ICAT labeling is significantly decreased and thus the potential to identify low abundance proteins is increased. In the above post-extraction labeling approaches, the labeling is completed via chemical reactions. However, stable isotopes can also be incorporated during enzymatic digestion of proteome samples. For example, trypsin-catalyzed $^{16}O/^{18}O$ exchange is such a type of labeling in which two oxygen atoms of the C-terminal carboxylate

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

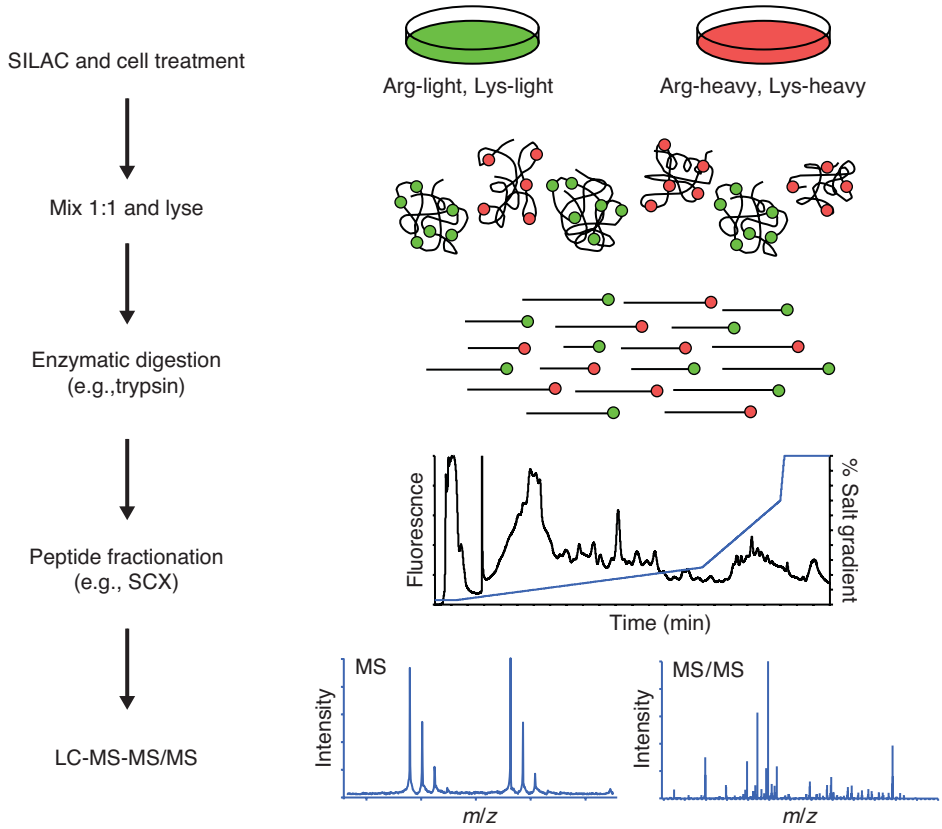

Figure 5. Quantitative proteome analysis using stable isotope labeling by amino acids in cell culture (SILAC), multi-dimensional LC separation, and mass spectrometry (MS). Two populations of cells are cultured in normal and stable isotope-coded arginine and lysine amino acids (Arg-light and Lys-light versus Arg-heavy and Lys-heavy). One population of cells is then stimulated and the other serves as a control. Cells are then mixed 1:1, lysed, and digested with trypsin. The resulting peptides are then fractionated by HPLC such as strong cation exchange (SCX). Each fraction is analyzed by reversed-phase liquid chromatography coupled on-line with tandem mass spectrometry (LC-MS-MS/MS). The MS scans are used to reconstruct the chromatographic peaks of the pair of labeled peptides, and relative quantitation is performed by comparing the peak areas of the peptides.

group of each peptide are replaced by ^{18}O atoms offered by ^{18}O-water via trypsin-catalyzed oxygen exchange mechanism (Schnolzer, Jedrzejewski and Lehmann, 1996; Yao *et al*., 2001). The enzyme-catalyzed $^{16}O/^{18}O$ labeling can be combined with ICAT to improve protein coverage of quantitation (Blonder *et al*., 2006).

Strategies have also been developed to absolutely quantify protein abundances and associated changes in proteome samples. Gygi's lab developed the absolute quantification (AQUA) method (Gerber *et al*., 2003) in which the stable-isotope labeled (heavy) peptides were synthesized and spiked in known quantities into the proteome sample to be analyzed. By comparing the peptides derived from the proteome sample with the "heavy" peptides (i.e., internal standards), the quantities of measured peptides can be calculated. To mix the isotope-coded molecules with proteome samples as early as possible and for more accurate quantitation, stable isotope labeled artificial proteins of concatenated signature peptides were synthesized (i.e., QconCAT) recently, which allowed the standards to be spiked into samples before trypsin digestion (Beynon *et al*., 2005). To further improve the quantitation, isotope-labeled full-length protein standards called Protein Standard Absolute Quantification (PSAQ) were *in vitro* synthesized and introduced into proteome samples (Brun *et al*., 2007). The advantage of this method is that the isotope-coded protein standards can be spiked at the earliest time and processed in the same way

(e.g., pre-fractionation) as the analyzed sample to a maximum degree so that absolute quantitation can be performed robustly. For each quantitative approach, it should be noted that high-resolution mass spectrometers (e.g., FTICR-MS and Orbitrap-MS) are expected to achieve better quantitation and higher confidence of protein identification. The power of these types of instrument could be demonstrated particularly when intact protein biomarkers are analyzed in conjunction with isotope-labeled standards and efficient fragmentation techniques.

6 TOXICITY BIOMARKER DISCOVERY

Tissue and organ toxicity as a result of exposure to environmental toxicants or drug treatment remains a major public health issue. For example, many incidences of organ toxicity in liver, kidney, heart, brain, and so on, have been reported to be associated with chemotherapeutic agents. Cardiotoxicity (manifestations of heart failure, ischemia, hypotension, hypertension, edema, bradycardia, etc.) (Yeh, 2006) is one adverse event that can be caused by a wide range of non-targeted anticancer therapeutic agents (Floyd *et al*., 2005). It has been reported that doxorubicin, the most commonly used anthracycline anticancer drug, exerts a dose-limiting cardiotoxicity that effects up to 49% of patients treated for lymphoma (Hershman *et al*., 2008). Although better therapeutic efficacy and less organ toxicity have been expected for the new generation of targeted anticancer therapies (Shawver, Slamon and Ullrich, 2002), recent clinical practice and investigations suggest that these types of "magic bullets", including trastuzumab, imatinib, and sunitinib, often induce adverse effects on the heart in a small population of patients (Sengupta *et al*., 2008; Kerkela *et al*., 2006; Chu *et al*., 2007).

To prevent the development of adverse events and complications of disease management, it is critical to detect toxicity at the earliest stage. Early toxicity detection relies on the biomarkers that are indicative of the development of toxicity, and these detection tools should be very sensitive and specific. For cardiotoxicity, the most practical monitoring tool currently in clinical use is serial assessment of left ventricular function with echocardiography or radionuclide ventriculography (Sengupta *et al*., 2008). However, echocardiography has been found to be associated with limitations such as poor reproducibility and high variability (Telli *et al*., 2007). Protein biomarkers could be invaluable tools in early detection of disease, toxicity and organ injury. Quantitative proteomic technologies can be used to discover potential toxicity biomarkers and these technologies have been employed for many years to identify disease biomarkers (Anderson, 2005). Proteomic biomarker discovery has focused on biofluids such as human serum and plasma that can be collected by relatively non-invasive means. However, there is a wide range of protein abundance (10–11 orders of magnitude) within sera or plasma (Rifai, Gillette and Carr, 2006) yet one can expect that many important biomarkers, particularly at early stages of disease or toxicity, would enter the blood stream at very low levels. Therefore, it has been challenging to identify biomarkers from blood. Nonetheless, investigators have focused on blood as the biomarker source since it represents a collection from all organs and cell types, and can be collected in large volumes and in a relatively non-invasive manner (compared to sampling tissue, for example). Urine represents another type of body fluid for biomarker research. It is easily collectable and has shown utility particularly for biomarkers of nephrotoxicity and injury. Since proteins altered in neurotoxicity and neurological diseases may not enter the blood stream or urine, the focus has been on the cerebrospinal fluid (CSF). More recently, efforts have been made to identify biomarkers using solid tissues and interstitial fluids as starting materials since these types of samples may theoretically contain biomarkers with higher abundance. Once biomarker candidates are identified, a more focused approach for body fluids can be made. Another drawback in the search for biomarkers of toxicity is the relatively low throughput of the current proteomic platforms. This needs to be increased since time- and dose-dependent toxicology studies usually generate hundreds or even thousands of samples.

7 BIOMARKER VALIDATION AND QUALIFICATION

Biomarkers must be qualified by regulatory agencies (e.g., US Food and Drug Administration) prior to routine clinical application specified in labels for drugs approved by the FDA. Biomarker candidates have to be biologically qualified and the analytical test has to be validated. Clinical qualification can be quite challenging since it usually requires

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat212
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

prospective studies and large numbers of clinical samples (Rifai, Gillette and Carr, 2006) that are independent from those used at the biomarker discovery stage. Baseline variations of measured biomarkers as a result of different ages, lifestyles, nutrition, sex, and so on, should be determined. Other challenges include proper patient recruitment for prospective studies, simultaneous measurement of multiple biomarkers, high stringency in biomarker measurement, high specificity and sensitivity, and so on.

For routine use of such biomarkers, assays must be available and validated. The assay should provide robust, specific, accurate, and precise analytical measurements along with adequate dynamic range. This kind of analytical validation should be closely associated with the specific biomarkers measured and include many aspects of the validation process, including sample handling, instrument analysis and data processing. For a specific protein biomarker, antibody-based assays such as enzyme-linked immunosorbent assay (ELISA) might be readily developed. However, in most cases it is likely that multiple biomarkers need to be assessed and thus there is an urgent need for multiplex assays that are capable of measuring tens or even hundreds of biomarkers in a single assay. It would be a great challenge to multiplex antibody-based assays since not all antibodies are available for the discovered biomarker candidates and development of a number of antibodies is a time-consuming and expensive process. Emerging proteomic technologies, for example, MS-based multiple reaction monitoring (MRM) (Anderson and Hunter, 2006), are being developed toward realization of these platforms as valid tools for protein biomarker validation and disease diagnosis as well as toxicity detection.

Selected reaction monitoring (SRM) or MRM (when multiple product ions are monitored) has great potential as an MS-based tool for protein biomarker validation and qualification owing to its high selectivity, sensitivity, dynamic range, and throughput. These features allow high-throughput measurement of biomarkers and absolute quantification can be performed potentially when standards are incorporated. In the biomarker discovery stage, the current proteomic workflow and throughput permit only 10–20 samples to be analyzed per experiment as discussed by Carr *et al.*, but thousands of proteins can be quantitated (Rifai, Gillette and Carr, 2006). In the validation and qualification stages, however, hundreds or even thousands of samples but a small number of proteins (e.g., 1–10) should be analyzed (Rifai, Gillette and Carr, 2006). Therefore, the MRM approach potentially is the method of choice for protein biomarker validation and qualification. MRM is usually performed in a triple quadrupole MS, in which the first quadrupole (Q1) is used as a filter to select a peptide (i.e., biomarker) with a predefined specific *m/z* value. The selected peptide ions are then transmitted to the second quadrupole (Q2) for CID to generate fragment ions. Ions of one or more specific fragments are filtered in the third quadrupole (Q3) and then detected (Figure 6). The process to detect a single peptide with one fragment ion transition only takes several milliseconds. Therefore, hundreds and even thousands of biomarkers can be quantified in a single analysis using the state-of-the-art MS. It should be noted that development of a specific MRM assay is a time-consuming process. MRM was able to directly quantify plasma proteins at high hundreds of ng ml^{-1} range with in-run coefficients of variation (CVs) of 2–22% and a dynamic range of 4.5 orders of magnitude (Anderson and Hunter, 2006). When stable isotope dilution (SID) or immunoaffinity enrichment such as Stable Isotope Standards and Capture by Anti-Peptide Antibodies (SISCAPA) is applied, the limits of detection (LODs) and limits of quantification (LOQs) have been achieved to the low ng ml^{-1} range in plasma (Keshishian *et al.*, 2007; Anderson *et al.*, 2004). With continual improvements in MS detection, the LODs are expected to be at pg ml^{-1} levels. A recent study showed that the interlaboratory CVs of MRM for plasma proteins ranged from 4–14% for the samples prepared on one site and the CVs increased to 10–50% for the samples prepared in each individual lab (Addona *et al.*, 2009). That the large number of biomarkers can be quantified by MRM along with its high sensitivity potentially makes this technique the major tool for candidate biomarker verification although the performance of the current technology is not as stringent as that currently required and approved in assays by US Food and Drug Administration (Addona *et al.*, 2009).

8 PROTEOMIC ANALYSIS OF TOXICITY MECHANISMS

Although the initiating event leading to organ damage may differ between drugs, environmental

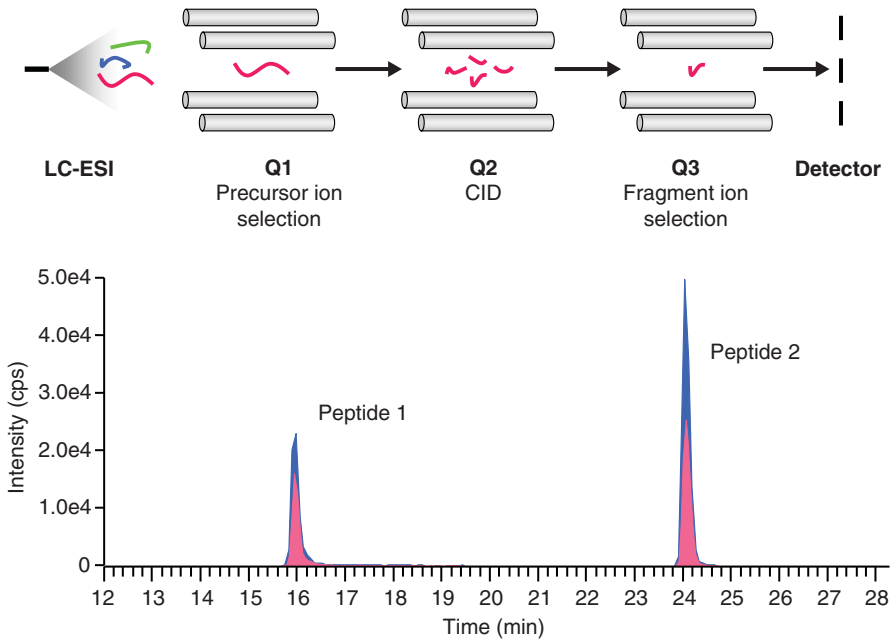

Figure 6. Schematic diagram of multiple reaction monitoring (MRM) for targeted analysis of peptides on a triple quadrupole mass spectrometer. In selected reaction monitoring (SRM) or MRM, the first quadrupole (Q1) is used as a filter to select a peptide with a predefined specific *m/z* value. The selected peptide ions are then transmitted to the second quadrupole (Q2) where they are fragmented by CID. Ions of one or more specific fragments are filtered in the third quadrupole (Q3) and then detected (upper panel). The lower panel is stable isotope dilution-multiple reaction monitoring (SID-MRM) quantitative assays of two targeted peptides. Shown are the extracted ion chromatograms (XIC) peaks of MRM Q1/Q3 ion pairs for natural (blue) and heavy (red) isotope-coded peptides.

toxicants and diseases, cells and organs have limited ways to respond to insults and thus there may be similarities downstream of the initiating event. Elucidation of toxicity mechanisms can provide essential information for better disease prevention, diagnosis and treatment. The unique capabilities of proteomic technologies are able to provide valuable information to unravel the cellular events related to the toxicity mediated by: (i) on-target effects of drugs interacting with tissues other than the selected organ; (ii) off-target effects. As an example of the former, some chemotherapeutic agents target tyrosine kinases that are ubiquitous and present on tissues such as the heart leading to unwanted cardiotoxicity (Force, Krause and Van Etten, 2007). In contrast, acetaminophen (discussed below) induces toxicity in the liver through off-target effects. Phenotypically similar organ toxicity could be caused by different compounds with diverse initiating mechanisms. Therefore, systematic analysis of toxicity at the molecular level using quantitative proteomic approaches could reveal toxicity mechanisms and biomarkers unique for a particular compound as well as those shared by multiple compounds. Both can be valuable depending on the question being asked.

Proteomic approaches have been applied to a variety of systems for the understanding of toxicity mechanisms. Main areas of mechanistic studies using proteomics include quantitative protein profiling of drug- or environmental toxicant-induced organ toxicity, toxicity pathway mapping, assessment of chemical/metabolite-induced protein modifications, and measurement of oxidative responses (Fountoulakis *et al.*, 2000; Ruepp *et al.*, 2002; Dowling and Sheehan, 2006; Andringa *et al.*, 2008; Moon *et al.*, 2008). For example, proteomic studies have provided some insights on the hepatotoxicity caused by overdose of acetaminophen, *N*-acetyl-*p*-aminophenol (APAP). A 2D-PAGE-based proteomic analysis of liver from an APAP-induced mouse hepatotoxicity study revealed altered expression of about 35 proteins and many of these are known targets for covalent modification by *N*-acetyl-*p*-benzoquinoneimine (NAPQI), a metabolite of APAP (Fountoulakis *et al.*, 2000).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat212
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Proteomic analyses of mitochondrial proteins of the liver exposed to APAP indicated that the abundance of chaperone proteins (Hsp10 and Hsp60), ATP synthase subunits, and beta-oxidation pathway proteins was decreased (Ruepp *et al*., 2002), and the protein thiol content of catalase (a key enzyme in hydrogen peroxide metabolism) was modified (Andringa *et al*., 2008). These studies suggest that quantitative proteome analyses of protein expression changes, protein modifications, and specific subcellular contents would provide novel insights into the mechanisms of drug-induced toxicity.

Since many environmental toxicants and therapeutic drugs induce oxidative responses of biological systems, proteomic investigation of protein oxidation is another approach for a mechanistic study of toxicity. Acute exposure of MDMA (3,4-methylenedioxymethamphetamine, ecstasy), as a result of abuse, causes damage to many organs including the liver and brain. A proteomic study was designed to specifically enrich and identify oxidatively modified mitochondrial proteins for the mechanistic understanding of rat liver damage caused by MDMA (Moon *et al*., 2008). Exposure of MDMA resulted in a great inhibition of the activities of mitochondrial aldehyde dehydrogenase, 3-ketoacyl-CoA thiolases, and ATP synthase. In addition, a significant increase of protein oxidation was observed for the proteins involved in energy supply, fat metabolism, antioxidant defense, and chaperone activities (Moon *et al*., 2008). The above data suggest that oxidative inactivation of a class of mitochondrial enzymes likely contributes to MDMA-induced mitochondrial dysfunction and subsequent liver damage. In contrast, oxidation of a single protein at specific sites may contribute to oxidative stress-mediated cell death. A proteomic study of oxidative stress caused by the oxidant taurine chloramine (TnCl) resulted in the identification of more than 20 oxidized proteins (Klamt *et al*., 2009). Further study revealed that oxidation of cofilin (an actin-regulatory protein) causes it to lose its affinity for actin and to translocate to the mitochondria, where it induces swelling and cytochrome c release. Oxidation of cofilin by TnCl results in the formation of intramolecular disulphide bonds and Met sulphoxide, but only Cys oxidation causes cofilin to induce mitochondrial damage. Oxidant-induced apoptosis is independent of Bax activation and requires both oxidation of cofilin Cys residues and dephosphorylation at Ser3 within the protein (Klamt *et al*., 2009). The above studies demonstrate that proteomics is a powerful tool to elucidate the mechanisms of chemical compound- or drug-induced cell and tissue damage.

9 CONCLUSIONS

System biological approaches to understanding toxicity require proteomic methods and many quantitative proteomic technologies are currently available to meet these needs to some extent. These technologies can be classified into two basic approaches: gel-based and solution-based approaches. Mass spectrometry is the core technology for both approaches, providing the capabilities of protein identification and quantitation. Global proteome quantitation using either stable isotope labeling or label-free approaches enables not only the discovery of toxicity biomarkers but also the understanding of toxicity mechanisms. Targeted proteomic approaches such as MRM could play important roles in biomarker validation and quantitative analysis of targeted proteins and pathways. Stable isotope labeled peptide/protein standards are novel tools for both relative and absolute protein quantification. Analytical and clinical validation of biomarkers is essential to qualify biomarkers for clinical application. With further development of novel proteomic tools and an increase in sample throughput, the full spectrum of mass spectrometry-based proteomic research will greatly advance systems toxicology and an understanding of the mechanisms of cellular injury.

1 INTRODUCTION

Proteins are the major targets in cells or tissues for toxicant exposure, and play central roles in a system view of toxicological processes because they are ultimately the functional molecules for many cellular processes. To understand the toxic mechanisms and/or modes of action, we need to understand the toxic process at proteome level (proteomics), and to integrate the disparate proteomic and toxicology data. The linking of conventional toxicological research with functional proteomics has resulted in the emergence of toxicoproteomics. This systematic proteomic approach to investigating toxic processes and mechanisms could give information on integrated responses of tissues to toxic stress over time, on variability between exposed groups, and may provide data necessary for building predictive computational models. Proteomics is a high throughput approach that permits the simultaneous analysis of thousands of proteins. It can often detect molecular changes before the appearance of visible morphological changes and thus reduce toxicity testing time. For clinical toxicology, it is feasible that biomarkers may be detected for use as early indicators of later disease. Therefore, proteomics is an essential component of systems toxicology. The challenge will be to differentiate between specific and unspecific changes in the proteome, and to decide on the relevancy of such changes for further toxicological research. The major objectives of toxicoproteomics include elucidation of the molecular mechanisms of toxicity and xenobiotic interactions with biological systems, and identification of protein targets for application as signatures or biomarkers of a specific toxicity for chemical toxicity testing, diagnosis and monitoring of disease onset and progression, drug development, and human health risk assessment.

Proteomics was originally defined as the high throughput separation, display and identification of proteins (Anderson and Anderson, 1998; Balckstock and Weir, 1999). Traditional proteomics mainly focuses on protein expression levels in cells and/or tissues, which consistently change in response to the exposure of toxicants. Protein expression profiling of cells (Jin *et al*., 2004), tissues (Witzmann *et al*., 1999), and body fluids (Son *et al*., 2003) exposed or treated with toxicants for identification of toxic mechanisms, toxicity pathways, drug targets, toxicity and disease biomarkers, is probably the most popular application of proteomics to toxicological research. It provides a powerful means for defining relative protein levels, a molecular signature for any physiological, pathological, or toxicological process, as well as

for disease development. Chowdhury and Aposhian (2008) identified 75 and 52 differentially expressed proteins in the livers and urinary bladders, respectively, of hamsters exposed to sodium arsenite in drinking water. In a study of protein expression profiles of human neuroblastoma (NB) cell line SH-SY54 using two dimensional gel electrophoresis (2-DE) and mass spectrometry (MS), GRP75 protein, a potential brain cancer biomarker, was found to be dramatically unregulated in the NB cells (Hsu, 2008). In a proteomic analysis of human prostate cancer cells exposed to benzo[a]pyrene (BaP) using 2-DE and MS, 26 differentially expressed proteins were identified (Chaudhary, Pechan and Willett, 2007). Among those proteins, some proteins such as acid leucine-rich nuclear phosphoprotein and cyclophilin A were previously reported to be changed at protein expression levels in other cancers. Proteomics-based immunochemical analysis of snake venom toxicity and immunoresponse provides valuable information for the selection and design of *in vitro* assessment of preclinical efficacy of antivenom, development of antivenom drugs, and treatment of snakebite injury (Gutiérrez, 2009).

As proteomics studies progress, the goals of proteomics are not only to identify proteins and analyze protein expression levels in mixtures, but also to derive more information on functional status of proteins from the samples that are analyzed. Modern proteomics can address the functional status of proteins, for instance through protein posttranslational modifications (PTMs), protein-protein interactions, protein intracellular location, and the rates of protein synthesis and degradation. Proteomics becomes a comprehensive study of proteins and their biological functions within a given biosystem. Generally, proteins are converted to their mature form through a complicated process of PTMs (Khidekel *et al*., 2004). Many of the PTMs are regulatory and reversible, and control biological functions in cells (Khidekel *et al*., 2004; Ptacek, 2005). For instance, phosphorylation can confer enzymatic binding or signaling transduction activities (Ptacek, 2005). Phosphorylation on serine, threonine and tyrosine residues is extremely important modulator of protein functions (Nagao and Yanagida, 2002). Altered phosphorylation of the proteins such as myosin light chain 1 has been reported in the failing heart (Abdelaziz *et al.*, 2005). The detailed phosphorylation status of six isomers of stathmin was characterized in hepatocellular carcinoma (HCC) (Muller *et al*., 1999). In addition to protein expression and PTMs, studies of protein interactions comprise another major application of proteomics to toxicology, which is becoming increasingly important. The tandem affinity purification (TAP) method (Bouveret *et al*., 2000) combined with LC/MS has helped improve the examination of protein complexes, which provides critical insight into protein function within biological processes (Rout *et al*., 2000).

In summary, applications of proteomics to toxicology mainly focus on relating changes at protein expression levels, PTMs, and protein interactions in cells or tissues after exposure to toxicants, with adverse health outcomes. The ability of proteomics to efficiently identify protein expression, PTMs, and protein interactions yields in-depth information on protein structure and function, which, in turn, provide valuable information for the understanding of toxic processes, pathways and mechanisms. Implementation of proteomics into toxicology has recently been catalyzed by the report of the US. National Research Council (NRC) on Toxicity Testing in the twenty-first century (National Research Council, 2007), which outlined the promise that new technologies, including proteomics, could dramatically increase the efficiency and accuracy in evaluating both chemical toxicity and adverse human health outcomes. Substantial efforts have been made towards the development of alternative methods for safety studies that do not require using laboratory animals. In the EU, timelines for phasing out many standard tests using laboratory animals were established in amendments to the cosmetics directive. Also, the new European Chemicals Legislation (REACH) favors alternative methods to conventional *in vivo* testing, if validated and appropriate. In the fields of safety and risk assessment it is expected that the development and validation of *in silico* methods, testing batteries, and tiered testing systems will be needed to overcome limitations in available resources and limited knowledge of the biological processes involved in complex biological endpoints (Lilienblum *et al*., 2008). To accomplish these goals, innovative toxicoproteomic strategies and high throughput experimental systems for low-cost and efficient identification of toxicity pathways and biomarkers, and for chemical toxicity testing need to be established. The huge amount of proteomic data and specific toxicological endpoints need to be integrated for an effective and comprehensive understanding of modes of action and

mechanisms of chemical induced toxic responses and disease processes.

2 PROTEOMICS TECHNOLOGIES

The specific technologies that have been used for toxicoproteomic investigations are numerous and include 2-DE and MS (2DE-MS), multi-dimensional protein identification technology (MudPIT), and MS stable isotopic labeling such as Isotope-Coded Affinity Tags (ICAT) methodology, retentive chromatography-mass spectrometry (RC-MS) such as Surface-enhanced laser desorption/ionization (SELDI), and protein arrays (Figure 1). These technologies used for toxicology investigations could be generally combined into three main technology platforms: 2-DE gel-based, mass spectrometry (MS)-based, and non-gel/non-MS-based proteomic methods. In the following discussion of key proteomic technologies methodologies, we do not attempt to be exhaustive. Rather, we focus on their most important features and the recent applications of these proteomic platforms to toxicology research.

2.1 2-DE Gel-Based Proteomics

2.1.1 Protein Expression Profiling Using 2-DE

In 2-DE gel electrophoresis, proteins are separated first on the basis of isoelectric point, and then in a second dimension on the basis of molecular mass (Bischoff and Luider, 2004; Hanash, 2003; Gygi *et al*., 2000). 2-DE is the most powerful technique for protein separation. Thousands of proteins can be efficiently resolved on a single 2-DE gel. For each protein, the isoelectric point, molecular weight (MW), and the related quantities can be easily determined. The information content of the 2-DE gel data is high. 2-DE is also the most powerful technique for protein visualization and quantitation. Separated proteins and their modified forms can be visualized after gel staining by silver (Gharahdaghi *et al*., 1999), fluorescent dyes such as Sypro Ruby (Lopez *et al*., 2000; Berggren *et al*. 2000) and Coomassie Blue (Westermeier, 2006). Differences between samples can be compared and relative quantities can be determined by directly measuring the ratios of protein spot intensities in independent gels (Lilley, Razzag and Dupree, 2002). The software for protein quantification of 2-DE gel images is sophisticated and reliable after years of extensive development. Other advantages of 2-DE gel electrophoresis include easy gel storage and protein identification. In a recent study from our laboratory, proteins spots in 2-DE gels stained by Sypro Ruby and stored for two years could still be clearly visualized and accurately identified by MS. 2-DE has been the workhorse in the application of proteomics to toxicology especially in differential display analysis to find proteins that are differentially expressed between control and chemical-exposed samples. Figure 2 shows a typical 2-DE gel-based proteomic workflow for toxicological research. In this

workflow, 2-DE provides a powerful means for protein separation and MS for obtaining peptide mass fingerprints or sequences for protein resolved on 2-DE gels. The development of mass spectrometry for the sensitive identification of gel-separated proteins in late 1980s, coupled with large-scale expressed sequence tag databases and computational methods for the correlation of the results of mass spectrometric analysis with the content of sequence databases, has greatly facilitated global protein analysis. With this platform, differentially expressed protein can be efficiently detected by 2-DE and identified by MS. If the proteins are shown to change consistently in samples treated with or exposed to toxicants, they may be associated with a toxic process. A comprehensive profiling of changes in protein expression of soluble proteins in livers from mice treated with the mouse liver tumorigen propiconazole to uncover the pathways and networks altered by this fungicide has been performed recently using 2-DE and MS (Ortiz *et al*., 2010). This study has revealed a series of alterations in livers induced by propiconazole: nuclear receptor activation, metabolism of xenobiotics, metabolism of biochemical intermediates, biosynthesis of biochemical intermediates, and oxidative stress in mouse liver, and provides novel insights into toxic mechanisms and/or modes of action of propiconazole. The information generated is valuable and necessary as well for human health risk assessment of this environmental chemical. Using 2-DE and MS, 682 distinct proteins in 90 lung adenocarcinoma specimens were identified. A 20-protein profile was shown to be able to predict survival among stage 1 lung cancer patients (Azad *et al*., 2006). 2-DE and MS also aid in analysis of small pathological samples obtained by minimally invasive biopsy (MacKeigan *et al*., 2003). Although only a small portion of the proteome in cells or tissues has been analyzed in these studies, pronounced changes in its composition that are associated with toxic mechanisms and toxicity pathways have been found.

2.1.2 Protein PTM Profiling Using 2-DE

2-DE gel analysis provides a unique opportunity for identifying PTMs and isomeric forms of proteins. PTMs can be readily localized in 2-DE gels because they appear as distinct horizontal or vertical clusters of protein spots. Below, we will briefly discuss 2-DE gel-based proteomic approaches for analysis of protein phosphorylation, oxidation, and glycosylation, which may be the three most important functional attributes for the studies of chemical-induced toxicity. Significant progress has been made in the analysis of protein phosphorylation during the past several years (Wolf-Yadlin *et al*., 2007). Advanced techniques have been developed to isolate, purify, and enrich phosphorylated proteins or peptides (Schulenberg, Beechem and Patton, 2003; Schulenberg *et al*., 2004). Selective phosphoprotein staining with fluorescence dyes following 2-DE gel electrophoresis is commonly used to identify the potentially phosphorylated protein targets (Schulenberg, Beechem and Patton, 2003; Schulenburg *et al*., 2004; Kinoshita *et al*., 2006). With this new method, the phosphoproteins could be detected with good sensitivity and visualized with a variety of fluorescent gel image scanners. A combination of Western blotting with 2-DE is another common approach for the detection of phosphorylated proteins. Approximately 100 phosphorylated proteins were detected and 21 phosphorylated proteins were identified by MS from murine fibroblast cells stimulated with tumor necrosis factor-α (Kaufmann, Bailey and Fussenegger, 2001). Several studies on the role of protein oxidation in chemical induced toxicity and disease have been published (Delfino, Sioutas and Malik, 2005). Utilizing a 2-DE gel based proteomic approach combined with Western blotting and cell toxicity assays, an integrated approach for the systematic measurement and identification of protein oxidation in the livers from propiconazole-treated mice was developed (Bruno *et al*., 2009). This study identifies 17 carbonylated proteins and establishes a novel mode of propiconazole-induced toxicity in mouse liver that primarily involves oxidative damage to cellular proteins. Compared to traditional approaches, 2-DE gel-based proteomic approaches give much greater scope for detection and identification of oxidized proteins, and offer greater sensitivity for detecting oxidative changes. Xiao *et al.* (2003) demonstrated that diesel exhaust particles (DEP) induced a hierarchical oxidative stress response in which some proteins may serve as markers for oxidative stress during particulate matter (PM) exposure. In addition to protein phosphorylation and oxidation, the specific functional implications of protein glycosylation have been well studied. Protein glycosylation is one of the most important fields of study on PTMs due to the involvement of such modification in a variety of important biological activities such as carcinogenesis (Alam, Singha and Singh, 2005). More than half of human proteins are glycosylated by N- and O-linked glycans. Glycosylation patterns of proteins vary under different conditions. Heterogeneous glycoforms of the same protein may have different properties or biological activities (Dwek, 1996). The analysis of protein glycosylation is thus of interest in many areas such as diseases (Ohtsubo and Marth, 2006) and environmental toxicology. 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) is the most toxic environmental pollutant and a potent liver carcinogen. In order to understand the toxic mechanisms of TCDD, multiple proteomic approaches were used to identify differential profiles of protein glycosylation and phosphorylation in human Chang liver cells treated with TCDD (Kim, 2008). In this study, the several glycosylations on cathepsin B, HSP60 and two other proteins were found to be increased and identified. The toxic effects of TCDD may require the down regulation of cathepsin B activity, and enhanced glycosylation of cathepsin B may antagonize existing cathepsin B activity. These results suggested the roles of protein glycosylation in regulation of chemical toxicity in a biological system. Using 2-DE and MS, a total of 80 glycoproteins from human hepatocellular carcinoma cell lines were identified (Zhou *et al.*, 2007). The focus of glycoproteomics has recently changed from global glycosylation profiling to characterization of site-specific glycosylation (Kaji *et al*., 2006). In addition to the detection of PTMs individually, a technique capable of detecting phosphorylation, glycosylation, and total protein expression in a single 2-DE gel using three different fluorescent dyes has been reported (Ge *et al*., 2004). This novel platform was applied to the proteomic analysis of pregnancy-induced refractoriness to breast cancer using a rat breast cancer model system. Differential analysis of enriched rat mammary epithelial cell proteins from susceptible and refractory animals resulted in the identification

of multiple proteins with altered phosphorylation, glycosylation, or expression patterns.

2.1.3 Limitations of 2-DE Based Proteomics Approaches

Although 2-DE gel electrophoresis is a powerful tool for discovery-phase toxicology research, not all expressed proteins can be displayed in a single gel. Low-abundance proteins, very large and small proteins, basic and acidic proteins and hydrophobic proteins present their own special challenge for 2-DE gel electrophoresis (Krapfenbauer *et al*., 2001). Regulatory and signaling proteins involved in important toxicity pathways are usually expressed at low levels or are hydrophobic. Efficient display of these proteins in 2-DE gel, to some extent, is the key to the success of a proteomic project. To overcome the limitations of 2-DE gel electrophoresis, a large effort has been made to improve the capabilities of 2-DE gel systems (Elrick *et al*., 2006), protein sample fractionation techniques, and new 2-DE gel based proteomics strategies, such as narrow 2D gel (ZOOM gel) (Tang and Speicher, 2005) and the Difference In Gel Electrophoresis (DIGE) system (Wu, 2006). To enrich low-abundant or specific groups of proteins, protein fractionation prior to 2-DE gel electrophoresis has been widely used (Issaq *et al*., 2002; Meistermann *et al*., 2006; Murayama *et al*., 2001; Guimaraes de Araujo and Huber, 2007; Lenstra and Bloemendal, 1983; Righetti *et al*., 2005). In addition, a proteomic technology platform combining different protein fractionation techniques and gel running systems in order to maximize the capabilities of 2-DE gel systems for protein separation and display has been reported (Ge *et al*., 2004). A combination of different protein fractionation techniques with different protein gel electrophoresis systems has demonstrated a significant capability of 2-DE gels in protein separation including those proteins, which are usually excluded by conventional 2-DE gel systems.

2.2 MS-Based Proteomic Technologies

The ability of mass spectrometry to identify even small amounts of protein from complex mixtures is a primary driving force in current proteomics. This gel-free mass spectrometric analysis of complex protein mixtures with much higher throughput and sensitivity enables a true proteome dynamic and comprehensive capture of cellular responses at any moments. Therefore, it has become an indispensable proteomic method for toxicology research. Electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) are the two techniques that have been widely used for mass spectrometric analysis of proteins or peptides (Bantscheff *et al*., 2007; Yates, Ruse and Nakorchevsky, 2009). MALDI techniques immobilize protein samples in an energy-absorbing matrix in a chip or plate. It is usually coupled to time-of-flight (TOF) analyzers that measure mass of intact peptides, and is widely used to identify proteins by peptide mass mapping. It is well-suited for identification of small proteins, and has many advantages such as simplicity, mass accuracy, high resolution, and sensitivity. Recently, MALDI ion sources have been coupled to quadrupole ion-trap mass spectrometers and two types of TOF instruments for fragmentation of MALDI-generated precursor ions for peptide sequence. ESI is mainly coupled to ion traps and triple quadrupole instruments and used to generate fragment ion spectra, collision-induced (CID) spectra. It provides information about peptide sequence in addition to peptide mass. It is ideal for the analysis of both large and small proteins since it is efficient for obtaining fine structural information from the molecules.

To improve efficiency, accuracy, and quantification capabilities of MS in identification of proteins from complex mixtures, various combinations of protein and peptide separation schemes have been coupled with MS instrument before peptide mixtures are applied for mass spectrometric analysis. The most popular peptide separation approaches are 2D or 3D chromatographic separation of peptide mixtures obtained from tryptic digestions of protein samples. Multidimensional Protein Identification Technology (MudPIT) system is a 2D (strong cation exchange and reversed phase) liquid chromatography (LC) separation method that can be coupled with online MS to produce thousands of tandem mass spectra (Yates, Ruse and Nakorchevsky, 2009). It has been developed as a method to analyze the highly complex samples necessary for large-scale proteome analysis by electrospray ionization, tandem mass spectrometry (MS/MS), and database searching. Bottom-Up approaches are often applied on protein mixtures in comparative proteomics using the MudPIT methodology (Yates, Ruse and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat213
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Nakorchevsky, 2009). The term Bottom-Up reflects the reconstruction of the primary structure of the proteins from the little pieces of sequences of the peptides that could either be identified in databases or derived from the analysis of their mass spectra. It usually begins with direct digestion of protein mixtures to complex peptide mixtures, and then peptide analysis by LC-MS. MudPIT/LC-MS was applied to the analysis of potential susceptibility factors in drug-induced liver disease (Welch *et al*., 2005) and effects of chronic morphine exposure on the synaptic plasma-membrane subproteome of rats (Prokai, Zharikova and Stevens, 2005). It can also increase the detection of PTMs especially protein phosphorylation (Zhai *et al*., 2008). Within the bottom-up approach, protein phosphorylation on a highly enriched protein is characterized with the goal of location of a specific phosphate group or detection of a phosphorylation site within complex mixtures.

To add a quantitative dimension to peptide LC-MS/MS experiments, stable-isotope tags are introduced to proteins via metabolic labeling using heavy salts or amino acids or via chemical reactions using isotope-coded affinity tags or similar reagents (Han *et al*., 2001; Tam *et al*., 2004; Whetstone *et al*., 2004). So far, isotope-tags that are specific for sulhydryl groups, amino groups, N-linked carbohydrates, phosphate ester groups, and for active sites of serine and cysteine hydrolases have been developed (Zhang, Yan and Aebersold, 2004). For example, the ICAT reagent usually has a thiol-specific reactive group adjacent to an alkyl linker, which contains either nine [^{12}C] or nine [^{13}C] atoms - thus resulting in a mass difference of 9 daltons between the control versus the corresponding experimental version of the same tryptic peptide (Han *et al*., 2001; Tam *et al*., 2004; Whetstone *et al*., 2004). One advantage of the ICAT approach is that the *in vitro* incorporation of a stable isotope into one of the two samples enables the analysis of control and experimental samples simultaneously. Using ICAT and 2-DE LC-MS/MS, 644 proteins were qualitatively identified and 261 proteins were quantified from miscrodissected hepatocellular carcinoma (HCC) tissues (Li, 2004). Fifty-one out of 560 identified proteins showed a two-fold or greater change in expression in response to salinity stress in yeast (Li, Steen and Gygi, 2003). The major limitation of the isotope tagging approach is that it requires substantial time to analyze a large number of peptides, and therefore it is not suitable for high-throughput proteomic analysis.

Retentate chromatography-MS (RC-MS) is an analytical chemistry technique that combines the physical separation capabilities of LC with the mass analysis capabilities of MS. One of the most popular RC-MS is SELDI. SELDI has been widely applied to diagnosis and classification of disease, most notably for cancer characterization using patient sera (Yang *et al.*, 2005). Only a few microliters of serum are needed for each analysis. Yang *et al.* (2005) explored an application of serum SELDI proteomics patterns to distinguish lung cancer patients from healthy subjects. The correlation between pathological changes within an organ with the proteomic patterns in serum was also reported (Petricon, 2002; Lin *et al.*, 2006). SELDI-TOF MS has been used to identify clusters of proteins differentially present in normal tissue and early stage ovarian cancer, which are able to discriminate between healthy individuals and early stage ovarian cancer patients with specificity of 95% and sensitivity of 100%. Three potential biomarkers to distinguish glioblastomas from oligodendrogliomas were identified by SELDI. Using protein chip SELDI-TOF MS system, a 11.7 kDa ovarian cancer biomarker was detected (Moshkovskii *et al.*, 2005), and a prostate cancer-specific biomarker of amyloid A was found (Le *et al*., 2005). Altered expression of serum proteins in diabetic rats treated with ginsenoside-Re were detected using SELDI-TOF MS (Cho, 2006). This was the first study demonstrating that C-reactive protein could be altered by ginsenoside-Re treatment and that ginsenoside-Re may improve diabetes and its complications through suppression of inflammation.

So far, MS analyses of protein sequences have been successfully used in toxicological research for protein identification, identifying PTMs, and studying protein interactions. As a quantitative method, MS has been used to analyze protein expression and PTM profiles to define protein status and to infer their cellular functions. Pandey *et al.* (2000) isolated newly-phosphotyrosine-modified proteins using an antibody against phosphotyrosine and cells stimulated with epidermal growth factor. Peng, 2003 have used affinity purification to capture the ubiquitinated proteins in yeast cells. More than 1000 ubiquitinated proteins and 100 ubiquitation sites were identified by MS. MS-based proteomics have made and will continue to make a unique contribution to identification and mapping of PTMs in order to address important biological questions.

MS-based proteomics has had a significant impact on the analysis of protein interactions too. To study protein interactions, one protein is often used as an affinity reagent to isolate its binding partners. In yeast, 232 stable complexes were isolated and protein constituents were identified by MALDI MS (Gavin, 2002). This study provides valuable information on phosphatases, kinases, and other protein interaction networks and signaling pathways. MS has also been extensively used to analyze PTMs especially to determine the type and site of a modification on single and purified proteins. Olsen *et al.* (2006) have detected 6600 phosphorylaton sites and 2244 proteins in epidermal growth factor stimulated Hela cancer cells for the study of phosphorylation dynamics and mapping of entire signaling cascades. Large-scale MS analysis of other large complexes and organelle such as nucleolus has been reported (Lam, Trinkle-Mulcahy and Lamond, 2005). More than 400 nucleolar proteins have been identified by MS. Compared with the *in vitro* techniques such as two-hybrid system and protein array, MS-based methods are able to detect protein interactions *in vivo*. All these studies on identification and mapping of signaling cascades provide a solid molecular basis for further analysis of toxic processes and mechanisms of these organelles or biosystems.

2.3 Non-gel/non-MS-Based Proteomic Technologies

Protein array analysis is a promising way to assess protein interactions systematically, and represents a promising new and complementary proteomic tool to 2-DE and mass spectrometry-based approaches (MacBeath and Schreiber, 2000). In this approach, individually purified proteins are separately attached to a surface and then analyzed for their activities. It provides a multiplexed approach for identifying protein-protein interactions, protein substrates, transcription factor protein-activation, as well as identifying the targets of biologically active small molecules (Arenkov and Kukhtin, 2000; Haab, 2005). The most popular protein-based chips are the antibody arrays that directly separate proteins from each other by antibody binding to specific protein targets. Using the protein microarray, it has been possible to demonstrate significant differences in the serum protein profiles of lung cancer patients when compared with healthy individuals and patients with chronic obstructive pulmonary disease (Gao, 2005). Sera from disease-free individuals and pancreatic cancer patients were successfully classified, and patients and normal control subjects were successfully discriminated using a novel protein array (Honda, 2005). In a study to evaluate the potential of proteomics as a tool for ecological biomarker discovery using protein arrays and SELDI TOF, mussels were exposed to environmentally relevant concentrations of oil, alkylphoenols, and polycyclic aromatic hydrocarbons (PAHs). The results indicated that protein expression profiles could be used to distinguish control from exposed organisms, types of exposure, and degree of exposure (Bjornstad *et al.*, 2006). Various protein-array formats allow rapid and high throughput investigation of protein activity and interaction on a proteomic scale. Liu, Patricelli and Cravatt (1999) created probes that specifically target serine hydrolases. These probes contain a fluorophosphonate-reactive group, which binds to most members of the serine hydrolase superfamily. In addition to protein arrays, peptides can also be analyzed using peptide microarrays (Volkmer, 2009).

3 APPLICATIONS OF PROTEOMIC TECHNOLOGIES TO TOXICOLOGY

Proteomics has recently been used in the studies of mechanistic toxicology, clinical toxicology, pharmacoproteomics, safety assessments of chemicals, and environmental toxicology. A general summary of the major applications of proteomics to toxicology is shown in Figure 3.

3.1 Mechanistic Toxicology

Alterations in the proteome may provide a highly sensitive means of detecting toxicity responses because toxicants or chemicals frequently alter the profile of proteins in the sample by inducing changes in the expression levels of specific proteins or by altering protein structure via modulation of posttranslational modifications. Protein profiling itself provides little information about the underlying mechanisms of toxic response. However, once the differentially expressed or modified proteins or pathways are identified, biological function can be

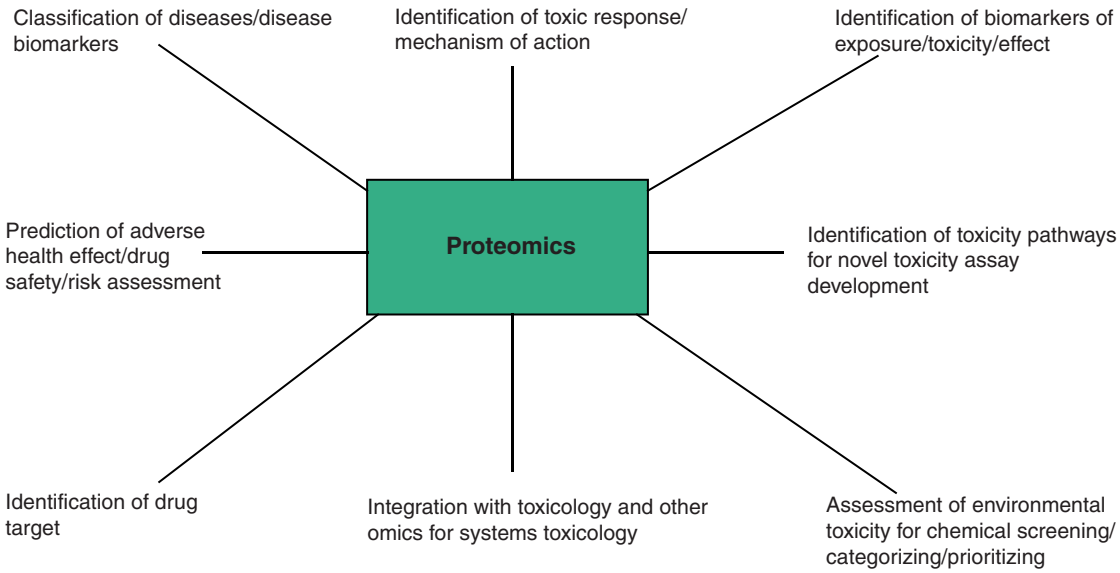

Figure 3. A summary of the applications of proteomics to toxicology.

inferred by mapping components to known biological pathways and verified in follow-up functionality studies. Therefore, the altered protein profile provides a sensitive indicator of toxicant exposure, disease state, and altered cellular metabolism for characterization of adaptive changes of cells and organisms to toxic stressors. Because of this, molecular characterization of the proteome using proteomics represents a powerful tool for developing a complete understanding of toxic events and processes starting with the interaction of a toxicant with a cell, through physiological and tissue/organ changes, resulting in disease development.

In the clinical application of proteomics to toxicology, it was found that shorter survival times of patients with B-cell chronic lymphocytic leukemia may be associated with the altered expression of some redox enzymes, heat shock protein 27, and protein disulphide isomerases, which may confer resistance to cytotoxic drugs to the cancer cells (Alaiya, Al-Mohanna and Linder, 2005). A study on proteome response to ochratoxin A (OTA), a naturally occurring mycotoxin, suggested that coordinated regulation of molecular networks is involved in the OT-induced cytotoxicity, and that proteome response can be an indicator of neurodegeneration (Yoon *et al.*, 2009). A total of 488 proteins associated with Alzheimer's disease were identified. These proteins included well-known components of plaques such as amyloid beta, alpha1-antichymotrypsin, and apolipoprotein E. Protein expression profiling of arsenic-treated human cells and animal tissues has revealed a mechanism of cellular stress response in which several heat shock protein family members including Hsp60, 70, and 90 are up-regulated (Lau, He and Chiu, 2004; Welsh and Gaestel, 1998). All of these studies suggest that proteomics methods can provide valuable information on toxic mechanisms and pathways that are essential parts of mechanistic toxicology.

Proteomics is a powerful tool for whole proteome profiling to identify substance specific alterations in protein expression patterns after *in vivo* treatment. In combination with other toxicology tools and OMICS including transcriptomics and metabolomics, it is a promising approach for generating toxicity signatures, which are needed to foster predictive toxicology. The potential of such novel toxicology is to predict adverse health effects after short-term exposure of laboratory animals. It will lead to a reduction in the duration of screening studies and reduction in the number of required animals per dose group (Hengstler *et al.*, 2006). Carcinogenic potential is conventionally measured using a two-year study, incurring notable expense in both animal and human resources (Perera *et al.*, 1991). It is therefore of great interest to identify biomarkers of carcinogenicity that can be detected

in short term. Proteomic profiling of liver samples after one day of exposure to the carcinogen N-nitrosomorpholine (NNM) revealed significant up-regulation of proteins involved in response to cellular stress induced by NNM (Fella *et al*., 2005). Several interesting cancer-related proteins or biomarkers were identified by proteomic analysis of animal tissues with 18 weeks of exposure to the carcinogen. An investigation on the identification of new proteomics biomarker signatures predicting hepatic carcinoma/adenoma, as well as hepatotoxicity has also been reported (Fella *et al*., 2005).

3.2 Clinical Toxicology and Disease Related Research

Most diseases are manifested through changes in protein levels or functions, and existing drug therapies typically aim to interfere with the activity of a specific protein. Proteomics has advanced disease research. The emphasis of the application of proteomics to clinical toxicology is in understanding disease pathways and mechanisms, identifying protein targets or biomarkers for detection, progression, and therapy of diseases. They have also facilitated the differentiation of normal from diseased states correctly by characterizing protein expression profile, PTMs and signaling pathways altered in diseased cells or tissues. As toxicoproteomics progresses, more emphasis will be placed on its capability to identify diagnostic biomarkers of the presence and staging of diseases, as illustrated in ovarian cancer (Petricoin and Liotta, 2002), lung cancer (Tang *et al*., 2006) and rheumatoid arthritis (de Seny, 2005).

The detection of protein profiles associated with disease states dates back to the very early application of 2-DE gel electrophoresis to analysis of clinical materials (Tyers and Mann, 2003). The robust and high throughput MS has recently revolutionized protein based diagnosis (Rodland, 2004). Protein arrays have been extensively used for clinical research (Witte and Nock, 2004). These proteomics technologies have allowed scientists to simplify the study of diseases by using different tissues and cell populations, blood, and other biofluids. It has recently been reported that only the phosphorylated form of stathmin is highly correlated with leukemia, illustrating the power of proteomics in understanding disease mechanisms (Sowell *et al*., 2009). An extensive 2-DE-based proteomic analysis of 21 HCC patients identified 60 proteins that demonstrated significant changes in the expression level between nontumorous and tumorous tissue (Kim, 2003). Recently, proteomics methods for analysis of small amounts of diseased tissues have been developed. Laser capture microdissection (LCM) is an ideal technology for extracting disease cells from specimens in which the exact morphologies of both captured cells and surrounding tissues are preserved (Emmert-Buck *et al*., 1998). LCM preserves the molecular composition and architecture of the cells so that direct comparison of the protein profiles can be made in a micro compartment of the same sample. To date, LCM in combination with 2-DE is one of the most widely used tools for identification of disease biomarkers (Roy and Shukla, 2008). A combination of LCM and SELDI to analyze prostate cancers, a protein present in 94% of prostate cancers was identified (Roy and Shukla, 2008). Proteomics was used to define tumor subsets among resected lung specimens to distinguish between primary adenocarcinomas and primary squamous cell carcinomas with 98% accuracy (Conrad *et al*., 2007). To increase pancreatic cancer survival rates, clinicians are actively seeking an assay capable of classifying samples as normal or carcinogenic when cancer is at its early stage. Using LC-MS/MS and ELISA microarrays for the identification of breast cancer biomarkers, 64 altered proteins were identified from nipple aspirate fluid (Woodbury, Varnum and Zangar, 2002), and 15 of the identified proteins had been reported to be potential markers for breast cancer. Another interesting area in clinical toxicology is quantitative proteomic analysis of host-pathogen interactions. It has been reported that two state-of-art quantitative proteomics approaches, metabolic labeling SILAC and chemical isobaric tagging iTRAQ were used to study changes on macrophage protein expression in response to exposure to M. tuberculosis lipids. 166 macrophage differentially expressed proteins involved in immune response, oxidation, and reduction as well as in other cellular processes were identified (Shui *et al*., 2009).

3.3 Pharmacoproteomics

It is well-known that most drug targets are proteins. The application of proteomics within

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat213
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

the pharmaceutical industry has been defined as pharmacoproteomics. The major proteomics applications in the drug industry are drug target identification and validation, identification of biomarkers of drug efficacy and safety from readily accessible biological fluids, and investigation of toxic mechanisms/modes of action of drugs. The use of pharmacoproteomics promises to reduce the investment of time and money required for drug development.

3.3.1 Drug Target Identification

The application of proteomics to the pharmaceutical industry has been a powerful tool for candidate selection and detection of new targets for desired effects and should have the same power for preventive strategies in individualized medicine. Target identification involves identifying altered protein expression, posttranslational modification, and activity. There are about 400 known protein drug targets and the number could rise to more than 10 000. Proteomics research holds the key to identifying those thousands of new drug targets since it is a powerful tool for identification of hundreds to thousands of protein expression changes, PTMs, and activities in model systems during disease progression. Using proteomics approaches, four biochemical pathways relevant to Type 2 Diabetes Mellitus (T2DM) were identified, including up regulation of protein biosynthesis, down regulation of insulin secretion, energy use, and metabolism (Lu *et al*., 2009). Proteomics analysis of whole cell homogenates, cytosolic, and myofilament subfractions of ischemic/reperfused rabbit hearts elucidated abundance changes in multiple proteins involved in stress response and energy metabolism in mitochondria (Jäger, Jungblut and Müller-Werdan, 2002). In 2-DE and mass spectrometric analysis of platelet-dense granules from abdominal aortas of aneurysm patients, 40 proteins involved in several important cardiovascular disease pathways and some atherosclerosis-associated proteins were identified (Hernández-Ruiz, 2007). Using the 2-DE proteomics platform to analyze atherosclerotic carotid arteries, the effect of atorvastation on secretome from plaques was observed (de la Cuesta *et al*., 2009). 2-DE and MS was used to analyze a rat model of endothelin-induced cardiac hypertrophy (Macri and Rapundalo, 2001), tyrosine phosphorylation status in a study of lymphocytes with Scott syndrome (Imam-Sghiouar, 2002), and protein glycosylation in pancreatic adenocarcinoma tumor cells (Tarbé *et al*., 2005). Once a protein target has been identified and validated, the expression and purification of the target for crystallization frequently follows. The knowledge of the crystal structure of the protein can provide very important drug binding information for the production of drug targets. Such a structural proteomic approach has been used for the development of drugs for HIV, influenza, and some other infectious diseases (Schmid, 2002). The most rapid impact that toxicoproteomics is likely to make in the near future is through the discovery and validation of biomarkers of disease and disease progression.

3.3.2 Pharmacological Safety

In an early study, a proteomic profile database describing xenobiotic effects on protein expression in rodent liver was built using proteomic techniques (Anderson *et al*., 1996). Using this proteomic database, it was possible to detect, clarify, and characterize a broad range of liver toxicity mechanisms. The use of proteomics gave insights into the molecular mechanisms of the pharmacological action of a hypoglycemic agent (Arce *et al*., 1998). The results strongly suggested the association of the chemical toxic effects with microsomal proliferation and induction of the P450 enzyme system. The proteomic study from Edvardsson *et al*. (1999) confirmed the agonistic mechanisms of action of the peroxisome proliferator activated receptor (PPAR). Proteomic analysis of HK-2 cells exposed to oxalate and calcium oxalate crystals provides novel insights into the molecular mechanisms of renal injury and stone formation (Fu, Xu and Yu, 2005). Proteomics, especially when combined with conventional methods such as histopathology and clinical chemistry, offers the prospect of new insights into toxic mechanisms. Cyclosporin A, an immunosuppressant drug, is toxic to kidney. In a study for clarification of toxic mechanisms of cyclosporin A, a cytosolic calcium-binding protein, calbindin was found to be altered and associated with cyclosporin A-induced renal impairment (Aicher *et al*., 1998). When the monoclonal anti-calbindin antibody was used to perform enzyme-linked immunosorbent assays and immunohistochemistry with renal tissues from rat, dog, monkey, and human, a close correlation between calbindin decrease and nephrotoxicity was

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

confirmed. In a proteomic analysis of drug candidate toxicity and safety, the safety profiles of all of the 20 compounds were successfully predicted (Gao, 2004). Craig (2006) has used a combination of genomic, proteomic, and metabolomics approaches to study the effects of methapyrilene in male rats. The hepatotoxic mechanisms of this drug at multiple levels in a biosystem were uncovered. In another study, cytokeratins were identified as nonspecific indicators of renal damage in the urine of gentamicin-treated rats (Kennedy, 2002). In a proteomic analysis of fatty liver disease, changes in protein expression associated with steatosis were detected prior to the onset of overt toxicity. The protein changes including upregulation of pyruvate dehydrogenase and phenylalanine hydroxylase were detected only 6 h after the exposure of rats with the steatosis-induced compound (Meneses-Lorente *et al.*, 2006, 2004). In summary, proteomics has been successfully used for the assessment of efficacy and safety of drug compounds.

3.4 Safety Assessment of Chemicals

Decades ago, safety measurements for chemicals were generally to limit exposure and to define the circumstances of use in production and transport. This strategy is valid for working places and is still implemented into modern safety science (Foth and Hayes, 2008a). However, the evaluation and control of dangerous substances is very complex because they are widely distributed in consumer products and impact the environment. Safe handling of industrial chemicals needs information on sensitization potential, organ toxicity after repeated exposure, germ cell mutagenicity, carcinogenesis, reproductive toxicity, behavioural toxicity, and fate in the environment (Foth and Hayes, 2008b).

The challenges to fully characterizing the toxicity of hundreds and thousands of chemicals using conventional toxicity methods have long been recognized. Complete toxicity testing of these chemicals by standard protocols requires the use of multiple mandatory tests that far exceed available resources time, experienced personnel, laboratory capacity and money. The situation can be improved by applying screening technologies to predict the rank order toxicity of a group of chemicals to establish priorities for further testing.

Use of high-throughput methods that allow efficient and economical screening of large numbers of chemicals is in an urgent need. The belief that a specific group or class of chemicals will induce specific protein changes provides a basis for the application of proteomics to predictive toxicology. Such changes or signatures could be used to screen novel compounds. Proteomics permits proteome wide assessment of protein changes associated with chemical exposure and toxicity. Compounds that belong to the same class reveal discernible protein signatures with higher degree if similarity to each other than to the protein signatures corresponding to exposure to compounds from a different class. Several early studies on the changes in the protein expression patterns for chemical toxicity screening have been reported (Anderson *et al.*, 1995; Witzmann, Fultz and Lipscomb, 1995). The effects of perfluoro-n-octanoic acid and perfluoro-n-decanoic acid on the expression of a set of heat shock and glucose-regulated proteins were analyzed. This study demonstrated that 2-DE electrophoresis stress protein patterns could be used for future toxicological screening. It has been reported that the stress response to perfluorocarboxylic acids is tissue-, toxicant-, and stress protein class-specific and dose-related, and the 2-DE stress protein pattern is suitable to future toxicologic screening applications based on the fingerprints of the abundant stress-response proteins (Witzmann, Fultz and Lipscomb, 2005). A proteomic study has recently evaluated the biological responses to multi-walled carbon nanotubes using human monoblastic leukemia cells. This proteomic approach provided a promising new method for safety evaluation of nanomaterial toxicity (Haniu *et al.*, 2010). The identification of responding proteins or protein changes can provide valuable information on toxicity pathways or toxicity signatures, which are important for chemical screening and development of novel chemical toxicity assays. Proteomics has the potential to detect the "fingerprints" of a specific toxic effects and identification of protein expression signatures that predict carcinogenic potentials of chemicals.

3.5 Environmental Toxicology

The major application of proteomics to environmental toxicology is the clarification of toxic modes of action and identification of toxicity pathways

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat213
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

describing key toxic events and processes starting with the interaction of a pollutant with a cell, through physiological and tissue/organ changes, resulting in disease development. In an early study, the effects of jet fuel vapor on protein expression in the rat lungs, kidney, and liver was investigated, and possible risk of the fuel vapor exposure to human health was suggested (Drake *et al*., 2003). In order to investigate the multiple effects of PAH on protein expression, proteomics analysis of MCF-7 cells treated with benzo[a]pyrene and dibenzo[a]pyrene and standard extracts from coal tar and diesel exhaust were performed. The similarities and differences in the acute response to individual PAH were compared. Interestingly, each PAH generated unique patterns of alterations in protein expression (Hooven and Baird, 2008). Recently, an overview and illustrative study to assess the effects of endocrine disrupting chemicals (EDC) in fishes has been reported (Ankley *et al*., 2009). In the study, a systematic approach including genomics and proteomics was used to delineate toxicity pathways for 12 model EDC with different known or unknown toxic modes of action. This study established the basis of toxicity prediction approaches for species, end point, and chemical extrapolation. In addition to these toxicoproteomics studies using animal and human tissues and cells, body fluids including serum and urine have also been used for the study of toxicity of environmental chemicals. An innovative proteomic technique for qualitative and quantitative assessment of urinary protein modulation associated with acute uranium exposure in rats has been reported (Malard *et al*., 2009). Fourteen differentially expressed proteins involved in nephrotoxicity were identified, suggesting the value of urinary proteomics for profiling of uranium toxicity. A combination of genomic, proteomics, and bioinformatics approaches have also been used to study toxic mechanisms of environmental chemicals.

Recently, environmental toxicity biomarker discovery has been a popular area of applications of proteomics to environmental toxicology research. Biomarkers of exposure and toxicity are cellular indicators of the physiological state and changes during a toxic or diseased process at a specified time. By comparing the protein profile of chemically treated cells or tissues to a database containing profiles induced by known toxicants, protein biomarkers of exposure and toxicity may be identified. Using SELDI-TOF-MS, 20 altered plasma proteins (Harezlak *et al*., 2008), and a human beta-defensin-1 (HBD-1) peptide (Hegedus, 2008) were found to be associated with arsenic exposure. These biomarkers have great potential value and predictive accuracy that could be used for exposure and toxicity assessment in humans. A biomarker could also provide information about potential physiological effects and help to determine the nature of the toxicity and toxic injury. In 2-DE gel analyses of metal toxicities, both cytokeratin 8 and cytokeratin 14 were significantly altered in cells exposed to arsenite and cadmium, respectively, suggesting these two proteins might play important roles in metal-mediated apoptotic processes (Gonsebatt *et al*., 2006). The results obtained from several proteomic analyses of 2,3,7,8-tetrachlorodibenzo-p-dioxin toxicity suggest that TCDD affects the liver and immune systems (Bruno, 2002; Lee *et al*., 2005; Pastorelli, 2006). Using SELDI and LC-MS, three inflammation biomarkers, calgranulin A, calgranulin B and anaphylatoxin C3a were identified in bronchoalveolar lavage fluid of rats exposed to diesel exhaust particles (DEP), suggesting that one of the major mechanisms through which DEP cause toxicity is inflammation (Lewis *et al*., 2007). Detection and profiling of small molecular changes on the protein level at early time points could lead to early biomarkers, which could enhance the predictive value of alternative short-term chemical toxicity including carcinogenicity assays. A number of inflammatory response proteins that may be associated with the early phases of inflammation in response to DEP exposure were identified. The results show that histopathology studies at different time points correlate the histopathology changes with protein expression changes.

One of the major challenges in environmental toxicology is to decide whether identified hazardous chemicals will affect human health and the environment. To date, many of the chemical toxicity testing approaches are primarily based on endpoints from animal toxicity studies. Thus, an appropriate toxicity data extrapolation needs to be performed to correct the differences in toxic responses as well as ages, health status and living environment within the exposed group between animals and humans. Another big challenge is to extrapolate dose and species responses of environmental chemical exposure. Toxicity repair, adaptation, and mitigation of a biological system may lead to a robust tolerance

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat213
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

against very low exposure levels of environmental stressors. It is well known that different species react differently from one another, and within a species, sensitive individuals may react differently from the majority of subjects. To extrapolate the data regarding differences in species and doses, a clear understanding of similarities or differences in proteome profiles and toxicity pathways is critical, but this information is sparse.

4 CONCLUSIONS AND FUTURE DIRECTIONS

Toxicity pathways, toxic processes, and mechanisms are enormously complex. Simultaneous measurement of proteomics parameters in a given system under defined toxicity conditions, and integration of the proteomic data with toxicity end points is the trend of current toxicology, a new perspective for molecular toxicology. The combined analysis of multiple data sets may be able to define the links between proteomic data and particular toxic processes or diseases under investigation. Integration of proteomics data with classical toxicology end points and clinical observation allows for more sensitive and earlier detection of adverse health effects, precise identification of toxicity signatures, and development of models for toxicity.

Today, modern toxicology is committed to the 3Rs concept, which was defined first by Russel and Burch in 1959. It states the need to refine, to reduce, and to replace animal testing whenever possible. For this reason, innovative proteomic toxicology focuses on the development and improvement of short- and medium-term toxicity studies. For this, a variety of human cell culture systems instead of animal models will be generated and extensively used for toxicoproteomic research (Oberdorster *et al.*, 2005). The cell culture based test system could help overcome cost and throughput limitations associated with animal testing, thereby, enabling the efficient investigation of toxicity profiles of toxicants. A human cell culture *in vitro* toxicity testing system, combined with a minimum number of *in vivo* animal systems may be the optimal approach for future applications of proteomics to the evaluation of toxicity. Recent analytical developments have made the global and simultaneous assessment of multiple biomolecules such as DNA, RNA, proteins, and metabolites possible. These OMICS approaches will be integrated and the results of this integration are expected to be able to reveal patterns of regulation within and among networks, and provide a systems level description of an organism's responses to any chemical or disease. *In vitro* toxicity testing systems and systems toxicology approaches represent two important trends of current and future toxicological research.

ACKNOWLEDGMENTS

The authors would like to thank Barbara Collins, Witold Winnik, Sheau-Fung Thai, Jeffrey Ross, and Ram Ramabhadran for their very helpful comments on this review paper. Application of Quantitative Proteomic Approaches to Toxicology

T.S. Keshava Prasad[1] **and Raghothama Chaerkady**[2]

[1]*Institute of Bioinformatics, Bangalore, India* and [2] *McKusick-Nathans Institute of Genetic Medicine and Departments of Biological Chemistry, Pathology and Oncology, Johns Hopkins University, Baltimore, MD, USA*

1 INTRODUCTION

The genome provides a static blueprint of the molecular make up of biological systems in organisms. Unlike the genome, however, the protein complement of a cell or organism is very dynamic. Proteins interact with each other and also with other molecules including DNA, RNA and lipids to maintain homeostasis. In addition, proteins undergo post-translational modifications (PTMs), exist as different isoforms, shuttle from one cellular compartment to other and are sometimes expressed in a tissue-specific manner (Prasad *et al*., 2009). Biological systems respond to external stimuli through cell-surface receptors in the extracellular space that ultimately relay information to the transcriptional machinery in the nucleus resulting in modulation of expression of specific sets of genes (Kandasamy *et al*., 2010).

Quantitative proteomic technologies coupled with high-resolution mass spectrometry can be used effectively to unravel key biological roles of proteins by differential profiling and measuring their dynamic changes in expression levels and PTMs (Chaerkady *et al*., 2008; Chaerkady *et al*., 2009; Chaerkady and Pandey, 2008). Especially, phosphorylation and glycosylation status can be monitored using specific affinity enrichment methods (Chaerkady *et al*., 2008; Harsha *et al*., 2008). As proteins are the functional units which are directly involved in biological processes, differential proteomic analyses provide better insights into dynamics of molecular changes specific to disease and normal status. In this study, we review important applications of quantitative proteomic tools in environmental toxicology.

2 QUANTITATIVE PROTEOMIC TECHNOLOGIES TO STUDY ENVIRONMENTAL TOXICITY

Quantitative mass spectrometry of complex proteomic samples using *in vitro* or *in vivo* stable isotope-based labeling has become the method of choice for identification of differentially regulated proteins. Table 1 lists various approaches in common use today for quantitative proteomics along with their salient features. The high reliability of these methods is a consequence of high-resolution mass spectrometers, availability of multiplexed labeling methods and robust multidimensional protein and peptide separation tools (Chaerkady *et al*., 2009; Molina *et al*., 2009). Stable isotope-labeling methods are advantageous because the chemical nature of the peptides and

proteins from different samples of interest remains the same thereby allowing for pre-fractionation of combined samples prior to mass spectrometric analysis. There are several stable isotope-labeling methods available for quantitative proteomic analysis. These include *in vivo* labeling methods, such as stable isotope labeling with amino acids in cell culture (SILAC) (Ong *et al*., 2002; Harsha, Molina and Pandey, 2008) and *in vitro*-labeling methods, such as iTRAQ (Keshamouni *et al*., 2006), ^{18}O labeling (Chaerkady *et al*., 2008), and ICAT (Shiio and Aebersold, 2006).

Table 1. Approaches for quantitative proteomics.

Method	Features
Stable isotope labeling with amino acids in cell culture (SILAC)	Metabolic labeling using heavy amino acids for *in vivo* differential labeling of proteins
Isobaric tags for relative and absolute quantitation (iTRAQ)	Isobaric tags (up to eight different tags) for labeling-free N-terminal amino groups and ε-amino group of lysine residues allows robust labeling of all peptides
Tandem mass tags (TMT)	Isobaric tags (up to six different tags) for labeling free N-terminal amino group and ε-amino group of lysine residues allows robust labeling of all peptides
Acrylamide labeling	Differential labeling of cysteine residues using ^{13}C-labeled acrylamide
Isotope-coded affinity tags (ICAT)	Differential labeling of cysteine residues
^{18}O labeling	Trypsin incorporates two ^{18}O atom at C-terminal carboxyl groups of peptides during digestion of proteins
Label-free quantitation	Normalization of chromatograms and retention times followed by mass spectral counting and/or peak area measurements
Absolute quantitation (AQUA) using multiple reaction monitoring	Targeted quantitation of peptides by analyzing pre-selected peptide ions and calculating abundance based on a corresponding heavy peptide

Stable isotope labeling with amino acids in cell culture (www.silac.org) is a simple metabolic-labeling approach where "light" or "heavy" forms of amino acids (e.g., arginine or lysine) are incorporated into proteins. The heavy form of amino acids contain substituted stable nuclei (e.g., ^{13}C, ^{15}N) and thus cells grown in heavy media behave exactly like the control-cell population grown in the presence of natural amino acids. After several cell divisions, light amino acids are replaced by heavy amino acids. Figure 1 illustrates a SILAC-based strategy for quantitation and identification of proteins from three different samples. The SILAC strategy has become a routine technique in many areas of cell biology (Harsha, Molina and Pandey, 2008). It has been applied to globally characterize the effects of antitumor agents (Harsha *et al*., 2008; Zhang and Neubert, 2009), phosphoproteomes (Hilger *et al*., 2009), and cellular differentiation (Molina *et al*., 2009; Prokhorova *et al*., 2009). It has also been used to study secreted proteins in cell-based systems (Molina *et al*., 2009; Grønborg *et al*., 2006). Several signaling pathways have been dissected using specific enrichment of the phosphoproteome such as in insulin and epidermal growth factor receptor signaling (Kruger *et al*., 2008; Guha *et al*., 2008). Thus, the SILAC approach can be adopted for toxicological studies in global profiling, signaling, and PTM analysis, which can now be used to compare up to five different conditions simultaneously (Molina *et al*., 2009).

Molecular effects of exposure to toxicants can be tested using standard and appropriate cell lines using quantitative proteomics. The secretome of cells can be a good source of potential biomarkers (Chang *et al*., 2009; Srisomsap *et al*., 2010; Zhong *et al*., 2008). Analysis of the secretome provides a good complementary approach to search for potential biomarkers in serum because these low abundant proteins are often masked by high amounts of other proteins in serum. It is advantageous to use a cell line because the secreted proteins can be easily isolated from culture media. In addition, using the SILAC labeling allows differential labeling of secreted proteins from control and treated cells. Secreted biomarkers of pancreatic and esophageal cancers have been investigated using cell lines (Harsha *et al*., 2008; Grønborg *et al*., 2006). This strategy can also be easily adapted to investigate biomarkers in environmental toxicology.

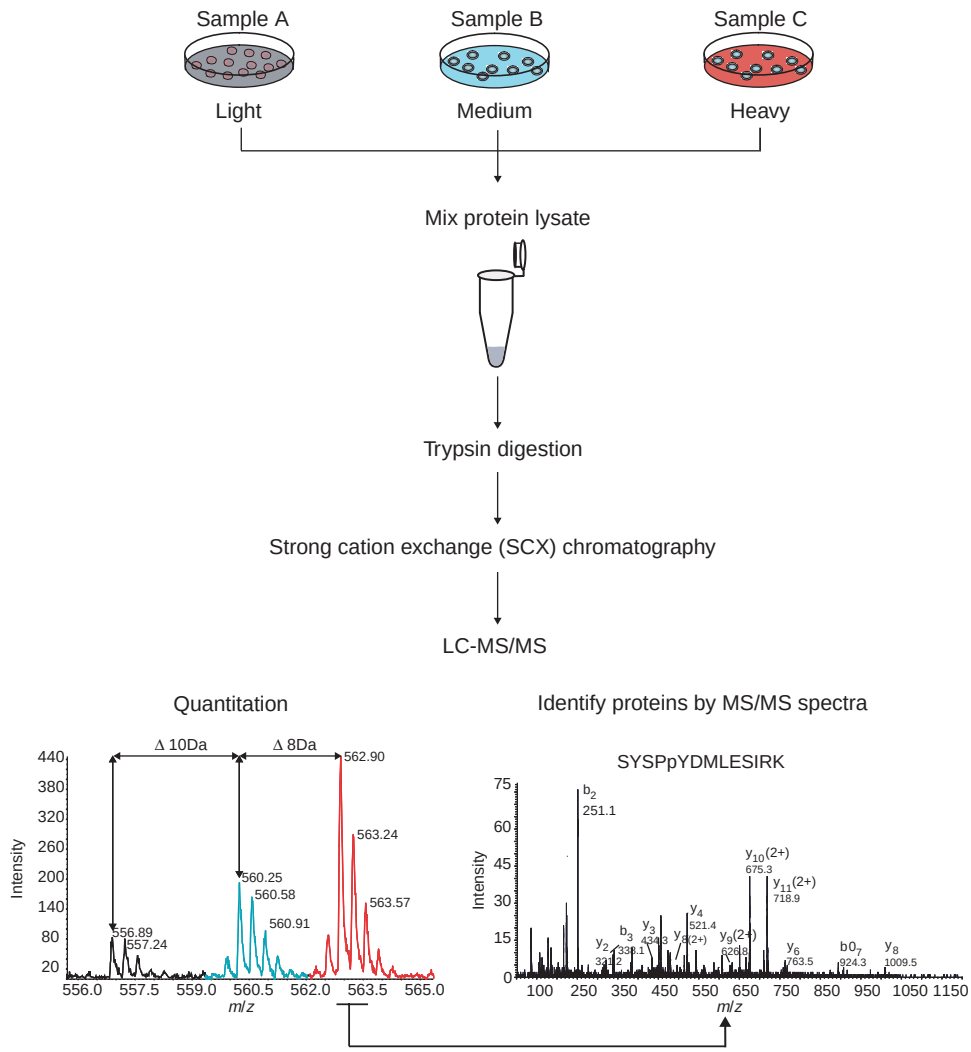

Figure 1. Schematic of SILAC strategy for comparing expression of proteins in three different states. Cells are grown separately in media containing light, medium, or heavy amino acids. Upon completion of labeling, cells are exposed to various conditions and equal amounts of protein lysates are mixed. The samples are then processed at protein and peptide levels before mass spectrometric analysis. Relative intensities (extracted ion chromatograms) of peptide ions provide expression levels of the peptides under different conditions.

There are a number of quantitative proteomic methods available for *in vitro* protein profiling, among them, iTRAQ method has been used most extensively. The iTRAQ reagents are made up of a set of primary amine-specific isobaric reagents that allow the identification and quantitation of proteins. The current iTRAQ method allows simultaneous labeling of up to eight different samples. In an eight-plex method, the isobaric tags consist of reporter ions of 113, 114, 115, 116, 117, 118, 119, and 121 Da. In the iTRAQ method, all peptides with one or more primary amine groups are uniformly labeled increasing the reliability of quantitation. Unlike other labeling methods, in the iTRAQ strategy, the MS signal of a peptide from different samples is summed and hence even peptides of low abundance can be quantitated. This is important because the iTRAQ reporter ions used for quantitation are released only during fragmentation. Figure 2 illustrates a typical scenario of iTRAQ-based quantitation and identification of proteins. Table 2 catalogs several published proteomic

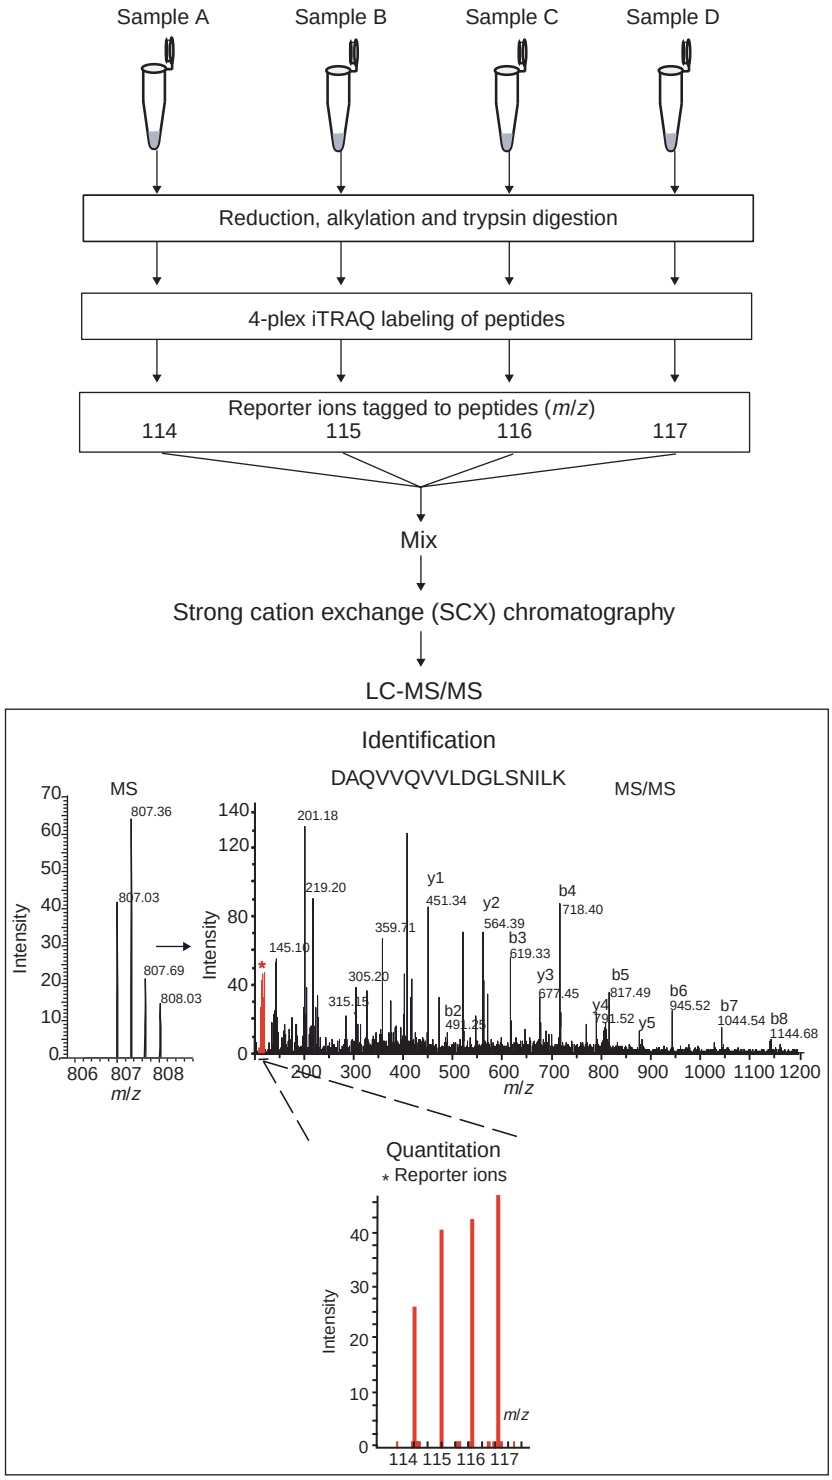

Figure 2. Schematic of iTRAQ strategy for comparing expression levels of proteins in four different states. Peptides are labeled with reagents containing tags that yield specific reporter ions upon CIS fragmentation. Relative intensities of these reporter ions are observed in the low mass region at 114.1, 115.1, 116.1, and 117.1 *m*/*z* values. The relative abundance of any peptide in the four different samples is calculated from the relative intensities of these reporter ions.

studies, where different quantitative proteomic methods have been applied to toxicology.

Because of widespread contamination in food, water, and household items, arsenic toxicity is quite common in some areas of the world. Arsenic accumulation in the body can affect many organs leading to cancer (skin, lung, liver, and bladder), cardiovascular disease, diabetes, and reproductive defects (Banerjee *et al*., 2008; Banerjee *et al*., 2009; De Chaudhuri *et al*., 2008; Ghosh *et al*., 2008; Huang *et al*., 1999). Although the effects of its toxicity have been studied well, no detailed investigation has been carried out to understand the biological process and early markers of exposure at the protein level. We have used a quantitative proteomic approach for identifying specific differentially expressed proteins in HepG2 liver cells in response to arsenic exposure. Protein extraction was performed from HepG2 liver cells grown for 24 and 48 h with or without exposure to arsenic by adding sodium arsenite to the media. After digestion with trypsin, peptides were labeled using four-plex iTRAQ-labeling strategy as illustrated in Figure 2. Labeled peptides were pooled and fractionated using strong cation-exchange chromatography followed by high-resolution tandem mass spectrometry. Mass spectrometry-derived data were searched against a human protein database. Several proteins that were differentially regulated in response to arsenic exposure were identified. These included HSP70-1B, which was elevated ~four fold

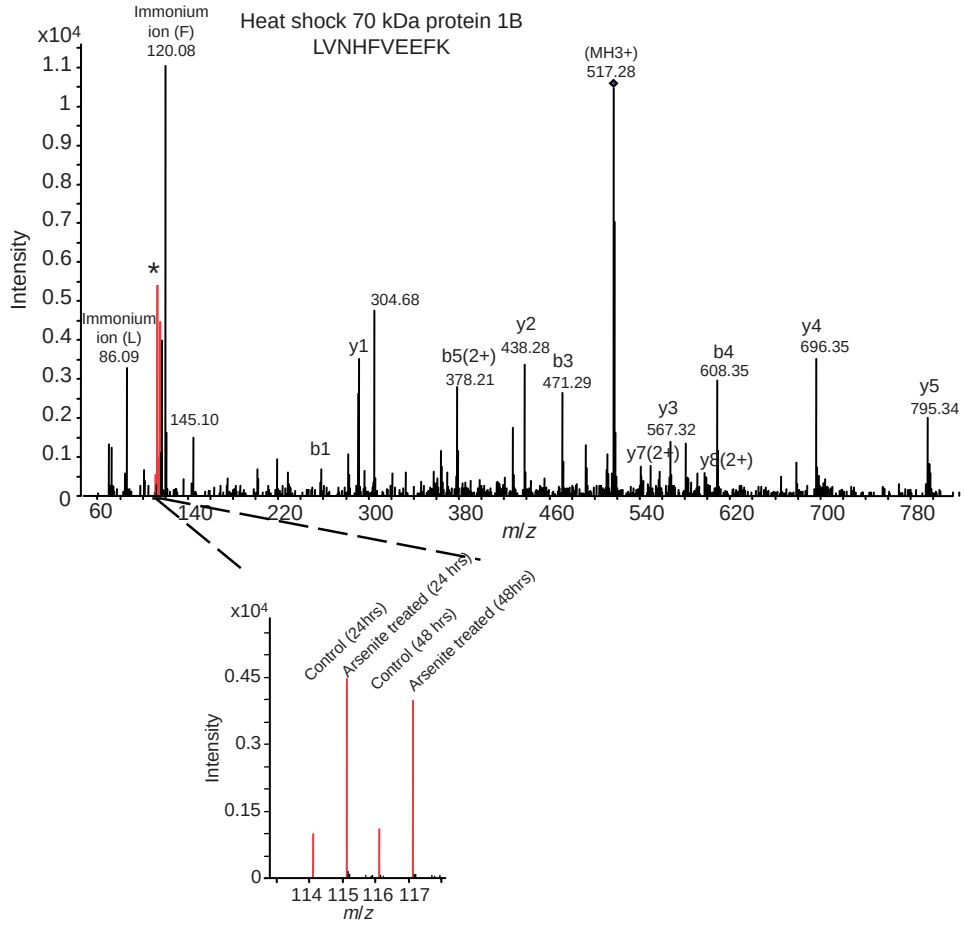

Figure 3. iTRAQ-based quantitation of up-regulation of HSP701B upon arsenic exposure. The figure shows the MS/MS spectrum of a representative iTRAQ-labeled peptide (LVNHFVEEFK) derived from *HSP701B*. A zoomed in view of the relative intensities of the reporter ions from four different conditions (denoted by an asterisk in the MS/MS spectrum) is shown. The peptides from 24 and 48 h untreated controls were labeled using iTRAQ reagents with 114.1 and 116.1 mass tags, respectively, whereas peptides from arsenic-treated samples for 24 and 48 h were labeled with iTRAQ reagents with 115.1 and 117.1 mass tags, respectively.

in arsenic-treated cells. Figure 3 shows the MS/MS spectrum and reporter ion intensities of a representative peptide from the HSP70-1B protein. Similar investigations could be carried out to identify protein signatures from other biological samples, such as serum or urine obtained from arsenic-exposed patients. The candidate biomarkers identified from these studies can be validated using tissue microarrays and/or ELISA in a separate set of patients. Results from such studies will help to elucidate the key molecules involved in response to arsenic toxicity.

3 QUANTITATIVE PROTEOMICS TO IDENTIFY ALTERED LEVELS OF PROTEIN PHOSPHORYLATION

Phosphorylation of proteins can be differentially induced in response to exposure to toxic compounds even though overall expression levels of these proteins remain unchanged. A knowledge of the exact phosphorylation sites that are inducibly regulated can lead to the development of valuable biomarkers or therapeutic targets (Bose *et al.*, 2006). In addition, a set of hyper- and hypophosphorylated

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat214

molecules can indicate activation or repression of specific signaling pathways associated with exposure to toxicants. Identification of such signaling pathways associated with exposure to a particular toxicant can aid in discerning the molecular mechanisms involved in the deleterious effects associated with toxicants (Harsha *et al*., 2008). Enrichment of phosphorylated proteins/peptides is an essential step in the identification of differentially induced phosphorylation events. TiO_2 and anti-phosphopeptide antibody-based methods are commonly used for the enrichment of phosphopeptides. Quantitative proteomic strategies such as iTRAQ or SILAC can be combined with phosphopeptide enrichment methods in order to profile the phosphoproteomes. TiO_2 affinity chromatography approach has been used in many phosphoproteomic studies (Boja *et al*., 2009; Mayya *et al*., 2009; Olsen *et al*., 2010). Phosphopeptides/proteins can be enriched from affected tissues (e.g., skin lesions, tumors) obtained from patients or cells exposed to toxicants. Phosphopeptides isolated from controls can be labeled differently than those from test samples. Once labeled, these phosphopeptides can be pooled and be analyzed by LC-MS/MS and quantitated using dedicated software. Identification of differentially phosphorylated proteins and aberrantly regulated signaling pathways will help in understanding the molecular dynamics associated with the exposure to toxicants.

4 GLYCOPROTEOMIC PROFILING OF SERUM HELPS IN IDENTIFICATION OF GLYCOSYLATED BIOMARKERS

Identifying biomarkers that are detectable in the serum is beneficial as blood is an easily accessible compartment for diagnostics (Chaerkady and Pandey, 2008). Membrane proteins and glycoproteins represent most likely candidates that are shed into the circulation; analysis of these sub-proteomes provides an attractive option for biomarker discovery (Kristiansen *et al*., 2008). However, abundant proteins in serum that include albumin and immunoglobulins, often interfere with the characterization of low-abundant proteins by mass spectrometry. Depletion of abundant proteins can be achieved by using conventional spin column strategies or more advanced multiple antigen removal system columns. The glycoproteome component can be enriched in order to detect the less abundant glycosylated proteins using lectin affinity chromatography (Chaerkady *et al*., 2008; Kristiansen *et al*., 2008). A combination of several different lectins (e.g., concanavalin A, wheat germ agglutinin, and jacalin) is generally preferred for enrichment purposes. Owing to different binding specificities, the use of multiple lectins in the enrichment step can capture a more diverse set of glycoproteins. For identification of *N*-linked glycopeptides, the extracted tryptic peptides can be treated with PNGaseF, which removes *N*-linked glycans. A deamidation reaction occurring during cleavage at the glycan-linked asparagines, converts asparagine to aspartic acid, which increases the mass by 1 Da that is very easily identified by mass spectrometry (Chaerkady *et al*., 2008; Kristiansen *et al*., 2008). Over-expressed proteins and/or glycoproteins in the serum of patients which are specifically associated with exposure to environmental toxicants, such as arsenic or lead, can lead to discovery of biomarkers.

5 DEVELOPMENT OF MASS SPECTROMETRY AS A DIAGNOSTIC AND MONITORING TOOL

Advances in proteomic technologies have ushered in the possibility of using mass spectrometers as diagnostic tools in addition to their established role as a discovery platform. Improved precision of nanoflow liquid chromatography combined with the increased sensitivity of mass spectrometers allow a more comprehensive analysis of biological samples for discovery of biomarkers and inclusion of PTMs in biomarker screening. As explained above, iTRAQ- and SILAC-based differential proteomics methods have been widely employed to discover candidate biomarkers in several human diseases (Chaerkady *et al*., 2008; Harsha *et al*., 2008; Harsha, Molina and Pandey, 2008; Grønborg *et al*., 2006). Immunohistochemistry and ELISA are commonly used methods for validation of candidates identified from discovery screens. However, a major limitation of these techniques as validation platforms is the non-availability of antibodies for newly discovered biomarkers. Multiple reaction monitoring (MRM)

using triple quadrupole mass spectrometers can be a reliable alternative to immunochemical methods for validation purposes (Anderson and Hunter, 2006; Wolf-Yadlin *et al*., 2007). Using triple quadrupole mass spectrometers, specific peptide ions can be selected based on their mass to charge (m/z) ratios, which provides high sensitivity and increased accuracy that is often comparable to antibody-based detection methods. Several peptides can be analyzed simultaneously, which implies that a number of biomarkers can be assessed in a single experiment. The use of proteotypic peptides (experimentally derived peptides which serve as unique identifiers of a given protein or isoform in tandem mass spectrometry experiments) can further increase the sensitivity and specificity of MRM analyses (Gupta *et al*., 2009; Kuster *et al*., 2005; Kuzyk *et al*., 2009; Picotti *et al*., 2010).

6 CONCLUSIONS

Quantitative proteomics using high-resolution mass spectrometry coupled with state-of-the-art stable isotopic-labeling technologies has already proven to be a robust platform for proteomic profiling. Dose–response studies in toxicology can be performed at the proteome level to study responses to diverse toxicants that could provide molecular signatures for diagnosing and monitoring environmental safety hazards or drug toxicities. Apart from being a discovery tool, we anticipate that mass spectrometry will evolve into a reliable and sensitive platform for validation and diagnosis in clinical settings.

1 INTRODUCTION

Over the last decade, the environmental sciences have witnessed an incredible movement towards the utilization of high through-put molecular tools that are capable of detecting simultaneous changes of hundreds and even thousands of molecules and molecular components after exposure of organisms to different environmental stressors. These techniques have received lots of attention because they not only offer the potential to unravel novel mechanisms of physiological and toxic action, but they also are amenable for the discovery of biomarkers of exposure and effects (for some recent reviews see Viant, Rosenblum and Tjeerdema, 2003; Rochfort, 2005; Dowling and Sheehan, 2006;Lin, Viant and Tjeerdema, 2006; Calzolai *et al*., 2007; López, 2007; Nesatyy and Suter, 2007; Nunn and Timperman, 2007; Samuelsson and Larsson, 2008; Tjeerdema, 2008; Viant 2007, 2008). In this chapter we will review the state of knowledge of two of these holistic tools in ecotoxicological research: proteomics and metabolomics. We will follow this review with a presentation of three of our own case studies utilizing proteomic and metabolomic tools for the assessment of effects and mechanisms of toxicity in different animal models exposed to a variety of environmental pollutants. We will end with some final conclusions and research needs.

1.1 Proteomics

Proteomics is defined as the simultaneous analysis and quantification of cellular or extracellular protein abundance. Compared to genomics, proteomics can provide functional mechanistic information since mRNA is a "disposable" message and only a limited amount of it gets translated into proteins. In addition, proteomic techniques can capture changes in the activity of proteins measured as post-translational modifications (see also Mechanistic Investigation of EMD335823s Hepatotoxicity using Multiple Omics Profiling Technologies , Systems Biology: Integrating '-Omics'-Oriented Approaches to Determine Foodborne Microbial Toxins, Application of Quantitative Proteomic Approaches to Toxicology and Application of Proteomics to Study Mechanisms of Toxicity and Dose Response Relationships of Chemical Exposure). One major drawback of using proteomics in ecotoxicological research is that the genome of most organisms used for these studies is largely unknown. This results in the identification of a limited number of proteins. However, *de novo* sequencing is becoming an approachable alternative when working with

organisms that have poorly annotated gene and protein databases. This is achieved by a variety of mass spectrometry (MS)-based techniques such as high-resolution liquid chromatography -MS (LC-MS/MS) as described in more detail below.

The first proteomic studies conducted in ecotoxicology employed the study of protein expression signatures (PES) (e.g., Bradley *et al*., 2002; Shrader *et al*., 2003). Since these studies do not report peptide sequences, they provide little information regarding mechanisms of toxicity and will not be discussed in this chapter. In addition, studies that have used ProteinChip® array technology and have not reported protein identifications are not included in this review (e.g., Knigge, Monsinjon and Andersen, 2004; Bjørnstad *et al*., 2006; Larsen *et al*., 2006). A summary of proteomic studies conducted in tissues or whole organisms collected after exposure to different contaminants under laboratory controlled conditions is summarized in Table 1. Field studies that have utilized proteomics to evaluate responses of free-ranging organisms are summarized under Section 1.3. It can be seen that most studies separate proteins based on their molecular weight and charge using two-dimensional electrophoresis (2-DE). Later staining of gels results in the visualization of up to several hundred gene products. Proteins can also be separated by LC and only a limited number of ecotoxicology studies have used this approach (Table 1). Compared to 2-DE, multi-dimensional LC is more automated, faster, and can produce very accurate data on protein quantification when coupled with isotopic labeling techniques. In addition, very large, very hydrophobic and/or very basic proteins are difficult to separate using gel techniques (López, 2007). Regardless of the technique used for protein separation, identification is conducted using MS.

From Table 1 some findings of interest include: strong gender-specific responses and lack of correspondence between gene and protein responses. Female zebrafish (*Danio rerio*) exposed to flame retardants responded with changes at the protein level that were different to those observed in males (Kling *et al*., 2008). Similarly, Wei *et al*. (2008) reported marked gender differences in protein profiles in rare minnows (*Gobiocypris rarus*) exposed to perfluorooctanoic acid. In terms of the relationship between transcription of mRNA and protein abundance, studies have reported a general lack of correspondence between the two. For instance, Wei *et al*. (2008) reported discrepant results between mRNA and protein levels in rare minnows exposed to perfluorooctanoic acid. Likewise, we found a similar result in largemouth bass (*Micropterus salmoides*) exposed to a variety of different contaminants as discussed under Section 2.1.

1.2 Metabolomics

Animals are known to produce hundreds of metabolites (low molecular-weight compounds, <1 KDa) that are involved in general metabolic reactions or required for the maintenance, growth, and normal function of an organism. Host and environmental factors influence the type and abundance of these metabolites. For instance, several studies have shown a change in metabolite profiles after exposure to specific environmental stressors, such as disease (Moalemiyan *et al*., 2006), temperature (Rosenblum *et al*., 2005), nutritional quality (Nikiforova *et al*., 2005), and as reviewed in this chapter, toxicants. Thanks to recent technological advances, it is now possible to profile the metabolome of an organism, a method also known as "metabolomics". Metabolomics can be defined as the quantitative systematic analysis study of the metabolome, the total quantitative collection of metabolites present in a cell or organism (Fiehn, 2001) (see also Chapters Systems Biology: Integrating '-Omics'-Oriented Approaches to Determine Foodborne Microbial Toxins and Application of Metabonomic Approach in Target Organ Toxicity). The size of the metabolome is unknown, but it has estimated to range from a minimum of 600 (yeast) to hundreds of thousands (plants) of metabolites (Samuelsson and Larsson, 2008).

Metabolomic techniques can simultaneously measure the concentration of hundreds of metabolites from a single individual, which are later interpreted using pattern recognition algorithms that determine differences on metabolite profiles across individuals. A major advantage of this high-throughput approach is that by examining all metabolites present in a biological system, there is no bias associated with the choice of metabolites to be studied. In addition, metabolomics offers several advantages over other "omic" techniques. First, since metabolites are the end-products of gene expression and protein activity and are crucial to cellular regulatory processes, metabolomics provide a closer link to functional physiological processes

compared with transcriptomics and proteomics. This is because changes at the gene and protein level do not always end in phenotypic effects. Another great advantage of metabolomics is that it can be applied to widely diverse species with relatively little time required for re-optimizing protocols for a new species (i.e., it is species-independent). This is because metabolites in primary metabolism are highly conserved, compared to gene sequences which are much more diverse.

A summary of ecotoxicological metabolomic studies published to date are presented in Table 2. This table only summarizes laboratory-controlled experiments. Field studies that have utilized metabolomics to evaluate responses of free-ranging organisms are summarized under Section 1.3. As can be seen from Table 2, the majority of the metabolomic studies have utilized ^{1}H nuclear magnetic resonance (^{1}H NMR) analyses. ^{1}H NMR spectroscopy is considered a broad-based method for detecting metabolites because it detects proton-containing molecules and the majority of known metabolites contain protons (Ong *et al*., 2009). Other advantages of this technique are that results are highly reproducible, it requires minimal sample amount and preparation, and it can be run using samples collected non-destructively (e.g., urine). Despite constant improvement, major limitations of NMR-based metabolomic techniques include its relatively low sensitivity that results in an examination of a limited number of metabolites (Keun, Beckoner and Griffin, 2002; Wang, Bollard and Keun, 2003). Since biological samples are quite complex, the likelihood of characterizing a comprehensive metabolome in a biological system may prove difficult. An alternative approach is the use of LC or gas chromatography (GC) for separation of metabolites and MS for their quantification and identification. Indeed, two-dimensional gas chromatography coupled with time-of-flight mass spectrometry (GCxGC/TOF-MS) has been successfully used to characterize metabolite profiles in complex biological mixtures (Welthagen *et al*., 2005; Mohler *et al*., 2006; Ralston-Hooper *et al*., 2008). Advantages of GCxGC/TOF-MS over ^{1}H NMR include the ability of the former to deconvolute chromatographic peaks for identification as well as accurate quantification (Marriott and Shellie, 2002). Disadvantages of GC/MS are that it only detects volatile metabolites and samples need to be prepared for derivatization. Despite its sensitivity, LC/GC-MS based metabolomics has not been widely utilized to study the impacts of environmental contaminants or stressors on organisms. Since the number of metabolites produced by an organism is quite extensive, one instrument or technique will not be able to detect and identify all metabolites. Thus an approach that capitalizes on the advantages of the different metabolomic tools available will produce a more comprehensive view of the metabolome of cells and organisms.

Based on the studies presented in Table 2, a few interesting metabolomic findings are worth mentioning here. (i) Several studies have demonstrated that metabolomics can be more sensitive than traditional endpoints. For example, Viant *et al*. (2005) showed that when Japanese medaka (*Oryzias latipes*) embryos were exposed to trichloroethylene, NMR metabolomics was close to 20 times more sensitive compared to traditional endpoints (developmental abnormalities, hatching success and mortality). (ii) Very small samples can be collected non-destructively (urine, 10 – 30 μl) for successful metabolomic analysis (Ekman *et al*., 2007). (iii) Metabolomics data have resulted in good correlation with traditional toxicity endpoints. Metabolite changes in Japanese medaka embryos exposed to the herbicide dinoseb correlated to changes in growth, survival, and development (Viant *et al*., 2006). Using earthworms exposed to different types of pollutants, Guo *et al*. (2009) showed that metabolic responses were related to changes in reproduction measured as cocoon production rates. (iv) Visualization of non-overlapping clusters of metabolite profiles along a Principal Component Analysis (PCA) grid has been used to differentiate among different modes of toxic action. For instance, Japanese medaka embryos exposed to dinoseb responded with a dose-response increase in metabolite changes (Viant *et al*., 2005; Viant, Pincetich and Eerderna, 2006a). Furthermore, embryos exposed to the higher dose also showed a shift in metabolite profiles, opposite to control and low dose groups. The authors speculate that this separation is related to differences in modes of toxic action at different doses, and that a higher dose not only perturbs the same or similar biochemical pathways to a greater degree, but rather induces an entirely different metabolic condition (Viant, Pincetich and Eerderna, 2006; Viant *et al*., 2006).

1.3 Proteomic and Metabolomic Field Studies

Proteomics and metabolomics have also been applied for the analysis of animals naturally exposed to environmental pollutants. These field studies are summarized in Table 3. Although the number of studies is quite limited, a main outcome of these studies has been the ability of protein and metabolite profiles to predict site of origin. For instance, NMR metabolomic profiles in earthworms sampled from sites contaminated with different types and levels of metals were good predictors of site (Bundy *et al.*, 2007). More importantly, these authors determined that most of the metabolite differences across sites were due to differences in the concentration of zinc. The same can be said about protein profiles being predictive of the field site of origin (Knigge, Monsinjon and Andersen, 2004). In this latter study, the authors combined sets of protein markers in a tree-building algorithm and were able to correctly classify samples from these sites with an accuracy of 90%. These are examples of how these techniques can prove to have significant impact as diagnostic tools under field conditions.

2 CASE STUDIES

In this section, we will present some examples of proteomic and metabolomic application in ecotoxicological research. We will describe the methods in some detail, but in some cases we have directed the reader to published articles that describe the methods in more detail. The studies presented include: (i) Analysis of proteomic responses in fish exposed to different types of contaminants using GeneGo™; (ii) Comparison of proteomic and metabolomic responses in aquatic invertebrates exposed to herbicides; and (iii) Use of metabolomics to characterize egg quality in fish-eating birds exposed to persistent organic pollutants.

2.1 Analysis of Proteomic Responses in Largemouth Bass Exposed to Pollutants with Differing Modes of Action using GeneGo™

In many cases, genomic and proteomic experiments result in a large amount of data indicating the over-expression or suppression of genes and proteins. Interpretation of this high-throughput data can be very difficult and time consuming if analyzed manually. Many efforts have been put forward to develop data mining software to provide solutions to this problem. GeneGo Inc., a privately owned company founded in 2000, developed MetaBase, the most comprehensive manually curated database available in systems biology. MetaBase compiles all human known information related to protein interactions, networks, signaling pathways, toxicogenomics, and metabolomics. MetaCore is the platform that utilizes MetaBase database to built networks, canonical pathways, and predict toxicity and diseases. MetaCore utilizes sophisticated statistical algorithms to predict which pathways, cellular processes or networks are most likely being affected by the experimental conditions. In addition, thresholds and *p* values can be adjusted to the experiments' need. While GeneGo is based on human proteins/genes for the analyses, experimental data from other organisms can also be used via orthologs. Organisms supported via orthologs include mouse, rat, bovine, chimpanzee, dog, zebrafish, chicken, fruit fly, mosquito, *Arabidopsis*, rice, blast of rice, fission yeast, and baker's yeast. It is GeneGo's goal to expand this list within a few years. Using this type of software for the analysis of genes and proteins derived from fish (in our case largemouth bass) has of course some limitations. For instance, vitellogenin is an egg-yolk precursor protein present in all egg-laying vertebrates including fish, but does not have a human homologue. Nevertheless, we believe that use of this software is still very helpful for elucidating mechanisms of toxicity in non-model species.

2.1.1 Materials and Methods

Exposure Experiments

Seven groups of 12 adult (1 year old) largemouth bass were exposed to one of five chemicals (cadmium chloride [$CdCl_2$], atrazine, phenanthrene, toxaphene, and polychlorinated biphenyl, PCB 126) or one of two control vehicles (water or fish oil) via intraperitoneal injection (1 ml injectate volume) using a 3 ml syringe with a 1.5 inch, 26 gauge needle on the ventral side, anterior of the anal fin. Cadmium chloride and atrazine were dissolved in water, while phenanthrene, toxaphene, and PCB 126

Table 3. Summary of field studies that have utilized proteomics or metabolomic techniques for ecotoxicological research.

Species	Contamination of field sites/location	Age and gender of organisms	Tissue	Method	Major findings	Reference
Proteomics						
Rainbow trout, *Oncorhynchus mykiss*	Sewage discharge/Grabo, Sweeden/	Juveniles, mixed genders	Liver	2-DE-FT-ICR	Total of four proteins changed in expression in relation to animals collected from the reference site.	Albertsson *et al.* (2007)
Blue mussels, *Mytilus edulis*	Organic chlorines, polyaromatic hydrocarbons, heavy metals, dioxins, furans, polychlorinated biphenyls/Gothenburg, Sweeden	Age and genders not reported (~5 cm in size)	Digestive gland	2-DE/LC ESI-MS/MS	Contaminated sites could be distinguished from the reference based on the expression of 13 proteins involved in amino acid metabolism, detoxification, β-oxidation, and protein folding and degradation.	Amelina *et al.* (2007)
Smallmouth bass, *Micropterus dolomieu*	Polychlorinated biphenyls, arsenic, carbon disulfide, mercury, nitrogen, phosphorous, sewage discharge/Shenadoah River, Virginia, USA	Adults (~2.5 y), mixed genders and intersex males	Anterior kidney	2-DE-MALDI-TOF-MS	Protein expression differed among the three sites studied with proteins involved in immune and stress responses being the most important.	Ripley *et al.* (2008)
Goldfish, *Carassius auratus*	Sewage discharge and high temperatures/Gaobeidian Lake, Beijing, China	Adult males	Liver	2-DE-MALDI-TOF-MS	Several proteins related to energy metabolism and oxidative stress were up-regulated in fish from the polluted site.	Wang *et al.* (2008)
Metabolomics						
Earthworms, *Lumbricus rubellus, L. terrestris, Eisenia andrei*	Cadmium, zinc, lead, smelting works UK	Juveniles and adults, hermaphrodites	Whole worms	^{1}H NMR	Earthworms from the most contaminated site had an increased concentration in maltose.	Bundy *et al.* (2004)
Earthworms, *L. rubellus*	Metal-contaminated soils UK	Adults, hermaphrodites	Whole worms	^{1}H NMR	Individual sites could be resolved on the basis of NMR spectral profiles. Zinc was identified as the major metal causing metabolic changes in earthworms.	Bundy *et al.* (2007)

2-DE = Two-dimensional electrophoresis; ESI = Electrospray ionization; FT-ICR = Fourier transform ion cyclotron resonance; LC = Liquid cromatography; MALDI = Matrix-assisted laser desorption; TOF = Time-of-Flight; MS = Mass spectrometry; ^{1}H NMR = ^{1}H Nuclear magnetic resonance spectrometry.

were dissolved in fish oil (Zeigler Brothers, Harleysville, PA, USA). Target body burdens for cadmium chloride, atrazine, phenanthrene, toxaphene, and PCB 126 were 0.00067, 3.0, 50, 100, and 2.5 $\mu g\ g^{-1}$, respectively. These target body burdens were intended to be sufficiently high enough to elicit sublethal physiological responses but not overt toxicity based on a literature review (Eisler and Belisle, 1996; Jarvinen and Ankley, 1999; Shailaja and D'Silva, 2003). Immediately after injection, fish were transferred to aerated, 75.7 l flow-though glass tanks (4 fish per tank) held at 25 °C with a 16:8 hr (light:dark) photoperiod for 96 h. Fish were not fed during this time. After the exposure period, fish were euthanized via emersion in a lethal concentration (500 mg l^{-1}) of MS-222 (tricaine methanesulfonate, Finquel®, Redmond, WA, USA). Livers were removed and immediately frozen in liquid nitrogen. To validate the concentration of the specified toxicants in exposed fish, two whole-body fish samples per treatment and control group were saved and submitted for chemical analyses as described in Sanchez *et al.* (2009).

Proteomic Analyses

Liver tissue from three individuals per treatment and control were prepared for protein separation. Briefly, 0.05 g of liver tissue from each individual was immersed in lysis buffer (16 M urea, 4 M thiourea, 2% CHAPS, 0.8% ampholyte, 65 mM DTT) and mechanically homogenized with a 7 mm × 95 mm saw tooth stainless steel generator probe (Omni International, Marietta, GA, USA). Samples were then placed in a 37 °C water bath for 15 min, sonicated with 10, 1 sec bursts and returned to the water bath. This process was repeated 4 times. Samples were centrifuged at 1600 × g for 10 min to remove any debris. The supernatants were then collected and moved to a clean 1.5 ml Eppendorf tube (Eppendorf AG, Hamburg, Germany). Proteins were precipitated in a 1:1 (v/v) solution of 25% trichloroacetic acid at 4 °C for 4 hr. Precipitated samples were centrifuged and the supernatant removed leaving the protein pellets intact. Protein pellets were washed twice using 200 µl of 100% cold acetone and then centrifuged for 5 min at 16300 × g. The remaining acetone was evaporated using a Sevant SPD 131DDA SpeedVac Concentrator (Thermo Electron Corporation Milford, MA, USA). Dried pellets were then diluted in 400 µl of rehydration buffer (8M urea, 2M thiourea, 4% CHAPS, 65mM DTT, 0.8% ampholytes). A Bradford protein assay (1976) to determine protein concentration and a test of conductivity with a TwinCond meter (Spectrum Technologies, Inc., Plainfield, IL) were conducted.

Nonlinear IPG strips (18 cm, pI 3-10, BioRad Laboratories, Inc., Hercules, CA, USA) were rehydrated with 300 g total protein in 350 µl rehydration buffer (8 M urea, 2 M thiourea, 2% CHAPS, 0.8% ampholyte, 65 mM DTT) overnight and proteins separated in 1st dimension for 24.5 hr using an Investigator Running System (Genomic Solutions, Inc., Ann Arbor, MI) at 20 °C (100,000 Vh with a maximum current of 80 uA per strip). After focusing, strips were equilibrated for 30 min in reducing buffer (0.375 M Tris-HCl solution pH8.8, 6 M Urea, 20% glycerol, 2% SDS containing 2% DTT) followed by re-equilibration for an additional 30 min in a alkylation buffer (0.375 M Tris-HCl solution pH 8.8, 6M Urea, 20% glycerol, 2% SDS, and 2.5% iodoacetamide). Strips were then loaded onto 12% SDS-PAGE and proteins separated in SDS running buffer (25 mM tris, 190 mM glycine, 0.1% SDS) for 16 h or until the tracking dye neared the bottom of the gel (225 mV at constant current). Gels were removed, fixed in acidic solution (50% methanol, 7% acetic acid), stained with Coomassie Brilliant Blue G-250 (Amresco Inc., Solon, OH) for 48 hr, and destained with washing solution (20% methanol, 5% acetic acid) until the gel background was clear (approximately 48 hr). Gels were then scanned into a BioRad GS-800 Densiometer (BioRad) and images analyzed with PDQuest software (BioRad). Matchsets were created for each treatment and their appropriate control ($CdCl_2$ and atrazine treatments vs. H_2O control; phenanthrene, PCB 126 and toxaphene vs. oil control). Within each matchset, gel images were aligned, the optical densities of spots averaged across treatments and compared to controls. Gel images were normalized to the total density of the gel image to remove variance based on saturated spots or differential staining. Only gels displaying acceptable protein separation (i.e., minimum 150 spots matched to master gel) were included in the subsequent statistical analysis (three gels were included in the $CdCl_2$, atrazine, phenanthrene, and H_2O control groups and two gels were included in the toxaphene, PCB 126 and oil control groups). Spots identified in treatment groups as differing (t-test, $\alpha = 0.05$) from

controls were manually excised, washed with 50% acetonitrile 100 mM ammonium bicarbonate (ABC) buffer, dried, and swelled in 50 mM ABC buffer. Proteins within each gel spot were trypsin-digested (15 ng l^{-1} trypsin) overnight at 37 °C. Peptides were extracted from the gel spots with 5% trifluoroacetic acid/60% acetonitrile and dried in a SpeedVac. Peptides were then resolubilized in 0.01% trifluoroacetic acid, cleaned with C18 ZipTips (Millipore, Bellerica, MA, USA), plated onto a MALDI plate with an α -Cyano-4-hydroxycinnamic acid matrix, and analyzed in a 4800 Plus MALDI TOF/TOF™ Analyzer mass spectrometer (Applied Biosystems, Framingham, MA, USA). MS/MS spectra were searched against ray-finned fishes NCBI databases using GPS Explorer software (Applied Biosystems) utilizing MASCOT (Matrix Science Ltd., Boston, MA, USA) to identify excised proteins. Total ion score confidence intervals (C.I. %) above 95% were considered as significant database matches.

Data Analysis and Upload using GeneGo™

Differentially expressed proteins obtained after each exposure were analyzed using GeneGo. Using the GeneGo Data Manager, experimental data (which included fold change in relation to controls) were uploaded in the format of EntrezGene (Locus Link). Human was selected as the organism to allow GeneGo to find homologue genes. From this point on, all analyses were done with respect to the human homologues of the corresponding genes. Datasets from each exposure experiment were compared using the "compare experiment workflow" tool. Threshold was left as the default value of 0.005. The threshold value corresponds to the minimal positive expression or the maximum negative expression for the protein list. Since the proteins included in the data file had already been selected as significant based on their *p*-values, no *p*-values were included in the data file for GeneGo analysis.

For enrichment analyses, we sorted the gene ontology database (i.e., networks, maps, and cellular processes) by statistical significance, with *p*-values corresponding to the degree of intersections between the experimental genes and the genes from the networks in the database. Taking into account sampling without replacement, the probability of intersections between the experimental data and a network/pathway being random follows a hypergeometric distribution:

$$P(r, n, R, N) = \frac{C_R^r \cdot C_{N-R}^{n-r}}{C_N^n} = \frac{C_n^r \cdot C_{N-n}^{R-r}}{C_N^R} = \frac{R! \cdot (N-R)!}{N!} \cdot \frac{n! \cdot (N-n)!}{r! \cdot (R-r)!} \cdot \frac{1}{(n-r)!(N-R-n+r)!} \quad (1)$$

In equation (1), N corresponds to all nodes in the MetaCore database of interactions whereas R corresponds to the subset of nodes coming from the data set. The n represents the amount of nodes in a particular network module (i.e., nodes related to a cellular process), while r is the number of nodes from the data set that are present among the n nodes.

Finally, we also utilized the "toxicity analysis workflow" tool as another approach for examining mechanisms of toxicity for the chemicals under study. The toxicity analysis uses a licensed database on MetaCore that contains organ-specific toxicogenomics and drug response information. The ontologies were sorted by statistical significance.

2.1.2 Results and Discussion

A detailed description of proteome changes in largemouth bass exposed to different contaminants is presented in Sanchez *et al*. (2009). Overall, changes were observed in the expression of proteins associated with cellular ion homeostasis (toxaphene), oxidative stress (phenanthrene, PCB 126), and energy production including glycolysis ($CdCl_2$, atrazine) and ATP synthesis (atrazine). When these data were analyzed using GeneGo, 11, 16, 5, 15, and 4 significantly altered proteins were considered for pathway analysis for the atrazine, $CdCl_2$, PCB 126, phenanthrene, and toxaphene treatments, respectively. A summary of unique (present only in each exposure) and overlapping proteins is presented in Figure 1. As can be seen from this figure, expression of several proteins was uniquely associated with a particular contaminant. Phenanthrene and $CdCl_2$ stood out as the chemicals that induced the largest number of unique proteins (total of 8 proteins each), followed by atrazine (6), toxaphene (2) and PCB 126 (1) (see Figure 1 and Appendix 1 for a name list of all these proteins). Some proteins were also shared between treatments. For instance, expression of FABP7, HSPA1A, and HSPAIB was

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat215
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

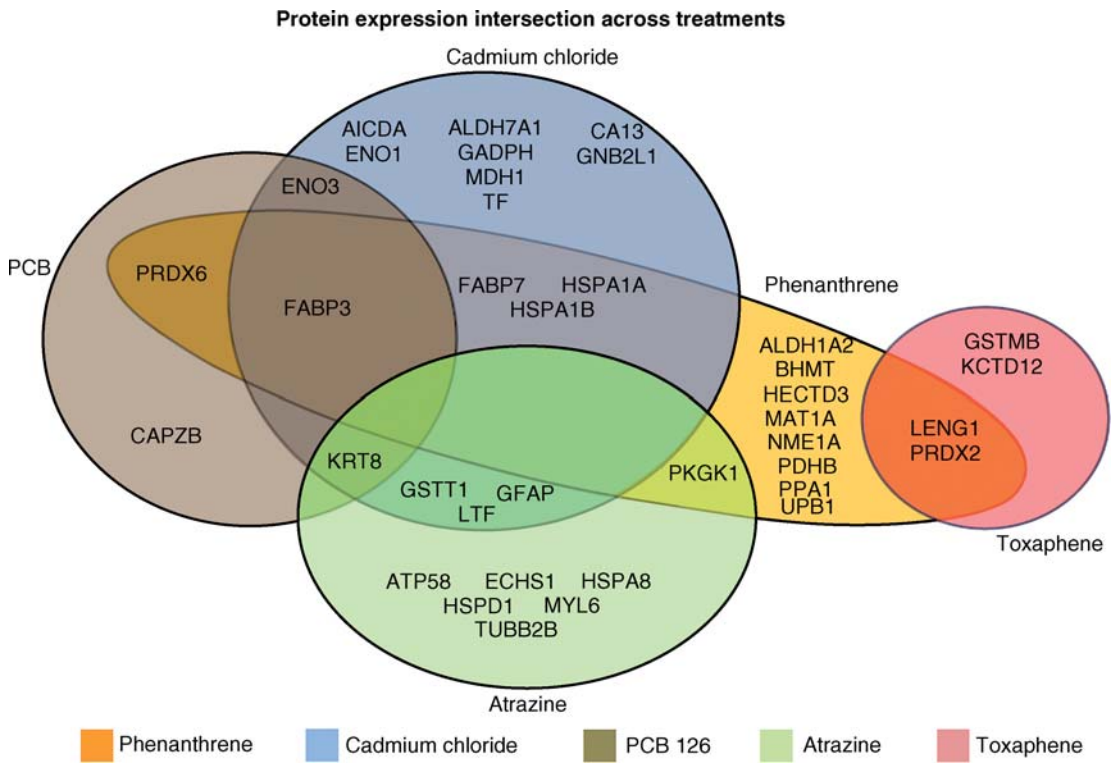

Figure 1. Comparison of protein expression data from livers of largemouth bass exposed to phenanthrene (50 μg^{-1}), cadmium chloride (0.00067 μg^{-1}), PCB 126 (2.5 μg^{-1}), atrazine (3 μg^{-1}), and toxaphene (100 μg^{-1}) after a 96 h exposure. Protein expression data were analyzed using GeneGo. Appendix 1 lists the names of the genes shown on this figure.

affected by both $CdCl_2$ and phenanthrene. Similarly, expression of KRT8 was affected by atrazine, PCB 126, and $CdCl_2$. Several other instances of overlapping expression across treatments can be seen from Figure 1.

Pathway analysis of protein data sets indicated that phenanthrene, $CdCl_2$, and PCB 126 significantly affected processes associated with liver toxicity (Figure 2). Proteins designated as similar among these three treatments were found to be involved in liver toxicity end point processes such as ischemia-induced cellular changes, hypoxia, apoptosis via mitochondrial membrane dysfunction, inflammation, and steatosis (Figure 2). Unique proteins from individual treatments were also found to affect liver toxicity endpoint processes such as hypoxia ($CdCl_2$), peroxisomal proliferation (phenanthrene), cell cycle progression of mitosis (PCB 126), and oxidative stress (phenanthrene).

We also had the opportunity to input gene expression data onto GeneGo from these same liver samples that were produced using largemouth bass microarrays developed by EcoArray® (see Sanchez *et al.* (2009) for a detailed description of the genomic analyses conducted). We wanted to see what, if any, overlap existed between changes in the gene and protein expression in these tissue samples. Within each treatment, protein data sets exhibited lower *p*-values suggesting higher effects at the protein level compared to the gene level after 96 hr of exposure to the abovementioned chemicals. In addition, we observed little overlap of significantly affected pathways within chemical treatments determined from gene and protein data sets. Indeed, phenanthrene was the only treatment that showed an overlap of significant pathways when gene and protein data sets were compared. Common pathways included thymidine triphosphate (TTP) metabolism, deoxyguanosine triphosphate (dGTP) metabolism, and deoxycytidine triphosphate (dCTP)/deoxyuridine triphosphate (dUTP) metabolism (Figure 3).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat215
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

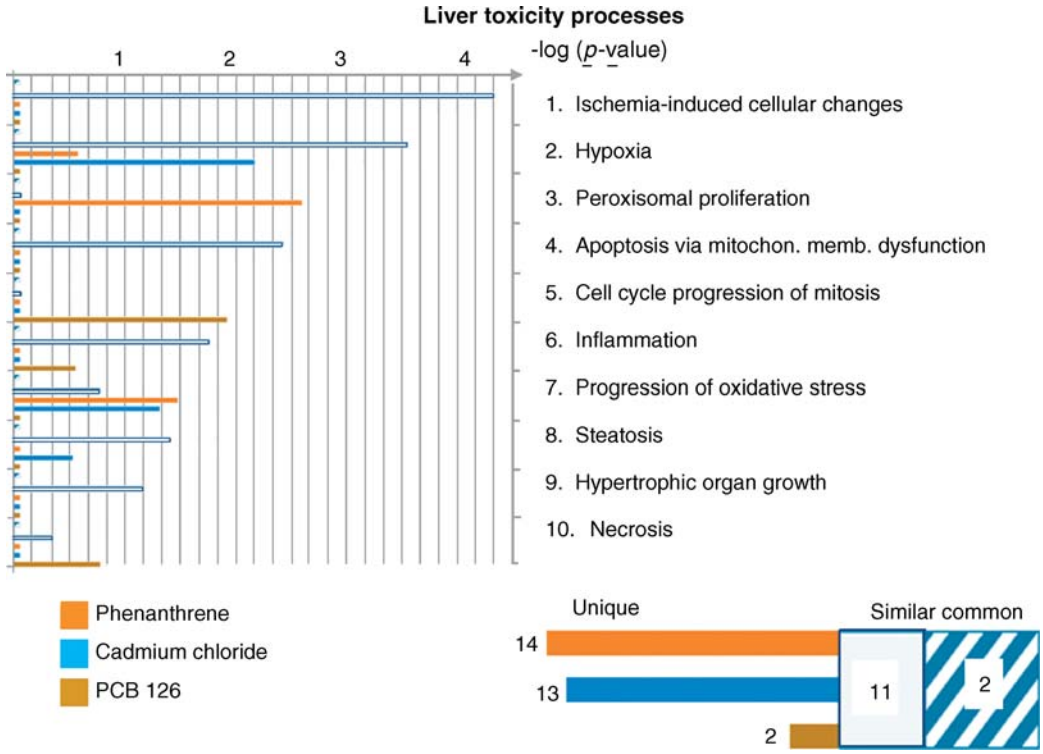

Figure 2. Liver toxicity processes induced by phenanthrene (50 μg^{-1}), cadmium chloride (0.00067 μg^{-1}), and PCB (2.5 μg^{-1}) in largemouth bass after a 96 h exposure. Protein expression data was analyzed using GeneGo.

While the lack of intersection between gene and protein responses may appear anomalous, it has been widely documented that mRNA levels do not typically reflect cognate protein levels (Anderson and Seilhamer, 1997; Gygi *et al*., 1999). Based on the typical absence of an mRNA/cognate protein correlation, Steiner and Anderson (2000) suggest that the two approaches (i.e., gene and protein profiling) be viewed as complementary and used in parallel to determine meaningful physiological effects. For example, the authors highlight the usefulness of genomic profiling when attempting to determine the expression changes of low abundance transcripts, which are typically difficult to monitor at the protein level. Further, they highlight the advantages of proteomic approaches that enable a researcher to observe and evaluate post-translational modifications that are not detectable at the mRNA level of expression. Taken together, a more complete snapshot of physiological processes and/or responses to chemical stressors is possible.

As such, it is interesting that we observed an overlap of pathways derived from gene and protein data sets for the phenanthrene treatment. In particular, we determined that pyrimidine deoxyribonucleotide (dCTP, dUTP, TTP) metabolism was affected. Polycyclic aromatic hydrocarbons (PAHs) have been shown to alter pyrimidine incorporation (Hellman, d'Argy and Ullberg, 1984) and benzo(a)pyrene, in particular, has been shown to affect pyrimidine metabolism in mice (Wu *et al*., 2009). PAHs have also been implicated in causing G to T nucleotide transversions via adduction in mammalian (Mass *et al*., 1996) and fish tissues (Amanuma *et al*., 2002). Imbalances in dNTP concentrations in cells are potentially mutagenic or lethal (Mathews, 2006). This analysis provides novel evidence that pyrimidine metabolism in fish hepatic tissues is affected by phenanthrene exposure and that this effect is determinable by pathway analyses of genomic and proteomic data.

Groupings of chemical treatments based on similarly affected proteins indicated that phenanthrene was the most toxicologically nonspecific chemical among those evaluated while toxaphene was shown to induce the most disparate toxicological

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat215

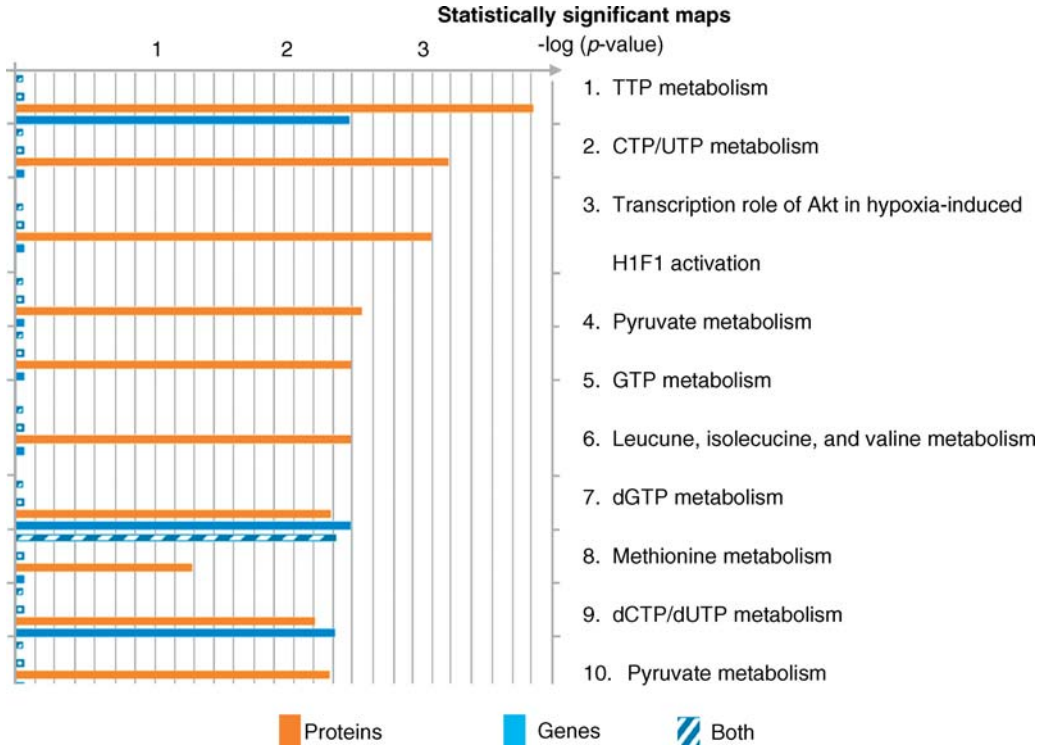

Figure 3. Metabolic pathways affected by largemouth bass exposed to phenanthrene (50 μg^{-1}) for 96 h. Livers were collected and both genomic and proteomic analyses conducted (see text for more details). Phenanthrene was the only chemical out of the five tested that showed an overlap of significant pathways between gene and protein data. Common pathways included thymidine triphosphate (TTP) metabolism, deoxyguanosine triphosphate (dGTP) metabolism, and deoxycytidine triphosphate (dCTP)/deoxyuridine triphosphate (dUTP) metabolism.

response based on this analysis. Toxaphene is an alicyclic organochlorine insecticide whose mode of toxic action involves binding at the picrotoxinin site in the γ-aminobutyric acid (GABA) complex, which prevents nerve Cl^- influx (Lawrence and Casida, 1983; Bloomquist and Soderlund, 1985; Coats, 1990). In a study of channel catfish (*Ictalurus punctatus*), Desaiah and Koch (1977) documented a reduction in the function of Mg^{2+}-ATPase and Pałecz, Komuński and Gabryelak (2005) noted a reduction in Na^+K^+-ATPase function in freshwater mussels (*Unio tumidus*). The specificity with which toxaphene tends to target ion channels and ion fluxes may be reflected in its uniqueness among tested chemicals analyzed herein.

In summary, we have shown that bioinformatics software developed primarily for mammalian animal models can be utilized for the analysis of gene and protein data collected from non-mammalian organisms. Although we were unable to find human homologues for all the genes and proteins that were significantly affected in largemouth bass exposed to different chemicals (overall match of 80%, range of 50–100%), the results obtained make toxicological as well as biological sense (e.g., evidence of liver toxicity and of pyrimidine toxicity after phenanthrene exposure and general lack of overlap between gene and protein responses, respectively). Thus, this approach should be helpful for elucidation of mechanisms of toxicity utilizing data derived from non-mammalian vertebrates.

2.2 Proteomic and Metabolomic Responses in *Hyallela azteca* Exposed to Atrazine and its Metabolite DEA

Atrazine remains one of the most controversial herbicides on the market today. It has elicited endocrine disrupting effects in vertebrate (Diana *et al*., 2000; Wiegand *et al*., 2001; Hayes *et al*.,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat215
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

2002; Stoker *et al*., 2002) as well as invertebrates species (Schober and Lamber, 1977; Dodson *et al*., 1999). However, the mechanism of action (MOA) of atrazine remains unclear especially in invertebrate species. Incorporating a global approach, which utilizes genomics, proteomics, and metabolomics would result in valuable information on the MOA of atrazine. In this case study, we examined the proteomic and metabolomic profiles of chronically exposed *Hyalella azteca* to atrazine and one of its metabolites, deethyl-atrazine (DEA) in order to better understand how these contaminants impact freshwater invertebrates.

2.2.1 Materials and Methods

Exposure Experiments

H. azteca organisms used during the 42 d exposures were purchased from Aquatic BioSystems Inc. (Fort Collins, CO). *H. azteca* juveniles ($\leq$7 d old) were collected from cultures raised in the Purdue Ecological Risk Assessment (PERA) laboratory and allowed to acclimate for 7 d before test initiation. Ten organisms were placed in 70 ml of 60:40 tap/deionized water at 25 °C and allowed to acclimate for 24–48 h prior to the initiation of toxicity tests. After acclimation, water was spiked with known volumes of aqueous stock solutions to achieve target concentrations of 30 or 0 $\mu g\,l^{-1}$ atrazine and DEA. Organisms were fed 200 µl of *Pseudokirchneriella subcapitata*, yeast, cerophyll, and tetramin (YCT) daily. Water changes were performed three times per week by removing 10% of the water volume and replacing it with fresh solution. At 42 d, organisms were classified as either males by the presence of a large gnathopod or females by the presence of eggs in the marsupial plates as previously described (Ralston-Hooper *et al.*, 2009). Organisms were then flash frozen and stored at −80 °C until proteomic and metabolomic analysis could be performed.

Metabolomic Analyses

For metabolomic analysis, three *H. azteca* organisms per sample were used and wet weights ranged from 0.0036 – 0.0129 (average 0.0064) g per sample. Samples were first homogenized for 20 s in 300 µl of methanol and 150 µl of water using a 7 mm × 95 mm saw tooth stainless steel generator probe (Omni International, Marietta, GA, USA) and then sonicated using 10, 1 s bursts. In order to extract non-polar metabolites, 450 µl of chloroform was added to the sample, thoroughly vortexed, and then centrifuged at 3,000 g for 20 min. The polar and non-polar phases were then collected and separated by placing each fraction in new vials. Each extract was dried using a Sevant SPD 131DDA SpeedVac Concentrator (Thermo Electron Corporation Milford, MA, USA). Once dried, the methanol:water extracted samples (polar metabolites) were prepared for GCxGC/TOF-MS analysis (Ralston-Hooper *et al.*, 2008). The non-polar fraction or chloroform extracted samples were re-suspended in mobile phase (50% water, 25% Methanol, 25% Acetonitrile) and injected onto the LC/TOF-MS for analysis. The HPLC was an Agilent 1100 (Agilent Technologies, Santa Clara, CA, USA) equipped with a micro well plate autosampler, capillary, and nano-pumping device. Reverse phase liquid chromatography was used to analyze the samples. A zorbax-C8 column (Agilent Technologies, Santa Clara, CA) with 2.1 × 150 mm, 5 µm dimensions was used for the separation. Solvent A consisted of water +0.1% piperidine. Solvent B contained acetonitrile:methanol (50:50 v/v) +0.1% piperidine. The flow rate was 300 $\mu l\,min^{-1}$ and 10 µl of sample was loaded on the column. The gradient was as follows: time 0 50% B held for 5 min, ramped to 95%B over 20 min, held at 95% B for 20 min, ramped down to 50% B over 5 min, and held for 10 min. The MS analysis was done using a time-of-flight instrument. The samples were evaluated with negative polarity electrospray ionization. The capillary voltage was set to 3500 V, desolvation gas 9.0 $l\,h^{-1}$, desolvation temperature 350 °C, and nebulizer 40 psi. The mass range scanned was 100–1800 with a scan rate of 1. The fragmentor was 175 V, skimmer 65 V, and octapole RF of 250 V. The samples were evaluated with Agilent Masshunter version 01.03 and downstream alignment done with Agilent GeneSpring MS software version 01.02. Metabolites were identified by blasting m/z values against the human metabolome database (HMDB) using negative ion mode (Wishart *et al.*, 2007). See Figure 4 with some examples of mass spectra utilized for metabolite identification. Chromatographic peaks were then aligned, matched, normalized, and compared.

Analysis of variance (ANOVA) and Tukey means separation post hoc testing were used to detect significant metabolite differences among the three treatment groups and were performed using SAS

statistical software version 9.1 (Statistical Analysis Software, Cary, NC, USA). Unsupervised divisive cluster analyses (DIANA) were performed using R statistical software version 2.8.1 (R Foundation for Statistical Computing, Vienna, Austria).

Proteomic Analyses

For proteomic analysis, *H. azteca* whole body tissues from three individuals exposed to 30 $\mu g\,l^{-1}$ atrazine and DEA were prepared for protein separation (average 0.009 g wet weight). Proteomic analysis was performed similar to that of fish tissue, which was described previously under "Proteomic Analyses" in Section 2.1.1.

2.2.2 Results and Discussion

Metabolites and proteins were identified that suggests atrazine and DEA may disrupt energy metabolism in atrazine and DEA exposed organisms. Metabolomic analysis yielded an up-regulation of carnitines and fatty acids when compared to control organisms whereas proteomic analysis resulted in a down-regulation of glyceraldehyde 3-phosphate dehydrogenase (GAPDH), enolase, and ATP synthase as well as other proteins associated with energy production (Table 4). GAPDH, enolase, and ATP sythase are commonly reported glycolic enzymes identified during 2-DE research (Petrak *et al*., 2008). GAPDH is an enzyme used during glycolysis that catalyzes the synthesis of 1,3-bisphosoglycerate, a high-energy intermediate used for the synthesis of ATP. Enolase is responsible for the catalysis of 2-phosphoglycerate (2-PG) to phosphoenolpyruvate (PEP) during the final step of glycolysis. When analyzed independently of metabolomic data, this down-regulation would suggest disruption in glycolysis. Ultimately,

disruptions in glycolysis would result in a decrease in ATP thus reducing the overall energy status of exposed organisms. However, these organisms were physically larger than control organisms (data not shown, but see Ralston-Hooper *et al*., 2009) and did not experience high incidences of mortality when chronically exposed (Ralston-Hooper *et al*., 2009). Additionally, research has reported increases of these enzymes when exposed to various environmental contaminants (Dihazi *et al*., 2005; Tanguy *et al*., 2005; Gunnarsson, Nordberg and Selstam, 2007) lending to the difficulty of putting these proteins into biological context.

However, metabolomic analysis of polar and non-polar metabolites indicated an up-regulation of carnitines, fatty acids, glycerols, and urea when compared to control organisms, indicating β-oxidation of fatty acids. The mitochondrion catalyze *β*-oxidation of fatty acids and is the major process by which fatty acids are oxidized to generate energy (ATP) (Reddy and Hashimoto, 2001). The physiological role of carnitines is to facilitate the transfer of fatty acids across the mitochondrial membrane that results in generation of ATP (Arrigoni-Martelli and Caso, 2001). In general, an increase in fatty acids or carnitines results in increased energy of the exposed organism.

When proteomic and metabolomic data are used in conjunction, a clearer picture emerges. It appears that atrazine and DEA do indeed reduce glycolysis in exposed invertebrates. However, since invertebrates are comprised mostly of lipids, *H. azteca* organisms can rely on β-oxidation of fatty acids in order to meet their energy demands.

Overall, this case study demonstrates the advantages of utilizing both proteomic and metabolomic data to understand how environmental contaminants impact exposed organisms.

2.3 Use of Metabolomics to Characterize Egg Quality in Fish-Eating Birds Exposed to Persistent Organic Pollutants

Maternal exposure to environmental contaminants can impact vitellogenesis and thus the nutritional quality of developing avian eggs. For instance, alterations of fatty acid profiles in yolk (Stanton *et al*., 2003) and protein contents in albumin (Fernie *et al*., 2000) have been reported in avian eggs exposed to several chlorinated organics, including PCBs. Since effects of contaminant exposure are most pronounced in early-life stages, we hypothesize that exposure of great blue heron (*Ardea herodias*) embryos to these contaminants can result in failure to hatch or fledge. The goal of the current study was to evaluate sublethal effects of environmental stressors by studying the metabolomic profile of great blue heron eggs naturally exposed to PCBs, polycyclic aromatic hydrocarbons (PAHs), and organochlorine pesticides (OCPs) using a metabolomics approach. A review of the literature indicates this is the first metabolomics study conducted in wild birds.

2.3.1 Materials and Methods

Samples

Great blue heron eggs were collected from six colonies located across the southern, central, and northern regions of Indiana during the springs of 2005 and 2006 (Baker and Sepúlveda, 2009). Eggs collected from southern Indiana (Brown County, N39°16′3″, W86°15′46″) were expected to be less contaminated than those from the central region (Tippecanoe and Carroll Counties, N41°16′50″–N41°37′7″, W86°57′3″–W87°09′5″), and eggs from the central region were expected to be less contaminated than those from the northern region (Lake and Porter Counties, N40°16′5″–N40°24′4″, W86°44′8″–W87°00′3″) (refer to Baker and Sepúlveda, 2009 for more detailed information about the colonies sampled). Half of each of the yolk samples collected from the eggs was sent to the University of Florida Analytical Toxicology Core Laboratory for quantification of PCBs, PAHs, and OCPs. Remaining yolk samples were retained for GCxGC/TOF-MS metabolomic analyses.

Metabolomic Analyses

Wet weights for great blue heron egg yolk samples ranged from 0.44–0.97 g. GCxGC/TOF-MS metabolomic procedures were described in detail in "Proteomic Analyses" (Section 2.1.1.).

2.3.2 Results and Discussion

Heron eggs contained an overall mean of 3,101 (range 164–27,703) $\mu g\,kg^{-1}$ PCBs, 7.20 (range 2.76–13.48) $\mu g\,kg^{-1}$ PAHs, and 2,869 (range 262–11,896) $\mu g\,kg^{-1}$ OCPs. Principle component analyses (PCA) identified no significant metabolites ($p > 0.05$) based on level of exposure to PCBs, OCPs, or the total contaminant load. However, PCA results did indicate differences in metabolite profiles for eggs exposed to varying PAH concentrations; based on the range of values observed, eggs were divided into three exposure categories: low ($<7\,\mu g\,kg^{-1}$), medium (7–10 $\mu g\,kg^{-1}$), or high ($>10\,\mu g\,kg^{-1}$) PAH concentrations (Figure 5). Fourteen significant metabolites were identified based on PAH concentration; of these, eight were identified to metabolite type with sufficient confidence (i.e., similarity value >700) but three were by-products of the derivatization process and are not listed (Table 5). Overall, metabolites were up-regulated in eggs with low PAH concentrations and down-regulated in eggs with high PAH concentrations.

Additional analyses were performed to determine the potential relationship between the region where eggs were collected and metabolomic profiles. When analyzed based on the region (southern, central, or northern) of the State of Indiana from which the eggs were collected, six significant metabolites were identified, three of which were identified to metabolite type with sufficient confidence (Table 5); eggs from the southern region expressed significant up-regulation of metabolites, whereas metabolites were not detected in the northern region and were not significantly different in the central region. Of the significant metabolites observed, three metabolites were identified as significant based on both PAH concentration and region: oleic acid, octadecanoic acid, and androstan-17-one.

The relationship between PAH concentration and metabolomic profiles suggests that eggs exposed to low versus medium/high PAH concentrations have metabolomic differences (Figure 5). PAH exposure has impacted overall health and reproduction of many vertebrate species such as loggerhead sea turtles (*Caretta caretta*) (Alam and Brim, 2000) and brown bullheads (*Ameiurus nebulosus*) (Steyermark *et al*., 1999). More importantly, exposure to PAH mixtures has resulted in decreased hatchability, increased mortality, and severe deformities in mallard duck (*Ana platyrhynchos*) embryos (Hoffman and Gay, 1981) as well as significant effects on survival and deformity rates of snapping turtle (*Chelydra serpentina*) embryos (Van Meter, Spotila and Avery, 2006). Differences in metabolite profiles may help explain the reported adverse effects of exposed embryos. For example, in egg-laying vertebrates, such as great blue herons, embryonic growth and survival are profoundly dependent on egg nutritional composition, or more specifically, its fatty acids concentration. Two fatty acids, oleic acid and octadecanoic acid, were identified in eggs exposed to all levels of PAHs; however, eggs exposed to low PAH concentrations had significantly higher levels of these fatty acids. This suggests that higher concentrations of PAHs reduced fatty acid content of the exposed embryos, which could lead to increased mortality or developmental effects.

Interestingly, ergost-5-en-3-ol, cholesta-3,5-diene, and androstan-17-one, all sterol structures, were greater in eggs associated with low PAH

concentrations. The biological context of these metabolites is not clear. For example, high concentrations of sterol lipids may be detrimental to egg development, since sterols such as ergost-5-en-3-ol are not as readily absorbed as cholesterol, which may interfere with nutritional status and membrane formation in the developing egg (Child and Kuksis, 1983; Salen *et al*., 2000). Also, higher levels of ergost-5-en-3-ol were identified in unfertilized eggs of brown trout (*Salmo trutta lacustris* L) (Lehtinen *et al*., 1999). However, these sterol structures may also play an important role in lipoprotein transport or steroid synthesis so higher concentrations may not necessarily have adverse effects on egg development. Most interestingly, the steroid, androstan-17-one, was identified in eggs exposed to low PAH concentrations. Maternally derived hormones such as androgens have been implicated in egg laying behavior, hatching, and clutch size of American coot (*Fulica americana*) eggs (Reed and Vleck, 2001). In general, chicks that hatched from eggs with higher androgen levels had behavioral as well as growth advantages over chicks hatched from eggs with lower androgen levels.

In general, it appears that eggs exposed to various PAH levels have different metabolomic profiles. Eggs exposed to lower PAH levels may indeed have an advantage over those exposed to higher PAH concentrations. Furthermore, these compounds where not only associated with PAH levels but were also found in higher concentrations in eggs collected from nests in northern Indiana verses those from central and southern Indiana colonies. However, it is also possible that we not only observed metabolite differences due to PAH concentration, but year of sample collection may also be playing a role. These eggs were sampled over multiple years, which could result in metabolomic profiles differences due to changes in maternal resources or environmental factors, which vary from year to year (e.g., temperature and rainfall). Overall, this research demonstrates the feasibility of utilizing GCxGC/TOF-MS to successfully identify differentially expressed metabolites in egg yolks of birds. To our knowledge, this is the first metabolomic study conducted in wild birds.

3 SUMMARY AND CONCLUSIONS

Proteomics and metabolomics are powerful tools in environmental toxicology. They offer great potential as biomarker discovery tools as well as for increasing our understanding of the cellular mechanisms involved in stress response. Thus, the major potential of these tools is based on their ability to predict adverse impacts of stressors to invertebrates, fish, and wildlife. Because organisms are rarely exposed to a single chemical, these high-throughput mechanistically-based tools can also improve our knowledge of the effects of mixtures. However, several major challenges remain before these tools can be successfully applied for environmental risk assessment. Some of these challenges include:

1. Linking expression profiles to phenotypic and population-level effects. Integration of "omic" data with phenotypic changes and ecologically relevant endpoints is a must if these tools are to be implemented by regulatory agencies as predictors of risk to free-ranging animals. The use of "omic" approaches in existing risk assessment approaches would allow for a high-throughput screening of simultaneous changes in thousands of molecules and thus provide a more rapid evaluation of the toxicity of chemicals.
2. More field studies that utilize "omic" approaches are needed. As discussed at the beginning of this chapter, few field studies have employed proteomic and metabolomic tools to evaluate exposure and effects of biota to pollutants. Results are promising in that multivariate analysis of protein and metabolite profiles are predictive of site and thus specific contaminant exposure. Field studies that can tie protein and metabolite changes to sublethal effects represents a major data gap.
3. All current "omic" techniques provide only a static snapshot of the molecular profile at a particular point in time. More studies are needed that add a temporal component and evaluate changes in proteins and metabolites over several time points as well as during embryo and larval development.
4. A major challenge will involve separating "biological noise" with effects elicited by specific stressors. It is known that factors such as gender, age, and physiological condition can affect the profile of proteins and metabolites. These types of effects must be taken into consideration during experimental design and data interpretation.
5. Serious weaknesses remain in the areas of data analysis and integration of "omic" databases.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat215
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Although there have been considerable advances in this field over a very short period of time, most of these have been over equipment development, with less attention being paid to data analysis. Likewise, very few ecotoxicological studies have integrated "omic" data collected from the same organisms. This is of great importance because toxicological responses are under regulation of a complex array of genes, proteins, and metabolites. Integration of "omic" databases would help in the identification of genes that are linked to particular toxic outcomes.

6. A big challenge is to annotate the proteomes and metabolomes of species routinely used in ecotoxicological research. In proteomics research this gap could be overcome in the short-term with the use of *de novo* sequencing approaches.
7. Another important task is the standardization of general protocols, including experiments, data handling, and reporting. The Metabolomic Standards Initiative (MSI) was recently launched with the goals of standardizing chemical analysis, data processing, ontology, and minimum reporting guidelines for anyone conducting metabolomics work.
8. Finally, it should be pointed out that only a limited number of taxonomic groups have been evaluated utilizing proteomic and metabolomic tools. For example, only a handful of such studies have been conducted with amphibians and mammals. No studies have been published with birds (with the exception of the study presented in this chapter) or reptiles.

Regardless of all the pressing challenges, there is no doubt that these holistic measures of organism response to environmental stressors will continue to make a great impact in the ecotoxicological field.

APPENDIX 1

Summary of genes shown under Figure 1.

Gene symbol	Protein name (*Homo sapiens*)
FABP3	Fatty acid binding protein 3, muscle and heart
FABP7	Fatty acid binding protein 7, brain
HSPA1A	Heat shock 70 kDa protein 1A
HSPA1B	Heat shock 70 kDa protein 1B
LENG1	Leukocyte receptor cluster (LRC) member 1
PGK1	Phosphoglycerate kinase 1
PRDX2	Peroxiredoxin 2
PRDX6	Peroxiredoxin 6
ALDH1A2	Aldehyde dehydrogenase 1A2
BHMT	Betaine-homocysteine methyltransferase
HECTD3	Probable E3 ubiquitin-protein ligase HECTD3
MAT1A	S-adenosylmethionine synthetase isoform type-1
NME1	Nucleoside diphosphate kinase A
PDHB	Pyruvate dehydrogenase E1 component subunit beta, mitochondrial
PPA1	Inorganic pyrophosphatase
UPB1	Beta-ureidopropionase
ENO3	Beta-enolase
GFAP	Glial fibrillary acidic protein
GSTT1	Glutathione S-transferase theta-1
KRT8	Keratin 8
LTF	Lactotransferrin
AICDA	Activation-induced cytidine deaminase
ALDH7A1	Alpha-aminoadipic semialdehyde dehydrogenase
CA13	Carbonic anhydrase 13
ENO1	Alpha-enolase
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
GNB2L1	Guanine nucleotide-binding protein subunit beta-2-like 1
MDH1	Malate dehydrogenase, cytoplasmic
TF	Transferrin
GSTM3	Glutathione S-transferase mu 3 (brain)
KCTD12	Potassium channel tetramerisation domain containing 12
ATP5B	ATP synthase subunit beta, mitochondrial
ECHS1	Enoyl-CoA hydratase, mitochondrial
HSPA8	Heat shock cognate 71 kDa protein
HSPD1	Heat shock protein 60 kDa, mitochondrial
MYL6	Myosin light polypeptide 6
TUBB2B	Tubulin beta-2B chain
CAPZB	Capping protein (actin filament) muscle Z-line, beta

Application of Proteomics to Study Mechanisms of Toxicity and Dose–Response Relationships of Chemical Exposure

Zheying Zhu and Robert J. Edwards

Experimental Medicine and Toxicology, Hammersmith Hospital Campus, Imperial College London, London, UK

1 INTRODUCTION

Toxicoproteomics, the application of proteomic technologies in toxicology, enables studies of the adverse effects of xenobiotic substances in relation to changes in protein profiles. Through the application of technologies that provide global protein expression information, it should be possible to determine the biological response to a toxic insult. As a result, critical proteins and hence pathways in biological systems that are important in toxicological responses may be identified. Identifying proteins whose expression is associated with specific toxic end points is an initial step in predicting, characterizing and understanding toxicity. Subsequent analysis of protein function and the pathways of protein expression changes represent additional methods to generate hypotheses relevant to developing a better understanding of the mechanisms of toxicity. The application of proteomics promises biomarkers for early detection and new toxicity endpoints to facilitate the identification and characterization of toxicity and will provide a better understanding of the mechanisms of toxicity of compounds. It is anticipated that toxicoproteomics will facilitate a means that will provide more sensitive and earlier detection of adverse effects at low doses, which may lead to more accurate determinations of the no observed effect concentration (NOEC) of a given compound in toxicity studies and hence improved risk assessment.

The application of proteomic technologies in toxicology and their usefulness for biomarker discovery have been reviewed previously (Kennedy, 2002; Wetmore and Merrick, 2004). Toxicoproteomics applied to the study of mechanisms of toxicity has been increasingly adopted in recent years and, in some cases, has been integrated with other 'omics' technologies; these have been the subject of some reviews, although much of the focus has been on the application of genomics (Ellinger-Ziegelbauer *et al.*, 2008; Blomme, Yang and Waring, 2009). In this report, proteomic technologies and their latest applications in studies of the mechanisms of toxicity and dose–response relationships are reviewed and discussed.

2 PROTEOMIC TECHNIQUES

A number of different techniques have been developed to investigate protein profiles in complex samples. Here, some of the main techniques that have been applied in toxicoproteomic studies are described and the relative merits and limitations of the various approaches considered.

Two-dimensional polyacrylamide gel electrophoresis (2D-PAGE), often in conjunction with matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-ToF MS), is a very commonly applied approach. Relative quantification of stained protein spots seen in 2D gels by image analysis may be used to locate proteins of interest which are then identified following tryptic digestion and analysis by MS, often MALDI-ToF MS. This widely used approach has the advantage of being available to most laboratories. Many protein spots can be resolved in a 2D gels and the visual appearance of a stained gel provides a ready readout of the data, although, in practice, meaningful interpretation requires the use of dedicated software. Often post-translational modifications that cause a shift in p*I* are apparent and may be confirmed by subsequent MS analysis. However, this approach has a number of drawbacks, including a rather limited dynamic and molecular mass range, difficulty in detecting low-abundance proteins, poor resolution of membrane-bound, highly acidic or basic and low-molecular-weight proteins, and a need for careful sample preparation to remove salts and other contaminants. The technique has a low throughput and is laborious. Some of the disadvantages have been addressed through the application of 2D-differential in-gel electrophoresis (2D-DIGE), which uses multiple fluorescent dyes to label protein samples prior to running the gel. This allows multiple samples to be co-separated and visualized in a single 2D gel, and makes quantification easier. However, the limited number of DIGE dyes available allows only a few samples to be analysed at any one time.

Instead of attempting to separate and quantify proteins before digesting them with trypsin to identify proteins by MS, an alternative approach is to first digest the protein mixture and then attempt to separate and quantify the peptides present. The principle behind this approach is that it is easier and more reproducible to separate and quantify peptides than proteins. Large-scale analysis of highly complex protein mixtures from whole cells, organs, organelles or biofluids has been achieved in this way (Fang *et al*., 2006; Ono *et al*., 2006; Cutillas and Vanhaesebroeck, 2007). Separation of peptides prior to MS analysis, typically by tandem mass spectrometry (MS/MS), has been achieved by reverse-phase LC or a combination of cation-exchange chromatography and reverse-phase LC (Le *et al*., 2006), an approach that has been termed multi-dimensional protein identification technology (MudPIT) (Paoletti, Zybailov and Washburn, 2004). Although this approach has been shown to provide increased protein coverage compared with 2D-gel-based approach (Domon and Aebersold, 2006), it is technically more demanding, requires robust and reproducible ion-exchange as well as reverse-phase LC, and produces large, extremely complex datasets that need specialized software to interpret.

Elements of both of these approaches are combined in the so-called GeLC-MS approach. In this case, samples are resolved by simple one-dimensional sodium dodecylsulphate–PAGE to separate proteins on the basis of their relative mass, the entire gel is then cut into a series of slices and the mixtures of proteins contained within each are digested with trypsin before being analysed by LC-MS (Rezaul *et al*., 2005; Nicholas *et al*., 2006). The procedure has a number of advantages including the use of a high-resolution method to fractionate proteins and making LC separation of the resultant tryptic peptides less demanding.

Although knowledge of the protein constituents of organs, tissues and cells under any given time or condition is useful, it often does not allow researchers to address issues of biological importance. In order to answer questions of biological relevance, it is often necessary to establish the dynamics involved, for example, to determine how the expression levels of proteins vary in response to an externally applied stimulus, such as exposure to a toxicant. A variety of comparative and quantitative proteomic techniques have been developed to address this important issue. It should be appreciated that quantification of any analyses by MS is best achieved using heavy isotope-labelled internal standards. This is a well-established approach (Gevaert *et al*., 2008; Kito and Ito, 2008) and can be applied to determine the absolute quantification of specific peptides (Goshe and Smith, 2003; Tao and Aebersold, 2003) or a variety of peptides in a multiplexed format (Beynon *et al*., 2005; Yan and Chen, 2005;Morano, Zhang and Fricker, 2008). However,

such approaches require knowledge of the proteins of interest and usually this is not the starting point of a proteomic experiment. More usually, it is the relative level of expression of proteins or peptides that is determined. A number of labelling approaches have been developed that can accomplish this (Chen *et al*., 2007). Ideally, labelling should be applied early in the protocol so that variation due to sample handling before the labels are attached and the samples combined for subsequent fractionation and analysis is minimized. The labels attached are chemically similar but can be distinguished by either their physical characteristics or mass, and so by comparing their levels on specific proteins or peptides a measure can be produced indicative of the relative amounts of the labelled proteins or peptides. The most commonly applied labels include the use of the DIGE fluorescent tags, stable isotope labelling by isotope-coded affinity tags (ICAT) (Smolka *et al*., 2001; Turecek, 2002) and stable isotope labelling with amino acids in cell culture (SILAC) (Chen *et al*., 2005; Asara *et al*., 2006). Another technique termed isobaric tags for relative and absolute quantification (iTRAQ) is also available, although this can only be applied to labelling of peptides after trypsin digestion (Zieske, 2006). The usefulness of the labelling approach is limited by the number of different tags that are available and this compromises experimental design often to a simple one-to-one comparison, for example, of samples derived from a pre- and post-treatment. Commercially sourced labels are costly, which may be a factor in the design of more complex experiments. Consequently, analysis of comparative levels is often limited to consideration of fold differences above an arbitrary threshold as often insufficient samples are analysed to allow the use of statistical analysis to compare between treatments.

As an alternative, a variety of label-free quantitative approaches have been developed (Colinge *et al*., 2005; Heller *et al*., 2007; Stalder, Haeberli and Heller, 2008; Seibert *et al*., 2009). In comparison with labelling approaches, label-free analyses are often based on more unique identified peptides (Patel *et al*., 2009). Label-free approaches are not limited by the number of different labels available and are not costly. This means that more samples can be analyzed. Consequently, experiments can be designed to include a suitable number of samples per group to facilitate appropriate statistical analysis.

Surface-enhanced laser desorption/ionization (SELDI)-ToF-MS provides an alternative approach to label-free proteomic analysis. This technique combines the use of an interactive chip with MALDI-ToF MS. Complex mixtures of proteins are applied to one of several interactive chips under conditions where a fraction of proteins bind to the surface. The interaction on the chip surface may be ionic, hydrophobic, hydrophilic, metal ion chelating or affinity-based and the conditions of binding may be manipulated by varying the buffering conditions employed. The bound proteins are then subsequently analysed by ToF-MS under conditions that ionize but do not fragment the proteins. The mass of each protein ion is determined from its ToF and relative quantification is based on the ion current intensity. Application of SELDI-ToF-MS requires minimal sample preparation and only small amounts for analysis; it is rapid and hence is amenable to the analysis of tens or hundreds of samples in a single run (Petricoin, Ornstein and Liotta, 2004). This allows the design of suitably scaled experiments to be performed and comparisons based on appropriate statistical analyses. This technique has been widely applied to identify potential biomarkers for prognosis, diagnosis and treatment of human diseases in patients, particularly in plasma or serum samples (Wulfkuhle *et al*., 2001; Carter *et al*., 2002; Laronga *et al*., 2003). SELDI-ToF-MS is sensitive and useful for the detection of protein ions with masses of less than 20 kDa, but above this mass, the resolution of the proteins becomes increasingly poor. The MS data output is not suitably informative to identify protein ions of interest. To achieve this, it is necessary to use other methods, typically purification followed by trypsin digestion and MALDI-ToF MS or LC-MS/MS, to identify the proteins (Abdul-Salam *et al*., 2006; Zhu, Edwards and Boobis, 2009).

3 MECHANISMS OF TOXICITY

Although toxic effects may result from exposure to numerous man-made and naturally occurring chemicals, the mechanism(s) of toxicity involved remain largely unknown. Proteomic studies may aid in the elucidation of the underlying mechanisms of toxicity. In the case of pharmaceuticals, sensitive markers may be used in screens for toxicity early in the development process and could ultimately provide sensitive surrogate markers for clinical studies. In

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

the case of industrial chemicals and environmental contaminants, an increased understanding of the mechanisms involved is expected to help in the identification of responsive biomarker proteins that may be used to aid risk assessment.

3.1 Drug-Induced Toxicity

The inability to predict with any accuracy the pharmacological and toxicological effects of drug candidates in pre-clinical studies has contributed to the decline in the number of new drugs which make it to market and the rise in cost associated with drug development. Identifying molecular interactions associated with therapeutic and toxic outcomes early in the development of drugs is of great importance. Traditional mechanism-elucidation strategies are narrow, often focusing solely on the identification of a single molecular target. An approach that is able to establish the spectrum molecular effects following exposure to a toxic compound and the biochemical consequences that ensue would be of great benefit.

Understanding the mechanisms of toxicity for drugs is critical in forming a rational plan for developing efficient screens for toxicity. Often safety assessment in the pharmaceutical industry is performed in the later stages of the drug discovery process, in part because the tools for early safety screening are lacking. A better understanding of the mechanisms involved may change this practice.

Proteins are the principal targets of drug discovery. The common aims of proteomics in the drug development process include the identification of molecular targets, investigations into mechanisms of drug action or toxicity and the identification of biomarkers of efficacy and toxicity from readily accessible biological fluids. Biomarkers of toxicity may be used to screen compounds in pre-clinical studies for target organ toxicities as well as, later on, in the development process during clinical trials. The application of proteomics might be expected to lead to a greater understanding of processes involved and explain why particular organs are often affected.

Hepatotoxicity is commonly found not only during the discovery and development of new therapeutic molecular entities but also once drugs have been in widespread use (Holt and Ju, 2010). Indeed, hepatotoxicity is the focus of much published work that aims to explore mechanisms of drug-induced toxicity (Russmann, Kullak-Ublick and Grattagliano, 2009). For instance, Dail *et al.* (2008) have illustrated the value of toxicoproteomics in comparison with traditional methods by studying the hepatic response to phenobarbital (PB) toxicity. PB is a well-characterized xenobiotic known to cause hepatotoxicity in the rat. A proteomic approach using LC-MS was applied to identify proteins altered after exposure to PB for 5 days at a dose that did not cause liver damage (as evident by a lack of release of hepatic enzymes into the serum). Protein changes included those affecting P450-mediated metabolism, cell cycle, apoptosis and cellular proliferation. Many alterations in the hepatic protein profile corresponded well to known effects of PB elucidated in previous studies (Dail *et al.*, 2007), and at the same time revealed a large amount of additional information which may help explain the mechanism of PB liver toxicity. The authors suggest that proteomic analysis performed in this way may be useful for the identification of chemicals with carcinogenic potential at an early stage and propose that it may, in combination with systems biology modelling, form the basis of a new screening methodology that can be incorporated into toxicological studies.

The mechanism of hepatotoxicity following acetaminophen (APAP) overdose in mice has been examined by 2D-DIGE. APAP is known to be converted into the reactive metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI), and it is this chemical that is responsible for hepatotoxicity (Ruepp *et al.*, 2002). Using 2D-DIGE treatment with APAP was shown to cause changes in mitochondrial proteins, suggesting a decrease in energy production pathways, an effect that was consistent with a change in the morphology of the mitochondria, as well as the release of chaperonin proteins. Others (Yamamoto *et al.*, 2007) have observed using 2DE-MS and 1H-NMR that the effects of APAP on both human hepatocyte transplanted chimeric mice and normal mice involve pathways of lipid and fatty acid metabolism, glycolysis and energy metabolism, oxidative stress and the tricarboxylic acid cycle.

3.2 Chemical Contaminants in the Environment

Many chemicals released into the environment have the potential to disrupt the normal function of exposed organisms, either through an effect on the

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat216
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

endocrine system or by targeting specific organs. Proteomics have been applied to study the toxicity of such chemicals, particularly those that may cause endocrine disruption, hepatotoxicity and lung toxicity.

Exposure to oestrogens or chemicals with oestrogen-like properties may induce changes in both reproductive and non-reproductive organs, including some persistent molecular alterations (Morgan, Schulkin and Pfaff, 2004; Verdier-Sévrain *et al*., 2006; Warri *et al*., 2008; Roy *et al*., 2009). Identification of oestrogen-responsive genes and proteins allows an understanding of the molecular mechanisms of oestrogenic activity. Label-free quantitative GeLC-MS has been used to examine the effect of 17β-oestradiol on the human breast cancer cell line, MCF-7, and has demonstrated up-regulation of 55 proteins that together describe an up-regulated pathway consistent with the events of cell proliferation (Zhu, Boobis and Edwards, 2008a). There are many chemicals in the environment that have oestrogenic activity and they are derived from a number of different potential sources including phyto-oestrogens (e.g., genistein), industrial contaminants (e.g., bisphenol A) and organochlorine pesticides (e.g., endosulfan). SELDI-ToF-MS has been used to show that genistein, bisphenol A and endosulfan cause protein profile changes similar to that of 17β-oestradiol in MCF-7 cells. The most responsive proteins were identified as histones H2A, H2B, H3 and H4 (Zhu, Edwards and Boobis, 2009).

Possible mechanisms of hepatotoxicity due to exposure to the environmental pollutants 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) (Sarioglu *et al*., 2006, 2008) and benzo[a]pyrene (BaP) (Shen, Liu and Yu, 2008), as well as microcystins in cynobacteria-contaminated drinking water (Fu, Yu and Xu, 2009), suggest the involvement of a wide range of pathways including regulation of transcription, cell cycle, apoptosis, transport, signal transduction, metabolism, protein degradation and cell differentiation. In particular, the roles played by p53 and PP2A A subunit have implicated the ubiquitin-proteasome pathway in response to microcystins. Interestingly, up-regulation of voltage-dependent anion channel-selective protein 2, which was dependent on the presence of a functional aryl hydrocarbon receptor and an inhibitor of the activation of the proapoptotic protein BAK and the mitochondrial apoptotic pathway, implies an unrecognized mechanism by which TCDD may affect cellular homeostasis and survival (Sarioglu *et al*., 2008). These results aid in understanding hazardous effects of these compounds as well as providing the possibility of the establishment of potential biomarkers.

The potential risk of environmental nanoparticles on human health, particularly in the lung, has been the subject of increased concern in recent years (Asgharian and Price, 2007). Nano-particles present possible dangers, both medically and environmentally. The concerns are that due to their small size they are able to pass through cell membranes in organisms, they have a high surface-to-volume ratio, which can make them very reactive or catalytic, and their interactions with biological systems are largely unknown (Sayes, Reed and Warheit, 2007; Rupp, 2009). Ultrafine carbon black has been suggested to cause oxidative stress and lung injury, but mechanisms have not been clearly demonstrated. A GeLC-MS approach has been used to examine the proteins present in bronchoalveolar lavage fluid following ultrafine carbon black-induced lung injury. This was found to cause an increase in leukaemia inhibitory factor receptor and epidermal growth factor receptor, suggesting an effect on the rate of epithelial shedding from the lung (Chang *et al*., 2007).

In another study the response of rat lung epithelial cells to exposure to acrolein was examined. Acrolein is a highly toxic unsaturated aldehyde that can be formed from the breakdown of certain pollutants in outdoor air or from burning tobacco or gasoline. This chemical was found to produce changes in a diverse range of proteins including those included in all proliferation and apoptosis (Sarkar and Hayes, 2009).

3.3 Food Additives/Contaminants

Two-dimensional PAGE and MALDI-ToF-MS or LC-MS/MS have been used to investigate the effect of feeding rats a betaine-supplemented ethanol diet and have shown the prominent up-regulation of betaine homocysteine methyltransferase-1, methionine adenosyl transferase-1 and glycine *N*-methyltransferase in the liver (Kharbanda *et al*., 2009). Up-regulation of these methionine metabolic pathway enzymes is a protective mechanism by which betaine restores a normal metabolic ratio of liver *S*-adenosylmethionine to *S*-adenosylhomocysteine. Ethanol also caused down-regulation of carbonic anhydrase-III protein

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat216
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

levels which were not restored by betaine supplementation. One function of carbonic anhydrase-III is to moderate the effects of oxidative stress; therefore, reduction in its levels may contribute to ethanol-induced redox stress.

Surface-enhanced laser desorption/ionization-ToF-MS has been used to examine protein profiles of plasma and urine in rats treated with the neurotoxicants such as acrylamide and methylmercury. These chemicals may be present in food, acrylamide being formed from certain cooking processes and methylmercury as a contaminant from industrial sources. Protein ions that vary in intensity with dose and duration of treatment were found at levels of exposure that did not cause neuropathology in rats, suggesting their possible use as protein biomarkers in serum and urine for the assessment of sub-clinical neurotoxicity (Fang, Boobis and Edwards, 2007).

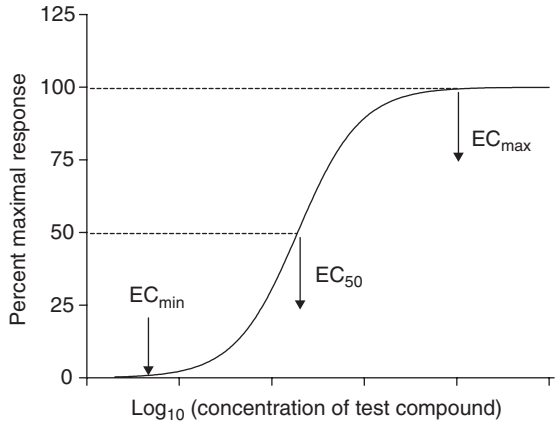

Figure 1. An idealized dose–response curve. EC$_{min}$ is the highest concentration that produces no detectable effect. EC$_{max}$ is the lowest concentration that produces a maximal effect. EC$_{50\%}$ is the concentration that produces a 50% maximal effect.

4 DOSE–RESPONSE RELATIONSHIPS

Proteins that are found to be responsive to toxicants may serve as biomarkers. A useful biomarker would need to possess a number of properties including being mechanistically relevant, sensitive and dose-responsive so that the information can be used to make meaningful risk assessments. Three important parameters can be generated from a dose–response curve. These are the concentrations of the toxicant that produce a maximal response or EC$_{max}$, a half maximal response or EC$_{50}$ and no detectable effect or EC$_{min}$ (Figure 1). The EC$_{max}$ value is important as it indicates the threshold concentration above which no further response to dose can be achieved. The EC$_{50}$ value provides an accurate measure of the relative responsiveness of a given toxicant. The EC$_{min}$ value is the highest concentration that produces no detectable effect and is otherwise known as the NOEC. This concentration is important as it provides the basis for risk assessment in combination with an appropriate estimate of a safety margin (Eason and O'Halloran, 2002; Janssen and Heijerick, 2003; Rietjens and Alink, 2006; Van Wijngaarden *et al*., 2007). The introduction of concepts such as thresholds of toxicological concern (TTC) and dose-dependent transitions in mechanisms of toxicity has emphasized the complexities associated with dose–response characterization of chemical exposure, especially low-level exposure to mixtures such as environmental co-exposures (Holsapple and Wallace, 2008). The concept of TTC acknowledges that there are doses of toxicants that are safe (doses that do not elicit a toxic response) and that all chemicals can elicit a toxic response (if the dose is high enough). An improved understanding of dose-dependent transition in mechanisms of toxicity and the need for better study design with suitable choice of doses, particular in the region of the dose transition, will impact on the risk-assessment process (Slikker *et al*., 2004).

Often current testing strategies do not precisely capture transitions in the dose–response relationship, leaving unanswered the critical question of where within the dose–response relationship the transition occurs with respect to other critical reference points, for example actual human exposure or the experimentally derived NOEC. An area of major difficulty is estimating where on the dose–response curve human exposure is likely to be. The central role played by proteomics, more generally as speculated, is emphasized as is the value of dose–response curves in exploring low-level exposure.

Studying dose–response relationships of chemical exposures using proteomics approaches is an extremely challenging task because of complexities arising from the large number of samples to be analysed and the techniques to be used for identification of protein biomarkers to indicate these relationships. For these reasons, there are only a few publications on this aspect. Our laboratory has employed SELDI-ToF-MS to determine dose–response relationships

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat216
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

of chemical exposure on human cells and animals. It has been reported (Zhu, Edwards and Boobis, 2008b) that dose–response relationships of mixtures of oestrogenic compounds such as 17β-oestradiol, genistein, bisphenol A and endosulfan on human breast cancer MCF-7 cells exhibit simple concentration additivity and by measuring the levels of histone proteins is indicative biomarkers of the effects, (Zhu, Edwards and Boobis, 2009). This is perhaps one of the most successful applications of SELDI-ToF-MS in the determination of dose–response relationships of chemical mixtures, partially because the protein biomarkers (histones H4, H2B, H2A and H3) that indicate these relationships have molecular weights around 15 kDa, which are readily detected by SELDI-ToF-MS. As sample preparation for SELDI-ToF-MS is relatively quick and simple, it is possible to analyse many samples in a single batch and so produce sufficient data to construct reasonable dose–response curves, in this case allowing comparison between the effects of several compounds with oestrogenic activity (Figure 2). In another study conducted in our laboratory, SELDI-ToF MS was used to profile rat serum and urinary proteins in response to treatment with neurotoxicants. Proteins that responded to treatment with both acrylamide and methylmercury in a dose-dependent manner were found (Fang, Boobis and Edwards, 2007) and could potentially be used to produce dose–response curves in appropriately designed experiments. However, as the proteins in this study were not identified, mechanistic information is lacking at present. This would need to be addressed to underpin the relevance of proteins to the toxic effect of compounds.

Other methods to identify dose-responsive proteins can also be applied. Kleno *et al*. (2004) have described the application of 2D-DIGE combined with the use of principal component analysis and partial least squares regression to find patterns of hepatotoxic change following treatment of rats with hydrazine at different doses and times. Altered expression profiles in proteins involved in lipid metabolism, Ca21 homeostasis, thyroid hormone pathways and stress response were found. The authors claimed that several of the identified proteins have not previously been implicated in hydrazine toxicity and may thus be regarded as new potential biomarkers of induced liver toxicity (Kleno *et al*., 2004). The robustness of the patterns of changes will need further study to assess their specificity. Also 2D-DIGE is too cumbersome to be applied usefully to routine dose–response assessments. Ideally, amongst the responsive proteins one or two may be found that represent accurately the response of the liver to the toxin.

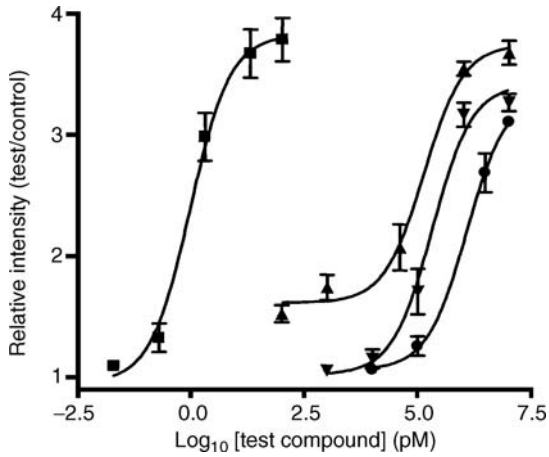

Figure 2. Dose–response curves of oestrogenic effect using histone H4 as a responsive protein to oestrogenic chemicals: 17β-oestradiol (■); genistein (▲); bisphenol A (▼); endosulfan (●).

5 CHALLENEGES AND PERSPECTIVES

The application of proteomics to understand the mechanisms of toxicity by drugs, environmental chemicals and food additives is still at an early stage and a number of challenges exist.

An ideal proteomic approach would enable comprehensive characterization of the proteome of a target organ or tissue in a high-throughput manner. Currently, the proteomic techniques involved are complex, costly and time-consuming. At present, there is no standardized or agreed methodology or platform in place. This is understandable as different methods may be applicable in different circumstances and not one approach is likely to answer all questions asked. However, different methods do vary in their sensitivity and reproducibility and this needs to be appreciated when interpreting such data. The sensitivity of MS instruments may be improved but they are probably close to their maximum detection limits. Methods that increase reproducibility mostly based on the well-established use of heavy isotope labels are being improved (Pan *et al*., 2008). If current technical limitations can be addressed,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat216
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

it will allow workers to perform more suitably designed experiments. Too often, the quality of the proteomic data is limited by the ability to analyse only a handful of samples. Thus, sample numbers are often inadequate making dose–response experiments impractical. At present, there are very little confirmatory data and this needs to be addressed. Techniques such as proteomics that produce a host of changes need to be considered carefully as a proportion of the data will be falsely positive. Standardization of the processes of data handling and interpretation, using statistically-based methods, would be helpful. The development of the tools needed for productive proteomics data analysis is still in its infancy.

It is difficult to attach toxicological significance to observed changes in protein levels. Often it is not possible to determine whether a pattern of protein-expression changes is representative or associated with an adverse event. One way to approach this is to combine information with various studies in a toxicoproteomics database. Integrating protein expression data with traditional toxicity endpoints will provide an increasingly valuable source of information. It should also be possible to combine this information with data from other disciplines such as genomics and metabonomics ('omics' technolgies) as well as epigenetics to develop a systems toxicology approach. The resultant information may be used to elucidate mechanisms of toxicity and biomarkers related to the mechanisms, as well as the identification of potential molecular targets for therapeutic intervention by drugs.

6 CONCLUSIONS

The field of toxicoproteomics is still evolving. The application of proteomics to toxicology is not without its limitations and may not be suitable in all circumstances, but it is anticipated that toxicoproteomics will contribute meaningfully to furthering our understanding of the process of toxicity.

Metabolomics in Systems Toxicology: Towards Personalized Medicine

Laura K. Schnackenberg, Jinchun Sun and Richard D. Beger

Division of Systems Biology, National Center for Toxicological Research, US Food and Drug Administration, Jefferson, AR, USA

1 INTRODUCTION

Toxicology assessments are routinely used in pre-clinical animal studies to evaluate the effects of a potential new drug candidate. Despite the rigorous testing of new drug candidates in the screening and pre-clinical developmental phases, there are still some drugs that have toxicity issues that arise in the clinical testing phase and post-market. The failure of a drug candidate during the clinical testing phase and post-market results in patients that have been treated with a drug that is not completely safe and is an enormous loss to the pharmaceutical company in terms of both time spent in development and overall costs involved with research development (R&D). It is estimated that the cost of developing a new drug candidate is over 1 billion dollars and rising (Harrigan and Yates, 2006) whereas the time for development, testing and ultimate approval by the US FDA averages 8–10 years. However, only one in five new drug candidates actually make it through the approval process, with half failing in phase III clinical testing. This means patients were given drugs that were either not effective or possibly toxic. Therefore, novel and early translational biomarkers of toxicity are needed that will reduce the time and cost associated with drug discovery and approval.

It is clear that the current set of clinical chemistry biomarkers used to diagnose organ injuries have shortcomings. Table 1 shows a list of the currently used clinical chemistry markers and the tissue primarily associated with that marker. These markers are either late biomarkers, meaning that they increase only after significant organ damage has occurred, as is the case for blood urea nitrogen (BUN) and creatinine for renal injury, non-specific in the case of lactate, or not very specific as in the case of alanine aminotransferase (ALT), which can increase due to causes other than liver injury.

Table 1. Clinical chemistry measurements and the tissue primarily associated with that marker.

Plasma measurement	Tissue marker
Albumin	Liver and kidney
Alkaline phosphatase (AP)	Liver
Alanine aminotransferase (ALT)	Liver
Aspartate aminotransferase (AST)	Liver
Bilirubin	Liver
Bile Acids	Liver
Blood urea nitrogen (BUN)	Kidney
Cholesterol	Liver
Creatinine	Kidney
Glutamate dehydrogenase (GDH)	Liver
Glucose	Liver and Kidney
Glutathione-*S*-transferase (GST)	Liver
Lactate	Non-specific
Lipocalins	Multiple
Neutrophils	Multiple
Platelets	Multiple
Sorbitol dehydrogenase (SDH)	Liver

Therefore, the pharmaceutical industry and regulatory agencies have invested significant energy and monetary efforts towards the identification of novel biomarkers of toxicity that can be applied in both pre-clinical and clinical studies. The omics technologies, which comprise transcriptomics, proteomics and metabolomics, are promising platforms for the discovery of new translational biomarkers of toxicity and health status. Additionally, the data acquired using multiple 'omics' platforms may be integrated to obtain a more comprehensive understanding of the toxicity in terms of the molecular pathways affected. Metabolomics and systems biology will not only benefit the field of toxicology but also play a large role in furthering the concept of personalized medicine. Because the metabolome encodes an individual's metabolic phenotype in addition to their genotype, the pre-dose spectrum may be useful in determining how a particular individual will respond to a drug regimen. This chapter will start with a general discussion regarding the role of metabolomics in systems toxicology, followed by some discussion related to metabolomics standards and quality control. Furthermore, examples of pre-clinical and clinical applications of metabolomics in toxicology will be discussed in some detail with an emphasis on recent works in the field. This will be followed by reviews on dynamics and metabolic fluxes, which are specialized areas of metabolomics. This chapter will also cover the role of metabolomics in personalized medicine, which plays an important role in directing medical science towards a greater mechanistic understanding of health, disease and treatment. The significance of metabolomics in the investigation of the complex relationships between drug–drug and drug–nutrition interactions elucidating health maintenance and disease development will be discussed before ending the chapter with a discussion on challenge tests in metabolomics.

2 ROLE OF METABOLOMICS IN SYSTEMS TOXICOLOGY

2.1 Omics Technologies and Systems Toxicology

Systems toxicology has been defined as "the study of the perturbation of biological systems by chemicals and stressors, monitoring changes in molecular expression and conventional toxicological parameters, and iteratively integrating response data to describe the functioning of an organism" (Waters and Fostel, 2004). A systems toxicology approach involves the integration of traditional toxicology endpoints (i.e., clinical chemistry and histopathology data) with data acquired using omic technologies. The omics platforms include genetics, transcriptomics, proteomics and metabolomics, and provide snapshots of the system at various time-points (Fiehn *et al.*, 2000). Figure 1 shows how genetics, transcriptomics, proteomics and metabolomics, are connected and are used to define systems biology or systems toxicology. Genetics relates the inherited genetic code of a patient or other animal species in pre-clinical and clinical testing with health status and responses to medical treatments. Transcriptomics studies changes at the level of mRNA expression; proteomics investigates alterations in protein translations and metabolomics evaluates modifications in the small molecule metabolites following a toxic insult or after a change in health status with the onset of disease. Often the effects of external factors such as environment, age, nutrition, physical exercise, gut microflora and others are neglected when evaluating omics endpoints but these external factors need to be considered as they can affect all the omics analyses. Many metabolites are under homeostatic control in the cell through feedback networks that are shown as dashed lines in Figure 1. Metabolomic profiles are primarily connected with downstream changes in transcription and

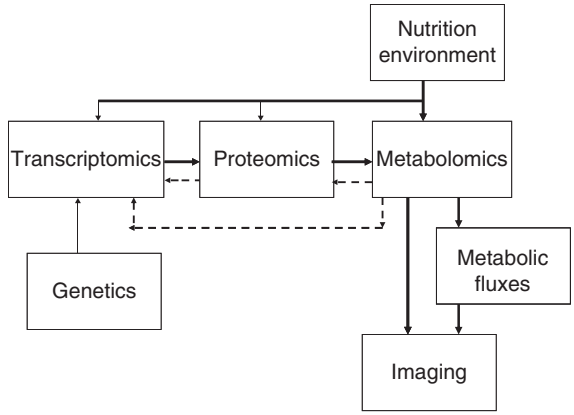

Figure 1. A schematic connection of genetics, transcriptomics, proteomics and metabolomics in systems toxicology.

proteomic changes and also with nutrition and other environmental factors. Because metabolic changes are related to many different inputs, understanding the changes in the metabolome can be challenging. One way is to correlate these changes to transcriptomic or proteomic changes but this is limited by the fact that genomics and proteomic alterations occur on different time scales and usually only one time point is evaluated per animal, which makes understanding dynamical responses in most systems biology experiments hard to achieve. Another way to evaluate the changes in the metabolome is through evaluating flux analysis, which employs isotope-labelled tracers such as U-^{13}C6 glucose to analyse the incorporation of ^{13}C from glucose into metabolites in downstream metabolic pathways. Additionally, some metabolic changes and metabolic fluxes can be evaluated by MRI imaging (Kanamatsu *et al.*, 2007). Metabolomics, metabolic flux analyses and imaging can play a major role in both toxicology studies and the advancement of personalized medicine.

A systems-level understanding of a drug's mechanism of action or toxicity can be obtained through evaluation of the complex interactions between genes, proteins and metabolites together with traditional toxicology and histopathology endpoints. The ability to better understand mechanism(s) and mode(s) of action is beneficial on several fronts. First, a better mechanistic understanding of drug-induced toxicity will allow for the rapid screening of compounds under development earlier in the pipeline. Second, the non-invasive translational biomarkers can be used in pre-clinical and clinical studies. Third, the ability to identify new biomarkers using a systems toxicology approach may make it feasible to identify a susceptible subset of the population that may benefit by avoiding specific drugs.

To implement a systems toxicology approach, a strong bioinformatics component is required. The bioinformatics element is necessary to elucidate biomarkers, pathways and mechanism(s) from the diverse, highly dimensional omics datasets. Furthermore, it is required that traditional clinical endpoints be tied in to the data analysis to generate models and derive mechanism(s) and mode(s) of action. The genetics, transcriptomics, proteomics and metabolomics datasets are usually analysed to determine mechanism and biomarkers of toxicity and disease status. However, there is rarely a direct correlation between the gene transcript for instance and a specific protein or metabolite. The bioinformatics component can assess all the datasets and changes at all levels to fully elucidate the molecular pathway that is operating under a given set of conditions whether it be due to a toxic response or altered health status.

The metabolite changes noted in biofluids and tissue samples are the result of many influences including altered gene expression and environmental changes. However, changes at the transcript level do not cause instantaneous alterations in protein levels or metabolite concentrations; rather there is a time lapse before or after gene activity is altered. Furthermore, there is not necessarily a one-to-one correlation with a particular transcript and associated metabolite(s). Therefore, in order to establish modes of toxicity or mechanisms of disease, it is important to characterize these components at multiple time-points, doses and associated toxicological effects. By evaluating changes in the transcripts, proteins and metabolites at different times, a more complete analysis of pathway perturbations can be accomplished to qualify a particular biomarker or pathway. Once a marker has been proposed, it needs to be evaluated at different times to determine how the biomarker level progresses with recovery or as the disease progresses. Because unfocused metabolomics data are generally obtained more rapidly than the other omics technologies, this platform can be used in studying development and design for systems analyses by determining time-points of interest for the other omics platforms.

Technologies and methods such as metabolic profiling have the potential to identify toxicity early in the drug discovery process, thus protecting patients and saving medical institutions and pharmaceutical companies' resources such as time and finances. As noted previously, the estimated cost and time for developing a new chemical entity (NCE) in 2006 was high with a large attrition rate especially at the phase III clinical testing stage (Harrigan and Yates, 2006). Therefore, a major effort of omics research in toxicology has been in pharmaceutical drug discovery with the goal of identifying new biomarkers of drug toxicity that can be used in pre-clinical and clinical studies (Robertson, 2005). Identification of biomarkers that can accurately detect toxicity in clinical studies remains a high priority because the traditional

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat217
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

markers do not have the accuracy and sensitivity required. More accurate toxicity biomarkers that can be used in pre-clinical drug development and later in clinical trials have the potential to impact pharmaceutical drug discovery by lowering both the cost and time associated with the development and marketing of a NCE, thus improving patients' access to high-quality therapeutics. For example, metabolomics methods were used in a pre-clinical study at Merck on a compound known to cause hepatotoxicity in several species (Mortishire-Smith *et al.*, 2004). Statistical analyses showed that the treated group was distinguished from the control group by the relative depletion of tricarboxylic acid cycle intermediates and the appearance of medium-chain carboxylic acid. *In vitro* experiments with this compound showed it caused defective metabolism of fatty acids. Metabolomics therefore provided mechanistic insight into the hepatotoxicity of a drug. This type of knowledge may be applied in future drug discovery to identify compounds that will also cause hepatotoxicity in the same species.

Metabolomics along with systems biology data also has the potential to further our understanding of toxicity and increase our ability to predict idiosyncratic drug-induced toxicity, which accounts for 6–10% of all adverse drug reactions (Ju and Uetrecht, 2002). An idiosyncratic reaction is defined as "any adverse effect that cannot be explained on the basis of the known mechanisms of action of the drug and occurs mostly unpredictably in susceptible individuals only, irrespective of dosage" (Zaccara, Franciotta and Perucca, 2007). Idiosyncratic adverse drug reactions (IADRs) are not generally diagnosed due to their rare occurrence but are of great concern for the pharmaceutical industry, regulatory agencies and consumers (Zaccara, Franciotta and Perucca, 2007). Furthermore, cause–effect relationships are difficult to establish because IADRs may be produced by many factors that are unique to an individual (Navarro and Senior, 2006). Some of the specific risk factors proposed include underlying disease, differences in nutrition, polypharmacy, individual drug metabolism and bioactivation, inhibition of cell function, age, physical activity, genetics and inherited metabolic defects, and the innate immune system (Ulrich, 2007). These risk factors will also have an impact on an individual's overall metabolome, which may be useful for the prediction of idiosyncratic reactions on a case-by-case basis. Generating more complete omic analyses in many individuals will be necessary to test classification algorithms of IADRs in clinical studies. Analyses of biofluids by metabolomic and proteomic methods would add critical data for the development of personalized medicine. The USFDA has started a biomarker qualification process, which aims to evaluate data for new drug-independent biomarkers and determine whether these biomarkers can be qualified (Goodsaid and Frueh, 2007).

2.2 Metabolomics Platforms

The most commonly used platforms for metabolomics studies have been proton nuclear magnetic resonance spectroscopy (1^{H} NMR) (Clarke and Haselden, 2008; Wei *et al.*, 2008, 2009; Park *et al.*, 2009; Powers, 2009; Um *et al.*, 2009) and mass spectrometry (MS) (Clarke and Haselden, 2008; Dorman *et al.*, 2008; van Vliet *et al.*, 2008). The increase in sensitivity of NMR with the availability of higher field strength instruments along with the introduction of the cryoprobe has made it possible to measure hundreds of metabolites within several minutes. NMR offers other advantages including the fact that all the protons within a molecule are detected the same and the data are highly quantitative by nature. NMR data are also highly reproducible in both intra- and inter-laboratory experiments with less than 2% variation between laboratories using spectrometers with different field strengths. However, there is a great deal of overlap in the metabolite chemical shift resonances, so that it requires 2D NMR experiments or additional techniques such as LC or MS to uniquely identify a metabolite of interest. Furthermore, metabolites present at submicromolar concentrations are not detected by NMR.

Magic angle spinning (MAS) NMR technology makes it possible to analyze intact tissue samples in a non-destructive manner. This technique can be applied to analyse tissue biopsy samples in the clinical setting and allows for a direct link between the biofluid metabolic profile and histopathology. MAS NMR spectroscopy has been demonstrated in metabolic profiling studies of drug toxicity, disease and health. The biochemical composition of intact liver tissue from mice administered acetaminophen (APAP) was

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat217
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

investigated using MAS NMR (Coen *et al*., 2003). The results indicated that there was a possible mitochondrial inability to utilize pyruvate along with an impairment of fatty acid beta-oxidation in the liver. The effects of tamoxifen in endometrial cells were evaluated by Griffin *et al*. (2003) by high-resolution MAS NMR. Several metabolites were affected and together indicated altered RNA transcription and cell membrane turnover. Hydrazine is a compound known to have both hepatotoxic and neurotoxic effects in animals. Therefore, the effects of hydrazine on liver, brain and kidney tissue from Sprague–Dawley rats were evaluated by MAS NMR (Garrod *et al*., 2005) and showed many changes in the endogenous metabolites, including an increase in alanine in all tissues, that may be indicative of a general inhibition of alanine transaminase activity.

Historically, MS and gas chromatographic (GC) methods combined with pattern recognition have been applied for metabolic profiling studies but these approaches targeted specific chemical classes (Lehnert and Hunkler, 1986; Bamforth *et al*., 1999; Chace, Kalas and Naylor, 2002). More recent studies use MS not only to profile specific classes of chemicals but to profile the entire biofluid or tissue sample. Continuing advances in sensitivity and reproducibility of MS technology have led to its resurgence as a popular tool for metabolic profiling. MS detection is generally coupled with an initial separation step usually accomplished by high-performance liquid chromatography (HPLC) or GC methods. Ultra-performance liquid chromatography (UPLC) is another method that has been coupled to MS in metabolomics experiments because of its higher sensitivity and speed over HPLC. MS methods offer greater sensitivity than NMR and the ability to measure metabolites at concentrations down to the picogram level. Because biofluids and tissues contain a wide range of molecules including acidic, basic, amphoteric and neutral components, the ionization method and acquisition parameters will directly influence the types of metabolites that can be measured, making it possible that several experiments will need to be run. For example, if an electrospray source is used, it may be necessary to collect data in both positive and negative ionization modes. Ion suppression or enhancement can also affect quantitation and reproducibility of the MS data. Finally, LC/MS data require reproducibility in both chromatographic retention time and *m/z* mass measurement. Column, flow rate, voltage and gradient conditions can all affect the LC/MS data, making it extremely difficult to make direct comparisons between laboratories.

Although most studies have used either NMR or MS for metabolic profiling, the application of both technologies allows for a more complete characterization of the changes in metabolome that occur in biofluids or tissues. The use of both techniques in tandem on a sample set provides a powerful means of elucidating changes in the metabolome as a result of drug efficacy, toxicity or disease status. These changes can be assessed in terms of the molecular pathways being perturbed and allow for the elucidation of the mechanism(s) at work under a particular set of conditions.

3 METABOLOMICS STANDARDS AND QUALITY CONTROL

There are two types of metabolomics experiments: one is an unfocused approach (a global profiling) that usually involves chemometric analysis of NMR or MS data to determine new biomarkers or patterns of toxicity or health status. The other is a focused metabolic profiling approach when preselected chemical classes (e.g., vitamins, amino acids, bile acids, steroids or lipids) are evaluated and related to health status. In either case, standards and quality control measures are required during NMR, LC/MS or GC/MS data acquisition.

A major challenge in the interpretation of NMR and MS spectral data is in the identification of peaks of interest. Although early studies simply focused upon spectral features that differed between classes, it has become a necessity to identify the chemical that gives rise to a particular spectral feature especially when trying to put forth that feature as a biomarker (Trygg, Holmes and Lundstedt, 2007; Wishart, 2008a). Identification is complicated by the fact that there are few public databases available (Wishart, 2008b). It has been reported that a high-field proton NMR spectrum may contain from 2 to 3000 peaks of which 10% are known and an MS spectrum may contain up to 15 000 peaks of which 5% are known (Clarke and Haselden, 2008). However, these are only estimates and the number of peaks detected and identified depends highly upon the specific analytical technique and sample preparation. The generation of appropriate databases is

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat217
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

a major challenge for metabolomics studies especially with regards to MS in which the spectral data depends highly upon the analytical conditions and chromatography.

In order to generate appropriate databases, there needs to be an agreed-upon set of standards for different types of experiments, samples, etc. The goal of standardization is to optimize the amount and quality of the biological information generated in metabolomics experiments by defining the use of chemometrics and quantitative approaches, defining the best-practice procedures and defining the minimum reporting requirements, such as has already been performed for microarray analysis (Brazma *et al*., 2001). Although the metabolomics standards initiative was formed in 2005 and, in 2007, this group published reporting standards for the metabolomics society and publication in the journal *Metabolomics*, there still remains no set of standards for metabolomics analyses that have been accepted by other journals and the medical community at large (Sansone *et al*., 2007).

Scalbert *et al*. (2009) recently published a review article that addressed some of the issues with MS-based metabolomics approaches. Many of the issues raised apply not only to MS approaches but to NMR approaches as well. In some cases, the issues raised are more problematic in terms of metabolomics studies with human subjects because animal studies can be more stringently controlled. The problems described include: (i) protocols that are not optimized for metabolomics studies, such as uncontrolled diet and time of sample collection; (ii) variations between individuals that are larger than treatment effects; (iii) variation in methods of sample collection and storage; (iv) profiling methods that do not sufficiently cover the metabolome; (v) spectral quality; (vi) MS data that cannot be easily compared between studies or laboratories; (vii) inconsistent results due to data extraction method; (viii) overfitting of data and incomplete reporting; (ix) failure to adequately identify metabolites; and (x) difficult interpretation of changes in metabolomics profiles. The authors suggest solutions and recommendations to address the aforementioned issues, with the biggest commonality among the solutions being related to the need to develop standardized procedures for sample collection, analysis and interpretation that are widely disseminated among the metabolomics community.

4 PRE-CLINICAL AND CLINICAL EXAMPLES OF METABOLOMICS IN TOXICOLOGY STUDIES

4.1 Pre-clinical Studies

There have been numerous examples of the use of metabolomics for toxicology studies. Much of the early work in metabolomics was focused on its use in the pharmaceutical industry as a tool for safety assessment in drug discovery (Griffin and Bollard, 2004; Robertson, 2005). One of the initial and most well-known efforts aimed at applying metabolomics technologies to toxicology was the Consortium for Metabonomic Toxicology (COMET), which was initiated by Jeremy Nicholson at Imperial College (London, UK) along with six pharmaceutical companies. The consortium investigated approximately 150 known toxicants to generate an expert system that could be applied in future drug development studies to determine whether a compound under development had the potential to be toxic especially with regards to liver and kidney function. The final reports of the consortia indicated that models predictive of liver and kidney toxicity were successfully developed and are now being applied by the pharmaceutical companies involved in the consortium in pre-clinical drug development studies (Lindon *et al.*, 2003, 2005; Ebbels *et al.*, 2007; Nicholson, Keun and Ebbels, 2007).

In a review by Robertson (2005), the advantages of metabolomics in toxicology are discussed with regards to its potential impact in the pharmaceutical industry especially in pre-clinical toxicology. Several applications of metabolomics in pharmaceutical development are discussed including screening, biomarker identification and elucidation of mechanism(s) of toxicity. In terms of screening, it has been envisioned that metabolomics can play a role not only as a generic screen of potential toxicity but also as an early screen for biomarkers of toxicity from a compound known to have a particular effect. Robertson *et al.* (2001) have shown metabolomics to be a useful screening tool for drug-induced vasculitis, which usually requires tissue biopsies to detect.

Biomarker discovery has also been a major effort in metabolomics research. The current clinical chemistry measurements generally lack sensitivity and specificity and often only show a significant change when tissue damage has occurred. In contrast, metabolomics along with the other omics

DOI: 10.1002/9780470744307.gat217
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

technologies offers the potential to discover earlier biomarkers of toxicity that have greater sensitivity and specificity. To date, the major focus of biomarker discovery in the pre-clinical setting has been towards the identification of markers of liver and renal toxicity. The early identification of liver toxicity is of interest because it represents the major reason that a drug fails in the later stages of development or is removed from the shelf post-market. There are many recent examples where metabolomics has been used to investigate potential new biomarkers of specific organ toxicity as described below.

Lee *et al.* (2007) used a GC/MS-based approach to investigate the toxicological effects of nonylphenol (NP), an endocrine disrupter. Rats were injected with vehicle, 50 or 250 mg NP/kg for 4 days and urine samples were collected. Two potential urinary biomarkers of NP toxicity were identified related to steroid metabolism. In addition to biomarkers of toxicity that are altered post exposure, it has also been shown that metabolomics studies may be useful in discovering biomarkers of susceptibility. In one study, the metabolic pattern in the urine NMR spectrum prior to dosing rats with APAP correlated with the degree of liver damage found after drug administration (Clayton *et al.*, 2006). Similar results were found in a study of the hepatotoxicant, galactosamine, wherein models built using the pre-dose spectra were able to predict a toxic outcome, which has 0.99 correlation with the post-dose days 2 and 3 clinical parameters ALT and AST (Schnackenberg *et al.*, 2007).

Metabolomics in systems biology also has the ability to elucidate mechanisms of toxicity. A well-designed systems toxicology approach will be able to identify mechanisms and pathways of interest. One of the issues in pre-clinical and clinical research is that often a mechanism is not identified. Metabolomics offers the ability to not only help to identify mechanisms but also discover corresponding biomarkers that can then be used to classify compounds based upon similar mechanisms. Nicholls *et al.* (2007) provided a mechanistic hypothesis to the neurotoxic effects of hydrazine. Their metabolomics analyses revealed an increased level of 2-aminoadipate, which is an intermediate in the metabolism of lysine and tryptophan (Candito *et al.*, 1995) and related to the kynurenic acid levels in the brain. Kynurenic acid is an important endogenous metabolite that antagonizes the actions of glutamate and aspartate and prevents the neurotoxic action of quinolinic acid (Moroni *et al.*, 1988). An NMR-based metabolomics study identified markers that were associated mechanistically with phosphodiesterase type 4 inhibitor-induced vascular lesions in rats (Slim *et al.*, 2002).

One pathway of interest related to drug toxicity is the *trans*-sulfuration pathway, which describes the production of glutathione from S-adenosylmethionine (SAMe). There have been numerous reports that have indicated a role of glutathione in detoxification following administration of a toxic drug dose (Comporti, 1987;Jaeschke, Knight and Bajt, 2003; Martin, Racz and Forkert, 2003; Kaminskas, Pyke and Burcham, 2004; Hudson *et al.*, 2005; McMillan and McMillam, 2006;Zegura, Lah and Filipic, 2006; Lotkova *et al.*, 2007;Saravanan, Sindhu and Mohanakumar, 2007). Our previous studies have shown a decrease in SAMe, which is the primary source of the sulfur group that is donated to produce glutathione, following acute or chronic dosing with APAP (Schnackenberg *et al.*, 2009). These results indicate that the trans-sulfuration pathway may be of great importance in terms of toxicity following administration of a drug that can be biotransformed to a reactive metabolite through cytochrome P450 oxidation. Following formation of the reactive metabolite, a cellular oxidative stress response is initiated to detoxify the reactive species and remove it from the system. Figure 2 shows the pathway from SAMe to glutathione (GSH) and eventually *N*-acetyl-cysteine (NAC) conjugates in the *trans*-sulfuration pathway and how this pathway is directly connected to one-carbon metabolism and folic acid including the roles of vitamin B_{12} and vitamin B_6. Vitamin B_{12} donates its methyl group to homocysteine, which is then converted back to methionine, an important source of methyl groups for several reactions involving SAMe. SAMe is the primary source of sulfur for glutathione (GSH) production which is often used for detoxification of reactive metabolites. Drug–NAC conjugates are the breakdown products of the detoxified drug–GSH conjugates through the reduction of the reactive drug metabolites with GSH. We and others have observed correlations between drug–NAC conjugate levels with clinical chemistry and histopathology results (Wagner *et al.*, 2006, 2007). Reactive metabolites have been reported to be necessary in most drug-induced toxicities but are not sufficient by

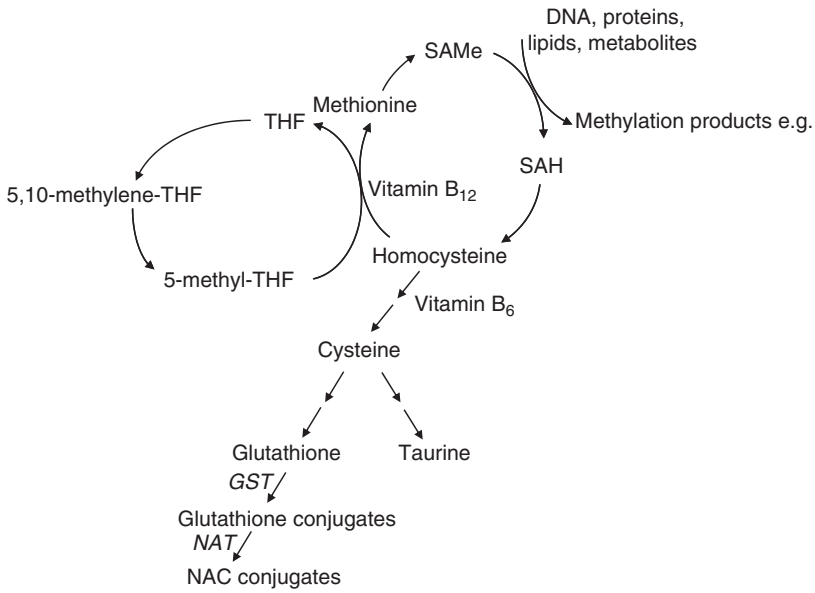

Figure 2. The *trans*-sulfuration metabolic pathways (related to drug toxicity) from SAMe to glutathione and eventually to drug conjugation with GSH.

themselves to cause the toxicity (Walgren, Mitchell and Thompson, 2005). Detection of endogenous or xenobiotic mercapturic acids (MAs) would be useful to monitor the patient more closely in the clinic and possibly supplement the patient with sulfur-containing metabolites such as NAC.

Based on the previous results, perturbations in the *trans*-sulfuration pathway were further assessed through the evaluation of creatine [byproduct of the conversion of SAMe to *S*-adenosylhomocysteine (SAH)], taurine (byproduct of the synthesis of glutathione in the *trans*-sulfuration pathway) and SAMe (Schnackenberg *et al.*, 2009). The results showed that urinary levels of creatine were increased on day 1 or 2 in eight high-dose liver toxicity studies and the taurine concentration in urine was increased in three of five liver toxicity studies whereas SAMe was found to be reduced in four of five liver toxicity studies. Transcriptomic results showed that some genes involved in the *trans*-sulfuration pathway were disturbed, which validated the metabolomics data that *trans*-sulfuration pathway from SAMe to glutathione was perturbed due to the administration of hepatotoxicants. In another liver toxicity study, we utilized the high-throughput LC/MS-based metabolomic assay to investigate APAP and its metabolites excretion profile in urine from rats treated with a single dose of 0.2% carboxymethylcellulose (CMC, vehicle control), 400 or 1600 mg APAP/kg body weight (Sun *et al.*, 2008;Sun, Schnackenberg and Beger, 2009). The results showed that urinary APAP–NAC had high and statistically significant correlations with clinical chemistry data, creatine and histopathology data at 48 h post-dosing. SAMe concentration alterations were also detected as inversely proportional with urinary APAP–NAC concentration changes in this study. A high concentration of urinary SAMe indicated low level of urinary APAP–NAC. All these liver toxicity studies suggest that metabolomics techniques are very useful to access the potential toxicity of a drug through drug metabolite pharmacokinetic profile studies from reactive metabolites and endogenous metabolites involved in *trans*-sulfuration pathway. Additionally, metabolites involved in one-carbon metabolism and vitamins B_6 and B_{12} may be important indicators of overall toxicity status following a toxic insult as noted in Figure 2.

Metabolomics approaches were used to discover biomarkers of nephrotoxicity in Sprague–Dawley rats treated with the nephrotoxins gentamicin, cisplatin or tobramycin (Boudonck *et al.*, 2009). Non-targeted metabolomics analysis was performed on urine and kidney samples collected from rats after 1, 5 and 28 dosing days. Increases in urinary levels

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat217
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

of polyamines and amino acids were observed in drug-treated rats after one dose. The changes were seen prior to any observable histological kidney damage and conventional clinical chemistry indications of nephrotoxicity. After prolonged chronic dosing, there was a progressive loss of branched-chain amino acids in urine and a concomitant decrease in amino acids and nucleosides in kidney tissue. The increase of amino acids in urine is consistent with previous studies (Macpherson, Moscarello and Goldberg, 1991; Ghiculescu and Kubler, 2006; Portilla *et al*., 2006; Niemann and Serkova, 2007; Xu *et al*., 2008). Aminoaciduria may have to do with diminished renal reabsorption by the tubules or increased permeability of the glomerular membranes (Macpherson, Moscarello and Goldberg, 1991; van de Poll *et al*., 2004).

To date, there have been few reports of integrated systems biology studies. This may have been due in part to the complexity of integrating and understanding data generated on the three different platforms. In two studies of bromobenzene-induced hepatotoxicity, changes in gene expression, protein expression and select metabolites were analysed (Heijne *et al.*, 2003, 2004). A systems biology study of valproic acid (VPA)-induced hepatotoxicity in CD-1 mice indicated a perturbation in the glycogenolysis pathway (Schnackenberg *et al.*, 2006). Craig *et al.* 2006 utilized a systems toxicology approach to investigate the hepatotoxicity of methapyrilene, a histamine antagonist that causes periportal liver necrosis in rats. The integrated genomics, proteomics and metabolomics results indicated altered energy use as well as oxidative stress following dosing. Recently, Bundy *et al.* (2008) reported a systems toxicology study using cDNA transcript microarrays and NMR-based metabolic profiling to investigate the response to copper in earthworms. Both the microarray and metabolomics results indicated a disruption in energy metabolism especially with regards to carbohydrate use and oxidative phosphorylation. The Liver Toxicity Biomarker Study (LTBS) was developed to investigate drug-induced liver injury using omics technologies (McBurney *et al.*, 2009). The differences in molecular events caused by two compounds with similar structure and mechanism of action but with different hepatotoxic potential were evaluated (McBurney *et al.*, 2009). The first phase of the study using entacapone and tolcapone as the model compounds yielded potential markers and, more importantly, illustrated the value of a systems approach.

4.2 Clinical Studies

There have been numerous examples of clinical metabolomics in toxicology assessments. Following organ transplant, some patients have toxic reactions to cyclosporine, which is an immunosuppressive drug frequently prescribed to prevent rejection. Several studies have investigated the metabolic changes in urine to detect biomarkers of cyclosporine cytotoxicity. Serkova and Christians (2005) investigated the metabolic effects of cyclosporine using an NMR-based approach. Spectra from urine were acquired following dosing with cyclosporine alone and in combination with other immunosuppressants, sirolimus or everolimus, to determine the effects of co-administration on the nephrotoxic effects of cyclosporine. Treatment with cyclosporine resulted in increased levels of glucose, hydroxybutyrate, creatine, creatinine, trimethylamine-*N*-oxide (TMAO) and cholesterol and a decreased concentration of glutathione. Co-administration of cyclosporine with sirolimus resulted in an enhanced toxicity, whereas co-administration with everolimus showed some protection against the cyclosporine toxicity based upon the acquired metabolic profile. Metabolomic approaches have been used to access other aspects of health. For example, Constantinou *et al.* (2004) developed rapid methods for detection of inborn errors of metabolism using metabolomics methods. It was also shown that metabolomics could be used to detect and assess the severity of coronary heart disease in a clinical setting (Brindle *et al.*, 2002). Brindle *et al.* (2003) also showed a link between serum metabolic profile and hypertension.

5 DYNAMICS AND METABOLIC FLUXES

A major initiative of systems biology is to obtain a better understanding of the integrated omics data (Kell, 2006). Much of the omics emphasis is on the individual collection of transcript, protein or metabolite changes with very little value placed on the system as a whole and the dynamical interaction of transcripts, proteins and metabolomics. As metabolomics data can be obtained easily over

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat217

multiple time-points, it offers an opportunity to gain dynamical systems biology information. Figure 3 shows the nine possible states for transcript levels and metabolites at any point in time. Most of the time, many transcripts and endogenous metabolites in tissues and blood are under homeostatic control, which is the centre of the diagram. However, at any one time, genes can be expressed at higher or lower levels and metabolites can be either up- or down-regulated. If a gene and the genes' corresponding metabolite are significantly increased, this would be an in-phase increase in the pathway at that time-point. Conversely, if a gene and a metabolite directly associated with that gene are both reduced, this would be an in-phase decreased pathway at that time-point. As the metabolites are downstream of the gene changes, the temporal response of the gene to associated metabolite changes would reveal whether the system is overdamped (tightly controlled), underdamped (loosely controlled) or critically damped. Diabetes is an example of an underdamped system between glucose and insulin. These are not the only scenarios, there will be time-points where the genes are up but the metabolites associated with that gene are down, which could represent a slow response to return the metabolites to their homeostatic levels. Alternatively, the metabolites in a gene pathway may be increased while the gene is decreased and this would be an alternative out-of-phase response. Gene transcripts and metabolites may be out of phase because of different time lag responses and the timing and effectiveness of feedback loops. Usually, metabolites are directly affected by more than one gene, so there is no one-to-one correspondence and the system biology response is connected to timing and nutritional value of dietary intake.

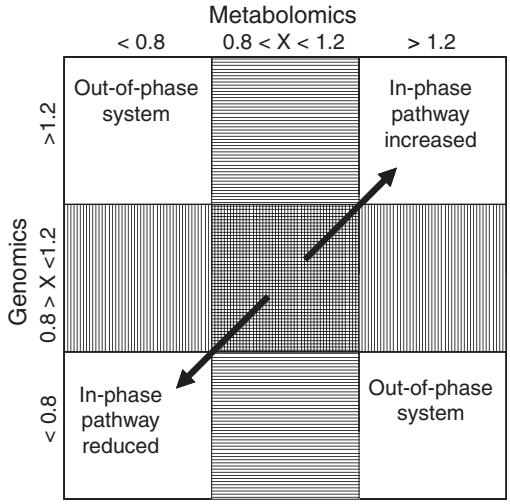

Figure 3. A dynamic relationship between transcript levels and metabolites at any time-point.

In the four cases described above, omics data represent snapshots in time of genes, proteins and metabolites that are changing in response to an agent and they will usually return to homeostatic levels provided no permanent organ damage or health status changes have occurred. However, the one time-point may not be enough to determine whether the system is underdamped, overdamped or critically damped. The dynamical route back to homeostasis will be different for each gene, protein and metabolite, which is why one time-point systems biology analyses are so hard to reproduce and mechanistically interpret. One of the biggest challenges for systems biology will be connecting transcriptomics, proteomics and metabolomics data to form consistent integrative mechanistic understanding of toxicity and health status. If one finds in-phase correlations between transcripts, proteins or metabolites in tissue or blood, this is usually a significant, interpretable finding. One way to improve the chance of finding usable metabolomics biomarkers is to use biofluids such as urine which is collected over a time period (usually 24 h). The metabolomics analysis of urine allows biomarkers to be built up over time, and therefore there is less dependence on a single time-point from one animal but the down side is there is less likely to be a significant in-phase correlation of the metabolite biomarkers with gene transcripts or proteins detected in tissues.

A potential way to better understand the dynamics of system biology at this level is through the analysis of metabolic fluxes (Marin *et al*., 2004). Metabolic flux analysis involves a labelled metabolite (usually ^{13}C-labelled glucose) and measurements of ^{13}C-labelled products over time. In this way, the kinetic analysis (turnover) of the metabolites can be determined. The addition of transcriptomics or proteomics flux data will increase our dynamic understanding of specific pathways (Zhao *et al*., 2009).

Metabolic flux analysis of ^{13}C-labelled glucose has been used to determine the turnover of select metabolites to develop biomarkers of toxicity, efficacy and disease states that can be used in

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

pre-clinical and clinical studies (Lee *et al*., 1998; Boren *et al*., 2003; Marin *et al*., 2004; Boros *et al*., 2005; Beger *et al*., 2009; Kominsky *et al*., 2009). We have used ^{13}C glucose fluxes to evaluate the effect of VPA (Beger *et al*., 2009). Briefly, we observed that ^{13}C-labelled glucose deposited as liver glycogen or as ribose of RNA was decreased by VPA treatment and incorporation of ^{13}C via acetyl CoA into plasma cholesterol was significantly lower at 60 min. The flux markers, as well as decreased glucose re-absorption and an increased disposal via urine, all serve as early flux biomarkers of VPA-induced adverse metabolic effects in mice. These observations are consistent with our previous metabolomics analysis of VPA (Schnackenberg *et al*., 2006).

6 METABOLOMICS IN PERSONALIZED MEDICINE

Personalized medicine is based on the concept that a person's genetic information can be used to predict whether that individual will respond favourably or adversely to a drug or medical therapy (Nebert and Vesell, 2005; van der Greef, 2005;van der Greef, Hankemeier and McBurney, 2006; Schnackenberg and Beger, 2006). Based on this genetic information, health care professionals would be able to determine the optimum drug and drug regimen for each patient. The ability to tailor therapies to an individual would result in more effective medical treatments when avoiding or reducing adverse drug reactions. Considerable effort has been made to use genetic information, especially with regard to single nucleotide polymorphisms (SNPs), for individualizing medical therapies (Nebert, Jorge-Nebert and Vesell, 2003; Nebert and Vesell, 2005). However, most SNPs tests do not predict an individual's response because a single gene acts in concert with other genetic and environmental factors; that is, SNPs are context specific (Helgadottir *et al*., 2006). A person's phenotype results from the action of many genes and their interactions with environmental factors that include, for example, nutrient intake over the lifetime of the individual. Other external factors such as diet, antioxidant status, energy status, gut microbiota, health status, alcohol consumption, BMI and age will influence the expression of one's genetic potential. Therefore, the ability to accurately assess an individual's genotype and phenotype will be a critical component in determining the correct drug treatment or the potential response following a therapeutic intervention. The phenotypic make-up of an individual may provide a more relevant and current picture of how an individual may respond under a given set of circumstances. For instance, many drugs and alcohol are known to interact with other drugs adversely (Gorard, 2006;Phillips, Barker and Eguchi, 2008). Metabolomics has the potential to provide information about the patient's genotype and phenotype because it represents the interaction of gene and environment and this interaction can be monitored over time.

The omics platforms have generated data that can be related to mechanisms of disease or drug toxicity and drug efficacy (Fiehn, 2001; German *et al*., 2004). These research platforms will lead to new opportunities for personalized health because they add additional details that can improve our current knowledge about the health and disease continuum. A major advantage of metabolomics is that it can be collected from a patient's biofluid samples, which can be gathered over a period of time or throughout the lifetime of the patient. The drawback of metabolomics is that the markers from biofluids are less likely to be directly related to a specific tissue (Jordan and Cheng, 2007;Spratlin, Serkova and Eckhardt, 2009) and one may need additional information such as imaging to determine the source of the biofluid biomarkers. Of the omics platforms, metabolomics has the potential to greatly impact personalized health due to its ability to provide complementary information to one's genetic profile. This information contains information on phenotype characteristics such as age, nutritional status, polypharmacy, alcohol usage and other phenotype characteristics that can be combined with genetics and related to drug efficacy, drug toxicity and drug clearance. Therefore, biomarkers will need to be utilized based on a patient's age, gender, genetic and other characteristics. The metabolic phenotype information has been referred to as "metabotype" of individuals or populations (Holmes, Wilson and Nicholson, 2008). The pool of metabolites detected in biofluids and tissues at a given time will be affected not only by genetic and environmental factors but also by factors such as homeostasis, which tends to limit metabolic changes to short periods. Specific ways on how to deal with homeostasis will be discussed later. Regardless, the

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat217
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

combination of genetic and phenotypic factors is likely to be the most descriptive aspect in determining whether an individual may experience an adverse drug reaction or respond favourably to a drug. Furthermore, the ability to link changes in the metabolite profile with genetic factors using a bioinformatics approach should elucidate mechanism(s) of drug efficacy and toxicity. Combining these platforms will lead to a more precise characterization of an individual's genotype and phenotype characteristics, which should enhance the probability of success for personalized medicine (Hall *et al*., 2002; Griffin, 2003; Ippolito *et al*., 2005).

Metabolomics has the capability to capture the metabolic profile at a given point in an individual's life, which is dynamic throughout the lifespan. We have shown in two pre-clinical age-related toxicity studies that there were similar metabolic urinary changes in control rats as a function of age (Espandiari *et al*., 2007, 2008). We observed changes in ketone bodies, metabolites involved in the Krebs cycle, amino acids and hippurate as a function of age in control rats in these studies. In the clinic, it will be necessary to associate these point-in-lifetime measurements with phenotype conditions that will affect how a patient responds to a medical treatment to develop the concepts and biomarkers needed for personalized medicine. For instance, how does antioxidant status affect drug toxicities that are caused by reactive metabolites and oxidative stress? Are the effects of antioxidants age or disease dependent? Analysing an individual's metabolic profile will be an essential component for detecting drug elimination and drug metabolism pathways, and assessing the effectiveness or toxicity of a particular medical treatment. It has been hypothesized that genomics, transcriptomics, proteomics, metabolomics and omic responses to challenges may be applied for sorting a patient population into those who would respond favourably, those who would not respond or those who would have an adverse response to a given medical treatment. For those patients classified as non-responders or at risk of adverse reactions, lower doses or alternate treatments could be used.

The incorporation of metabolic profiling data into the concepts and methods of personalized medicine will present substantial challenges given the vast genetic and dietary variation among the human population. The analyses of complex gene–environment interactions will require genetic and metabolic characterizations for each individual in greater depth than has been performed in any study to date. Such in-depth analyses will need to be carried out in several large studies to determine the validity of genetic and metabolic biomarkers due to the tremendous amount of genotype–phenotype interactions possible. Among the confounding factors for linking metabolic biomarkers to effects in specific organs is the fact that the concentrations of endogenous metabolites in biological fluids are linked to dietary intake. Because the majority of endogenous metabolites are used in most cells, very few metabolites can serve as a biomarker specific to a select organ. One approach that may address this complexity is to use patterns of metabolites as markers. Another approach is to use stable non-radioactive labelled tracers such as U-13C6 glucose to analyse downstream endogenous metabolic products related to specific pathways (Boros, Brackett and Harrigan, 2003; Harrigan *et al*., 2006; Maguire *et al*., 2006). In addition to providing pathway information, metabolic fluxes may also be associated with evaluating drug efficacy or toxicity for a given patient non-invasively using techniques such as magnetic resonance imaging (MRI) or magnetic resonance spectroscopy (MRS) (Wang and Yan, 2008).

Recent literature has shown that genetics and environmental factors, including the gut microbiota, interact to produce outcomes following a drug intervention or dietary alteration (Nicholson, Holmes and Wilson, 2005). The review described how the composition of the gut microbiota can be affected not only by diet but also by other environmental factors such as stress, which can lead to altered metabolism. Therefore, it is necessary to understand the function of the gut microbes to understand how they might also affect human health. NMR-based metabolomics has shown that even on a controlled diet, there is variation in the urine and plasma samples collected from healthy male subjects (Lenz *et al*., 2003). Within the subject population, minor variability was observed between inter-individual plasma samples but significant variability was observed between urine samples from different individuals over a 2-week study. The inter-individual variability in urine samples may have been due to dietary and gut microflora differences as noted in the review (Nicholson, Holmes and Wilson, 2005). Although the intra-subject variation in urine samples was much less, clear diurnal effects were noted. The alterations in urinary metabolites

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat217
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

may reflect each individual's effort to maintain homeostasis in the plasma. This study reiterates the necessity of understanding the effects of diet and gut microbiota compositions because these may directly affect urinary metabolite biomarkers of drug toxicity. In another study, dietary and cultural effects on the metabolic profile have been examined and shown to influence the metabolic profile in urine (Lenz *et al*., 2004). In particular, cultural differences were noted between Swedish and British volunteers primarily based upon the dietary preferences, with the Swedish subjects excreting large amounts of trimethylamine-*N*-oxide due to their preference for a fish diet. This study indicates the strong influence of diet and stresses on the importance of dietary and/or lifestyle restrictions during clinical trials where possible. Dumas *et al*. (2006) also examined the metabolic profiles of individuals from several different regions in a large-scale epidemiological study and showed cross-population differences related to genetics, diet and gut microbiota composition using NMR. Holmes *et al*. (2007) recently reported an epidemiological study that addressed the large-scale population use of prescription and non-prescription drugs. NMR-based analysis was used to screen populations for self-administered drugs. The metabolic profiles were significantly influenced by dietary habits of the countries and this information may play a role in personalized medicine. Assfalg *et al*. (2008) showed that the day-to-day variability in the urinary metabolic profile could be removed by analysing multiple samples from the same individual over several months. Various algorithms identified invariant components, which were not only distinct but also reproducible for each healthy individual over the time of the study. Therefore, it appears that a process for eliminating daily metabolic "noise" from single individual and individual metabolic phenotypes now exists. These studies indicate that for an individual, the metabolic profile is relatively stable unless perturbed by drugs or changes in health status.

There are two potential general applications of metabolic profiling data in relation to personalized health. Metabolites and proteins from biofluids can be analysed before a patient receives a medical treatment and used with a metabolomic and protein phenotype database to discover biomarkers associated with favourable response to the drug. Some of these metabolic markers can be used as susceptibility markers to help identify patients who may develop IADRs, which has been called pharmacometabotyping or pharmacometabonomics (Clayton *et al*., 2006). Alternatively, biofluid samples can be obtained during drug treatment for analyzing pharmacodynamics and drug clearance as well as drug efficacy and toxicity markers. Clayton *et al*. (2009) recently published a proof of principle pharmacometabonomics study conducted in human subjects. Samples were collected from 99 healthy male volunteers that ranged in age from 18 to 64 years. Pre-dose urine samples were collected and then samples from 0 to 3 h and 3 to 6 h post-dosing with a therapeutic dose of APAP. Analysis of the pre-dose and post-dose spectra indicated that subjects with high pre-dose levels of *p*-cresol had a lower capacity to sulfonate APAP. It is known that saturation of phase I sulfonation and glucuronidation pathways during APAP dosing can lead to the increased formation of *N*-acetyl-*p*-benzoquinone imine (NAPQI), the toxic metabolite of APAP. A patient with lower capacity for APAP sulfonation could be more susceptible to forming NAPQI and having an adverse event. In addition to demonstrating the pharmacometabonomic approach in human subjects, this study also demonstrates the role of the gut microbiome and how it might be manipulated to improve drug efficacy and reduce adverse events.

Phase I and phase II clinical trials may be the optimal settings for evaluating metabolites in biofluids because control of diet and other patients' activities can be implemented. The ability to control diet or other confounding factors such as time of sample collection would aid the interpretation of the metabolic analyses. Dimensionality reduction algorithms (Motsinger and Ritchie, 2006) could be employed to analyse these metabolomic datasets with data from genetic analyses of candidate genes (Bauchet *et al*., 2007;Zembrzuski, Callegari-Jacques and Hutz, 2006). Such analyses may identify the critical biomarkers or pathways that need to be evaluated in phase III and IV trials besides identifying individuals that should or should not participate in phase III and IV trials. Generating "training sets" of single or multiple metabolites would allow for validation of biomarkers in phase III trials and potentially provide valuable information for the drug label.

The concept of using metabolomic data to determine susceptibility prior to dosing has been described as "pharmaco-metabotyping" (Clayton *et al*., 2006). This landmark paper demonstrated the

importance of phenotype analyses in predicting a toxic outcome following administration of APAP. The pre-dose urine spectra correlated with the degree of liver damage found after administration of APAP. The authors reported higher levels of pre-dose taurine correlated with lower degrees of liver injury, which can be explained in terms of the known protective effects of taurine or the availability of inorganic sulfate that is used to form APAP sulfate. We have produced similar pharmacometabonomic models in a study of the hepatotoxicant galactosamine. Models built using the pre-dose spectra of four rats were able to predict a toxic outcome and clinical chemistry parameters (Schnackenberg *et al*., 2007). Analysis of the models and spectra revealed that most of the metabolites in the Krebs cycle were down-regulated in the urine from rats that had increased susceptibility to galactosamine-induced liver toxicity. A GC/MS-based pharmacometabonomic approach demonstrated that metabolite pools resulting from physiological and environmental changes play a major role in how different interventions are closely associated with variation in pre-dose (baseline) urinary metabolic profiles of rats (Li *et al*., 2007). These studies have shown that many factors can impact a patient's pharmacometabonome and metabolomics should play a role in personalized medicine (Haselden and Nicholls, 2006).

7 DRUG–DRUG AND DRUG–NUTRIENT INTERACTIONS

Metabolomics can also be applied to study polypharmacy, which is described as the concurrent use of multiple medications in a single patient. Polypharmacy is of special interest for the FDA due to the fact that drug–drug interactions can increase the negative consequences of a drug, i.e. its potential toxicity (Phillips, Barker and Eguchi, 2008). Detecting and monitoring drug intake and changes in metabolism in polypharmacy studies can be particularly problematic due to the easy access to many over-the-counter drugs in addition to those that have been prescribed. Metabolomics can provide a suitable analytical platform to monitor the exogenous metabolic profile in an individual. Drug–drug adverse interactions are becoming more prevalent, especially in the elderly where the number of polypharmacy patients (those taking more than five drugs concurrently) is increasing (Gorard, 2006). This is a problem because the use of multiple medications increases the risk for drug-related adverse events and drug interactions. For example, many antidepressants are metabolized by CYP2D6 or inhibit CYP2D6 and therefore can lead to drug interactions that can increase the possibility of adverse events when multiple antidepressants are taken simultaneously (Pollock *et al*., 1996). Many HIV antiretrovirals are metabolized by CYP2D and have shown adverse drug interactions (Dickinson, Khoo and Back, 2009). Additionally, the use of multiple medications creates a more complicated drug regimen for the medical staff and patient, potentially making compliance more difficult. Similarly, it has been demonstrated that patients who perceive they are taking too many medications are less likely to comply with their drug regimen. Furthermore, taking multiple medications may confound the effects of one or more of the drugs and the likelihood of drug interactions increases with the number of drugs taken simultaneously. In a patient taking multiple medications, a prescriber may not be able to distinguish which medications are helping, and which are causing adverse events in the patient. In addition, each drug could lower the availability of certain metabolites such as SAMe, glutathione or vitamins that are needed for protection against potentially harmful drugs (Sun *et al*., 2008; Wopereis *et al*., 2009). Most drug–drug interactions are primarily caused by one drug either inhibiting or inducing the enzymes that metabolize the other drug. When this occurs, idiosyncratic reactions could occur that may be responsible for idiosyncratic drug toxicities. Metabolomics can be used in monitoring polypharmacy and for personalized medicine because it has the ability to monitor multiple drug levels based on xenobiotic and endogenous metabolite levels at the same time. Therefore, metabolomics can provide information on pharmacokinetics and the underlying metabotype of the patient that is being medically treated.

Polypharmacy does not only refer to a prescribed drug regimen but can be expanded to include the concurrent use of any of the following: prescribed drugs, over-the-counter drugs, alcohol or street drugs. The death rate in the United States due to fatal medication errors (FME) combined with alcohol and/or street drugs rose 3196% from 1983 to 2004 whereas the death rate due to non-domestic FME not involving alcohol or street drugs increased only 5%.

During this time, the number of per capita prescriptions increased 73.6%, so drug adverse interactions with alcohol and illegal drug stressors are most likely to be responsible for this alarming increase in FMEs (Phillips, Barker and Eguchi, 2008). Again, metabolomics could play a role in understanding these adverse drug interactions by monitoring multiple drug levels and many important endogenous metabolites.

Drug–nutrient interaction is another area where metabolomics can play a role. Nutritional needs vary with specific medication, gender, gut microflora and age (Blumberg, 1997; Drewnowski and Warren-Mears, 2001; McKevith, 2005; Kennedy, 2006; Baker, 2007; Rivlin, 2007), making it necessary to monitor nutrient intakes and physical activity over long periods of time, which is a distinct challenge for analysing the nutrient–drug interactions. Many biologically relevant nutrients in a diet are present at low concentrations and can be affected by chronic exposures to drugs and malnutrition. Because the effects of an unbalanced diet are cumulative, these nutritional imbalances can become biologically relevant and are known to play a role in the development of certain diseases such as cancer and diabetes (Block *et al*., 2000; Krebs-Smith and Kris-Etherton, 2007; Moore *et al*., 2008). To date, metabolomics has the capability to detect hundreds of metabolites simultaneously, and it is expected that similar nutrition interactions will be found not only for disease states such as cancer and diabetes but also for identifying nutrient interactions in drug toxicity.

Technological advances in analytical instrumentation make it feasible to analyse hundreds of metabolites accurately, providing the ability to assess the effect of certain nutritional factors on personalized health. The relatively new field of nutrigenomics (Whitfield, German and Noble, 2004; Gibney *et al*., 2005; Kaput *et al*., 2005; Zeisel *et al*., 2005;Kussmann, Raymond and Affolter, 2006; Trujillo, Davis and Milner, 2006) analyses gene–nutrient interactions using transcriptomics, proteomics and metabolomics technologies to better understand the effects of nutrition on health status and drug toxicity. The liver is the primary organ responsible for processing both dietary and xenobiotic components and for phase I and phase II drug metabolism. Many liver cytochrome P450 enzymes can be either activated or suppressed by bioactive nutritional components or other drugs, and these interactions can affect drug metabolism and drug clearance from the liver (Walter-Sack and Klotz, 1996;Harris, Jang and Tsunoda, 2003; Murray, 2006; Murray and Petrovic, 2006; Nekvindova and Anzenbacher, 2007). Therefore, nutritional and metabolic status may be an important factor in determining whether a toxic reaction occurs in the liver and, if so, the capability of the patient to overcome the toxic episode (Kaput *et al*., 2007).

Many nutrigenomic studies have demonstrated that diets interact with gene variants to produce different phenotypic outcomes (Veech, Eggleston and Krebs, 1969; Djuric *et al*., 2001; Duffy *et al*., 2001). For example, some ingredients in foods inhibit or activate gene expression (Harris, Jang and Tsunoda, 2003; Milner, 2004; Ross, 2007). Grapefruit juice (Bailey *et al*., 2000;Bailey, Dresser and Bend, 2003; Arayne, Sultana and Bibi, 2005; Saito *et al*., 2005; Sica, 2006) has been shown to affect many drugs through inhibition and/or inactivation of CYP3A4 in the intestine and at high enough doses in the liver. Recent reports suggest that the active ingredients in grapefruit juice inhibit intestinal CYP3A4 activity (Bailey *et al*., 2000;Bailey, Dresser and Bend, 2003). Other citrus juices have also been shown to affect drug metabolism of certain compounds (Saito *et al*., 2005). Metabolomics has the potential to identify the ingredient(s) in grapefruit juice and nutrients that alter CYP3A4 activities. Garlic is shown to have the ability to induce CYP3A4, which can interact with drugs such as saquinivir (an HIV protease inhibitor) and decrease exposure (Harris, Jang and Tsunoda, 2003). Other effects of some chemicals in food include delaying gastric emptying time, solubilizing the drug by food and digestive fluids, complex interactions between the drug and food components, altered hepatic blood flow and modulation of drug-metabolizing enzymes (Harris, Jang and Tsunoda, 2003).

Other nutrients can also alter drug pharmacodynamics; a prime example in this case is the effect of foods rich in vitamin K and warfarin activity. The liver uses vitamin K to produce prothrombin and this can change the effectiveness of warfarin. Foods that are high in vitamin K can decrease the effects of warfarin, whereas consuming less vitamin K can increase the effect of warfarin (Suttie, 1990; Booth and Centurelli, 1999; Merli and Fink, 2008). Warfarin activities can also be affected by alcohol (Sellers and Holloway, 1978; Weathermon and Crabb, 1999) and many herbal supplements

(Izzo and Ernst, 2001; Hu *et al*., 2005; Shalansky *et al*., 2007). In one study, a longitudinal analysis of the risk of warfarin-related bleeding events with the co-administration of complementary and alternative medicine was evaluated. The risk of bleeding was associated with use of cayenne, ginger, willow bark, St John's wort and coenzyme Q(10) (Shalansky *et al*., 2007). Moon, Wang and Morris (2006) recently reviewed the effects of flavonoids on cytochrome P450 and other phase II enzymes involved in the metabolism of xenobiotics. The flavonoids are prevalent in vegetables, nuts, fruits and beverages including coffee, tea and red wine (Hollman and Katan, 1997). Flavonoids play a potentially protective role against cancer (Shih, Pickwell and Quattrochi, 2000) and can inhibit the activities of many enzymes including cytochrome P450 enzymes involved in phase I metabolism (Moon, Wang and Morris, 2006). In addition to the effect on phase I drug metabolism, flavonoids have also been shown to influence enzymes involved in phase II drug metabolism (Harris, Jang and Tsunoda, 2003; Moon, Wang and Morris, 2006). Dietary effects of flavonoids have been noted for enzymes including uridine diphosphate glucuronoyltransferases (UGTs), glutathione-*S*-transferases (GSTs) and quinone reductase (Moon, Wang and Morris, 2006).

The influence of nutrients on drug metabolism is exemplified by the various antioxidants in the diet, which apparently ameliorate toxic reactions to some drug compounds (Waters *et al*., 2001; Han *et al*., 2006). APAP is responsible for 50% of all drug-induced acute liver toxicities in adults (Lee, 2004; Amar and Schiff, 2007). Glutathione and taurine are sulfur-containing antioxidants that can reduce or prevent APAP-induced drug toxicity by binding to NAPQI, the toxic metabolite of APAP (Bessems and Vermeulen, 2001). Our previous studies have shown that the precursor for glutathione, SAMe, is also significantly lowered in urine samples after dosing with APAP (Sun *et al*., 2008; Schnackenberg *et al*., 2009). Therefore, dietary components that would increase the levels of antioxidants and SAMe could potentially help protect a subject from APAP toxicity. Pre-treatment of mice with the peroxisome proliferator, clofibrate, have been shown to protect against APAP-induced hepatotoxicity. Clofibrate-mediated hepatoprotection is associated with increased VANIN-1 and increased cystamine synthesis; cystamine is a potent antioxidant capable of ameliorating APAP toxicity in rodents and humans (Moffit *et al*., 2007).

Antioxidants may play a role in drug toxicities and health status. Ascorbic acid (vitamin C) is an important antioxidant that is involved in immune system functions, synthesis of carnitine and catecholamines, and absorption of iron in the body (Sies, Stahl and Sundquist, 1992; Arrigoni and De Tullio, 2002). Because vitamin C is only obtained through the diet, its concentration will vary greatly from person to person and from day to day within an individual. Vitamin D and calcium supplementation in diets have been shown to significantly reduce cancer incidence, and associated serum level of 25-hydroxyvitamin D was noted to be a predictor of cancer risk. (Lappe *et al*., 2007). Vitamin E has been shown to protect against cisplatin toxicity (Salganik, 2001; Leonetti *et al*., 2003; Ali and Al Moundhri, 2006; Ajith *et al*., 2007). Hence, metabolomic methodologies are contributing essential data in studies designed with nutrigenomic concepts and may improve the ability to link dietary exposures with disease development and individual responses to drug therapy.

8 METABOLOMICS OF CHALLENGE TESTS

One problem facing metabolomics is that much of the metabolome is under homeostatic control in the tissue and blood, so subtle temporal changes may be masked by evaluating the samples at the wrong time-point. One proposed way around the homeostatic control issue is to challenge a patient's system and record how they respond at several time-points using clinical chemistry parameters and new technologies such as metabolomics and proteomics (van Ommen *et al*., 2009). An oral glucose tolerance test (oGTT) represents a challenge to a patient and is how type-2 diabetes is commonly diagnosed. Generally in an oGTT, only blood glucose and insulin are monitored over time but new technologies can measure many other relevant changes occurring concurrently in blood. Two groups have recently measured metabolomics responses to oGTTs and shown that many other metabolites are altered during an oGTT challenge. Zhao *et al*. (2009) reported decreases in saturated and monosaturated free fatty acids and acylcarnitines, and increases in bile acids and lysophosphosphatidylcholines. Wopereis *et al*. (2009) reported that metabolites in the glutathione

synthesis pathway showed time-dependent suppression in response to the oGTT challenges, which may be linked to inflammatory modulation that may be further linked to insulin signalling. Another group has reported the lipid response of three people with the same body mass index who were provided a controlled meal that had high lipid content for three consecutive days. They reported that the intra-individual variation within each subject across the 3 days was lower than the inter-individual differences (Zivkovic *et al*., 2009). This lipid challenge study along with the two oGTT metabolic profiling studies showed that detecting metabolic phenotype is possible and could play a major role in personalized medicine.

The ultimate goal of systems toxicology is to integrate data obtained from genomics, proteomics, metabolomics and imaging platforms to better understand the causes and progression of drug toxicity or disease. As an integral component of systems toxicology, metabolomics will have a major impact on personalized healthcare based upon the fact that metabolomics can identify biomarkers with real biological endpoints and provide a global systems interpretation of biological effects, including drug–drug and drug–nutrient interactions, for example.

9 CONCLUSIONS

Metabolomics is relatively new platform compared with transcriptomics and proteomics. Metabolomics requires multiple analytical platforms to detect as many of the metabolites in a tissue or biofluid sample as possible. Due to the wide range of concentrations and tremendous chemical and structural diversity of metabolites, one analytical platform is insufficient. Currently, it has been estimated that only 5–10% of the peaks detected by metabolomics analytical technologies are determined and therefore a lot of work still needs to be done to determine the remaining unknown peaks. Nonetheless, the use of metabolomics in toxicity and personalized medicine studies has the potential to aid systems toxicology studies in providing phenotype and metabolic pathway information. Metabolomics has the ability to deliver non-invasive biomarkers that can be detected early before major organ damage occurs. Pharmacometabolomics is extremely promising in providing markers for a patient's susceptibility to drug toxicity, and will play a pivotal role in personalized medicine. To validate metabolomics biomarkers, it will be important to apply the developed metabolomics standards initiative (MSI). However, significant work is still needed for broader acceptance of the quality control standards for metabolomics (Sansone *et al*., 2007). New sensitive and specific surrogate markers or accepted biomarkers of drug toxicity will facilitate the development of safer drugs at reduced developmental costs by removing drugs earlier in the drug development process. Most endogeneous metabolomic biomarkers of drug toxicity are relatively easily translated so that they can be used in both preclinical and clinical trials. Metabolomics should be used in personalized medicine studies because it can provide complementary information to a patient's genetic code. Genotype, nutritional status and the environment will be critical factors in determining a patient's potential outcome, which is information encoded in his/her pre-dose or pre-treatment metabolic profile. Finding the link between genetics, transcriptomics, proteomics, nutrition and gut microflora in relation to patient health or disease status is an essential component of the FDA's critical path to personalized medicine.

1 INTRODUCTION

Comprehensive metabolomics is clearly distinct from conventional metabolism studies in the sense that it addresses whole cellular activities rather than just focusing on enzymes, reactions, or metabolites in a specific pathway. Metabolomics research currently confronts a problem associated with high-throughput data acquisition technologies, including mass spectrometry, which have facilitated simultaneous detection and quantification of a large variety of metabolite-derivative peaks without appropriate assignment of metabolites (Hall, 2006). To assign the metabolites in the peaks of spectra, we need to survey natural products reported in the literatures, which is a very daunting data collection process. Therefore, in order to feasibly translate peak information to metabolite, we have developed a metabolite database concerning species–metabolite relations called KNApSAcK (Shinbo *et al*., 2004). There are at least three publicly available databases concerning natural products: PubChem (Wheeler *et al*., 2008), KEGG (Kanehisa *et al*., 2008) and KNApSAcK (Shinbo *et al*., 2006). The PubChem database comprises records for over 19.6 million compounds with over 11 million unique structures including small molecules, with particular emphasis on diagnostic and therapeutic agents. The huge amount of information, however, makes it inconvenient to assign metabolites to spectral peaks because no distinction is made on the origin of compounds, for example whether they are synthetic or natural compounds. In KEGG, the metabolic pathways are constructed by interspecies gene relations such as orthologues and paralogues, so metabolite–species relations can be obtained via information on enzymes; however, the KEGG database mainly focuses on metabolites related to well-established metabolic pathways and includes only about 13,000 metabolites. On the other hand, the relationships between metabolites and their biological origins have been addressed systematically in the KNApSAcK database. Here, KNApSAcK database makes it possible to assign metabolites to spectral peaks tractably. In the present study, we review the current

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat218
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

status of KNApSAcK database and its application to metabolomics and introduce multifaceted retrieval system KNApSAcK Family.

2 KNApSAcK DB FAMILY (http://kanaya.naist.jp/KNApSAcK/)

Accumulation of species–metabolite relationships from scientific literature has been started since 2004 by six individuals (K.K, Y.N, H.A, Y.S., M.A and S.K). So we call this project KNApSAcK by taking and rearranging the initial letters of the family names of the members (Shinbo *et al*., 2004). The additional letters pc means the database can be accessed and used by a personal computer in the situation that databases including all phytochemical metabolites still need to be constructed through collaboration among scientists who have undertaken the task of constructing databases for plant secondary metabolites.

The KNApSAcK package when installed on the user's computer provides tool for analysing his/her own datasets of mass spectra that are prepared according to a particular format, as well as for retrieving information on metabolites by entering the name of a metabolite, the name of an organism, molecular weight or molecular formula. A list of metabolites that are associated with a taxonomic class can be obtained by searching with the taxonomic name, from which information on individual metabolites can be retrieved. Detailed manual can be obtained from the following URL: http://kanaya.aist-nara.ac.jp/KNApSAcK/Manual/KNApSAcKManual.html, and Web Version of Keyword search is provided at http://kanaya.naist.jp/knapsack_jsp/top, which makes it possible to link any website to KNApSAcK core database as indicated in the following examples. (i) Information on the metabolite assigned to C00000001 (a C_ID) can be retrieved by http://kanaya.naist.jp/knapsack_jsp/info.jsp?sname=C_ID&word=C00000001 and the reported metabolites in *Bacillus* (an organism) can be retrieved as http://kanaya.naist.jp/knapsack_jsp/info.jsp?sname=organism&word=bacillus.

Currently we have accumulated 76,357 species–metabolite relations involving 37,693 metabolites (last update: August, 27, 2009) and noted a power law relationship between the number of species and the associated number of metabolites (Figure 1). In a previous study (Shinbo *et al*., 2006), we observed the power law distribution for the number of species and the number of metabolites in each species. It is noteworthy that the metabolic pathways of individual organisms also follow the power law, i.e., the probability $P(k)$ that a metabolite interacts with k other metabolites in the metabolic pathway decays as a power law, following $P(k) \sim k^{-r}$, where r is constant (Ravasz and Somera, 2002).

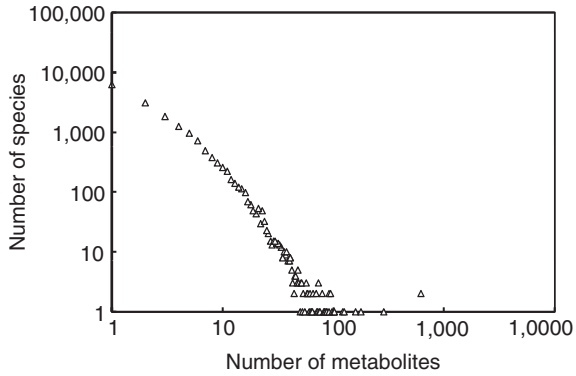

Figure 1. Power law distribution in the metabolite and species.

3 KNApSAcK FAMILY (http://kanaya.naist.jp/KNApSAcK_Family/)

Figure 2 shows the main window of KNApSAcK family, which consists of seven parts. The "Pocket" includes search system for species and metabolites related to human life such as edible plants in Japan ("Lunch Box"), herb teas ("Tea Pot", in progress), traditional Japanese medicine ("KAMPO"), poisonous plants ("Poison", in progress), and bio-fuel resources ("Fuel", in progress). "KNApSAcK from around the world" (at the top center, with the world map) includes medicinal and edible plants utilized in each country. Figure 3 shows the main window of "KNApSAcK from around the world" which consists of 119 nations and 7356 pairwise relationships between medicinal/edible plants and nations accumulated in 4538 species from scientific literature records (last update: Sept. 16, 2009). The list of plants in a certain country is obtained by clicking on the national flag of the country. By typing the scientific name of a species (e.g. *Brassica* or

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat218
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

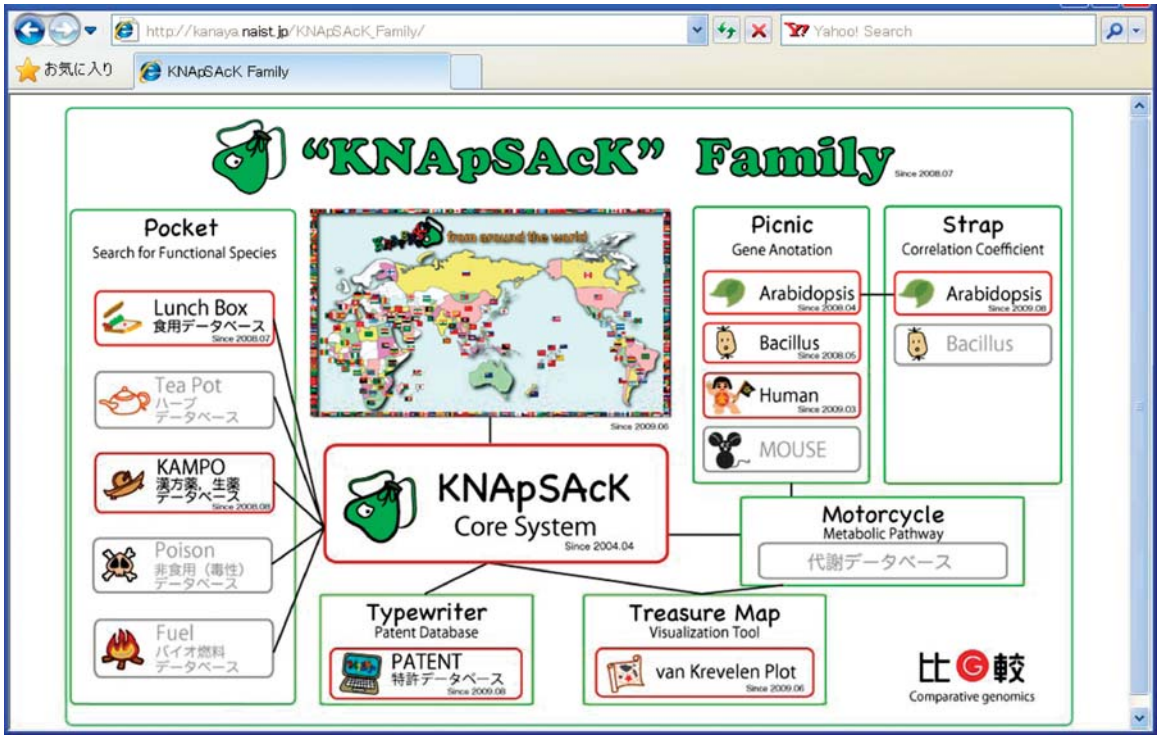

Figure 2. Main window of "KNApSAcK" family (http://kanaya.naist.jp/KNApSAcK_Family/).

Brassica hirta) in the text box and then clicking the List button, the national flags of the countries which utilize the plant start blinking. Then, information for metabolites contained in the species can be obtained if "KNApSAcK" icon is displayed for the species.

As shown in Figure 4, a power law relationship is also observed between the number of medicinal species and the number of metabolites. Figure 4 shows the number of medicinal plants utilized in individual countries. The 10 most utilized medicinal plants in the world are *Psidium guajava* (32 nations), *Ricinus communis* (17), *Zea mays* (15), *Ruta chalepensis* (15), *Ruta graveolens* (14), *Glycyrrhiza glabra* (14), *Zingiber officinale* (13), *Punica granatum* (13), *Foeniculum vulgare* (13), and *Apis indica* (13).

"Typewriter" includes patent information in Japan related to plants, and "Treasure Map" is a visualization system for metabolites by van Krevelen plot, which is also connected to the KNApSAcK core system. Gene annotation system called "Picnic" and highly correlated genes for a targeted gene can be searched using "Strap".

4 UTILIZATION OF KNApSAcK DATABASE IN SCIENTIFIC RESEARCH

The usefulness of KNApSAcK DB has been reported in several papers (Kikuchi and Kakeya, 2006; Want *et al.*, 2007;Saito, Hirai and Yonekura-Sakakibara, 2007; Moco *et al.*, 2007; Hummel *et al.*, 2007; Fardet *et al.*, 2008; Dunn, 2008; Oikawa *et al.*, 2008; Hagel and Facchini, 2008; Tohge and Fernie, 2009) We have accumulated 76,357 records (species–metabolite pairs) encompassing 37,693 metabolites on August 2009. The total number of secondary metabolites for which molecular structures have been elucidated is speculated to be 50,000 (De Luca and St Pierre, 2000), of which around 75% have been compiled in the KNApSAcK database. Furthermore, it is reported that the total number of secondary metabolites produced by entire plants together is more than 200,000 (Dixon and Strack, 2003). So KNApSAcK project is important for systematization of diversity of chemical structures and for mining useful natural compounds having industrial and medicinal significance.

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Figure 3. Main window of "KNApSAcK from around the world" (http://kanaya.naist.jp/KNApSAcK_Family/).

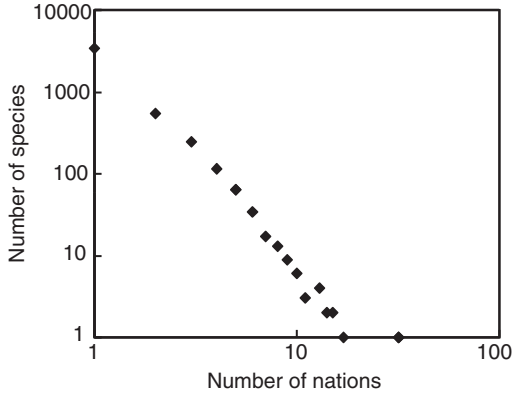

Figure 4. Power law distribution in the nation and utilized medicinal species.

Information on metabolites in the database can be searched by the name of the metabolite or organism, molecular weight, and molecular formula. Estimation of metabolites from an accurate mass peak is the first step of non-targeted analysis in metabolomics. In KNApSAcK DB, we can retrieve metabolites by a mass spectra data set consisting of *m/z* and corresponding intensities in the individual experimental conditions taking ionization mode into consideration. Using this function, a list of candidate metabolites is feasibly constructed for any species including model plants, because metabolites reported to closely related species as well as a target species are simultaneously retrieved by molecular weight in ionization mode (*m/z*). A number of researchers utilized this function to examine metabolites in various organisms such as tomato fruit (Iijima *et al*., 2008; Mintz-Oron *et al*.,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat218
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

2008), *Arabidopsis thaliana* (Oikawa *et al*., 2006; Nakamura *et al*., 2007; Yonekura-Sakakibara *et al*., 2007;Ohta, Sihbata and Kanaya, 2007; Böttcher *et al*., 2008; Malitsky *et al*., 2008; Kai *et al*., 2009), strawberry (Hanhineva, 2008), cabbage (Hounsomea *et al*., 2009), rice (Kind, Scholz and Fien, 2009), turmeric (Xie, Ma and Gang, 2009), *Arabidopsis lyrata* ssp. *petraea* (Davey, Woodward and Quick, 2008), oriental folk medicine *Angelica acutiloba* (Tianniam, Bamba and Fukusaki, 2009) and bacterium *Escherichia coli* (Takahashi *et al*., 2008). Metabolomics protocols incorporating KNApSAcK DB were proposed by Giavalisco *et al*. (2008), Overy *et al*. (2008), Oishi *et al*. (2009), Matsuda *et al*. (2009), Draper *et al*. (2009), and Sawada *et al*. (2009). Some biodatabases such as MetHouse (Gaida and Neumann, 2007, http://msbi.ipb-halle.de/), KEGG (http://fire3.scl.genome.ad.jp/dbget-bin/www_bfind?knapsack), Omicspace (http://omicspace.riken.jp/) and PRIMe (http://prime.psc.riken.jp/, Akiyama *et al*., 2008) are linked to KNApSAcK DB via web version (http://kanaya.naist.jp/knapsack_jsp/top.html/). Search extension transformation of Wiki into a relational system was proposed using species–metabolite relation in KNApSAcK database (Arita and Suwa, 2009). Evolutional interpretation of the diversity of flavonoid species was also carried out based on the DB (Takamoto and Arita, 2009).

5 CONCLUSION AND REMARKS

Considering that the KNApSAcK system covers a large number of species, not just only few model organisms, KNApSAcK DB has strong potential to contribute to metabolomics research society by way of applying it not only to simple metabolite search but also to further metabolomics analysis. We aim to accumulate 50,000 metabolites in total by 2010.

6 ACKNOWLEDGMENTS

This work was performed as one of the technology development projects of the “Green Biotechnology Program” supported by NEDO (New Energy and Industrial Technology Development Organization), Japan. Biomarkers for the Assessment of Acetaminophen Induced Liver Injury

Wimal Pathmasiri,[1] Rodney W. Snyder,[1] Jason P. Burgess,[1] James A. Popp,[2] Timothy R. Fennell[1] and Susan J. Sumner[1]

1 INTRODUCTION

Drug-induced liver injury (DILI) is the leading cause of acute liver failure in the United States and Europe (Fontana, 2008; Williams *et al*., 2010), and acetaminophen (APAP) is the leading cause of drug-related liver transplants within the United States accounting for 49–50% of all reported cases (Russo *et al*., 2004). DILI has also led to the failure of development of new drugs, preventing their future use in clinical trials, and removal of approved therapeutics from the market (Martin-Murphy, Holt and Ju, 2010). The liver becomes a primary target for adverse drug reactions because of its central role in biotransformation and excretion of foreign compounds, and its location within the circulatory system providing preferential exposure to a wide variety of substances administered orally.

APAP is a commonly available single ingredient or combination over-the-counter and prescription analgesic and antipyretic drug worldwide (Hinson, Roberts and James, 2010). APAP has been believed to be safe and effective when consumed at doses according to label; however, recent investigations have raised concerns regarding safety even when taken according to label (Watkins *et al*., 2006). It is also known that severe liver injury and liver failure can occur when the recommended dose of APAP has been exceeded by taking one or more over the counter or prescription medications that contain APAP. APAP is metabolized in liver by cytochrome P-450 enzymes; mainly by CYP2E1 isozyme (Hinson, Roberts and James, 2010). The parent drug or metabolites are also conjugated with glutathione, sulfate or glucuronide to produce water-soluble compounds. Consequently, the compounds can then be excreted from the body in bile or urine. Liver damage due to APAP has been attributed to *N*-acetyl-*p*-benzonaphthoquinone (NAPQI), a reactive metabolite generated during the metabolism of APAP by CYP enzymes (Han *et al*., 2010). NAPQI is a highly reactive metabolite, which reacts with protein and non-protein thiols. At low doses, NAPQI is mainly detoxified by glutathione (GSH) in hepatocytes. However, the GSH pool in hepatocytes is severely depleted at high, hepatotoxic doses of APAP. Because of this, NAPQI will be able to bind with thiols in amino acid residues of proteins affecting cellular protein targets such as mitochondrial proteins resulting in mitochondrial dysfunction. A loss of cellular ATP occurs, which leads to necrosis. GSH depletion itself can also induce apoptosis in hepatocytes.

There is an urgent need for clinical tests that will help distinguish DILI from other common causes of liver injury (Watkins, 2009), and to enable clinicians to identify specific drugs that are responsible for DILI in the instances of poly-pharmacy. In addition, new tests are required that can differentiate patients, who may develop DILI from those who can be treated safely. At present, serum enzyme levels (e.g., alanine amino transferase, ALT; aspartate amino transferase, AST) are used in the clinic as gold standards for evaluating hepatic injury. However, these markers may not be specific to liver damage and more importantly these markers do not indicate specific types of liver pathology. Furthermore, invasive biopsy and histopathological evaluations can be painful, time consuming, and result in some level of risk to the patient.

Emerging insights into the mechanisms underlying DILI suggests that desired biomarkers possibly exist, which can be discovered through the application of new technologies for analysis of noninvasive biological fluids, such as blood and urine. For example, circulating miRNAs (Wang *et al*., 2009) in mice have been identified as potential biomarkers for liver injury, and plasma from rats exposed to APAP and D-Galactosamine have liver-specific mRNA not found in vehicle control groups (Wetmore *et al*., 2010).

Clayton *et al.* (2009) used a pharmacometabonomic approach to show that the pattern of endogenous metabolites in urine collected prior to and following dosing with APAP could be used to determine biomarkers for drug fate. ^{1}H nuclear magnetic resonance (NMR) based metabonomics analysis was applied to urine samples obtained from 99 human healthy nonsmoking male volunteers between 18 and 64 years old. After collecting predose urine samples, subjects were given a single dose of 1000 mg of APAP. Post dose urine samples were collected over two consecutive periods (0–3 h and 3–6 h). Analysis of ^{1}H NMR data have shown that the individuals having high levels of p-cresol sulfate in their predose urine had low post dose urinary ratios of APAP-sulfate to APAP-glucuronide. The study has concluded that, in individuals with high bacterially generated p-cresol generation, competitive O-sulfonation of p-cresol reduced the effective systemic capacity to sulfonate APAP. This study further showed the possibility of predicting those who are susceptible to AILI.

Using metabolomics analysis of human urine samples, Winnike *et al.* (2010) demonstrated urinary profiles obtained shortly after the start of APAP treatment, could distinguish responders from nonresponders; response being determined by measurement of ALT at later time-points. While statistical analyses revealed that predictive metabolites included those derived from the toxic metabolite NAPQI the authors concluded that the inclusion of endogenous metabolites was necessary for significant prediction.

It has recently been shown that hepatotoxicants can produce compound specific changes in the peripheral blood (PB) transcriptome in rats (Lobenhofer *et al*., 2008; Miyamoto *et al*., 2008; Wang *et al*., 2009). Transcriptomic and metabolomics analysis of PB samples obtained from six healthy human adults treated with 4 g bolus dose of APAP and from three receiving placebo have been used to characterize changes in the transcriptome and serum metabolome (Fannin *et al*., 2010). In addition, blood was also collected from individuals on each of the clinical days (predose and at the following post dose time points: 30 min, 90 min, 2, 3, 4, 5, 6, 8, 12 h) for the measurement of clinical chemistries and complete blood count. Traditional liver chemistries did not indicate liver injury. However, 48 h after exposure, treated subjects showed marked down regulation of genes involved in oxidative phosphorylation/mitochondrial function that was not observed in the placebos. Unbiased analysis of the serum metabolome revealed an increase in serum lactate from 24 to 72 h postdosing in the treated subjects alone. The single 4 g APAP dose produced a transcriptome signature in PB cells characterized by down-regulation of oxidative phosphorylation genes accompanied by increased serum lactate. Similar gene expression changes were observed in rats and several patients after consuming hepatotoxic doses of APAP.

The ability to predict the risk of idiosyncratic DILI by using *in vitro* covalent binding (CB) levels has been investigated by using 12 drugs positive to DILI (including APAP) and 12 negative drugs (Usui *et al*., 2009). In this investigation, each drug was incubated with liver microsomes in the presence of reduced nicotinamide adenine dinucleotide phosphate (NADPH), UDP-GA (UDP-Glucuronic Acid), or GSH. The CB level alone was not sufficient for assessment of DILI risks, but when the CB level was multiplied by the maximum daily dose

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat219
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

(which may reflect maximum hepatic exposure) the positive and negative outcomes groups did discriminate. Taken together, these findings suggested that the combination of CB level and daily dose may estimate the risks of idiosyncratic DILI.

A liquid chromatography/mass spectrometry (LC/MS) based metabolomic assay and NMR spectroscopy, using Sprague-Dawley rats dosed with APAP (vehicle, 400 mg kg^{-1}, and 1600 mg kg^{-1}) was used to investigate a drug's excretion kinetic profile in urine (Sun, Schnackenberg and Beger, 2009) to obtain drug toxicity information. Ultra performance liquid chromatography/ mass spectrometry (UPLC/MS) and NMR were used to evaluate the excretion kinetics of major drug metabolites. They found that N-acetyl-L-cysteine acetaminophen (APAP-NAC) had statistically significant correlations with clinical chemistry data, endogenous metabolite concentrations, and histopathology data.

Cheng *et al*. (2009) exposed humanized mice for pregnane X receptor (PXR) to rifampacin and APAP and measured CYP3A4 and conducted metabolomics on plasma and serum, using the human PXR and CYP3A4 double transgenic (TgCYP3A4/hPXR) mouse line. They found that toxicity was coincident with depletion of hepatic glutathione (GSH) and increased production of hydrogen peroxide, suggesting increased oxidative stress upon hPXR activation. Moreover, mRNA analysis demonstrated that CYP3A4 and other PXR target genes were significantly induced by rifampicin treatment. Urinary metabolomic analysis indicated that two APAP derived metaoblites (cysteine-APAP and S-(5-acetylamino-2-hydroxyphenyl)mercaptopyruvic acid) as the major contributors to the toxic phenotype. Quantification of plasma APAP metabolites indicated that the APAP dimer formed coincident with increased oxidative stress. In addition, serum metabolomics revealed reduction of lysophosphatidylcholine in the APAP-treated groups. These findings demonstrated that human pregnane X receptor (hPXR) was involved in regulation of APAP-induced toxicity through CYP3A4-mediated hepatic metabolism of APAP in the presence of PXR ligands.

Profiling of major known APAP metabolites in urine and serum (Chen *et al*., 2008), using wild type and CYP2E1-null mice, LC-MS based method, and various assays, revealed that the ratio of metabolites derived following CYP2E1 conversion of APAP to metabolites derived from direct conjugation with APAP decreased with increasing APAP doses administered 24 h after administration of APAP at 200 mg kg^{-1} and 400 mg kg^{-1} dose levels, serum ALT and AST activities in wild-type mice were dramatically increased in both treatment groups studied but their activities in CYP2E1-null mice were unaffected by 200 mg kg^{-1} and slightly increased by 400 mg kg^{-1} treatment. It further indicated that the CYP2E1-null mice were significantly resistant to APAP-induced hepatotoxicity. Measurement of hepatic glutathione and hydrogen peroxide levels in the study revealed the importance of oxidative stress in determining the consequence of APAP overdose. Overall, the oxidative stress elicited by CYP2E1-mediated APAP metabolism might significantly contribute to APAP-induced toxicity. Furthermore, it has also been revealed that mechanisms involving P450 isozymes other than CYP2E1 were also contributing to APAP-toxicity by identifying novel APAP metabolites.

Using the LC/MS based metabolomic analysis of the serum from wild type and CYP2E1 null mice the same group (Chen *et al*., 2009) further showed the accumulation of long-chain acylcarnitines in serum from wild-type mice dosed with APAP at levels to induce hepatotoxicity; while these long-chain aceylcarnitines did not elevate in the CYP2E1 null mice. This observation, in conjunction with the increase of triglycerides and free fatty acids in the serum of APAP-treated wild-type mice, suggested that APAP (and not a metabolite derived from APAP) disrupted fatty acid beta-oxidation (Chen *et al*., 2009). A time-course study further indicated that both wild-type and CYP2E1-null mice had elevated serum acylcarnitine levels within the early hours of APAP treatment. While serum palmitocarnitine levels remained high in wild-type mice after 2 h of APAP treatment, its level in CYP2E1-null mice has slowly returned to basal levels at the end of 24 h. This result indicated that the homeostasis of acylcarnitines in both mouse lines was significantly affected by 400 mg kg^{-1} APAP treatment, and the increase of serum palmitoylcarnitine was an early event in the APAP-induced toxicity.

Distinct from serum aminotransferase activity and hepatic glutathione levels, the pattern of serum acylcarnitine accumulation suggested that acylcarnitines may function as complementary biomarkers for monitoring the APAP-induced hepatotoxicity.

Overall, serum metabolomics of APAP-induced hepatotoxicity revealed that the CYP2E1-mediated metabolic activation and oxidative stress following APAP treatment could cause irreversible inhibition of fatty acid oxidation, potentially through suppression of PPARα -regulated pathways.

Urinary metabolic perturbations associated with acute and chronic acetaminophen-induced hepatotoxicity was investigated (Sun *et al*., 2008) using NMR spectroscopy and ^{1}H NMR to determine biomarkers of APAP induced hepatotoxicity. Acute and chronic doses of APAP were administered to male Sprague-Dawley rats. NMR and UPLC/MS were able to detect both drug metabolites and endogenous metabolites simultaneously. The principal component analysis (PCA) of NMR or UPLC/MS spectra showed that metabolic changes observed in both acute and chronic dosing of acetaminophen were similar. Histopathology and clinical chemistry studies were performed and correlated well with the PCA analysis and magnitude of metabolite changes. Depletion of antioxidants (e.g., ferulic acid), trigonelline, S-adenosyl-L-methionine, and energy-related metabolites indicated that oxidative stress was caused by acute and chronic acetaminophen administration. Similar patterns of metabolic changes in response to acute or chronic dosing suggest similar detoxification and recovery mechanisms following APAP administration.

Toxicological responses to APAP overdose were examined using 2-dimensional gel electrophoresis (2DE)-based proteomics and (1) H-nuclear magnetic resonance (NMR)-based metabonomics to evaluate human hepatocytes transplanted in chimeric mice (Yamamoto *et al*., 2007). Proteins expressed in chimeric mouse liver that correlated with the presence of histopathological findings were identified that involve lipid/fatty acid metabolism, glycolysis and energy metabolism/production pathways. In addition, oxidative stress-related proteins showed altered expression. The metabonomic analysis of urine and plasma revealed alterations of endogenous metabolites which were the intermediates involved in the tricarboxylic acid (TCA) cycle, as previously observed in normal mice.

A metabolome differential display method based on capillary electrophoresis time-of-flight mass spectrometry (Soga, 2007) to profile liver metabolites following acetaminophen-induced hepatotoxicity has globally detected 1,859 peaks in mouse liver extracts and highlighted multiple changes in metabolite levels, including an activation of the ophthalmate biosynthesis pathway. The work confirmed that ophthalmate was synthesized from 2-aminobutyrate through consecutive reactions with gamma-glutamylcysteine and glutathione synthetase. Changes in ophthalmate level in mouse serum and liver extracts have been closely correlated and ophthalmate levels increased significantly in conjunction with glutathione consumption. Overall, their results provided a broad picture of hepatic metabolite changes following acetaminophen treatment. It was also found that serum ophthalmate is a sensitive indicator of hepatic GSH depletion, and may be a new biomarker for oxidative stress.

Human subjects taking 50 mg and 500 mg of APAP had increased levels of mercapturic acids (MA) as determined via constant neutral loss (CNL) scanning using linear ion-trap MS (Wagner *et al*., 2006) and suggested APAP-MA as an interesting class of marker compounds formed during the APAP detoxification process, even at low-doses. The authors in the study further suggested that the method could easily be transferred to other metabolites such as glucuronides and sulfates in the area of toxicotikentcs.

Gene chip array (Affymetrix) data from liver tissue and high resolution ^{1}H NMR spectra from intact liver tissue, tissue extracts and plasma (Coen *et al*., 2004) identified the major metabolic change as comprised of a decrease in hepatic glucose and glycogen in intact tissue, coupled with an increase in lipid content, with increases in the levels of glucose, pyruvate, acetate and lactate in plasma, and increases in alanine and lactate in the aqueous tissue extracts. Collectively these data provided evidence for an increased rate of hepatic glycolysis. The metabolic observations were consistent with the altered levels of gene expression relating to lipid and energy metabolism in liver, which both preceded and were concurrent with the metabolic perturbations.

An integrated metabonomics study using high-resolution ^{1}H NMR spectroscopy investigated the biochemical composition of intact liver tissue (using magic angle spinning), liver tissue extracts, and blood plasma samples obtained from control and acetaminophen-treated mice (Coen *et al*., 2003). Metabolic effects in intact liver tissue and lipid

DOI: 10.1002/9780470744307.gat219
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

soluble liver tissue extracts from animals treated with the high dose level of acetaminophen included an increase in lipid triglycerides and monounsaturated fatty acids together with a decrease in polyunsaturated fatty acids, indicating mitochondrial malfunction with concomitant compensatory increase of peroxisomal activity. In addition, a depletion of phospholipids was observed in treated liver tissue, which suggested an inhibition of enzymes involved in phospholipid synthesis. There was also depletion in the levels of liver glucose and glycogen. In addition, the aqueous soluble liver tissue extracts from high dose animals also revealed an increase in lactate, alanine, and other amino acids, together with a decrease in glucose. Plasma spectra showed increases in glucose, acetate, pyruvate, and lactate. These all observations provide evidence for an increased rate of glycolysis. These findings could indicate a mitochondrial inability to use pyruvate in the citric acid cycle and also reveal the impairment of fatty acid beta-oxidation in liver mitochondria of such treated mice.

Alterations in metabolic profiles of serum from rabbits administered APAP have been investigated in a ^{1}H NMR based metabonomics approach (Zira *et al*., 2009) in order to study the effect of antidote, *N*-acetylcysteine (NAC), and other proposed antidotes (silybinin (SIL), cimetidine (CIM) and SIL/CIM). A single dose of APAP (2 g kg^{-1} b.w., i.g.) or doses of APAP combined with the antidotes SIL, CIM, and NAC was administered to rabbits. Serum ALT and AST levels and histopathological findings were used to estimate AILI and to monitor the effect of antidotes in the treatment of AILI. Metabolomics data of serum samples obtained from the controls and treated animals revealed the separation of APAP-treated, APAP-antidote treated, and control animals from each other and the variation of metabolic profiles in each group.

Our laboratory has also used metabolomics of urine to identify non-invasive biomarkers of APAP induced liver injury, and examined the relationship of alterations in changes in urinary metabolite levels with changes observed for the right, left, and median lobe of the liver tissue. APAP was used in this metabolomics study because it is the most common cause for DILI that results in acute liver failure, and because considerable literature is available to compare results from our investigation with other metabolomic investigations as well as with other biomarker investigations.

2 MATERIALS/METHODS

2.1 Study Design and Sample Collection

Male Sprague Dawley rats were obtained from Charles River, Raleigh, NC, and arrived at 8 weeks of age. They were provided food (Purina rodent chow 5002) and water ad lib and housed in microisolator cages for 2 weeks. At least six rats per dose and time point were administered by gavage 0, 10, or 1500 mg kg^{-1} APAP (dissolved in CMC/Tween) per kilogram body weight (mg kg^{-1}) per day for up to 9 days. Urine was collected over dry ice (0–6 h and 6–24 h) from rats in all glass metabolism cages prior to the first dose (pre-dose), and again following day 1 (day 1 urine) and following Day 8 (day 9) of dosing, and stored at -70° C. The focus of the metabolomics analysis was on urine collected 6–24 h following exposure to APAP doses.

2.2 Serum Enzymes and Histopathology

Groups of rats were sacrificed following the 24 h urine collection on day 1 (termed the day 1 group) or day 9 (termed the day 9 group) for the collection of blood and liver. Blood was processed to serum for the measurement of ALT and AST using standard commercial kits and procedures. Sections of the right, median, and left lobes of the liver were collected and stained with H&E stain. Histopathologic assessment was made by evaluating approximately 20 histological parameters of the liver by Experimental Histopathology Laboratories (EPL), Inc. (Research Triangle Park, NC). The extensive list of histological diagnoses in this investigation was utilized to correlate to the metabolomics profile with DILI. The individual histological observations were given a "score" of 1–4 to indicate the magnitude of the effect as determined by the semiquantitative histological observation. A score of 1 indicates a minimal effect while a score of 4 indicates the greatest change noted for each histological observation.

2.3 Metabolomics; Sample Preparation, data acquisition, and processing

Urine samples were prepared for NMR analysis by mixing an aliquot (~630 μL) of urine with 70 μL

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat219

of a solvent buffer solution containing two internal standards (4,4-dimethyl-4-silapentane-1-sulfonic acid, DSS, and imidazole) for line shape analysis and spectral assignment and quantitation using the library in NMR Suite 6.0 Professional software. The left lobe, right lobe, and median lobe were individually prepared for NMR analysis by homogenization of each liver lobe (3:1 by weight; water:liver) and extraction with acetonitrile. Following extraction, the sample was dried under N_2(g) and reconstituted in 630 μL D_2O with 70 μL of the solvent buffer solution (DSS and imidazole). NMR spectra were acquired on a Varian Inova 600 MHz instrument located in the NMR facility at Duke University, Durham, NC. ^{1}H NMR spectra were acquired using the first increment of a NOESY sequence, with a 100 ms mixing time, 1 s relaxation delay, a spectral width of 12 ppm, and 32 transients. The water resonance was suppressed using resonance irradiation during the relaxation delay. All spectra were acquired at 25 °C, and the quality of each NMR spectrum was assessed for the level of noise and alignment of identified markers. Spectra were assessed for missing data and underwent quality checks.

NMR data was processed using a traditional binning approach (Lindon, Nicholson and Holmes, 2007) by automated integration (increments of 0.04 ppm) over the spectral window (producing 237 bins after excluding urea and the region of water suppression), and normalized to the total spectral intensity. NMR data were also processed using Chenomx NMR Suite 6.0 Professional software, which deconvolutes the entire spectrum based on chemical shift and coupling patterns, and then matches signals to a reference library of approximately 300 low molecular weight metabolites (Sumner *et al*., 2009; Sumner *et al*., 2010a, 2010b, 2010c). The internal standards (DSS and imidazole) were used as the references for performing the library matching. This software contains an internal library adjustment for increments in chemical shift based on pH variations (Weljie *et al*., 2006). A concentration determination for each metabolite was made by relative integration of the analyte to the internal standard, where the library of concentrations was developed to account for differences in integral values as related to the relaxation time of the signal (Weljie *et al*., 2006). This method has some advantageous over binning in two major ways. First, small increments in pH can result in portions of metabolite signals aligning with different bins when using the binning approach, while deconvolution circumvents this problem. A second advantage is that this analysis depends on the concentration of each metabolite, while the binning approach results in situations where each metabolite has multiple signals that fall within separate bins. For subsequent data reduction of the data derived from library matching, the concentration of each metabolite was normalized to total creatinine.

2.4 Data Reduction and Visualization

Data captured by NMR (metabolite id and concentration; or bin region and integral value) were transferred to software for data reduction and visualization using SIMCA P+ 12.0 (Umetrics AB, Umeå, Sweden). Several approaches were taken to analyze the NMR data to provide the best set of analytes that could distinguish the study groups (day 1 vehicle, day 1 low dose, day 1 high dose, day 9 vehicle, day 9 low dose, day 9 high dose) and that could provide the best correlation between the metabolomic profiles and the histopathological findings. For analysis with binned data, the integrals were normalized to the total integral for each spectrum. For analysis using data from library matching, the concentration of each metabolite was normalized to creatinine. Principal component analysis (PCA), partial least squares projection to latent structures discriminant analysis (PLS-DA) and orthogonal partial least squares projection to latent structures discriminant analysis (OPLS-DA) were conducted using SIMCA-P 12.0 for the binned and metabolite data. Loadings and variable importance plots were examined to determine the bins or metabolites that best correlated with dose groups, and to find the bins and metabolites that best correlated with histopathological findings. Subsequently, PCA using only the bins or analytes selected from the loadings and variable importance plots was conducted to demonstrate that the analysis with the subset of bins or metabolites could provide clear separation of the dose groups, and could provide correlation with the histopathological findings. Metabolites identified as important for the separation of dose groups or for correlation with histopathological findings were mapped to biochemical pathways.

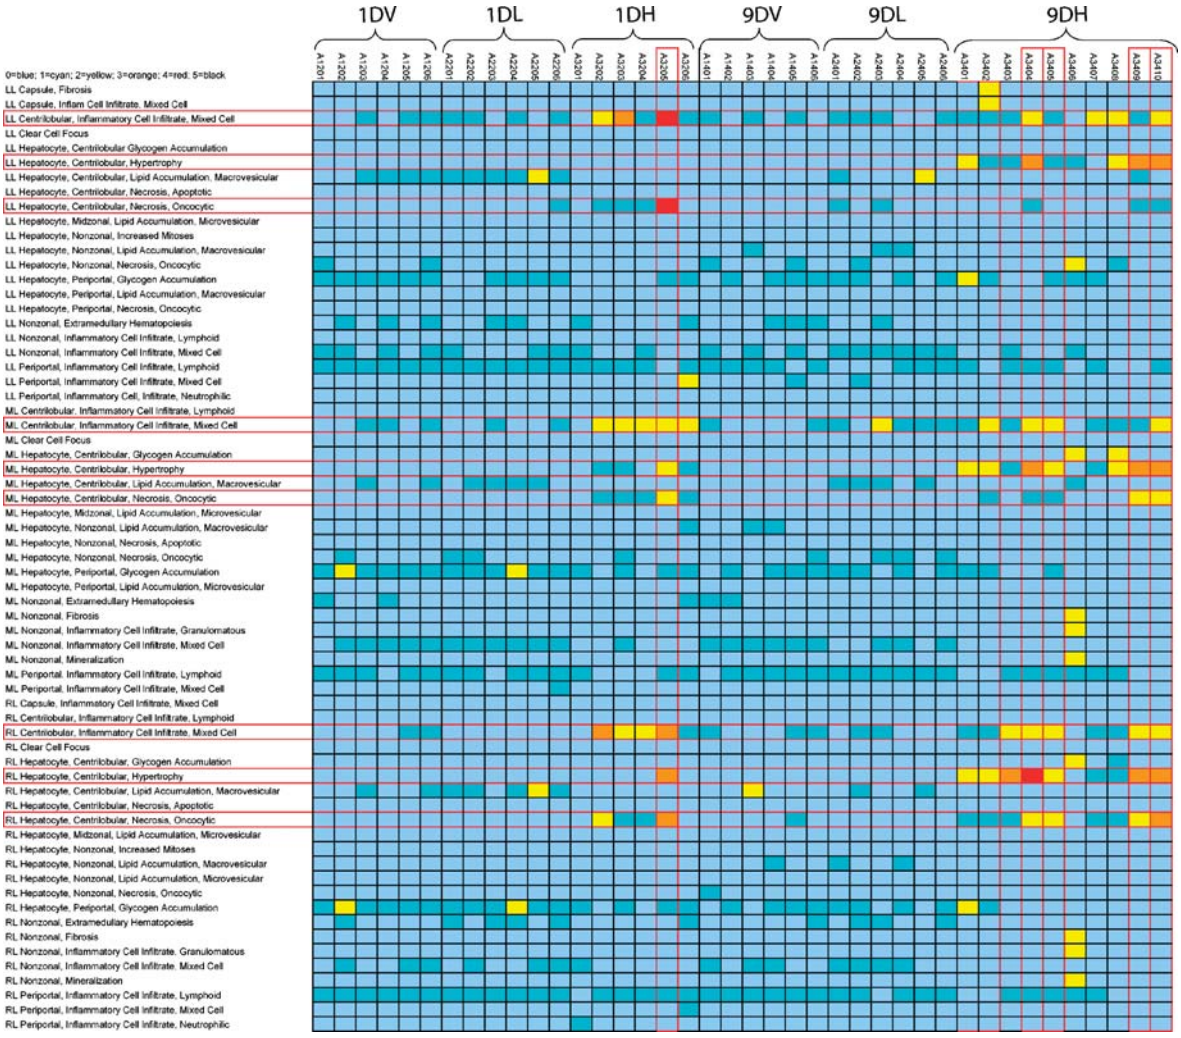

Figure 1. Histopathology findings for the left, median, and right liver lobes of rats administered 0, 10, or 1500 mg kg^{-1} APAP for up to 8 days. Centrilobular inflammatory cell infiltrate (mixed cell), centrilobular hypertrophy, and centrilobular necrosis (oncolytic) comprise the major incidence of pathologies. Abbreviations: 1DV, 1 Day vehicle group; 1DL, 1 Day low dose group; 1DH, 1 Day high dose group; 9DV, 9 Day vehicle group; 9DL, 9 Day low dose group; 1DH, 9 Day high dose group. Color codes for severity of incidences: blue, no effect; teal, minimal; yellow, mild; orange, moderate; red, severe.

2.5 Library matching

Full library matching using the NMR Suite 6.0 Professional Software (Chenomx, Edmonton, Alberta, Canada) provided a list of metabolites (and their respective concentrations) that demonstrated a match within each of the urine spectra. The concentration for each metabolite was normalized to the creatinine concentration for each urine sample and PCA analysis was conducted using the concentration based data. For liver extracts, the concentrations of the metabolites were normalized to DSS concentration.

3 RESULTS AND DISCUSSION

3.1 Histopathology of Liver

An extensive panel of liver pathologies was investigated by using approximately 20 histological parameters (Figure 1) for each of the three lobes evaluated. Centrilobular necrosis, centrilobular

Table 1. Liver pathology incidences (necrosis, inflammation, and hypertrophy). LL, left lobe; ML, middle lobe; RL, right lobe).

Histopathology	1500 mg kg^{-1} after 1 day exposure	1500 mg kg^{-1} after 9 days exposure
LL Centrilobular, Inflammatory Cell Infiltrate	5/6	9/10
LL Hepatocyte Centrilobular Hypertrophy	0/6	9/10
LL Hepatocyte Centrilobular Necrosis, Oncolytic	4/6	3/10
ML Centrilobular, Inflammatory Cell Infiltrate	5/6	9/10
ML Hepatocyte Centrilobular Hypertrophy	4/6	9/10
ML Hepatocyte Centrilobular Necrosis, Oncolytic	5/6	5/10
RL Centrilobular, Inflammatory Cell Infiltrate	5/6	9/10
RL Hepatocyte Centrilobular Hypertrophy	1/6	9/10
RL Hepatocyte Centrilobular Necrosis, Oncolytic	4/6	9/10

inflammation, and centrilobular hypertrophy were the major pathological entities identified in treated animals. After one day of exposure to APAP, centrilobular necrosis and inflammation treated with a high dose (1500 mg kg^{-1}) were the two lesions most frequently noted and had the highest severity grade in rats treated with the high dose (1500 mg kg^{-1}) (Table 1). However, it should be noted that not all animals had these lesions with one animal not having these lesions in any of the three liver lobes evaluated (Figure 1). Hypertrophy was also frequently noted in the livers of animals receiving 1500 mg kg^{-1} although this lesion was in general less severe and less common than necrosis and inflammation (Table 1). Hypertrophy was most prominent in the median lobe. Necrosis, inflammation and hypertrophy were noted in similar incidence and severity in the 10 mg kg^{-1} group as compared to the control indicating that there was no histological effect noted in 1 day in this dose group. The findings after 8 days of exposure to APAP were similar to those after one day of exposure; the high dose group (1500 mg kg^{-1}) had increased incidences of severities of centrilobular necrosis, inflammation, and hypertrophy when compared to the control group. Similar to the results after 1 day, there was no histological difference between low dose and control. In the high dose group, the incidence and severity of hypertrophy was greater after 9 days of APAP exposure as compared to 1 day of exposure (Table 1, Figure 1). The liver pathology due to APAP is complex with several histological types of injury being present in the high dose groups with variability among the lobes sampled for the 1-day and the 9-day study. Thus, any non-invasive marker profile cannot be specific to one specific pathologic entity, but rather an indicator of acetaminophen induced liver injury (AILI).

3.2 Serum clinical chemistry data

The serum ALT and AST enzyme levels in the plasma were elevated in some but not all rats dosed with 1500 mg kg^{-1} APAP for 1 day or 8 days compared with vehicle controls (Figure 2a and b). Some animals receiving 1500 mg kg^{-1} of APAP had serum enzyme concentrations similar to control animals while other animals had very high serum enzyme levels for both ALT and AST. There was not a consistent correlation between serum enzyme elevation and histopathology findings.

3.3 Metabolomics of urine

Metabolomics analysis was conducted on urine (6–24 h) collected from rats administered by gavage 0, 10, or 1500 mg kg^{-1} APAP for 1 or 8 days. PCA was conducted using binned data normalized to the total intensity, and excluding the region of water suppression (Figure 3). PCA analysis of the bin data shows good separation of the groups by dose and duration. At both day 1 and 9, the high dose is clearly distinguished from the low dose and control, which are similar.

Targeted profiling using Chenomx software (Weljie *et al*., 2006) was performed for urine samples with subsequent multivariate analysis including PCA, PLS-DA, and OPLS-DA. PCA of all urine samples (Figure 4a) as well as PLS-DA analysis of 1 day (Figure 4b) and 9 day samples (Figure 4c) showed a clear separation of vehicle and low dose groups from high dose groups after both 1 day and 9 days dosing. The low dose groups (1 day and 9 day) were closely grouped with those of

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

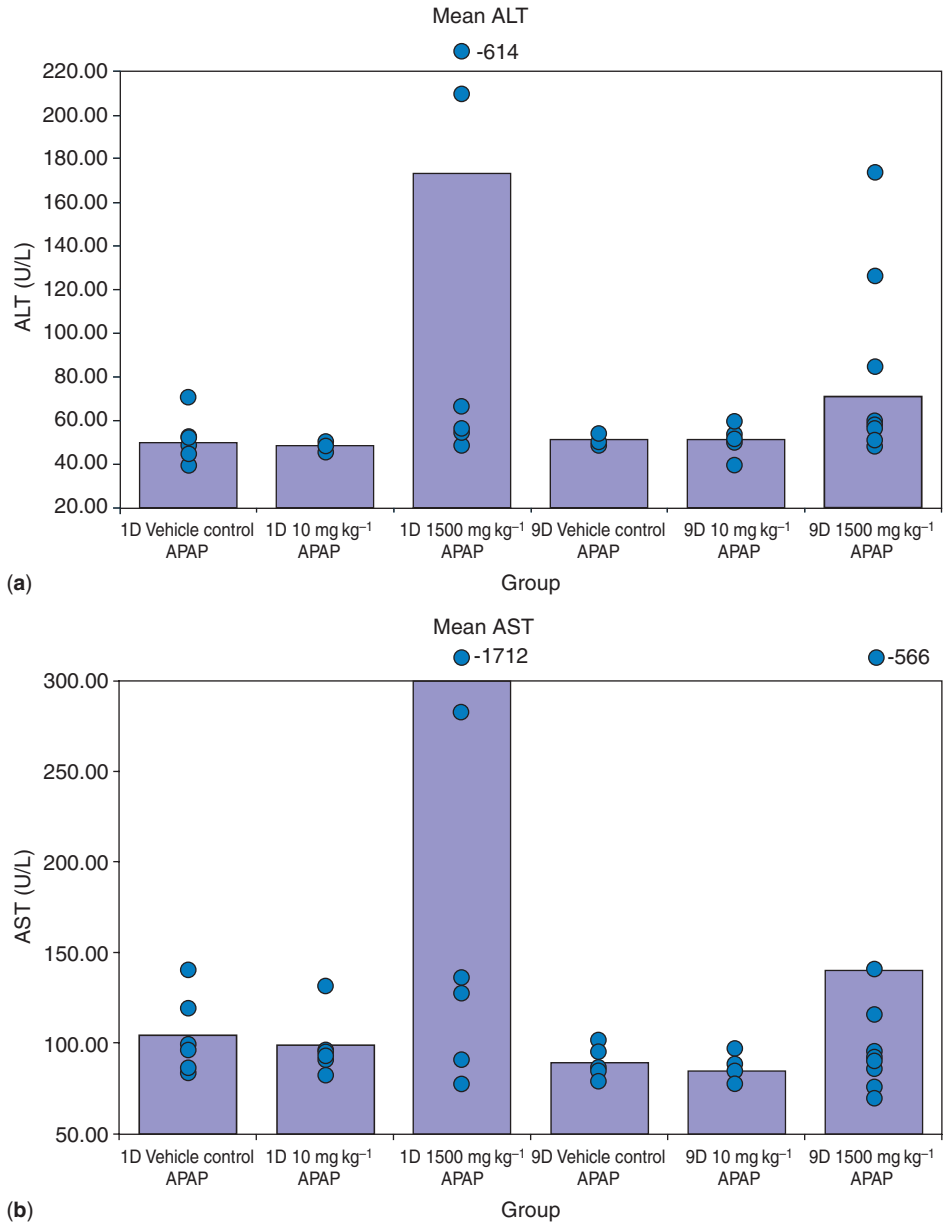

Figure 2. Analysis of serum ALT (a) and AST (b) indicates an average increase in serum enzyme levels in the rats administered a 1500 mg kg^{-1} APAP dose compared with vehicle control, although the level of serum enzyme elevation was not consistent with the severity of liver injury.

vehicle indicating that this relatively low dose of APAP (10 mg kg^{-1}), even after nine days of exposure, did not introduce significant perturbation on the metabolite profiles. A multivariate data analysis using concentration data normalized to time-matched vehicle control was performed to improve separation between groups and the resultant PLS-DA score plot is shown in Figure 5. A clear separation between the low and high dose groups for 1 day and 9 day urine samples is demonstrated.

Loadings plots and variable importance plots were evaluated to determine the subset of

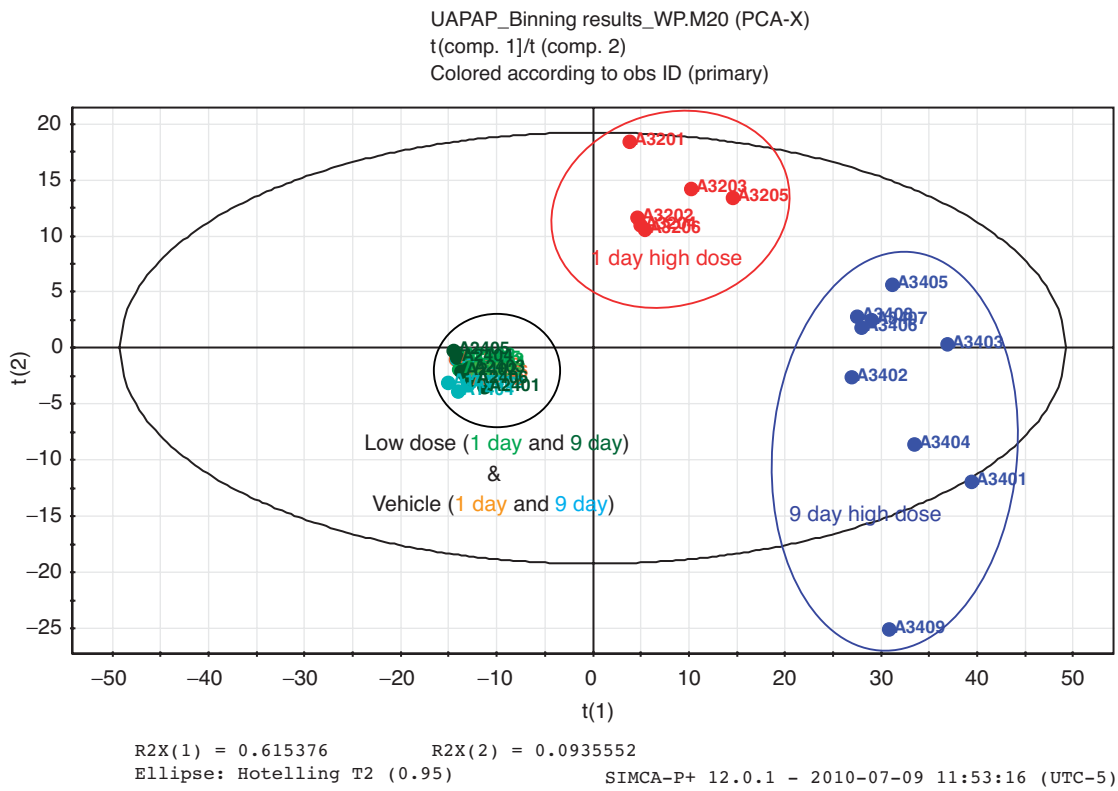

Figure 3. PCA analysis of binned NMR data obtained for urine (6–24 h) samples collected following 0 mg kg dose (orange, 1 day; teal, 9 days), 10 mg kg^{-1} dose (green, 1 day; and dark green, 9 days), and 1500 mg kg^{-1} dose (1 day, red); 9 days, (blue) with APAP.

metabolites that are responsible for the separation of different dose groups from the time-matched vehicle controls. Subsets of metabolites responsible for separating different dosing groups (for example, 1 day high dose group from 1 day vehicle group, 9 day high dose group from 9 day vehicle group, 9 day high dose group from 1 day high dose group) were identified. The urinary metabolites that best separated these groups were determined through evaluation of the variable importance plots, contribution plots, loading plots and are shown in the Table 2. PCA analysis was then conducted using the subsets of metabolites that were most responsible for the separation of these groups (Figure 6).

3.4 Metabolomics analysis of liver extracts

The left lobe, right lobe, and median lobes of liver were individually homogenized (3:1 by weight; water:liver), extracted with acetonitrile, dried under $N_{2(g)}$, and reconstituted with D_2O and a solvent buffer containing DSS and imidazole. Metabolomics analysis of the liver was conducted as described for urine. Multivariate data analysis was conducted independently for the a) right lobes; b) left lobes; or c) median lobes.

Multivariate data analysis **(**OPLS-DA) of all liver samples from both 1 day after exposure and 9 days of exposure demonstrated the separation of the study groups. Subtraction of time matched control values from the APAP exposed groups is shown in Figure 7a, also demonstrating the separation of 1-day samples from 9-day samples. Analysis of the 1-day samples using PLS-DA showed that the separation of groups by dose was greater than the separation of groups by lobe of liver (Figure 7b). This same trend was apparent for the 9 day group (Figure 7c). Multivariate analysis (PCA and PLS-DA) was performed for each individual lobe separately following subtraction of the time-matched vehicle control. For the left lobe (Figure 8a), the profiles for

Figure 4. (*Continued*)

the 1-day (green) and 9-day (dark green) low dose groups were distinct from the 1-day (red) and 9-day (blue) high dose groups. The high dose groups in the right lobe (1 day and 9 days, Figure 8c) were more separated from the other study groups, when compared to the median (Figure 8b) and left (Figure 8a) lobes. PCA and PLS-DA analysis of data obtained for all lobes at each day (1 day and 9 day) were performed separately. It was noted that the median lobe was separated from left and right lobes at day 1 (Figure 9) while the right lobe was more separate from left and median lobes at the day 9 time point (Figure 10). The separation of median lobe from the left and right lobe for the 1-day study is consistent with more prominent centrilobular hypertrophy in the median lobe (1-day study). Lobe variation in transcriptional profiles has been demonstrated after APAP administration (Irwin *et al.*, 2005).

Subsets of metabolites in liver extracts were determined that separate the high dose groups from the control groups in each liver lobe (left, median, and right) by evaluating the variable importance, contribution, and loading plots of multivariate data analyses and are shown in the Tables 3, 4, 5. It was possible to identify a common subset of metabolites that separate the dose groups in all three lobes, as well as additional metabolites that separate groups in each individual lobe. Multivariate analysis (PCA and PLS-DA) were performed using these subsets and two representative score plots are shown for the analyses using the common subset and a subset that is found to be specific to the middle lobe in Figures 11 and 12, respectively.

3.5 Defining pathways relevant to the urinary and liver markers

Metabolites that define AILI were mapped to metabolic pathways. Our metabolomics study on both urine and liver extracts suggests that interruptions in amino acid metabolism (glycine, glutamine, glutamate, tyrosine), glutathione metabolism, citric acid cycle, Krebs cycle, purine and pyrimidine metabolism, benzoate metabolism, norepinephrine,

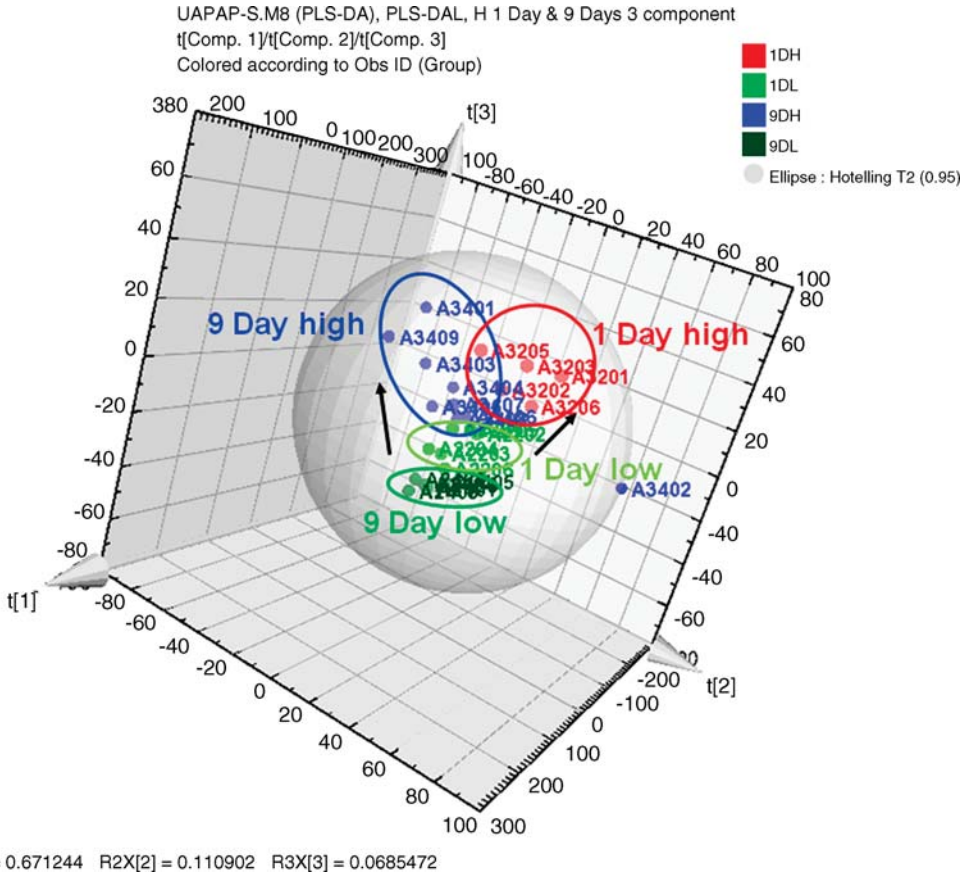

Figure 5. PLS-DA using concentration data of urinary metabolites subtracted from the time matched vehicle controls shows a separation of high-dose groups (1 and 9 day) from the low-dose groups.

mitochondrial fatty acid β-oxidation, metabolism of nicotinamide, urea cycle, and AMP metabolism.

Consistent with our investigations were earlier metabonomics (and metabolomics) studies, which showed perturbations in cellular metabolism and functions in liver corrolarry with the presence of AILI (Coen *et al*., 2003; Coen *et al*., 2004; Sun *et al*., 2008; Zira *et al*., 2009; Bollard *et al*., 2010). Metabonomics and transcriptomics studies using an animal model of AILI showed dose- and time-dependant biochemical changes in energy and lipid metabolism (Coen *et al*., 2003; Coen *et al*., 2004) and an increase in lipid triglycerides, monounsaturated fatty acids, with a decrease in polyunsaturated fatty acids- also indicating mitochondrial malfunction and related compensatory increase of peroxisomal activity. A depletion of phospholipids in liver tissue in the animals treated with APAP and perturbation of amino acid, glucose and glycogen metabolism were also observed.

Bollard *et al*. (2010) showed differences in levels of urinary metabolites measured for rats following partial heptectomy compared with matched controls. This included elevated levels of taurine, hypotaurine, creatine, guanidoacetate, betaine, N,N-dimethylglycine, and bile acids and decreased levels of triglycerides. In addition, in the liver, triglycerides, cholesterol, alanine, and betaine were elevated after partial hepatectomy while choline and its derivatives were decreased (Bollard *et al*., 2010). Analysis of urine from rats following acute or chronic dosing with APAP (analyzed by both NMR and UPLC/MS) showed multiple time dependent metabolic changes in acetaminophen drug metabolites, antioxidants, and energy-related metabolites,

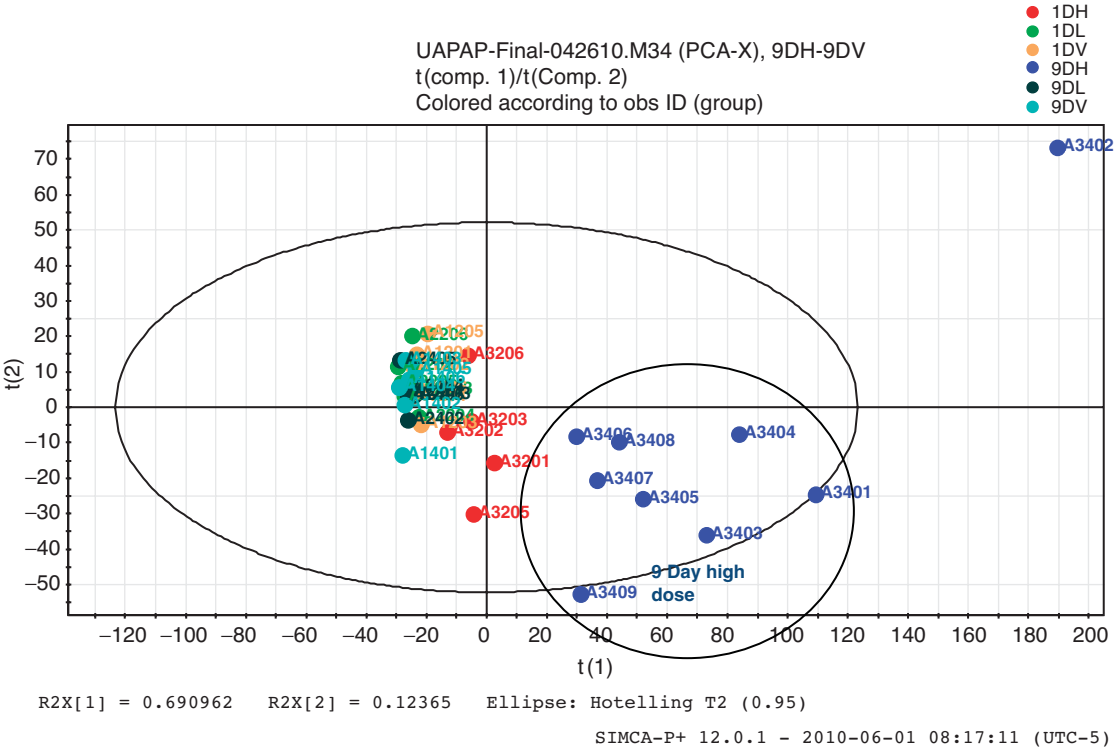

Figure 6. PCA of urine data (concentrations) obtained by using the subset of metabolites that are responsible for separation of the 9-day high-dose group from the time-matched vehicle control (1-day vehicle, orange; 1-day low, green; 1-day high, red; 9-day vehicle, teal; 9-day low, dark green; 9-day high, blue).

in the urine of rats when compared with control samples (Sun *et al*., 2008).

Reactive oxygen species and reactive nitrogen species in normal hepatocytes are critical for normal physiological processes, including oxidative respiration, growth, regeneration, apoptosis, and microsomal defense (Diesen and Kuo, 2010a, 2010b; Han *et al*., 2010). When the levels of these species exceeds the normal antioxidant capacity of cells, oxidative stress occurs, leading to various damaging effects to all liver cells. AILI is shown to deplete glutathione pool in the liver cells, reduces ATP production by perturbing pathways involved (Soga *et al*., 2006; Hinson, Roberts and James, 2010). Recent gene expression profiling studies (Boorman *et al*., 2005a, 2005b; Irwin *et al*., 2005; Powell *et al*., 2006; Toyoshiba *et al*., 2006; Bushel *et al*., 2007) on APAP-induced toxicity have also shown that there is differential expression of genes in the liver after APAP exposure when compared to controls. The differentially expressed genes in the other studies included those responsible for oxidative stress, and energy metabolism (Heinloth *et al*., 2004; Powell *et al*., 2006). Studies using blood and liver gene expression profiles found that the genes that discriminate the subtoxic and nontoxic dose levels from toxic levels were genes involved in the activation of immune or inflammatory responses against an external stimulus. Examples of overrepresented categories were defense response, immune response, response to stress,regulation of phagocytosis, regulation of endocytosis, response to bacteria, and inflammatory response (Bushel *et al*., 2007). To summarize, there is impairment in energy metabolism, protein synthesis, and mitochondrial function in AILI. It further suggests that the activation of cellular signaling and immunity could be the major cause of liver

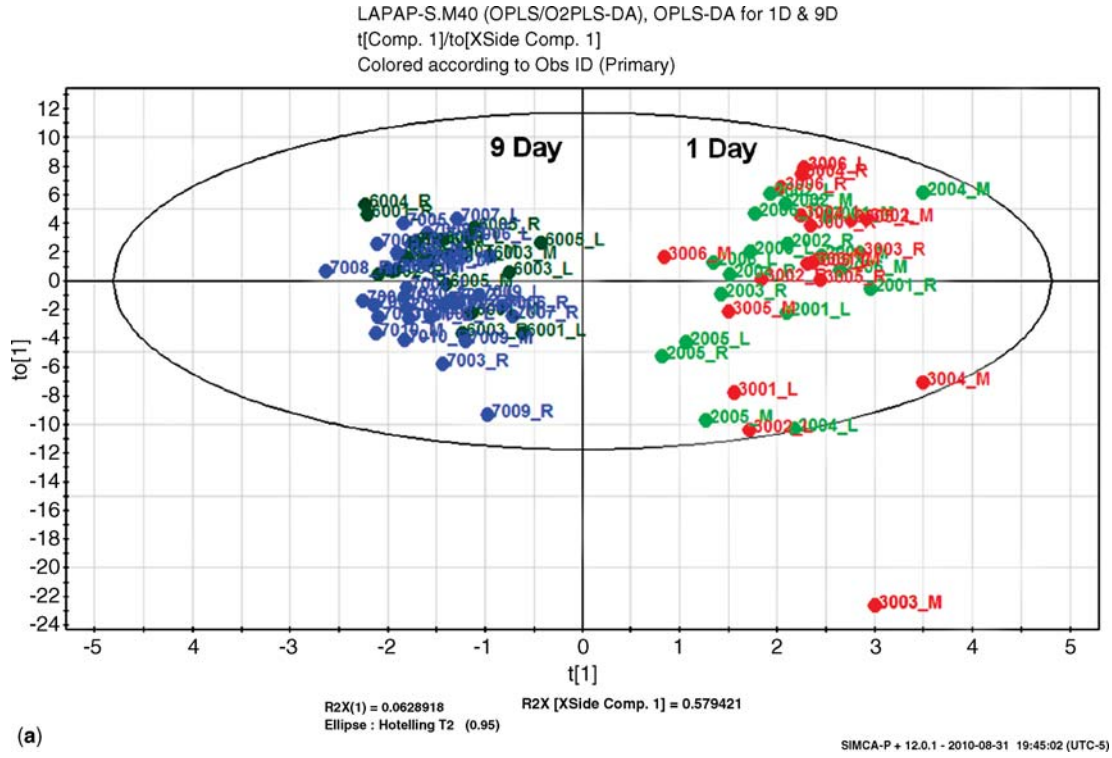

Figure 7. (a) OPLS-DA analysis of liver metabolite data (concentrations) subtracted from the time-matched vehicle controls show a separation of 1-day samples from 9-day samples; (b) PLS-DA of urine samples obtained after 1-day exposure shows a separation caused by dose (1-day vehicle, orange; 1-day low, green; 1-day high, red); and (c) PLS-DA of urine samples obtained after 9 days exposure shows a separation caused by dose (9-day vehicle, teal; 9-day low, dark green; 9-day high, blue).

damage due to APAP intoxication. Perturbation in amino acid metabolism and the changes in amino acid levels are accounted for the disturbed protein synthesis and protein synthesis because of the necrosis and other liver damaging effects (Zira *et al.*, 2009).

4 CONCLUDING REMARKS

Our investigation has demonstrated a promising non-invasive urinary marker profile that could be further evaluated for the early detection of APAP induced liver injury. Early diagnosis of reversible liver injury induced by APAP would greatly enhance treatment options and benefits. Our studies reveal that the liver from rats with AILI has a significant perturbation of amino acids metabolism (glycine, leucine, arginine, alloisoleucine, asparagine, alanine, and aspartate) purine and pyrimidine metabolism, glycolysis, Krebs cycle, cysteine metabolism, and glutathione), and that there is a common subset of metabolites that define liver injury irrespective of the lobe. Furthermore, there are subsets of metabolites that are specific to defining the biochemical profile of each lobe. Urinary metabolites consistent with the presence of AILI suggested interruptions in some of the same pathways (amino acid metabolism, energy metabolism, purine, and pyrimidine metabolism) and indicate the possibility of developing a non-invasive surrogate marker for AILI that may correlate with the lobe response. Using a metabolomics approach for the validation of the marker profile will enable the determination of any additional metabolites that should be included in a marker profile to reveal AILI related histopathologies in human investigations.

Application of Metabonomic Approach in Target Organ Toxicity

Athina Zira and Stamatios Theocharis

Department of Forensic Medicine and Toxicology, Medical School, University of Athens, Athens, Greece

1 INTRODUCTION

Toxicology studies the adverse effects of diverse agents, such as drugs, industrial-, agricultural- and biological-origin chemicals, on living systems. Upon entering the organism, these agents could induce functional and structural alterations in cells, tissues and organs. A toxic substance could interact at similar subcellular sites in different organs, although the level of toxicity in each one would depend on differences in the absorption, distribution, metabolism and response of a specific cell type to the toxic effect (Zimmerman, 1999).

Toxicological studies are usually based on histopathological evaluation and blood biochemistry measurements. Recently, conventional toxicological approaches combined with new technologies, such as the "omics" ones (genomics, proteomics and metabonomics), are used for both the characterization and the understanding of the mechanisms underlying toxicity (Gatzidou, Zira and Theocharis, 2007). Genomics represents the study of the genome of an organism including the alterations occurring during a toxic insult. The proteome, the entire complement of proteins, including the modifications made to a particular set of proteins, produced by an organism or system is termed as proteomics. Based on the definition given by Nicholson, Lindon and Holmes 1999, "Metabonomics is the dynamic multiparametric response of living systems to pathophysiological stimuli or genetic modifications." The term metabonomics has been used to describe the study of the global metabolite profiles in cells, tissues or biofluids of an organism under physiological or pathological conditions. Metabolomics is usually coupled with statistics and especially pattern recognition techniques such as principal component analysis (PCA), providing information concerning low-concentration metabolites that could not be measured using conventional biochemical methods.

Nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS), coupled with either liquid or gas chromatography (LC-MS and GC-MS, respectively), are the most commonly used methods that lead the metabolic profiling studies. Both NMR and MS have the ability to measure simultaneously variations in the levels of metabolites. Although MS is more sensitive than NMR, it is not very often used due to the discrimination required before the sample reaches the MS. NMR spectroscopy is a method of choice for the metabonomic studies because it is quick, requires little or no sample preparation and is not catastrophic for the sample. High-resolution NMR of biofluids, tissues or cells can give valuable information concerning alterations in the levels of metabolites under pathological conditions, including toxicity.

The purpose of the present study is to record the existing data in the recent literature concerning

metabonomics and its application in toxicology, focused on different metabolic alterations occurring post-toxin-induced injury in target organs (liver, kidneys, heart and brain). Target organ toxicity studied using the metabonomic approach provides a holistic picture of the alterations leading to the discovery of metabolites that could be correlated with the toxins and their mechanism of action.

2 METABONOMICS AND TARGET ORGAN TOXICITY

The existing metabonomic studies on target organ toxicity categorized for different organ and mode of toxic effect (acute and chronic) are summarized in the following section. Descriptive tables regarding the animal, dose, route of administration, type of experimentation (time- and/or dose-dependent) used, the examined biofluids and methodology applied are also provided (Tables 1–3).

2.1 Liver Toxicity

The liver is more susceptible to toxins because it is the major site for xenobiotic metabolism. To that end, many experimental animal models are used to determine whether the exposure to different substances poses any risk either to animals or to humans. The metabonomic approach has been widely applied in the models of hepatotoxicity induced by chemicals or drugs (Table 1).

Acetaminophen (paracetamol, APAP) is a well-known mild analgesic drug, safe in therapeutic doses, that induces centrilobular hepatic necrosis at high doses. It is regularly used as an experimental hepatotoxin because it provides a model of acute liver failure (Zimmerman, 1999).

A dose- and time-dependent metabonomic study was performed to characterize the biochemical alterations in mice after APAP administration (Coen *et al*., 2003). ^{1}H-NMR spectra of intact liver tissue, tissue extracts (aqueous and lipid) and blood plasma samples were obtained from APAP-treated [50,150 and 500 mg kg^{-1} of body weight (BW), intraperitoneally (i.p.)] and control animals, killed at 15, 30, 60, 120 and 240 min after the drug administration. PCA was applied to cluster the cases based on their common metabolic profile recorded by NMR. The decreased hepatic glucose and glycogen levels and the increased lactate levels in the aqueous soluble liver extract reflected a rise in the rates of glycogenolysis and glycolysis during APAP-induced injury. Furthermore, the enhanced lactate levels, glucose and glycogen noted in plasma samples indicated mitochondrial malfunction leading to incapacity to use pyruvate in the citric acid cycle. The elevated triglyceride levels appearing in spectra of intact liver tissue, lipid-soluble liver extract and blood plasma can be attributed to an energy shift resulting from APAP toxicity. Histopathological examination was in concert with the results obtained from the lipid-soluble liver extracts presenting impairment of mitochondria that could lead to decreased energy levels and lipid accumulation in the liver.

Based on this experimental model, the APAP-induced liver injury was further investigated using the combination of metabonomics and transcriptomics, in an effort to better understand the time-dependent biochemical consequences (Coen *et al*., 2004). Alterations in the levels of metabolites, as glucose, choline/phosphocholine, lipoproteins, lactate and acetate, were parallel with those observed in gene expression [Insulin-like growth factor binding protein 1 (IGFBP-1), phospholipase, lipoprotein lipase], suggesting modifications in lipid metabolism, mitochondrial dysfunction and energy metabolism as a result to the toxic insult (Coen *et al*., 2004).

More recently, metabolic profile alterations in serum samples post-acute APAP-induced liver injury in rabbits were monitored using ^{1}H-NMR spectroscopy, by our group (Zira *et al*., 2009a). The effect of the established antidote *N*-acetylcysteine (NAC) and the proposed antidotes silybinin (SIL), cimetidine (CIM) and SIL/CIM was also examined using the same methodology. Animals were administered with a single dose of either APAP (2 g kg^{-1} BW, intragastrically) or APAP combined with the antidotes SIL [100 mg kg^{-1} BW intramuscularly (i.m.), 30 min after APAP administration], CIM (50 mg kg^{-1} BW, i.m.) and NAC (150 mg kg^{-1} BW, i.m.) and were killed at 24 h post-treatment. Elevated lipid levels (LDL/VLDL, *N*-acetylglycoproteins, CH=CH) in the APAP-treated group compared with controls confirmed the previously mentioned observation of the energy metabolism shift due to the toxic agent. Co-administration of APAP with CIM, SIL/CIM and NAC decreased the lipid levels compared with

Table 1. Summary of the experimental models examined in liver toxicity.

	Liver toxicity							
	Experimental animals	Dose used	Root of administration	Time-dependent experiment	Dose-dependent experiment	Biofluids examined	Methods	References
APAP acute	Mice	50, 150, 500 mg kg^{-1} BW	i.p.	Yes	Yes	Tissue, plasma	NMR	Coen *et al.* (2003)
	Mice	50, 150, 500 mg kg^{-1} BW	i.p.	Yes	Yes	Tissue, plasma	NMR, transcriptomics	Coen *et al.* (2004)
	Rabbits	2 g kg^{-1} BW	i.g.	No	No	Serum	NMR	Zira *et al.* (2009)
	Rats	400, 1600 mg kg^{-1} BW	Oral	Yes	Yes	Urine	NMR, UPLC/MS	Sun *et al.* (2008)
	Rats	6, 25, 110, 450, 1800 mg kg^{-1} BW	Oral	Yes	Yes	Urine	NMR	Schoonen *et al.* (2007)
APAP chronic	Rats	200, 400,800 mg kg^{-1} BW	Oral	Yes	Yes	Urine	NMR, UPLC/MS	Sun *et al.* (2008)
	Rats	2 g kg^{-1} BW	Oral	No	No	Urine	NMR	Kim *et al.* (2008)
Hydrazine acute	Rats	75, 90, 120 mg kg^{-1} BW	Oral	No	Yes	Urine, plasma	NMR	Nicholls *et al.* (2001)
	Rats, mice	30 and 90 mg kg^{-1} BW (rats), 100 and 250 mg kg^{-1} BW (mice)	Oral	Yes	Yes	Urine	NMR	Bollard *et al.* (2005)
	Rats	20, 30 mg kg^{-1} BW	Oral	No	Yes	Serum	NMR, genomics, proteomics	Klenø *et al.* (2004)
CCl_4 acute	Rats	1 ml kg^{-1} BW	i.p.	Yes	No	Tissue, plasma	NMR	Zira *et al.* (2007)
	Rats	1 ml kg^{-1} BW	Oral	Yes	No	Urine	LC-MS	Lin *et al.* (2009)
	Rats	1 ml kg^{-1} BW	Oral	Yes	No	Urine	NMR	Kim *et al.* (2008)
CCl_4 chronic	Rats	0.05–0.5 ml	Oral	No	Yes	Tissue	NMR	Harvey *et al.* (1999)
D-Galactosamine	Rats	0.8 g kg^{-1} BW	i.p.	Yes	No	Urine	NMR	Kim *et al.* (2008)
ANIT acute	Rats	150 mg kg^{-1} BW	Oral	Yes	No	Tissue	NMR	Waters *et al.* (2002)
	Rats	0, 50 75, 100, 150 mg kg^{-1} BW	Oral	Yes	Yes	Urine	NMR	Azmi *et al.* (2005)
TAA acute	Rats	150 mg kg^{-1} BW	Oral	Yes	No	Tissue, plasma, Urine	NMR	Waters *et al.* (2005)
	Rats	400 mg kg^{-1} BW	i.p.	No	No	Tissue, serum	NMR	Zira *et al.* (2009)
TAA chronic	Rats	300 g l^{-1}	Oral	Yes	No	Tissue, serum	NMR	Constantinou, Theocharis and Mikros (2006)
Bromobenzen acute	Rats	1.5 g kg^{-1} BW	Oral	Yes	No	Tissue, plasma, Urine	NMR	Waters *et al.* (2007)
	Rats	2, 8, 32, 125, 500 mg kg^{-1} BW	Oral	No	Yes	Urine	NMR	Schoonen *et al.* (2009)
Realgar chronic	Rats	1.0 g kg^{-1} BW	i.g.	Yes	No	Urine, serum, tissue	NMR	Wei *et al.* (2005)
Methapyrilene chronic	Rats	50 mg kg^{-1}, 150 mg kg^{-1} BW	Oral	No	Yes	Tissue,	NMR, genomics, proteomics	Craig *et al.* (2007)
Ethionine	Rats	80 mg kg^{-1}, 800 mg kg^{-1} BW	Oral	Yes	Yes	Urine, liver	NMR	Skordi *et al.* (2006)
Allyl formate	Rats	75 mg kg^{-1} BW	i.p.	Yes	No	plasma, Urine, tissue	NMR	Yap *et al.* (2006)
PFDoA chronic	Rats	0.02, 0.05, 0.2, 0.5 mg kg^{-1} BW	Oral	—	Yes	Tissue, serum	NMR	Ding *et al.* (2009)

the APAP group. The decreased glucose and the increased lactate levels revealed the augmented rate of glycogenolysis and glycolysis. Alterations in the levels of other metabolites such as alanine, valine, leucine and isoleucine were related to the degree of liver damage because the protein synthesis was disturbed and necrosis caused protein degradation. The beneficial effect of the antidotes SIL, CIM and NAC were in agreement with histopathological and serum biochemical findings.

An NMR and UPLC/MS metabonomic analysis of urine obtained from either acutely or chronically, orally, APAP-treated rats was also performed (Sun *et al*., 2008). Acute APAP intoxication was achieved by a single dose of either 400 or 1600 mg kg^{-1} BW. Chronic APAP intoxication was achieved by treatment with 200, 400 and 800 mg kg^{-1} BW APAP a day for seven consecutive days. Urine samples were collected at different time-points. In contrast to the acute APAP intoxication, clinical chemistry and histopathology in the chronic toxicity study did not reveal any evidence of toxicity. Regenerative changes occurred 48 h post-acute administration as demonstrated by both histopathology and metabonomics. Krebs' cycle intermediates (citrate, pyruvate, succinate and 2-OG), as well as glucose, trimethylamine N-oxide (TMAO), taurine and betaine, were found reduced after both acute and chronic APAP treatment. Additionally, an increase in acetate levels suggested a switch in the energy metabolism, due to the APAP intoxication.

Hydrazine is a metabolite of many pharmaceutical substances such as isoniazid (anti-tuberculosis) and hydralazine (anti-hypertensive) and its hepatoxic, neurotoxic, carcinogenic and mutagenic effects have been widely studied (Zimmerman, 1999).

The biochemical effects induced by hydrazine orally administered in rats at doses of 75, 90 and 120 mg kg^{-1} BW have been investigated (Nicholls *et al*., 2001). ^{1}H-NMR spectra were obtained in blood plasma samples and urine pre- and post-hydrazine treatment. The increased urinary levels of both creatine and taurine have been correlated with the reduced liver function. ^{1}H-NMR blood plasma spectra revealed an increase in tyrosine levels that have been previously reported as a consequence of hydrazine administration (Runge-Morris, Iacob and Novak, 1998).

The "omics" technologies were combined to investigate the mechanisms of hydrazine-induced hepatotoxicity in rats (Klenø *et al*., 2004). A single oral dose of hydrazine (30 and 20 mg kg^{-1} BW) was administered in rats that were sacrificed at 48 and 168 h post-dosing. Hydrazine administration caused changes in genes, proteins and metabolites that can be related to glucose and lipid metabolism and to oxidative stress.

Furthermore, interspecies variations, between rats and mice administered with hydrazine, have been studied (Bollard *et al*., 2005). Comparison of the ^{1}H-NMR spectra presented common metabolic changes in both rats and mice: a drop in succinate and citrate levels and an increase in creatine and 2-aminoadipate were noted in urine samples, the latter being related to neurological effects.

Acute carbon tetrachloride (CCl_4) administration in rats causes centrilobular hepatic necrosis (Jin *et al*., 2006) and steatosis followed by a regenerative process (Theocharis *et al*., 2001; Taniguchi *et al*., 2004), whereas chronic administration leads to cirrhosis and induces hepatic carcinoma in experimental animals (Zimmerman, 1999).

The time-dependent acute CCl_4 intoxication in rats was examined by ^{1}H-NMR-based metabonomics (Zira *et al*., 2007). Animals were administered with 1 ml CCl_4 kg^{-1} BW (i.p.) in a mixture with corn oil 1 : 10 (v/v) and were sacrificed at 0 (controls), 12, 24, 36, 48, 60 and 72 h post-dose. Alterations in the levels of lactate, glucose, LDL/VLDL, glutamine, glutamate and UFA/PUFA were associated with shift in the energy metabolism, increased rates of glycolysis/glycogenolysis, disturbed protein synthesis and lipid accumulation caused by CCl_4 treatment. The changes in the examined metabolites reached their maximum between 24 and 36 h (toxic phase) but gradually regained the control levels at 72 h (regenerative state). The pathways disturbed are in agreement with the findings of another studythat comprised a GC/MS-based metabonomic analysis on plasma in mice (Huang *et al*., 2008).

An integrated LC-MS metabonomics approach was applied on urine to monitor the metabolic alterations caused by a single dose of CCl_4 (1 ml kg^{-1} BW) in rat urine (Lin *et al*., 2009). Urine samples were collected at day 0 (controls) and at days 1–6. Oral administration of CCl_4 increased serum biomarkers AST and ALT and caused restorable liver damage evident by biochemical assays and histopathological examination. The decrease noted in the levels of citric acid was due to TCA

dysfunction under oxidative stress caused by CCl_4. ATP insufficiency resulted in increased free creatine levels, which is degraded to creatinine, giving elevated urinary levels.

The alterations caused in the hepatic metabolism during CCl_4-induced cirrhosis were also investigated (Harvey *et al*., 1999). Rats were administered with weekly oral doses of CCl_4 (ranging from 0.05 to 0.5 ml) for 10 weeks. The animals were sacrificed 3 weeks after the last CCl_4 administration. ^{31}P- and ^{1}H-NMR spectra were obtained in perchloric acid-extracted liver tissues. Based on the ^{1}H- and ^{31}P-NMR experiments, alterations in all detectable metabolites in CCl_4-treated compared to untreated rats were noted. Cirrhotic rats presented a significant increase in the Pi level and Pi : ATP ratio and a significant decrease in ATP levels and ATP : ADP ratio, pointing to a poorer energy state. A significant decrease in NAD was apparent in cirrhotic rat livers, illustrating alterations in either the biosynthetic and/or the degradative pathway. Elevated levels of phosphocholine and phosphoethanolamine were presented in rats and were attributed to the stimulation of membrane biosynthesis in response to CCl_4 membrane damage.

1-Napthylisothiocyanate (ANIT) is a known toxin that induces reproducible and dose-dependent intrahepatic cholestasis by injuring biliary epithelial cells (Wu *et al*., 2005; Tanaka *et al*., 2009). ANIT, when administered acutely, leads to necrosis of portal bile ducts and inflammation of portal areas, whereas prolonged administration leads to bile ductal proliferation and cirrhosis induction (Zimmerman, 1999; Kodali *et al*., 2006).

Changes in the liver metabolites levels of ANIT-treated rats, sacrificed at different time-points post-treatment, were examined using ^{1}H-NMR spectroscopy of aqueous and lipid-soluble extracts and intact liver tissue (Waters *et al*., 2002). Rats were administered with a single ANIT dose of 150 mg kg^{-1} BW, p.o., and were sacrificed at 3, 7, 24, 31 and 168 h later on. Glucose and glycogen levels were decreased being characteristic of ANIT-induced toxicity. The declined levels of fumarate suggested alterations in the citric cycle. ^{1}H-NMR spectra and PCA of the aqueous liver extract presented an increase in the resonances assigned to inosine, adenosine, uridine, adenine, uracil and the nucleotide 5′ monophosphates GMP and TMP. Such observations may be attributed to ANIT or its metabolites that inhibit the enzymes involved in nucleotide metabolism. The elevated choline and phosphocholine levels observed in the ^{1}H-NMR aqueous soluble liver extract could be explained by the membrane breakdown and the accelerated lipid metabolism.

^{1}H-NMR spectroscopy was also employed to investigate the effects of ANIT and distinguish them from the effects of 1-napthylisocyanate (NI) and 1-napthylamine (NA), two main products of ANIT metabolism (Azmi *et al*., 2005). ^{1}H-NMR spectroscopy of rat urine from ANIT-treated animals revealed changes in the metabolites in a dose-dependent manner for all doses used. A single oral dose of ANIT (0, 50, 75, 100 and 150 mg kg^{-1} BW), NI and NA (75 mg kg^{-1} BW) was administered to rats. Decreased citrate, succinate, 2-oxoglutarate (2-OG), dimethylglycine and hippurate urine levels were noted. In addition, elevated urine levels of glucose, lactate, acetate, creatine, taurine and bile acids were recorded at the different time-points examined. TMAO and choline levels declined at first and increased later compared with controls. Elevated glucose and TMAO levels and decreased LDL/VLDL, choline and lactate levels were observed in plasma samples. ^{1}H-NMR of the intact tissue revealed dose-dependent decrease of glucose and glycogen levels together with increased lipid resonances, TMAO, choline and glycerophosphocholine levels. Following NI and NA administration, ^{1}H-NMR spectra of urine, blood plasma and intact tissues revealed that similar metabolite alterations occurred after treatment with either compound; however, the authors concluded that ANIT is the most toxic followed by NI and NA.

Thioacetamide (TAA) causes centrilobular hepatic necrosis and nephrotoxic damage when administered acutely (Waters *et al*., 2005) and bile duct proliferation leading to liver cirrhosis after chronic administration (Constantinou, Theocharis and Mikros, 2006).

Waters *et al*. have studied liver and kidney toxicity induced by acute TAA administration (150 mg kg^{-1} BW in water, sacrificed at 3, 7, 24, 31 and 79 h post-dosing) using the metabonomic approach (Waters *et al*., 2005). ^{1}H-NMR spectra of intact liver tissue, blood plasma and urine were recorded and their results were correlated with clinical chemistry and histopathological examination. ^{1}H-NMR spectroscopy of blood plasma from animals treated with a single TAA dose revealed an increase in choline and creatine levels at all time-points

examined and a rise in the amino acids valine, glutamine, leucine, isoleucine, glutamate, lysine and alanine that could be associated with the elevated levels of 3-D-hydroxybutyrate and acetoacetate. Citrate and LDL levels were decreased while acetate was augmented. ^{1}H-NMR spectra of intact tissue revealed a decrease in the glucose, glycogen, TMAO and betaine levels. The signals assigned to lipids, choline and phosphocholine were elevated accompanied by a rise of isoleucine, leucine and creatine levels. The depletion in hepatic glucose and glycogen levels was correlated with the elevated plasma lactate, suggesting increased rates of glycogenolysis and glycolysis. The elevated lipid levels monitored in the ^{1}H-NMR of the intact liver demonstrate the drug-induced lipid accumulation, a common response to toxicity.

Rat serum and liver tissue extracts from TAA-induced fulminant hepatic encephalopathy (FHE) rats (Theocharis *et al*., 2003) were studied using NMR-based metabonomics, by our group (Zira *et al*., 2009b). Rats were administered with acute dose of TAA (400 mg TAA kg^{-1} BW, i.p., at three consecutive time intervals of 24 h) and were sacrificed 1 h after the last TAA administration. NMR analysis revealed an overall decrease in the hepatic levels of lactate, acetate, valine, leucine, isoleucine, choline, glutamine, glutamate, glutathione, $N^+(CH_3)_3$ of the choline headgroup, glucose and glycogen in treated animals as a result of TAA-induced FHE. Serum lipoproteins in TAA-treated rats were also decreased, suggesting induction of lipid peroxidation.

Moreover, the NMR-based metabonomic approach of chronic TAA-induced liver injury, representative of early and late fibrosis and cirrhosis, has been studied (Constantinou, Theocharis and Mikros, 2006). Animals were chronically treated with TAA (300 mg l^{-1} in drinking water) and were sacrificed at the end of the first, second and third months from the onset of treatment. The changes in the metabolic profile were recorded by ^{1}H-NMR spectroscopy in liver tissue extracts (aqueous, lipid) and serum. A decrease in the resonances assigned to glucose and glycogen combined with the increased lactate levels in serum during the second and third months suggest a rise in the rates of glycogenolysis and glycolysis. The augmented hepatic lactate may be attributed to an energy shift towards ketone body formation. ^{1}H-NMR spectra of the aqueous liver extract revealed a decrease in the glucose levels that could be related to the observed deficiency of Krebs' cycle intermediates (e.g., fumarate). In addition, the observed increase in glycerophosphorylcholine and choline could be characteristic of lipid catabolism and the depletion of hepatic TMAO may suggest a TAA-induced block in the N-oxidation pathway of choline and glycerophosphorylcholine.

Bromobenzene administration causes hepatic centrilobular necrosis along with kidney and lung necrosis. The bromobenzene-induced hepatotoxicity was studied using the metabonomic approach (Waters *et al*., 2006). The alterations caused after oral bromobenzene administration (1.5 g kg^{-1} BW, in corn oil) were monitored by ^{1}H-NMR spectroscopy of intact rat liver tissue, blood plasma and urine. ^{1}H-NMR urine analysis presented a rise in creatine along with a decrease in taurine levels, indicating hepatic necrosis with glutathione reduction. A number of metabolites involved in energy generation (glucose, glycogen, Krebs' cycle intermediates) were altered pointing to increased energy metabolism. The changes observed in the levels of amino acids, in either liver tissue or blood plasma, were related to the amino acid and nucleotide metabolism. Lipid degradation was verified by increased choline/phosphocholine levels together with decreased liver lipid and plasma LDL. 5-Oxoproline, a new metabolite associated with the γ-glutamyl cycle, was detected in rat liver, plasma and urine and following bromobenzene administration.

Realgar is an ore crystal containing more than 90% tetra-arsenic-tetrasulfide (As_4S_4) and has been used as a traditional Chinese medicine. However, it is known that arsenic is a poison and carcinogen possibly through chromosomal abnormalities, oxidative stress, altered growth factors, cell proliferation and altered DNA repair (Wei *et al*., 2009).

The time-dependent toxicological effects of realgar in male Wistar rats after intragastric administration (1 g kg^{-1} BW) were investigated using the metabonomic approach. Animals were treated with realgar for a time period of 21 days, and ^{1}H-NMR spectra of urine, serum and liver tissue aqueous extracts were recorded (Wei *et al*., 2009). Metabonomics revealed alterations in the levels of metabolites related to energy metabolism. Decreased levels of glucose and glycogen represent elevated rates of glycolysis and glycogenolysis. Decreased levels of pyruvate and lactate followed

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat220
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

by elevated urinary excretion of Krebs' cycle intermediates (citrate, succinate and α-ketoglutarate) suggested an expansion in Krebs' cycle pool. Alteration in the levels of ATP/ADP in aqueous soluble liver extract also suggested disturbance in energy metabolism. The increased levels of choline-containing metabolites after realgar treatment were possibly caused by realgar-induced membrane toxicity. Furthermore, the decreased levels of alanine and glucose in both liver and serum imply a delay in the glucose-alanine cycle and the drop in the levels of glutathione is the way the organism protects cells from the free radicals created by the toxic agent.

Methapyrilene is a histamine antagonist causing periportal liver necrosis in rats, and its effect was investigated using a combination of genomics, proteomics and metabonomics (Craig *et al*., 2005). Male rats were orally administered with methapyrilene for 3 days with a subtoxic dose of 50 mg kg^{-1} day^{-1} or a toxic dose of 150 mg kg^{-1} day^{-1} (causing liver necrosis). Administration of methapyrilene caused a number of dose-related changes in gene, protein and metabolite profiles. Alterations in the expression of genes associated with stress (e.g., heat shock protein expression at gene and protein levels) and apoptosis, and in the metabolic pathways of glucose, fatty acids, choline metabolism and urea, were noted. Hepatic glucose and glycogen levels were decreased, as recorded by ^{1}H MAS NMR of intact liver, in agreement with the decrease noted in the gene and protein levels of intermediates related to carbohydrate metabolism. These observations suggest increased glycolysis and decreased gluconeogenesis that could be further supported by the decline of fructose 1,6-bisphosphatase and pyruvate carboxylase. The elevated triglycerides levels observed in ^{1}H MAS NMR along with the altered proteins involved in the phenylalanine catabolism and the synthesis of ketone bodies suggested impairment in mitochondrial fatty acid β-oxidation.

Ethionine, an analogue of the amino acid methionine, induces fat accumulation, steatosis and pancreatitis post-acute administration while post-chronic administration it induces bile duct proliferation, cirrhosis and hepatic carcinoma (Lombardi, 1976; Zimmerman, 1999).

The ethionine-induced liver injury in rats was recently investigated using NMR-based metabonomics (Skordi *et al.*, 2007). Animals were orally treated with a single low and high dose of ethionine (80 and 800 mg kg^{-1} BW, respectively). Rat urine was collected 7 and 17 h after dosing and over a 7-day period at 7- and 17-h intervals; the animals were sacrificed on days 2 and 8, respectively. MAS NMR of the intact liver presented accumulation of triglycerides, increased diacyl glycerol and increased hepatic bile acid concentration, which indicate liver damage caused by ethionine administration. Ethionine also interferes with the methylation reactions, γ-glutamyl cycle and energy metabolism (decreased levels of TCA intermediates, citrates, 2-OG, fumarate and succinate).

Allyl formate is a toxic agent that causes periportal hepatotoxicity (Obata, Egashira and Yamanaka, 1989; Yap *et al*., 2006). ^{1}H-NMR-based metabonomics were used to study the alterations induced in rats following allyl formate treatment. Spectra from intact liver tissue, blood plasma and urine were recorded for controls and rats administered with a single dose of allyl formate (75 mg kg^{-1} BW, i.p.) and sacrificed at days 2 and 8 post-treatment (Yap *et al*., 2006). Allyl formate administration induced hepatic lipidosis with significant increases in liver lipids and lower hepatic glucose, glycogen, taurine and TMAO levels. The decreased hepatic levels of glucose and glycogen also suggested increased energy demand. Furthermore, the reduced hepatic and urinary TMAO levels could be related to reduced food intake, disruption of liver function or intestinal bacteria. Moreover, the increased plasma tyrosine suggested impaired protein synthesis in the liver.

Peroxisome proliferators (PPs) are industrial/commercial chemicals presenting tumor promoter activity in rodents in a mechanism not completely clarified (Kawashima *et al*., 1995; Reo and Adinehzadeh, 2000). Among the PPs, perfluorododecanoic acid (PFDoA), a member of the perfluorocarboxylic acids (PFCAs) extensively used in food packaging, cosmetics, surfactants, surface protectors and fire-retardant foams, lacks promoter activity (Reo and Adinehzadeh, 2000; Prevedouros *et al*., 2006).

NMR-based metabonomics was applied to study the effect of PFDoA chronic exposure (110 days) on rat liver. PFDoA was orally administered via gavage at doses of 0.02, 0.05, 0.2 and 0.5 mg kg^{-1} BW/day (Ding *et al*., 2009). Increased lipid concentrations in liver tissue and decreased lipids and lipoproteins in serum suggested alterations in lipid metabolism due to PFDoA-induced hepatotoxicity. The increased levels of acetate and ketone bodies (3-HB and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat220
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

acetoacetate) were a sign of lipid peroxidation. Elevated levels of sugars, lactate, pyruvate, acetate and creatine suggested alterations in carbohydrate and energy metabolism after PFDoA administration.

A combined study of the effect of APAP and bromobenzene was conducted to compare NMR urine analysis with histopathological and biochemical parameters (Schoonen *et al*., 2007). A single dose of each of the toxic agents at five different concentrations (2, 8, 32, 125 and 500 mg kg^{-1} BW for bromobenzene and 6, 25, 110, 450 and 1800 mg kg^{-1} BW for APAP) was administered to rats and urine samples were collected at days 1 and 2 post-treatment. Changes in the plasma AST and ALT levels at both time-points post-treatment at the highest dosages are in agreement with the centrilobular necrosis induced by each of these compounds alone. NMR data presented an increase in lactate, acetate, pyruvate, glucose and 3-hydroxybutyrate, attributed to increased rates of glycolysis and disrupted oxidative phosphorylation from fatty acids, caused by APAP. Bromobenzene administration produced decrease citrate and α-ketoglutarate levels, which could also be attributed to a decreased oxidative phosphorylation.

In addition, the metabonomic approach was used in a combined study to discover potential biomarkers of hepatotoxicity induced by three agents, CCl_4, APAP and D-galactosamine (Kim *et al*., 2008). A single dose of either CCl_4 (1 ml kg^{-1} BW, orally) or D-galactosamine (0.8 g kg^{-1} BW, i.p.) was administered and urine was collected at days 1 and 2. APAP (2 g kg^{-1} BW, orally) was administered for 2 days and urine was collected 24 h after last treatment. NMR spectroscopic data combined with PCA from rats treated with CCl_4 present alterations in the levels of citrate, allantoin, taurine, 2-OG, acetate, lactate, betaine, succinate, benzoate and hippurate. PCA and NMR spectroscopic data from rats treated with APAP present alterations in the levels of citrate, allantoin, taurine, 2-OG, acetate, lactate, betaine, succinate, benzoate and hippurate, among other metabolites. Finally, in rats treated with D-galactosamine, the levels of 2-OG, acetate, taurine, citrate, lactate, allantoin, succinate, benzoate, betaine and hippurate were altered. Certain metabolites were altered in all three hepatotoxins. Decreased levels of citrate, 2-OG and succinate suggest hepatic necrosis. The elevated levels of taurine could be associated with the reduced hepatic function.

2.2 Kidney Toxicity

The kidney, after the liver, is one of the main target organs of xenobiotic-induced toxicity. Unfortunately, early detection of toxicant-induced kidney toxicity is still inadequate, yet the application of the "omics" technology could provide new biomarkers for kidney toxicity. The available data regarding metabonomics and kidney toxicity are depicted in Table 2.

Aristolochic acid (AA) is a chemical compound present in plants of the *Aristolochia*, *Bragantia* and *Asarum* species and is considered to be responsible for acute renal failure (ARF) associated with interstitial fibrosis, hyperproteinemia, severe anaemia, uraemia and carcinoma (Liu *et al*., 2003; Chen *et al*., 2007). Chen *et al*. used the metabonomic approach to identify the characteristic metabolic profile associated with AA-induced nephrotoxicity

Table 2. Summary of the experimental models examined in kidney toxicity.

	Kidney toxicity							
	Experimental animals	Dose used	Root of administration	Time-dependent experiment	Dose-dependent experiment	Biofluids examined	Methods	References
Aristocholic acid acute	Rats	50 and 96 mg kg^{-1} BW	i.p.	Yes	No	Urine	LC-MS	Chen *et al.* (2006)
Doxorubicin acute	Rats	5 and 15 mg kg^{-1} BW	i.v.	Yes	Yes	Urine	NMR	Park *et al.* (2009)
Gentamycin chronic	Rats	120 mg kg^{-1} BW	Subcutaneous	Yes	No	Urine	NMR	Lenz *et al.* (2005)
	Rats	60 and 120 mg kg^{-1} BW	Subcutaneous	Yes	Yes	Urine	NMR, GC-MS	Sieber *et al.* (2009)
Cyclosporine chronic	Rats	10 and 25 mg kg^{-1} BW (alone or combined with Rapa)	Oral	Yes	Yes	Urine	NMR	Klawitter *et al.* (2008)

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat220

(Chen *et al.*, 2006). Rats were divided into three groups receiving either 0.9% saline solution (controls), or a single dose of AA (50 mg kg^{-1} BW on day 0) or CAM (*Caulis Aristolochiae manshuriensis*, 30 g kg^{-1} day^{-1}, equivalent with 96 mg kg^{-1} day^{-1} AA). Urine samples were collected pre-dose (−12–0 h) and 1–12, 12–24, 48–60, 84–96 and 132–144 h post-dose. Histopathological examination and plasma biochemistry confirmed severe kidney damage after the AA administration at high dosage. Both AA and CAM presented similar biochemical perturbations as noted by the LC-MS metabonomics analysis. Increased adenosine levels led to the accelerated formation of homocysteine, suggesting AA-induced renal dysfunction. The elevated levels of serine and 5-CH_3-tetrahydrofolate indicate elevated rates of the folate cycle. The up-regulated D-serine might be an indication of the perturbation of the D-serine metabolism after the AA administration. The depleted levels of arachidonic acid could be possibly attributed to the blocked phospholipase A(2)-catalysed release of arachidonic acid caused by AA.

Doxorubicin (adriamycin) possesses therapeutic activity against human neoplasms; however, its clinical use remains limited due to cardiac and renal toxicity. ^{1}H-NMR-based metabonomics have been used to evaluate urinary metabolic alterations in rats treated with doxorubicin (Park *et al.*, 2009). A single intravenous (i.v.) injection of 5 and 15 mg doxorubicin hydrochloride per kg BW was administered to rats and urine samples were collected pre- and post-dose. PCA and particularly the mean scores plots showed that low- and high-dose -groups presented a dose-dependent shift. The low-dose group presented its maximum shift from controls at 48 h and returned to control levels. However, the high-dose group has not reached control levels at 168 h, suggesting irreversible toxicity. Animals treated with the high dose of doxorubicin presented either moderate recovery or no recovery towards control levels. Elevated urinary levels of taurine and creatine suggested hepatic toxicity. Increased urinary levels of creatine were apparent in the high-dose group at 168 h post-treatment, indicating inhibition of creatine kinase by doxorubicin. Elevated levels of *N*-methylnicotinamide in moderate recovery group animals of the high dose provided evidence for recovery from the toxicity. Increased phenylacetylglycine levels were the result of the doxorubicin-induced phospholipidosis in the liver. Urinary levels of TMAO in the low-dose group reached their maximum at 48 h post-dose and then recovered to control levels, suggesting that osmotic stress in the renal medulla resulted in metabolite alterations. The concomitant elevation in lactate, alanine and glucose levels (known as markers of renal cortical injury) indicated progression of renal toxicity induced by doxorubicin. In the high dose, both moderate- and no-recovery animals presented elevated lactate, alanine and glucose levels that were not altered compared with controls at 168 h. The excessive proteinuria might be provoked by doxorubicin, resulting in renal damage. Furthermore, the intermediates of the TCA cycle (citrate, 2-2-OG and succinate) were decreased, suggesting increased energy metabolism.

The application of HPLC-MS and ^{1}H-NMR spectroscopy to the study of the effects of the aminoglycoside antibiotic gentamycin was also reported (Lenz *et al.*, 2005). Male Wistar rats were treated with gentamycin at a dose of 120 mg kg^{-1} BW per day (subcutaneously), in the form of two separate doses of 60 mg kg^{-1} twice daily 8 h apart, for seven consecutive days. Urine samples were collected at day 1 and daily thereafter for 9 days. In addition to the metabonomic analysis, gentamycin-induced nephrotoxicity was also estimated using histopathological kidney examination and standard plasma and urine biochemical analysis. A decrease in TMAO and betaine and a gradual increase in the levels of citrate, glucose and lactate were noted, typical of gentamycin-induced nephrotoxicity.

The effect of gentamycin was studied using a combined ^{1}H-NMR and GC-MS metabonomics approach in order to find novel urinary markers for early detection of chemically induced nephrotoxicity (Sieber *et al.*, 2009). Male Wistar rats were treated with gentamycin at doses of 60 and 120 mg kg^{-1} BW per day (subcutaneously), for seven consecutive days. Urine samples were collected at 24-h intervals, whereas blood was withdrawn 24 and 72 h after the first dosing. Apart from the metabonomic approach, clinical chemistry (in urine and plasma), enzyme-linked immunosorbent assay (ELISA) in urine, immunohistochemistry and quantitative RT-PCR were also performed. Based on the metabonomic analysis, a clear dose- and time-dependent separation of gentamycin-treated rats compared to controls was observed. Decreased levels of citrate, hippurate, trigonelline and 3-indoxysulfate and increased

levels of glucose, lactate and dimethylglycine were observed. Creatine was not detected in controls; on the contrary, it was excreted in urine of gentamycin-treated rats. Enhanced urinary levels of creatine have been associated with hepatotoxicity; however, in the present study, this might be the result of drug-induced oxidative modification of mitochondrial or cytosolic creatine kinases, enzymes susceptible to oxidative stress. Increased lactate levels may be attributed to the mitochondrial toxicity induced by gentamycin.

The immunosuppressant calcineurin inhibitor cyclosporine (CsA) is used to protect against allograft rejection (Ojo *et al.*, 2003). However, extended use of calcineurin inhibitors is associated with a high risk of complications that can affect both graft and patient survival. CsA toxicity, acute or chronic, involves oxidative stress, apoptosis, metabolic changes and an increase in vascular resistance, resulting in decreased renal blood flow (Humes *et al.*, 1985; Sullivan, Hak and Finn, 1985; Campistol and Grinyó, 2001; Chapman, O'Connell, Nankivell, 2005). CsA combined with other drugs [proliferation signal inhibitors such as sirolimus (known as rapamycin, Rapa)] presents additive or synergistic immunosuppressive activity, allowing for lowering CsA doses. The time-dependent effects of CsA and Rapa, alone or in combination, on the rat kidney were studied (Klawitter *et al.*, 2008). Rats were divided into nine treatment groups that received orally CsA alone or with Rapa: I, controls (skim milk for 6/28 days); II, CsA 10 mg kg^{-1} day^{-1} for 6 days; III, CsA 25 mg kg^{-1} day^{-1} for 6 days; IV, Rapa 1 mg kg^{-1} day^{-1} for 6 days; V, CsA 10 mg kg^{-1} day^{-1} + Rapa 1 mg kg^{-1} day^{-1} for 6 days; VI, CsA 25 mg kg^{-1} day^{-1} + Rapa 1 mg kg^{-1} day^{-1} for 6 days; VII, CsA 10 mg kg^{-1} day^{-1} for 28 days; VIII, Rapa 1 mg kg^{-1} day^{-1} for 28 days; IX, CsA 10 mg kg^{-1} day^{-1} + Rapa 1 mg kg^{-1} day^{-1} for 28 days. On days 5 and 27, rats were placed in metabolic cases for the 24-h urine collection. On the final day, 2 h after the time of last administration, the animals were sacrificed. All rats receiving CsA for 28 days with or without Rapa presented impairment of renal function and histomorphologic alterations typical of CsA-induced toxicity. Compared with controls animals treated with CsA after 6 days presented decreased levels of citrate, succinate and 2-OG and increased levels of acetate, lactate, trimethylamine and hippurate. CsA alone or combined with Rapa, after 28 days, increased urinary lactate and glucose and decreased Krebs' cycle intermediates, suggesting that the proximal tubulus cells cannot use lactate and glucose as energy substrates; therefore, they substract urinary Krebs' cycle intermediates. Although Rapa alone does not induce nephrotoxicity, this study proves that even though serum creatinine levels are not altered changes in kidney histology are apparent after 28 days, typical of tubular system atrophy.

2.3 Heart Toxicity

The cardiovascular system is a potent target of toxicity because drugs and a wide range of compounds in industry and domestic life present a potential hazard. The recent metabonomics studies concerning heart toxicity are summarized in Table 3.

Table 3. Summary of the experimental models examined in heart and brain toxicity.

	Heart toxicity							
	Experimental animals	Dose used	Root of administration	Time-dependent experiment	Dose-dependent experiment	Biofluids examined	Methods	References
Doxorubicin acute	Rats	20 mg kg^{-1} BW alone or combined with Oleu)	i.p.	No	No	Tissue	NMR	Andreadou *et al.*, (2009)

Doxorubicin (adriamycin, DXR) presents dose-dependent cardiotoxicity (Cole *et al*., 2006). The alterations caused by DXR administration on male Wistar rats were examined in order to identify and quantify metabolites that could be considered as potential biomarkers (Andreadou *et al*., 2009). Furthermore, the effect of the antioxidant oleuropein (Oleu) on the DXR-induced cardiotoxicity was studied. Animals were administered (i.p.) with a single dose of saline (control group), DXR (20 mg kg^{-1} BW), and a combination of Oleu and DXR at different dose regimens (rats treated with 100 or 200 mg Oleu/kg/BW, 2 days before, on the same day and 2 days after the administration of DXR and rats treated with 100 and 200 mg Oleu/kg/BW immediately after DXR administration and for two consecutive days). DXR-treated group presented elevated levels of acetate that could be attributed to the decarboxylation of pyruvate by reactive oxygen species produced by DXR. Furthermore, acetate accumulation may be responsible for the inhibition of fatty acid β-oxidation induced by DXR. Increase in succinate levels in the DXR group compared with the control group was noted, probably due to a rapid inactivation of mitochondrial succinate dehydrogenase by DXR. A decrease in valine, leucine and isoleucine levels may be attributed to the DXR-induced reduction of ATP production through inhibition of β-oxidation of fatty acids and Krebs' cycle impairment, using amino acids as an energy reservoir. On the other hand, Oleu at both doses tested reduced both succinate and acetate accumulation, indicating that energy consumption is restored in DXR-induced cardiotoxicity. PCA of the examined groups did not separate the two groups treated with 100 mg Oleu from the DXR group. In contrast, the two groups administered with 200 mg Oleu were well separated from the controls and the DXR group but without any distinction between the two groups.

The plasma perturbations caused in the metabolite levels during heart ischaemia–reperfusion (I/R) in rabbits were also examined (Constantinou *et al*., 2007). Furthermore, the effect of melatonin (a natural hormone of the indole family) and of a novel synthetic indole derivative was examined. Animals were grouped into six main groups: baseline, controls, melatonin-(I/R), ischaemic pre-conditioning, melatonin-pre-conditioning and indole derivative. Alterations in the plasma levels of LDL/VLDL, unsaturated fatty acids, glucose, alanine, glutamine, glutamate, phenylalanine, tyrosine and histidine were observed compared with controls. The lactate/glucose ratio was increased in the reperfusion group compared with baseline, whereas the lactate + alanine/acetate ratio was decreased, suggesting an increase in the anaerobic metabolism during reperfusion and an increased consumption of lipids, respectively. Both ratios remained unchanged during reperfusion when hearts were subjected to pre-conditioning, indicating that glycolysis followed the aerobic pathway and lipid consumption was not increased. PCA grouped all reperfusion samples away from baseline; still, reperfusion samples that were subjected to pre-conditioning were placed among the baseline ones. Melatonin-treated rats formed their own cluster away from beseline; however, no clustering could be achieved between melatonin–ischaemia and melatonin–reperfusion animals. Furthermore, rats treated with the synthetic indole were discriminated from melatonin-treated ones and the baseline; nevertheless, no discrimination between I/R was apparent.

2.4 Brain Toxicity

The risk of neurotoxic damage from exposure to environmental pollutants and industrial chemicals placed the nervous system in the category of target organs for toxic injury, although limited studies exist in this field (Table 3).

3-Nitropropionic acid (3-NP) is a neurotoxin, naturally produced by certain legumes and fungi (Gustine, 1979). It is extensively used in laboratories because it gives rise to behavioural and histological features similar to Huntington's disease (HD) (Tsang, Haselden and Holmes, 2009).

The dose-dependent alterations caused by 3-NP in selected brain regions were examined (Tsang, Haselden and Holmes, 2009). Sprague–Dawley rats were administered with 3-NP i.p. at doses of 0 (controls), 5.0 (low dose) and 10 mg kg^{-1} day^{-1} (high dose, which was reduced to 7.5 mg kg^{-1} from day 3 onwards) for 14 consecutive days. In general, controls presented an increase in body weight, whereas 3-NP-treated rats presented a decrease in body weight on the final day of the dosing. In all brain regions, a dose-dependent increase in the levels of succinate and decreases in *N*-acetylaspartate and taurine levels were noted, after treatment with 3-NP. Region-specific alterations included a decrease in

γ-aminobutyric acid (in the brainstem, ventral striatum and frontal cortex) and alterations in lipids occurring in the globus pallidus and dorsal striatum. Increased lactate levels (in the cortex and dorsal striatum) in the rats treated with 3-NP suggest a deficiency of oxidative metabolism. ^{1}H-NMR data of the aqueous extracts of the frontal cortex revealed decreased levels of *N*-acetylaspartylglutamate, whereas the lipid extract revealed a dose-dependent decrease of phosphatidylcholine and an increase of glycerol. The alterations in the levels of choline and phosphocholine were associated with changes in the membrane composition and with decreased anabolic and/or increased catabolic activity in the ventral striatum.

3 CONCLUSIONS

The "omics" technologies, especially metabonomics, have been widely applied to the investigation of target organ toxicity. Especially when coupled with NMR spectroscopy metabonomics has been characterized as a powerful tool that studies simultaneously the fluctuations of low-molecular-weight metabolites that could be further characterized as biomarkers. Nevertheless, the target organ toxicity studies performed, using the metabonomic approach, remain limited to experimental animal models (Tables 1–3), and to our knowledge, no clinical toxicological data have been recorded up to now.

In the metabonomic studies stated, a complete separation of experimental from control samples was achieved. However, no clear biomarker(s) of toxicity was established in any of them. Additionally, the existing data are not sufficient to predict either the toxic and recovery phases or a state of organ failure where the recovery is not possible. The reason for unclear conclusions from the existing data that simply report differences between toxic and healthy states is the lack of databases that could collect, combine and extrapolate all useful information from each study.

As previously demonstrated the existing data on metabonomic approach and target organ toxicity are mainly related with different models of acute and/or chronic liver injury. Further use of metabonomics is imperative in other models of tissue injury such as lung, heart, brain and gastrointestinal tract. For better exploitation of the results from metabonomic studies, the creation of databases is imperative. Such databases would comprise all metabolites altered during the toxic insult so that the toxic agents could be clustered in groups based on common alterations.

The metabonomic approach in combination with data obtained from genomics and proteomics studies could provide valuable information regarding the underlying mechanisms of target organ toxicity.

Toxicoinformatics for Systems Toxicology

Lyle D. Burgoon

Center for Integrative Toxicology, Department of Biochemistry and Molecular Biology, Michigan State University, East Lansing, MI, USA

1 AN INTRODUCTION TO TOXICOINFORMATICS

Systems biology by its nature is a data intensive enterprise. The idea behind systems biology and systems toxicology is to integrate data from varying and disparate data sources to create a clearer understanding of how chemicals affect organ systems, entire organisms, and ecosystems.

Generally, when we think of toxicoinformatics and its impact on systems toxicology, we think about the creation of biological networks. To others, the term systems toxicology really focuses on mathematical modeling of biological phenomena. And to others, the focus is on the integration of biological networks with mathematical models. This chapter discusses systems biology with respect to network biology, and next steps after creating a gene expression network.

No matter how you define systems toxicology, one requirement will always remain: how do we manage this data? When working in a team science environment, the next question is generally "how do we exchange data?" This chapter attempts to address many of these issues, and gives some guidance on how teams can manage and organize their data.

2 DATA MANAGEMENT

Data management concerns the acquisition, handling, storage, and ways of making data available. This includes ensuring data security, the creation of databases and data warehouses, and making these databases and warehouses available to yourself or others for later use in data analyses. This chapter highlights important topics in each of those areas; however, readers should consult specialty texts on these topics for more depth.

2.1 Data Security

Usually, when we think of data security, we envision antivirus software, firewalls, and data encryption to prevent unintended release of our sensitive information. However, data security includes ensuring data that are copied from the source to the destination is a bona fide copy of the original (e.g., copying data from a laboratory computer to your office computer). This section discusses the more practical elements of data encryption, especially their use in ensuring copies of data are bona fide copies of the original.

2.2 Digitally Signing Data

Generally, data encryption is a means to ensure that only the intended recipient can read a piece of data, such as a data file. Encryption works by applying some algorithm to a set of data to transform it. When the intended recipient (could be yourself) wants to read the file, they need to use the decryption algorithm. Both the encryption algorithm and the decryption algorithm require the use of a key. The

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat221
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

algorithms use the key to either encrypt or decrypt the file. The encryption and decryption algorithm typically use different keys.

One of the most common encryption schemes in use today is the asymmetric cryptosystem. There are numerous examples of asymmetric cryptosystems that we use every day, and probably do not realize it. For instance, when you purchase a product online from your favorite retailer, most of us look for the "closed padlock" icon in our web browser.

First, the entity operating the server contacts a certificate authority (CA) to obtain a certificate. This digital certificate contains a public and a private key, and is signed by the CA. When a client (e.g., web browser) sends an SSL connection request to the server, the server responds by sending its certificate with only the public key and the CA's signature. Most web browsers will check the CA's signature to ensure authenticity. This is performed by decrypting the signature using the CA's public key, and comparing that decrypted signature to a plaintext (non-encrypted) signature contained in the certificate. The key here is that when the CA signed the certificate, they encrypted the plaintext key using their private key, and this encrypted key is the signature. Because of the relationship between a public and private key pair, the only way for the decrypted signature to match the plaintext key is if the proper private key was used to encrypt the signature (remember, the signature was encrypted using the private key by the CA, and the client is decrypting the signature using the public key). If the signatures check out, then the client encrypts a random key using the server's public key. The only way to decrypt this random key is to use the private key on the server. From here, all transmissions are encrypted using the random key – this is a form of symmetric encryption.

As we have seen in this example, asymmetric encryption methods allow data to be signed and encrypted. This is useful for data transmissions between parties through an insecure channel, such as the internet, but this is overkill if we want to ensure data going from one hard drive to another is the same.

2.3 File Signatures/Fingerprints

One very common problem in systems biology today is ensuring that data coming from one source are actually a bona fide copy of the original. As the size of files from instruments and machines continues to increase, so the number of data will transfer problems. Consider for instance the ubiquitous practice of compressing large datasets. Depending upon the algorithm, problems in data transmission can either be a nuisance (e.g., loss of some bytes) or catastrophic (e.g., unable to read the file). In other cases, if we were to have an issue in transmitting a text file, we may lose the file structure (this can be fixable), or may lose data. In all of these cases, the concern is that we lose data.

One way to ensure that data are a bona fide copy of the original is to compare the checksums, also known as file signatures or fingerprints, of the original file and copy. If the checksums are identical, then you know the files are the same. However, if the checksums are different, then the file contents are different. The most commonly used checksum algorithms are MD5, SHA-1, and the SHA-2 family (includes SHA-256 and SHA-512). The MD5 and SHA256 checksums can be calculated in Linux using the md5sum and sha256sum utilities. In Windows, you can calculate MD5 and SHA-1 using the File Checksum Integrity Verifier (FCIV) available from Microsoft (http://support.microsoft.com/kb/841290).

The process of checking the checksums is rather simple: you run the appropriate program on the file of interest on the original computer. You keep track of the checksum value it returns. For instance, for a database I created recently, the MD5 and SHA-256 checksums are:

- MD-5: 026616c0b802605d3c0df47fe742e65c
- SHA-256: cd6b3eee03e3da12dcd6b67013bfe4d c6d7b75999c40b0833e93774b90b0db65

Then you calculate the checksum of the copied file, and compare the checksum of the original file and the checksum of the copied file. If they are different, then you know the copied file is corrupted. For instance, when I distribute the database file to colleagues, I ask that they verify that the checksum value for their copy is the same as the ones listed above.

2.4 Creating Databases and Data Warehouses

Databases are combinations of hardware and software that facilitate data storage and retrieval.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat221
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Building databases is more of an art than a science; however, as the amount of data that we need for understanding our systems continues to increase, investigators will soon understand why spreadsheets are not appropriate for making sense of their data.

The most basic rule of designing a database is to reduce, as much as possible, any data redundancy. The corollary to this is to not to go so far as to make your database difficult to use. For instance, if we were to create a database for an organization, such as the US National Toxicology Program, we may need to create a table storing vendor information. This table would contain the vendor's name, street address, city, state, and zip code. Remembering the first rule stated above, we might believe that city, state, and zip code may become redundant within the table (i.e., multiple vendors may be in the same zip code, and thus, in the same city and state). Thus, we might want to create a separate table that incorporates the US Postal Service's zip code database, which associates zip codes with the city and state. This would be an ideal situation if we were also going to design a graphical user interface front-end, such as a website to enter this information. However, if our use case is instead that our users are going to be uploading legacy data from spreadsheets or text files, it might be better to just allow the city, state, and zip code to remain in the vendor table.

The second most important rule in designing databases is to make sure each table has a unique key or identifier. We call this unique key the primary key and it serves as a means to hook tables together. For instance, if we want to create a database to manage animal end-point assays, such as histopathology data, we would need to capture information about the animals (e.g., sex, age, species, strain, and laboratory identifier), their cage (e.g., bedding, cage mates, access to and type of food and water), and other environmental factors (e.g., light–dark cycle, humidity, temperature), in addition to tables to manage the end-point data itself. One solution is to create an animal table, a cage table, an environmental factors table, and a table for the end-point data. For this solution to work, a unique identifier must be assigned to each animal, each cage, each environmental factor, and each end-point data point. Next, when we construct the animal table, we include a column for the cage identifier. The cage table will include a column for the environmental factor identifier. The end-point data table will include a column for the animal identifier.

By including these identifiers in the tables, we are able to perform queries against the database where the tables are joined together. The simplest way to think of table joining is to imagine replacing the foreign unique identifier, known as a foreign key, in a table (e.g., the cage table contains an animal identifier foreign key) with its associated values in its primary table. For instance, imagine replacing all instances of the animal identifier = 1 in the cage table with the data in the animal table associated with animal identifier = 1 (e.g., the strain, species, age, sex, and laboratory identifier).

Data warehouses are slightly different from databases with respect to the scope of data contained. Databases are intended to store the raw data from projects, experiments, and studies. As a result, databases can become massive. If, users are only interested in aggregated data (e.g., group mean values and standard deviations), then it may be more useful to create a data warehouse.

A data warehouse only stores aggregated information. Data warehouses have a similar design feel as databases in that they should not contain redundant information. However, the underlying table designs for a data warehouse may differ substantially from the database. Again, the primary motivator for design should always be the intended usage of the database or data warehouse.

Querying databases and data warehouses is carried out using the Structured Query Language (SQL). SQL is a relatively straightforward language for investigators to learn. The exact ways in which to use SQL and how to write SQL queries is beyond the scope of this book chapter, so readers should consider reading an SQL reference. One can be found in the "References" section of this chapter (Viescas and Hernandez, 2008).

3 NETWORK MODELING AND GENE REGULATORY ELEMENT IDENTIFICATION

Systems toxicology datasets are much larger than those that many toxicologists find familiar. Consider that the average gene expression microarray will provide data for 10 000–40 000 probes. Multiply that by a number of time-points in a time–course experiment, or several doses in a dose–response dataset, along with biological replication, and the data quickly number in the hundreds of thousands to millions of data points.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat221
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Most investigators when approached with massive datasets, such as these, will naturally turn to pattern recognition techniques to identify some type of underlying structure. This typically results in agglomerative hierarchical clustering heat maps, k-means clustering, and self-organizing maps to visualize patterns or identify unique patterns. Although these methods are useful for visualizing correlative structures within the data, new methods have been emerging that focus more explicitly on constructing gene regulatory networks.

3.1 Gene Network Modeling

The goal of gene network modeling is typically to discover some hidden regulatory structure underlying gene expression across dose, time, or developmental stage. For instance, an investigator may be interested in the gene regulatory network underlying exposure to a particular drug. In this case, the investigator may perform a dose–escalation, a time–course study, or a combination of both. By identifying genes that are "connected" to each other in the network, the investigator may hypothesize that these connected genes, or some subset of these connected genes, are regulated by the same transcription factor(s). Following up on these hypotheses may lead to new data that can enable the creation of systems toxicology mathematical models that drive further understanding of the system as a whole.

The first step in constructing a gene network is to identify an appropriate gene expression microarray normalization method. In the past, this step was often overlooked; however, it has recently been recognized that normalization methods that are appropriate for identifying differential gene expression may not be appropriate for constructing gene networks (Lim *et al*., 2007). Additional work needs to be performed in this area on real biological and simulated biological networks before any definitive advice on specific normalization methods can be made.

Data quality issues may also hamper network construction; thus, investigators are encouraged to ensure they are using data from the highest quality microarrays available (Burgoon *et al*., 2005). For instance, especially when combining data from multiple studies, differences in the overall signal intensity of arrays may create false-correlative structures, while simultaneously destroying true correlations. This is another area that requires further study.

After data normalization and quality items have been addressed, investigators must choose what metric they will use for generating the network. Rather than focus on complicated and computationally intensive methods, such as Bayesian networks and dynamic Bayesian networks, this chapter focuses on simpler correlation and mutual information-based methods that are relatively common today, and are significantly less computationally intense.

The correlation methods are the Pearson's and Spearman's correlations. The Pearson's correlation is the correlation most of us are used to:

$$\text{Correlation} = \frac{\text{cov}(X, Y)}{\text{SD}(X)\text{SD}(Y)} \tag{1}$$

where SD is the standard deviation. The Spearman's correlation, also known as the Spearman's rank correlation, is defined as:

$$p = 1 - \frac{6\sum d_i^2}{n(n^2 - 1)} \tag{2}$$

where d_i is the difference between x_i and y_i.

In R, the Pearson's and Spearman's correlations are calculated using cor(gene_expression_matrix, method = "pearson") and cor(gene_expression_matrix, method = "spearman"), respectively. The rows in the input matrix are the individual microarrays, whereas the columns are the genes or probesets (i.e., the input matrix is the transpose of the gene expression matrix). If using any of the standard microarray analysis packages, this gene expression matrix is usually part of an expression set, and can be assigned to a variable using something like:

$$\text{gene\_expression\_matrix} \leftarrow \text{exprs(expression\_set)} \tag{3}$$

After applying the methods, a new square matrix is created, where the rows and columns are the genes or probesets from the original data matrix. Thus, the rows and columns in this square matrix represent the correlation between the genes or probesets. The resulting square matrix is referred to as a correlation

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat221
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

matrix. Most investigators calculate the absolute value of the correlation values in the square matrix.

Similarly, mutual information methods take the same type of matrix as input as the correlation methods. Mutual information is calculated as:

$$I(X;Y) = \sum_{y \in Y} \sum_{x \in X} p(x, y) \log_2 \left(\frac{p(x, y)}{p(x)p(y)} \right) \quad (4)$$

where the mutual information $I(X;Y)$ is measured in bits, $p(x)$ and $p(y)$ are the marginal probabilities, and $p(x, y)$ is the joint probability. The output of the mutual information methods is typically a square matrix, similar to what is constructed by the correlation methods.

To create a graph, typically this square matrix is converted to an adjacency matrix, where all correlation and mutual information values above a given threshold are converted to 1, and all other values are converted to 0. Each gene or probeset is both a row and a column. Thus, the diagonal of the matrix is set to 1 (because a gene or probeset is always correlated with itself and the mutual information is always 1). The graph will consist of nodes (genes or probesets) and edges between these nodes. An edge is drawn between nodes if the corresponding value in the adjacency matrix is 1. For instance, if two genes, cyp1a1 and cyp1b1, have a value of 1 in the adjacency matrix, then the graph will have an edge connecting these two nodes.

Generally, graphs for the correlation methods are drawn based on the adjacency matrix. Similar mutual information graphs can also be drawn; however, several groups have begun exploring methods of "pruning" these mutual information graphs to get rid of spurious, or false, edges. Discussion of these multitudes of methods is beyond the scope of this chapter. Instead, investigators are encouraged to monitor the results from the ongoing DREAM competition (http://wiki.c2b2.columbia.edu/dream/index.php/The_DREAM_Project).

DREAM is a competition where groups to test their method against other methods for constructing biological networks. Thus far, the competition has not identified any particular methods that consistently outperform the others. It remains unclear what the poorly performing methods are (the competition organizers only disclose those methods that perform the best within the competition). Perhaps the most significant open question is whether the more complicated mutual information pruning methods (e.g., ARACNE) outperform the simpler correlation and mutual information based methods (i.e., using the adjacency matrix resulting from the correlation or mutual information matrices).

Once you have a gene expression network, the next question is generally "what do I do with this network?" One possible next step is the use of network structures to identify possible gene regulatory binding sites. The way this works is given below:

- Perform community analysis of the network.
- Obtain the region approximately 5KB-10KB upstream of each gene's transcription start site.
- Perform a supervised position weight matrix search using position weight matrices from a database such as TRANSFAC (Frericks *et al*., 2008; Liu, Taylor and Edenberg, 2006; Wingender, 2004) or JASPAR (Frericks *et al*., 2008; Hannenhalli and Wang, 2005).
- Identify those gene regulatory elements that are over-represented in the community versus random sequences or all of the genes in the network (Lo *et al*., 2010).

Community analysis is a network theoretic method for identifying genes in the network that are more connected with each other, than they are with the rest of the network. Several methods exist for identifying communities in networks, and this remains an open-research question in network theory. If performing network analysis in R, I suggest investigators try using the igraph library, which contains several community analysis methods. The spin-glass method has worked well in my previous applications.

Once the investigator has identified the community, they need to obtain the region upstream of each gene's transcription start site (TSS). For species where the genome is well known and annotated, these data can be obtained easily from the UCSC Genome Browser or possibly a model organism genome database. Once these sequences have been obtained, the investigator should obtain a list of position weight matrices, from databases such as TRANSFAC or JASPAR, and perform an analysis of these upstream gene regions.

Then the investigator needs to perform an enrichment analysis. This can be as simple as counting the frequency of the each binding site within the upstream regions for all of the genes

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat221
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

in the community. Then, generally, we would scramble these upstream regions and perform the position weight matrix searches again. This process is repeated thousands of times and a distribution of the random sequence frequencies is calculated. Then, the investigator can calculate the likelihood of finding a hit from each position weight matrix due strictly to chance.

From here, the investigator can now generate new hypotheses regarding the regulation of the genes within each community. Using this new information, the investigator can begin to plan chromatin immunopreciptation experiments, to further identify how the genes are regulated. Once a more complete picture of the transcriptional regulation of the genes is created, along with further analysis for putative co-regulators, the investigator can begin to think about creating mathematical models of the transcriptional response.

4 CONCLUDING REMARKS

By combining all of these data into a database and including data from other sources, including pathology, and data across multiple organs, investigators can begin to create a more complete picture of the entire system. Over time, as more data become available and more investigators make these data publicly available, we as a community will be able to achieve the true aims and goals of systems biology. However, until we begin making our data more available, and public databases become available and easily searched, using cutting-edge web technologies, such as the Semantic Web, we will not be able to fully realize the true potential of systems biology.

1 INTRODUCTION

Advancements in the fields of medicinal and pharmaceutical chemistry have depended on the convention trial and error process. As this process is slow and tedious, even after several years of research, it was feasible only to identify few chemicals with drug-like property. Also, it was not experimentally feasible to understand why certain molecules have the drug-like property and few others related to these molecules do not have that property. Only recently, more systematic investigation of drug-like compounds in biological system, called as "chemical biology," has evolved.

2 CHEMOINFORMATICS

The field of "chemoinformatics" involves the use of information technology to manage chemical information and solve chemical problems, with specific emphasis on manipulation of structural information and utilization of chemical databases. This field deciphers the chemical information needed for drug discovery. For the first time, Frank Brown defined the term "chemoinformatics" as the utilization of chemical information resources to transform data into information and knowledge for the intended purpose in making better decisions faster in the area of drug lead identification, organization and also general purpose such as chemical library construction and enrichment. The basic goal of this field is to transform data into knowledge through information processing. The new discipline of chemoinformatics covers the application of computer-assisted methods to chemical problems such as information storage and retrieval, the prediction of physical, chemical or biological properties of compounds, spectra simulation, structure elucidation, reaction modelling, synthesis planning and drug design.

High-throughput screens (HTS) of small molecules for drug discovery and chemical genomics have evolved for analysing protein functions and cellular networks. At the same time, structures of millions of drug-like molecules and related information are freely available in the online compound database projects, such as PubChem, ChemBank, ChemMine, ChemDB. To search and analyse the vast amounts of available compounds and screening information, and to assemble diverse screening libraries, efficient compound analysis is very difficult. Chemoinformatics-based tools are very useful to solve the chemical problems efficiently.

Chemical informatics typically handles the massive amounts of data and manages the data using information systems that assist chemists in making sense of the data, often accurately predicting the properties of chemical substances (Figure 1).

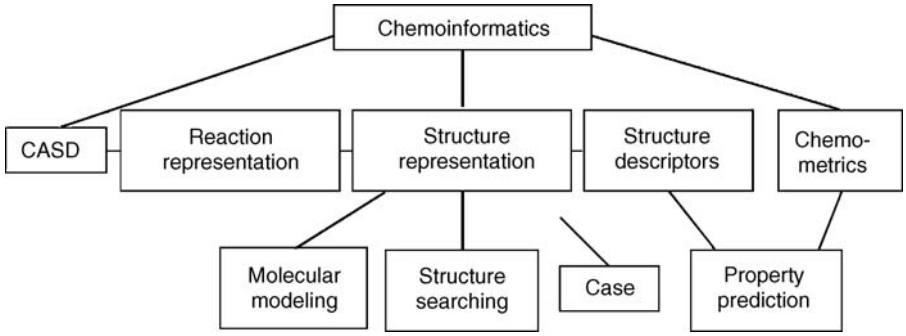

Figure 1. High-throughput screens of small molecules for drug design.

3 CHALLENGES IN CHEMOINFORMATICS

Much of the current attention in chemoinformatics is centred on the drug industry. When a potential drug is developed, libraries of compounds are screened for activity with one or more relevant assays using high-throughput screening techniques. Candidate compounds are then evaluated for binding, potency, selectivity and functional activity. Pharmaceutical companies now use sophisticated modelling techniques to predict the toxicity of compounds long before they are tested on human beings in order to save cost and time involved and avoid sacrifice of animals, and can easily reject the chemical compounds.

Two most important challenges of chemoinformatics are:

- To extract knowledge from large-scale raw HTS databases in shorter time periods.
- To be able to provide efficient *in silico* tools to predict adsorption distribution, metabolism, excretion and toxicity (ADMET) properties.

Chemical informatics may concentrate on molecular modelling, chemical structure coding and searching, chemical data visualization or a number of other areas of specialization. Chemoinformatics system should give information about structure [e.g., Simplified Molecular Input Line Entry System (SMILES)], molecular connectivity (e.g., SDfile), 3D chemical structure, pharmacophore, structure similarity, molecular similarity and diversity, chemical property, HTS and activity fingerprint, lead identification and optimization, combinatorial library design and synthesis and metabolic profile.

4 CHEMOINFORMATICS TASKS

The following tasks in chemoinformatics research are common:

- analysis of HTS data;
- similarity search of chemicals;
- design of combinatorial libraries;
- design of focused libraries;
- comparison of the similarity/diversity of libraries;
- virtual screening;
- docking;
- *de novo* design;
- pharmacophore perception;
- prediction of affinities, physicochemical properties and pharmacokinetic properties;
- establishment of QSAR models which can be interpreted and guide the further development of a new drug.

Tools which are commonly used in chemoinformatics include: statistical tools (e.g., recursive pairing), data analysis tools, visualization tools, Chemically-Aware Web Language (CML).

The applications of chemoinformatics in drug discovery are compound selection, virtual library generation, virtual screening, structure–activity relationship (SAR) on HTS data, sequential screening and *in silico* ADMET.

5 CHEMICAL DATA COLLECTION TECHNOLOGY

There are two important driving forces for chemical data collection: high-throughput screen and combinatorial library. Combinatorial chemistry and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat222
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

high-throughput screening are data-dependent and data-rich technologies. When making combinatorial libraries of chemical compounds, you need information on the molecular components, their biological effects and information on how to prepare the compound. There is also data collection technology for managing and storing the libraries. In high-throughput screening, the test results need to be captured, stored and then analysed. This is followed by applying chemoinformatics tools to collect, manage, analyse and disseminate the chemical information needed for drug discovery.

6 ALGORITHMS IN CHEMOINFORMATICS SYSTEM

Chemoinformatics systems employ a wide variety of algorithms for indexing and retrieving chemical compounds in databases, generating all isomers with a constitutional formula, or for computer-assisted organic synthesis. All these tasks involve three classes of algorithm for chemical graphs:

- the canonical coding problem, for generating a unique representation of a chemical compound;
- the automorphism partitioning problem (also known as constitutional symmetry perception, graph symmetry or topological symmetry), for detection of equivalent atoms and bonds in a molecule; and
- the graph isomorphism problem, for determining whether two connection tables represent the same chemical compound.

7 STEPS INVOLVED IN CHEMOINFORMATICS SYSTEMS:

Several steps are involved in most of the chemoinformatics systems. Outline about the few important steps are given below:

- In chemical documentation process, unique chemical structure representations (one-, two- and three-dimensional) are developed for chemical data management and searching.
- The computer generation of chemical compounds consistent with given structural constraints is used both in synthesis design and in structure elucidation.
- Artificial intelligence systems for synthesis design use canonical codes and constitutional symmetry information to generate and evaluate reaction paths.
- The synthesis by computer-aided molecular design of new compounds that conform to various physical property requirements can reduce the time and effort required using traditional empirical approaches. This process generates chemical structures compatible with experimental and structural restrictions.
- Canonical coding and symmetry perception are used to uniquely generate all possible isomers that adhere to the design constraints.
- Quantitative SARs (QSAR) are used to model the biological effect of a set of compounds. It makes extensive use of structure generation, substructure search and symmetry perception algorithms.
- Modern drug-design procedures make extensive use of large combinatorial libraries and *in silico* screening of chemicals, both using algorithms based on canonical coding, graph isomorphism and constitutional symmetry perception.

8 CHEMOINFORMATICS SOFTWARES/TOOLS

8.1 Chemoinformatics Tool Kit

It consists of similarity search, clustering, cluster and active compound inspection. Similarity searching measures: Tanimoto, Cosine, Euclidean, Hamman, Tversky or composite similarity or dissimilarity measures.

Clustering measures output Ordered Pair, Sparse Matrix or Square Matrix.

9 REPRESENTATION OF CHEMICAL STRUCTURE

The representation of chemical structures must follow chemical structure theory. IUPAC has long been involved in the development of systematic and standard procedures for naming chemical substances on the basis of their structure. The aim of the IUPAC Chemical Identifier Project (IChIP) is to establish a unique label. The IUPAC Chemical Identifier (IChI) would be a non-proprietary identifier for chemical substances that could be used in printed

9.2 Chemical Nomenclature

The name is used to identify any chemical substance that is potentially important. In this, chemical structure is represented as text string. Another form of chemical nomenclature is the trivial name. Trivial names are usually short and easy to pronounce but do not usually give much information about the structure. *Systematic* names are usually long and difficult to pronounce but usually describe structure in considerable detail.

9.3 Line Notations

In this form of chemical representation, structures are shown as compact linear string of alphanumeric symbols. This has the advantage of easy handling by computer; also, compact storage can be easily transmitted over a network. Simultaneously, this representation allows rapid manual coding/decoding by trained users and is much faster for input than using a structure drawing program.

9.3.1 Simplified Molecular Input Line Entry System

Dave Weininger developed SMILES representation of chemical molecules. SMILES contain the same information as might be found in an extended connection table. The primary reason SMILES is more useful than a connection table is that it is a linguistic construct, rather than a computer data structure. They are true language, albeit with a simple vocabulary (atom and bond symbols) and only a few grammar rules. SMILES representations of structure can in turn be used as "words" in the vocabulary of other languages designed for storage of chemical information (information about chemicals) and chemical intelligence (information about chemistry).

With standard SMILES, the name of a molecule is synonymous with its structure; with unique SMILES, the name is universal, that is, anyone in the world who uses unique SMILES to name a molecule will choose the exact same name.

One other important property of SMILES is that it is quite compact compared with most other methods of representing structure. Typical SMILES will take 50–70% less space than an equivalent connection table, even binary connection tables. A database of 23 137 structures, with an average of 20 atoms per structure, uses only 1.6 bytes per atom when represented with SMILES. In addition, ordinary compression of SMILES is extremely effective. The same database cited above was reduced to 27% of its original size by Ziv-Lempel compression (i.e., 0.42 bytes per atom).

SMILES representation has found wide use among researchers and chemical information programmers. Some of the areas where it is employed include as keys for database access, as a mechanism for researchers to exchange chemical information, as an entry system for chemical data and as a part of languages for artificial intelligence or expert systems in chemistry.

SMILES denote a molecular structure as a graph with optional chiral indications. This is essentially for representing the two-dimensional picture drawn by chemists to describe a molecule.

9.3.2 SMILES Specification Rules

SMILES notation consists of a series of characters with no spaces. In its notation, hydrogen atoms may be omitted (hydrogen-suppressed graphs) or included (hydrogen-complete graphs) and the aromatic structures may be specified directly or in Kekulé form.

There are five generic SMILES encoding rules, corresponding to specification of atoms, bonds, branches and disconnections.

Atoms

Lowercase letters specify atoms in aromatic rings; for example, aliphatic carbon is represented by the capital letter C and aromatic carbon by lowercase c. As attached hydrogens are implied in the absence of brackets, the atomic symbols represented in Table 1 are valid SMILES notations.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat222
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Table 1. Showing few valid SMILES notations.

C	Methane	(CH_4)
N	Ammonia	(NH_3)
S	Hydrogen sulphide	(H_2S)
O	Water	(H_2O)
Cl	Hydrochloric acid	(HCl)

Table 2. Showing valid SMILES notations for denoting bonds.

C=C	Ethane	(CH_2=CH_2)
O=C=O	Carbon dioxide	(CO_2)

Bonds

Single, double, triple and aromatic bonds are represented by the symbols –, =, # and:, respectively. Adjacent atoms are assumed to be connected to each other by a single or aromatic bond (single and aromatic bonds may always be omitted) (Table 2).

Branches

Branches are specified by enclosing them in parentheses, and can be nested or stacked. In all cases, the implicit connection to parenthesized expression (a "branch") is to the left (Table 3).

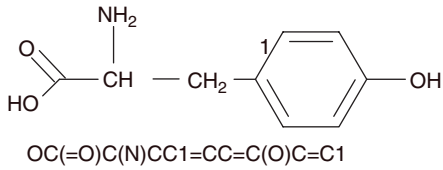
Disconnections

Disconnected compounds are written as individual structures separated by a "." (period). Adjacent atoms separated by dot (.) imply that the atoms are not bonded to each other. This is true whether or not the atoms are in the same connected component.

For example: C1.C1 specifies the same molecule as CC (ethane)

Simplified SMILES encoding rules are as follows (Figure 7):

- Atoms are shown by atomic symbols: B, C, N, O, F, P, S, Cl, Br and I.



OC(=O)C(N)CC1=CC=C(O)C=C1

Figure 7. Sample SMILES notation developed by Dave Weininger (daylight).

- Hydrogen atoms are assumed to fill spare valencies.
- Adjacent atoms are connected by single bonds.
- Double bonds are shown as "="; triple bonds are "#."
- Branching is indicated by parentheses.
- Ring closures are shown by pairs of matching digits.

9.3.3 Wisswesser Line Notation

This representation format was invented by William J. Wisswesser in the early 1950s. This notation was the first comprehensive line notation capable of representing arbitrarily complex molecules correctly and compactly. It is a fragment-oriented description of a molecule, which is similar to how a chemist thinks of the molecule. Wisswesser line notation (WLN) is a very brief way to describe a compound, to search for compounds based on chemist-defined criteria (instead of indexer-defined criteria) and, when combined with cleverness, has provided new ways to deal with chemical data.

For example, sorting a list of compounds gives a way to do similarity searches because the parent fragment (which is the most important part for most chemists) is given first.

$$1H = CH4 \ \textit{Methane}$$

$$2H = CH_3 - CH_3 \ \text{Ethane}$$

Table 3. Showing SMILES notations for branching patterns.

		CCN(CC)CC	CC(C)C(=O)O	C=CC(CCC)C(C(C)C)CCC
Triethylamine	Isobutyric acid	3-propyl-4-isopropyl-1-heptene

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.
This article is © 2011 John Wiley & Sons, Ltd.
DOI: 10.1002/9780470744307.gat222
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

$$3H = CH_3 - CH_2 - CH_3 \text{ Propane}$$

$$QVR\ BG\ CG\ DG\ EG\ FG = C_7HCl_5O_2 \text{ Pentachlorbenzoate}$$

Wisswesser line notation was the first line notation to feature a canonical form; that is, the rules for WLN meant there was only one "correct" WLN for any particular molecule. Scientists and researchers well versed in WLN were able to write molecular structure in a line format and communicate molecular structure to one another and to computer programs. Unfortunately, WLN's complexity prevented widespread adoption.

As the rules for correct specification of WLN are huge, encoding those rules into a computer proved difficult, and the rules for the canonicalization were computationally intractable. WLN provided a way to describe a molecule, but it did not produce a canonical name. That is, it did not include a set of rules, which could be applied to a molecule to get the same name every time.

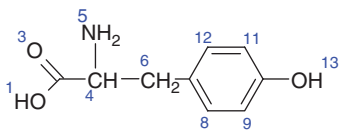
9.3.4 *Representation of Organic Structure Description Arranged Linearly (ROSDAL) (Beilstein)*

Structure in Figure 7 is linearly represented as follows:

$$1O - 2 = 3O, 2 - 4 - 5N, 4 - 6 - 7 = -12 - 7, 10 - 13O$$

9.3.5 *Sybyl Line Notation (Tripos)*

SYBYL line notation (SLN) is a powerful way to represent molecular structures, reactions, libraries of structures, molecular fragments, formulations, molecular queries and reaction queries. Nearly any chemical structure imaginable, including macromolecules, pharmaceuticals, catalysts and even combinatorial libraries, can be represented as an SLN string (refer Figure 8).



OHC(=O)CH(NH2)CH2C[1]=CHCH=C(OH)CH=CH@1

Figure 8. Sample of SLN format for a molecule.

$$OHC(=O)CH(NH2)CH2C[1]=CHCH=C(OH)-CH=CH@1$$

9.3.6 *InChI*

InChI is the latest and most modern of the line notations. It resolves many of the chemical ambiguities not addressed by SMILES, particularly with respect to stereocentres, tautomers and other "valence model problems."

9.4 Connection Table

Most of the early (and some modern) representations of molecules were in a connection table, literally, a table enumerating the atoms, and a table enumerating the bonds and which atoms each bond connected.

9.4.1 *Redundant Connection Table (Figure 9)*

1.	O	1	2 1		
2.	C	0	1 1	3 2	4 1
3.	O	0	2 2		
4.	C	1	2 1	5 1	6 1
5.	N	2	4 1		
6.	C	2	4 1	7 1	
7.	C	0	6 1	8 2	12 1
8.	C	1	7 2	9 1	
9.	C	1	8 1	10 2	
10.	0	9 2	11 1	13 1	
11.	C	1	10 1	12 2	
12.	C	1	11 2	7 1	
13.	O	1	10 1		

9.4.2 *MDL Connection Table*

This is a proprietary file format developed by MDL available for download at the following website: http://www.mdl.com/downloads/public/ctfile/ctfile.jsp. It is a standard for exchange of datasets, and several different flavours and versions are known among researchers that include the following:

- Molfile (single molecule)
- SDfile (set of molecules and data)
- RGfile (Markush structure)
- Rxnfile (single reaction)
- RDfile (set of reactions with data)

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat222

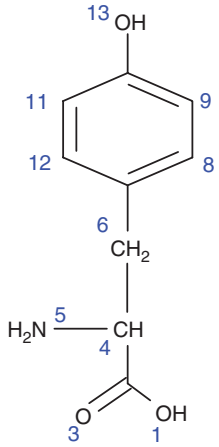

Figure 9. Structure corresponding to redundant connection table.

Chemoinformatics represents molecules as objects in a chemical space defined by molecular descriptors. Among thousands of descriptors, fragment descriptors occupy a special place.

- Fragment descriptors represent selected subgraphs of a 2D molecular graph.
- Structure–property approaches use their occurrences in molecules or binary values (0, 1) to indicate their presence or absence in the given graph.

The unique properties of fragment descriptors are related to the fact that:

- any molecular graph invariant (i.e., any molecular descriptor or property) can be uniquely represented as a linear combination of fragments descriptors;
- any symmetric similarity measure can be uniquely expressed in terms of fragment descriptors;
- any regression or classification structure–property model can be represented as a linear equation involving fragment descriptors.

10 LIST OF SOME OF THE SIGNIFICANT CHEMOINFORMATICS DATABASES

- The Accelrys' Biotransformation, Metabolism databases is marketed by Accelrys (San Diego, USA).
- ACD/Labs Physico-Chemical Property databases are marketed by Advanced Chemical Development, Inc.(Toronto, Canada).
- The AQUASOL dATAbASE of Aqueous Solubility, sixth edition, is marketed by the University of Arizona (Tucson Arizona, USA).
- The Available Chemical Directory (ACD) is marketed by MDL Information Systems Ltd (San Lenandro, USA).
- The Cambridge Structural Database (CSD) is maintained and distributed by the Cambridge Crystallographic Data Centre (Cambridge, UK).
- CASE and MultiCASE, MultiCASE, Inc. (Beachwood, OH, USA).
- The Derwent World Drug Index (WDI) and Derwent Drug File are published by Thomson Derwent (London, UK).
- MDL Drug Data Report (MDDR) is marketed by MDL Information Systems Ltd (San Lenandro, USA).
- The Physical Properties Database (PHYSPROP) is marketed by Syracuse Research Corporation (SRC) (North Syracuse, USA).
- The Protein Data Bank (PDB) is operated by Rutgers, The State University of New Jersey; the San Diego Supercomputer Center at the University of California, San Diego; and the Center for Advanced Research in Biotechnology of the National Institute of Standards and Technology, and funded by NSF, NIH and the Department of Energy.
- Toxicological Data Network (TOXNET) is a collection of databases, published by various services, and made accessible free of charge over the Internet by National Library of Medicine (Bethesda, USA).
- The WOrld of Molecular BioActivities database (WOMBAT) is published by Sunset Molecular Discovery LLC (Santa Fe, USA).
- PubChem.
- eMolecules.
- Zinc.
- Chemspider.

10.1 QSAR

Quantitative structure–activity relationship (sometimes QSPR: quantitative structure–property relationship) is the process by which chemical structure is quantitatively correlated with a well-defined

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat222
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

process, such as biological activity or chemical reactivity. It is the calculation of QSAR and QSPR values and is employed to predict the activity of compounds from their structures. In this context, there is also a strong relationship to chemometrics. Chemical expert systems are also relevant because they represent parts of chemical knowledge as an *in silico* representation.

For example, biological activity can be expressed quantitatively as in the concentration of a substance required to give a certain biological response. Additionally, when structures or physicochemical properties are expressed by numbers, one can form a mathematical relationship, or QSAR, between the two. The mathematical expression can then be used to predict the biological response of other chemical structures.

Quantitative structure–activity relationships represent an attempt to correlate structural or property descriptors of compounds with activities. These physicochemical descriptors (otherwise called as molecular descriptor) include parameters to account for hydrophobicity, topology, electronic properties and steric effects, and are determined empirically or, more recently, by computational methods. Activities used in QSAR include chemical measurements and biological assays. QSAR currently are being applied in many disciplines mostly pertaining to drug design and environmental risk assessment (Figure 10).

10.2 Hammett Equation

The Hammett equation in organic chemistry describes a linear free energy relationship relating reaction rates and equilibrium constants for many reactions involving benzoic acid derivatives with *meta*- and *para*-substituents to each other with just two parameters: substituent constant and reaction constant (Figure 11). This equation was developed and published by Louis Plack Hammett in 1937 as a follow-up to qualitative observations in a 1935 publication.

The basic idea is that for any two reactions with two aromatic reactants only differing in the type of substituent, the change in free energy of activation is proportional to the change in Gibbs free energy. This notion does not follow from elemental thermochemistry or chemical kinetics and was introduced by Hammett intuitively.

The basic equation relates the equilibrium constant, K, for a given equilibrium reaction with substituent R and the reference K_0 constant when R is a hydrogen atom to the substituent constant σ, which depends only on the specific substituent R and the reaction constant ρ, which depends only on the type of reaction but not on the substituent used.

$$\log \frac{K}{K_0} = \sigma\rho$$

10.3 Taft Equation

The Taft equation is a linear free energy relationship used in physical organic chemistry in the study of reaction mechanisms and in the development of QSAR for organic compounds. Robert W. Taft developed it in 1952. It is a modification to the Hammett equation. Although the Hammett equation accounts for how field, inductive and resonance effects influence reaction rates, the Taft equation also describes the steric effects of a substituent.

The Taft equation is written as:

$$\log\left(\frac{k_s}{k_{\mathrm{CH3}}}\right) = \rho^*\sigma^* + \delta E_s$$

where $\log(k_s/k_{CH3})$ is the ratio of the rate of the substituted reaction compared to the reference reaction, σ^* is the polar substituent constant that describes the field and inductive effects of the substituent, E_s is the steric substituent constant, ρ^* is the sensitivity factor for the reaction to polar effects and δ is the sensitivity factor for the reaction to steric effects.

An important aspect of chemoinformatics is the development of QSARs or SARs, which are used to predict chemical behaviour from molecular structure. Behaviours that are predicted in this way include physical properties (e.g., boiling point, vapour pressure, aqueous solubility, hydrophobicity, dipole moment), reactivity (e.g., hydrolysis, oxidation rates) and bioactivity (e.g., inhibition of an enzyme, antibiotic activity, toxicity). These methods are typically based in chemical thermodynamics coupled with statistical methods.

There are four chemical problems that should be solved by chemoinformatics:

- store a molecule;
- find exact molecule;

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

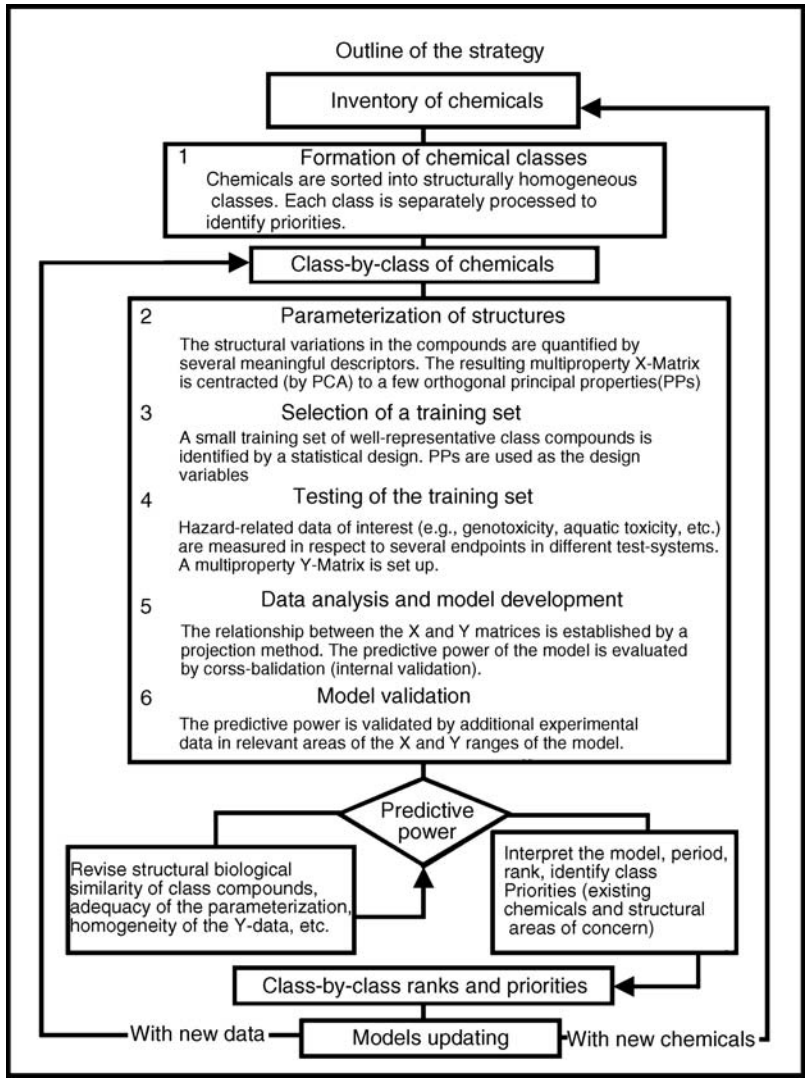

Figure 10. Strategy adopted for QSAR analysis.

- substructure search;
- similarity search.

Among these similarity search and substructure search are very difficult tasks in chemoinformatics.

10.4 Similarity Search

Many chemical information systems can find molecules similar to a given molecule, ranked by similarity. There are several ways to measure molecular similarity, such as SMILES, WLN, connection table, etc.

10.5 Substructure Search

Structural similarity searching and clustering of small molecules play an important role in drug discovery and chemical genomics.

A good similarity search would find the target structure accurately and find the substructure of it. There are many ways to measure similarity.

Figure 11. Hammet's constants.

10.6 2D Topology

The best-known and most widely used similarity metrics compare the two-dimensional topology; that is, they only use the molecule's atoms and bonds without considering its shape. Tanimoto similarity is perhaps the best known, as it is easy to implement and fast to compute.

10.7 3D Configuration

One of the most important uses of similarity is in the discovery of new drugs, and a molecule's shape is critical to its medicinal value. 3D similarity searches compare the configuration (also called the "conformation") of a molecule to that of other molecules. The "electronic surface" of the molecule is the important bit – the part that can interact with other molecules. 3D searches compare the surfaces of two molecules, and how polarized or polarizable each bit of the surface is.

3D similarity searches are uncommon, for two reasons: they are difficult and they are slow. The difficulty comes from the complexity of molecular interactions – a molecule is not a fixed shape, but rather a dynamic object that changes according to its environment. And the slowness comes from the difficulty: to get better results, scientists employ more and more complex programs.

10.8 Physical Properties

The above 2D and 3D similarities are based on the molecule's structure. Another technique that compares the properties – either computed or measured or both – and declares that molecules with many properties in common are likely to have similar structure. It is the idea of QSAR taken to the database.

QSAR-based methods ultimately go with the application of statistical methods:

- GFA
- clustering
- PCA
- PLS
- simulated annealing

10.9 Statistical Methods

10.9.1 Clustering

"Clustering" is the process of differentiating a set of things into groups where each group has common features. Molecules can be clustered using a variety of techniques, such as common 2D and/or 3D features. Note that clustering is not a similarity metric but it may use various similarity metrics when computing clusters. It is included here because it can be used as a "cheap substitute." That is, when someone wants to find compounds similar to a known compound, you can show them the group (the cluster) to which the compound belongs. It allows you to pre-compute the clusters, spending lots of computational time up front, and give answers very quickly (Figure 12).

10.9.2 Non-Hierarchical Clustering

In this method, compounds are placed in clusters without a hierarchical relationship between the clusters. Several non-hierarchical methods are available:

- single pass
- relocation
- nearest neighbour method.

11 CONCLUSIONS

Chemoinformatics has developed over the past 40 years to a mature discipline that has applications in all areas of chemistry. Chemists have to become more efficient in planning their experiments and extract more knowledge from their data. Chemoinformatics can help in this endeavour, and so many researchers and scientists in pharmaceutical chemistry and medicinal chemistry are focusing on implementing chemical informatics in their research works. There are still many problems that await a solution, and therefore we still will see many new developments in chemoinformatics.

Biomarker Discovery: Introduction to Statistical Learning and Integrative Bioinformatics Approaches

Dirk Repsilber[1] **and Marc Jacobsen**[2]

[1]*Genetics and Biometry/Bioinformatics and Biomathematics Group, Research Institute for the Biology of Farm Animals, Dummerstorf, Germany* and [2]*Department of Immunology, Bernhard-Nocht Institute for Tropical Medicine, Hamburg, Germany*

1 INTRODUCTION

Biomarker detection seems a straight forward objective. Making use of high-throughput technology as part of a study where participants have been in contact with different doses of the xenobiotic in question may reveal indicators of the belonging physiological reactions and, for example, allow for characterizing susceptibility groups. However, a biomarker is not only a measurable, differentially regulated molecule. It has to demonstrate generalizability in the sense that a *new* sample can be measured and correctly classified or characterized on the basis of the biomarker's values. There are strong requirements towards reproducibility and validity which have to be tested for each candidate biomarker prior to its possible first clinical use. This is especially important in a setting of different individuals with distinct genetic background and living conditions. Moreover, screening tens of thousands of molecules for their biomarker qualities – using only in the order of hundred samples, often less – involves the intrinsic problem of overfitting, yielding candidate biomarkers with poor generalizability.

This chapter wants to bridge between the toxicologist's physiological approach to analyze studies to detect molecular biomarkers and the statistical bioinformatics view on biomarker discovery. Towards this objective we first define the term biomarker and outline its role in toxicology research in Section 2. Throughout the following sections we make use of a famous gene expression dataset by Golub *et al.* (1999) as well as the statistical programming language `R` (Ihaka and Gentleman, 1996) and its packages collection, the Bioconductor suite (Gentleman *et al.*, 2004) to reproducibly demonstrate different approaches, possible stumbling blocks and their solutions (Ruschhaupt *et al.*, 2004). In Section 3 we exemplify the search for univariate molecular biomarkers, including discussion of sample selection, sample size, comparison of three shrinkage approaches as well as how to deal with multiplicity issues. In section 4 we introduce the leave-one-out cross validation approach to estimate a candidate biomarker's prediction error rate. Section 5 introduces the multivariate biomarker panel (biosignature) and exemplifies three statistical learning methods using the Golub gene expression dataset (Golub *et al.*, 1999). In Section 5.5 we compare uni- and multivariate feature selection results for the example of a random forest analysis. If a priori information about the molecular features is

available (functional gene-sets, covariance structure, regulatory topological information) it can be used to enhance both detection and efficiency of biomarker signatures – we approach related objectives in Section 6. In Section 7 we introduce the concept of integrative bioinformatic analysis and its application to biomarker discovery. Section 8 reasons about the circumstances for using biomarkers to infer the underlying causes for the biomedical phenomenon under study, and in section 9 we summarize the approaches to biomarker discovery presented in our chapter.

2 BIOMARKERS IN TOXICOLOGY?

2.1 What is a Biomarker?

A biological marker (biomarker) is defined as "a characteristic that is objectively measured and evaluated as an *indicator* of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention" (Biomarkers Definitions Working Group, 2001). Hence, in the current context of toxicology we would understand a biomarker also as indicating responses to contact with chemicals in humans and animals. We propose to use "indicator" in this chapter for features which alone or in combination consistently allow classification of an individual to a unique group with defined characteristics regarding the traits of interest in toxicology, such as, for example, susceptibility to adverse effects. These features can, but do not have to, be functionally related to the unique group characteristics (Jacobsen *et al.*, 2008).

Classical examples of biomarkers include the tuberculin skin test (TST) for presence of tuberculosis infection (reviewed in Jacobsen *et al.*, 2008), pro-inflammatory indicators such as TNFα, IL2 and IL6 (Dinarello, 2000), or specific antigen titers – measured with antibodies – to indicate presence of specific pathogens.

There are a number of different molecular species available as candidate biomarkers which belong to the OMICs levels of gene expression: features of transcriptome (including miRNAs), proteome (including cytokines, antigens, antibodies, and hormones), or metabolome. Effects of xenobiotics are conceivable in each of these levels, also in parallel.

2.2 Importance of Biomarkers in Toxicology

As in toxicology biomarkers should be eligible for use in screenings, time series and dilution series exposure studies for safety evaluation and risk assessment, they need to be characteristics which are easily and reproducibly measurable. Such biomarkers could then be used to characterize different types of physiological answers (Cariello *et al.*, 2005; Morgan *et al.*, 2005), groups of susceptibility or even indicate the beginning of adverse events before their clinical onset, which may be too severe to allow exhaustive clinical studies (for example see Watterson *et al.*, 2009).

The hope in toxicology is that an optimum integration of clinical and chemical measurements, and biomarker responses would lead to an improved understanding of adverse effects and their significance in both human and ecological risk assessment (Eason and O'Halloran, 2002). It is, however, not necessarily the causal background of detected biomarkers itself that might contribute to such improvements, but the improved characterization of the involved samples or classification abilities, as shown later in this chapter.

3 FINDING BIOMARKERS

3.1 Biomedical and Clinical Studies to Detect Biomarkers

Toxicology, the study of the adverse effects of chemicals on living organisms, represents an interdisciplinary science that requires both expertise on the chemical nature of the studied compounds and precise knowledge of the normal cellular mechanisms that can be compromised by toxic substances. In the clinical context, the contribution of toxicology is primarily the identification of adverse effects, ideally at an early stage of pharmaceutical drug development. Such side-effect biomarkers anticipated in a clinical study are based on various toxicological information gleaned from non-clinical studies. Such prior studies involve experiments *in vitro*, for the cell culture level as well as in the animal model. On these levels prior to a clinical study, different molecules are conceivable as biomarkers when compared to the clinical study situation. This is due to the different sources of variation and biases (confounders) in these situations (as an example consider tissue heterogeneity

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

as analyzed by Jacobsen *et al.*, 2006). Nevertheless, a biomarker in the animal model may correctly point to problems of tolerance or toxicity, even if not accessible in the situation of a clinical study involving patients. Most valuable conclusions are to be expected from study designs which include well-established principles of clinical studies in epidemiology and medical biometry (Repsilber *et al.*, 2005; Feng *et al.*, 2004; Wacholder *et al.*, 1992). In fact, drug development may be discontinued if no biomarkers can be detected using conventional clinical laboratory methodology; therefore, new approaches for finding biomarkers are needed. The use of molecular toxicological methods using OMICs technology is expected to be an effective future approach (Naraoka *et al.*, 2008; Bolt and Stewart, 2009).

OMICs technologies (transcriptomics, proteomics, metabolomics) when applied in clinical studies have the advantage that they benefit from the usually higher sample sizes, still for biomarker detection this approach has a core problem: Usually the number of samples n, that is, molecular profiles available for biomarker screening (usually one hundred or less), is much smaller than the number of features p to choose from (usually hundreds to tens of thousands). This so-called "small n large p"-problem leads to some important implications for biomarker candidate detection – which are going to be illustrated in the following together with existing approaches to their solution. For illustration, and to enable practical "hands-on" experience by reproducing the analyses we introduce, we make use of an example gene expression dataset.

3.2 A Prominent Illustrative Example: The Golub 1999 Gene Expression Dataset

Golub *et al.* (1999) issued and analyzed a gene expression study involving 47 patients with acute *lymphoblastic* leukemia (ALL) and 25 patients with acute *myeloid* leukemia (AML). Gene expression of these samples were measured using Affymetrix Hgu6800 microarrays. Data on the expression of 7129 genes (Affymetrix probes) are publicly available (Golub data website, 2009). Here, and in the following, `R` code chunks are integrated in the text such as to exemplify our explanations with a "hands-on-example." The reader may install the `R` software from http://www.r-project.org/cran and enjoy the reproducibility of these analyses (Ruschhaupt *et al.*, 2004): `R` script inputs are with lightblue, results with orange backgrounds:

```
library(golubEsets) # load public Golub dataset
data(Golub_Merge)
dat ← exprs(Golub_Merge) # extract gene expression matrix
index.ALL ← (1:ncol(dat))[Golub_Merge@phenoData$ALL.AML == "ALL"]
index.AML ← (1:ncol(dat))[Golub_Merge@phenoData$ALL.AML == "AML"]
all.names ← c()
all.names[index.ALL] ← paste("L", 1:length(index.ALL),sep='')
all.names[index.AML] ← paste("M", 1:length(index.AML),sep='')
colnames(dat) ← all.names
rownames(dat) ← featureNames(Golub_Merge)
DAT ← as.data.frame(dat)
class(DAT)
dim(DAT)
genes ← rownames(DAT) # retrieve Affymetrix identifiers
```

```
heatmap(as.matrix(DAT),labRow="")
```

As a common first data-mining step, we perform a two-way clustering (independently for samples and features), using hierarchical clustering with average linkage algorithm and Euclidean distance measure (Eisen *et al.*, 1998; Datta and Datta, 2006). The results is shown in Figure 1, a so-called *heatmap*.

It is already illustrating that the two classes, ALL and AML are not detected as separate clusters. Hence, we have to begin searching for valid candidate biomarkers.

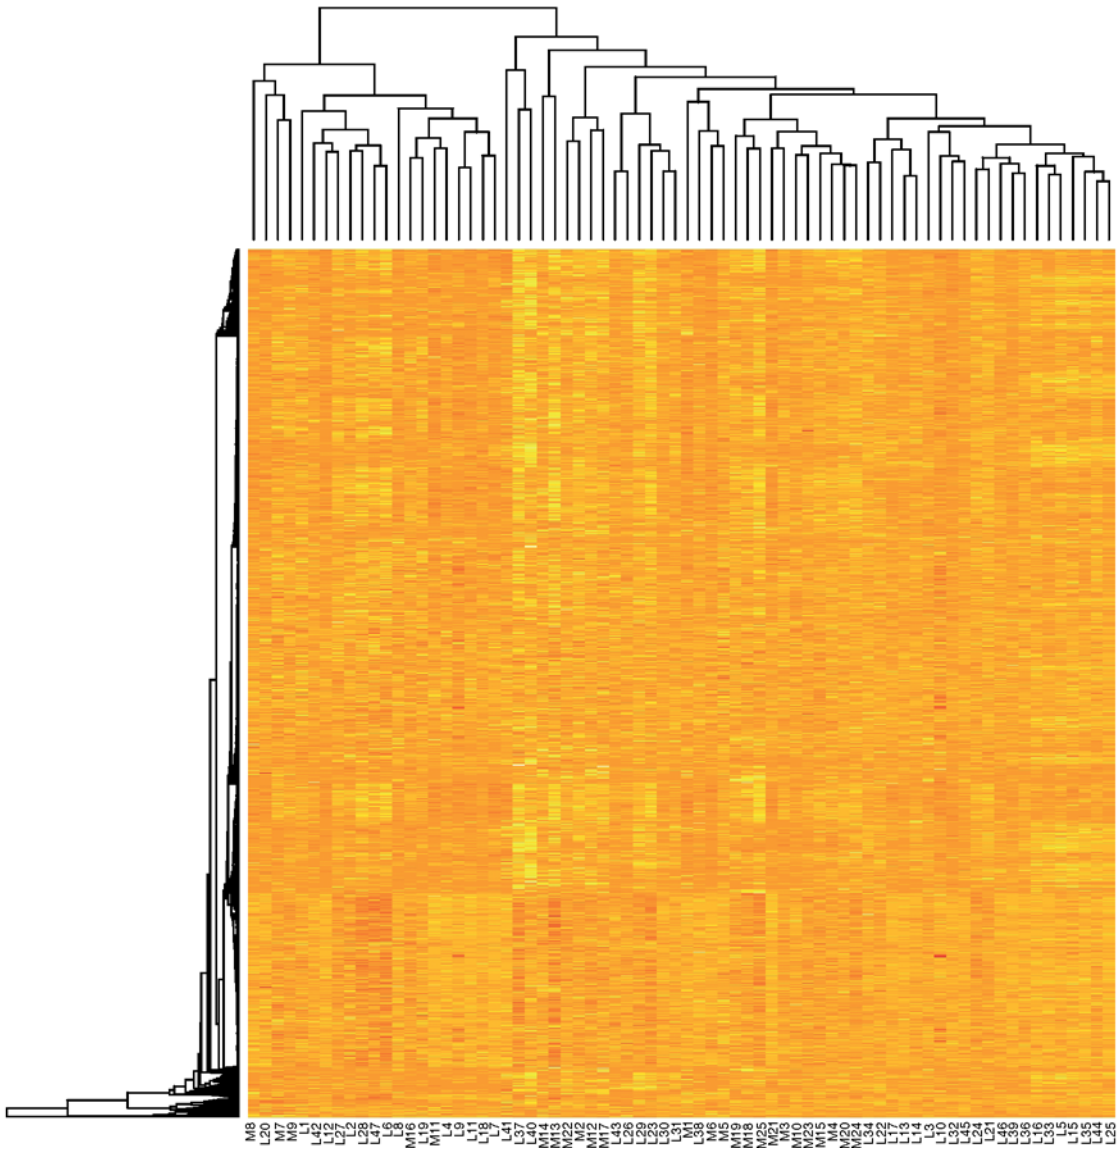

Figure 1. Heatmap of the Golub dataset. Genes as well as samples are clustered using hierarchical clustering, Euklidean distance measure and average linkage algorithm.

3.3 Normalization of OMICs Datasets – Necessity and Danger

OMICs datasets have to be prepared prior to uni- or multivariate analysis for biomarker detection. This preparation is necessary to ensure that biases from technical sources are removed (normalization), as well as for choosing a scale for which the screened features will be comparable (variance stabilization).

For different OMICs technologies there exist numerous approaches towards these objectives (see for example Smyth and Speed, 2003; Lisec *et al.*, 2006).

Without normalization, the screening study is at risk to deliver wrong candidates – which will fail in a validation study – as known technical error sources are not accounted for. However, such biases may be rather specific for the dataset under analysis. The

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

corrections applied to correct for biases in the current study may not be the same for a new sample – possibly measured in another lab. After all attempts to make OMICs profiles comparable over labs, technological platforms and experimental designs – this issue has not yet been fully resolved, and it is to be seen as a major stumbling block for valid biomarker detection (Members of the Toxicogenomics Consortium, 2005; Moreau *et al.*, 2003). *Validity* with regard to a biomarker in this context would mean the ability to reproducibly measure it in different labs and come to coherent classification predictions.

3.4 A First Approach to Detect Univariate Candidate Biomarkers: The Classical *t*-Test

In the case of the illustrative Golub dataset, we base our presentation on a normalized dataset. As a first step, we look for single gene expression signals which would allow to classify a new sample as belonging either to the class AML or ALL.

For a biomarker two properties are key:

1. showing a *large* difference Δ between the classes
2. showing *small* variation σ within the classes

For a good biomarker the quantity $T = \Delta/\sigma$ (test-statistics) should be *large* in the sense that differences between groups are sufficiently high compared to individual variation. To learn about what *sufficiently high* means, we take a look on the illustrative example dataset by Golub *et al.* (1999). We begin with gene-wise t-tests and have a look at those candidates ranked top regarding their large test-statistics (and corresponding small p-values):

```
p.values ← apply(DAT,1,function(x){
   t.test(x[index.ALL],x[index.AML])$p.value
 })
ttest.ranking ← names(sort(p.values,decreasing=FALSE))
ttest.ranking[1:4]
```

```
[1] "X59417_at"    "M92287_at"    "M31523_at"    "M31211_s_at"
```

Feature "X59417_at" is ranked top regarding its p-value. (The following features are at positions two, three and four: "M92287_at," "M31523_at" and "M31211_s_at.") It is, however, conceivable, that when tens of thousands of features are screened – especially in studies with small sample sizes – there are possibly many with very small values for σ just as a random result. These features would get high values for T – and add to the number of false positives.

3.5 Improvements for Detection of Univariate Biomarkers: Shrinkage Approaches

There has been several similar proposals how to deal with the problem of random small variances: A very first, but continuously used, approach is to use a constraint for values of $\Delta > \theta$, where θ usually is some log fold-change – like for example $\theta = 1$, in the case of log-2 values corresponding to a minimum fold-change of two-fold. One could argue that changes in gene expression have to reach a certain limit to be *relevant* (not only *significant*). In any case, there is no alternative to validating candidate molecules using independent samples and an independent technique, such as for example quantitative Real-Time PCR (VanGuilder *et al.*, 2008) in the case of RNA or Westernblot (Renart *et al.*, 1979) for protein candidates. However, certainly, threshold values ("cutoffs") for relevant fold-changes, are gene-specific values. This leads us back to alternative estimates for the variances.

Towards preventing too small values for the estimated variances, Tusher, Tibshirani and Chu (2001) proposed a shrinkage approach, where they add a so-called fudge factor a_0 to the denominator of the ranking statistics: $T_{\text{Tusher}} = \Delta/(a_0 + \sigma)$. Here, a_0 is chosen according to some optimality criterion, but in principle, if σ becomes arbitrarily small, a_0 prevents T_{Tusher} from getting too large. For similar penelized versions of the t-test statistics see also Lönnsted and Speed (2003) or Efron *et al.* (2001). Here, we exemplify SAM (significance analysis of microarrays) by Tusher, Tibshirani and Chu (2001) for our illustrative example:

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

```
library(siggenes)
cl ← rep(0,ncol(DAT)) # contains the class labels: 0: ALL, 1:AML
cl[index.ALL] ← 1
sam.out←sam(DAT, cl ,B=100,rand=123)
sum.sam.out ← summary(sam.out , 2.4)
sam.ranking ← rownames(sum.sam.out@mat.sig)
sam.ranking[1:10]
```

```
 [1] "X59417_at"        "M92287_at"        "M31523_at"        "U05259_rna1_at"
 [5] "X95735_at"        "M84371_rna1_s_at" "M11722_at"        "M31211_s_at"
 [9] "X17042_at"        "J05243_at"
```

The first three top ranked features in this case are the same as for the t-test, however, "M31211_s_at," which was ranked position 4 for the standard t-test, has now been shifted to position eight.

Smyth (2004) further developed the approach by Lönnsted and Speed (2003) and generalized the penelized t-test approach towards linear modelling and arbitrary contrasts. Their ideas are implemented in the R-package limma (Smyth, 2005). Let us have a look at their analysis in the case of the Golub dataset:

```
library(limma)
design ← cbind(Grp2vs1=cl)
design ← model.matrix(~factor(design))
fit ← lmFit(DAT, design=design)
eb ← eBayes(fit ,proportion=0.5)
raw.p.smyth ← eb$p.value[,2]
smyth.ranking ← genes[order(raw.p.smyth ,decreasing=FALSE)]
smyth.ranking[1:10]
```

```
 [1] "X95735_at"   "X17042_at"   "M23197_at"   "M84526_at"   "L09209_s_at"
 [6] "U46499_at"   "M27891_at"   "M16038_at"   "M22960_at"   "M63138_at"
```

Jaffrezic *et al.* (2007) take a mixed model approach to estimating the variances of the features in the ranking. They describe a simulation study where – for different benchmark datasets – they are able to outperform the suggestions by Tusher, Smyth and co-workers. Here comes the implementation for our example:

```
source("SMVar-adjFunctions.R") # see Appendix for this R-function!
genes ← as.data.frame(genes)
res ← SMVar.q(X=DAT,y=cl ,geneNumbers=genes ,threshold=1.0)
```

```
[1] "7129 differentially expressed genes"
```

```
raw.p.jaffrezic ← res[["Adj.p-value"]][order(res[[1]])]
jaff.ranking ← res$genes
jaff.ranking[1:10]
```

```
 [1] X59417_at        M92287_at        M31523_at        U05259_rna1_at
 [5] M31211_s_at      M84371_rna1_s_at M11722_at        J05243_at
 [9] X17042_at        M89957_at
7129 Levels: A28102_at AB000114_at AB000115_at AB000220_at ... Z97074_at
```

The top ranked features for all four approaches to find differentially expressed genes are different, figure 2 gives the details.

As for the Golub dataset we are dealing with comparatively large sample sizes, variance estimates used by the *t*-test can be considered stable. For the three shrinkage methods we observe different levels of concordance with the t-test ranking: Results for the approach by Jaffrezic *et al.* (2007) are closest, for the approach by Smyth, Yang and Speed (2003) we find the largest deviations.

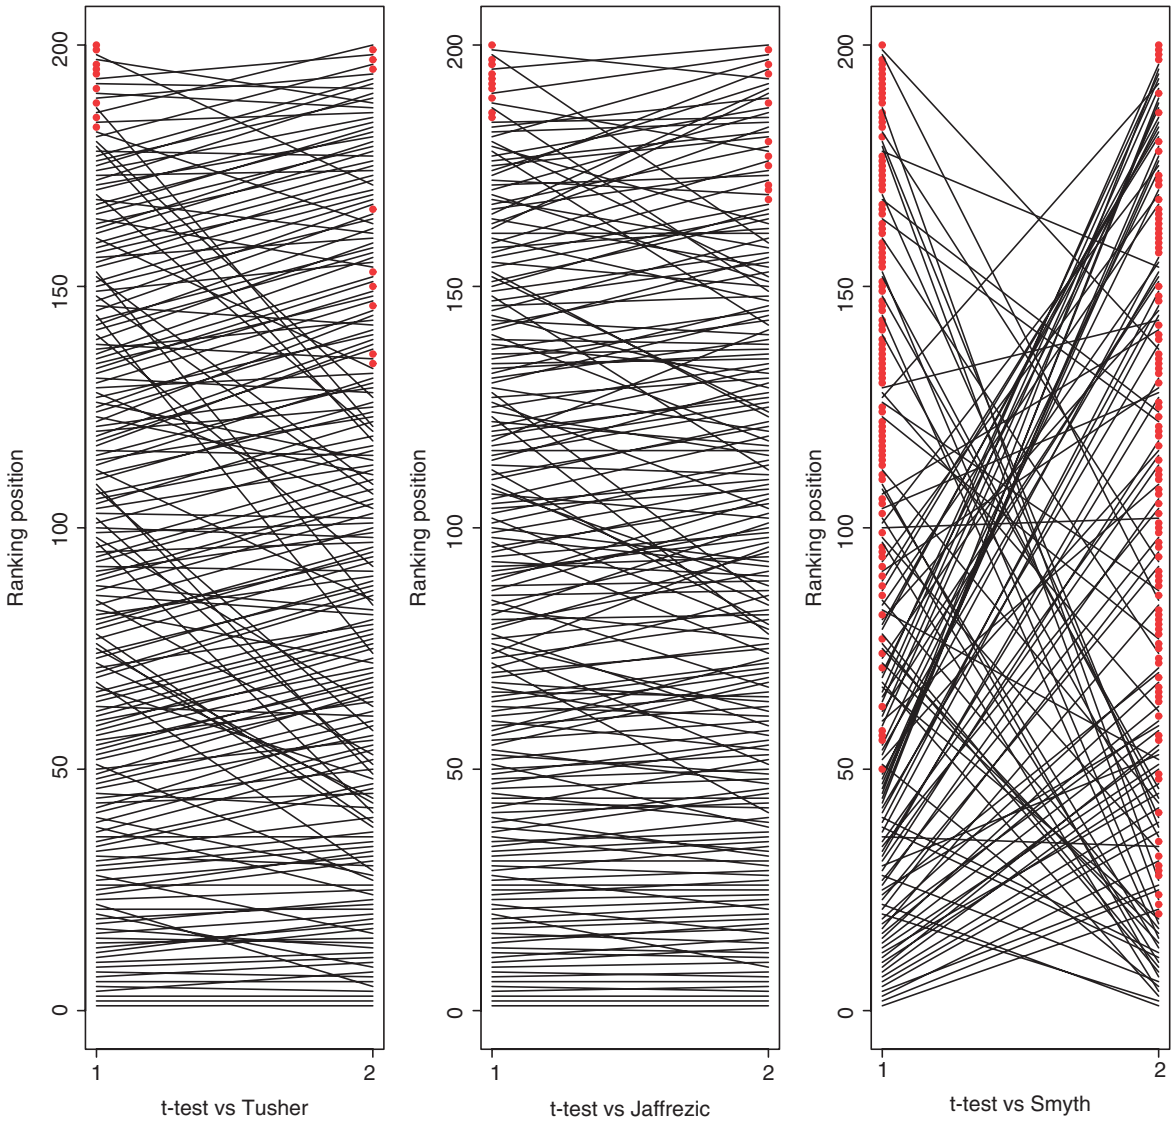

Figure 2. Comparison of ranking lists obtained by classical *t*-test and the approaches by Tusher, Tibshirani and Chu (2001), Jaffrezic *et al*. (2007), and Smyth, Yang and Speed (2003).

3.6 Role of Multiplicity During Screening for Biomarkers

If multiple statistical tests are used to rank features with respect to their p-values, one has to be aware of the fact that with fixing the error of type I – to falsely reject the null hypothesis of no differential expression – the number of false positives in a screening experiment involving tens of thousands of features can be a relevant number (the "multiple testing problem"): For example for a significance level of $\alpha = 0.05$ and $p_{\text{features}} = 10000$ we expect 500 false positive candidates for differential gene expression if no feature would be differentially regulated. The so-called false discovery rate, FDR, controls the expected proportion of incorrectly rejected null hypotheses. There are numerous approaches to estimate false discovery

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.
This article is © 2011 John Wiley & Sons, Ltd.
DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

rates for gene expression experiments, for example, as proposed by Benjamini and Hochberg (1995), Benjamini and Yekutieli (2001), or by Storey and Tibshirani (2003), to name some examples, see Pounds (2006) for a review. Considering these multiplicity corrections is certainly of value for the detection of biomarkers, as these results may hint to the actual rate of truly differential expression in an experiment. For example, if there are no features left as candidates with an FDR smaller than 0.2, using such a result may lead to inreproducible results for any biomarker candidates selected from the corresponding ranking list. Whereas for the case with hundreds of candidates on FDR values all below 0.01, we can expect a lot of ongoing true differential expression.

Let us examine to which of these cases our illustrative dataset by Golub *et al.* (1999) belongs (based on the p-values resulting from the approach by Jaffrezic *et al.* (2007) and the FDR correction approach by Storey and Tibshirani, 2003):

```
library(qvalue)
q ← qvalue(raw.p.jaffrezic)$qvalue
sum(q<0.01)
```

```
[1] 731
```

Hence, in the Golub dataset we expect a lot of differentially expressed genes. This is also what we await, since with ALL and AML tumors we are comparing two different cell types.

3.7 Sample Size Considerations for Biomarker Screenings

A crucial question concerning experimental design is the assessment of study group sizes for biomarker discovery (Feng *et al.*, 2004). Different variables influence the appropriate size of samples to provide the basis for statistically valid analyses. These include technical and biological variances. Both parameters can be predicted by pilot surveys including repeated measurements of the same samples for assessing technical variance, and different samples within the study groups for assessing biological variance. Based on these pilot experiments the number of comparisons required to reach a certain power at a given significance level can be predicted. Important in this context is the problem of multiple testing which markedly increases the proportion of false positives when analyzing thousands of genes (proteins, metabolites, or lipids) in parallel, as discussed above. Ultimately, independent verification (e.g. by quantitative PCR of *new independent* samples) is the only way to exclude false-positive candidates and, consequently, no threshold for differential gene expression (e.g., 2-fold) assures exclusive selection of true positives. In conclusion, the experimental design of global OMICs analyses requires decisions prior to the set-up of experiments which strongly influence possibilities of analysis and interpretation of such results (Jacobsen *et al.*, 2008; Repsilber *et al.*, 2005).

How good is the top ranked single candidate for differentially gene expression – as biomarker for classification? We address this question in the following section.

4 QUALITY OF BIOMARKER CANDIDATES

Biomarker quality for classification is the best characterized by classification error proportion tested on a validation dataset (Martens and Næs, 1989). The principle of validation is to confront the biomarker candidate with samples which were not used (during training) to find this candidate. Such samples could be newly measured (external validation) or left out from the training process of a dataset already available (internal validation). A systematic way to efficiently use all available data is a special form of the internal validation – the cross-validation. One possible form of cross-validation is the "leave-one-out" cross validation: Each sample of the dataset is left out once and used as test case (when the remaining data are used for training). For a discussion of different forms of cross-validation we refer to Vapnik (1995).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

We will now demonstrate a leave-one-out (LOO) cross-validation to estimate the classification error rate using the best t-test candidate of the Golub dataset:

```
pred ← c() # empty vector to store predictions of left out cases
for(cv in 1:length(cl)){
   print(paste(round(cv/length(cl)*100,digits=2),"%"))
   train.X ← DAT[,-cv]
   train.Y ← cl[-cv]
   p ← apply(train.X,1,function(x){
     t.test(x[train.Y==0],x[train.Y==1])$p.value
   })
   ind ← order(p,decreasing=FALSE)[1] # select best candidate from training
   mean.0 ← mean(as.numeric(train.X[ind,train.Y==0]))
   mean.1 ← mean(as.numeric(train.X[ind,train.Y==1]))
   cut ← 0.5*(mean.0 + mean.1) # assuming identical variances in both groups
   if(mean.1 > mean.0){
     pred[cv] ← sum(DAT[ind,cv] > cut)
   } else { pred[cv] ← sum(DAT[ind,cv] < cut)}
 }
sum(cl!=pred)/length(cl) # proportions of prediction errors
```

```
[1] 0.2222222
```

Hence, we have to expect a classification error of 22%. Is this already the optimum, or could we expect a better classification from combinations of single biomarkers to so-called biomarker panels or biosignatures (cf. Jacobsen *et al.*, 2008)?

5 DETECTING BIOMARKER SIGNATURES: STATISTICAL LEARNING

5.1 Biomarker Signatures – Better Biomarkers?

Significant differential expression of a *single* feature often is insufficient for a good biomarker (see for example the various examples in Eriksson *et al.*, 1999). Biomarkers should allow consistent classification of an individual to a predefined group with distinct features. In principle a *single* gene would suffice as a biomarker but, obviously, a biomarker *signature* (i.e., a combination of several single biomarkers) has two advantages: First, it is more robust with respect to outlier results for a single marker part of the signature. Second, it enables capturing multi-dimensional predictive patterns with dependencies between multiple features. The latter makes biosignatures appropriate for use in highly complex systems as in the case of "OMICs"-studies, where we have to suspect such multivariate dependencies ("patterns").

5.2 The Basic "Learning" Cycle

Classification tools have been developed for analyzing multiple features to reveal the optimal biosignature for discrimination, as, for example, various types of discriminance analysis, partial least squares approaches, boosting logistic regression, support vector machines, or random forests (Kapetanovic *et al.*, 2004; Vapnik, 1995). In principle, classification tools follow the same basic procedure: In a first step the chosen algorithm specific model is parametrized using a training data set where the correct classification for each sample together with the candidate gene values is provided. During this training step the program "learns" how to assess the different candidates and identify the minimal and the most efficient gene cluster as biosignature. In a second step of evaluation, an independent test data set is used to validate the capacity of the chosen candidate molecular profile data to correctly classify *new independent* individual samples.

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

5.3 Overfitting

Various publications on this topic stress the immense importance of sound cross-validation approaches to escape the threats of *overfitting* in multivariate classification (Feng *et al.*, 2004; Simon *et al.*, 2003). Serious overfitting problems arise if the number of features p, e.g. transcripts measured during a microarray gene expression experiment, far exceeds the number of samples n (isolates from different patients). In cases like this, all samples can always be correctly classified, but perhaps without having found any general feature pattern. Therefore, the generalizability of any feature panel, like a biomarker signature, has to be optimized in a cross-validation approach – and validated with external data. An alternative to external validation for cases which already use cross-validation during learning (for optimization of internal parameters) is *double* cross-validation: In each *external* cross-validation run the dataset is split into training and testset. The training set is then split again into *internal* training and internal test sets. To each external cross-validation run belong several internal cross-validations for optimization of the learned biosignature.

5.4 Statistical Learning for the Golub Data Example

Here, we continue our illustrative sample study of the famous gene expression study by Golub *et al.* (1999). We compare different methods of Statistical Learning using appropriate cross-validations and compare with the results from using *single* biomarkers for classification. Methods for supervised learning eligible for classification in OMICs datasets are countless. We chose frequently applied methods, freely available on the Biocondcutor platform (Gentleman *et al.*, 2004, 2005): Random Forests (Breiman, 2001), Powered Partial Least Squares Discriminant Analysis (PPLS-DA, Indahl *et al.*, 2009; Nguyen and Rocke, 2002; Eriksson *et al.*, 1999; Boulesteix and Strimmer, 2007), and K-nearest neighbor classification (Ripley, 1996; Venables and Ripley, 1999). We begin our illustration with a cross-validation of Random Forest classifications for the Golub data:

```
library(randomForest)
pred.RF ← c()
print(length(cl))
for(cv in 1:length(cl)){
   if(cv%%10==0) print(cv)
   train.X ← t(DAT[,-cv])
   train.Y ← as.factor(cl[-cv])
   trainedRF ← randomForest(x=train.X,y=train.Y)
   pred.RF[cv] ← predict(trainedRF,newdata=t(DAT[,cv]))
 }
```

Cross-validation error rate for the Random Forest example (given in %) is

```
sum(pred.RF - cl - 1)/length(cl)*100
```

```
[1] 1.388889
```

Next example, an implementation of the PPLS-DA for our dataset, first the internal cross-validation for optimizing the number of latent variables:

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

```
library(cppls)
library(MASS)
library(multicore)
inner.cv ← function(k){
   ## create inner training set and inner test set
   inner.index ← sample(1:nrow(train.X),
                        size=round(nrow(train.X)*0.9),
                        replace=FALSE)
   inner.train.X ← train.X[inner.index,]
   inner.train.y ← train.y[inner.index]
   inner.train.data ← list(x=inner.train.X,
                           y=dummy(inner.train.y))
   inner.test.X ← train.X[-inner.index,]
   inner.test.y ← train.y[-inner.index]
   plsda ← cppls(y~x, ncomp=ncomp,
                 data=inner.train.data,
                 method="cppls", lower=0, upper=1)
   lda.x ← inner.train.X %*% plsda$loading.weights[,1:ncomp]
   lda.data ← list(x= lda.x, y= inner.train.y)
   lda.res ← lda(y~x,data=lda.data)
   ## predict inner test set:
   test.data ← list(x= inner.test.X
                    %*% plsda$loading.weights[,1:ncomp])
   inner.pred ← predict(lda.res,newdata=test.data)$class
   err ← 1 - sum(inner.pred==inner.test.y)/length(inner.test.y)
   return(err)
 }
```

And, second, the external cross-validation implementation for this case:

```
n.CV.inner ← 10
ncomp.max ← 10
pred.pplsda ← ncomp.opt ← outer.errs ← c()
loading.weights ← list()
err.prop ← matrix(NA,nrow=ncomp.max,ncol=n.CV.inner)
for(cv in 1:length(cl)){## outer cross-validation loop
   print(paste("cv=",cv,"of",length(cl),"␣->␣",date()))
   train.X ← t(DAT[,-cv])
   train.y ← as.factor(cl[-cv])
   ## optimizing ncomp:
   for(ncomp in 1:ncomp.max){
     print(paste("ncomp=",ncomp))
     res.cv.inner ← mclapply(1:n.CV.inner,# here: inner CV!
                             FUN=inner.cv,mc.cores=2)
     err.prop[ncomp,] ←  as.numeric(res.cv.inner)
   }## ncomp-loop
   means ← apply(err.prop,1,mean)
   ncomp.opt[cv] ← (1:ncomp.max)[means==min(means)][1]
```

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

```
    ## fit optimal pplsda-model (ncomp=ncomp.opt):
    outer.train.data ← list(x=train.X,y=dummy(train.y))
    pplsda.opt ← cppls(y~x, ncomp=ncomp.opt[cv],
                       data=outer.train.data,
                       method="cppls", lower=0, upper=1)
    loading.weights[[cv]] ← pplsda.opt$loading.weights
    lda.data.opt ← list(x=train.X %*%
              pplsda.opt$loading.weights[,1:ncomp.opt[cv]],
             y= train.y)
    lda.res.opt ← lda(y~x,data=lda.data.opt) # discriminant analysis
    ## test optimal model on outer test data:
    test.X ← t(DAT[,cv,drop=FALSE])
    test.y ← cl[cv]
    outer.test.data ← list(x=test.X %*%
                pplsda.opt$loading.weights[,1:ncomp.opt[cv]])
    outer.pred ← predict(lda.res.opt,
                         newdata=outer.test.data)$class
    outer.errs[cv] ← 1 - sum(outer.pred==test.y)/length(test.y)
  }## end external cv
```

```
sum( outer.errs)/length(cl)*100
```

```
[1] 2.777778
```

And the K-nearest neighbour classification:

```
library(class)
pred.knn ← c()
for(cv in 1:length(cl)){
    train.X ← t(DAT[,-cv])
    train.Y ← as.factor(cl[-cv])
    test ← t(DAT[,cv])
    pred.knn[cv] ← knn(train.X, test, train.Y, k = 10, prob=TRUE)
  }
sum((pred.knn-1)-cl)/length(cl)*100
```

```
[1] 9.722222
```

Even a simple learning method like *k*-nearest neighbors has a better classification error rate in the leave-one-out cross-validation than the single feature approach. Note that, the parameter k from the nearest neighbors fitting (which we set to $k = 10$ in the last code chunk) could have been optimized taking an internal cross-validation approach (alike that we demonstrated for the PPLS-DA).

5.5 Feature Selection: The Biosignature from Statistical Learning

When a statistical learning machine is trained, we are of course interested which of the features were mainly used for prediction. A biomarker signature should not contain thousands of features, but a few – of the order of 25 – to be able to build a cheap

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

testing device for field trials. As an example for such a testing device consider microfluidic cards (Ricco *et al.*, 2002). Dutkowski and Gambin (2007) propose to *combine* feature selection lists from different algorithms to arrive at what they call a "consensus biomarker selection." For our Golub dataset example, and the objective to predict the status "AML" or "ALL" from a gene expression signature, we exemplify the feature selection capabilities using the Random Forest approach again. The algorithm for feature selection in this context often is the *Gini-index*, which describes the increase in classification error (from cross-validation) as variable importance.

Here comes our "hands-on" example regarding the Golub dataset:

```
library(randomForest)
pred.RF.imp ← c()
for(cv in 1:length(cl)){
   train.X ← t(DAT[,-cv])
   train.Y ← as.factor(cl[-cv])
   trainedRF ← randomForest(x=train.X,y=train.Y,importance=TRUE)
   ## now select 20 most important features:
   imp.index ← order(trainedRF$importance[,4],decreasing=TRUE)
   trainedRF.imp ← randomForest(x=train.X[,imp.index[1:20]],
                                y=train.Y,importance=TRUE)
   pred.RF.imp[cv] ← predict(trainedRF.imp,# RF using 20 best features
                             newdata=t(DAT[imp.index[1:20],cv]))
 }
```

Figure 3 shows all feature importances for the Golub dataset classification using random forests. From these values it is now possible to pick the 20 most important.

Here we compute the cross-validation error rate for random Forest prediction using only the 20 most "important" (Gini index) variables:

```
sum(abs(cl - (pred.RF.imp -1)))/length(cl)*100
```

```
[1] 2.777778
```

This is a little worse than the random forest error rate using all features, but still comparable to PPLS-DA and much better than for the best univariate candidate.

Figure 4 compares random forest feature importance with the classical t-test ranking – there are new features which become important for the multivariate pattern.

Also for PLS-based algorithms, there are powerful possibilities to use feature selection (Le Cao *et al.*, 2008; Chong and Jun, 2005).

6 USING A PRIORI INFORMATION

A main problem in detecting single biomarker molecules taking a screening approach using one (or more) OMICs technologies is the high number of variables (features) from which to choose.

As pointed out by Feng, Prentice and Srivastava (2004), a special form of including a priori knowledge is the so-called "hypothesis driven approach" (as opposed to the purely "data driven approach"): If it is possible, based on information from pilot studies or other prior experiences, to focus on a special tissue, or cell type, background variance (other tissues or cell types) is significantly reduced and, hence, the power to detect promising biomarker candidates enhanced.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

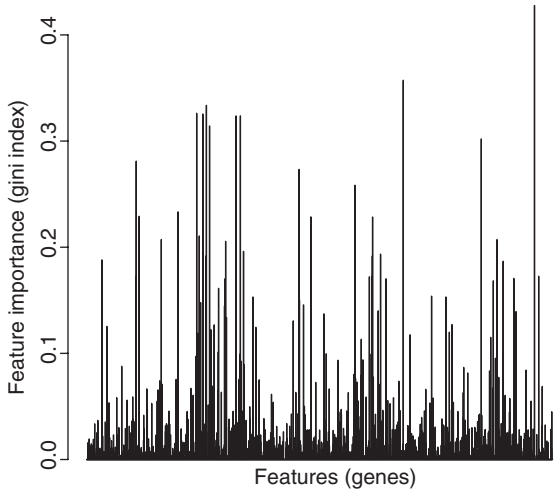

Figure 3. Feature importance plot (Gini index) for Random Forest learning applied to the Golub data. Some features show especially large importance, most are unimportant.

We want to stress the importance of using such possibilities, especially regarding limited sample sizes for the first phases studies for drug discovery.

Another possibility to exploit prior knowledge would be the notion that genes (and also proteins, miRNAs, or metabolites) do not act on their own but together with other features. Prior knowledge of such *functional relationships* between features should be a possibility to reduce the problem given above.

There are several possibilities of including prior information about functional grouping structures of features of which we want to highlight three in the subsequent subsections: Gene set enrichment analyses and related approaches, first steps to consider network structures in classification analyses, and an example to use knowledge about covariance structures in multivariate classification. A functional grouping, or "gene-set," sometimes "pathway," can have several forms: It could be for example a Gene Ontology (GO) term (Ashburner *et al.*, 2000; Falcon and Gentleman, 2007; Alexa *et al.*, 2006), a "molecular signature" (Broad Institute (MIT & Harvard), 2009), or some other functional group of features as available from one of the many "pathway databases" (Kanehisa and Goto, 2000; Bader and Donaldson, 2009). If a specific functional set representation for analyzing an OMICs experiment has been targeted, the next step is a database-assisted mapping of array

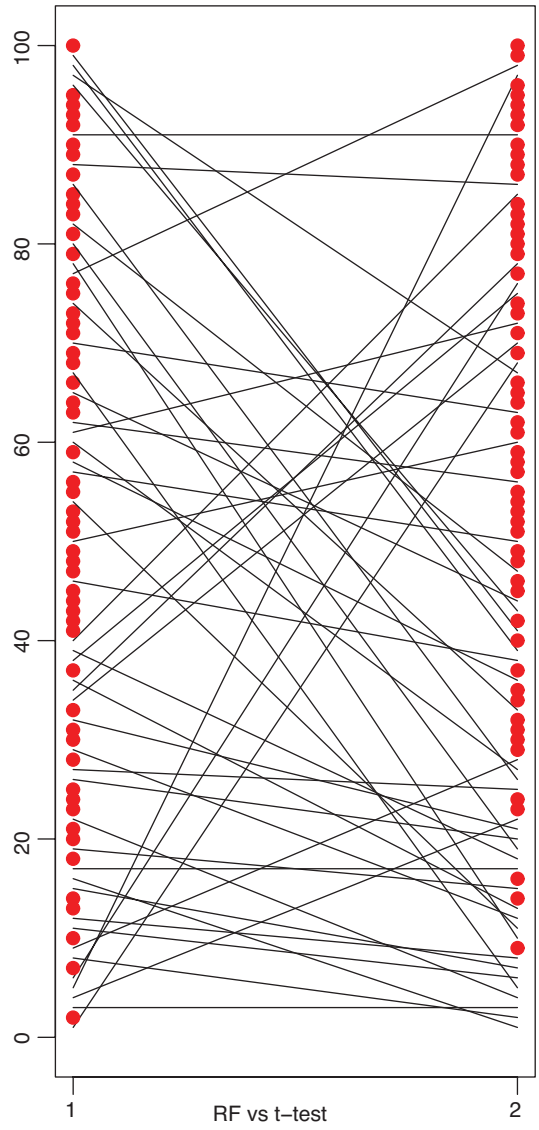

Figure 4. Comparison of an univariate feature ranking (t-test) and an example for a statistical learning method's feature ranking (Random Forest). The best t-test ranked features are also important for the Random forest prediction, but there is not much coherence in general.

features to gene identifiers used in the targeted representation of the functional sets under investigation (Durinck *et al.*, 2005).

Here, we map Affymetrix features of the Golub dataset on Human Gene Symbols to be able to use "molecular signatures" of Broad Institute (MIT &

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Harvard) (2009) in three different gene set enrichment analyses, as explained below:

```
library(biomaRt)
human ← useMart("ensembl", # connect to Ensembl database
                dataset = "hsapiens_gene_ensembl")
affy.genes ← as.character(genes[[1]])
res.query ← getBM(attributes = c("affy_hugenefl","hgnc_symbol"),
                filters ="affy_hugenefl",
                values=affy.genes,
                mart = human)
HGS ← unique(res.query$hgnc_symbol)[-1] ## no 1 is empty
DAT.HGS ← matrix(NA,nrow=length(HGS),ncol=ncol(DAT))
for(hg in 1:length(HGS)){
   h ← HGS[hg]
   affyids ← res.query$affy_hugenefl[res.query$hgnc_symbol==h]
   index ← (1:length(affy.genes))[affy.genes %in% affyids]
   DAT.HGS[hg,] ← apply(DAT[index,],2,mean)
 }
```

The result is a new dataset, "DAT.HGS," for which features are human gene symbols.

6.1 Gene Set Enrichment and Related Approaches

Ackermann and Strimmer (2009) give a comprehensive overview, a *taxonomy*, of existing methods to analyze gene set enrichment. Such methods can be used to test either of three possible null hypotheses:

1. Is a list of differentially expressed single features over-represented in a given set of genes? (e.g., Backes *et al.*, 2007; Falcon and Gentleman, 2007)
2. Is a set of genes differentially regulated? (e.g., Hummel *et al.*, 2008; Goeman *et al.*, 2005, 2004)
3. Is a special set of features more differentially regulated than all other sets of genes in the collection? (e.g., Subramanian *et al.* 2005, Efron and Tibshirani 2007)

Here comes the analysis according to Efron and Tibshirani (2007):

```
library(GSA)
geneset.obj ← GSA.read.gmt("c2.all.v2.5.symbols.gmt") # read in gene sets
GSA.res ← GSA(x=DAT.HGS,y=c1+1,genenames=HGS,
                genesets=geneset.obj$genesets, method='maxmean',
                resp.type="Two␣class␣unpaired", nperms=1000)
```

```
GSA.listsets(GSA.res, geneset.names=geneset.obj$geneset.names,
              FDRcut=0.2,maxchar=200)$negative[,2:4]
```

	Gene_set_name	Score	p-value
[1,]	"YAGI_AML_PROGNOSIS"	"-1.4315"	"0"
[2,]	"GOLUB_ALL_VS_AML_DN"	"-4.5843"	"0"
[3,]	"PARK_RARALPHA_MOD"	"-1.0089"	"0"
[4,]	"VERHAAK_AML_NPM1_MUT_VS_WT_UP"	"-1.2842"	"0"

```
GSA.listsets(GSA.res, geneset.names=geneset.obj$geneset.names,
              FDRcut=0.2,maxchar=200)$positive[,2:4]
```

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

```
      Gene_set_name                                Score     p-value
[1,] "GOLUB_ALL_VS_AML_UP"                        "3.4794" "0"
[2,] "DNA_DAMAGE_SIGNALING"                       "0.5801" "0"
[3,] "HADDAD_HSC_CD10_UP"                         "1.2333" "0"
[4,] "ZHAN_MMPC_PC"                               "1.2626" "0"
[5,] "HADDAD_HPCLYMPHO_ENRICHED"                  "1.1587" "0"

[7,] "ZHAN_TONSIL_PCBC"                           "0.8334" "0.001"
[8,] "ZHAN_MULTIPLE_MYELOMA_SUBCLASSES_DIFF"      "1.4857" "0.001"
[9,] "ZHAN_MMPC_EARLYVS"                          "0.7251" "0.001"
```

Observe the genesets "GOLUB_ALL_VS_AML_DN" and "GOLUB_ALL_VS_AML_UP" as controls. Next, we demonstrate the "globaltest" alternative:

```
library(globaltest)
rownames(DAT.HGS) ← HGS
globaltest.res ← globaltest(X=DAT.HGS,
                            Y=cl,genesets=geneset.obj$genesets)
```

```
library(globaltest)
library(multtest)
head(globaltest.res)
```

```
Global Test result:
Data: 72 samples with 5949 genes; 6 gene sets
Model: logistic
Method: Asymptotic distribution

```

Last, the enrichment analysis using the hypergeometric distribution. This method relies on a specific list of differentially expressed genes (candidates) as analysis result prior to gene-set enrichment – we take the top 100 candidates from the *t*-test comparison of AML and ALL profiles:

```
p.val.ttest <- apply(DAT.HGS,1,function(x){
   return(t.test(x[cl==0],x[cl==1])$p.value)
 })
top100 <- HGS[order(p.val.ttest,decreasing=FALSE)[1:100]]
ref.genes <- HGS
## Enrichment computation:
thresh.l <- 15
gs.pval <- gs.name <- gs.SetSize <- gs.k <- c()
gs.l <- gs.expect <- c()
count <- 1
for (i in 1:length(geneset.obj$genesets)){
   k <- sum(top100%in%geneset.obj$genesets[[i]])
   l <- sum(ref.genes%in%geneset.obj$genesets[[i]])
   m <- length(ref.genes)
   n <- length(top100)
   k.expect <- n*l/m
   if(k.expect < k & thresh.l < l){
     gs.pval[count] <- phyper(k, l, m-l, n, lower.tail=FALSE)
     gs.name[count] <- geneset.obj$geneset.names[i]
     gs.SetSize[count] <- length(geneset.obj$genesets[[i]])
     gs.k[count] <- k
     gs.l[count] <- l
     gs.expect[count] <- k.expect
     count <- count + 1
   }
 }
## Adjust for multiple testing:

Within the molecular signature pathways "c2.all.v2.5.symbols.gmt" Broad Institute (MIT & Harvard), 2009, "GOLUB_ALL_VS_AML_UP" and "GOLUB_ALL_VS_AML_DN" appear as controls throughout. As in this dataset two different cell types – which are the bases of the AML and ALL tumors respectively – are compared, we expect a rather large number of differentially expressed pathways.

6.2 A Systems Biological Approach to Classification: Considering Network Structures

Using a priori knowledge about functional groups of genes (pathways, molecular signatures, etc.) for most approaches does not depend on any topological regulatory structures between the features of a functional group. However, some approaches promise change: Draghici *et al.* (2007) exemplify how the analysis of pathways could profit from including more topological details of the underlying regulatory network. Schadt (2009) points out that in the context of common human diseases, the disease states can be considered emergent properties of molecular networks, as opposed to the core biological processes associated with a disease being driven by responses to changes in a small number of genes. Promising implementations of systems biological approaches for classification algorithms are underway, but currently in experimental status. As example, we want to refer to the work of Sæbø and Martens (Sæbø *et al.*, 2008, 2006), who propose to implement a third matrix for the PLS-algorithm, which could supply information about prior knowledge on covariance structures of features. Such covariance structures could in principle also be deduced – and be dependent – on topological information about regulatory networks.

7 THE INTEGRATIVE BIOINFORMATICS APPROACH

In the previous sections we were concentrating on describing the extension of the classical univariate approach, based on *t*-test and its relatives from classical statistical testing, to multivariate methods. These combine several features to biomarker panels, also called biosignatures, for classification. A further extension is now straightforward, the combination of features from different levels of gene expression – variation on the genomic level (measured as variation in genetic markers

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat223
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

(polymorphisms)), on the transcriptome, proteome, and metabolome may be combined: There is a major motivation to use several OMICs levels at the same time, which relates to a data quality as well as the multiplicity problem inherent to most high-throughput studies: Each experimental technique will not only measure the biological variation it was designed for, but also add technical variance and possibly a methodological bias to the results. Together with the high-throughput character of genome-wide experiments, this probably results in high rates of false positive discoveries. There are also technologically biased results, which among other effects are partly responsible for false positives (Searls, 2003; Steinfath *et al.*, 2007). Here, if data from two or more different platforms, different levels of gene expression or biological organization, point to the same biomarker candidates, their relevance can be established with greater confidence. Such integration can also be seen as a means of verification of isolated results, or as if gathering additional degrees of freedom to be able to test a given hypothesis together with the high level of signal errors typical for high-throughput experimental data (Aitchison and Galitski, 2003).

Frequently, measured data are not independent across different experiments, but data obtained from distinct platforms are more likely to be independent observations. Based on these motivations, Aitchison and Galitski (2003) describes integrated data analysis as a way of going "from inventories to insights" and propose the following general approach:

The first level of integrated data analysis is also referred to as "data integration" (storage, organization in databases, mapping of feature annotations, joint normalization) to distinguish it from the following components. Data integration itself cannot explain the dynamical behavior of the biological system and is not a replacement for a dynamical qualitative or quantitative model. However, data integration is needed to increase the information available for the individual unit, the feature of interest, by adding more measured values, thus making systems features well distinguished from an otherwise overwhelmingly noisy background. A second component of integrated data analysis takes a pattern finding and correlation analysis point of view. Here, the goal of analysis is to find common patterns in data of different origin (see for example Patil and Nielsen 2005). Finally, as a third component of integrated data analysis, the formulation of quantitative as well as conceptual system models.

Practically, during integrative analysis, not only additional features can be included for a classification task, but also the information about which of these features from the different OMICs levels belong functionally together. Such information could be extracted systematically from appropriate biological databases (Kanehisa and Goto, 2000; Bader and Donaldson, 2009; Broad Institute (MIT & Harvard), 2009). Durinck *et al.* (2005) demonstrate how to use biomaRt (Durinck *et al.*, 2009) and Bioconductor (Gentleman *et al.*, 2004) as to build and use the powerful link between biological databases and OMICs data analysis.

8 CAUSALITY AND BIOMARKERS

It can be helpful if toxicologists also identify the mechanisms responsible for adverse effects. This knowledge can be particularly relevant when therapeutic and adverse effects are due to different mechanisms and can therefore contribute to a rational design of safer drugs. Examples are the recent reviews on mechanisms of telomere maintenance (Liew and Norbury, 2009) and genomic instability (Florl and Schulz, 2008). Schadt (2009) hopes that integrating large-scale, high-dimensional molecular and physiological data holds promise not only for defining the molecular networks that directly respond to genetic and environmental perturbations that associate with disease but also for causally associating such networks with the physiological states associated with disease. Also Klipp *et al.* (2005) and Searls (2005) point to the necessity to integrate the analysis of different levels of biological organization to identify functional biological themes revealing how biological molecules interact with each other. As shortly discussed above, involving causative reasoning into biomarker discovery is related to a "hypothesis driven approach," which can enhance power of biomarker detection through focussing and minimization of disturbing variation (and biases) (Feng *et al.*, 2004).

Besides the hopes that integrative biomarker signatures may help elucidating causal reasons for certain clinical phenotypes, we want to point to the problem of inseparability of first and second order effects: Candidate biomarkers may reflect

only second order effects of some prior impact, as these second order effect often are measurable in more features and also of larger magnitude than the first order effects which are the first steps of the whole system's reaction. Often such – causative – first order effects are near to under detection level, think for example of the well-known systems of phage λ and its repressor which is present only in a few copies per cell.

9 SUMMARY

Our chapter on Biomarker discovery gives a statistical bioinformatics view of the field, combined with a "hands on"-example to reproduce on the reader's own desktop. It should be straight ahead to implement and apply the collection of methods mentioned here to the specific dataset in a systems toxicological approach, to

- find single biomarkers for classification from OMICs screening studies
- combine single markers to biosignatures with empowered prediction using several methods of statistical learning
- estimate classification errors using appropriate validation techniques
- approach an integrated analysis by either collecting data on different OMICs levels – or by taking into account existing systems biological a priori knowledge on gene-sets or regulatory topologies

We show that integrated data analysis as the combination of disparate experimental data (experiments, platforms, but in particular from heterogeneous biological OMICs-levels) can be a useful approach for the validation of analysis results on the one hand, and to establish biological models for the functional interplay of the different levels of biological organization aiming at a functional and holistic understanding.

Our hope is that this methodological collection, which is mostly based on the authors' experiences with transcriptome and metabolome studies in a molecular medical background will prove its applicability for the systems toxicologist hunting for valid biosignatures.

Supplements

R-scripts implementing the approach proposed by Jaffrezic *et al.* (2007), to store as file "SMVar-adjFunctions.R":

Mechanistic Investigation of EMD335823s Hepatotoxicity Using Multiple Omics Profiling Technologies

Alexandra Sposny, Christina S. Schmitt and Philip G. Hewitt

eTox, Institute of Toxicology, Merck Serono Research, Merck KGaA, Darmstadt, Germany

1 INTRODUCTION

Development of a new drug is time-consuming, expensive and complex, and the possibility of failure to reach the market is high. Therefore, any advance in technology that can shorten development times and/or more accurately reflect the liabilities of a drug once it enters the general population would be of tremendous benefit.

So far, classical toxicology, with up to 2-year animal carcinogenicity studies, followed by traditional investigations (clinical chemistry, urinalysis, pathology, etc.) of biological endpoints is the gold standard in the drug development process. Beside the fact that these long-term studies need a lot of animals, we also have the problem that such observations do not provide information about a drug's mode of action, which is however important to know in order to better evaluate any adverse effects associated with drug exposure (Guerreiro *et al*., 2003). As drugs are expected to induce/alter a multitude of molecular/cellular pathways, it makes more sense to elucidate these on a molecular basis. Omics technologies (genomics, proteomics, and metabonomics) permit simultaneous monitoring of hundreds or thousands of macro and small molecules together with the promise to allow functional monitoring of multiple key cellular pathways simultaneously (MacGregor, 2003). In addition, changes in gene, protein, and metabolite expression are often more sensitive and characteristic of the toxic response or process than currently employed endpoints of pathology. Consequently, these expression changes do have the potential to indicate toxicity already at lower doses and/or earlier timepoints (Guerreiro *et al*., 2003). Toxicogenomics and, to a smaller degree, toxicoproteomics are already known as powerful tools for compound classification, mechanistic studies, and detection of toxicity biomarkers (Ellinger-Ziegelbauer *et al*., 2008; Geurts *et al*., 2005). However, recent publications (Craig *et al*., 2006; Kleno *et al*., 2004; Ruepp *et al*., 2002; Coen *et al*., 2004) have demonstrated that systems toxicology/systems biology can be of even more benefit in elucidating a drug's mode of action. Classical toxicology together with genomics, proteomics, and metabonomics has been shown to work synergistically in order to allow the generation of hypotheses about a drug's mechanism of toxicity. This understanding could therefore provide information on whether observed changes are species specific or predictive for human risk.

The FP6-PredTox project, a pilot project for the innovative medicines initiative (IMI), was started to help improve the drug development process through a series of public–private collaborations. The major aim was to find new technologies/biomarkers that

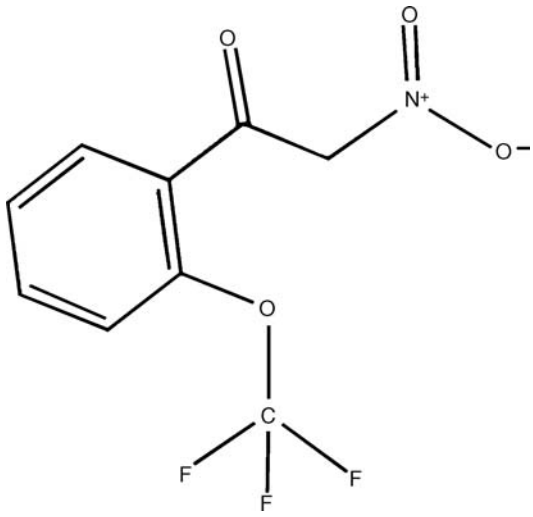

Figure 1. Structure of EMD 335823, an aldose reductase inhibitor.

could better predict drug safety earlier during development. The 14 participating companies offered test substances that could not enter the market, in part because of their hepato- or nephrotoxicity.

These substances have been analyzed in a systems toxicology approach with a combination of classical toxicology together with genomics [both whole genome (Affymetrix) and focused (Illumina DASL^{TM} technology for gene expression profiling from FFPE tissues)], proteomics (2D-DIGE), as well as metabonomics (both NMR- and LC/MS-based). The substance we focus on here, EMD 335823 (Figure 1), was developed by Merck KGaA as an aldose reductase (AR) inhibitor.

Aldose reductase is a monomeric, nicotinamide adenine dinucleotide phosphate-oxidase (NADPH)-dependent enzyme that is a member of the aldo-keto reductase family and is highly distributed in many tissues, such as nerve, lens, inner medulla of the kidney or renal cortex, etc. It catalyzes the reduction of aldo sugars and other saturated and unsaturated aldehydes, and constitutes the first step of the polyol pathway where glucose is reduced to the sugar alcohol sorbitol (Figure 2). As sorbitol does not easily cross cell membranes and its subsequent conversion to fructose via sorbitol dehydrogenase is slow, it accumulates inside cells resulting in changes in osmotic pressure, alterations in the redox state of pyridine nucleotides, and depleted intracellular levels of myoinositol. For example, too much sorbitol trapped in eye and nerve cells can damage these cells, leading to retinopathy and neuropathy, two common symptoms that can be found in diabetic patients (Boulton *et al*., 1985; Ranganathan *et al*., 1993). AR inhibitors are a class of drugs that have been shown to be effective in preventing the development of various diabetic complications because they prevent or slow the action of AR.

2 METHODS

2.1 Animal Study, Dosing, and Sample Collection

The animal study was performed on 10-week-old male Wistar rats (Han:Rcc_WIST) from RCC Ltd. (Füllingsdorf, Switzerland) with an average body weight of 170–200 g. Five rats were used for each treatment group and time-point, which were individually housed in Makrolon type-3 cages (‘Lignocel‘Schill AG, Muttenz, Switzerland), except on days −4/−3, 1/2, 3/4, and 12/13 when they were housed individually in metabolism cages (Tecniplast, Buguggiate Italy). Animals were kept under standard laboratory conditions with a light/dark cycle of 12 : 12 h. The test item EMD335823 was applied by oral gavage on a daily basis for up to 14 days. The compound was given in two different doses: a low (no observed adverse effect level, NOAEL) dose (15 mg kg^{-1}) and a high (maximal tolerated dose, MTD) dose (350 mg kg^{-1}). These doses were chosen based on the data from a previous 2-week pilot study. Animals were sacrificed on days 1, 3, and 14 after a 24-h fasting period.

2.2 Toxicogenomics

2.2.1 Affymetrix Whole Genome Array

Liver, kidney, and blood were profiled by toxicogenomics. RNA from target organ tissues was extracted using QIAGEN RNeasy® Mini Kit followed by DNA digestion using the RNase-free DNase Set (Qiagen GmbH, Hilden, Germany). For RNA extraction from blood samples, the samples

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

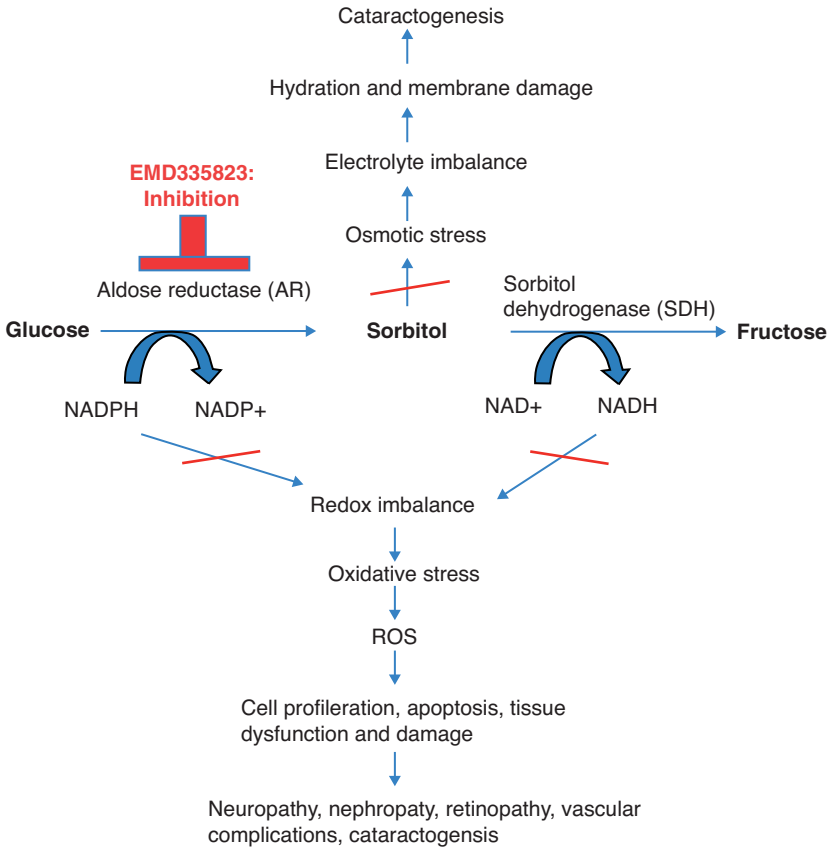

Figure 2. In the polyol pathway, glucose is reduced to sorbitol via aldose reductase, and afterwards, aldehyde dehydrogenase converts sorbitol into fructose. EMD 335823 inhibits aldose reductase and prevents from too high levels of sorbitol and resulting effects in diabetic patients (adopted from Srivastava, Ramana and Bhatnagar, 2005).

were collected from each animal and placed in special tubes containing PAXgene stabilizing solution (PAXgene® blood RNA tubes; PreAnalytiX Hombrechtikon, Switzerland). After collection, the tubes were gently inverted 10 times and left for 3 h at room temperature (RT) for cell lysis. Furthermore, RNA isolation was performed following the handbook from the PAXgene® Blood RNA System (PAXgene® Blood RNA Kit handbook).

The resulting RNA from both tissue and blood samples was processed using Affymetrix kits following the standardized protocol as provided by the supplier. For blood gene expression analysis, however, additional globin reduction reagents (provided by GeneLogic, Gaithersburg, MD, USA) were used. *In vitro* transcripts (cRNAs) were hybridized onto Affymetrix RAE 230 plus microarrays. Microarray quality was evaluated using the Genedata Expressionist® Refiner software (Genedata, Basel, Switzerland), and RMA-condensed data (provided by Genedata) were used for further evaluation using different software. A first overview on the data was given by principal component analyses (PCA) to test the data sets for any general differences. Statistical tests such as *t*-test and way ANOVA (factors: time, dose, time/dose interaction) have been applied in order to derive *P*-values (<0.05), and the ratio of medians (>1.5 and <-1.5) between different timepoints and/or doses using Genedata Expressionist® Analyst software (Genedata). Biological interpretation of pre-selected gene lists was subjected to pathway and network analyses employing ingenuity

pathways analysis (IPA) from Ingenuity® Systems as well as GeneGO's MetaCore™ Pathway software.

2.2.2 DASL™ Assay

When using formalin-fixed paraffin-embedded (FFPE) tissue specimen for toxicogenomic assessments, special platforms are needed because RNA derived from formalin-fixed tissue is highly degraded (Bibikova *et al*., 2008). The DASL™ assay (Illumina Inc., San Diego, CA, USA) is one technology enabling the analysis of poor-quality RNA and was used in this study.

The FFPE tissue samples, used for transcription profiling, were derived from livers of treated and control animals. Livers were transferred to 10% buffered formalin for fixation and afterwards embedded in paraffin. Paraffin blocks were stored at RT until needed. Five sections of one block with a thickness of 5 μm were taken for gene expression analyses. FFPE tissue was deparaffinized by transferring the sections into xylol, followed by an ethanol wash. Afterwards, the RNA was extracted using the High Pure RNA Paraffin Kit (Roche, Mannheim, Germany) following the protocol suggested by the manufacturer. After isolation, the RNA was quantified using a NanoDrop® ND-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA). RNA quality was checked via gel electrophoresis using the total RNA 6000 Nano Chip assay on an Agilent 2100 Bioanalyzer (Agilent Technologies GmbH, Waldbromm, Germany). Furthermore, as a quality check, the RPL13a gene was analyzed with TaqMan qPCR as recommended by Illumina.

Total RNA was processed/labeled according to the manufacturer's protocol. One thousand five hundred thirty-six oligonucleotide probe groups are multiplexed together in one reaction. In this study, three probe groups per gene were used, corresponding to 512 toxicologically relevant genes (Zidek *et al*., 2007).

DASL™ data were extracted with the BeadStudio software (Illumina Inc.) and summarized to one expression value per gene. These data were exported and further analyzed in Genedata Expressionist® Analyst software (Genedata). PCA was carried out for a general overview, and putative differentially detected genes were determined using *t*-test ($P \leq 0.05$), ANOVA, and fold regulation (>1.5 and <-1.5). GeneGo's MetaCore™ software was used to support mechanistic interpretation.

2.3 Toxicoproteomics

2.3.1 2D-DIGE

Liver tissue of 14-day high-dose and control animals was processed for 2D-DIGE analysis at NovoNordisk. Protein extracts from individual control and treated animals were labeled with Cy3 and Cy5, respectively. Additionally, a mix of protein extracts from control and treated animals was labeled with Cy2 (internal standard for the normalization of spot abundances). Mixtures of Cy2, Cy3, and Cy5 samples were run using two-dimensional gel electrophoresis. The first dimension was performed with IPG strips pH 5.5–6.7 using a Multiphor II apparatus. For the second dimension, IPG strips were transferred onto uniform polyacrylamide gels. Gels were run in an Ettan Dalt II electrophoresis unit. Scanning was performed using a Typhoon Trio+ (GE Healthcare, Munich, Germany), and global fluorescence intensities of the scanned images were normalized by adjusting the exposure times to the average pixel values acquired. DeCyder software version 6.5 (GE Healthcare) was used for image analysis. Significantly modulated spots were determined by performing a Student's *t*-test with the following thresholds: $P \leq 0.01$ and fold change ≥ 1.3. Protein identification of deregulated spots was carried out by MALDI-MS and MALDI-MS/MS. Protein identification and statistics of the modulated and identified proteins have been used for interpretation using IPA from Ingenuity® Systems.

2.4 Metabonomics

2.4.1 NMR Analysis

Urine and serum samples were analyzed at LipoFIT Analytic GmbH (Regensburg, Germany) or at the University of Wuerzburg, following standardized protocols (Völkel *et al*., 2005; Mally *et al*., 2007). Spectra were phase-corrected, calibrated, baseline-corrected (no negative values), normalized to the total integral, and binned in 0.04 (urine only), 0.01, and 0.001 ppm bins. Lists of statistical values per matrix and analytical technique, including two-way ANOVA *P*-values and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat224
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Benjamini–Hochberg *Q*-values for the effects "dose," "time," and "dose–time interaction," and *t*-test *P*- and *Q*-values between treated and control replicates for each dose–time-point combination were prepared. For the PCA analysis, the data were Pareto-scaled.

For qualitative multivariate analysis NMR raw data (acquired at 600 MHz with the noesygpr1d pulse sequence from the Bruker library) were binned into 0.04-ppm-wide buckets, with the region from δ 4.40 ppm to δ–6.20 ppm excluded to avoid distortion by water suppression. The spectra were normalized to the total integral. Multivariate data analysis was performed using SIMCA P+ 11.5 software. All models were constructed with mean-centered and Pareto-scaled data.

2.4.2 LC-MS Analysis

Urine and serum samples were analyzed at Metabometrix Ltd. (London, UK) using LC-MS based on standardized protocols. Lists of statistical values per matrix and analytical technique, including *P*- and Benjamini–Hochberg *Q*-values from two-way ANOVA for the effects "dose," "time," and "dose–time interaction," as well as *t*-test *P*- and *Q*-values between treated and control replicates for each dose–time-point combination were generated.

3 RESULTS AND DISCUSSION

3.1 Clinical Investigations and Pathological Outcome

Investigation of clinical pathology parameters showed that high dose-treated animals (only 1-day-treated animals) had increased blood urea nitrogen (BUN), creatinine, sodium, and phosphorus levels. In addition, decreased total cholesterol, triglycerides, fatty acids, relative β-globulin, and absolute β-globulin levels were recorded. In liver, there were no microscopic findings of toxicological relevance on day 1, but in animals treated for 3 and 14 days, hepatocellular hypertrophy was recognized, which was in correlation with the enlargement of the livers seen, especially in day 14 animals. In addition, animals treated with high dose for 14 days showed clear test item-induced findings. Animals of this group were affected to a varying degree, with animals 42 and 45 showing the severest lesions: marked bile duct inflammation with bile duct and liver cell necrosis. In animal 44, the necrosis was only limited to the bile ducts in combination with marked bile duct inflammation. Bile duct inflammation, liver cell necrosis, and bile duct necrosis were considered to be adverse responses.

3.2 Toxicogenomics

3.2.1 Affymetrix Whole-Genome Arrays and DASL™ Assay

Global gene expression analysis was carried out for liver, kidney, and blood samples. A first PCA with all animals showed that there is a moderate treatment-related effect shown by a clear separation of high-dose animals from the vehicle control and low-dose animals (Figure 3a). A further PCA analysis for the detection of time-related effects especially indicates two animals of the high-dose 14 day treatment group (A42 and A45) behaving differently from the others (Figure 3b) corroborating the histopathological outcome that these animals had the most severe effects. Both effects could also be detected by analyzing degraded RNA with the DASL™ assay (Figure 3c). The PCA from the Affymetrix data additionally displayed one of the 3 day high-dose-treated animals (A29) clustering closer to the high-dose animals, which was the only rat of this treatment group showing signs of hepatotoxicity (hepatocellular hypertrophy). The data showed very large differences between individual animals in their response to EMD 335823, especially at high doses. This high variation was also reflected in the clinical chemistry and histopathology data. Based on these highly variable data, global gene interpretation proved to be difficult.

In addition, analysis of gene expression data from vehicle control animals alone suggests that day 1 animals may have been treated differently than the 3 and 14 day animals. ANOVA analyses of Affymetrix, as well as DASL™ data, from vehicle-treated samples clearly showed a distinct number of deregulated genes (e.g., 446 genes for Affymetrix) at different time-points with the over-representation of gene groups such as lipid biosynthesis and response to starvation (Figure 4). This result, based on both array technologies, leads to the assumption that day 1 animals were not starved overnight before sacrifice. This also correlates well with the pathological

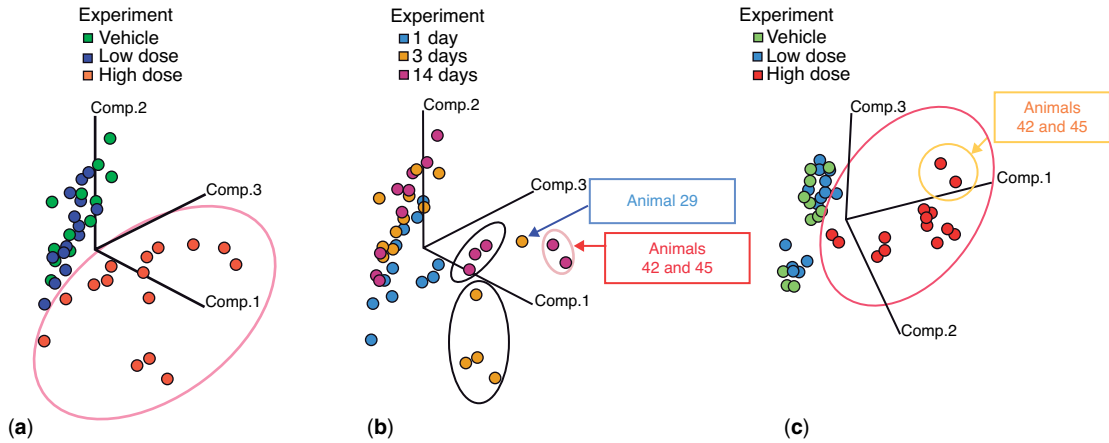

Figure 3. PCA of all liver gene expression data [Affymetrix (a, b) and DASL™ assay (c)]. (a) Clear separation of high-dose animals from control and low-dose animals can be achieved in a dose-dependent manner; (b) Day 3 high dose (yellow circled) and day 14 high dose (purple circled) animals showed effects after treatment with EMD335823, with two animals from day 14 high-dose group (42 and 45; showing most severe effects in histopathology) behaving differently from the others; (c) DASL™ assay data also showed clear separation of high-dose animals (red) from control and low-dose animals in a dose-dependent manner. Additionally, animals 42 and 45 separated from the rest of the high-dose group.

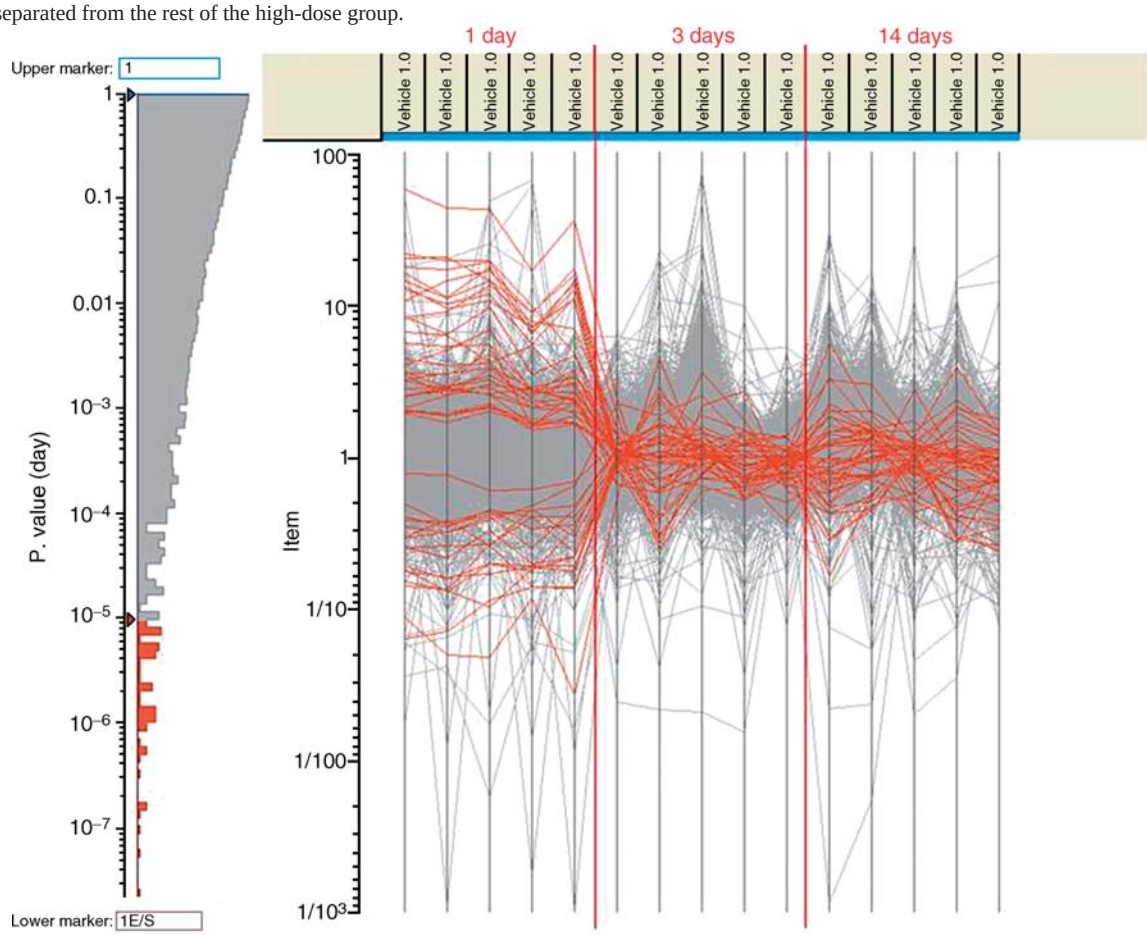

Figure 4. ANOVA on untreated "vehicle" samples: effect of experiment duration, gene expression from Affymetrix whole genome analysis.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat224
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

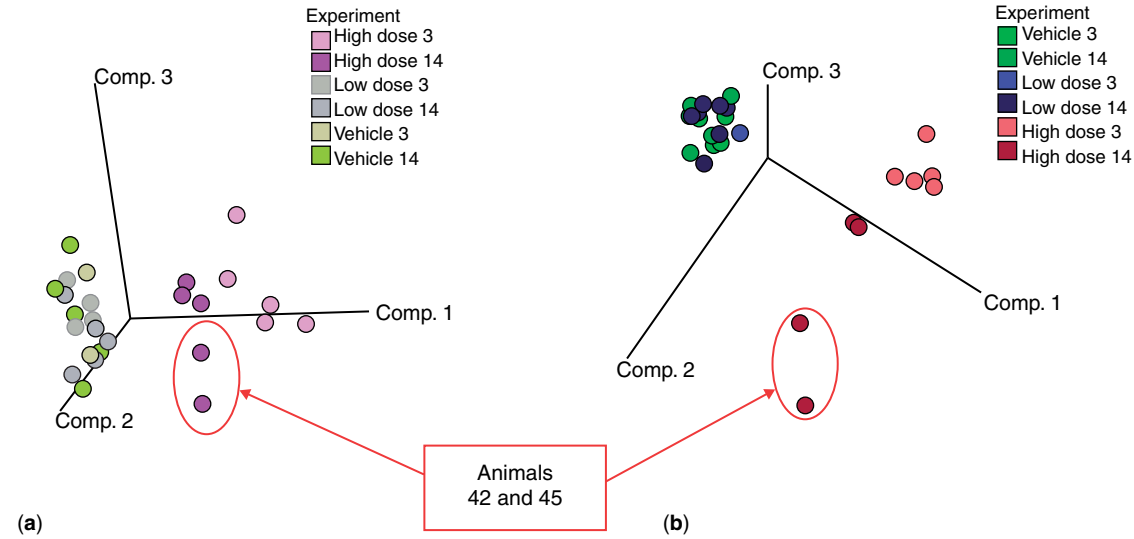

Figure 5. PCA for Affymetrix data (a) and data from the DASL™ assay (b) for days 3 and 14 animals only. The resulting data sets display a much clearer separation between high-dose and low-dose/control animals. Again, animals 42 and 45 are separated from the rest of the high-dose animal group.

finding of high glycogen content in the hepatocytes from this group, and observed glycogen depletion on days 3 and 14 animals indicating overnight starvation (as originally planned).

This fact has obvious implications for further data analysis. As such, data were re-analyzed excluding the day 1 animal samples. The PCA shown in Figure 5 shows that the dose-related effects are more obvious than before and interpretation of the data was made easier.

For analysis of the DASL™ data, only vehicle- versus high-dose-treated animals were compared, focusing on the 14-day treatment. By analyzing the deregulated genes (fold change ≤ 1.5 and ≥ -1.5 *t*-test: $P \leq 0.05$) glycolysis and gluconeogenesis were significantly deregulated, indicating a direct damage of hepatocytes, and confirming the histopathological necrosis of bile duct and hepatocytes. The data suggest that pathways of cell proliferation and immune response, including inflammation, were affected, which could be linked to the inflammation observed of the bile duct. In addition, bile acid synthesis was activated. The specific bile acid transporter abcc3 was strongly up-regulated in day 14 high-dose animals, which was confirmed by analysis of the Affymetrix data. Furthermore, many deregulated pathways corresponding to lipid and fatty acid metabolism were observed, correlating well with Affymetrix gene expression data.

After the application of a two-way ANOVA for "dose," "time," and "dose–time interaction," lists of significantly deregulated genes have been extracted from the whole-genome Affymetrix data set. These probe sets were separated into up- and down-regulated genes and graphically displayed with a one-dimensional clustering heat map (Figure 6). Characteristic profiles are obvious after exposure to high doses, with increasing number of gene expression changes after 3 days. Over-represented categories in this data set included protein folding, protein transport, and cell redox homeostasis, which indicates that oxidative stress and xenobiotic metabolism, as well as AR inhibition, are going on. In addition, several toxicologically relevant pathways showed a tendency to increase over time, such as acute phase response, tissue regeneration, fibrinolysis, bile acid synthesis, and bile acid transport.

Probe sets of all three time-points deregulated by at least 1.5-fold with *P*-values of less than 0.05 were uploaded into GeneGo's MetaCore™ pathway software. The most significantly affected canonical pathways are shown in Figure 7. As fatty acid metabolism and lipid metabolism are highly over-represented within these data sets, we suggest that

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat224

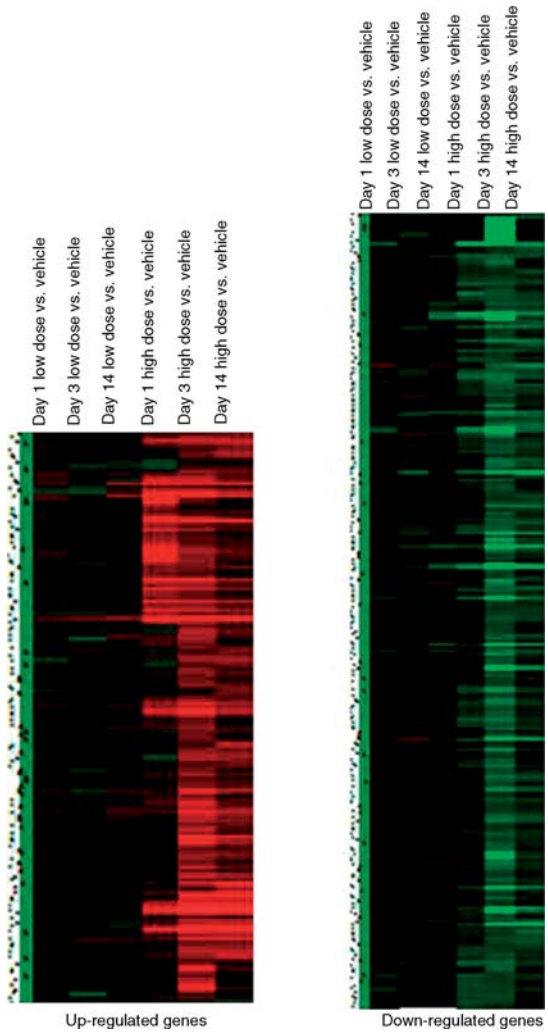

Figure 6. One-dimensional clustering heat map of up- and down-regulated genes from whole-genome Affymetrix data set. All three time-points and doses are given versus their matched vehicle. Red indicates up-regulated genes, green indicates down-regulated genes, and non-regulated genes are marked with black.

this is a major effect of our compound at both dose levels. The increase in fatty acid β-oxidation is also known to be significantly affected by PPARα agonists and to positively influence dyslipidemia (Cariello *et al.*, 2005).

This analysis revealed effects on multiple genes involved in bile acid biosynthesis (Figure 8), especially in high-dose animals, and furthermore some effects also in tryptophan metabolism. This effect can be based on the fact that a large number of genes are common between the fatty acid metabolism and tryptophan metabolism pathways, such as many aldehyde dehydrogenases and cytochrome P450s. However, tryptophan is also a key amino acid in the biosynthesis of nicotinamide adenine dinucleotide (NAD^+) (Murray *et al.*, 2000). A subtype of PPAR ligands increases NAD^+*in vivo* in the rat liver by alteration of the tryptophan–NAD^+ pathway (Shibata *et al.*, 1996; Shin *et al.*, 1998, 1999). Interestingly, Delaney *et al.* (2005) have proposed using urinary metabolites from the tryptophan–NAD^+ pathway as a marker of peroxisome proliferation.

Categorization of all the resulting canonical pathways that were common to both time-points (days 3 and 14) and doses (low and high) outlined the following networks (networks are prioritized based on the number of fragments of canonical pathways on the network): cellular lipid processing, very long chain fatty acid metabolism, lipid metabolic processing, lipid transport, cholesterol metabolic processing, acetyl-CoA biosynthetic process from pyruvate, cell surface receptor linked signal transduction, and stress response. All these gene expression changes seem to be related to the compound's mechanism of action because the inhibition of the target molecule AR leads to an increased use of the glycolysis pathway in connection with the citrate cycle and lipid metabolic processes. On one hand, the stress response can be interpreted as a general stress response reflecting a general hepatic damage as it was also shown by the pathological investigations. But it could also be due to the livers response to the pharmacological action of the molecule. AR is not only the first and rate-limiting enzyme of the polyol pathway, but it has also a detoxifying function in the body by reducing glutathione (GSH)-conjugated aldehydes formed during lipid peroxidation, such as 4-hydroxyononenal-3-yl-glutathione (HNE)-GSH. In case of AR inhibition, we also assume that reduction of aldehydes is diminished as well and concentrations of 4-hydroxy-2(*E*)-nonenal (HNE)-conjugated and unconjugated molecules can increase in the organ over time. This suggests that AR inhibition *in vivo* leads to an increase in downstream products of lipid peroxidation. In addition, according to the literature, significant increases in HNE concentrations in the tissue have been detected

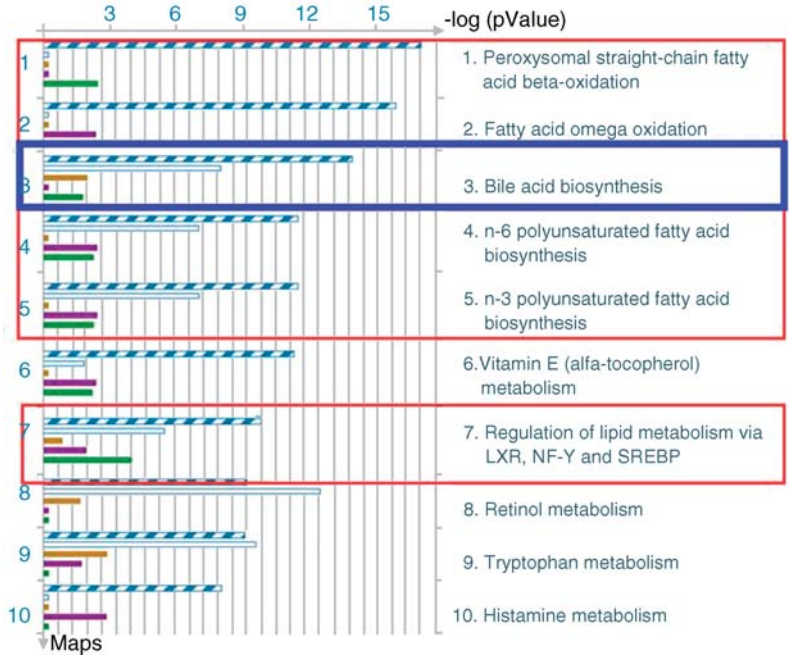

Figure 7. Distribution by canonical pathway maps given by GeneGo's MetaCore™ software. Colored bars indicate single time-points and doses (green: high dose day 1; brown: high dose day 3; violet: high dose day 14) whereas striped bars represent common genes across all samples.

in combination with higher frequencies of apoptotic cells (Rittner *et al.*, 1999).

Overall, the gene expression data (and histopathology, clinical chemistry) of all animals showed a large variation in animal response, especially at a high dose. Therefore, animals 42 and 45 (the most severely affected animals of the day 14 high-dose group) were analyzed separately. In comparison with the other three animals of the high-dose group, approximately 680 probe sets were found to be differentially expressed specifically by animals 42 and 45. Examination of these deregulated genes displayed an obvious decline of the effect on lipid/fatty acid metabolism on days 3 and 14 low- and high-dose animals. Instead, a much clearer picture of hepatotoxicity was seen as it was indicated by the following toxicologically related processes: (i) acute phase response/inflammation↑, (ii) protein damage (necrosis)↑, (iii) transport (necrosis)↑↓, (iv) oxidative stress↑, (v) regeneration↑↓, (vi) proliferation↑↓, (vii) regulation of transcription↑↓, and (viii) apoptosis↑↓. All these processes can be directly related to the observed histopathology.

3.3 Toxicoproteomics

3.3.1 2D-DIGE

Overall, 244 spots were found to be modulated with 130 spots up-regulated and 114 down-regulated. One hundred fifty-four spots were used for further protein identification by MALDI-MS and MALDI-MS/MS, resulting in 72 proteins with unique accession numbers (37 up-regulated and 35 down-regulated). Modulated proteins were analyzed using IPA from Ingenuity® Systems. Even though only samples from day 14 were processed, it was clearly observed that not only cell damage and response to drug treatment were prominent but also regeneration processes had been initiated.

From the IPA "Tox Functions," three main important processes were affected: liver cholestasis, liver steatosis, and liver proliferation (Figure 9). The first two effects fit to the known toxicity and pharmacological action of EMD 335823, namely bile duct toxicity and strong effects on lipid metabolism. As only day 14 samples were processed with 2D-DIGE, it seems that the liver proliferation shown above is likely to be a treatment-related effect rather than an

acute response. This was also confirmed by other proteins that were involved in inflammatory and regeneration processes (shown in Figure 10a).

The up-regulation of fatty acid metabolism was identified as the most significantly affected pathway, indicating that this is a major effect of our compound. This assumption is supported by the top 10 up-regulated proteins given in Figure 10b. Additionally, proteins were identified to be connected, either directly or indirectly, to PPAR alpha/RXR alpha activation as well as PXR/RXR activation. These proteins (e.g., Acot1↑, Acot2↑, MAPK1↑, ASL↓) could indicate that EMD335823 acts via PPAR regulation.

A comparison of protein IDs from 2D-DIGE with results from whole-genome gene expression

Figure 9. Most significantly deregulated "Tox Functions" based on 2D-DIGE protein changes. Liver cholestasis and liver steatosis are effects that fit to the known toxicity and pharmacological action of EMD 335823.

analyses using IPA resulted in 10 overlapping genes and proteins with the same direction of deregulation. Most were related to detoxification or xenobiotic metabolism, as well as PPARα /RXR activation (Table 1). This shows that there is a good concordance between genomics and proteomics even when only a limited number of identified proteins are available.

3.4 Metabonomics

3.4.1 NMR and LC/MS Analysis of Urine and Serum Samples

A general overview on the NMR urine data as well as serum data revealed, in the same way as the genomics data, a clear separation of high dose from

Most significantly affected canonical pathways

- Fatty acid metabolism
- LPS/IL-1 mediated inhibition of RXR function
- Oxidative stress response mediated by Nrf2
- Aryl hydrocarbon receptor signaling
- Bile acid biosynthesis

(a)

The top ten upregulated proteins:

- Fatty acid metabolism:
  – Delta(3,5)-Delta(2,4)-dienoylCoA isomerase
  – Carnitine O-palmitoyltransferase 2
- Detoxification/Xenobiotic metabolism:
  – Aldo-keto reductase family 7
  – Epoxide hydrolase
- Stress response:
  – T-complex protein 1 subunit gamma
- Others:
  – Selenocysteine lyase
  – Carboxyl esterase isoenzyme
- PPARα regulation/fasting over 24h:
  – Acyl-coenzyme A thioesterase 1
  – Acyl-coenzyme A thioesterase 2

(b)

Figure 10. Results from IPA analysis of 2D-DIGE data of day 14 animals. Most significantly affected pathways (a) indicate fatty acid metabolism as the most prominent effect of our compound. This is also given by the top 10 up-regulated proteins (b).

control but no clear separation between the different time-points. The best separation was again seen for high-dose animals in comparison with control animals for days 3 and 14, and confirmed by analysis of LC/MS data (Figure 11a) whereas on day 14 both animals 42 and 45 again showed the most pronounced separation (Figure 11b). In addition, serum metabonomics also showed a clear separation of day 1 animals from day 3 and day 14 animals, which could also give a hint on the effect of non-starved animals at day 1 (Figure 11b).

Outliers were removed from the model in a subsequent PCA analysis, which results in a clearer picture of high-dose animals being separated from controls at all time-points (data not shown).

To identify altered bins, an orthogonal partial least squares discriminant analysis (OPLS-DA) model was constructed using control and pre-dose versus low- and high-dose animals (outliers animal 43 pre-dose and animal 45 day 12 were excluded). Similar to PCA analysis, treated animals were separated from control and pre-dose samples in a dose-dependent manner (data not shown). S-plots, which combine the contribution or magnitude (covariance P) with the effect and reliability (correlation P_{corr}) of the variables, were used to identify regulated bins. A cut-off value of 0.05 for the covariance and 0.5 for the correlation was chosen; therefore, modulated bins are located at the extreme ends of the S-shaped curve (Figure 12a).

These qualitative analyses carried out for all three time-points revealed a decrease in citrate and *2*-oxoglutarate (Figure 12b) and potential changes in the excretion of trimethylamine-*N*-oxide (TMAO), betaine, and creatinine. Up-regulated bins include aromatic metabolites (around 7.0–8.0 ppm) that

may represent drug metabolites, aromatic amino acids, or polyphenol degradation products originating from altered gut microflora and CH_2 and CH_3 groups of aliphatic amino acids and short-chain fatty acids (around 1.3–2.3 ppm).

The Chenomx Suite NMR software (Chenomx Inc., Edmonton, Canada) includes a database with more than 250 endogenous compounds, enabling quantitative analysis of the 16 major urinary metabolites, based on integration of NMR signals. Spectra of high-dose animals of days 1 and 3 could not be integrated because the signals were too small, probably due to very dilute urine. Consistent with the qualitative data analysis, a decrease in urinary concentrations of 2-oxoglutarate and citrate was observed in treated animals. Although these changes were not always statistically significant because of large variability between animals, the decrease of these molecules could imply a general increase in energy metabolism (Thomas, Holmes and Robertson, 2005). Phenylacetylglycine was significantly increased on day 12. This may be derived from altered gut microflora, although it has previously (controversially) been discussed as a marker of phospholipidosis (Reasor and Kacew, 2001; Sawada *et al*., 2005). Methylamine, formate, 1-methylnicotinamide, and TMAO were significantly increased in high-dose animals on day 12. Formate is part of the C_1-metabolism and carbon from ^{14}C-marked formate occurs in transmethylation products. 1-Methyl-nicotinamide is a metabolite of nicotinamide. As already mentioned with the toxicogenomics results, 1-methyl-nicotinamide is an end product of the tryptophan–NAD^+ pathway in rats. Urinary excretion has previously described as enhanced in rats after treatment with peroxisome proliferators (Delaney *et al*., 2005; Cariello *et al*., 2005).

3.5 Mechanistic Investigations

Based on the analysis of gene, protein, and metabolite profiles, several different potential mechanisms of action of EMD 335823 could be postulated. (i) A significant up-regulation of genes (e.g., ACOX 1, CTE1, CYP4a) and proteins specifically regulated by PPARα. This leads to the assumption that this compound is probably a PPARα activator. PPARs are nuclear receptors that control a variety of genes involved in several pathways of lipid metabolism, cellular differentiation, and glucose homeostasis. PPARα mainly acts on lipid and lipoprotein catabolism genes, predominantly in the liver (e.g., fatty acid β-oxidation). This would fit with some primary effects that were observed in treated animals within this study. However, this has to be further evaluated and confirmed via other techniques (e.g., a transactivation assay studying the interaction of the compound with the PPARα receptor *in vitro*). (ii) Oxidative stress, mediated by the transcription factor Nrf2, is postulated. This basic leucine-zipper transcription factor, nuclear factor erythroid 2 p45-related factor 2 (Nrf2), deregulated by EMD 335823, is a cellular oxidative stress sensor and anti-apoptosis factor, which regulates many antioxidative, cytoprotective genes and has been shown to play a pivotal role in protecting cells from

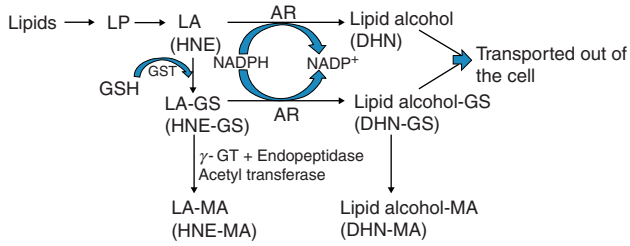

Figure 13. A schematic representation of the role of aldose reductase in the detoxification of free radicals and lipid aldehydes. LP, lipid peroxide; LA, lipid aldehyde; AR, aldose reductase.

oxidative stress. A number of genes normally associated with stress response were up-regulated and included genes such as GSH-dependent antioxidant enzymes for the reduction of reactive metabolites and detoxification, such as glutathione peroxidase 2 (GPX2), glutathione *S*-transferases (e.g., GST A2) or UDP-glucuronosyltransferases (e.g., UGT1A6), heme oxygenase-1 (Hmox1), metallotheonein (Mte1a), and NAD(P)H dehydrogenase, quinone 1 (Nqo1) (Harvey *et al*., 2009). (iii) We could confirm the inhibition of the pharmacological target. AR is involved in biotransformation of reactive aldehydes and corresponding GSH conjugates, which are formed during lipid peroxidation (Figure 13). Therefore, we can hypothesize that reduced detoxification of toxic lipid peroxidation products caused by inhibition of AR by EMD 335823 can lead to liver injury. GSH-derived metabolites of HNE and 1,4-dihydroxy-2-nonene (DHN), namely 4-hydroxyononenal-3-yl-mercapturic acid (HNE-MA) and 1,4-dihydroxynonenal mercapturic acid (DHN-MA) (also Figure 13), were found in liver, blood, and urine samples by LC-MS.

Even though the results showed a dose-dependent increase of both metabolites, the ratio of DHN-MA/HNE-MA was decreased. The fact that the ratio decreases with higher concentration of EMD335823 leads to the assumption that we had an increase in the inhibition of our target molecule AR. As it is shown in Figure 13, DHN-MA can only be produced via AR, and therefore with decreasing AR function we also have a decreased ratio of DHN-MA/HNE-MA. HNE-MA is still being produced in high amounts via acetyl-transferase reflected by an up-regulation of this gene. Additionally, HNE-protein adducts were detected by immunoblot/immunohistochemistry (IHC), agreeing with this proposed hypothesis. Furthermore, AR is an enzyme catalyzing the first step of the polyol pathway. The inhibition of AR will result in the increase of glucose metabolism via glycolysis and consequently result in alterations in fatty acid metabolism. Whether the changes in lipid metabolism seen in this study are purely related to the pharmacological action or are in fact a result of hepatocyte damage is difficult to distinguish. However, AR is a high-K_m enzyme and therefore its activity is very low at normal glucose concentrations. Accordingly, the flux through the polyol pathway as an alternative to glycolysis only increases significantly when very high glucose levels saturate hexokinase, the enzyme responsible for the transformation of glucose into glucose-6-phosphate, the first metabolite of glycolysis (Cárdenas, Cormish-Bowden and Ureta, 1998; Beyer and Hutson, 1986). In addition, these types of effects are commonly seen with hepatotoxic compounds. Disturbances in lipid metabolism could result in lower energy resources in the liver, which may also contribute to the pathogenesis of liver damage. Based on this, it more likely seems to be a sign for hepatotoxic damage instead of being a result based on the pharmacological action of EMD335823.

4 CONCLUSION

In a previous 2-week rat study with EMD335823 (other doses), clear toxicity could be detected in the liver already after 2 days even with the low dose. These effects included large increases in alanine aminotransferase (ALAT), aspartate aminotransferase (ASAT), and alkaline phosphatase (PAL) as well as effects on the bile ducts (hyperplasia, necrosis). In this study, similar effects were observed in the liver. Additionally, animals of the 14-day high-dose group showed hepatocellular hypertrophy and

multifocal necrosis. Hepatocyte and biliary necrosis in the liver were considered to be test-item related and of adverse character.

Different technologies for genomics, proteomics, and metabonomics were applied in order to find out which single technology or even a combination of technologies would generate the best information to carry out in-depth mechanistic investigations.

Gene expression analysis was the most powerful technology and showed good concordance to the histopathological outcome. Even analysis of FFPE tissues revealed reliable gene expression data, which confirmed data from fresh frozen samples and histopathology. The other technologies were able, at least to some extent, to corroborate these gene expression changes. In all cases, the majority of deregulations observed were linked to an alteration in the liver's lipid/fatty acid/cholesterol metabolism. There was an adaptive detoxification response, with many phase I and II enzymes being up-regulated. This may help explain the hepatocellular hypertrophy observed in all high-dose animals (day 14). The large number of genes involved in translation/transcription (major categories when day 1 animals were removed from the analysis and seen specifically in animals 42 and 45) could also be linked to this hepatocellular hypertrophy.

There were several clear effects on the bile duct system, followed by deregulation of genes representing tissue reorganization and bile duct proliferation, probably as a result of necrotic processes. When looking specifically at the two animals (42 and 45) that showed the greatest bile duct hyperplasia/hepatocyte necrosis/inflammation histopathologically, a specific gene expression pattern was observed. Indeed, these two animals also showed an effect in the blood gene expression profile that may be linked to the more severe effects on the liver.

No gene expression changes were clearly identified that occurred at a lower non-toxic dose. However, there were some indications that a compound-specific signature was visible at an earlier time-point, when no histopathological changes were observed (high dose). It is feasible that this was only an adaptive response to stress (and/or related to the hypertrophy seen at earlier times). The large number of genes deregulated and the fact that the pharmacological actions of the compound may have "masked" the more subtle changes related to the underlying hepatotoxicity highlight the difficulty of analyzing such large datasets.

2D-DIGE identified several proteins that were significant and relevant to the compound's proposed mechanisms of toxicity. This is based not only on the number of deregulated proteins but also on their biological effect. Strong effects on carbohydrate metabolism (e.g., glucose metabolism) can be interpreted as a result of the known pharmacological effect of the substance. Several proteins were also involved in fatty acid β-oxidation, which is a known effect of PPARα agonism. The deregulation of proteins that are known to be under regulation of PPARα (e.g., Acot2, AHCY, ASL) further supports the suggestion that EMD 335823 is a PPARα activator. A comparison of deregulated proteins and genes resulted in 10 overlapping items with the same deregulation, with an excellent concordance between them. Even though this is only a small number (based on the limited number of identified proteins) the deregulation of biologically relevant mechanisms, such as detoxification, xenobiotic metabolism or PPARα /RXR activation, further supports the suggested mechanism of toxicity. However, it is clear that 2D-DIGE alone would not have been able to provide enough knowledge about the compound's mechanism of action.

Metabonomics also showed its potential usefulness with the identification of several effects that were not prominent using genomics or proteomics. Multivariate data analysis was able to discriminate treated from pre-dose and control animals in a dose-dependent manner. Metabolic changes included altered excretion of Krebs cycle intermediates, TMAO, and metabolites presumably derived from gut microflora. These changes are frequently observed in response to toxic insults and may represent signs of general toxicity. However, it should be emphasized that this analysis is limited by the software package applied and lacks information on potential changes of minor metabolites. In concordance with genomics and proteomics, it was clear from both urine and serum metabonomic analysis (NMR and LC/MS) that animals 42 and 45 were more severely affected than the others.

Due to the limited numbers of proteins and metabolites identified, these technologies probably would not have identified all the relevant mechanisms if used in isolation. The performance of global gene expression profiling greatly enhanced the understanding and the ability to interpret the other data types. Therefore, we can conclude that the use of toxicogenomics is essential for

future mechanistic studies. However, the additional "omics" profiling technology data show the added benefit of such a multiple approach, enabling a more detailed analysis when all are used in conjunction.

"Omics" profiling technologies, in addition to traditional toxicology, greatly improved the overall toxicity study for this hepatotoxic compound. It must be noted that a lot of time is required to reach a more molecular understanding of the mechanism, even with the availability of advanced/novel bioinformatics tools. Especially from the gene expression data, there are distinct indications that molecular changes are occurring at earlier time-points, before any visible pathological changes are seen. This shows that there is the potential for shortening existing animal study designs, with the added benefit of reducing animal welfare issues. In addition, using FFPE samples would also allow the possibility to carry out retrospective analyses without the need for new animal studies. Even if these "omics" analyses take some time in themselves, they might have a great benefit for supporting the drug development process in the future.

ACKNOWLEDGMENTS

The contribution of all members of the PredTox Consortium (www.innomed-predtox.com) is gratefully acknowledged. We wish to thank all colleagues who have contributed to performance of the various studies, measurements and analyses for this project, since without their commitment, the performance of the studies and the data collection would not have been possible. The PredTox Project was supported by partial funding by the 6th Research Framework Program of the European Union (Innomed PredTox, LSHB-CT-2005-518170) and by consortium members.

1 INTRODUCTION

Since the US Congress passed the Dietary Supplement Health and Education Act (DSHEA) in 1994, the use of herbal dietary supplements has become increasingly popular in the United States. It has been reported that over 70 million Americans used alternative medical therapies in 2002, and that herbal therapies were among the most common, with sales of approximately $5 billion each year in the United States (Tindle *et al*., 2005). Many herbs have been used in constrained regions or countries of the world for many years, and recently have gained global attention. The American Herbal Products Association (AHPS) estimates that there are about 3000 species of plants in as many as 50 000 different products sold as herbal supplements in the United States (Zurer and Hanson, 2004). Despite many human toxicity reports associated with the use of herbal dietary supplements, safety issues concerning potential side effects of herbal products remain to be addressed adequately. The mechanisms of toxicity remain unclear for many herbal products and the data on the identification of toxic ingredients are also largely lacking. Thus, assessment of the safety of herbal dietary supplements is critically important for human health protection (Coppens *et al*., 2006; FDA, 2004; Fu *et al*., 2009; Kaplowitz, 1997; Rietjens *et al*., 2008).

Assessment of safety or efficacy of an herbal product should take into account the quality of the material, because it may not contain the correct plant species as claimed or it may be contaminated with other herbs, microorganisms, pesticides, metals, or even adulterated with unlabeled ingredients, such as synthetic drugs. Thus, quality control is a fundamental procedure in the standardization of medicinal herbs, including herbal dietary supplements. High-quality and contaminant-free raw herbal plants are a pre-requisite for quality assurance and safety of the herbal products, for example, herbal dietary supplements. Authentication of plant species used for preparation of herbal dietary supplements is the first step in achieving safety assurance.

Scientific efforts have been made to identify the risk factors and underlying mechanisms of herbal products-induced toxicity (Clayton *et al*., 2007; Fu *et al*., 2008; Guo *et al*., 2008; Han *et al*., 2004). Given the fact that the majority of herbal products are mixtures of many chemical constituents whereas pharmaceutical drugs normally contain a single pure entity with a well-understood chemical structure, there are challenges and complexities regarding determination of toxic mechanisms and evaluation of risks for such mixtures.

Toxicogenomics, which combines toxicology with genomics or other high-throughput molecular profiling technologies (NAP, 2005), has been

applied broadly in toxicant or toxin characterization, toxicity prediction, biomarker discovery and identification, toxicant classification, environmental chemical/compound prioritization, and underlying mechanism elucidation (Boverhof and Zacharewski, 2006; Dix *et al*., 2007; Waring *et al*., 2001a, 2001b; Waters and Fostel, 2004). Although this approach has been applied to study drugs or chemicals since the application of DNA chips from the late 1990s (Afshari, Nuwaysir and Barrett, 1999), the use of a toxicogenomic approach for mechanistic study of toxicity associated with herbal dietary supplements has only recently been initiated.

In our laboratories, we have applied DNA microarray technology to study the alterations in gene expression and associated molecular pathways and networks, responsible for herbal dietary supplement-induced liver toxicity (Guo *et al*., 2006, 2009; Mei *et al*., 2007, 2008). We also proposed that through subsequent studies, the hypothesized mechanism of toxicity based upon the DNA microarray results can be further confirmed and validated (Guo *et al*., 2010b). In this chapter, we highlight, and provide examples of, applications of DNA microarrays in product authentication and mechanistic studies related to the use of herbal dietary supplements.

2 APPLICATION OF DNA MICROARRAY FOR SAFETY ASSURANCE OF HERBAL DIETARY SUPPLEMENTS

Quality control is a fundamental procedure in the standardization of herbal plants and herbal products, including herbal dietary supplements for human consumption (Larimore and O'Mathuna, 2003). Herbal products exhibit great variability due to different environmental and cultivation conditions. Herb samples prepared from different parts of a plant (e.g., from leaves, stems, or roots) can result in great differences in their composition. Harvest of the herbal samples from different geographic regions and seasons may also result in products with drastically different constituents, including those with beneficial or toxic effects. Authentication and a well-designed sampling plan are of utmost importance for safety assurance of herbal dietary supplements because this can prevent misuse and careless or intentional adulteration of raw plant materials. A number of methodologies for authentication of herbal plants have been established. These include plant taxonomic identification, morphological and microscopic examination, and fingerprint chromatographic marker characterization. DNA-related techniques, such as DNA molecular marker characterization, have been increasingly used over the past two decades (Joshi *et al*., 2004), and most recently, DNA microarray-based methods have been recognized because of the capability of detecting multiple molecular markers simultaneously and rapidly. The combination of DNA-based methods with conventional taxonomic methodologies is revolutionizing the field of plant authentication.

Morphological and histological approaches are frequently used for authentication, although they are not sufficiently precise if the herbs are intentionally substituted or adulterated by plants with similar morphological shape and tissue constructs. Chemical fingerprint uses the spectroscopic pattern and/or chromatographic profile of constituents as markers for quality assurance of a herbal plant. UV–visible absorption and infrared spectroscopy are commonly used to determine spectroscopic patterns; and HPLC is used to determine chromatographic profiles, although gas chromatography/mass spectrometry, liquid chromatography/mass spectrometry, and liquid chromatography/mass spectrometry/mass spectrometry are also utilized. Recently, chemical fingerprinting, representing a group of constituents with both known and unknown identities in the parent herb, has become increasingly popular and is a widely accepted method for quality control of medicinal herbs (Chen *et al*., 2007). However, the multi-chemical constituents in a herbal plant could interfere with authentication, and deliberate adulteration also hinders authentication.

DNA sequencing based on particular markers has also been applied to plant authentication (Carles *et al*., 2001). This approach requires distinct DNA sequences that are unique to each species of herbal plants. Sequences such as the 5S rDNA spacer and the internal transcribed spacer (ITS) located between 16S and 26S ribosomal DNA (rDNA) vary from species to species and can be used for the purpose of authentication at the species level; sequences such as the nuclear 18S DNA are conserved among species and therefore suitable for discrimination at the plant family level (Chavan, Joshi and Patwardhan, 2006; Wenzig and Rudolf Bauer, 2009; Zhang *et al*., 2007). Although the DNA-sequencing-based approach has been used widely, the low-throughput

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat225
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

property of the technology, especially when dealing with a large number of samples and multiple markers, has been recognized as a limitation. The rapid development of plant DNA sequence databases makes it possible to develop probes for construction of DNA microarrays for identifying and authenticating herbal plants. Expanded use of DNA microarray technology will dramatically increase the throughput and enhance the accuracy of plant identification for quality control of herbal products.

In order to generate DNA microarrays for such purposes, distinct DNA sequences need to be employed to synthesize a corresponding probe on a gene chip. When the sample is analyzed, the resulting probes have to be able to detect the targeted complementary DNA sequences. Examples of studies using DNA microarray technology in plant authentication are summarized below.

Ding *et al*. (2002) designed a microarray of the ITS1-5.8S-ITS2 regions from 28 *Dendrobium* species, two other orchids, and two non-orchids. Determination was made based on the distinctive hybridization profiles. The data showed that 24 *Dendrobium* species may be differentiated from one another. The four species, *D. officinale* and *D. hercoglossum*, *D. nobile* and *D. moniliforme*, were differentiated by 5S rDNA arrays. Thus, all 28 species could be distinguished by a simple microarray based on either the ITS or the 5S DNA sequence. This study demonstrated that ITS microarrays could be used to establish the identities of the various *Dendrobium* species and to authenticate the medicinal *Dendrobium* from adulterant orchids (Ding *et al*., 2002; Zhang *et al*., 2007).

A silicon-based DNA microarray was developed for the identification of toxic traditional Chinese medicinal plants (Carles *et al*., 2005). Species-specific oligonucleotide probes were derived from the 5S ribosomal RNA gene and also from the leucine tRNA gene of a number of toxic herbs, including *Aconitum carmichaeli*, *A. kusnezoffi*, *Alocasia macrorrhiza*, *Croton tiglium*, *Datura inoxia*, *D. metel*, *D. tatula*, *Dysosma pleiantha*, *Dy. versipellis*, *Euphorbia kansui*, *Hyoscyamus niger*, *Pinellia cordata*, *P. pedatisecta*, *P. ternata*, *Rhododendron molle*, *Strychnos nux-vomica*, *Typhonium divaricatum*, and *T. giganteum*. These probes were immobilized via dithiol linkage on a silicon chip and each chip contained probes corresponding to 20 plant species. The genomic target sequences were amplified and fluorescently labeled by asymmetric polymerase chain reaction (PCR) before hybridization. By this approach, multiple toxic plant species were identified by parallel genotyping. Based on the results, the authors concluded that the DNA chip-based authentication of herbal plants may be useful and feasible for screening toxic plant species (Carles *et al*., 2005).

A DNA microarray was developed specifically for the identification of various *Panax* plants and drugs (PNX array) (Zhu, Fushimi and Komatsu, 2008), as a method for the authentication of *Panax* plants and drugs as well as their derived health foods. A PNX array was developed on the basis of specific polymorphic nucleotides of the nuclear 18S rRNA gene of 13 *Panax* taxa determined by DNA sequencing. Thirty-five specific oligonucleotides were designed, synthesized, and printed as probes on a glass slide, which contained 33 probes corresponding to the species-specific nucleotide substitutions and two probes as positive and negative controls. The species-specific probes were 23–26 nucleotides in length and the species-specific substitution nucleotide was located at the central part. Partial 18S rRNA gene sequences amplified from *Panax* plants and drugs, as well as their derived health food products, were fluorescently labeled as targets to hybridize to the PNX array. After hybridization, distinct fluorescent patterns were generated and the specific patterns were used to identify *Panax* species. Based on the results, this newly developed PNX array offered a rapid and reliable method for the authentication of *Panax* plants and drugs as well as their derived health foods.

3 APPLICATION OF DNA MICROARRAY IN MECHANISTIC STUDIES OF TOXICITY INDUCED BY HERBAL DIETARY SUPPLEMENTS

3.1 Complexity of Toxicity Induced by Herbal Dietary Supplements

There are a wide variety of complex toxicities associated with the use of herbal dietary supplements. First, adverse reactions may be caused by plant material contamination, adulteration, or misuse. One example of misusing plant material in dietary supplements occurred in the early 1990s and involved a rapidly progressive interstitial nephropathy in Belgian patients who used Chinese herbs as

part of a weight-loss program (Cosyns *et al*., 1994; Vanherweghem *et al*., 1993). It was later discovered that *Stephania tetrandra* (*fangji* in Chinese), one of the herbs in the weight-loss formula, had been inadvertently replaced by *Aristolochia fangchi*, perhaps as a result of confusion between "*fangji*" and "*fangchi*" (Cosyns, 2003; Vanherweghem *et al*., 1993). The latter (*fangchi*) contains aristolochic acids that were found to induce DNA adducts, mutations, and tumors in humans and animals (Arlt, Stiborova and Schmeiser, 2002; Chen *et al*., 2006; Cosyns, 2003; Mei *et al*., 2006).

The second type of herbal dietary supplements-related toxicity can be considered as intrinsic to the product, that is, toxic effects are from the plant itself. The plant may contain toxic constituents, or the metabolites of some constituents are toxic. For example, *Senecio* species are used in herbal medicines and as food worldwide. Riddelliine is an abundant component in *Senecio*. Toxicity and carcinogenicity studies have shown that riddelliine is metabolized to two major metabolites, 6,7-dihydro-1-hydroxymethyl-5*H*-pyrrolizine (DHP) and riddelliine *N*-oxide (Yang *et al*., 2001). Further studies showed that DHP-derived DNA adducts were formed both *in vivo* and *in vitro* after exposure to riddelliine (Chou *et al*., 2003a, 2003b); G:C → T:A transversions were the major type of mutation induced in the liver of riddelliine-treated rats (Mei *et al*., 2004a, 2004b); and riddelliine caused liver tumors in male mice and both sexes of rats, mononuclear cell leukemia in rats, and lung neoplasms in female mice (Chan *et al*., 2003).

The third type of herbal dietary supplements-related toxicity relates to its idiosyncratic nature. The toxicity occurs with low frequency and it is normally associated with patients who show hypersensitivity reactions or some specific populations with genetic make-ups that make them more prone to the toxic effects (Kaplowitz, 2005). Lastly, herb–drug interactions are generally accepted to be a major cause for some herbal dietary supplements-associated toxicity. It has been shown that herbal dietary supplements can induce or inhibit the activities of drug-metabolizing enzymes, thus affecting both the pharmacokinetics and pharmacodynamics of co-administered drugs (Driver, Baxter and Williamson, 2009; Kaplowitz, 1997). This may result in decreased pharmacological effects or increased toxic effects of the co-administered drugs (Zhou *et al*., 2003). A well-studied example of an herbal dietary supplement causing herb–drug interaction is St. John's wort, which is widely used to treat depression, anxiety, and insomnia. Numerous clinical reports have shown that St. John's wort interacted with conventional drugs such as carbamazepine, benzodiazepines, cyclosporine, chlorzoxazone, and many others (Driver, Baxter and Williamson, 2009; Wenzig and Rudolf Bauer, 2009). Through extensive studies, it was found that St. John's wort induced the activity of cytochrome P450 3A4 (CYP3A4), the drug-metabolizing enzyme involved in metabolizing the majority of drugs. In addition, CYP2C19, CYP2C8, and CYP2E1 were also induced by St. John's wort. Comprehensive induction and inhibition studies of drug-metabolizing enzymes can provide the molecular basis for elucidating the mechanisms of interaction between herbal dietary supplements and drugs, and also the needed information to make informed safety decisions on the use of dietary herbal supplements. Applying microarray technology may be an effective initial approach for obtaining the whole spectrum of drug-metabolizing gene alterations caused by dietary herbal supplements (see detailed information in Guo *et al*., 2010b).

3.2 Pathway Analyses after Treatments with Herbal Dietary Supplements

The process of determining how genes and proteins interact and influence biological pathways, networks, and cellular physiology is facilitated by the field of genomics, which allows the simultaneous molecular analysis of thousands of genes. In many toxicogenomic studies, gene expression profiling using DNA microarrays has been identified as a key component to addressing biological and toxicological questions. Once altered genes are identified, the perturbed pathways and networks can be generated using pathway analysis software and database information. For instance, Ingenuity Pathway Analysis (IPA) software (www.ingenuity.com) may be used to determine the most relevant biological pathways of the affected genes. This analysis identifies the pathways from the IPA library of canonical pathways that are most significantly altered in the differentially expressed gene data set. The significance of the association between the data set and the canonical pathway is measured in two ways: (i) a ratio of the number of genes from the data set

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat225

that map to the pathway divided by the total number of genes that map to the pathway and (ii) Fischer's exact test, in which a *P*-value is calculated to determine the probability that the association between the genes in the data set and the canonical pathway is explained by chance alone.

Kava-containing products remain popular and their consumption is dramatically increasing, despite the fact that kava has been banned in several Western countries following reports of hepatotoxicity (CDC, 2002). *Ginkgo biloba* is one of top five sold products in health food stores in the United States with a total sale exceeding $100 million (Chan, Xia and Fu, 2007), even though some ingredients identified in *Ginkgo biloba* are known mutagens (NTP, 1998). Using microarray technology and the IPA database, we investigated the gene relationships, functional clustering, and mechanisms involved in kava and *Ginkgo biloba* exposure in animal models (Guo *et al*., 2009, 2010a, 2010b), as summarized below.

F344 male rats or B6C3F1 male mice were gavaged with kava extract at the doses of 0.125–2 g kg^{-1} body weight/day for 14 weeks. B6C3F1 male mice were gavaged with *Ginkgo biloba* extract at the doses of 0.2–2 g kg^{-1} day^{-1} for 104 weeks. Pathway analyses were performed based on the differentially expressed genes observed in the highest dose group of three studies using DNA microarray (Guo *et al*., 2009, 2010a, 2010b). Table 1 lists the canonical pathways altered by these three treatments, with a cut-off of $P < 0.01$. After 14 weeks of a diet containing 2 g kg^{-1} kava, 42 and 31 molecular pathways were changed in the livers of rats and mice, respectively (Table 1). The finding of similar pathways alterations in mice and rats after the same chemical treatment may suggest similar effects and toxicities. For example, kava altered 17 canonical pathways in rat and mouse, including xenobiotic metabolism signaling, metabolism of xenobiotics by CYP, glutathione metabolism, nuclear factor erythroid 2 (NRF2)-mediated oxidative stress response, and lipopolysaccharide (LPS)/Interleukin (IL)-1-mediated inhibition of retinoid X receptor (RXR) function (Table 1).

A living organism has a series of pathways and enzymatic activities, including xenobiotic metabolism signaling, metabolism of xenobiotics by cytochrome P450, and glutathione metabolism, which are designed to detoxify and eliminate a xenobiotic (a foreign chemical compound such as a drug or toxin). These processes can be divided into three main phases: modification, conjugation, and excretion. The phase I enzymes, such as the CYPs, act to modify the xenobiotic compounds by adding polar groups through oxidation or reduction. Sometimes, the process of metabolism gives rise to metabolites that are more toxic than the original compound. A well-known example is the procarcinogen, benzo[*a*]pyrene. Its carcinogenetic effect depends on enzymatic metabolism of benzo[*a*]pyrene to the ultimate mutagen, benzo[*a*]pyrene diol epoxide. Benzo[*a*]pyrene is first oxidized by CYP 1A1 to form (+)benzo[*a*]pyrene-7,8-epoxide, and it is further metabolized by epoxide hydrolase to form (−)benzo[*a*]pyrene-7,8-dihydrodiol. The ultimate carcinogen, (+)benzo[*a*]pyrene-7,8-dihydrodiol-9,10 epoxide, is formed after another reaction with CYP1A1 (Pfeifer *et al*., 2002; Shou, Gonzalez and Gelboin, 1996). In phase II, the electrophilic and nucleophilic intermediates are conjugated by transferases, such as the glutathione *S*-transferase family, with charged species such as sulfate, glutathione, or glucuronic acid. These reactions result in bulkier and more polar metabolites that may then be actively removed from the cell by phase III transporters, such as members of the multidrug resistance protein transporter family.

In kava-treated rats, 72 drug-metabolizing genes were significantly changed by 2 g kg^{-1} kava treatment. Among them, 19 genes were associated with phase I metabolizing enzymes, 21 genes with phase II enzymes, and 32 genes with phase III transporters (Guo *et al*., 2009). In addition, 16 genes were commonly regulated by the three highest doses of kava treatments (0.5, 1.0, and 2.0 g kg^{-1}), including dose-dependent increases for Cyp1a1, 1a2, 2c6, 3a1, and 3a3. In this study using kava-treated mice, we found 95 drug-metabolizing-enzyme-associated genes significantly altered, including 28 phase I metabolizing enzymes genes, 29 phase II genes, and 38 transporters (Guo *et al*., 2010c). Based on the results of microarray and Taqman assays, genes whose expression was significantly altered included Gstal, Gsta2, Cyp1a1, Cyp1a2, Cyp2a5, Cyp2b20, Cyp2c55, and Cyp3a11. Cyp1a1 is primarily expressed in extra-hepatic tissues, with low amounts being expressed in the liver. The Cyp1a1 isozyme can metabolize a number of xenobiotics, including those with flat and planar structures, which include the highly toxic and tumorigenic polycyclic aromatic hydrocarbons (PAH) (Conney,

DOI: 10.1002/9780470744307.gat225
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

2003; Shou *et al*., 1996; Martignoni, Groothuis and de Kanter, 2006). Therefore, induction of the Cyp1a1 gene by kava treatment in mice and rats would enhance metabolic activation of the hazardous environmental PAHs and jeopardize human health. Our results demonstrated that many drug-metabolizing genes were altered in response to kava treatment, which is consistent with the report that kava-induced herb–drug interaction through modulation of metabolizing enzymes is a highly possible cause of hepatotoxicity (Fu *et al*., 2008).

Chemical compounds may induce oxidative stress due to an imbalance between the production of reactive oxygen and the detoxification of reactive intermediates. The NRF2-mediated oxidative stress-response pathway plays a critical role in protecting cells from endogenous and exogenous stresses, and is involved in antioxidative response, detoxification of xenobiotics, and proteome maintenance. Under normal physiological conditions, the transcription factor NRF2 is localized in the cytoplasm and interacts with Keap1. Upon oxidative stress, NRF2 is released from Keap1, translocated to the nucleus, and subsequently activates its various downstream target genes (Kensler, Wakabayashi and Biswal, 2007). The target genes show a wide spectrum of functions including inactivating oxidants, increasing the levels of glutathione, and enhancing toxin export via transporters to improve cell survival. As expected, NRF2 knock-out mice are more susceptible to acetaminophen-induced hepatocellular injury (Chan, Han and Kan, 2001) and benzo[a]pyrene-induced tumor formation (Ramos-Gomez *et al*., 2001). This susceptibility is partly due to a reduced level in the expression of detoxification enzymes (Aleksunes and Manautou, 2007; Kensler, Wakabayashi and Biswal, 2007). Activation of detoxification enzymes plays a pivotal role in protecting cells from oxidative insult when cells encounter toxin challenge.

Chronic *Ginkgo biloba* treatment in mice altered 12 canonical pathways (Table 1), including xenobiotic metabolism signaling, metabolism of xenobiotics by cytochrome P450, glutathione metabolism, NRF2-mediated oxidative stress response, and LPS/IL-1 mediated inhibition of RXR function. For example, the NRF2-mediated oxidative stress response pathway was identified with 23 genes involved. Most of these genes were up-regulated whereas two genes were down-regulated (Guo *et al*., 2010). In response to *Ginkgo biloba* treatment, NRF2-regulated genes, including various Gst genes that are involved in GSH-conjugate formation, were altered. The Gst genes (Gsta2, Gsta4, Gstms, and Gstp1) and Ugt1a2 were up-regulated following *Ginkgo biloba* treatment. In turn, the resulting enhancement of GST enzymes is used for neutralizing the electrophiles and the process generally is considered an important detoxification mechanism. The NADPH-dependent enzyme NQO1 was also up-regulated, which has a cell protective role by detoxification of xenobiotic carbonyls and quinones. *Ginkgo biloba* treatment also elevated Gsr (glutathione reductase) gene expression, and GSR regulates cellular GSH homeostasis by catalyzing the reduction of GSSG to GSH using NADPH as a reducing cofactor (Harvey *et al*., 2009). *Ginkgo biloba* treatment reduced the activity of Sod3, which is one of the superoxide dismutases (SODs) that are the most important line of antioxidant enzyme defense systems against reactive oxygen species (ROS), and particularly superoxide anion radicals (Zelko, Mariani and Folz, 2002).

3.3 Common Mechanisms for Classes of Components in Herbal Dietary Supplements

Using the pathway analysis knowledge databases, the differential expressed genes that are identified in one or more studies may be used to elucidate molecular mechanisms, providing an improved understanding of toxicity and identifying common mechanisms that could define classes of chemicals. For example, we compared the expression of genes and biological functions in rat liver after treatment with carcinogens (comfrey and riddelliine). Comfrey (*Symphytum officinale*) is a perennial plant and has been consumed by humans as a vegetable, a tea, and a herbal medicine for more than 2000 years. It has also been demonstrated that comfrey is hepatotoxic and carcinogenic in experimental animals and hepatotoxic in humans, due to a mixture of pyrrolizidine alkaloids (PAs). PAs exist in many plants and many of them cause liver toxicity and/or cancer in humans and experimental animals. Riddelliine is one of the tumorigenic PAs and has been studied as a prototype PA. Riddelliine is a major component of *Senecio*, which has been used in herbal medicines or food. The toxicity

DOI: 10.1002/9780470744307.gat225
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

and carcinogenicity of riddelliine have been studied by the NTP (Chan *et al*., 1994, 2003; NTP, 2003), and the mechanism of riddelliine-induced tumorigenicity in experimental animals has been studied at the National Center for Toxicological Research (NCTR/FDA) (Chou *et al*., 2003a, 2003b, 2003c; Mei *et al*., 2004a, 2004b; Yang *et al*., 2001a, 2001b). To examine the possible PA-induced effects on gene expression caused by comfrey, the gene expression profiles in the livers of comfrey-treated rats were compared with the gene expression profiles from rats treated with the purified PA riddelliine. The correlation of the gene expression and biological functions related to carcinogenesis between the two treatments was explored.

Groups of six Big Blue Fisher 344 rats were fed a diet containing 8% comfrey root for 12 weeks or gavaged with riddelliine at 1 mg kg^{-1} body weight five times a week for 12 weeks. Gene expression was investigated using Applied Biosystems Rat Whole Genome Survey Microarrays (Applied Biosystems, Foster City, CA, USA), and the biological functions were analyzed with Ingenuity Pathway Analysis software (IPA, Redwood City, CA, USA). Although there were large differences between the significant genes and biological processes that were altered by comfrey and riddelliine, there were a number of common genes and functional processes that were related to carcinogenesis. Particularly, there were strong correlations between the two treatments for fold-change alterations in expression of drug-metabolizing and cancer-related genes (Guo *et al*., 2007).

Biological processes were examined for the genes altered due to comfrey and riddelliine exposures individually, and the software placed the biological processes into functional processes or categories such as cancer and cell death. After a cut-off with a *P*-value less than 0.01, we observed that there were 83 and 118 functional processes for riddelliine and comfrey treatments, respectively. Among them, 46 of the functional processes were altered by both comfrey and riddelliine, which was about half of the functional processes altered by riddelliine and one-third of the functional processes altered by comfrey. The top categories for these functions included cancer, cell death, cell morphology, cell-to-cell signaling and interaction, and tissue development. These results suggest that common mechanisms may be responsible for the toxicity of both comfrey and riddelliine.

The alteration of cancer- and cell-death-associated genes by both comfrey and riddelliine treatments is likely due to the PAs. Microarray analysis showed that comfrey altered many more genes involved in cancer-related pathways than riddelliine. The expression of 387 cancer-related genes was significantly altered after comfrey exposure, and the expression of 84 cancer-related genes was significantly changed by riddelliine treatment. Among them, there were 42 genes whose expressions were significantly altered by both riddelliine and comfrey treatments (Guo *et al*., 2007), which may indicate the PAs' carcinogenic insults. Figure 1 shows a good correlation between the $\log_2$ fold changes in gene expression caused by the two treatments; only two of the genes were regulated in the opposite directions. The correlation coefficient (R^2) was 0.65, indicating good agreement between the two treatments. These common cancer-related genes include genes involved in apoptosis and cell death, invasion, cell growth, cell morphology, and cell cycle.

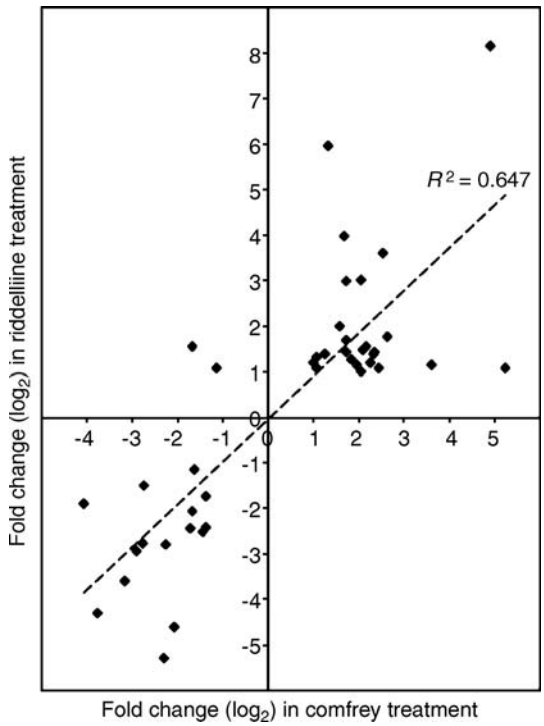

Figure 1. Comparison between $\log_2$ fold changes of cancer-related genes altered by comfrey and riddelliine treatments. The rats were treated with 8% comfrey roots in diet and 1 mg kg^{-1} day^{-1} riddelliine by gavage for 3 months, and the cancer-related genes were commonly regulated by both treatments.

These results also suggest that the carcinogenicity of comfrey is due to PAs.

Most of genes involved in apoptosis (Cdkn1c, Egr1, Fas, Gdf15, Hgf, Hrasls3, Hspa1a, Lama5, Smox, Tnfsf10) were up-regulated and may be explained by the removal of cells damaged by PAs. For example, early growth response 1 (Egr1), whose expression increased 12- and twofold over the control with comfrey and riddelliine treatments, respectively, has the ability to function in numerous capacities, including differentiation, growth, growth inhibition, and apoptosis depending on the cell type and the stimulus. We also observed that comfrey and riddelliine significantly up-regulated Hspa1a, the gene encoding heat shock protein (HSP) 70 family members. High levels of inducible HSP70s prevent stress-induced apoptosis and block caspase activity, mitochondrial damage, and nuclear fragmentation (Mosser *et al*., 1997). These genes may all be involved in repair and protection of the cell against the damage caused by the PAs.

As PAs require metabolic activation to exert their biological and toxicological effects, study and comparison of these genes altered by comfrey and riddelliine can provide valuable information about common mechanisms on PAs' biotransformation and metabolism. The results showed that there were 45 and 87 drug-metabolizing genes up- or down-regulated by the treatment with riddelliine and comfrey, when a cut-off of twofold change and $P < 0.01$ was used as the criteria to select genes (Guo *et al*., 2007). There were more drug-metabolizing genes altered by comfrey treatment than those by riddelliine treatment, probably because comfrey is a mixture of many substances in addition to PAs, and these other substances may be involved in the induction of other drug-metabolizing genes. About 50% of drug-metabolizing genes altered by the treatment with riddelliine were also found altered by the treatment with comfrey. It should be noted that the expressions of 22 of these genes were altered by both comfrey and riddelliine, with the changes in the same direction and a correlation coefficient of 0.72 (Guo *et al*., 2007). Although the process of drug metabolism is complicated, these results suggest that there is a common mechanism of drug metabolism involved in these two chemical treatments.

Comparative studies also showed that comfrey and riddelliine induced similar profiles of DHP-derived DNA adducts (Chou and Fu, 2006) and similar mutation spectrum profiles (Mei *et al*., 2006) in the liver. Gene expression analysis indicated strong correlations between the gene expression fold-change alterations in drug-metabolizing genes and cancer-related genes caused by both agents (Guo *et al*., 2007). Cumulatively, these results suggest that comfrey induces liver tumors by a genotoxic mechanism, that comfrey and riddelliine may share common mechanisms of drug metabolism and carcinogenesis, and that PAs contained in comfrey are the main active components responsible for genotoxicity and tumor induction in rat liver.

4 CONCLUSIONS

With the increased usage of herbal dietary supplements comes an increased demand for product standardization and authentication, as well as a better understanding of the molecular mechanisms underlying their functional and toxicological activities. It is critically important to establish reliable and fast methodologies for safety assurance of herbal dietary supplements. This review provides an overview of methods and proposals for studying mechanisms of toxicities induced by herbal dietary supplements.

To date, most of proposed mechanisms for herbal dietary supplements-induced toxicity focused on herb–drug interaction mediated by drug-metabolizing enzymes. Because of the high degree of correlation between gene expression and enzyme activity for phase I enzymes (Iyer and Sinz, 1999; Roymans *et al*., 2004), the simple and rapid measurement of gene expression instead of the complex and time-consuming measurement of enzyme activity is an attractive alternative for exploring the changes of phase I enzymes induced by herbal dietary supplements. DNA microarray technology is a powerful tool to monitor simultaneously relative expression levels of thousands of genes, including the induction or inhibition of drug-metabolizing enzyme genes after treatment with an herbal dietary supplement or its raw herbal plant. This rapid approach can provide valuable information about the changes in expression of the biologically potent phase I enzymes that can be useful in predicting potential herb–drug interactions. Moreover, microarray technology is also a powerful methodology for exploring toxicology mechanisms induced by herbal dietary supplements because of the comprehensive definition of gene

expression changes and the ability to generate testable hypotheses based on these data.

DNA microarray technology is an effective strategy for global gene expression profiling. However, understanding the functional relevance of gene expression profiles is a challenge and follow-up experiments are normally required. Although DNA microarrays offer a promising avenue for the study of herbal dietary supplement toxicity, it is anticipated that subsequent functional studies will be necessary to validate possible mechanisms. After obtaining initial information at the gene level, conventional methodologies, such as determining protein expression by immunoblotting and determining enzyme activity by quantitative metabolism, can be followed, and well-designed experiments that pinpoint particular pathways or mechanisms can be performed to investigate the molecular basis of mode of actions.

1 INTRODUCTION

Hepatotoxicity results in a significant number of drug candidates failing during the clinical stage of development and, even more harmful to the patients and drug manufacturer, to be withdrawn from the market post approval. With the increasing use of combinations of prescription and over-the-counter drugs, herbal remedies, dietary supplements and alcohol, the potential for adverse events is increasing dramatically. Consequently, drug-induced liver injury (DILI) has been identified by the FDA Critical Path Initiatives as a key area of focus in which better evaluation tools and safety biomarkers are needed (http://www.fda.gov/ScienceResearch/SpecialTopics / CriticalPathInitiative / CriticalPathOpportunitiesReports/ucm077248.htm#topic1). To help meet this goal, one effort underway by members of the Systems Biology Division at the National Center for Toxicological Research (FDA) is the development of a liver toxicity knowledge base (LTKB) to provide a content-specific resource for the regulatory and research communities (http://www.fda.gov/AboutFDA/CentersOffices/nctr/WhatWeDo/ResearchDivisions/ucm079059.htm).

In 1993, FDA published a guideline for the study and evaluation of sex differences in drug development (http://www.hhs.gov/ohrp/humansubjects/guidance/58fr39406.htm). [although "gender differences" are used more widely than "sex differences," the latter is more accurate as it cannot be influenced by cultural factors (Howard *et al.*, 2001). Thus, the term "sex difference" is used throughout this review.) Sex difference is observed in the prevalence of various liver diseases. For instance, autoimmune hepatitis (Beland, Lapierre and Alvarez, 2009) and alcoholic liver disease (ALD) (Van Thiel *et al.*, 1989) are much more common in females than in males. Women tend to develop more severe ALD with less consumption than men, a scenario that can be recapitulated by animal experimentation. However, cirrhosis is more prevalent among men and post-menopausal women in general. In patients with chronic hepatitis C, faster progression to fibrosis

is seen in men compared with women, regardless of age (Poynard *et al.*, 2001). Furthermore, non-alcoholic fatty liver disease (NAFLD), the most common aetiology of chronic liver diseases in the United States, is less prevalent among women during their reproductive years, although following menopause, the prevalence of NAFLD in women increases and exceeds that of men (Suzuki and Abdelmalek, 2009).

Given the sex differences observed in patients with various liver diseases, it seems pertinent to examine responses in animal studies to begin to understand sex-based susceptibilities to drugs and toxicants. Toxicology studies with oxamniquine in several laboratory animal species revealed a sex-biased hepatotoxicity with females being more sensitive than males (Gregory *et al.*, 1983). A National Toxicology Program (NTP) study conducted at the National Center for Toxicological Research demonstrated that fumonisin B_1 induced liver tumours in female but not in male mice (Howard *et al.*, 2001). Dehydroepiandrosterone (DHEA) is a naturally occurring steroid secreted from the human adrenal cortex and has been used as a drug and, by some, as a dietary supplement aimed at preventing age-related changes. Studies in Sprague–Dawley rats have shown that females are more susceptible than males to the development of hepatocellular tumours after exposure to DHEA. However, the reverse was seen when the same drug was tested in F-344 rats (Mayer and Forstner, 2004). Studies with acetaminophen (APAP) in rats have demonstrated both age- and sex-related differences, with males and old age being susceptibility factors (Tarloff *et al.*, 1996). In clinical and epidemiological studies, however, APAP-related DILI was seen more often in women than in men (Russo *et al.*, 2004; Ostapowicz *et al.*, 2002).

These studies demonstrate the complexity in trying to unravel apparent differences in susceptibility because differences in age, sex, reproductive status, genetics and drug under investigation, as well as cross-species extrapolation, may confound interpretation. Furthermore, different mechanisms (e.g. drug metabolism, generation of toxic metabolites, immune/inflammatory reactions and repair process) may be involved in different stages of DILI. Therefore, sex or other factors may differentially impact the disease course of DILI. Most importantly, care must be taken when evaluating results from human studies regarding sex-based susceptibilities to drugs and other agents. Rarely are the authors able to obtain information related to the number of females and males taking a particular drug or exposed to an environmental agent. Thus, although it may be true that the 'average' patient experiencing DILI is female, it is not clear whether that is because, for example, of a higher percentage of women versus men being exposed to the agent.

Recently, a great deal of effort has been placed in the field of -omics technologies, particularly genomics, with the hope of discovering novel insights into the mechanisms of various diseases and toxicity. The genomic approach has become an active field in drug development and research to determine inter-individual variability in drug response including study of sex-biased phenomena in disease and medicine. For example, a number of ALD studies have employed gene expression microarray technologies (Sharma *et al.*, 2008; Tadic *et al.*, 2002). These high-throughput genomic studies not only confirm some findings of the previous studies based on conventional approaches but further our knowledge for sex-driven liver injury and toxicity at molecular and functional levels.

The processes involved in DILI are complex. Sex-based differences (e.g. hormones, body weight, fat, organ blood flow, diet, environment, etc.) apparently are important sources of individual variability. However, the systematic evaluation of sex-biased phenomena, particularly related to increased female sensitivity, has received limited attention. In this review, we analysed the published studies to understand the basis for the often stated claim that women are more susceptible to DILI than men and to identify any factors important to sex-biased DILI. We then discuss the findings for sex differences related to disease and drug response at the molecular level with emphasis on the use of genomic approaches such as gene expression microarrays.

2 SEX DIFFERENCE IN DRUG-INDUCED LIVER INJURY

A number of clinical studies have demonstrated increased female sensitivity to DILI for some drugs in several studied populations, but contrary findings have also been observed. One major difficulty with assessing sex-specific sensitivity in the human population is the often unknown or, at best, imprecise exposure information, which is required for

assessing true sex-specific differences of DILI. Additional complication in analysis is that clinical diagnosis of DILI is challenging, sometimes inconclusive and difficult to confirm (Wilke *et al.*, 2007). This may improve with the establishment of an international consortium to standardize the diagnosis in a clinical setting (Fontana *et al.*, 2009). In this analysis, we reviewed studies which applied standardized causality assessment tools, although their case identification strategies and applied causality assessment tools are different. We first analysed five large population studies (Table 1) to gain a general picture on sex-biased DILI. Next, we focused our analysis on specific factors (e.g. drugs, acute liver failure and age) that could contribute sex-biased phenomena significantly.

Table 1 summarizes five clinical and epidemiological studies conducted in four different countries. There was no clear evidence for sex-biased DILI for the cases submitted to the Spanish Hepatotoxicity Registry between 1994 and 2004 (Table 1, Study 1) (Andrade *et al.*, 2005) and cases from an out-patient hepatology clinic in a Swedish University hospital (Table 1, Study 4) (De Valle *et al.*, 2006). In contrast, female dominance in DILI population was observed for the patients from the Mayo Clinic Hospital in the United States (Table 1, Study 5) (Carey *et al.*, 2008) and in some age groups (Table 1, Studies 2 and 3).

Drug could be a potential factor for sex-biased DILI. It has been reported that female sex is more prevalent among patients with APAP-induced acute liver failure (Russo *et al.*, 2004; Ostapowicz *et al.*, 2002). As shown in Table 2, female dominance in DILI has been observed for other drugs. For example, clinical trials of tolcapone, a catechol-*O*-methyl transferase inhibitor for the adjunctive treatment of Parkinson's disease, demonstrated the elevation in alanine aminotransferase (ALT) or aspartate aminotransferase (AST) in up to 3.7% of patients and female patients more frequently suffered this adverse event than male patients by a ratio of 5 : 2 (Olanow and The Tasmar Advisory Panel, 2000; Olanow and Watkins, 2007). Flucloxacillin is widely used in many European countries and Australia for treatment of staphylococcal infection. Its use has been associated with a characteristic cholestatic hepatitis. A couple of previous studies reported female dominance among patients with flucloxacillin-induced DILI, although none of them show statistical significance (Daly *et al.*, 2009). Halothane caused severe cases of DILI in thrice as many females as males (Bjornsson *et al.*, 2005). However, it is also evident that not all the drugs exhibit a female-dominant DILI. For example, disulfiram was found to cause severe DILI in three men with no women reporting this toxicity (Bjornsson *et al.*, 2005). As mentioned previously, a major complicating factor in assessing sex-specific DILI in many reports is that they are not generated from controlled clinical studies with known gender participation rates.

There is some evidence of sex bias in terms of reported liver failure cases (Table 3). More cases of APAP-induced acute liver failure in women than men have been noted in some studies (Larson *et al.*, 2005; Ostapowicz *et al.*, 2002). Of patients who survive DILI, women seem to be more prone to develop autoimmune liver disease (Bjornsson and Davidsdottir, 2009). The FDA Adverse Event Reporting System (AERS, 2009) database was queried for cases of liver failure associated with drug use for the time period April 2008 through March 2009. During this time period, the number of females versus males experiencing liver failure associated with drug use was 948 versus 916, respectively. Of these, 103 female and 37 male cases were associated with APAP exposure. Therefore, it would appear that female sex is predominant among patients with APAP-induced acute liver failure, which parallels previous studies (Ostapowicz *et al.*, 2002). Limitations with the AERS data include the fact that adverse events are typically under-reported; some cases had to be omitted because the sex was not identified, many cases involve exposure to multiple drugs and the incidence of adverse events in the US population cannot be calculated. However, they do provide some insight into the sex distribution of hepatic failures for those cases that are reported.

It is generally acknowledged that DILI occurs more often in older aged than younger patients. However, the sex dependency related to age is less clear. For examples, in Study 2 (Table 1) (Lucena *et al.*, 2009), there were more females than males in the 40–59 age group but not after the age of 60. This finding seems contrary to that reported in Study 3 (Sgro *et al.*, 2002) that shows a female dominance in the age group >50 years old. As shown in Table 3, both studies conducted in the United States with APAP as a main cause (Russo *et al.*, 2004; Ostapowicz *et al.*, 2002) of DILI show more women at a younger age (around 30 years old). The study conducted in Spain with amoxicillin clavulanate

Table 1. Summary of findings for sex-difference in drug-induced liver injury in human population.

Population	Inclusion criteria and causality assessment	Patterns of DILI	Drugs	Main findings
Study 1 • A Spanish population 1 [Andrade *et al.*, 2005) • No. cases = 461 (M/F = 244/217) • Age range = 13–88 years • Submitted to the Spanish Hepatotoxicity Registry between 1994 and 2004	• Inclusion: International Consensus meeting • Causality: Council for International Organizations of Medical Sciences (CIOMS) scale	Injury is characterized using the R = ALT/ALP ratio • Hepatocellular ($R > 5$) • Cholestatic ($R < 2$) • Mixed injury ($2 < R < 5$)	• 505 drugs involved • Anti-infective group of drugs involved most DILIs • Amoxicillin clavulanate accounted for 12.8% cases	• No clear evidence for sex-biased DILI across all the age groups • Female has a higher percentage in hepatocellular injury and fulminant hepatic failure
Study 2 • A Spanish population 2 (Lucena *et al.*, 2009) • No. cases = 603 (M/F = 310/293) • Age range = 13–88 years • Submitted to the Spanish Hepatotoxicity Registry between 1994 and 2007	• Inclusion: International Consensus meeting • Causality: Council for International Organizations of Medical Science (CIOMS)/Roussel Uclaf Causality Assessment Method scale	Injury is characterized using the R = ALT/ALP ratio • Hepatocellular ($R > 5$ or ALT $> 3 \times$ ULN) • Cholestatic ($R < 2$ or ALP $> 2 \times$ ULN) • Mixed injury ($2 < R < 5$)	• Amoxicillin clavulanate is the single drug with the highest number of cases • Overdose-induced DILI were excluded	• Patients aged > 60 years accounted for 46% of the cases with M/F = 158/118 • Patients aged 40–59 years had a female predominance
Study 3 • A French population (Sgro *et al.*, 2002): • No. cases = 34 (M/F = 12/22) • Age range = 25–80 years • The population selected from a region where the patients hardly go elsewhere for medical care • Study year: 1997–2000	• Inclusion: International Consensus meeting • Causality: French regulatory authorities	Injury is characterized using the R = ALT/ALP ratio • Hepatocellular ($R > 5$) • Cholestatic ($R < 2$) • Mixed injury ($2 < R < 5$)	Anti-infectious, psychotropic, hypolipidemic agents and non-steroidal anti-inflammatory drugs involved most cases	• No clear evidence for sex-biased DILI for the younger group (<50 years) • Female is dominant in the group of >50 years for DILI (M/F = 6/17)
Study 4 • A Swedish population (De Valle *et al.*, 2006) • No. cases = 77 (M/F = 34/43) • Age range = 16–86 years • A diagnoses database in an out-patient hepatology clinic in a Sweden University hospital was analysed between 1995 and 2005	• Inclusion: International Consensus meeting • Causality: International Consensus meeting	Types of DILI include hepatocellular, cholestatic and mixed	Antibiotics were the most common agents followed by non-steroidal anti-inflammatory drugs	• No clear evidence for sex-biased DILI • Sex difference does exist for some drugs • Female has a higher percentage in hepatocellular injury

Table 1. (*Continued*)

Population	Inclusion criteria and causality assessment	Patterns of DILI	Drugs	Main findings
Study 5 • An US population (Carey *et al.*, 2008) • No. cases = 40 • The DILI patients were identified from the Mayo Clinic Hospital	• Inclusion: International Consensus meeting • Causality: International Consensus meeting	Injury is characterized using the R = ALT/ALP ratio • Hepatocellular ($R > 5$ or ALT > 2 × ULN) • Cholestatic ($R < 2$ or ALP > 2 × ULN) • Mixed injury ($2 < R < 5$)	27 of 40 cases were related to acetaminophen	• Female is predominant in DILI • The hepatocellular injury occurs in all acetaminophen-related DILI

Table 2. Sex difference in drug induced liver injury for various drugs.

Population	DILI definition	Female/male ratio
Tolcapone (Olanow and The Tasmar Advisory Panel, 2000) • No. cases = 1535 treated with tolcapone, 3.7% affected • Age range = 15–78 years • Phase IIIa clinical trial studies during a period of approximately 6 months by Roche Laboratories	>3 × ULN in ALT or AST	5/2
Flucloxacillin (Daly *et al.*, 2009): • No. cases = 51 • Mean onset age = 63.1 years • Cases were collected between October 2004 and December 2007 sponsored by International Serious Adverse Events Consortium	The cases were defined by (i) clinically apparent jaundice or bilirubin 440 mmol/l (after exclusion of cases due to hemolysis), (ii) ALT > 5× ULN; or (iii) ALP > 2× ULN plus any elevated bilirubin above ULN	36/15
Halothane (Bjornsson *et al.*, 2005) • No. cases = 16 • Mean onset age = 59 years • Cases were collected between 1966 and 2002 from the Swedish Adverse Drug Reactions Advisory Committee (SADRAC)	Cases of DILI that resulted in death or liver transplantation were selected based on meeting the International Consensus Criteria (RUCAM)	12/4
Disulfiram (Bjornsson *et al.*, 2005) • No. cases = 3 • Mean onset age = 37 years • Cases were collected between 1966 and 2002 from the Swedish Adverse Drug Reactions Advisory Committee (SADRAC)	Cases of DILI that resulted in death or liver transplantation were selected based on meeting the International Consensus Criteria (RUCAM)	0/3

as the main causal agent (Andrade *et al.*, 2005) (Study 1 of Table 1) also demonstrated female dominance for the study population of much older ages (mean age: 53 years). However, for a Sweden population (Table 3) (Bjornsson *et al.*, 2005), most of the patients with acute liver failure were > 60 years old, and there was no clear evidence of female preference. It is noted that the drugs under investigation in these studies were dissimilar, which may account for the observed differences in age susceptibility. As shown in animal studies, age effects vary with the drug under investigation. It seems that although the DILI incidence occurs more in the older age groups, sex differences are not clear when all drugs are considered.

From the human studies summarized above, it is clear that sex-biased DILI is dependent on many factors including the drug under evaluation, age and pattern of hepatic injury. Unfortunately, most of these factors are difficult to control in a setting

Table 3. Sex-biased acute liver failure.

Population	Main drugs	Prevalence in female (%)
A Spanish population 1 (Andrade *et al.*, 2005) • No. cases = 18 • Age range = 14–83 years • The patients selected from the Spanish Registry between 1994 and 2004	Amoxicillin clavulanate	89
A US population (Russo *et al.*, 2004) • No. cases = 270 • Age range = 3–63 years • Cases were identified from the United Network for Organ Sharing liver transplant database in 1990–2002	Acetaminophen alone, or in combination with another drug, accounted for 49% of cases	76
A US population (Ostapowicz *et al.*, 2002) • No. cases = 308 • Age range = 15–78 years • Cases were identified from the consortium effort (The US Acute Liver Failure Study Group) between 1998 and 2001	Acetaminophen	73
A Swedish population (Bjornsson *et al.*, 2005) • No. cases = 103 • Age range = 12–91 years • Cases reported to the Swedish Adverse Drug Reaction Advisory Committee from 1996 to 2002	Halothane, paracetamol (APAP), flucloxacillin, sulfamethoxazole, trimethoprim, diclofenac	43

of clinical or epidemiological research without having a better understanding of potential mechanisms. Moreover, the differences in ethnicity of populations with unknown underlying diseases further complicate the observations and comparative analyses. For example, in a study using isolated human liver microsomes and cultured hepatocytes, Hispanics had about twice the average activity of CYP2A6, CYP2B6 and CYP2C8, and half the activity of CYP1A2 when compared with Caucasians and African Americans (Parkinson *et al.*, 2004). Thus, sex-specific sensitivity to hepatotoxicity needs to be better defined in patients by further evaluating in clinical as well as animal studies with an interdisciplinary collaboration. In summary, evidence suggesting DILI-related sex differences is less conclusive in literature.

3 SEX DIFFERENCES IN LIVER GENE EXPRESSION PROFILES UNDER PHYSIOLOGICAL CONDITIONS

As depicted in Figure 1, the development of DILI is a complicated process. It is believed that females may have a higher sensitivity than males for clinically relevant hepatic adverse reactions. This is biologically plausible because women differ from men both genotypically and phenotypically. Several mechanisms have been suggested but the exact systems involved have not emerged. For example, there are apparent differences between the sexes in pharmacokinetics and pharmacodynamics (Neutel and Walop, 2005). In addition, females typically have a higher percentage of body fat than males, leading to preferential accumulation of hydrophobic drugs. Further increasing the potential for female predominance in DILI is the fact that doses are typically not adjusted for body weight, so females often receive higher exposures than men. One or more of these factors could lead to a greater sensitivity to DILI in females compared with males. In addition, it is generally acknowledged that variation in drug metabolism plays a primary role in sex differences in pharmacokinetics (Waxman and Holloway, 2009).

Some studies are demonstrating a genetic link to DILI. For example, studies with flucloxacillin suggest that the HLA-B*5701 genotype is a major determinant of DILI (Daly *et al.*, 2009). A study examined the role of glutathione-*S*-transferase (GST), a phase II detoxifying enzyme, on DILI and found that GSTM1 and GSTT1 gene deletions

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

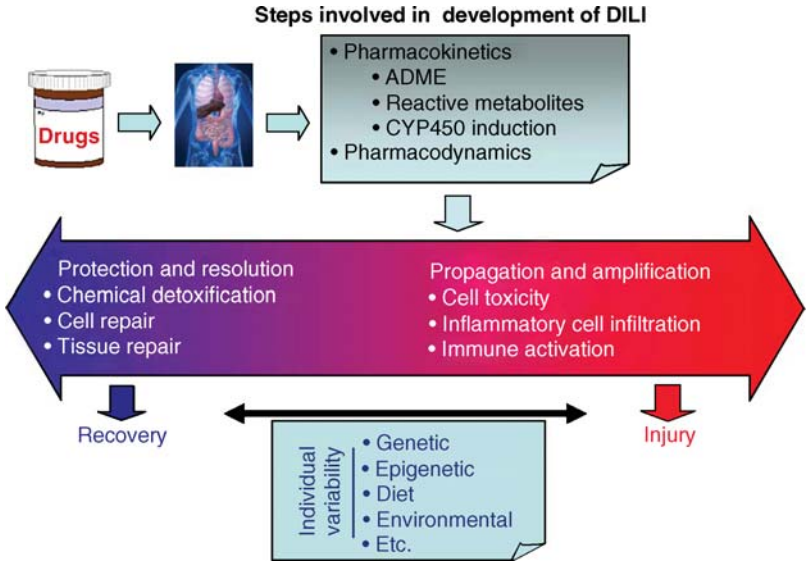

Figure 1. Steps involved in the development or avoidance of DILI.

were associated with susceptibility for several drugs (Lucena *et al.*, 2008). Similar to the genetic links to DILI above, sex differences in liver gene expression are considered a major contributing factor for the differential sex sensitivity to liver diseases and toxicity. For decades, efforts in unravelling sex-associated hepatic genes were largely based on the gene-by-gene approach. The higher-throughput DNA microarray techniques were introduced to address this issue (Tadic *et al.*, 2002). Liver genes showing sex differences, under both physiological and pathological conditions, have thereafter been greatly expanded and novel mechanisms for liver functions and dysfunctions have been revealed with unprecedented rapidity.

In 1932, it was reported that female rats were much more sensitive to the anaesthetic drug amytal sodium than males (Nicholas and Barron, 1932). Later studies revealed that the increased sensitivity was due largely to sex-biased expression of cytochrome P450s (Cyp), phase I drug-metabolizing enzymes. A large number of genes in the liver, besides Cyps, exhibit sex-specific expression. However, a comprehensive picture is still lacking. DNA microarray studies provide a powerful means to survey sex-associated gene expression (Rinn *et al.*, 2004; Mendrick, 2008; Mattes *et al.*, 2006; Boedigheimer *et al.*, 2008; Yang *et al.*, 2006). These studies greatly expanded the list of genes differentially regulated in each sex and a few of these found in the liver are listed in Table 4. A total of 4809 female-predominant liver genes and 4441 male-predominant liver genes have been identified (Yang *et al.*, 2006). It is apparent that such extensive differences could not have been revealed without the introduction of DNA microarray techniques and other emerging molecular biomarker technologies.

Because of differences in species/strains of animals, different microarray platforms and methods of data analysis, there exist great variations in the exact numbers and identities of sex-biased liver genes. However, consensus does exist. For example, differential expression of Cyp genes was unanimously observed (Rinn *et al.*, 2004). Genes related to steroid metabolism were also identified in most studies. These genes have in fact long been recognized by conventional techniques. Far beyond its ability to 'cover' the well-known differentially expressed genes, microarray techniques have made it possible to identify a wealth of new genes that display sharp differences between males and females, such as those involved in protein-tyrosine kinase activity, complement and coagulation cascades, cytokine signalling and solute carrier proteins. Over 70% expressed liver genes are sexually dimorphic in 24-week-old mice (Yang *et al.*, 2006). These extensive sex differences in liver gene expression profiles were

obviously not expected and they might provide better explanations for the sexual dimorphism in both liver physiology and pathology. These results may also warrant further studies aiming at exploring the unknown sex-biased liver phenotypes.

The sex difference in hepatic gene expression is largely due to the difference in hormone exposure. It is generally believed that growth hormone (GH) secreted from the pituitary gland plays a critical role in controlling sex-associated liver gene expression. The pattern of GH secretion differs between sexes. Males have a pulsatile pattern with a large release every couple of hours. Between releases, circulating GH is at a negligible level. In stark contrast, females have nearly continuous release of GH; however, the peak concentration of GH is much lower than the peak level in males (Waxman and Holloway, 2009; Mode and Gustafsson, 2006). The combination of the sex-specific patterns of GH release combined with the differences in GH peak concentration causes differential activation of the target transcription factors, which directly control the expression of a variety of liver genes, thus leading to sex-biased hepatic gene expression patterns. This general picture was originally derived from the expression profiles of several of the best studied Cyps and now DNA microarray data have not only confirmed but also further extended or refined this view.

As early as 2002, researchers reported that GH altered the expression level of genes in the rat liver in a sex-specific manner (Gardmo, Swerdlow and Mode, 2002). In a study, Ahluwalia, Clodfelter and Waxman (2004) compared more fully the effects of GH treatment on sex-biased gene expression. It was shown that continuous GH treatment of hypophysectomized male rats induced an increase of 73% of the female-predominant hepatic genes and a decrease of 90% of the male-predominant liver genes; however, among genes up-regulated or down-regulated by GH, only 10% were not sex-dependent. It was clearly demonstrated that GH treatment of male rats almost completely abrogated the sex differences in hepatic gene expression. This study firmly established that GH is a critical determinant for sexual dimorphic liver gene expression.

The GH signalling pathway is very complex and, although there remain unidentified components, the key events and factors have been characterized in the downstream gene regulation pathway. In brief, GH binds the GH receptor on the cell surface, inducing a conformational change that activates Janus kinase 2 (JAK2), a GH receptor-associated tyrosine kinase. JAK2 phosphorylates the GH receptor on several tyrosine residues. These serve as binding sites for various downstream signalling molecules that have SH2 (phosphotyrosine-binding) domains. One key factor is the binding of signal transducer and activator of transcription (STAT). Once bound, JAK2 phosphorylates the bound STAT, leading to activation and subsequent translocation to the nucleus where it binds DNA response elements and activates gene transcription (Waxman and Holloway, 2009; Mode and Gustafsson, 2006). Two different types of STAT, i.e. STAT5a and STAT5b, have received extensive attention. It has been suggested

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat226
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

that the pulsatile GH in males activates STAT5b with each pulse, whereas the constant GH level in females leads to partial desensitization or lack of full elicitation of STAT5b. This differential activation of STAT5 might constitute the molecular basis for the sexual dimorphic gene expression pattern in the liver. Microarray studies using STAT5 knockout animals have been used to test these hypotheses (Clodfelter *et al.*, 2006, 2007). In STAT5a knockout mice, only 15% female-predominant genes, such as Cyp2a12, Cyp2d22, Cyp3a16 and Cyp8b1, were decreased in female mice but not in males, indicating that STAT5a mainly plays an important role in controlling a portion of sex-biased hepatic genes in females. On the other hand, in STAT5b knockout mice, 90% of the male-biased genes were decreased and 61% of the female-biased genes were increased in males, essentially abolishing the male pattern of liver gene expression in males; however, 90% of sex-biased genes were hardly influenced in females, showing that STAT5b mainly plays a role in maintaining hepatic gene expression in males. A more detailed review of this literature can be found in an article by Waxman and Holloway (2009).

As with the DNA microarray technology itself, some controversies exist on the reliability of the results in profiling sex-associated genes in the liver. Delongchamp *et al.* (2005) argued that the extent of sex differences in human hepatic gene expression was fairly small, with the majority of fold-change falling below 1.4, and that this kind of minor difference is unlikely to be detected if gene selection were based on their *P*-values. This view appears incompatible with a majority of published investigations, but does highlight the importance of interpreting DNA microarray data in a cautious manner. Better designed and/or analysed microarray data might provide more convincing conclusions. As most raw DNA microarray data are now deposited in freely accessible public databases such as Gene Expression Omnibus (GEO), meta-analysis of the related data might be a convenient way to cross-validate the results and reach more balanced conclusions.

4 SEX DIFFERENCES IN LIVER GENE EXPRESSION PROFILES UNDER PATHOLOGICAL CONDITIONS

The incidence, treatment response and clinical outcome of many liver diseases display sharp sex differences. For example, men are more prone to developing hepatocellular carcinoma (HCC) and a more virulent form of acute hepatitis C than women (Altekruse, McGlynn and Reichman, 2009; Ozaras and Tahan, 2009). Many of these sex differences are also reproducible, and sometimes more striking, in animal models. For example, in mice treated with diethylnitrosamine, only 10–30% of females, but nearly 100% of males, developed HCC (Naugler *et al.*, 2007). In contrast, women are more susceptible to autoimmune hepatitis (Beland *et al.*, 2009). This sex bias in disease prevalence and severity would support the possibility of a sex-based predisposition to the development of DILI. However, the molecular pathogenesis of many diseases is ill defined.

Hepatocellular carcinoma is the most prevalent type of primary tumour in the liver, yet, to the best of our knowledge, there is only one report using sex-matched human samples in profiling liver gene expression in HCC (Takemoto *et al.*, 2005). The authors found that 27 genes were differentially expressed between males and females in human liver tumour tissues, among which 12 were male-predominant and 15 were female-predominant. These genes are either involved in antioxidant functions (such as Sod1) or related to cell cycle control and cell differentiation (such as Fgfr1∼3). Very interestingly, genes that display physiological sex differences were not detected in this study, indicating that the tumour *per se* can change the expression pattern more dramatically than sex itself.

To understand the sex-specific pathogenesis of HCC in humans and aid in the design of sex-biased therapy in treating this common type of liver cancer, an animal model that mimics human HCC was also studied using DNA microarrays. Gene expression profiling was studied for male-predominant HCC mice that were developed by knockout of the thioredoxin-interacting protein gene. This model is expected to be a good mimic of human HCC (Sheth *et al.*, 2006). In another animal model of HCC, DNA microarrays were used to characterize the hepatic gene expression profiles of liver-gender disrupted male mice (Rogers *et al.*, 2007). Male A/JCr mice were infected by *Helicobacter hepaticus* to facilitate the development of masculine-biased HCC, and castration was carried out to disrupt the gender-pattern of hepatic gene expression. It was found that 13% of all liver genes were castration-sensitive in normal males and 17% were castration-sensitive in HCC males, with a 29% overlap in both groups

of genes. The overlapped genes might be of critical importance in the male-predominant manner of HCC pathogenesis. Further bioinformatics analysis revealed that pro-inflammatory cytokine pathways played a central role in the altered expression of sex-biased genes. IFN-γ was then selected for in-depth biological experimentation, and it was confirmed that this cytokine alone could recapitulate the *H. hepaticus*-associated gene expression alterations. It was concluded that the liver of male mice is more vulnerable than that of the female to cytokine-mediated disruption of sexually dimorphic hepatic gene expression profiles, and are therefore more prone to develop HCC after *H. hepaticus* infection (Rogers *et al.*, 2007).

Both halogenated aromatic hydrocarbons (HAHs), such as 2,3,4,8-tetrachlorodibenzo-*p*-dioxin (TCDD), and polychlorinated biphenyls (PCBs), such as Aroclor 1254, are well-known liver carcinogens. Female rats seem to be more susceptible to these two agents with respect to liver tumorigenesis but the mechanisms are poorly understood. In a recent study by Silkworth *et al.* (2008), DNA microarray experiments were carried out to address this issue. It was demonstrated that TCDD and Aroclor 1254 significantly disrupted the expression pattern of a panel of sex-associated hepatic genes, particularly those involved in steroid metabolism. The disruptive effects were more dramatic in female rats than in males. This differential vulnerability to sex-gene disruption might underlie the sexually dimorphic response toward chemical carcinogens.

Inorganic arsenic is also a well-recognized carcinogen. It has been shown that adult male mice tend to develop HCC after transplacental exposure, but females do not. The mechanisms of such differential susceptibility have recently been explored by DNA microarray methods (Liu *et al.*, 2006). It was demonstrated that nearly 50 biological networks were disrupted in the males with HCC. One remarkable change was the feminization pattern of liver metabolic enzyme genes in the male, as evidenced by the marked increase of many female-dominant P450s including Cyp2a4, Cyp2b9 and Cyp2d9, and sharp down-regulation of several male-dominant genes such as Cyp7b1, Cyp2f2 and Cyp41. It was proposed that such disruptive effects on sex-associated genes could contribute a significant part in the pathogenesis of male-exclusive transplacental arsenic HCC.

5 FUTURE ASSESSMENT OF SEX DIFFERENCES IN DILI AND THE ROLE OF GENOMICS

Genomics has already provided a wealth of knowledge about liver genes that are regulated in a sex-specific manner. The ability to profile tens of thousands of genes at a single time point enables powerful comparisons of the systems that are differentially regulated in each sex under homeostatic conditions. Genomics extends these assessments to genes and systems that are differentially regulated in each sex after drug exposure. These changes can then be correlated with sex-specific sensitivity to a drug to determine the critical factors responsible for the increased sensitivity.

Pre-clinical toxicity studies are conducted in typical laboratory species (mice, rats, rabbits, canines and non-human primates) to assess the safety of new drug candidates. They generally involve multiple doses of a drug so that an accurate dose response can be constructed. Classical endpoints of toxicity are used such as clinical observations, body weight, feed consumption, clinical pathology (haematology, clinical chemistry, coagulation and urinalysis), gross pathology and histopathology. In addition, toxicokinetic assessments are increasingly being included in these studies. As these studies often include both sexes, toxicogenomics can be seamlessly integrated to study sex differences in liver gene expression after drug exposure.

A major advantage of integrating genomics in preclinical studies is that it helps in correlating sex-specific differences in liver gene expression with differential sex sensitivity based on the classical endpoints of toxicity collected in the study. In addition, if toxicokinetic samples are collected, powerful correlations can be made between gene expression, sensitivity and drug kinetics. The biggest hurdles in integrating this technology are cost and additional sample processing. However, costs are continuously decreasing as the technology matures and laboratories successfully integrate the additional sample processing steps into traditional preclinical study designs.

Genomics holds the promise of providing tremendous insights into potential sex-specific sensitivities in the human population. The main challenges are robust trial design and identification of appropriate biomarkers in easily collected samples. Clinical trials conducted under good clinical practices (GCPs)

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat226

are likely to provide the best opportunity for the successful integration of genomics for the assessment of sex-specific sensitivity to DILI. These trials are typically well designed, conducted and documented, allowing the best chance for drawing robust correlations between the types of collected data. As with preclinical studies, including genomic analysis in clinical trials would allow changes in gene expression to be correlated with adverse effects, greatly facilitating the assessment of sex-specific differences in DILI.

The major hurdle with integrating genomics in clinical trials for assessing sex-specific DILI will be identifying appropriate biomarkers that can be measured in easily collected samples. The gold standard would be assessing gene expression in the liver; however, obtaining biopsy samples for every DILI case would be impossible. Blood is an easily and routinely collected clinical sample that holds promise. Circulating white blood cells have been shown to identify patients exposed to high levels of APAP (Bushel *et al.*, 2007). Recent studies have detected both liver-specific mRNA and liver-enriched microRNA in peripheral blood after hepatotoxicant exposure (Miyamoto *et al.*, 2008; Wang *et al.*, 2009). Assessment of free mRNA or microRNA in the blood would be analogous to measuring serum ALT, a liver-specific enzyme released into the circulation after liver injury.

Integrating genomics in both preclinical and clinical studies will greatly facilitate the assessment of sex-specific sensitivity to DILI and the genes and systems involved with the differential sensitivity. In addition, identifying translational biomarkers (biomarkers in preclinical studies that can be used in clinical studies and vice versa) will increase the ability to prevent more serious injury to individuals in clinical trials that may be especially sensitive to a drug. This will in turn reduce the number of DILI cases and protect human health.

6 CONCLUDING REMARKS

With the introduction of DNA microarray technology, we have witnessed remarkable progression in profiling sexually dimorphic hepatic genes associated with liver physiology and disease. In males and females, the excretion of GH is pulsatile and constant, respectively, which in turn triggers the full or partial activation of transcription factor STAT5, thus leading to the differential expression of a panel of liver genes. STAT5a is responsible for sex-related hepatic genes in females, and STAT5b is responsible for sex-associated hepatic genes in males. Sex differences in liver gene expression are extensive, and disruption of the sex-dependent gene expression pattern is related to various liver disorders such as liver cancer and ALD. However, the existence of true female-predominant human DILI in terms of incidence is unclear as discussed above. To support or refute this belief, more preclinical and clinical studies need to be performed to understand the extent of this perceived gender bias where drugs are concerned. Future microarray studies involving both sexes and reproductive lifecycle would be useful to obtain new insights into the mechanisms of any sex-biased hepatotoxicity and response to injury. We have developed LTKB at NCTR/FDA and our focus is to assess sex differences in DILI, a part of the overarching efforts emphasized by the FDA's Office of Women's Health.

Commonality and Stochasticity in Systems Toxicology

Yoko Hirabayashi and Tohru Inoue

National Center for Biology and Safety Research, National Institute of Health Sciences, Tokyo, Japan

1 INTRODUCTION

Gene chip analysis, a microarray technology, is a type of "molecular microscopy" based on global gene expressions. Regarding its function, gene chip analysis, however, does not simply visualize "something" by this microscopy. The principles of "cells" and "pathology" were visualized and discovered with the development of photomicroscopy. It is not essential that photomicroscopy enabled the visualization of "objects," that is cellular structures, and provided pathological findings *per se*, but that photomicroscopy enabled the realization of concepts and/or principles explaining those "objects". Conceptually, gene chip analysis is not simply visualizing global gene expressions, but it is supposed to establish principles that have never been recognized in the past in the field of toxicology. What would they be?

When one treats 100 mice with a carcinogenic chemical compound, 46% of the mice develop pulmonary neoplasms, 36% acute myeloid leukaemias (AMLs) and the rest soft tissue tumours and angiogenic tumours. Although this treatment protocol is highly repeatable, generally, one cannot identify which mice would develop pulmonary tumours or angiovascular neoplasms. Why can such a particular outcome not be predicted? It may be speculated that those 100 mice may still be "different" despite their inbred genetic background. However, as we describe later, these uncertainties in each individual are based on a probabilistic hit; that is, a biological test at the individual level produces a probabilistic random outcome in mice whose genetic backgrounds are prohibitively identical. Each signalling pathway may be probabilistically different among individual mice, and probabilistic incidences of the routes of signalling pathways may be analysed computationally. A new concept of biological variability, i.e. stochasticity, is presented below.

When two holes as targets are hypothesized, a bullet can hit only one, not both at once. However, two or more bullets may hit at once in biology. The uncertainty law was originally established to account values in physics on the basis of the probabilistic quantum law. However, probabilistic stochasticities have also been focused on in the field of biology over the past decade, because biological scientists have realized the stochasticities in various biological reactions as quantum biology. Let us consider what happens next when multi-target holes exist and these holes are linked to individually different molecular signalling pathways; the induction of probabilistic adverse signalling by a hit would be multiplied. This is a stochastic probabilistic phenomenon in biology. Namely, this is the molecular probabilistic part of epigenetics. To understand xenobiotic responses in systems biology, a new method of analysing toxicological data called

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat227
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

"systems toxicology' based on genomic expression has been established.

Stochastic and different gene expression profiles were analysed for individual Purkinje cells in the cerebellum examined by single-cell microarray (Yagi K.). Thus, the overall cerebellar function in each mouse shows different probabilistic gene expression profiles, indicating individual differences among mice. If the development of individual mice were probabilistic, then cloned animals represented by the well-known sheep Dolly would not have an endemic infectious risk caused by their epigenetic inhomogeneity in immune responses. One problem associated with these conditions is the possible disappearance of stochasticity in the calculation of average values, because commonality tends to erode such a random stochasticity.

Previous toxicological data have been analysed frequently with their average endpoints focused on the commonality. However, probabilistic stochasticity may be analysed as specific stochastic clusters that elucidate other aspects of biological diversity in future "systems toxicology".

2 STEADY-STATE GENE EXPRESSION DURING AGEING

The Gompertzian formula, established by Benjamin Gompertz 1825 almost 185 years ago denotes human death rate during a unit time interval that increases linearly and exponentially with lifetime. The implications of Gompertzian linearity are considered to be based on the fact that lifespan may involve a function based on the integral of various life-threatening factors, such as neoplastic diseases, cardiovascular diseases and senile nephrosclerosis during ageing (the risk-integration theory) (Linzbach, 1972; Hruza, 1972). Namely, this linearity is based on a system in which each term of lifespan-linked diseases is independent of each other and is multiplicatively, not additively, linked to terms (equal diseases) (Equation 1).

$$N'(t) = -rN(t)\log[N(t)/K] \qquad (1)$$

where $N(t)$ is the number of individuals at time t, r is the intrinsic growth rate and K is the number of individuals in equilibrium. Namely, the risk across a lifespan is the total risk integration obtained by multiplication of the risk of a disease by that of another disease (Hirabayashi and Inoue, 2007).

According to the concept above, the age-related increase in the incidence of malignant neoplasms is believed to be based on the age-related exponential increase in genomic instability. However, a more important concept of Gompertzian linearity is that deaths from not only malignant neoplasms, but also cerebrovascular and other non-neoplastic diseases, are supposed to be concomitantly incorporated into an increase of curves as individual risk parameters, which is possibly based on an increase of genomic instability. The increases in risks associated with genomic instability and other factors with age would be studied in systems biology, whereas those increases in risks under toxicological impact are supposed to be studied in systems toxicology.

When one examines 100 senescent mice, senescent phenotypes may be observed in nearly all these mice. However, there may also be probabilistic phenotypes observed at different incidences individually. When one compares the phenotypes of these senescent mice with those of less senescent young adult mice by gene chip microarray, two different categories of gene expression profiles are recognized; that is, one corresponds to common ageing profiles (CAPs) and the other corresponds to stochastic ageing profiles (SAPs). The former were selected by two-way analysis of variance (ANOVA), and the latter were selected by principal component analysis (PCA) among others.

2.1 Common Ageing Profiles

Gene expression profiles for bone marrow cells from 2-month-old (five young mice) and 21-month-old (five old mice) male mice of the C3H/He strain are shown on the left and right panels of Figure 1, respectively, for comparison. In these linear configurations, expression intensities of the same genes in each mouse were connected to each other in the order of expression intensity from the top to the bottom as compared with those of the third mouse in the young mouse group (left panel). The characteristic differences between the young mouse group and the old mouse group are as follows. First, the gene expression order tends to be down-regulated in the 21-month-old mice (right panel). Second, the ranges of gene expression intensities in the 21-month-old senescent mice are broader than those in the 2-month-old young mice. When one compares the five 2-month-old mice with the five 21-month-old

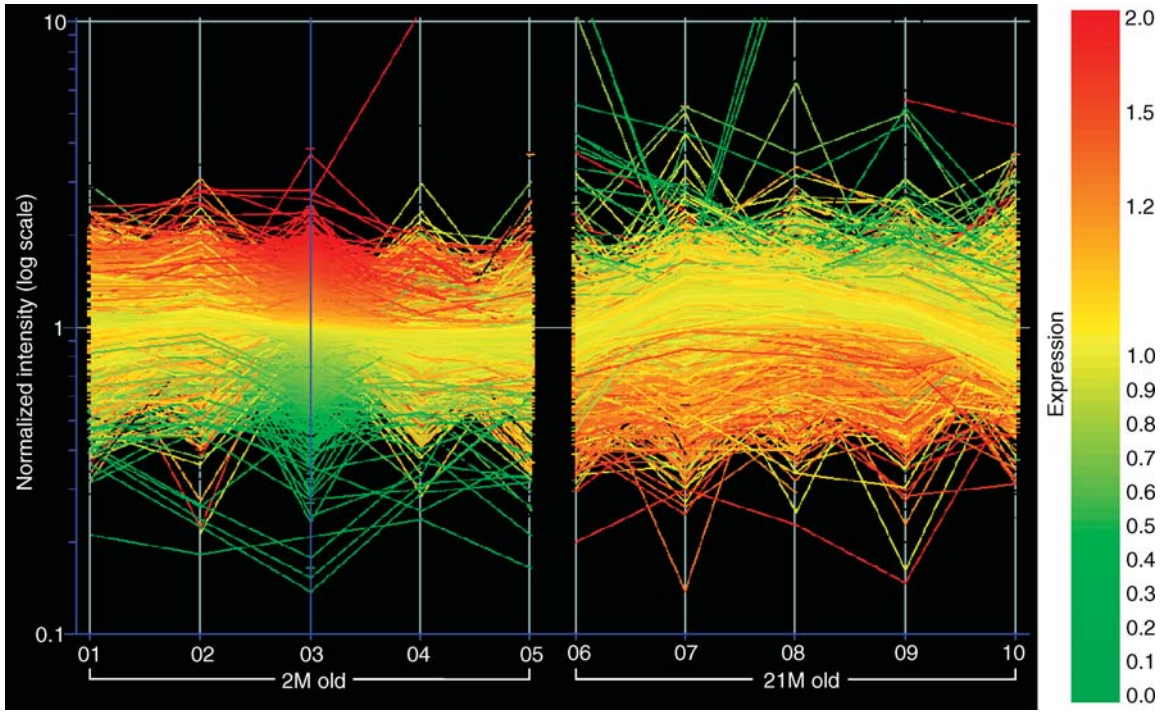

Figure 1. Linear configurations of gene expression profiles for bone marrow cells from 2- and 21-month-old mice: microarray profiles differentiate bone marrow cells from 2-month-old mice from those from 21-month-old mice. The five individual data points in the left panel are for bone marrow cells from 2-month-old C3H/He mice. The other five individual data points in the right panel are for bone marrow cells from 21-month-old C3H/He mice. Along the gene expression level scale from the highest (red) to the lowest (green) for No. 03 mouse, the same genes are connected and indicated by the same intensity of gene expression. Accordingly, genes over-expressed in 2-month-old mice are relatively under-expressed in the 21-month-old mice. Unless otherwise indicated, all the obtained microarray data presented in this chapter were normalized and analysed using GeneSpring GX 7.3.1 (Agilent Technologies Inc., Santa Clara, CA, USA).

mice concomitantly using a dendrogram without supervised information, both groups are not clearly separated from each other, probably because neither age-related common expression nor stochastic expression are only for minor genes as compared with 40 000 other probe sets.

Next, when one compares gene expressions in 2-month-old bone marrow cells with those in 21-month-old bone marrow cells by ANOVA, the finding depends on the range of confidential gains applied; 122 probe sets were chosen to be included in the list of CAPs (Figure 2). Among the 122 probe sets, as compared with gene expressions in 2-month-old bone marrow cells, those in 21-month-old bone marrow cells showed decreased expression levels of *cyclin D1* (Ghiaur *et al*., 2006; Matsumura *et al*., 1999), *cyclin G2* (cell cycle repressor; Arachchige Don *et al*., 2006; Horne *et al*., 1996), *FoxP* (monocyte differentiation and macrophage function; Shi *et al*., 2008), *Pax5* (B-cell differentiation; Nutt *et al*., 1997;Singh, Medina and Pongubala, 2005) and β-*catenin* (stem cell maintenance; Kim *et al*., 2009), as well as unstabilized self-determinant immunoglobulin-related genes. Along with these alterations in common gene expression levels, decreased expression levels of genes involved in the cell cycle in haematopoietic progenitor cells, increased expression levels of genes related to oxidative stress and an increased instability of genes for dormancy in haematopoietic progenitor niches are observed. However, *RUNKs*-related regulatory changes in haematopoietic progenitor cells were not observed (Figure 3).

Furthermore, genes interacting with the above-mentioned genes, as confirmed by the analysis of surrounding genes, were found to be involved in cell cycle regulation [e.g., *Trp53* (Hirabayashi *et al*., 2002b; Livingstone *et al*., 1992), *bcl2* (Zinkel, Gross

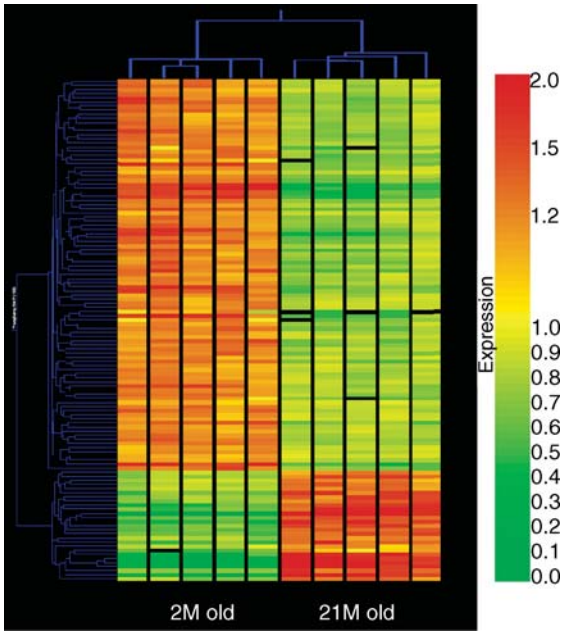

Figure 2. Probe sets selected to discriminate between age groups: One hundred and twenty-two probe sets (genes) were selected from gene expression profiles by ANOVA for bone marrow cells of C3H/He mice to discriminate between 2- and 21-month-old mice using dendrogram.

and Yang, 2006) and *myc* (Hirabayashi *et al*., 1992; Kelly *et al*., 1983)]. Oxidative stress responses [e.g. *FoxO* (Furukawa-Hibi *et al*., 2002), *Hif1* (Gorlach and Bonello, 2008) and *cyclin G2*] were also found to interact with *TNF-α* , *interferon-γ* and *PPAR-γ*. These findings imply that genes related to the maintenance of haematopoietic progenitor niches, including antioxidative notch signalling, and genes for maintaining immunogenicity are generally over-expressed in senescent mice (Appel *et al*., 2005; Hu *et al*., 2008; Zhang *et al*., 1995). In conclusion, in CAPs, senescence-related homeostasis is generally maintained and alterations of genes are limited within the range of homeostatic maintenance.

2.2 Stochastic Ageing Profiles

The characteristics of gene expressions, as shown in SAPs, in 21- and 2-month-old bone marrow from five mice each were found to be more exaggerated than those of gene expressions of those probe sets in CAPs. The CAPs show that the expressions of *cyclin D1*, *cyclin G2* and *FoxP* were down-regulated in 21-month-old bone marrow, and the SAPs also show that these genes were generally down-regulated. When the CAPs were overlapped with the SAPs, alteration was observed, for example increase in $p27^{kip1}$ expression level, decrease in *FoxO* expression level and increase in *FoxD3* expression level in the senescent group. Along with these alterations, *Hif1* expression was up-regulated in some bone marrow cells but also down-regulated in other bone marrow cells along with the down-modulation of MnSOD expression. There was no change in *Fas* expression, but the expression level of *Fas ligand* (FasL) decreased, and that of *Bcl2* increased in some bone marrow cells in the senescent group.

When one examines the relationships between CAP- and SAP-related signalling in more detail using the signalling network database, stochastic gene expressions scattered in the networks occasionally merged downstream towards the CAP genes stochastically. *Cyclin D1*, for example, that is one of the CAP members decreased during the senescence, receives several different negative signalling from the surrounding stochastic genes during senescence. Namely, *cyclin D1* is commonly down-regulated as follows: by negative signalling owing to the down-modulation of *NF-κ B* and *AP-1* and non-essential steady-state signalling from *KLF4* and *eIF4F*, in one case; by the down-regulation of *AP-1* and *NF-κ B* directly, and competitive relatively milder up-regulation by *eIF4F* and the consequent up-regulation by *KLF4* owing to double cancellation of *KLF4* upstream of *KLF5* in another case; by the same bilateral regulation as observed in the first case except for controversial down-regulation by *eIF4F* in the fourth case; and by prominent up-regulation by *eIF4F* and *Ap-1*, but with a strong negative up-regulation of *KLF4* owing to negative *KLF5* cancellation signalling, and down-regulation by *NF-κ B* in the last case [*NF-κ B* (Hinz *et al*., 1999), *AP-1* (Bakiri *et al*., 2000), *KLF4* (Shie *et al*., 2000), *eIF4F* (Barnhart *et al*., 2008), *KLF5* (Dang *et al*., 2002)].

Accordingly, xenobiotic responses may start from various xenobiotic stochastic gene expressions. Signals related to such responses may spread to surrounding genes and, finally, may occasionally merge with CAP member genes. Thus, the CAPs may receive different signalling with up-regulation and/or down-regulation stochastically differing from one case to another. Therefore, common

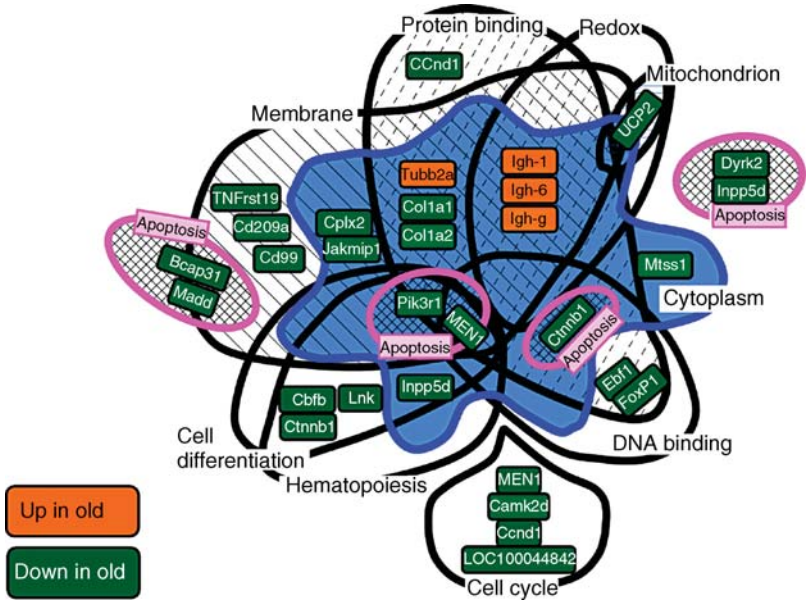

Figure 3. Up-regulation or down-regulation of genes from senescent mice identified by gene ontology: one hundred and twenty-two probe sets (genes) selected by ANOVA from genes expressed in bone marrow cells from five 2-month-old mice and five 21-month-old mice were analysed using gene ontological database to discriminate between both age groups [Bcap31: B-cell receptor-associated protein 31; Cbfb: core binding factor β; Camk2d: calcium/calmodulin-dependent protein kinase II, delta; Ccnd1: cyclin D1; Cd209a: CD209a antigen; Cd99: CD99 antigen; Col1a1: collagen, type I, α 1; Col1a2: collagen, type I, α 2; Cplx2: complexin 2, Ctnnb1: catenin (cadherin-associated protein), β1; Dyrk2: dual-specificity tyrosine-(Y)-phosphorylation-regulated kinase 2; Ebf1: early B-cell factor 1; Foxp1: forkhead box P1; Igh-1: immunoglobulin heavy chain I; Igh-6: immunoglobulin heavy chain complex; Igh-g: immunoglobulin heavy chain (gamma polypeptide); Inpp5d: inositol polyphosphate-5-phosphatase D; Jakmip1: janus kinase and microtubule interacting protein 1; LOC100044842: similar to cyclin fold protein 1; Madd: MAP-kinase-activating death domain; Men1: multiple endocrine neoplasia 1; Mtss1: metastasis suppressor 1; Pik3r1: phosphatidylinositol 3-kinase, regulatory subunit, polypeptide 1 (p85 α); Sh2b3/Lnk: SH2B adaptor protein 3/similar to lymphocyte-specific adaptor protein Lnk; Tnfrsf19: tumour necrosis factor receptor superfamily, member 19; Tubb2a: tubulin, β2a; Ucp2: uncoupling protein 2 (mitochondrial, proton carrier)].

gene expressions seem to be conciliatorily regulated by positive and negative signals from various stochastic genes differing from one case to another.

3 XENOBIOTIC RESPONSES

In this section, two aspects of xenobiotic responses examined by gene chip microarray analysis will be focused on: responses to benzene exposure and radiation. Senescent changes described in the first section can be categorically considered to be a type of xenobiotic response to "time", in which essential biological responses during ageing are based on a long-term relationship between living organisms and environmental xenobiotic materials (including oxidative stresses and photostimulation, among others). In this section, we focus on more active xenobiotic responses examined by gene chip microarray analysis so that a general principle on xenobiotic responses in systems biology may be established.

Whole-body exposure of mice to benzene (repeated, intermittent) and ionizing gamma-irradiation (single dose) was carried out. The reason that benzene exposure was chosen is its potential use as a model of xenobiotic relationship, which is mediated by aryl hydrocarbon receptors (AhR) expressed only on primitive haematopoietic progenitor cells in bone marrow tissue. Another reason for choosing radiation exposure was to elucidate the particular mechanism underlying the late effect after a single dose of exposure.

Tissues for gene chip microarray analysis were sampled and processed 28 days after the last exposure, in order to observe the earliest long-term responses to the late effect; not the acute reversible responses.

3.1 Benzene

3.1.1 Background

The haematopoietic toxicity of benzene is mediated by AhR (Yoon *et al*., 2002), and is thus specifically induced in haematopoietic progenitor cells in bone marrow because AhRs are only specifically expressed in progenitor cells at the steady state (Garrett and Gasiewicz, 2006; Harper, Riddick and Okey, 2006; Hirabayashi *et al*., 2002a; Hirabayashi and Inoue, 2010). Intermittent exposure by inhalation or gavage 6 h/day or once a day, 5 days/week, for 26 weeks is designed so as not to induce aplastic anaemia, using an appropriate concentration of benzene for exposure, that is 300 ppm (Cronkite *et al*., 1982, 1984; Kawasaki *et al*., 2009; Li *et al*., 2006; Snyder *et al*., 1980) in the present study, which produces 30–50% haematopoietic neoplasms (HPNs) depending on the mouse strain used. Gene chip microarray analysis was performed 28 days after 2 weeks of intermittent gavage exposure to benzene at 150 mg/kg b.w. to elucidate benzene-specific gene expression profiles, from which we can further define gene expression in terms of early plausible responses such as possible leukaemogenesis. Gene chip microarray analysis immediately after benzene exposure has been separately reported elsewhere (Yoon *et al*., 2003). Analysis on 28 days after 2 weeks of the last exposure to benzene was supposed to exclude acute signals such as those of cellular death and apoptosis, or those of advanced late effects. Because benzene exposure may lead to the development of human myeloid leukaemias (Aksoy, Erdem and DinCol, 1974; Delore and Borgomano, 1928; IARC, 1982; Yin *et al*., 1987), the incidence of myeloid leukaemias in the C3H/He mouse strain, which is prone to myeloid leukaemia (Seki *et al*., 1991; Yoshida *et al*., 2007; Yoshida *et al*., 1996), was compared with that in the C57BL/6 mouse strain, which is prone to malignant lymphoma (Hirabayashi *et al*., 2007a, 2007b; Kawasaki *et al*., 2009; Li *et al*., 2006), and gene expression profiles of both strains were examined. Interestingly, benzene exposure induced specific gene expressions in both strains on one hand, whereas individual mice expressed different stochastic and probabilistic gene expression profiles related to various gene ontologies including cellular functions plausible to leukaemogenesis on the other hand.

In conclusion, gene expressions related to maintaining functional haematopoiesis, and gene expressions balancing between the acceleration and deceleration of cell kinetics were regulated as the common gene expression profiles, whereas further up-regulation or down-regulation of individual genes was probabilistically observed as the stochastic gene expression profiles.

3.1.2 Long-Term Benzene Inhalation and Leukaemogenesis

In the protocol of intermittent inhalation of 300-ppm benzene mentioned above, the incidence of leukaemias induced was maximum because mice tended to develop aplastic anaemia and die at an exposure of over 300 ppm (Maltoni *et al*., 1989). Cumulative incidences of HPNs during the lifetime of mice after the intermittent benzene exposure protocol for 26 weeks are shown in Figure 4 (a and b: survival curves; c and d: incidences of whole HPNs; e and f: types of HPNs in C57BL/6 and C3H/He mice). Interestingly, when one looks at Figure 4f, only two cases (9%) of AMLs are observed in the higher-concentration exposure group, 300 ppm, on the left most column. Because much higher incidences of AMLs were observed in *Trp*53-deficient C3H/He mice in a previous report (Kawasaki *et al*., 2009), induction of myeloid leukaemia by benzene exposure was considered to be plausible not only in human but also in murine species. Further details on the incidences and histopathological findings of the study are described elsewhere (Kawasaki *et al*., 2009).

3.1.3 Benzene-Induced Strain Differences in Global Gene Expressions

Common Gene Profiles

The benzene dose for exposure by gavage equivalent to the above-mentioned inhalation exposure dose is 150 mg/kg b.w., which induces equivalent incidences of HPNs during the lifetime (French *et al*., 2001; NTP, 1986). Gene chip microarray analysis was performed 2 weeks after intermittent gavage exposure to the same amount of benzene. The 45 101 probe sets obtained were analysed using Affymetrix GeneChip® Mouse Genome 430 2.0 Array (Affymetrix, Santa Clara, CA, USA) and two-way ANOVA with false detection ratio (FDR) for the two strains with and without benzene exposure. Statistically, the number of significant benzene-exposure-specific probe sets (genes) whose *P*-values were lower than 0.05 was

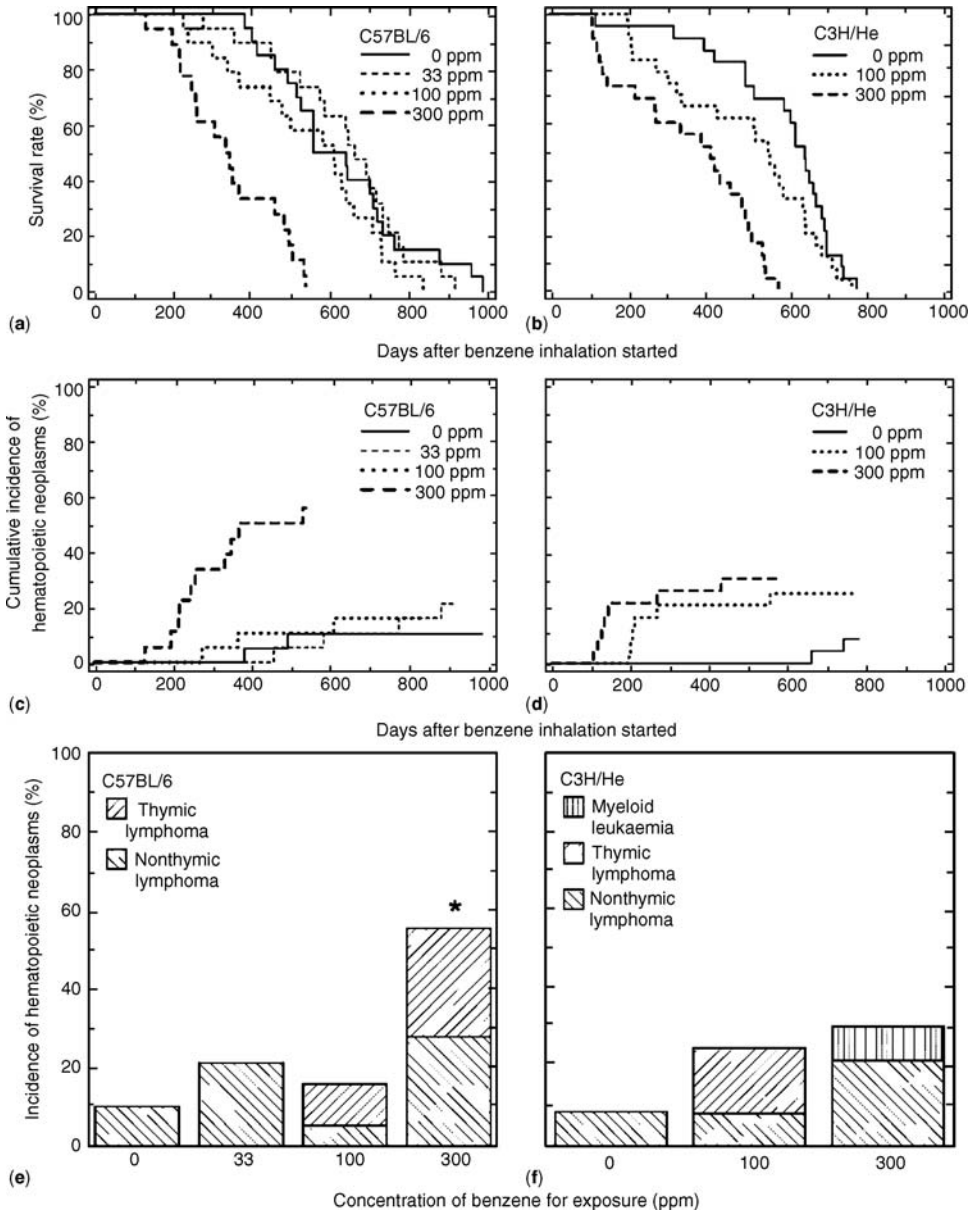

Figure 4. Survival rates, cumulative incidences of haematopoietic malignancies and their histological types in two strains after benzene inhalation. (a, b) Survival rates (%) are plotted on the vertical axis and survival time (days) after benzene inhalation on the horizontal axis for C57BL/6 mice (a) and for C3H/He mice (b). Bold dotted line for 300 ppm exposure group, regular dotted line for 100 ppm exposure group, fine dotted line for 33 ppm exposure group and solid line for sham exposure control. Statistical significance determined by log rank test: (a) 0 vs. 300 ppm, $P = 4.7 \times 10^{-6}$; 33 vs. 300 ppm, $P = 8.3 \times 10^{-6}$; 100 vs. 300 ppm, $P = 4.9 \times 10^{-4}$; (b) 0 vs. 300 ppm, $P = 5.6 \times 10^{-6}$; 100 vs. 300 ppm, $P = 4.9 \times 10^{-3}$. (c, d) The illustration shows the cumulative lifetime incidences of all haematopoietic malignancies (%) in C57BL/6 mice (c) and C3H/He mice (d). Bold dotted line for 300 ppm exposure group, regular dotted line for 100 ppm exposure group, fine dotted line for 33 ppm exposure group and solid line for sham exposure control. Statistical significance determined by log rank test: (c) 0 vs. 300 ppm, $P = 2.7 \times 10^{-4}$; 33 vs. 300 ppm, $P = 4.5 \times 10^{-4}$; 100 vs. 300 ppm, $P = 1.8 \times 10^{-3}$; (d) 0 vs. 300 ppm, $P = 7.0 \times 10^{-3}$. (e, f) Incidences of HPN histological types are shown in bar graphs for the C57BL/6 strain (e) and C3H/He strain (f). The incidence of HPNs is shown on the ordinate axis versus benzene exposure dose on the abscissa axis of each graph for the C57BL/6 strain (0, 33, 100 and 300 ppm) and C3H/He strain (0, 100 and 300 ppm). Histological types, such as AML, thymic lymphoma and non-thymic lymphoma, are designated by inset legends in each figure. The incidence in only the 300-ppm exposure group shows statistically significant difference (*$P < 0.05$) by Fisher's exact test.

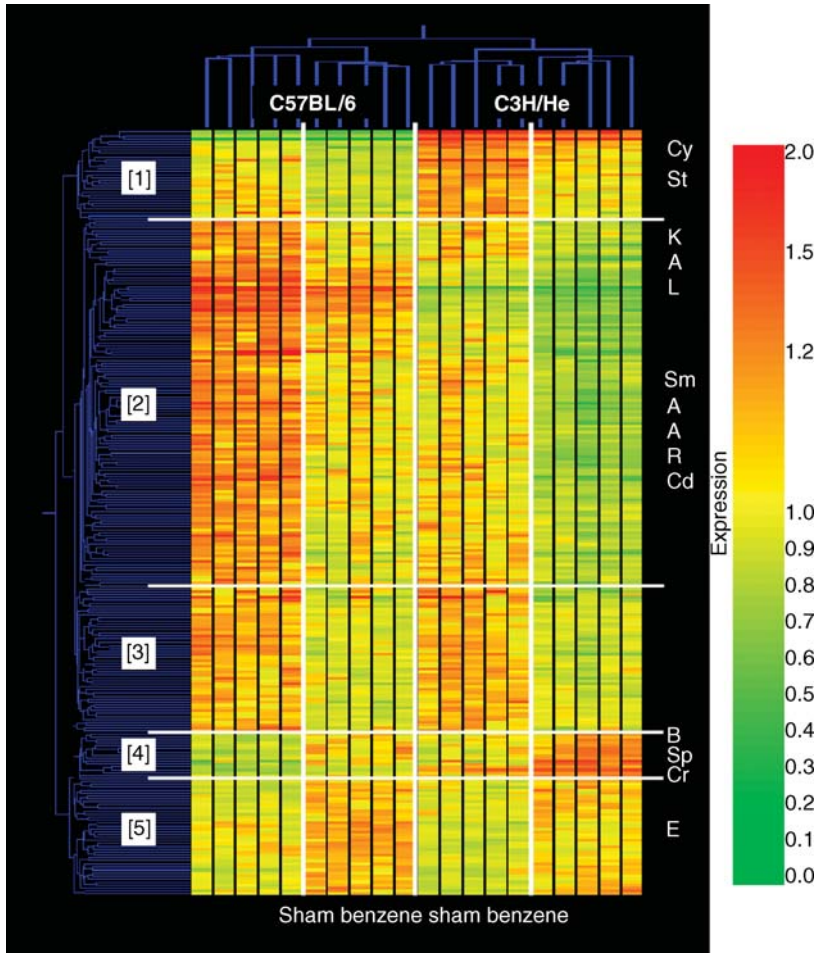

Figure 5. Probe sets selected to determine strain differences in response to benzene exposure: Two hundred and fifty-eight probe sets (genes) were selected from gene expression profiles by two-way ANOVA for bone marrow cells, from C57BL/6 and C3H/He mice (five mice each) with and without benzene exposure, and applied to a dendrogram to discriminate genes relevant to strain differences by benzene-specific gene expression intensities. Gene abbreviations on the right are listed in Table 1.

258. A dendrogram consisting of these 258 probe sets for the two strains is shown in Figure 5. In this figure, five categories were identified without supervision of information, in terms of four different components (two strains with and without benzene exposure). Benzene exposure induced the down-modulation of gene expressions in categories [1], [2] and [3], and benzene exposure induced the up-modulation of gene expressions in categories [4] and [5]. Among them, the C3H/He strain was dominant during the steady state in category [1], as compared with category [2], in which gene expression levels during the steady state were higher in C57BL/6 than in C3H/He. In category [3], gene expression levels in the steady state were higher than those in benzene exposure without significant differences between strains. In categories [4] and [5], both strains showed minimum gene expression levels in the steady state, but C3H/He showed higher expression level in category [4] whereas C57BL/6 showed a higher expression level in category [5] after benzene exposure. Representative probe sets of each category are shown in Table 1.

Category [1] consists of *Cryl1* and *Sltm*. The former is reported to be associated with genomic instability (Chen *et al.*, 2003; Etienne *et al.*, 2007), whereas the latter is associated with suppression of apoptosis (Chan *et al.*, 2007). Thus,

their expressions may be specifically induced by benzene exposure, which supports a plausibility of the predominant induction of HPNs in the C3H/He strain. In category [4], the genes that are up-regulated after benzene exposure are *WSTF*/*Baz1b* [Williams-Beuren syndrome transcription factor, also known as *BAZ1B*; a component of the *WICH* complex (*WSTF-ISWI* ATP-dependent chromatin-remodelling complex)], *Crnkl1* (Crn, crooked neck-like 1) and *Spg20* [spastic paraplegia 20, spartin (Troyer syndrome) homologue], whose functions are related to an enhanced double-strand break repair (Xiao *et al*., 2009), suppression of cell cycle (Chung *et al*., 2002) and up-regulation of potential suppressive factors (Bakowska *et al*., 2005), respectively.

The up-regulation of the repair of DNA damage associated with cell cycle suppression induced by benzene exposure was determined solely on the basis of the up-regulation of *Eme1*/*MUS81* (essential meiotic endonuclease 1 homologue 1, a component of *Mus81-Eme1* structure-specific endonuclease) (Hanada *et al*., 2006) in category [5] and the down-modulation of *Lmnb1* (lamin B1) (Fiume *et al*., 2009) in category [2]. However, many genes are identified to react with xenobiotics, which may lead to neoplastic changes, such as the down-modulation of $p27^{kip1}$ to release from cell cycle suppression (Nakayama *et al*., 1996; Payne and Kemp, 2003; Polyak *et al*., 1994), the down-modulation of *Kdm2a* to increase genomic instability (Frescas *et al*., 2008), the down-modulation of *Atrx*/*Rad54* to suppress DNA repair (Roy *et al*., 2008), the down-modulation of *Smc2* (structural maintenance of chromosome 2) to suppress double-strand break repair (Schar, Fasi and Jessberger, 2004) and the suppression of *Rb1cc* (*RB1*-inducible coiled-coil 1) to increase genomic instability caused by suppression of *Rb1*-inducible genomic stabilization (Ikebuchi *et al*., 2009). These are common trends of gene expression profiles for each strain or, in the case of both strains, plausible for induction of benzene-specific HPNs.

Stochastic Gene Profiles

In contrast to these common trends of gene expressions in these two strains, or each strain, each mouse often shows stochastically unique gene expressions, as shown in Figure 6. The five mice in each group show different expression levels: one signalling pathway comes down from *TCF* (T-cell-specific transcription factor) to *cyclin D1*, another pathway from *Bcl-6* to *cyclin D1* and another from *E2F* to *cyclin D1* in different expression intensities from mouse no. 1. Thus, three signalling pathways coming down to *cyclin D1* are different from one mouse to another among the five mice in this group (Bakiri *et al*., 2000; Hrzenjak *et al*., 2006; Liu and Habener,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

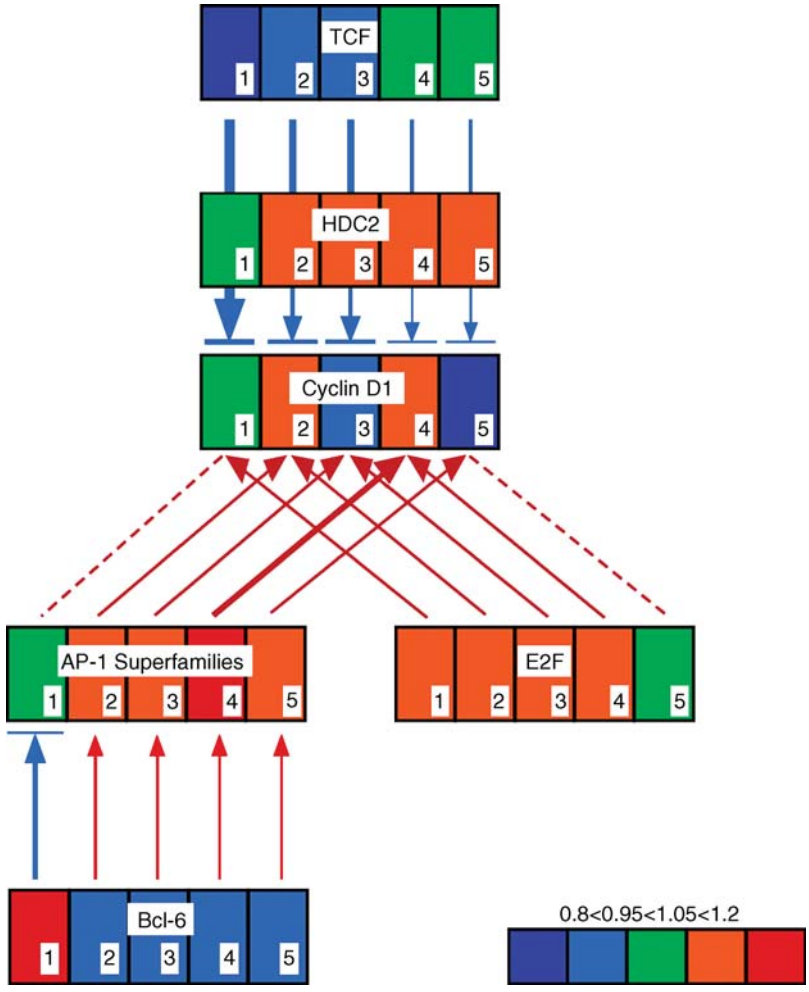

Figure 6. Sample stochastic gene expressions in three pathways upstream of *cyclin D1* and differences in gene expression levels among mice: To maintain the stochasticity of expression characteristics, gene expression profiles of the sham-control group were compared separately with individual expression profiles of the benzene-treated group by PCA followed by the selection of genes with high contribution scores from certain PCA components. A union gene list generated from the above-mentioned 878 probe sets (genes) for C57BL/6 mice was subjected to genetic interaction analysis (KeyMolnet Lite Version 4.8; Institute of Medicinal Molecular Design, Inc., Tokyo, Japan) to determine the interaction among the genes in the list and a sample stochastic gene expression three pathways upstream of *cyclin D1* is selected. Gene expression level in each C57BL/6 mouse was designated by scale for an expression level shown by fold changes in graded expression level. The gene abbreviations in the figure are as follows: *TCF*, T-cell-specific transcription factor, KMMC (KeyMolnet ID number) 03078; *HDAC2*, histone deacetylase 2, KMMC 05302; *cyclinD1*, cyclin D1, KMMC 00061; E2F, transcription factor E2F, KMMC 00143; *AP-1*, activator protein 1, KMMC 00101; *Bcl-6*, B-cell lymphoma 6, KMMC 03878.

2008; Shen *et al.*, 2008; Vasanwala *et al.*, 2002; Ye *et al.*, 2009). The stochasticity of mechanisms underlying these different stochastic signalling is not known yet, but each upstream signalling pathway towards *cyclin D1* from *AP-1* superfamilies and *E2F* is different from one mouse to another, as shown by the different expression levels of *cyclin D1* in these mice; thus, the epigenetic impact on cell cycling should be different from one mouse to another. These stochastic differences in gene expression levels in signalling pathways after benzene exposure are supposed to be linked to different pathological endpoints of mice. Thus, if a large number of experimental samples were used, each signalling pathway would be composed of a large number of gene clusters. Those possible probabilistic

signalling pathways would be established as a probabilistic signalling network in systems biology. Those gene clusters and pathways therefore predict probabilistic toxicological endpoints simultaneously. If a large number of experimental data would be obtained to elucidate those clusters in the near future, essential data obtained in the early phase may computationally predict future endpoints.

3.2 Ionizing Radiation

3.2.1 Background

Two radiation doses, 0.6 and 3 Gy, were used to compare gene expression profiles of irradiated mice with those of a non-irradiated control. ^{137}Cs-gamma-ray or X-ray at 3 Gy, in general, produces the maximum incidence of myeloid leukaemias in C3H/He mice because the risk of radiation-induced leukaemogenesis may be identified by the integral between the area under the stem/progenitor cell survival curve and the area above the curve for the minimum number of mutated stem/progenitor cells for the development of at least one case of leukaemia as a function of radiation dose (Hirabayashi and Inoue, 2007).

The maximum ratio of one curve to the other curve, in general, is calculated as 3 Gy, which produces about 30% leukaemias. With decreasing dose of radiation exposure on the other hand, the incidence of haematopoietic malignancy decreases, and the dose at which 5% haematopoietic malignancies is induced is estimated to be about 0.6 Gy. Five mice each for radiation exposure at 3, 0.6 and 0 Gy were examined by gene chip microarray analysis 28 days after radiation, by which time acute responses would have ceased and only long-term responses remained.

The common gene profiles and the stochastic gene profiles were focused, similarly to those in the previous section, on the ageing effect of steady-state gene expression. First, the common gene expressions were obtained by one-way ANOVA without FDR (the common gene profiles). Second, those common genes with specific functions in haematopoietic stem cells listed by Ivanova *et al*. 2002 were identified. Third, the union genes from individual significant expression profiles of each radiation-dose group and with specific functions listed by Ivanova and coworkers were selected by comparing their expressions with the general expressions of the non-irradiated group (the stochastic gene profiles).

For the common gene profile, 520 genes (probe sets) were selected by the Welch *t*-test with the confidence level set at a *P*-value smaller than 0.005, and their relationships were analysed using a dendrogram and shown in Figure 7. This dendrogram shows branches for dose-specific clusters and dose-dependent clusters. In this study, dose-response-dependent clusters were used to unsupervisedly select 226 probe sets from the 520 probe sets. The functions of genes were overviewed focusing on their effects on the irradiated recipients, and representative functional genes were identified, such as their effects on cell cycle regulation, DNA repair, apoptosis, induction of genomic and/or chromosomal instability, abnormal cellular proliferation and differentiation, dysfunction of suppressor genes and consequent enhancement of induction of neoplastic plausibility and, lastly, dysregulation and dysfunction of haematopoiesis.

The characteristics of the common and stochastic gene expression profiles that overlapped with those in Ivanova's list were focused on.

3.2.2 Common Gene Expressions

DNA Damage and Abnormal Repair

Genes that induce DNA damage and abnormal repair inhibit nucleotide excision repair owing to the down-modulation of the *Rad23* homologue *mHR23a* (Ng *et al*., 2003) and increase sensitivity to 5-fluorouracil and possibly also to ionizing radiation owing to the down-modulation of *UPB1* [ureidopropionase, beta (Thomas *et al*., 2008)], which is also related to hypotonia and dystonic movement (Moolenaar *et al*., 2001; Ohse *et al*., 2002). Concomitantly, as a type of cell cycle modulation, an attenuated *Trp*53 function owing to the down-modulation of *Setd7* was observed, inducing the plausible up-regulation of the pathway leading to tumourigenesis (Ivanov *et al*., 2007), namely enhancement of DNA damage as well as *Chk1*-dependent S-phase arrest owing to the down-regulation of *Setd8* (Jorgensen *et al*., 2007) and a delayed transition from the G2- to S-phase owing to *cyclin A/cdk 2* dysfunction induced by *SCAPER* (S-phase cyclin A-associated protein in the ER) down-modulation (Tsang *et al*., 2007). The down-modulation of *CT alpha*/*Pcyt1a* (phosphate cytidylyltransferase 1, choline, alpha

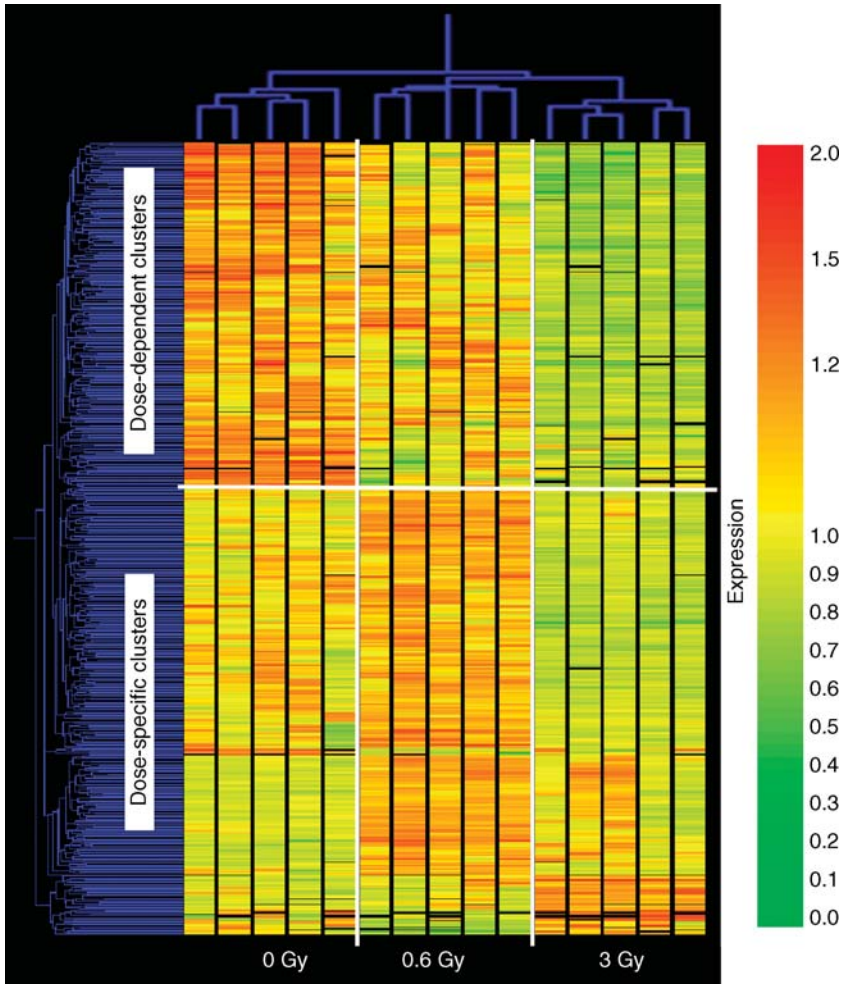

Figure 7. Welch *t*-test selected 520 probe sets from gene expression profiles for bone marrow cells from C57BL/6 mice with/without graded dose of gamma-ray irradiation, and dose-dependent cluster genes and dose-specific cluster genes discriminated by dendrogram: 520 probe sets (genes) were selected by Welch *t*-test ($P < 0.005$) from gene expression profiles among groups of bone marrow cells from C57BL/6 mice (five mice each) irradiated with 0.6 or 3.0 Gy ^{137}Cs-gamma-ray or mice without irradiation 28 days before gene chip microarray analysis, and applied to a dendrogram to discriminate dose-dependent cluster genes and dose-specific cluster genes.

isoform) induces cell cycle arrest (Banchio, Schang and Vance, 2004). The down-modulation of *G2E3* (G2/M-phase-specific E3 ubiquitin ligase) induces cell cycle dysregulation owing to consequent DNA damage (Brooks, Banerjee and Crawford, 2007), and the down-modulation of *Steap3* (STEAP family member 3)/*Tsap6* (tumour suppressor-activated pathway 6) induces downstream *Trp*53 to suppress the up-regulation of the cell cycle (Passer *et al*., 2003). Furthermore, the down-modulation of *SmarcA2* (SWI/SNF-related, matrix-associated, actin-dependent regulator of chromatin, subfamily a, member 2) induces cell cycle dysregulation (Zraly, Marenda and Dingwall, 2004), and the inhibition of S-phase transcription of *CT alpha*/*Pcyt1a* in turn inhibits phosphorylation during the cell cycle, resulting in the attenuated phosphorylation of *Cdk2* (Banchio, Schang and Vance, 2004).

Apoptosis-Related Gene Expressions

Concerning the alterations of apoptosis-related gene expressions, three types of apoptotic change, namely enhancement of apoptosis, suppression of apoptosis and apoptotic regulatory failures, are observed. *Atrx* (α thalassaemia/mental retardation syndrome X-linked homologue)/*Rad54* functions as

a radiation-induced helicase, which is a biomarker of breast cancer (Roy *et al*., 2008). With decreasing expression level of *Atrx/Rad54*, *Trp*53-dependent apoptosis is up-regulated (Seah *et al*., 2008). *Plagl2* (pleiomorphic adenoma gene-like 2) functions as a suppressor gene, collaborating with *Hif1* downstream of the *Hif1* pathway (Mizutani *et a*l., 2002), and with the down-modulation of *Plagl2*, apoptosis is down-modulated. Furthermore, apoptosis is suppressed by the down-modulation of *Steap3*/*Tsap6*, which consequently induces cell cycle arrest (Passer *et al*., 2003). Furthermore, the down-modulation of *Xiap* (X-linked inhibitor of apoptosis), which interacts with *Chek1* (Galvan, Kurakin and Bredesen, 2004), activates apoptosis and increases the level of reactive oxygen species (ROS) (Resch *et al*., 2008), which further activates apoptosis. *Rbm5* enhances the splicing regulation of antiapoptotic *caspase 2* (Fushimi *et al*., 2008), leading to *Rbm5* modulation that in turn suppresses apoptosis. There are apoptotic regulatory failures, such as that induced by a decreased expression level of *Rock1* (Rho-associated, coiled-coil-containing protein kinase 1), which is induced by the down-regulation of *caspase 3* (Ongusaha *et al*., 2008) and induces the down-regulation of *Fas*-mediated apoptosis via phosphorylation of *erzin* and *moesin* by *Rock1* itself (Hebert *et al*., 2008). Similarly, concerning apoptosis regulatory failure, when *Tr4* (testicular orphan nuclear receptor 4)*/NR2C2* (nuclear receptor subfamily 2, group C, member 2) is down-regulated, radiation-induced apoptosis seems to occur (Kim *et al*., 2007). The down-regulation of *Irf8* (interferon regulatory factor 8)/*ICSBP* (interferon consensus sequence-binding protein) regulates the induction of apoptosis and the expression of *Fas* (Yang *et al*., 2007). Furthermore, *Map3K5* is an apoptosis-regulating signal kinase of *ASK-1* (Ichijo *et al*., 1997), which usually binds to *thioredoxin* (*Trx*) (Saitoh *et al*., 1998). When *ASK-1* is activated along with the transformation of the *Trx* oxidative form by ROS, it then induces apoptosis (Fujino *et al*., 2007).

Instability of Genomic DNA and Chromosomes

Radiation induces regeneration failure and instability of genomic DNA and chromosomes. There are several notable findings on induction of genomic instability by the alteration of the *SMC* family (Losada and Hirano, 2005). First, genomic instability related to *ATM* failure is induced by the down-modulation of *SMC1a* (Kitagawa *et al*., 2004). Second, chromosomal instability is also induced by the down-modulation of both *SMC2* and *SMC4*, which form the core of codesin functioning in chromosome assembly and segregation (Losada and Hirano, 2005).
